In previous infrared and Raman studies[1] of trimethylamine oxide dihydrate, assignments of vibrational frequencies were based upon the polarization properties of the Raman lines and normal coordinate treatment. According to the results, the N–O bond of trimethylamine oxide in the solid state absorbs at 936 cm^{-1}. This value is in the same frequency region as for the N–O bonds of unconjugated oximes. The N–O stretching force constant obtained for trimethylamine oxide, 3.580 mdyn/Å,

was also very close to values ranging from 3.8 to 4.0 mdyn/Å for unconjugated oximes.[2,3] From these results, the N–O bond of trimethylamine oxide was concluded to have a pure single bond character in accordance with conclusions drawn from the results of X-Ray structure analysis[4] and electric dipole moment measurement.[5]

Recently, metal complexes with tertiary phosphine oxides[6] and tertiary arsine oxides[7] were prepared and studied by means of electronic spectra, infrared spectra, magnetic measurements and so on. It is known that the oxygen atom of tertiary amine oxide behaves as an electron donor and forms a coordinates to metal atoms.[8-11] Since the possibility of π-bond character is not present in trimethyl amine oxide, these studies were undertaken to compare the coordination of oxygen atoms in trimethyl amine oxide complexes and other types of complexes. However, the bond characters and molecular configurations in these kinds of complexes are not systematically interpreted yet.

In the present infrared study, addition compounds between trimethylamine oxide and the halides of the 2nd *b*-subgroup elements were dealt with, and attention was focused on the effect of coordination on ligand vibrations.

Experimental

Preparation. $ZnBr_2$ *and* ZnI_2 *Addition Compounds.* A solution of 0.01—0.02 mol of $(CH_3)_3NO\cdot 2H_2O$ in about 50 m*l* of ethanol was slowly added to a solution of 0.01 mol zinc halide in about 50 m*l* of ethanol. Needle crystals were formed in from a few hours to a few days. These crystals were collected, washed several times with ethanol and dried over phophorus pentoxide for several days. These complexes are slightly soluble in water, methanol and ethanol at room temperature, but decompose in warm solutions. Found: Zn, 17.4; C, 19.2; H, 4.85; N, 7.07%. Calcd for $ZnBr_2[(CH_3)_3NO]_2$: Zn, 17.41; C, 19.20; H, 4.83; N, 7.46%. Found: Zn, 14.0; C, 15.24; H, 3.91; N, 5.88%. Calcd for $ZnI_2[(CH_3)_3NO]_2$: Zn, 13.93; C, 15.34; H, 3.87; N, 5.97%.

$CdCl_2$, $CdBr_2$ *and* CdI_2 *Addition Compounds.* These compounds were prepared by the same procedure as that used for the zinc complexes. Precipitates were formed immediately from solutions. All complexes are soluble in water, methanol and ethanol. Found: Cd, 42.6; C, 14.22; H, 3.60; N, 5.21%. Calcd for $CdCl_2[(CH_3)_3NO]$: Cd, 43.5; C, 13.94; H, 3.51; N, 5.24%. Found: Cd 33.0%. Calcd for $CdBr_2[(CH_3)_3NO]$: Cd, 32.4%. Found: Cd, 25.1%. Calcd for $CdI_2[(CH_3)_3NO]$: Cd, 25.5%.

$HgCl_2$ *and* $HgBr_2$ *Addition Compounds.* The procedure of preparation was the same as for the zinc and cadmium complexes. White needle crystals were formed in a few minutes after the solutions were mixed. They decompose in water solutions. Found: Hg, 57.1%. Calcd for $HgCl_2[(CH_3)_3NO]$: Hg, 57.9%. Found: Hg, 46.7%. Calcd. for $HgBr_2[(CH_3)_3NO]$: Hg, 46.1%.

Measurement. Infrared spectra were taken using a grating infrared spectrophotometer model DS-402G of the Japan Spectroscopic Co., Ltd. The samples were run as Nujol mulls in the region 4000—250 cm^{-1}, and the regions of Nujol absorptions were examined with hexachlorobutadiene mulls. The 3 μ region was employed for checking the absence of hydrated water molecules in the complexes.

The observed frequencies for the complexes are listed in Table 1 together with those for trimethylamine oxide.[1]

Results and Discussion

All bands due to trimethylamine oxide remain practically unaltered in the spectrum of every complex under investigation. In addition, two new bands appear at about 550 and about 400 cm^{-1}. These additional bands are also observed at approximately the same position irrespective of the type of compounds. The zinc complexes give rise to more absorption bands at about 955 and about 270 cm^{-1}. Rodley *et al.* also dealt with this type of zinc halide complex, but mentioned nothing about these bands.[11] Bands at 946 and 492 cm^{-1} for the complex of cadmium iodide are relatively wide and are probably composite bands corresponding to the doublet bands of the other cadmium complexes.

Vibrations Associated with the Ligand. The cadmium and mercury complexes have two bands near 950 cm^{-1} corresponding to the degenerate C–N stretching vibration, $\nu(C_3N)$, and the N–O stretching vibration, ν(N–O), of the ligand, while the zinc complexes have three bands near 950 cm^{-1}. Kida *et al.*[12a] also observed two N–O stretching bands, ν(N–O), at about 1210 and about 1205 cm^{-1}, only for zinc and copper complexes of pyridine *N*-oxide, the former of which, $Zn(PyO)_2Cl_2$, is analogous to $ZnCl_2[(CH_3)_3NO]_2$ in its formula.

Generally, Zn(II) has a very strong tendency to appear in tetrahedral environments as indicated by the following examples: $ZnCl_2(NH_3)_2$ and $ZnBr_2(NH_3)_2$ crystals,[13] and $ZnCl_2$[thiourea]$_2$.[14] The zinc atoms of the addition compounds studied here probably follow this general tendency of coordination. If the two N-O bonds are arranged in close proximity to each other so as to have no center of symmetry, the ν(N-O) bands are possibly observed as two bands, even though the frequency separation between them might be small. Unlike Zn complexes, Cd and Hg complexes in the crystalline state form either a tetrahedral or octahedral arrangement about a metal atom according to the constitution of the complexes. The crystal of the type LCd(or Hg)X_2, such as [trimethyl-phosphine]$CdBr_2$ consists of halogen bridged dimeric molecules expressed by $L_2(CdX_2)_2$.[15] The single dimeric molecules, then, have a center of symmetry and approximately tetrahedral arrangement about the metal atoms. The type of Cd and Hg complexes treated in the present study is the same as the type compounds mentioned above. Therefore, it is quite probable that the crystals of the complexes in question are also built from dimeric molecules with a center of symmetry. Then, only one ν(N-O) should be observed. The metal-halogen stretching frequencies ν(M-X) of some complex halides of Zn, Cd and Hg were discussed by Coates and Ridley, and were successfully interpreted from this view point of structures as described above.[15]

It is reasonable to consider that the band near 400 cm^{-1} was caused by splittin of the de enerate vibration of the ligand upon coordination. Similarly, it is probable that the degenerate C-N stretching vibration of the ligand near 950 cm^{-1} splits appreciably and gives rise to the additional bands for zinc complexes. Furthermore, a band near 550 cm^{-1} is due probably to the splitting of the degenerate N-O rocking vibration of the ligand at 497 cm^{-1}.

No appreciable change in observed frequencies for trimethylamine *N*-oxide could be seen upon coordination to Zn, Cd and Hg atoms, except for some splittings of the degenerate vibrations. Similar phenomena were observed for $M[(CH_3)_3NO]_4^{2-}$ by Kida[9] and Drago *et al.*,[10] and for $Zn[(CH_3)_3NO]_2X_2$ by Rodley *et al.*[11] This is quite interesting upon comparison with changes in the vibrational frequencies of pyridine *N*-oxide or tertiary phosphine oxides upon coordination. The ν(N-O) of pyridine *N*-oxide[12] are lowered by about 45 cm^{-1} and the ν(P-O) of tertiary phosphine oxides[6b] by about 50 cm^{-1} upon coordination. These frequency shifts can be explained by a decrease in the double bond character of the N-O or P-O bonds upon coordination. Such an origin of frequency lowering can hardly be found for trimethylamine oxide. Therefore, the coordination of trimethylamine oxide to a metal atom will result in no appreciable change in the N-O bond nature.

Vibrations Associated with Metal-oxygen. The bands at about 270 cm^{-1} proper to the zinc

complexes appear to be associated with Zn–O, not with halogen atoms, because both the $ZnBr_2$ and the ZnI_2 complexes have bands at the same frequency and generally the zinc-bromine stretching frequencies of $ZnBr_4^{2-}$ or $ZnBr_2$ complexes are present in a lower frequency region.[15,16]

The band near 550 cm^{-1} appeared in a clear region of the ligand bands. On closer examination, these bands show slight but regular variations in positions according to the species of complexes. Rodley *et al.* proposed the assignment[11] to a metal-oxygen stretching vibration, ν(M–O). Although this possibility of assignment cannot be ruled out for the present case, a value of 550 cm^{-1} for ν(M–O) seems too high. Therefore, we adopt the assignment to the ligand vibration as mentioned in the foregoing section.

For a definite discussion of the origin and nature of the bands near 550 cm^{-1} and near 270 cm^{-1}, it is desirable to obtain other lower frequency bands below 250 cm^{-1}. Toward this end, far infrared studies are now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2029—2032 (1968)

A Theoretical Consideration on Chemical Reactions in the Kjeldahl Digestion

Yazaemon MORITA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received September 12, 1967)

The decomposition of organic nitrogen compounds by Kjeldahl digestion was discussed and some experiments were carried out. The relationship between the amount of sulfuric acid consumed and the amount of ammonia produced at various stages including final ones of the decomposition was examined. As a result, chemical reaction of decomposition was evaluated, and the temperature at the initial stage reveals one of the important factors which determine the ratio of oxidative action of hot concentrated sulfuric acid to reductive action of sulfur dioxide produced in the reaction system. It is concluded that, if the temperature of initial stage is adjusted properly, it is possible to decompose mostly nitro and azo compounds into ammonia by sulfuric acid containing potassium sulfate without reductive pretreatment which has previously been believed to be indispensable.

Since publication of the Kjeldahl method for nitrogen analysis,[1] a number of studies have been carried out on its applications and improvements, and this method, together with the Dumas', is extensively used in various fields for the determination of nitrogen. As reported previously,[2] however, many problems must be solved before this method is applicable to all types of nitrogen compounds. This statement is supported, for example, by a series of many years' studies by Bradstreet.[3]

As is known, the most important and fundamental of the Kjeldhal method is the digestion of nitrogen compounds with hot concentrated sulfuric acid, and a detailed study of this step is necessary for its application and its improvement. The decomposition reaction is extremely complicated and only very few studies concerning kinetics by Bredig *et al.*[4] and Schwab *et al.*[5] have been made. These studies gave some light on the rate of decomposition, but not on the applicability of this method.

This paper deals, experimentally as well as theoretically, with the thermal decomposition in concentrated sulfuric acid and the applicability of the Kjeldahl method.

Theoretical and Experimental

Thermal decomposition of organic compounds without nitrogen in concentrated sulfuric acid can be expressed by Eq. (1) as known previously;

1) J. Kjeldahl, Z. *anal. Chem.*, **22**, 336 (1883).
2) Y. Morita and Y. Kogure, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **88**, 1179 (1967).

4) C. Bredig and J. W. Brown, Z. *physik. Chem.*, **46**, 502 (1903).
5) G. M. Schwab and E. Schwab-Agallidis, *J. Am. Chem. Soc.*, **73**, 803 (1951); *Angew. Chem.*, **65**, 418 (1953); *Mh. Chem.*, **86**, 341 (1955); *ibid.*, **88**, 288 (1957).

$$C_nH_mO_l + (2n+m/2-l)\cdot H_2SO_4 \rightarrow n\cdot CO_2 + (2n+m/2-l)\cdot SO_2 + (2n+m-l)\cdot H_2O \quad (1)$$

where n, m, and l denote the numbers of atoms C, H, and O, respectively.

On the other hand, oxidative decomposition of various organic nitrogen compounds in a chromic acid-sulfuric acid mixture can be expressed by Eq. (2). This is derived from Eq. (1) by taking into account the nitrogen contained and the type of linkage of nitrogen shown in the studies of Jurecek *et al.*[6] as well as the present author[7]:

$$C_nH_mO_lN_{d=a+b+c} + (2n+m/2-l-1.5a+2.5b)\cdot O \rightarrow n\cdot CO_2 + (m/2-3a-b)\cdot H_2O + a\cdot NH_3 + b\cdot HNO_3 + c/2\cdot N_2 \quad (2)$$

where n, m, l, and $d(=a+b+c)$ denote the numbers of atoms C, H, O, and N, respectively, and a, b, and c denote respectively the numbers of nitrogen atoms present in the functional groups are shown in Table 1.

In such oxidative decomposition, the decomposition products are ammonia, nitric acid, and nitrogen molecule or a mixture whose proportion depends upon the nitrogen functional groups, and the consumption of oxigen varies with these groups.[6-7]

It is desirable in the Kjeldhal digestion to convert all the nitrogen atoms into ammonia and not to react as shown in Eq. (2).

But the actual decomposition reaction is mainly oxidation accompanied by reduction, dehydration, hydrolysis, substitution, and other complicated reaction, and can not be simply expressed by Eq. (2).

For example, the nitro group of 3-nitrosalicylic acid is quantitatively converted into nitric acid when oxidized with a chromic acid-sulfuric acid mixture,[7] but yields a calculated amount of ammonia when decomposed with hot concentrated sulfuric acid.[2] Thus, the Kjeldahl digestion does not proceed in accordance with Eq. (2).

Now, if the Kjeldahl digestion is the following oxidation-reduction reaction,

$$C_n + 2n\cdot H_2SO_4 \rightarrow n\cdot CO_2 + 2n\cdot SO_2 + 2n\cdot H_2O$$

$$H_m + m/2\cdot H_2SO_4 \rightarrow m/2\cdot SO_2 + m\cdot H_2O$$

$$O_l + l\cdot SO_2 + l\cdot H_2O \rightarrow l\cdot H_2SO_4$$

$$N_{d=a+b+c} + 1.5d\cdot SO_2 + 3d\cdot H_2O \rightarrow d\cdot H_2SO_4 + d/2\cdot (NH_4)_2SO_4$$

the sum of these reactions can be written as follows.

$$C_nH_mO_lN_d + (2n+m/2-l-d)H_2SO_4 \rightarrow n\cdot CO_2 + (2n+m/2-l-1.5d)\cdot SO_2 + (2n+m-l-3d)\cdot H_2O + d/2\cdot (NH_4)_2SO_4 \quad (3)$$

If the decomposition of nitrogen compounds proceeds ideally according to Eq. (3), Eq. (4) can be obtained.

$$\frac{x}{w} = \frac{(2n+m/2-l-d)\cdot H_2SO_4}{C_nH_mO_lN_d} (=K_1) \quad (4)$$

x=amount of sulfuric acid consumed.

w=weight of sample.

K_1=a proportional constant characteristic of a given sample.

As the Kjeldahl method does not fit the determination of nitrogen in all nitrogen compounds, it is obvious that Eqs. (3) and (4) have not universal validity.

In order to study this subject more closely, Eq. (4) must be replaced by Eq. (5) which is applicable to most cases.

$$\frac{x}{w} = K_1\alpha = K_1' \quad (5)$$

α=a factor which depends upon the mode of decomposition.

The value of K_1' is experimentally given and α can be calculated from Eq. (4).

When $\alpha=1$, Eq. (5) becomes identical with Eq. (4), but when $\alpha>1$, it does not so and in this case

6) M. Jureček, *Mikrochim. Acta*, **1962**, 926; *ibid.*, **1962**, 1101; *ibid.*, **1963**, 643; V. Novák, P. Kozák, P. Matousek and M. Jureček, *Collect. Czechoslov. Chem. Commun.*, **28**, 487 (1963); *ibid.*, **28**, 3443 (1963).

7) Y. Morita and Y. Kogure, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **86**, 87 (1965); *ibid.*, **86**, 508 (1965); *ibid.*, **86**, 601 (1965).

nitric acid or nitrogen molecule is produced by the decomposition. Some examples are now given below.

Two gramms of concentrated sulfuric acid is put into a micro Kjeldahl flask containing sample, and heated by 100 W electric heater with a variable resistor. When the solution in the flask becomes light brown, 0.5 g of potassium sulfate is added and the mixture is heated until it turns clear and colorless. In this way the decomposition is completed.

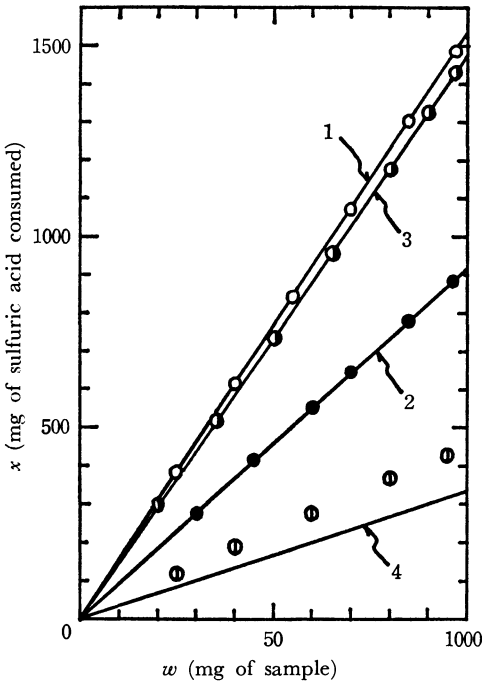

Fig. 1. Amount of sulfuric acid consumed *vs.* weight of sample in Kjeldahl digestion.
○, ●, ◑, ⓘ: Observed ——: Calculated
○, 1: Aniline ●, 2: Nitrobenzene
◑, 3: Azobenzene ⓘ, 4: 2,4-DNPH

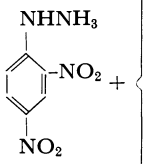
The mixture is then diluted with water, boiled to drive off SO_2 and the remaining sulfuric acid is titrated. The blank test is made and the actual amount of sulfuric acid consumed is obtained by subtracting the blank value from the titrated one. In Fig. 1, mg of sulfuric acid consumed (x) is plotted against mg of sample (w).

As shown in Fig. 1, Eq. (4) is not applicable to 2,4-dinitro-phenylhydrazine (2,4-DNPH) alone. Consequently, the decomposition of this compound can not be expressed by Eq. (3), but corresponds to

Table 2. Calculated values of α in decomposition of 2,4-DNPH and observed ones

Mode of reaction	I	II	III	IV	Observed
α	1.00	1.29	2.00	2.29	1.29

the case where $\alpha > 1$ in Eq. (5). Four possible decomposition reactions of 2,4-DNPH are shown below, and the values of α calculated for each reaction are shown in Table 2.



$$+ \begin{cases} 7\cdot H_2SO_4 \rightarrow 6\cdot CO_2 + 5\cdot SO_2 + 2\cdot H_2O + 2(NH_4)_2SO_4 & \text{(I)} \\ 9\cdot H_2SO_4 \rightarrow 6\cdot CO_2 + 8\cdot SO_2 + 8\cdot H_2O + (NH_4)_2SO_4 + N_2 & \text{(II)} \\ 14\cdot H_2SO_4 \rightarrow 6\cdot CO_2 + 13\cdot SO_2 + 12\cdot H_2O + (NH_4)_2SO_4 + 2\cdot HNO_3 & \text{(III)} \\ 16\cdot H_2SO_4 \rightarrow 6\cdot CO_2 + 16\cdot SO_2 + 18\cdot H_2O + 2\cdot HNO + N_2 & \text{(IV)} \end{cases}$$

It appears from Table 2 that in the decomposition of 2,4-DNPH, (II) may occur and this assumption is supported by the measurements of ammonia described below.

In this way, it is possible to interpret the reaction at the completion of the decomposition in terms of the amount of sulfuric acid consumed.

Because of the complex nature of the decomposition reaction, it is necessary to elucidate the steps involved to clarifiy the overall decomposition. For this purpose, the relationship between the amount of sulfuric acid consumed (x_t) and that of ammonia produced (y_t) after $t$hr must be considered.

If the amount of sulfuric acid consumed in Eq. (3) and the amount of ammonia produced are assumed to be proportional at all time, the degree of decomposition is x_t/x which is equal to y_t/y. Therefore, the equation

$$y_t = \frac{y}{x} x_t = K_2 \cdot x_t \qquad (6)$$

must be valid.

Equation (6) shows that the ratio of the amount of sulfuric acid consumed (x) to the amount of ammonia produced (y) at the completion of the decomposition is constant for a given sample, and K_2 can be determined by measuring x_t and y_t at various stages of decomposition. A comparison of these observed values with those calculated ones on the basis of Eq. (3) will give some insight into the mechanism of the reaction. It is clear from this experiments that the decomposition which is obeyed Eq. (6) always includes the chemical reaction shown by Eq. (3). However, Eq. (6) can not be applicable to acid amides and nitriles which yield ammonia on acid hydrolysis.

Next, some example are shown below ; the relationship between observed x_t and y_t at various stages of decomposition of typical organic nitrogen compounds is shown in Fig. 2. Conveniently, if y_t is plotted against x_t/x, $x_t/x=1$ means that the decomposition is completed and the solution becomes colorless and clear, whereas, $x_t/x<1$ means that the mixture is incompletely decomposed and the solution develops varying colors. The degree of decomposition can be controlled by adjusting the time of heating.

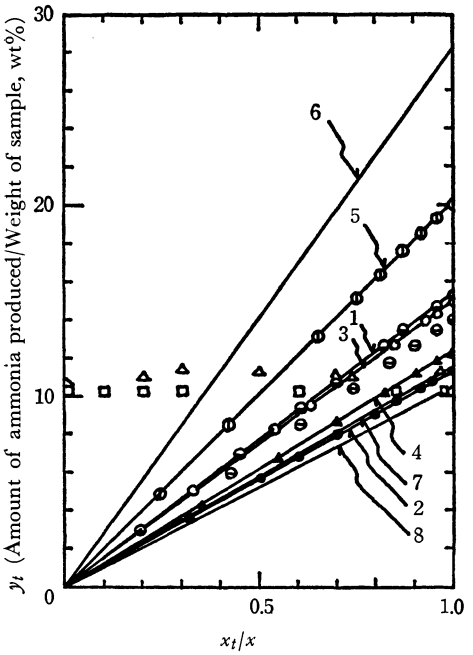


Fig. 2. Amount of ammonia produced *vs.* digestion degree in Kjeldahl digestion.
○, ●, ◒, ▲, ⓘ, ⊖, △, □: Observed
——: Calculated
○, 1: Aniline ●, 2: Nitrobenzene
◒, 3: Azobenzene

ⓘ, 5: 2,4-Dinitrophenylhydrazone of cyclohexanone ⊖, 6: 2,4-DNPH
△, 7: Benzamide □, 8: Anisonitrile

As shown in Fig. 2, aniline, nitrobenzene, cyclohexanone oxime, azobenzene, and 2,4-dinitrophenylhydrazone of cyclohexanone are decomposed in accordance with Eq. (6), and a complete agreement is obtained between observed and calculated values. It may be concluded that Eq. (3) is applicable to the main decomposition reaction of these compounds. It is found that 2,4-DNPH are decomposed according to Eq. (6). However, the reaction (II) mentioned earlier is the main reaction of this compound because that y at $x_t/x=1$ is 50% of the calculated value and the observed value of α in Eq. (5) supports the validity of Eq. (II). Contrarily, anisonitrile and benzamide are not decomposed in accordance with Eq. (6).

All amino compounds unexceptionally converted into ammonia by the oxidative decomposition as shown in Table 1. By the reductive preteatment, nitro and azo compounds are believed to be analyzed quantitatively, but nitrobenzene, azobenzene, and other nitro compounds are found by the author to be analyzed without the above-mentioned treatment as shown in Fig. 2.

This finding indicates that oxidation and reduction may occur side by side in the course of reaction depending upon the condition, and that the compounds containing nitro and azo groups are reduced preferentially.

On the other hand, a concentrated sulfuric acid mainly reacts oxidatively with a reducing functional group such as the hydrazino group. Consequently, when the hydrazino group becomes less reductive by substitution to form hydrazono group like 2,4-dinitrophenylhydrazone of cyclohexanone, the reductive effect of hydrazono group is the same as that of azo group.

The reduction reaction for nitro and azo groups is accompanied by the carbonization of organic samples at the initial stage of the decomposition and takes place slowly as the decomposition proceeds. Therefore, it is desirable to heat the sample initially at a temperatures as low as possible and to suppress excessive oxidation reaction and after appropriate decomposition, to raise the temperature to increase the oxidative action of sulfuric acid.

It may be concluded that nitro and azo compounds can be decomposed quantitatively into ammonia by sulfuric acid containing potassium sulfate similarly as amino compounds, and the reductive pretreatment hitherto made is found to be needless. Furthermore, failures in the past endeavor to decompose these compounds seem mostly to be due to a lack of the study on the heating condition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2033—2040 (1968)

Kinetics of Multidentate Ligand Substitution Reaction. III. Substitution Reactions of BT with Cobalt(II) and Nickel(II) Chelates of *N*-(2-Hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetic Acid and 2,2′-Ethylenedioxybis[ethyliminodi(acetic acid)]

Mutsuo KODAMA, Chifumi SASAKI and Tomohiko NODA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received October 25, 1967)

BT can displace EDTA-OH and GEDTA from their cobalt(II) and nickel(II) chelate as in the case of the substitution reaction of BT with cobalt(II)-EDTA chelate or nickel(II)-EDTA chelate. In this paper, kinetics of the substitution reactions of BT with cobalt(II)- and nickel(II)-chelates of EDTA-OH and of GEDTA was studied spectrophotometrically. All substitution reactions were found to be first-order in BT and first-order in metal(II)-chelate of EDTA-OH or GEDTA, and to proceed through two simultaneous reaction paths analogous to those proposed for the substitution reaction of BT with cobalt(II)-EDTA chelate. Although EDTA-OH differs from EDTA by the presence of a hydroxyethyl group in place of one acetate group, its metal(II) chelate behaves in a nearly identical manner with EDTA chelate in the substitution reaction and the cleavage of the metal-nitrogen bond of the glycinate group is considered to be the probable rate-determining step. The substitution reactions of BT with GEDTA chelates are considered to be more favored thermodynamically over the reactions of EDTA-OH chelates, but were found to be less favored kinetically. This fact may suggest that the geometrical structure of metal(II)-GEDTA plays an important role in determining the rate of the substitution reaction of GEDTA.

In the previous papers,[1,2] kinetics of the substitution reactions of Eriochrom Black T (BT) with cobalt(II) and nickel(II) chelates of ethylenediaminetetraacetic acid (EDTA) and of nitrilotriacetic acid (NTA) were studied. Reactions were first-order in BT and first-order in metal(II) chelate of 1 to 1 composition.

BT can also displace *N*-(2-hydroxyethyl)-ethylenediamine-*N*,*N*′,*N*′-triacetate (EDTA-OH) and 2,2′-ethylenedioxybis[ethyliminodi(acetate)] (GEDTA) from their chelates of cobalt(II) and nickel(II). In this paper, the kinetics of the substitution reactions of BT with EDTA-OH and GEDTA chelates of these metal ions were dealt with spectrophotometrically. From comparison of the rate constants of the substitution reactions of EDTA-OH chelates of cobalt(II) and nickel(II) with those of EDTA chelates, the reaction mechanism was assigned in detail.

Experimental

Reagents. The preparation and the standardization of solutions of cobalt(II) and nickel(II) perchlorates were described in the previous papers.[1,2] Reagent grade EDTA-OH and GEDTA were recrystallized from water. The concentration of EDTA-OH solution was standardized against the standard copper(II) solution by a volumetric titration with Murexide as indicator.[3] The standard solution of GEDTA was prepared by dissolving a known amount of GEDTA dried for two hours at 115°C into a diluted alkaline solution. The purification of BT was also described in the previous paper.[4] Other reagents were of guranteed reagent grade and used without further purification.

Apparatus and Procedure. The apparatus and the experimental procedures were the same as described previously.[1] In this study, all measurements were conducted in solutions of ionic strength 0.30 ($NaClO_4$), and no buffer reagent was used, because free EDTA-OH and GEDTA can have enough buffer capacity to maintain the pH values of solutions constant at the pH range from 8.00 to 10.50.

Results and Discussion

All exchange reactions were studied in solutions of pH from 8.00 to 10.50 containing large excesses of complexed and uncomplexed EDTA-OH or GEDTA. Therefore, the exchange reactions can be treated as pseudo first-order reactions. All exchange reactions of BT were found to give invariably the linear relations between log $(A_D/(A-A_{MD}))$ and time, t, with the intercept identical to log $(\varepsilon_{BT}/(\varepsilon_{BT}-\varepsilon_{MD}))$, holding the following relation (Fig. 1).

1) M. Kodama, This Bulletin, **40**, 2575 (1967).
2) M. Kodama, C. Sasaki and M. Murata, *ibid.*, **41**, 1333 (1968).
3) The same procedure as was proposed for the EDTA titration of copper was employed.
4) M. Kodama and H. Ebine, This Bulletin, **40**, 1857 (1967).

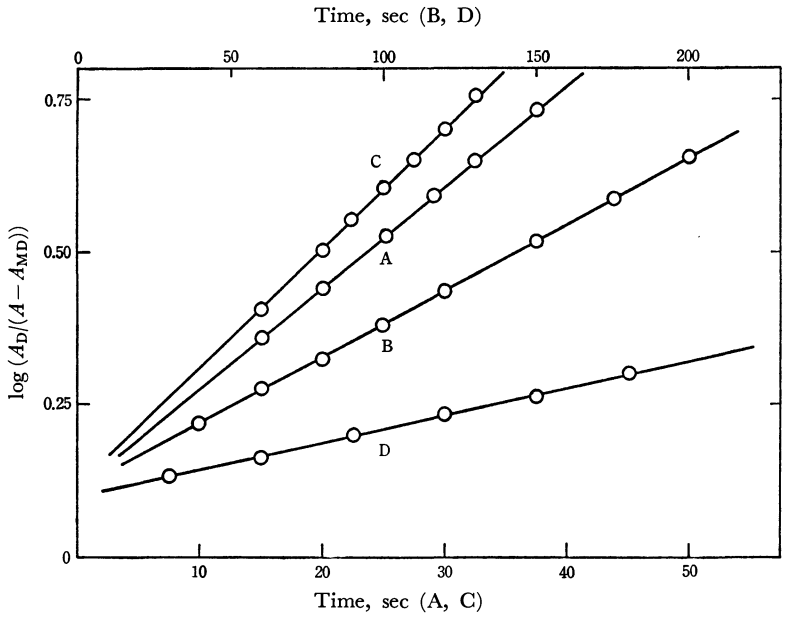

Fig. 1. The plot of log $[A_D/(A-A_{MD})]$ against t.
$\mu=0.30$, $\lambda=630$ mμ

A: Co(II)EDTA-OH system
$[BT]_0=1.50\times10^{-5}$ M, pH=8.23, $[CoZ^-]=1.0$ mM
Concentration of uncomplexed EDTA-OH=10.0 mM

B: Ni(II)-EDTA-OH system
$[BT]_0=3.05\times10^{-5}$ M, pH=10.17, $[NiZ^-]=8.25_5$ mM
Concentration of uncomplexed EDTA-OH=8.0 mM

C: Co(II)-GEDTA system
$[BT]_0=1.00\times10^{-5}$ M, pH=8.80, $[CoZ^{2-}]=0.30$ mM
Concentration of uncomplexed GEDTA=10.0 mM

D: Ni(II)-GEDTA system
$[BT]_0=2.90\times10^{-5}$ M, pH=10.10, $[NiZ^{2-}]=6.60$ mM
Concentration of uncomplexed GEDTA=10.0 mM

$$\log\frac{A_D}{A-A_{MD}}-\log\frac{\varepsilon_{BT}}{\varepsilon_{BT}-\varepsilon_{MD}}=\frac{k^+}{2.303}\cdot t \qquad (1)$$

where simbols, A_D and A, have the same meanings as used in the previous paper[4] and the other notation definitions are as follows. A_{MD}: Absorbance of the solution where all BT ions in the solution is considered to form the complex with nickel(II) or cobalt(II); ε_{BT}: The apparent extinction coefficient of uncomplexed BT at the given pH[2]; ε_{MD}: The true extinction coefficient of metal (II)-BT chelate.

As was stated previously,[1,2] when the stability constants of metal(II)-BT chelate are much greater than those of metal(II)-EDTA-OH or GEDTA chelates, and hence, the concentration of uncomplexed BT at equilibrium, $[BT]_e$, can be neglected as compared with the intial concentration of BT, $[BT]_0$, and with the BT concentration, [BT], at time t, in an early stage of the reaction, the left hand side of Eq. (1) must be equal to $\log([BT]_0-[BT]_e)/([BT]-[BT]_e)$. Therefore, if the above conditions are fulfilled by the systems, the slope of the linear relation between $\log(A_D/(A-A_{MD}))$ and t should correspond to the apparent rate constant of the forward reaction of the pseudo first-order reaction (2).

$$\left.\begin{matrix}HD^{2-}\\D^{3-}\end{matrix}\right\} \overset{k^+}{\underset{k^-}{\rightleftharpoons}} MD^- \qquad (2)$$

where HD^{2-}, D^{3-} and MD^- mean doubly and completely deprotonated BT anion and metal(II)-BT chelate, respectively.

Reported stability constants of metal(II)-BT chelate, K_{MD},s[1,2] indicate that the requirements are satisfied by the present systems. The following experimental facts were also found in the preliminary experiments where free EDTA-OH or GEDTA ranged from 5.0 mM to 25 mM, and its cobalt(II) or nickel(II) chelate from 0.30 mM to 25.0 mM.

i) In solutions of a given pH, given concentrations of cabalt(II) or nickel(II) chelate of EDTA-OH or GEDTA and the given initial concentration of BT, the slope of $\log(A_D/(A-A_{MD}))$ *vs.* t plot is independent of the concentration of uncomplexed EDTA-OH or GEDTA (Table 1).

Table 1. Dependence of the slope on the concentration of uncomplexed chelating agent

$\mu=0.30$

i) Cobalt(II)-EDTA-OH system

Concentration of EDTA-OH, mM	Slope, sec^{-1}	
10	1.62×10^{-2}	pH=8.23
15	1.68×10^{-2}	$[BT]_0=1.83\times10^{-5}$ M
20	1.65×10^{-2}	$[CoZ^-]=1.0$ mM

ii) Nickel(II)-EDTA-OH system

Concentration of EDTA-OH, mM	Slope, sec^{-1}	
8.0	1.90×10^{-3}	pH=10.0
15.0	1.87×10^{-3}	$[BT]_0=3.05\times10^{-5}$ M
25.0	1.91×10^{-3}	$[NiZ^-]=8.25_5$ mM

iii) Cobalt(II)-GEDTA system

Concentration of GEDTA, mM	Slope, sec^{-1}	
5	$1.18_2\times10^{-2}$	pH=8.10
10	$1.18_2\times10^{-2}$	$[BT]_0=1.00\times10^{-5}$ M
15	$1.16_5\times10^{-2}$	$[CoZ^{2-}]=0.30$ mM

iv) Nickel(II)-GEDTA system

Concentration of GEDTA, mM	Slope, sec^{-1}	
10	1.04×10^{-3}	pH=10.10
15	1.05×10^{-3}	$[BT]_0=2.90\times10^{-5}$ M
25	1.02×10^{-3}	$[NiZ^{2-}]=6.60$ mM

Table 2. Dependence of the slope on the initial concentration of BT

$\mu=0.30$

i) Cobalt(II)-EDTA-OH system

Concentration of BT, M	Slope, sec^{-1}	
7.31×10^{-6}	1.63×10^{-2}	pH=8.23
1.83×10^{-5}	1.62×10^{-2}	Concentration of free
2.56×10^{-5}	1.61×10^{-2}	EDTA-OH=10 mM
		$[CoZ^-]=1.0$ mM

ii) Nickel(II)-EDTA-OH system

Concentration of BT, M	Slope, sec^{-1}	
1.22×10^{-5}	1.45×10^{-3}	pH=9.86
2.14×10^{-5}	1.40×10^{-3}	Concentration of free
3.05×10^{-5}	$1.43\times10_{-3}$	EDTA-OH=8.0 mM
		$[NiZ^-]=8.25_5$ mM

iii) Cobalt(II)-GEDTA system

Concentration of BT, M	Slope, sec^{-1}	
8.45×10^{-6}	2.44×10^{-2}	pH=8.16
2.11×10^{-5}	2.40×10^{-2}	Concentration of free
2.54×10^{-5}	2.44×10^{-2}	GEDTA=10 mM
		$[CoZ^{2-}]=0.60$ mM

iv) Nickel(II)-GEDTA system

Concentration of BT, M	Slope, sec^{-1}	
5.80×10^{-6}	1.06×10^{-3}	pH=10.10
1.45×10^{-5}	1.02×10^{-3}	Concentration of free
2.90×10^{-5}	1.04×10^{-3}	GEDTA=10.0 mM
		$[NiZ^{2-}]=6.60$ mM

ii) In solutions of a given pH, given concentrations of uncomplexed EDTA-OH or GEDTA and of cobalt(II)- or nickel(II) chelate of EDTA or GEDTA, the slope of the linear relation is independent of the initial concentration of BT, $[BT]_0$ (Table 2).

iii) In solutions of a given pH, given concentrations of uncomplexed EDTA-OH or GEDTA, and of the given initial concentration of BT, the slope of the linear relation is proportional to the concentration of metal(II) chelate of EDTA-OH or GEDTA (Table 3).

iv) In solutions of a given initial concentration of BT, given concentrations of uncomplexed EDTA-OH or GEDTA, and of cobalt(II) or nickel(II) chelate of EDTA-OH or GEDTA, the slope of the linear relation is a linear function of the reciprocal of the concentration of hydrogen ion (Fig. 2), and given by

$$\text{slope} = k_\alpha + k_\beta/[H^+] \qquad (3)$$

These facts clearly indicate that the present substitution reactions of BT have the same reaction mechanism as was proposed for the substitution reaction of BT with cobalt(II)-EDTA chelate.[1] Consequently, k^+ in Eq. (1) or (2) should be given by

$$k^+ = (k_1^+ + k_2^+ \cdot k_2/[H^+]) \cdot [MZ] \qquad (4)$$

where k_2 refers to the dissociation of the second phenolic group of BT,[5] and [MZ] to the concentration of cobalt(II) or nickel(II) chelate of EDTA-OH or of GEDTA. Here, k_1^+ and k_2^+ in Eq. (4) are the second-order rate constants of the following reactions

$$\text{i)}\quad HD^{2-} + MZ^{2-n} \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} MD^- + HZ^{1-n}$$

$$\text{ii)}\quad HD^{2-} \overset{\text{rapid}}{\rightleftharpoons} H^+ + D^{3-}$$

$$D^{3-} + MZ^{2-n} \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} MD^- + Z^{n-} \qquad \text{rate determining step}$$

where MZ^{2-n} means metal(II)-EDTA-OH or -GEDTA chelate and Z^{n-}, completely deprotonated EDTA-OH or GEDTA anion.

From slopes of the linear relation between $k^+/[MZ]$ and $1/[H^+]$ and the intercepts, k_1^+'s and k_2^+'s

0.45	$1.72_0\times10^{-2}$	3.00	2.94	GEDTA=10 mM
0.60	$2.26_5\times10^{-2}$	4.00	3.88	$[BT]_0=1.40\times10^{-5}$ M

iv) Nickel(II)-GEDTA system

Concentration of Ni(II)-GEDTA, mM	Slope, sec^{-1}	Slope ratio calcd	Slope ratio obsd	
3.30	5.18×10^{-4}	1.00	1.00	pH=10.10
6.60	1.04×10^{-3}	2.00	1.97	Concentration of free
13.20	2.07×10^{-3}	4.00	3.99	GEDTA=10.0 mM
				$[BT]_0=2.90\times10^{-5}$ M

were determined (Fig. 2). These values are listed in Table 4 together with those for the substitution reactions of BT with EDTA chelates reported previously.[1,2]

We have mentioned previously[2] the importance of mixed ligand complexes as reaction intermediates in the proposed mechanism of the substitution reactions of BT with cobalt(II) and nickel(II)-EDTA chelates; prior to the complete dissociation of EDTA anion (Y^{4-}) from metal ion, BT may form coordinate bonds with metal ions, block the reformation of metal-EDTA bonds, and, thus, greatly increase the rate of dissociation of EDTA anion from the metal ion.

Electrostatically, the incompletely deprotonated BT anion (HD^{2-}) would have less repulsion against the negatively charged metal(II)-EDTA chelate. Therefore, kinetically, the reaction which proceeds through incompletely deprotonated BT anion can be expected to have an advantage over that proceeds through compltely deprotonated BT anion (D^{3-}). However, rate constants for the reactions through compltely deprotonated BT anion were much greater than those for the reactions through doubly deprotonated BT anion (HD^{2-}). This may suggest the need for the second phenolic oxygen to form the second metal(II)-oxygen bond prior to the rate determining step. Thus, the structure of a mixed ligand chelate as a reaction intermediate in the substitution reaction of BT with EDTA chelate should have metal-D^{3-} segment where two metal-oxygen bonds and one metal-nitrogen bond are included. Therefore, in this structure, at least, one half of Y^{4-} must be unwrapped.

Although EDTA-OH differs from EDTA by the presence of a hydroxyethyl group in place of one acetate group, its metal(II) chelate behaves kinetically in a nearly identical manner with EDTA chelate. Therefore, the structure of the reaction intermediate in the substitution reaction involving EDTA-OH chelate may be identical with that in the reaction of EDTA chelate.

Rate constants, $M^{-1} \cdot sec^{-1}$, $\mu=0.30$: a) 24.5°C b) 26°C c) 25°C d) 15°C.

In the kinetic studies of the electrophilic and the nucleophilic substitution reactions involving multidentate ligands, Margerum *et al.*[6,7] determined the detailed reaction mechanism by relating the experimental rate constant of the substitution reaction to the stability of the proposed reaction intermediate (a dinuclear complex or a mixed ligand complex). As was discussed above, the reaction intermediate in the present substitution reaction of BT may have one of these four structures listed in Fig. 3. To assign the detailed reaction mechanism, the treatment proposed by Rorabacher and Margerum[7] for the nucleophilic substitution reaction between EDTA and nickel(II)-polyamine complexes was applied directly to the present substitution reactions of BT with cobalt(II) and nickel(II) chelates of EDTA and of EDTA-OH. The direct application of their treatment leads to the conclusion that

* These values are calculated from the related stability constants in solutions of ionic strength 0.10 and the activity constants of the ions calculated by means of Davies equation.[1]

experimental rate constant ratio between EDTA and EDTA-OH systems should be equal to the ratio of the reaction intermediate stability, provided that the rate of the dissociation of tervalent EDTA-OH anion Z^{3-} from the reaction intermediate can be equated with that of Y^{4-}. As suggested by Margerum *et al.*,[7] the relative stability for the reaction intermediate given by the following relation was used in place of the actual one.

$$K_r^{7)} = \frac{K_{\text{chelon-segment}} \cdot K_{\text{BT-segment}}}{K_{MZ}} \qquad (5)$$

Where $K_{\text{chelon-segment}}$ corresponds to the stability

constant of metal(II)-glycinate or -iminodiacetate chelate, $K_{BT-segment}$, to the stability constant of metal(II)-BT chelate, and K_{MZ}, the stability constant of metal(II)-EDTA or -EDTA-OH chelate.

The relative stability of the proposed reaction intermediate calculated from the numerical values given in Table 5 are listed in Table 6 together with the rate constants. In the evaluation of the stability, the additional stability due to the electrostatic attraction of acetate group, K_{elec} (3.17),[6] and the statistical factor[6] were also taken into consideration. Here, *N*-methyl iminodiacetate and α-amino, α-methylpropionate were chosen as intermediate models.[6] Clearly, the structures type I fit the observed data best and are considered to be the preferred intermediates.

If the rupture of the second (EDTA or EDTA-OH anion) nitrogen-nickel bond accompanied by the rotation around a C–N or C–C bond and the formation of nickel-water bond is the rate determining step, the products of the rate constant for the rupture of nickel-nitrogen bond corrected for the rotational barrier involved[7] and K_r values must be equal to the experimental rate constants. However, K_r values in Table 6 clearly show that the experimental rate constants are much smaller than these products. Generally, it is very hard to consider that the rupture of the last nickel-oxygen bond is involved in the rate determining step, because the nickel-acetate cleavage is much faster than the nickel-amine cleavage.[6] Consequently, the above fact may indicate that the BT anion coordinated to the nickel(II) ion gives a serious effect on the rupture of nickel-nitrogen bond, the accompanied rotation around the C–N or the C–C bond of the leaving EDTA or EDTA-OH anion, other structural transformation or the formation of nickel(II)-water bond. To get additional information about this effect, further systematic investigations should be conducted.

As was tried in the substitution reaction of BT with EDTA-OH chelate, if the same reaction mechanism (glycinate intermediate) also fits the substitution reaction with GEDTA chelate, the rate of the reaction of BT with GEDTA chelate can be compared with that of EDTA chelate theoretically on the basis of the reaction intermediates.

Stability constant ratios of reaction intermediates between reactions with GEDTA chelates and those with EDTA chelates were also calculated by choosing α-amino, α-methylpropionate as an intermediate model and using stability constants listed in Table 5. Calculated values for cobalt(II) and nickel(II) systems were 1.02×10^4 and 1.07×10^5, respectively. This may suggest that the substitution reactions of BT with GEDTA chelates must be much favored thermodynamically over the reactions of BT with

EDTA chelates. However, rate constant ratios experimentally found for cobalt(II) and nickel(II) systems were 6.80 and 2.64, in a remarkable disagreement with the theoretically predicted ones. This probably means that the substitution reaction of BT with GEDTA chelate involves the reaction intermediate quite different from that for the reaction of EDTA chelate, or that the substitution reaction of BT with GEDTA chelate may have the same reaction intermediate as the reaction with EDTA, but, the steric effect due to the $-O-CH_2-CH_2-O-CH_2-CH_2-N-(CH_2COO^-)_2$ segment in GEDTA makes the reaction intermediate less stable to make the reaction less favorable kinetically. The latter explanation may be probable, because the rate constant ratio for the reaction of cobalt(II) chelate is not diffrent considerably from that for the reaction of nickel(II)-chelate.

If the glycinate mechanism also fits the reaction of BT with nickel(II)-NTA chelates, the stability constant ratio of reaction intermediates between the reaction with nickel(II)-NTA chelate and that with nickel(II)-EDTA chelate can be calculated to be 6.30×10^6. This result clearly suggests that if the reaction of BT with nickel(II)-NTA chelate had the same reaction mechanism as that with EDTA chelate had, the reaction of nickel(II)-NTA chelate would proceed very rapidly as compared with that of nickel(II)-EDTA chelate. As was reported previously,[2] the reaction was found to proceed rapidly in accordance with the above prediction.

Finally, we can mention that the kinetic study of substitution reactions of metal chelates with dyes other than BT would provide the additional information about the mechanism of multidentate ligand substitution reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2040—2044 (1968)

Studies of the Grinding of Condensed Phosphates. IV. Grinding of Sodium Trimetaphosphate at Low Pressure

Itaru MOTOOKA, Genzo HASHIZUME and Masamitsu KOBAYASHI

Department of Chemistry, Faculty of General Education, Kobe University, Nada-ku, Kobe

(Received December 22, 1967)

The change in sodium trimetaphosphate by grinding at low pressure was examined by the X-ray diffraction method and paper chromatography. The crystalline sodium trimetaphosphate became amorphous more rapidly when ground at low pressure than in dry air or nitrogen gas, and in these cases the chain phosphates higher than triphosphate were produced in addition to ortho-, pyro- and tri-phosphates.

In the previous papers,[1,2] it has been reported that the P–O–P linkages of cyclic sodium trimetaphosphate were severed to the chain phosphates due to grinding and the chain-length of some long-chain phosphates such as lithium, sodium and potassium polyphosphates decreased as a result of the cleavage of the P–O–P linkages upon grinding.

It was reported by Baramboim[3] that organic high polymers such as polystyrene depolymerize to the shorter-chain molecules upon grinding in the manner similar to the previous papers.[1,2] On the contrary, Kargin *et al.*[4] reported that styrene and other monomers polymerize by mechanical treatment.

In the case of phosphates, the possibility of producing the longer-chain phosphates by condensation can be anticipated. As the polymerization of phosphates is a condensation reaction in which water molecules are expelled, this reaction will be affected by the water molecules and so sodium trimetaphosphate was ground at low humidity and at low pressure, namely, one to several mmHg.

Experimental

Materials. Trisodium dihydrogen triphosphate, $Na_3H_2P_3O_{10}\cdot 1.5H_2O$, was prepared by the addition of alcohol to the aqueous solution of sodium salt which was adjusted to pH 4.6 with perchloric acid. The X-ray diffraction pattern of the precipitate*1 obtained was

*1 This precipitate contained ortho- and pyrophosphates of 10 to 20% in the analysis of paper chromatography.

identical with Corbridge's data.[5]

The preparation of sodium trimetaphosphate, $Na_3P_3O_9$, disodium dihydrogen pyrophosphate, $Na_2H_2P_2O_7$, and monosodium dihydrogen orthophosphate, NaH_2PO_4, has been described in a previous paper.[1]

Apparatus. The apparatus used in grinding was an Ishikawa's vacuum grinder (AGZ-type) and, in case of need, the same as in the previous paper[2] was used.

Procedure. One gram of phosphate was ground for a difinite time. The atmosphere during grinding was controlled in the following way. (1) In dry air: after the air in the grinding apparatus had been removed with a vacuum pump, the air dried by passing it successively through concentrated sulfuric acid, silica gel and phosphorus pentoxide was introduced into the apparatus. New phosphorus pentoxide was always provided in the apparatus. The relative humidity in it was 5 to 10% by a hair hygrometer. (2) In nitrogen gas: after the air had been removed, the apparatus was filled with dry nitrogen gas. New phosphorus pentoxide was also provided in it. The relative humidity was the same as in (1). (3) At low pressure: sample was ground while evacuating with a vacuum pump to below 5 mmHg pressure. The relative humidity was below 5% by a hair hygrometer.

Results and Discussion

Grinding of Sodium Trimetaphosphate at Low Pressure. As stated in the previous paper,[6] water molecules participate in the mechanism of the change which takes place when sodium trimetaphosphate is ground. Therefore, in order to investigate further the effect of water molecules, the grinding was carried out in an atmosphere evacuated to below 5 mmHg pressure as one method for reducing the water molecules.

Figure 1 shows the changes in X-ray diffraction patterns of sodium trimetaphosphate due to grinding in various atmospheres. It can be seen that the effect of grinding at low pressure is larger than that of grinding in dry air or nitrogen gas. For example, although the diffraction lines of sodium trimetaphosphate remain even after grinding for 6 hr in the dry air and nitrogen gas, the product ground for 6 hr at low pressure is amorphous. As regards the relative humidity, this result agrees with that of the previous paper[6]—that is, the grinding effect decreases with increase in relative humidity.

Rehbinder *et al.*[7] have investigated the effect of water on grinding of quartz, and reported that more amorphous layer was produced as the water content decreased. There is a good agreement between their results and ours. The results described above, however, can not be interpreted simply as due to low humidity since factors*2 other than water molecules must be taken into account in the case of low pressure.

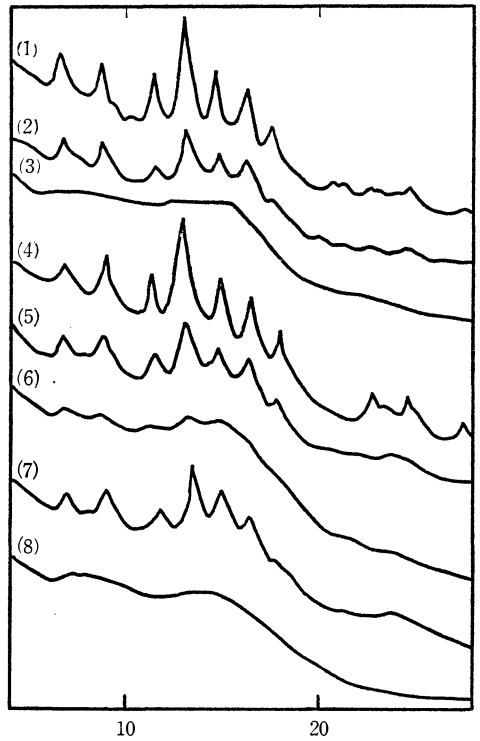

Fig. 1. X-ray diffraction patterns of $Na_3P_3O_9$ in various atmospheres.

(1) 3 hr grinding in dry air
(2) 6 hr grinding in dry air
(3) 24 hr grinding in dry air
(4) 3 hr grinding in nitrogen gas
(5) 6 hr grinding in nitrogen gas
(6) 9 hr grinding in nitrogen gas
(7) 3 hr grinding at low pressure
(8) 6 hr grinding at low pressure

The results of analyses of these ground samples by paper chromatography are given in Table 1.*3 The rate of decrease of trimetaphosphate molecules by grinding at low pressure is the fastest and this supports the results of the change in X-ray diffraction patterns in Fig. 1. They differ from those in the preceding paper[1] in that considerable tetra- and

*2 For example, the flow of air in the apparatus.[8]
8) G. Jimbo, *Hyomen (Surface)*, **1**, 47 (1963).

*3 Although the grinders used in this experiment were of the Ishikawa type, the grinding effect—for example, the rate of production of amorphous substance or the distribution of the various kinds of phosphates—was affected by its kind (AG-type or AGA-type) and by the use of other grinder even if of the same kind. An example is given in Table 2. In the case of grinder of AGA-type No. 2, the grinding effect is largest, and especially the amounts of tetra- and higher-polyphosphates is largest at humidity of 20% and temperature of 20°C. Even in the case of the same grinder, the grinding effect becomes poor because of the defacement of the rotating shaft and the weakening of the force by which the pestle is pressed when used for a long time.

TABLE 1. DISTRIBUTION OF PHOSPHORUS AMONG THE SAMPLES GROUND AT VARIOUS ATMOSPHERES

Atmosphere	Grinding time (hr)	Analytical value by paper chromatography (%)				
		Ortho	Pyro	Tri	Tetra~	Trimeta
Dry air	3	0	0	0	0	100
	6	0.2	0.8	1.0	0.4	97.6

TABLE 3. DISTRIBUTION OF PHOSPHORUS AMONG THE SAMPLES GROUND AT LOW PRESSURE

Sample	Atmosphere	Grinding time (hr)	Analytical value (%)			
			Ortho	Pyro	Tri	Tetra~
NaH_2PO_4	Low pressure	56	100	0	0	0
$Na_2H_2P_2O_7$	Low pressure	2	7.3	80.3	12.4	0
		6	17.1	49.8	20.8	12.4
	Dry air	6	5.8	94.2	0	0
$Na_3H_2P_3O_{10}$	Low pressure	3	10.3	37.7	40.7	11.3
		6	11.7	38.2	32.9	17.2
		9	13.3	37.8	26.3	22.7
	Relative humidity of 40%	6	14.5	28.0	57.5	0
		24	16.1	33.8	50.1	0
		48	20.1	44.0	35.9	0

higher- polyphosphates are produced in all cases of dry air, nitrogen gas and the evacuated state. This is due to the presence of smaller amounts of water molecules in the atmosphere of grinding and the following mechanisms can be assumed:

(1) Cyclic trimetaphosphates are severed to chain phosphates due to grinding and these chain phosphates are condensed to higher polyphosphates.

(2) The active molecules produced when the P–O–P linkages are severed are combined into longer-chain phosphates.

$$Na_3P_3O_9 \rightarrow Na_3P_3O_9: \quad (I)$$

$$Na_3P_3O_9: + H_2O \rightarrow Na_3H_2P_3O_{10} \quad (II)$$

$$Na_3H_2P_3O_{10} + H_2O \rightarrow Na_2H_2P_2O_7 + NaH_2PO_4 \quad (III)$$

$$Na_2H_2P_2O_7 + H_2O \rightarrow 2NaH_2PO_4 \quad (IV)$$

$$Na_kH_2P_kO_{3k+1} + Na_lH_2P_lO_{3l+1} \rightarrow Na_{k+l}H_2P_{k+l}O_{3(k+l)+1} + H_2O \quad (k, l = 1, 2, 3,\cdots) \quad (V)$$

$$m\mathrm{Na_3P_3O_9}: + n\mathrm{Na_3P_3O_9}: \rightarrow \mathrm{Na_{3(m+n)}P_{3(m+n)}O_{9(m+n)}}: \quad \text{(VI)}$$

$$\mathrm{Na_{3(m+n)}P_{3(m+n)}O_{9(m+n)}}: + \mathrm{H_2O} \rightarrow \mathrm{Na_{3(m+n)}H_2P_{3(m+n)}O_{9(m+n)+1}} \quad (m, n = 1, 2, 3, \cdots) \quad \text{(VII)}$$

Equations (I) to (V) show the mechanism of (1) and Eqs. (I), (VI) and (VII) the mechanism of (2). It has been reported in the previous papers[1,6] that the reactions shown in Eqs. (I) to (IV) take place. It is considered that, in the present investigation, the reactions in Eqs. (V) and (VI) take place much more easily than the ones in Eqs. (II), (III) and (IV) since the amount of water molecules in atmosphere is small.

Grinding of Monosodium Dihydrogen Orthophosphate, Disodium Dihydrogen Pyrophosphate and Trisodium Dihydrogen Triphosphate at Low Pressure. In order to examine the possibility of Eq. (V), the grinding of NaH_2PO_4, $Na_2H_2P_2O_7$ and $Na_3H_2P_3O_{10}\cdot 1.5H_2O$ was studied in an atmosphere containing a small amount of water molecules. The X-ray diffraction patterns of NaH_2PO_4, $Na_2H_2P_2O_7$ and $Na_3H_2P_3O_{10}\cdot 1.5H_2O$ by grinding are shown in Figs. 2, 3 and 4, respectively. The X-ray diffraction pattern of NaH_2PO_4 ground for 56 hr is essentially identical with the original sample. $Na_2H_2P_2O_7$ becomes almost amorphous when ground for 6 hr at low pressure, but in dry air some diffraction lines of $Na_2H_2P_2O_7$ remain after grinding for 6 hr. $Na_3H_2P_3O_{10}$ changes similarly.

The distribution of various phosphates determined by paper chromatography is given in Table 3. Sample of NaH_2PO_4 ground for 56 hr is entirely orthophosphate. This is probably due to the fact

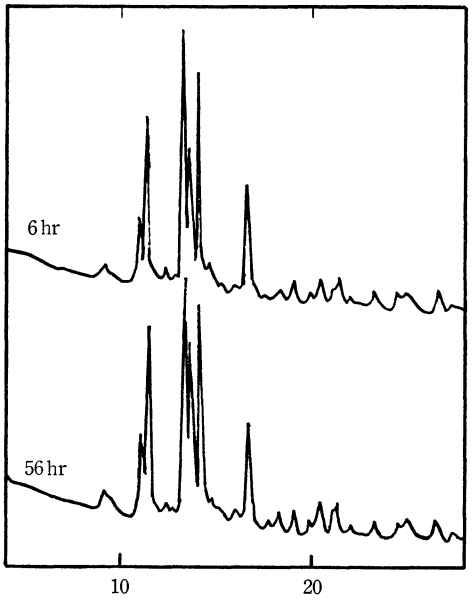

Fig. 2. X-ray diffraction patterns of NaH_2PO_4 ground at low pressure.
The numbers represent the grinding time.

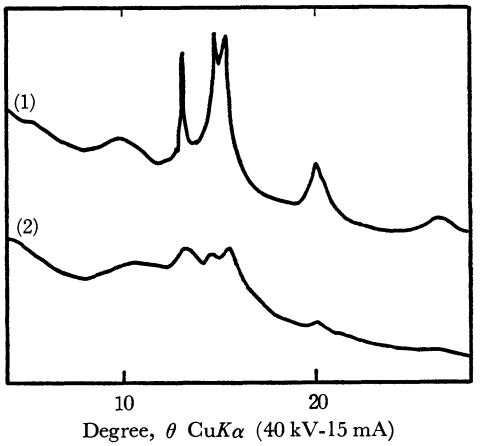

Fig. 3. X-ray diffraction patterns of $Na_2H_2P_2O_7$ ground in dry air and at low pressure.
(1) 6 hr grinding in dry air
(2) 6 hr grinding at low pressure

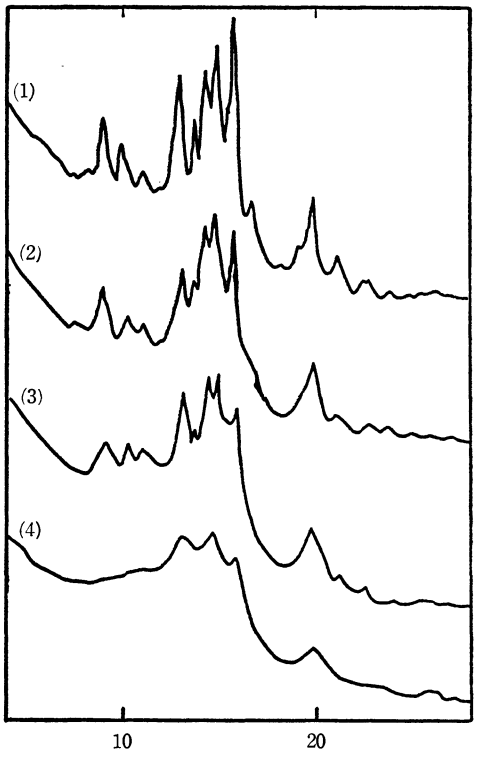

Fig. 4. X-ray diffraction patterns of the ground $Na_3H_2P_3O_{10}\cdot 1.5H_2O$.

(3) 3 hr grinding at low pressure
(4) 6 hr grinding at low pressure

that the crystal of NaH_2PO_4 is very stable for grinding or recrystallizes easily even if the lattice is disturbed.*4 Although $Na_2H_2P_2O_7$ becomes orthophosphates by grinding in air, it also condenses to tri- and higher-polyphosphates simultaneously at low pressure. $Na_3H_2P_3O_{10}$ shows a tendency similar to $Na_2H_2P_2O_7$, namely, some tetra- and higher- polyphosphates are produced at low pressure.

From the above results, it is possible for the mechanism of (1) to take place. However, it is difficult to confirm the mechanism of (2) and this must be studied further in the future but the fact that the amounts of tetra- and higher-polyphosphates produced when $Na_3P_3O_9$ is ground at low pressure are much more than those produced by grinding $Na_2H_2P_2O_7$ and $Na_3H_2P_3O_{10}$ indicates the possibility of the mechanism of (2).

*4 Monosodium dihydrogen orthophosphate is ready to adhere to the mortar during grinding, and it may decrease the efficiency of grinding.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2044—2049 (1968)

Syntheses and Properties of Some Dithio-β-diketonato Complexes*1

Akira OUCHI, Mitsuhisa NAKATANI and Yoshiaki TAKAHASHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received February 9, 1968)

Some compounds of type $M(L_{ss})_2$, where M is Ni(II) or Co(II) and HL_{ss} is some dithio derivative of β-diketones (benzoylacetone, trifluoroacetylacetone, trifluorobenzoylacetone or dibenzoylmethane), were obtained by passing hydrogen chloride and hydrogen sulfide into ethanol solutions containing β-diketone and metal chloride. Such compounds seem to be isostructural to the bis(dithioacetylacetonato) complexes and are stable. They are all deeply colored and their solutions show a characteristic absorption in the visible region, 16700 cm^{-1} for bis(dithiobenzoylacetonato)nickel(II) and 15200 cm^{-1} for bis(dithiodibenzoylmethanato)nickel(II). On the other hand, infrared spectra of these complexes show ν(C=S) bands at 1220—1240, 1170—1180 and 840 cm^{-1}. $M(L_{ss})_2Cl_4$ type complexes (where M=Fe(II) or Co(II) and HL_{ss}=dithiobenzoylacetone) were also obtained and they seem to be isostructural to $Fe(C_5H_7S_2)_2Cl_4$. Their magnetic susceptibilities and electronic and infrared spectra are shown and discussed.

The dithio-derivatives of acetylacetonato complexes were previously synthesized[1-5] and they seem to have very interesting properties. Recently, the present authors reported the syntheses of the dithioacetylacetonato complexes of various metals and found that (1) there are two kinds of dithioacetylacetonato complexes the $M(L_{ss})_2$ type and the $M(L_{ss})_2Cl_4$ type,[4] (2) in the case of nickel complexes of thio-derivatives of acetylacetonates, there is a regular change in the wave numbers of infrared and visible spectra from $Ni(C_5H_7SO)_2$ *via* $Ni(C_5H_7S_2)$-(C_5H_7SO) to $Ni(C_5H_7S_2)_2$.[3] As these compounds have characteristic absorption bands in infrared spectra as well as in electronic spectra owing to the metal-sulfur bond and the pseudo-aromaticity of their chelate ring, an investigation of the same type of complexes of other dithio-β-diketones, comparing them with the dithioacetylacetonates, should be interesting.

The dithio-β-diketonato complexes of nickel(II) were obtained using benzoylacetone, trifluoroacetylacetone, trifluorobenzoylaceton and dibenzoylmethane in the same manner as the synthesis of dithioacetylacetonates from acetylacetonates. However, the dithio-derivatives of hexafluoroacetylacetone, ethylacetoacetate and methylacetoacetate could not be obtained by the same method, being too unstable. In the case of monothio-β-diketonato complexes of nickel(II), the wavelength of the visible absorption spectral band of thioethylacetoacetate is longer than that of the monothio-derivative of acetylacetonate, although both can be synthesized.[6] In the case of the nickel complexes of dithio-β-diketones, the longer the wavelength of the above band, the less stable the complex. Perhaps this fact is related to the instability of these complexes.

Experimental

Materials and Instruments. Starting materials of GR grade were used without further purification. Infrared spectra were obtained with a potassium disc using Japan Spectroscopic Co., Ltd.'s, DS 403 G infrared spectrophotometer. Electronic spectra were obtained with a Hitachi EPS-2 automatic recording spectrophotometer. Magnetic moments were measured with a Gouy balance at room temperature (15°C).

Synthesis of Bis(dithiotrifluoroacetylacetonato)nickel(II). One and three tenth grams (0.01 mol) of anhydrous nickel(II) chloride and 3.1 g (0.02 mol) of trifluoroacetylacetone were dissolved in 20 m*l* of absolute ethanol. Into the clean, green solution, hydrogen chloride gas was bubbled for 30 min, then hydrogen sulfide for one hour. The solution was allowed to stand for one day at about 0°C. The black precipitate obtained was recrystallized from benzene and dried in vacuum. The yield was about 2.1 g (25% calculated for nickel(II) chloride).

Synthesis of Bis(dithiotrifluoroacetylacetonato)cobalt(II). This complex was obtained by almost the same method as the corresponding nickel(II) complex. As it is fairly soluble in ethanol, 5 m*l* of ethanol was enough par 0.01 mol of cobalt chloride. The yield was only about 15%.

Synthesis of Bis(dithiotrifluorobenzoylacetonato)nickel(II). The crude compound, obtained by the same method as was used for dithiotrifluoroacetylacetonates, contains by-products. The main impurity seems to be the dimer of dithio-β-diketone, but dithiolate salts may also be present. Repeated recrystallization was carried out with a mixture of chloroform and petroleum ether. The chromatographic method may also be applied to purification. The yield was about 30% or less due to loss in the recrystallization process.

Synthesis of Bis(dithiobenzoylacetonato)nickel(II). The crude complex, prepared in a manner similar to the above, was purified by the column chromatography. Alumina column chromatography, using benzene as the eluent, was effective. The yield was about 30%. Bis-(dithiodibenzoylmethanato)nickel(II) was also synthesized by the same method as was used in the synthesis of dithiobenzoylacetonate. The yield was less, about 20%.

Synthesis of Bis(dithiobenzoylacetonato)cobalt(II) Tetrachloride and Bis(dithiobenzoylacetonato)iron(II) Tetrachloride. The method of synthesizing the dithio-β-diketonato complex was applicable, using anhydrous cobalt(II) chloride or ferric chloride as the source of metal salts, respectively. Analytically pure products precipitated from the mother liquor, and chromatographic separation was not necessary. The yield was 30% and 42%, respectively (calculated for the metal salts).

Results and Discussion

Analytical data and the magnetic moments of these compounds are summarized in Tables 1 and

2, respectively. The relevant infrared frequencies of these complexes are shown in Table 3, and the wave numbers of their electronic spectra in Table 4 together with those of some related compounds.

From the magnetic moment data, the $M(L_{ss})_2$ type compounds are all low spin types; the nickel(II) complexes are all diamagnetic and the cobalt(II) complex has about one unpaired electron. This result is the same as that for the bis(dithioacetylacetonato) complexes, and these compounds would also have a planar structure as was the case of bis(dithioacetylacetonato)cobalt (II), which was found through X-ray crystallographic analysis.[5] The $M(L_{ss})_2Cl_4$ complexes are high spin octahedral types, as bis(dithioacetylacetonato)iron(II) tetrachloride, although the exact structure has not yet been determined.[2,4]

The general features of the spectra of these complexes resemble those of the acetylacetonates and dithioacetylacetonates, except for many additional bands due to the introduction of a phenyl or trifluoromethyl group. The tentative assignments given in Table 3 were made by referring to the acetylacetonates.

Sometimes, the compounds containing phenyl groups show a sharp weak band near 1590 cm^{-1}, but the band is different in shape from the ν(C=O) band; perhaps it is a skeletal inplane vibration band of the benzene ring.

The ν(C=S) bands of these compounds appear near 1220—1240; 1170 and 840—850 cm^{-1} in the case of $M(L_{ss})_2$ type compounds.

Thioacetylacetonato complex, $Ni(L_{ss})(L_{so})$, also exhibited three ν(C=S) at 1232, 1162 and 830 cm^{-1}. On the other hand, those of bis(dithioacetylacetonato)nickel(II) and cobalt(II) appear near 1160 and 840 cm^{-1} only. This fact seems to indicate that the C=S bond character of the $M(L_{ss})_2$ complexes resemble those of $M(L_{ss})(L_{so})$ type compounds, and there are two kinds of C=S bonds in these complexes; one sulfur atom may at least be more weakly bonded to the central metal atom than the other. Thus the chelate ring of the complexes now investigated may be more or less deformed, although it has been reported from X-ray crystallographic analysis that bis(dithioacetylacetonato)cobalt(II) has four identical Co–S bonds.[5]

The infrared spectra of bis(dithiobenzoylacetonato)cobalt(II) (or iron(II)) tetrachloride have ν(C=S) bands near 1257 and 870 cm^{-1}, as bis(dithioacetylacetonato-iron(II) tetrachloride. Generally, the infrared spectra of these three complexes resemble one another, and they seem to be isostructural.

The intensities of the visible region bands of these compounds are very strong compared with those of the corresponding β-diketonato complexes, as in the case of the thio-derivatives of acetylacetonates. From a comparison of the spectra of these complexes with those of the acetylacetonates,[7,8] tentative assignments are given in Table 4. The band near 16000 cm^{-1} of $M(L_{ss})_2$ type complexes may be taken as the d–d band from the wave number, but as its intensity is too high, it seems to be d–π band or at least a mixture of d–d and d–π bands.

The wave number of this band of nickel complexes of dithiotrifluoroacetylacetone and dithiobenzoylacetone is about 16800 cm^{-1}, and that of the dithiodibenzoylmethanato and dithiotrifluorobenzoylacetonato complexes about 15200 cm^{-1}.

On the other hand, the wavelengths of the bands of the series of thioacetylacetonatonickel(II) complexes are as follows; 17850 for bis(dithioacetylacetonate), 16380 for monothioacetylacetonatodithioacetonate and 15400 for bis(monothioacetylacetonato) (cm^{-1}).

From a comparison of the spectra of these two series of complexes, it is deduced at least that the substitution of trifluoromethyl or phenyl groups into the dithioacetylacetone chelate in place of methyl groups has the same effect as the substitution of sulfur by oxygen. Although the intensity of the band is almost the same in these substituted dithio-β-diketonato complexes, that of the oxygen substituted complexes is lowered when the number of oxygen atoms is increased.

These facts may be explained as follows. The introduction of oxygen into the chelate decreases the electron density of the six membered ring to some extent since the oxygen atom bonds to the central metal atom in a pure coordination bond. Thus, the sulfur-metal bond of the chelate ring is weakned. In the same way, the substitution of the methyl group of the acetylacetonato chelate with a phenyl or trifluoromethyl group also decreases the electron density of the ring by withdrawing electrons to the group. As a result, the electronic energy levels of these two series of compounds, as well as the wave numbers of the d–π band, should resemble each other.

From the absorption coefficients of the complexes of both series, back donation seems to be possible only from the central metal to sulfur, and not to oxygen in these chelate rings.

A benzene solution of bis(dithiobenzoylacetonato)-cobalt(II) tetrachloride shows a similar spectrum as the $M(L_{ss})_2$ type complexes; a band at 16660 cm^{-1} appears, although the intensity of this band is only one tenth that of $M(L_{ss})_2$ type complexes. This band does not occur in an alcoholic solution of the same complex. This fact suggests that the compound does not have simple ionic bonding between the tetrachloroiron(II) anion and the dithiolium cation, but has a kind of coordination bond between them. In alcoholic solution, as well as in aqueous solution, this complex seems to decompose into a

solvated metal ion and dithiolium ion, as is found from the absorption spectra.

To confirm the structure definitely, further investigation, especially X-ray analysis, is necessary, and is now going on in our laboratory.

The authors wish to thank Professor Mikio Katayama and the Analytical Division of the Department of Pharmacy for the infrared measurements and the elementary analyses. Helpful discussions with Professor Yukichi Yoshino, Dr. Kunihiko Watanuki and colleagues of our laboratory are also gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2049—2054 (1968)

Syntheses and Properties of Some Tetrabromobis(dithioacetylacetonato) Complexes

Akiko FURUHASHI, Toshio TAKEUCHI*1 and Akira OUCHI*1

Department of Chemistry, College of Engineering and Science, Aoyama Gakuin Uuiversity, Megurisawa, Setagaya-ku, Tokyo

(Received March 14, 1968)

Some compounds of type $M(L_{ss})_2Br_4$, where M is Mn(II), Fe(II), Co(II), Cu(II), Zn(II) and Cd(II) and HL_{ss} are dithioacetylacetone, were obtained by passing hydrogen bromide, adding bromine and passing hydrogen sulfide through an ethanolic solution containing an anhydrous metal bromide and acetylacetone. Such compounds, which seem to be isostructural with tetrachlorobis-(dithioacetylacetonato)iron(II), are stable. They are all of high spin, and their infrared spectra show characteristic bands at about 1200, 1000 and 860 cm^{-1}. $Cu^I(L_{ss})_2Br_3$ was also obtained from cupric bromide by the same method without using bromine, but from cupric chloride, an isostructural complex was not obtained but $[Cu(C_5H_8S_2)Cl]_n$. Electronic spectra are also shown and discussed.

The tetrachlorobis(acetylacetonato) complexes of iron(II),[1] manganese(II)[2] and mercury(II)[2] have already been synthesized and discussed. The present authors investigated the syntheses of the homologue of the complex, but chloro-complexes of other metals were hardly obtained. This seems due to the fact that, 1) the chloro complexes are relatively unstable and especially sensitive to water and alcohol, and the products may be decomposed by the solvent during synthesis; 2) in these complexes, dithioacetylacetone is probably in the form of dithiolium ion of unipositive charge; then some oxidant must be added during synthesis.

In the case of $Fe^{II}(L_{ss})_2Cl_4$, ferric chloride was used as the starting material and a tervalent ferric salt works as the oxidant. Manganese and mercury have another relatively stable oxidation state other than the bivalent state, and they may act as a kind of autooxidation catalyst in the process. On the other hand, zinc and cadmium, for example, have a very stable bivalent state and no oxidation ability nor oxidation catalytic effects are expected.

Consequently, an improved synthetic method for the $M^{II}(L_{ss})_2X_4$ (where HL_{ss} is dithioacetylacetone, X is Cl or Br) has been investigated in our laboratory and the complexes of many metals are newly obtained.

The $M^{II}(L_{ss})_2Br_4$ type complexes thus obtained are all of high spin, and show almost the same infrared spectra as that of $Fe^{II}(L_{ss})_2Cl_4$, and not that of $Co(L_{ss})_2$.[3]

When cupric bromid was used as the starting material and bromine not added, the cuprous complex $Cu^I(L_{ss})_2Br_3$ was obtained; but if bromine was added, the cupric complex precipitates. From cupric chloride, however, an isostructural complex was not obtained but $[Cu(C_5H_8S_2)Cl]_n$.

Experimental

Materials and Instruments. The starting materials were of GR grade and were used without further purification. Infrared spectra were obtained by the KBr

disc procedure using a Type DS 403 G infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. Electronic spectra were obtained with a Hitachi EPS-2 type automatic recording spectrophotometer. Reflectance spectra were obtained with an Ito Model QV-3 spectrophotometer, using a reflectance attachment and a magnesium oxide standard. Magnetic moments were measured with a Gouy balance at room temperature (15°C).

Syntheses of Tetrabromobis(dithioacetylacetonato)manganese(II). Three and three tenth grams (0.015 m*l*) of anhydrous manganese(II) bromide and 3.00 g (0.030 mol) of acetylacetone were mixed with 20.0 m*l* of absolute ethanol, and all solid materials*2 dissolved. To the solution cooled on ice, were added first dry hydrogen bromide for 30 min, then 1.1 m*l* (0.042 mol) of bromine dropwise while shaking and finally hydrogen sulfide for 5 min until a some precipitate appeared. The precipitate was filtered off and the filtrate kept in an ice bath for about one hour. The yellow precipitate thus obtained was filtered off and washed with carbon disulfide, ethyl alcohol, chloroform and petroleum ether in succession. The product was dried in a vacuum desiccator. The yield was about 4.0 g (42.0%). Though the product is soluble in water or polar organic solvents, it reacts with them and it is insoluble in non-polar organic solvents. For this reason recrystallization has not yet succeeded.

The syntheses of cobalt(II), zinc(II), cadmium(II) and copper(II) complexes were carried out by almost the same method; the yields were about 30—50%.

The iron(II) complex was obtained from ferric bromide without using bromine, as ferric ion itself worked as the oxidizing agent. The copper(I) complex was obtained from cupric bromide without bromine.

Synthesis of Chlorodithioacetylacetonatocopper(I). One and seven tenth grams of cupric chloride (0.010 mol) and 2.0 g (0.020 mol) of acetylacetone were dissolved in 30 m*l* of absolute ethanol, and the solution refluxed for 2 hr. The clean solution thus obtained was cooled on an ice bath and hydrogen chloride was bubbled in, then hydrogen sulfide. Yellow precipitate appeared immediately. The precipitated product was very unstable, but when washed with absolute ethanol repeatedly, a pale brownish white product was obtained which was very stable even in air. The yield was about 2.1 g (91.5%).

The attempt to synthesize $Zn(L_{ss})_2Cl_4$ or $Cu(L_{ss})_2Cl_4$ from the bivalent metal chloride using chlorine as an oxidant was not successful; perhaps the product is not stable to the solvent during synthesis. On the other hand, the bromo-complexes of these metals are sufficiently stable, and moreover, bromine is easier to handle quantitatively than chlorine; as the addition of a large exess of halogen should be avoided to minimize the side reaction. The syntheses of the iodo-complexes were also attempted, but iodine did not react easily, and the bonding was not very stable; consequently, stable iodo-complexes were not obtained. When ferric bromide was used as the starting material and bromine added, the iron(III) complex did not precipitate. Perhaps tervalent iron complex is not stable, as the formula of the iron(III) complex should be $Fe(L_{ss})_2Cl_5$ from the valence equilibrium, and the central metal ion should be heptacoordinated; it is probably not a stable state.

The attempt to synthesize the isostructural nickel complex was not successful by the same method, perhaps this is due to the fact that the dithioacetylacetonato complex is very stable.

*2 After the dissolution some crystal may appear, which is redissolved into the solvent when hydrogen bromide is passed.

Results and Discussion

Analytical data for these compounds are summarized in Table 1. Their magnetic moments are given in Table 2.

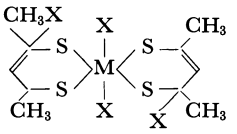
From the magnetic data, the $M(L_{ss})_2Br_4$ type complexes are all high spin types. Though their exact structures have not been determined yet, it may be octahedral.[1,2] $Co(L_{ss})_2Br_5$, for example, seems to have three unpaired electrons, though the observed value is higher than the calculated value, 3.8, as is commonly recognized for many cobalt(II) octahedral complexes.[4] On the other hand, bis(dithioacetylacetonato)cobalt(II), which has a planer structure,[5] is a low spin type and has only one unpaired electron.

Consequently, there are two types of dithioacetylacetonato complexes of the same metal; one is $M(L_{ss})_2$ and the other $M(L_{ss})_2X_4$ (general formulae).

The infrared spectral data for the complexes are summarized in Tables 3 and 4 together with those of some related compounds.[2,3] The general features of the infrared spectra of these complexes rather resemble that of $Fe(L_{ss})_2Cl_4$ and not that of $Co(L_{ss})_2$.

The wave numbers of the main peaks of $Fe(L_{ss})_2Cl_4$ and $Fe(L_{ss})_2Br_4$ are very similar in the 2000—400 cm^{-1} region, indicating that these two complexes are almost isostructural and chlorine or bromine does not affect the vibrational frequencies in that region seriously. This fact seems to suggest that the halogen atoms do not bond directly to the carbon atom in these complexes.[6]

Then one of the formulae proposed by Knauer,[1] (I), is not probable.



(I)

The characteristic bands which seem to be ν(C=S) bands or mixed bands containing ν(C=S)[7] appear

* per one mol of metal

near 1230 and 860 cm^{-1}. The exact assignment of these bands has not yet been made; those written in Table 3 are only tentative. But the general features of the infrared spectra of these complexes resemble those of potassium dichloroacetylacetonato-platinate(II) and related complexes.[8,9] In the latter compounds, there is a ring structure of acetylacetone, which is bonded to the central metal atom by γ-carbon atom or by the π-electrons of the C=C double bond. Strong 1200, 1000 and 860 cm^{-1} bands are also recognized in the spectra of the platinum complexes, but the band at 800 cm^{-1} is absent. However, this fact should not be taken as evidence of the existence of a γ-carbon bonding structure, since the thio- and dithioacetylacetonato chelate rings seem to have an electronic structure different from that of acetylacetonato chelate. The final decision should be arrived from an X-ray crystallographic analysis. But we can expect at least that the halogenobis(dithioacetylacetonato) complexes do not have usual MS_4 type coordination which is found in the $Co(L_{ss})_2$ complex. The dithioacetylacetonato ligands of these compounds seem to form rings themselves, unipositive dithiolium ion for example, and this is the reason that the infrared spectra of these compounds and that of γ-carbon bonding acetylacetonate coincide with each other. The ring form ligand may be a unidentate in these complexes, although it is not yet clear by which atom it bonds to the central metal.

This reflection spectra between 28000 and 13500 cm^{-1} are shown in Table 5. Cabalt(II) complex has an intense band at about 15900 cm^{-1}, and this peak seems to be not only the d–d band but a mixture of d–d and d–π bands. Iron(II) and copper(II) complexes also have an intense color, but their peaks are not clear; shoulders at about 20000—19000 cm^{-1} seem to correspond to them. The intense color of these compounds disappears when they are dissolved in water or methanol. Although weak bands are recognized in this absorption spectra, log ε is only about 2 in both cases; in other words, only about one tenth that of bis-(dithioacetylacetonato)cobalt(II).[3] This intense color of these solid complexes seems to indicate that there is a kind of bonding between the central metal and the ligands. They are not the MX_4^{2-}-$(L_{ss}^{+})_2$ type simple ionic bonding compounds, though, because the metal ion, as well as the dithiolium ion,

* These absorption spectra of the solutions should be those of some decomposition product of complexes with solvents and may not be the spectra of the complex itself.

do not have such intense color. Copper(I), manganese(II), zinc(II) and cadmium(II) complexes also have a less intense peak in this region in the solid state, but not in solution.

The absorptions near 23000 cm^{-1} and 28000 cm^{-1} are found both in their reflection and absorption spectra. These bands and the ones near 34500 and 37500 cm^{-1} of the methanolic solution can probably be assigned to π–π transitions of the dithiolium salts.[10,11] The latter two are also found for 3,5-dimethyl-1,2-dithiolium perchlorate too.[12] From this result, the dithiolium cation seems to exist without decomposition even if the metal-ligand bond is broken by dissolution of the compelexes in methanol, or other similar polar solvents. All of these $M_{ss}^{II}(L_{ss})_2X_4$ type complexes seem to dissociate almost completely into M^{++}, $(L_{ss})^+$ and X^-, as in the case of $Fe_{ss}^{II}(L_{ss})_2Cl_4$.[1] Although this fact was recognized previously, it is also recognized from the qualitative electric conductivity measurement of the aqueous and acetonitrilic solution of these compounds.

From these results, structure (III) is preferable to that proposed by Knauer,[1] which is shown in (II).

(II) (III)

An X-ray crystallographic study of these compounds, which is now in progress by the present authors, may clarify the detailed structure of these comples.

The infrared spectra of $[Cu(C_5H_8S_2)Cl]_n$ is very unique and resembles that of dithioacetylacetone dimer. But it is insoluble in nonpolar solvents and is stable. Though the exact structure is not yet clear, it may be a kind of adduct; a $(-Cu(C_5H_8S_2)-Cl-)_n$ type chain, in which dithioacetylacetone, $C_5H_8S_2$, molecules are bonded to each other copper atom as an unidentate is tentatively proposed.

The authors wish to thank the Analytical Division of the Department of Pharmacy, Professor Mikio Katayama, and the Biochemistry Laboratory of the College of General Education, The University of Tokyo for the elementary analyses of these complexes as well as for the measurement of the infrared spectra. The authors wish to express their appreciation to Professor Yasumasa Hayakawa and the staff of the Department of Chemistry of Aoyama Gakuin University; helpful discussions by Professors Yukichi Yoshino, and Kunihiko Watanuki and colleagues of our laboratory are also gratefully acknowledged.

(Received March 4, 1968)

Calcium oxalate is often used as a carrier for precipitating rare earth elements. Gadolinium was chosen as a rare earth element and X-ray powder diffractometry used for the identification of coprecipitated solids. The X-ray lattice spacings are tabulated for each of the coprecipitates of varying composition in the calcium-gadolinium oxalate system. From the spacings, the following facts were obtained: (1) The uptake mechanisms of gadolinium in calcium oxalate, and calcium in gadolinium oxalate are completely due to the formation of solid solutions. (2) Several new solid solution phases were formed. (3) When the gadolinium to calcium ratio is proper, precipitates having a weddellite structure, which is not obtained in usual analytical procedures, are formed.

The purpose of the present work is to show that the various forms of the hydrated calcium-gadolinium oxalate system can be built up from a trace amount to a large percentage of gadolinium ions in aqueous solutions, with emphasis laid on the fact that some of the unstable forms of hydrated calcium oxalate may be stabilized by the addition and intervention of the tripositive gadolinium ions.

It is well-known that calcium oxalate is often used as a good carrier to precipitate the rare earth elements and other elements. Among these may be mentioned the separation of rare earth elements from uranium, beryllium, aluminum and zirconium by simply agitating an acetic acid solution of the mixture with solid calcium oxalate monohydrate. A similar technique has been used to separate the rare earth elements and strontium from zirconium, niobium and ruthenium.[1-3]

Following an intensive study of the coprecipitation of rare earth elements with various calcium oxalate hydrates, it has been found that calcium oxalate dihydrate carries small amounts of rare earth elements through mixed crystal formation and that the uptake of rare earth elements by calcium monohydrate follows the Freundlich adsorption isotherm.[1] In the case of thorium, calcium oxalate trihydrate

does not take up thorium by way of mixed crystal formation, while dihydrate does.[2]

It was reported that the coprecipitation of a number of elements with calcium oxalate followed the logarithmic distribution law, and that some discrepancies existed in such systems as yttrium-calcium oxalates and scandium-calcium oxalates.[4] The former followed the logarithmic distribution law through a wide range of pH, while the latter obeyed the same law only below pH 3.5, and deviated gradually with increase in pH until pH 4 was reached, after which the system followed the homogeneous distribution law entirely.[8]

From the investigations cited above, it is obvious that the processes of coprecipitation are essentially affected by the forms of calcium oxalate crystals. A number of studies on the crystal forms of hydrated calcium oxalate are found in the literature.[5-7] Those on the phase diagrams and thermodynamic properties[8] have also been reported. For the most part of them, the description and identification of these crystalline species were given in terms of thermogravimetry, X-ray powder diffractometry and infrared spectrophotometry.

The conclusion may be drawn from the results of the above studies, that among various hydrates of calcium oxalate, the most stable one at room temperature is the monohydrate,[5] and the more unstable forms are the dihydrate, the trihydrates and the intermediate hydrates with nonintegral numbers of water molecules between two and three.[6] Some authors designated the monohydrate as form A, and the trihydrates as forms B, C, and D.[5,9] However, more proper names from mineralogy of whewellite[10] for form A and weddellite[11] for form B may be adopted in the investigation of the crystal structures.

Although the formation of solid solutions of trace amounts of rare earth elements with calcium oxalate has been studied by several groups of workers in recent years, little attention was paid to the study of precipitated phases of the calcium-rare earth element oxalate system when the percentage of rare earth element became high. On the other hand, many studies have been made on the phase relations by thermolysis between one hydrate and another, as well as between two forms of the anhydrous salt of calcium oxalate.[7,8,12] Nevertheless, investigations along these lines were scarcely extended beyond detailed information as to whether or not the phases of the calcium oxalate hydrates may have tendency to be changed or stabilized by other cations of similar size.

Experimental

Reagents. Gadolinium nitrate solution was prepared from 99.9% Gd_2O_3, supplied by Miyazaki Chemical Co., Tokyo, Japan. Calcium nitrate solution was prepared from the special grade (JIS) calcium carbonate. Concentrations of these solutions were determined by titration with standard EDTA solution.

Apparatus. All X-ray measurements were carried out with a Rigaku-Denki "Geigerflex" X-ray difractometer, and operated throughout this investigation at 30 kV and 15 mA, using a copper target.

Procedure. For the most of the data in this paper, a total of 200 m*l* of the solution containing about 3 mM of total ions was prepared as nitrate. Methyl red was used as an indicator, and a few drops of dilute ammonium hydroxide and then dilute nitric acid were added until the color just changed from yellow to pink. Most of the experiments were performed at the room temperature around 30°C.

To the above solution was added, with vigorous stirring, 50 m*l* of reagent solution containing 2 g of ammonium oxalate, sufficient to precipitate both the gadolinium and the calcium ions. The turbid mixture was allowed to settle over-night. Precipitated oxalates were collected on filter paper, and washed with a small amount of 0.5% ammonium oxalate, and then with deionized water.

The precipitation from hot solutions was made in the same manner as described above, except that the solutions containing calcium and gadolinium ions were heated to boil, and then hot solutions containing the ammonium oxalate were poured with vigorous stirring. Rapid precipitation set in almost immediately, and was usually completed within a few minutes.

Results

Since the main purpose of this experiment is to determine the forms of phases of the precipitates by means of X-ray powder diffraction, the d-spacings of the precipitates have been carefully compared with those of whewellite[10] and of weddellite.[11] The results are summarized and compiled in two tables.

(1) Precipitates prepared at room temperature

The precipitates containing 0—1 atomic % of gadolinium formed at room temperature consist of fine crystals with the characteristic spacings of whewellite. When the gadolinium content exceeds 2%, the precipitates no longer show whewellite-like structure, but exhibit the characteristic spacings of weddellite until the atomic percentage of gadolinium increases up to 30. The sharp contrast is readily seen in Table 1. For convenience, the two phases consisting of whewellite-like and weddellite-like

				2.11										2	G
				2.10							2	2	3		γ

structures are respectively designated as α and β forms of the Ca-Gd oxalate system.

As the gadolinium content attained a range of between 30 and 85% in the solution, the coprecipitated phases give diffraction patterns with entirely different spacings, comprising 4.80, 3.90, 3.21, 2.46, 2.38, 2.10 A, *etc.* These are designated as the γ form so as to be distinguishable from the other forms. It is noteworthy that the values of the d-spacings for any form stated above do not vary over a wide range of composition.

Pure hydrated calcium oxalate and pure hydrated gadolinium oxalate were also prepared by the same method as described in the paragraph under the heading of " Procedure." The former is a typical artificial whewellite, and is distinctly recognizable from its characteristic spacings. The latter is not known in nature, and the name " G form " is given to this solid phase that has spacings of 7.56, 4.93, 4.35, 3.92, 3.45 A, *etc.* Among these, the 7.56 A spacing gives the strongest diffraction.

(2) Precipitates prepared at elevated temperature

The results are quite different when the coprecipitation was carried out at an elevated temperature. The precipitates thus obtained with amounts of

1.81	13	1.82	7	5	5	4	6	7		α, δ

gadolinium varying from traces to a very large percentage are identified as fine crystals with characteristic spacings of whewellite, the α form according to our designation. No weddellite-like structure (β form) is found.

Pure hydrated gadolinium oxalate was also prepared. At temperatures around 100°C, a lower hydrate rather than a higher hydrate is formed. Its spacings are remarkably different from those of the G form, hence the name of G′ form is given to this phase. From solutions of high concentrations of gadolinium, still another phase appeared, which gave weak diffraction patterns. This phase is designated as the δ form. The various forms obtained from the solutions at the elevated temperature are summarized in Table 2.

Discussion

From the experimental results, proper formulas can be used to depict the various forms of the hydrated calcium and gadolinium oxalates which were precipitated in the respective solutions either at room temperature or at elevated temperatures.

TABLE 3. FORMULAS SUGGESTED FOR THE HYDRATED Ca-Gd OXALATES PRECIPITATED AT ROOM TEMPERATURE*

Form of phase	Formula
α	$(Ca_{1-x}, Gd_{2x/3})(COO)_2 \cdot H_2O$
β	$(Ca_{1-x}, Gd_{2x/3})(COO)_2 \cdot 2H_2O$*
γ	$(Gd_{1-x}, Ca_{3x/2})_3(COO)_3 \cdot mH_2O$
G	$(Gd_{1-x}, Ca_{3x/2})_2(COO)_3 \cdot nH_2O$

* The formula for the β form may be also expressed as

$$(Ca_{1-x}, Gd_{2x/3})(COO)_2 \cdot (2+y)H_2O$$

in which y has a value varying between 0 and 0.5. The fractional portion of the H_2O content is zeolitic.

TABLE 4. FORMULAS SUGGESTED FOR THE HYDRATED Ca-Gd OXALATES PRECIPITATED AT ELEVATED TEMPERATURES

Form of phase	Formula
α	$(Ca_{1-x}, Gd_{2x/3})(COO)_2 \cdot H_2O$
δ	$(Gd_{1-x}, Ca_{3x/2})_2(COO)_3 \cdot m'H_2O$
G'	$(Gd_{1-x}, Ca_{3x/2})_2(COO)_3 \cdot n'H_2O$

The formulas are listed in Tables 3 and 4.

Because no β form appears in the mixed crystals prepared at elevated temperatures, this form is evidently less stable toward heat than the α form. When the concentration of calcium ion is very high compared with that of gadolinium ion, the precipitated host lattice must be in the most stable form of whewellite. Owing to the very small amount of the guest gadolinium ions absorbed on the surface or entrapped by successive layers of the host lattice, the total amount of hydrated water of the guest lattice will also be small, and as a result, the α form rapidly aggregates.

When the concentration of gadolinium ions exceeds 2%, the number of water molecules brought into the lattice would be much greater than in the former case, and they may be capable of changing the monohydrate into the dihydrate of calcium oxalate. In other words, the host lattice of the whewellite-like phase is smoothly transformed into the other host lattice of weddellite-like phase following the reinforcement of gadolinium ions together with an abundant supply of hydrated water, resulting in the formation of the β form.

At elevated temperatures gadolinium ions are capable of migrating gradually into the lattice of calcium oxalate monohydrate up to a large amount without altering any spacing of the latter; as a result, words, the substitution of calcium ions by gadolinium ions in the α form phase under the experimental conditions can preceed to a great extent, sometimes expanding into the range of the δ form.

On the other hand, the G' form phase does not admit calcium ions into its lattice to an extent greater than a few percent. It follows that the phase of the δ form may be considered as a distorted phase of the G' form. With reference to Table 2, it is seen that any one set of spacings, possibly regarded as characteristic of the δ form, is almost identical with that of the G' form, or with only a very slight shift.

From the present study, it is tentatively suggested that a metastable solid phase like the β form may coexist temporarily with a more unstable phase like the γ form under ordinary experimental conditions. This is clearly seen from the data on the phases when the gadolinium content reaches 30%, as shown in Table 1. The same fact is observed with the α form and δ form which coexist with each other, as shown in Table 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2059—2064 (1968)

Polarographic Behavior of Tris(2,2′-bipyridine)cobalt(II) and Tris(2,2′-bipyridine)cobalt(III) in Acetonitrile Solutions

Nobuyuki TANAKA and Yuichi SATO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 18, 1968)

The electrode processes of tris(2,2′-bipyridine)cobalt(II) and tris(2,2′-bipyridine)cobalt(III) complexes at the dropping mercury electrode in acetonitrile solutions have been investigated by the measurement of direct current, alternating current and Kalousek polarograms. The cobalt(II) complex gave a one-step oxidation and a four-step reduction wave and the cobalt(III) complex, a five-step reduction wave, when tetraethylammonium perchlorate was used as supporting electrolyte. The solution containing the cobalt(II) and the cobalt(III) complexes gave a reversible composite wave. The limiting currents of the first two steps named from positive to negative potentials of the reduction wave of the cobalt(II) complex were diffusion-controlled, the first step being of a one-electron reduction process and the second step, of a two-electron reduction process. From the effect of free 2,2′-bipyridine and water on the reduction wave of the cobalt(II) complex and from the Kalousek polarograms, the electrode processes of the first two steps taking place in the presence of a large concentration of free 2,2′-bipyridine were estimated as,

$$[Co(bipy)_3]^{2+} \underset{-e}{\overset{e}{\rightleftharpoons}} [Co(bipy)_3]^{+} \underset{-2e}{\overset{2e}{\rightleftharpoons}} [Co(bipy)_3]^{-}$$

The effect of a small concentration of acrylonitrile on the reduction wave of the cobalt(II) complex was studied.

As acetonitrile is an aprotic solvent and has less oxidizing power than water, the electrode process in acetonitrile is sometimes quite different in water. Tris(2,2′-bipyridine)iron(II) complex cation in acetonitrile solutions is reduced to univalent tris-(2,2′-bipyridine)ferrate anion which cannot exist in aqueous solutions.[1,2] Such a low valent state is expected in bipyridine complexes of other metals.

In the present paper, the electrode processes of tris(2,2′-bipyridine)cobalt(II) and tris(2,2′-bipyridine)cobalt(III) complexes at the dropping mercury electrode (DME) are presented and the effect of acrylonitrile on the reduction wave of the cobalt(II) complex is discussed.

Experimental

Tris(2,2′-bipyridine)cobalt(II) perchlorate and tris-(2,2′-bipyridine)cobalt(III) perchlorate were prepared according to Burstall and Nyholm[3] and identified by elementary analysis. Acetonitrile, tetraethylammonium perchlorate and sodium perchlorate were the same as described in a previous paper.[2] Acrylonitrile used was of a reagent grade. The dropping mercury electrode used had an m value of 0.63_1 mg/sec and a drop time t_d of 4.84 sec, when measured in an air-free acetonitrile solution containing 0.05 M of $(C_2H_5)_4NClO_4$ at 25°C and at −0.5 V *vs.* SCE at 50 cm of the height of mercury reservoir. An aqueous saturated calomel electrode (SCE) served as a reference electrode. The electrolysis cell and other apparatus are the same as previously described.[2]

Results

Tris(2,2′-bipyridine)cobalt(II) complex gave a one-step oxidation wave from cobalt(II) to cobalt-(III) around +0.2 V *vs.* SCE, while tris(2,2′-bipyridine)cobalt(III) complex gave a reduction wave from cobalt(III) to cobalt(II) at almost the same potential. The plots of $\log \bar{i}/(\bar{i}_d - \bar{i})$ *vs.* E for the anodic and the cathodic wave gave straight lines. Half-wave potentials and the values of the slopes determined from the log-plot analysis were given in Table 1. The solution containing the same concentrations of the cobalt(II) and the cobalt(III) complexes showed a continuous oxidation-reduction wave and an equilibrium potential which was equal to the half-wave potentials of the oxidation wave of the cobalt(II) complex and the reduction wave of the cobalt(III) complex.

When tetraethylammonium perchlorate was used as supporting electrolyte, tris(2,2′-bipyridine)cobalt-(II) complex gave a four-step reduction wave as reproduced in Fig. 1 (curve a). In the solutions

TABLE 1. LOG-PLOT ANALYSIS FOR THE OXIDATION OF THE COBALT(II) AND THE REDUCTION OF THE COBALT(III) COMPLEXES (25°)*

Reaction	$E_{1/2}$, V *vs.* SCE	Slope, mV
Oxidation process	0.241	62
Reduction process	0.235	65

* Electrolytic solutions contain 0.5 mM complex and 0.05 M $(C_2H_5)_4NClO_4$.

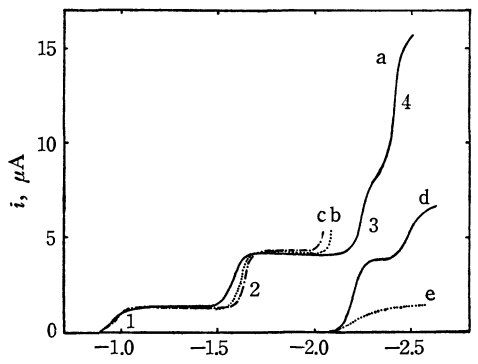

Fig. 1. D.c. polarograms of (a) 0.5 mM $[Co(bipy)_3](ClO_4)_2$, (b) (a) with 10.0 mM 2,2'-bipyridine, (c) (a) with 50.0 mM 2,2'-bipyridine, (d) 1.0 mM 2,2'-bipyridine and (e) 0.38 mM CH_2CHCN. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

containing sodium perchlorate as supporting electrolyte, the first two steps were observed, which were followed by the reduction of sodium ions. The cobalt(III) complex gave a five-step reduction wave, of which the second to the fifth steps were exactly the same as the first to the fourth steps of the cobalt(II) complex. In this paper, the polarographic behavior of the cobalt(II) complex is presented.

The limiting currents of the first (at −1.2 V) and the second step (at −1.8 V) named from positive to negative potentials were found to be proportional to the square root of the mercury pressure on the DME between 45 and 60 cm. The limiting currents were also proportional to the concentration of the complex. Upon the addition of free 2,2'-bipyridine to the solution containing 0.5 mM of the complex, the limiting currents of the first two steps were not affected, but those of the third and the fourth step were increased. The half-wave potential and the slope of the log-plot analysis (57 mV) of the first step were not affected, whereas the half-wave potential of the second step shifted to more negative potentials and the slope of the log-plot approached to the value of that of a reversible two-electron electrode process with increasing concentrations of free bipyridine (see Table 2). The half-wave potential of the third and the fourth step shifted to less negative potentials. Free 2,2'-bipyridine gave a two-step

TABLE 2. LOG-PLOT ANALYSIS FOR THE SECOND STEP OF THE REDUCTION OF THE COBALT(II) COMPLEX AT VARIOUS CONCENTRATIONS OF 2,2'-BIPYRIDINE*

Conc. of 2,2'-bipyridine, mM	$E_{1/2}$, V *vs.* SCE	Slope, mV
0	−1.580	57
10	−1.617	40

* Electrolytic solutions contain 0.5 mM $[Co(bipy)_3](ClO_4)_2$, 0.05 M $(C_2H_5)_4NClO_4$ and various concentrations of 2,2'-bipyridine.

reduction wave at potentials corresponding nearly to the third and the fourth step of the polarogram of the complex as shown in Fig. 1.

By the addition of a small concentration of water into the acetonitrile solution containing 0.5 mM of the complex and 0.05 M of $(C_2H_5)_4NClO_4$, the limiting currents of the first two steps of the reduction wave were scarcely affected, but the third and the fourth step shifted to less negative potentials and the limiting current of the third step increased (Fig. 2). By further addition of water, the third step shifted to less negative potentials and the second step became ill-defined. The polarogram of free 2,2'-bipyridine was also affected by the addition of water; its reduction potential shifted to less negative potentials and its limiting current increased.

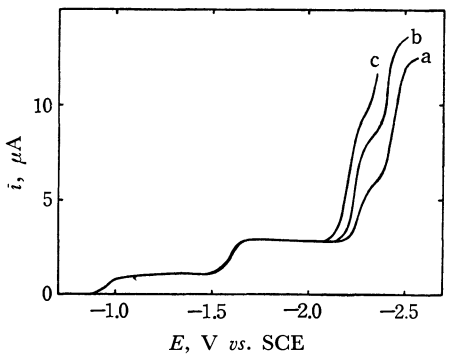

Fig. 2. D.c. polarograms of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ (a) in the absence and in the presence of (b) 0.028 M and (c) 0.139 M of water. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

The reversibilities of the first two steps were confirmed by the measurement of Kalousek polarograms, which are shown in Fig. 3. A two-step oxidation wave was obtained, when the electrode potential was set up at −1.9 V (curves b and b' in Fig. 3).

Acetonitrile often contains acrylonitrile as impurity, which gives a drawn-out cathodic wave at about −2.3 V as reproduced in Fig. 1 (curve e). Kalousek polarogram of acrylonitrile gave a one-step oxidation wave at about −0.6 V, when the electrode potential was set up at the potential of the

limiting current of the reduction wave of acrylonitrile. When acrylonitrile was present in the solution, the reduction wave of cobalt(II)-bipyridine complex was affected and two new steps appeared, which were named 2 A and 2 B (curves b and c in Fig. 4). The 2 A step started from about −1.3 V followed by the second step, and its limiting current

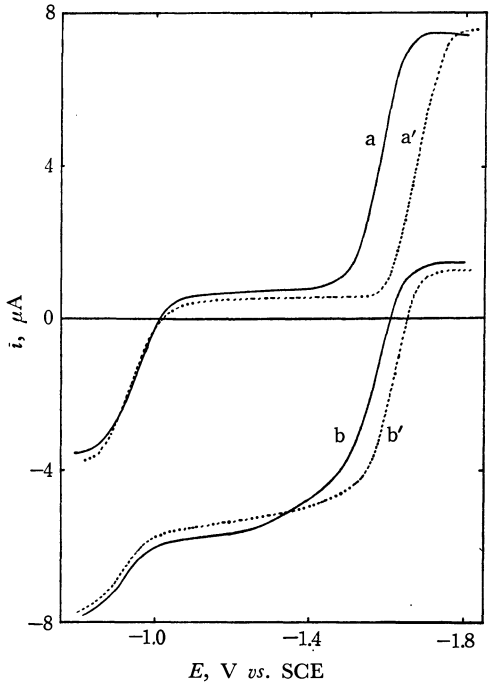

Fig. 3. Kalousek polarograms of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ (a and b) in the absence and (a′ and b′) in the presence of 50 mM of 2,2′-bipyridine. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$. E_2 potentials are set up at −1.20 V for a and a′ and −1.90 V for b and b′.

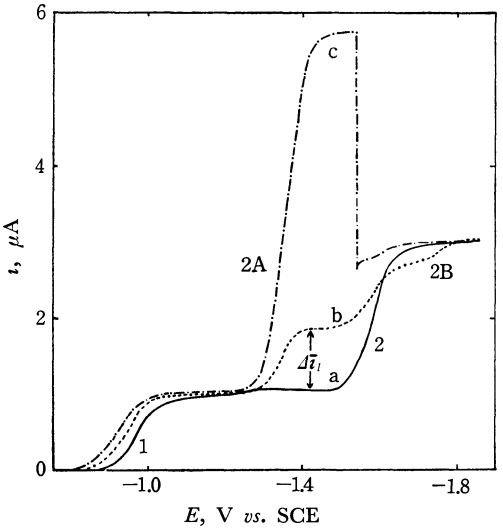

Fig. 4. D.c. polarograms of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ (a) in the absence and in the presence of (b) 0.38 mM and (c) 1.9 mM of CH_2CHCN. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

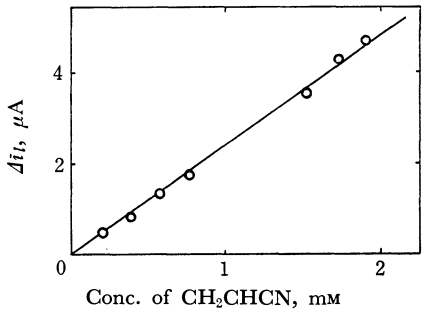

Fig. 5. Limiting current of the 2A step as a function of the concentration of acrylonitrile, obtained with the solutions containing 0.5 mM $[Co(bipy)_3](ClO_4)_2$, CH_2CHCN and 0.05 M $(C_2H_5)_4NClO_4$. For Δi_l, see curve b in Fig. 4.

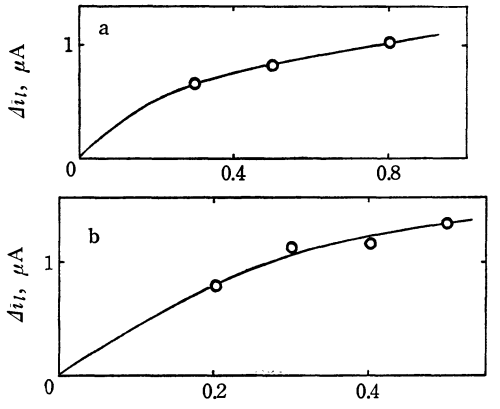

Fig. 6. Limiting current of the 2A step as a function of concentration of the complex, obtained with the solutions containing $[Co(bipy)_3](ClO_4)_2$, 0.05 M $(C_2H_5)_4NClO_4$ and (a) 0.38 mM CH_2CHCN and (b) 0.57 mM CH_2CHCN. For Δi_l, see curve b in Fig. 4.

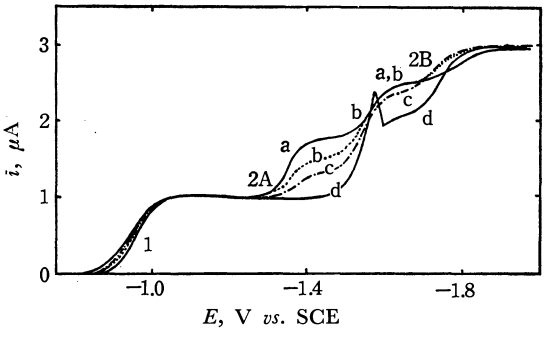

Fig. 7. D.c. polarograms of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ in the presence of 0.38 mM CH_2CHCN and (a) 0, (b) 1.0 mM, (c) 2.0 mM and (d) 10.0 mM 2,2′-bipyridine. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

(the difference of the limiting currents at -1.45 V in the presence and the absence of acrylonitrile, Δi_l) was proportional to the concentration of acrylonitrile at the constant concentration of the complex (see Fig. 5), and to the square root of the height of the mercury reservoir. Although the limiting current of the 2 A step was increased with increasing concentrations of the complex at the constant concentration of acrylonitrile, Δi_l was not proportional to the concentration of the complex, but approached to a definite value (Fig. 6). When the concentration of acrylonitrile was about five times larger than that of the complex, the 2 A step gave a peak current and its reproducibility was poor. By adding free 2,2′-bipyridine to the solution the 2 A step was depressed and the 2 B step became more noticeable, as seen in Fig. 7. In the solution containing 0.5 mM of the complex and 0.38 mM of acrylonitrile, the 2 A step almost disappeared by the addition of about 6 mM of free bipyridine.

A.c. polarograms of the cobalt(II) complex were recorded in the presence and in the absence of acrylonitrile and free bipyridine (Fig. 8). The solution containing only the complex showed four peakss which corresponded to the above-mentioned four steps of the d.c. polarogram. In Fig. 8, the first two peaks are reproduced. The other two peaks which appeared at more negative potentials are considered to be the reduction of the ligand coordinated to cobalt. By adding acrylonitrile two new peaks named 2 A and 2 B appeared. The addition of 10 mM of free bipyridine depressed the 2 A peak as shown in Fig. 8 (curve c). The solution

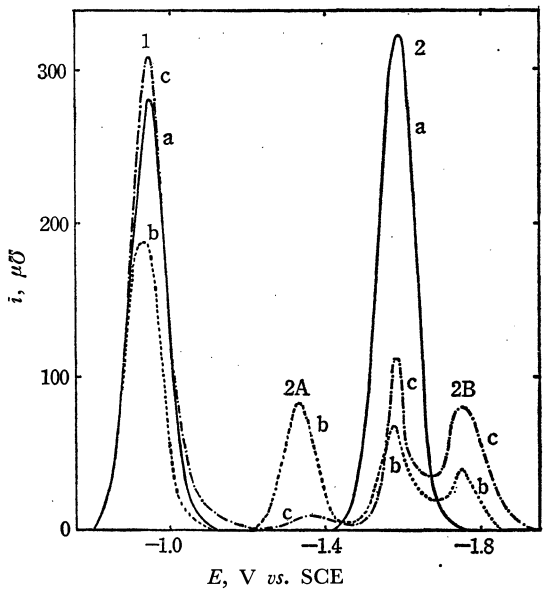

Fig. 8. A.c. polarograms of 0.5 mM $[Co(bipy)_3](ClO_4)_2$ (a) in the absence and in the presence of (b) 0.38 mM CH_2CHCN and (c) 0.38 mM CH_2CHCN and 10.0 mM 2,2′-bipyridine. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

containing only acrylonitrile showed a small peak of irreversible-type at about -2.2 V.

Discussion

The slopes of the log-plot and the half-wave potentials for the reduction of the cobalt(III) and the oxidation of the cobalt(II) complexes show that the electrode process of the coabalt(III) and the cobalt(II) system,

$$[Co(bipy)_3]^{3+} + e \rightleftharpoons [Co(bipy)_3]^{2+}$$

is reversible at the DME. The continuous oxidation-reduction wave which was obtained with a solution containing the same concentrations of the cobalt(III) and the cobalt(II) complex confirmed the above conclusion.

The limiting currents of the first two steps of the reduction wave of the cobalt(II) complex are concluded to be diffusion-controlled from the linearities of the limiting currents on the square root of the mercury pressure and on the concentration of the complex. The diffusion current constant for the first step obtained by the Ilkovič equation is 2.17, which is nearly equal to the value of a one-electron reduction of tris(2,2′-bipyridine)iron(II) complex.[2] The ratio of the wave heights of the first two steps is 1 : 2 after corrected for the drop time. The fact that the wave heights of the first two steps of the complex are not influenced by the addition of free 2,2′-bipyridine and a small concentration of water but those of the last two steps are influenced shows that the electrode processes of the first two steps and the latter two steps are different in nature.

From the same considerations as in the case of the reduction of the iron(II) complex[2] in addition to the fact that the reduction potential of free 2,2′-bipyridine is equal to the potential of the third and the fourth step of the reduction wave of the complex (see Fig. 1), the first two steps are concluded to be due to the reduction of the cobalt(II) complex itself and the latter two steps, the reduction of free bipyridine liberated from the complex. The second step seems to be a two-electron reduction from the cobalt(I) complex to the cobalt(-I) complex and the electrode process is considered to consist of various paths, such as a reduction from $[Co(bipy)_3]^+$, and that from $[Co(bipy)_{3-n}]^+$, the reduction potentials of the latter being less negative than the former. As the concentration of free bipyridine is increased, the reaction path from $[Co(bipy)_3]^+$ will be predominant because the half-wave potential shifted to more negative potentials and the reciprocal slope of the log-plot became smaller and approached to the theoretical value of a two-electron reversible process (see Table 2).

Kalousek polarograms also suggested the formation of the cobalt(I) and the cobalt(-I) complex at the electrode surface at the potentials of the first and the second step, respectively. Thus, the reaction

scheme may be written as,

$$
\begin{array}{ccc}
[Co(bipy)_3]^{2+} & & \\
+ & & \\
e & & \text{(the first step)} \\
\downarrow\uparrow & & \\
[Co(bipy)_3]^{+} & \rightleftharpoons & [Co(bipy)_{3-n}]^{+} + n\ \text{bipy} \\
+ & & + \\
2e & & 2e \qquad \text{(the second step)} \\
\downarrow\uparrow & & \downarrow\uparrow \\
[Co(bipy)_3]^{-} & \rightleftharpoons & [Co(bipy)_{3-n}]^{-} + n\ \text{bipy}
\end{array}
$$

Vlček[4] and Waind and Martin[5] found the cobalt(I) state polarographically and were successful in preparing the compound. Herzog, Klausch and Lantos[6] prepared the cobalt(0) complex, $[Co(bipy)_3]$, from $CoCl_2$ and Li_2bipy in tetrahydrofuran. The bipyridine complex of cobalt(-I) has not been prepared yet according to the author's knowledge. The reason why the reduction process to the cobalt(0) complex is not observed at the DME is probably in the fact that the cabalt(0)-bipyridine complex is not sufficiently stable in acetonitrile and the cobalt(I) complex is reduced directly to the cobalt(-I) state.

The reduction mechanism of acrylonitrile at the DME in acetonitrile has not been discussed,[7] although the reduction wave is often used for the analysis of residual acrylonitrile monomer in styrene-acrylonitrile copolymer.[8] The electrode process of acrylonitrile is considered to be irreversible from the shape of the drawn-out wave (curve e in Fig. 1) and the small peak current of the a.c. polarogram. Kalousek polarogram also confirmed the irreversibility of the electrode process. Proton will not take part in the reduction process because the electrode reaction proceeds in acetonitrile of aprotic solvent. If proton took part in, the reduction product of acrylonitrile at the electrode surface would be propionitrile, CH_3CH_2CN, as was found in aqueous solutions.[9] This is not the case because propionitrile gives no oxidation wave at about -0.6 V[10] where an oxidation wave is observed in a Kalousek polarogram. Since acrylonitrile polymer radical has been observed by e.s.r.[11] the reduction product of acrylonitrile is likely to be an acrylonitrile radical, but not a propionitrile molecule. Stylene, $C_6H_5CH=CH_2$, and crotonic acid, $CH_3CH=CHCOOH$ also give a reduction wave at about -2.45V and -2.3V, respectively, and at the Kalousek circuit, an anodic wave at about -1.15 V and $+0.1$ V, respectively. Although acrylonitrile itself is reduced at such a negative potential as -2.3 V, the reduction wave of the cobalt(II) complex is affected at about -1.4 V (2 A wave) and -1.7 V (2 B wave) in the presence of a small concentration of acrylonitrile (curve b and c in Fig. 4). From the proportionalities of the limiting current of the 2 A step on the concentration of acrylonitrile at the constant concentration of the complex (Fig. 5) and on the square root of the height of the mercury reservoir, the 2 A step seems to be controlled by the diffusion of acrylonitrile. The temperature coefficient of the limiting current of the 2 A step was found to be 1.3%/deg at 25°. Even when the concentration of acrylonitrile is larger than that of the complex, the limiting current of the 2 A step is proportional to the concentration of acrylonitrile. However, the limiting current suddenly decreased at the potential of the first half of the second step and the limiting current at -1.9 V is constant irrespective of the concentration of acrylonitrile as far as the concentration of the complex is the same (curve c in Fig. 4). The dependency of $\Delta\bar{i}_l$ on the concentration of the complex at the constant concentration of acrylonitile is almost in agreement with the Langmuir isotherm. All these results suggest that the 2 A step is not due to a reduction of the complex but due to that of acrylonitrile in the presence of cobalt(I) species at the electrode. Since the 2 A step was suppressed by the addition of free 2,2′-bipyridine as shown in Fig. 7, the reduction of acrylonitrile seems to require the species of $[Co(bipy)_{3-n}]^{+}$ at the electrode surface. The cobalt(I) complex formed at the electrode is considered to be substitution-labile, because the half-wave potential of the second step was shifted to more negative potentials with increasing concentrations of free bipyridine. Therefore, in the absence of free bipyridine, cobalt(I) species formed at the electrode surface at -1.1 to -1.5 V may be mainly $[Co(bipy)_{3-n}]^{+}$. An acrylonitrile molecule to be reduced approaches to the electrode and may be coordinated to the central cobalt ion in $[Co(bipy)_{3-n}]^{+}$ which is adsorbed on the surface of the electrode. The reduction of acrylonitrile will occur at this state. If free bipyridine is present in the solution, the coordination of acrylonitrile to the central cobalt(I) ion is hindered and consequently the limiting current of the 2 A step is decreased. In this electrode process, the cobalt(I) species acts as a role of bridge for the electron transfer from the electrode to acrylonitrile molecule. The complex formation between acrylonitrile and $[Co(bipy)_{3-n}]^{+}$ does not occur in the bulk of the solution but at the electrode surface, because the limiting current of the 2 A step is proportional to the concentration of acrylonitrile but not to that of the complex. An acrylonitrile molecule seems to be coordinated at its double bond

rather than at its CN group, because a solvent molecule (acetonitrile) has also a CN group and its concentration is about 5×10^4 times greater than that of acrylonitrile. In the case of iron(I) tetracarbonyl acrylonitrile ($Fe(CO)_4CH_2$=CHCN), both a double-bonded type and a σ-bonded type of bonding of acrylonitrile to the central iron are known.[12,13] The potential of the 2 A step is nearly the middle between the reduction potential of acrylonitrile and the oxidation potential of its reduction product obtained by the Kalousek circuit. The overpotential of acrylonitrile appears to be lessened by the coordination to cobalt(I) at the electrode surface. At the potentials of the 2nd step where cobalt(I) is reduced to cobalt(−I) state, the 2 A step vanishes, and acrylonitrile cannot coordinate to the cobalt(−I) and consequently the limiting current of the second step is constant at about −1.9 V irrespective of the concentration of acrylonitrile. A similar phenomenon as the 2 A step is observed in the case of crotonic acid but the situation seems to be more complicated. The 2B step appears to occur by the retardation of the electrode process of the acrylonitrile as the current-potential curve at the second step is seen to be cut off and the limiting current at about −1.9 V is always constant.

Polarographic Behavior of Tris(2,2′-bipyridine)manganese(II) in Acetonitrile Solutions

Yuichi SATO and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 27, 1968)

Polarographic behavior of tris(2,2′-bipyridine)manganese(II) perchlorate at the dropping mercury electrode in acetonitrile solutions has been investigated by the measurement of d.c., a.c. and Kalousek polarograms. The manganese(II) complex gave a five-step reduction wave and a one-step oxidation wave at the dropping mercury electrode when tetraethylammonium perchlorate was used as supporting electrolyte. In the presence of a large concentration of free 2,2′-bipyridine, the limiting currents of the first three steps of the reduction of the manganese(II) complex are all diffusion-controlled and of a one-electron reduction process. The electrode processes for these steps have been concluded to be the reductions to $[Mn(bipy)_3]^+$, $[Mn(bipy)_3]$ and $[Mn(bipy)_3]^-$, respectively.

The electro-reduction of tris(2,2′-bipyridine)manganese(II) complex at the dropping mercury electrode (DME) in ethanol solutions and the formation of tris(2,2′-bipyridine)manganese(I) cation, $[Mn(bipy)_3]^+$, at the electrode surface were briefly reported.[1]

In acetonitrile solutions the electro-reduction of tris(2,2′-bipyridine)manganese(II) complex is expected to proceed to the lower oxidation state as was observed with tris(2,2′-bipyridine)iron(II)[2] and tris(2,2′-bipyridine)cobalt(II)[3] complexes.

The present paper is concerned with the polarographic behavior of tris(2,2′-bipyridine)manganese(II) complex and the support on the formation of $[Mn(bipy)_3]$ and $[Mn(bipy)_3]^-$ at the DME in acetonitrile solutions.

Experimental

Tris(2,2′-bipyridine)manganese(II) perchlorate, $[Mn(bipy)_3](ClO_4)_2$ was prepared according to Burstall and Nyholm[4] and identified by chemical analysis. Acetonitrile, tetraethylammonium perchlorate and sodium perchlorate were the same as described in a previous paper.[2] The dropping mercury electrode used had an m value of 0.63_1 mg/sec and a drop time t_d of 4.83 sec when measured in an air-free acetonitrile solution

containing 0.05 M of $(C_2H_5)_4NClO_4$ at 25°C and at −0.5 V *vs.* SCE at 50 cm of the height of mercury reservior. An aqueous saturated calomel electrode (SCE) served as reference electrode. The electrolysis cell and other apparatus are previously reported.[2)]

Results

Tris(2,2'-bipyridine)manganese(II) complex gave a five-step reduction wave with a maximum at the second step when tetraethylammonium perchlorate was used as supporting electrolyte (Fig. 1). In the solutions containing sodium perchlorate as supporting electrolyte only the first two steps were observed which were followed by the reduction of sodium ions.

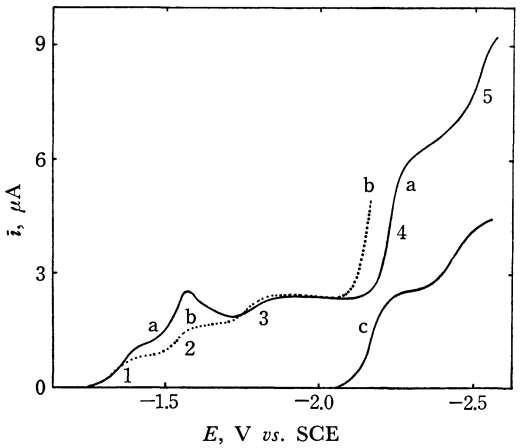

Fig. 1. D.c. polarograms of 0.5 mM $[Mn(bipy)_3](ClO_4)_2$ (a) in the absence and (b) the presence of 5.0 mM 2,2'-bipyridine and (c) that of 0.5 mM free 2,2'-bipyridine. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

Upon the addition of free 2,2'-bipyridine, the maximum at the second step was depressed (Fig. 2) and the limiting currents of the fourth and the fifth step increased. In the presence of 5.0 mM or more, the reduction potentials and the limiting currents of the first three steps which are shown by curve d in Fig. 2 were almost the same irrespective of the concentration of bipyridine. Therefore, the nature of the limiting currents of the first three steps was investigated with the solutions containing excess 2,2'-bipyridine. The limiting currents of the first three steps were found to be proportional to the square root of the mercury pressure between 45 cm and 60 cm on the DME and also to the concentration of the complex. The results of log-plot analysis of the first step of the reduction at various concentrations of 2,2'-bipyridine are given in Table 1. At a large concentration of 2,2'-bipyridine compared with the complex, the half-wave potentials and the slopes of log-plot seem to be constant irrespective of the concentration of bipyridine. Free 2,2'-bipyridine gave a two-step reduction wave at the potentials

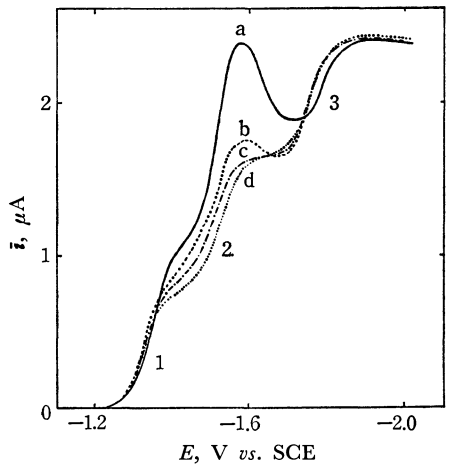

Fig. 2. The effect of free 2,2'-bipyridine upon the first three steps of the reduction wave of 0.5 mM $[Mn(bipy)_3](ClO_4)_2$. The concentrations of 2,2'-bipyridine are (a) 0, (b) 0.5 mM, (c) 1.0 mM and (d) 5.0 mM.

Table 1. Half-wave potentials and slopes of log-plots for the first step of the reduction wave of 0.5 mM $[Mn(bipy)_3](ClO_4)_2$ in acetonitrile solutions containing various concentrations of 2,2'-bipyridine and 0.05 M $(C_2H_5)_4NClO_4$ at 25°C.

Concn. of 2,2'-bipyridine mM	$E_{1/2}$ V *vs.* SCE	Slope mV
0	−1.347	69
0.5	−1.340	75
1.0	−1.335	71
2.0	−1.329	65
5.0	−1.333	65
10.0	−1.327	64

where tris(2,2'-bipyridine)manganese(II) complex gave the fourth and the fifth wave, respectively, as shown in Fig. 1.

Upon the addition of a small concentration of water into the acetonitrile solution, the first three steps of the reduction wave were scarcely affected, but the fourth and the fifth step shifted to less negative potentials and the limiting currents increased as seen in the five-step reduction wave of tris(2,2'-bipyridine)iron(II) cmplex.[2)]

The reversibilities of the first three steps were confirmed by the measurement of Kalousek polarograms, which are shown in Fig. 3. A one-step, a two-step and a three-step oxidation wave were obtained, when the electrode potentials were set up at −1.40 V, −1.65 V and −1.95 V respectively.

A.c. polarograms of the complex gave five peaks; their peak potentials were found to coincide with the half-wave potentials of the corresponding steps of the

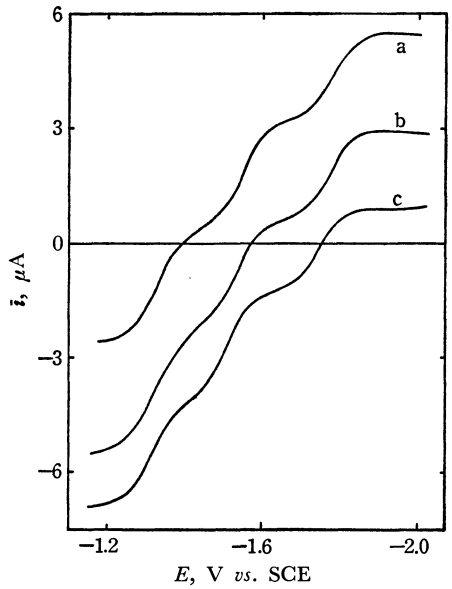

Fig. 3. Kalousek polarograms of the solution containing 0.5 mM $[Mn(bipy)_3](ClO_4)_2$, 50.0 mM 2,2′-bipyridine and 0.05 M $(C_2H_5)_4NClO_4$. Electrode potentials are set up at (a) −1.40 V, (b) −1.65 V and (c) −1.95 V. Exchange frequency is about 14 Hz.

d.c. polarogram. The addition of free 2,2′-bipyridine to the solution of the complex increased the fourth and the fifth peak current, but gave almost no influence on the first, the second and the third one.

The complex gave a one-step anodic wave at about +0.3 V which was almost the same as the potential of anodic wave of free 2,2′-bipyridine. However, neither the manganese(II) complex nor free 2,2′-bipyridine gave an anodic wave at less positive potentials than +1.9 V,[2] when the rotated platinum electrode was used as a working electrode.

Discussion

The limiting currents of the first three steps of the reduction wave of tris(2,2′-bipyridine)manganese(II) complex in the presence of excess 2,2′-bipyridine are concluded to be diffusion-controlled from the linearities of the limiting currents on the square root of the mercury pressure and the complex concentrations. The diffusion current constant for the first step calculated by the Ilkovič equation is 1.95, which is nearly equal to the values of one-electron reduction of various metal ions[5] and tris(2,2′-bipyridine)iron(II)[2] and tris(2,2′-bipyridine)cobalt(II)[3] in acetonitrile solutions. The ratio of the wave height for the first three steps obtained at a large concentration of 2,2′-bipyridine is 1 : 1 : 1 after corrected for the drop time. The slope of log-plot analysis for the first step approaches to the value of a reversible one-electron reduction with increasing concentrations of 2,2′-bipyridine (Table 1). 2,2′-Bipyridine seems to act as a maximum suppressor. The effect of 2,2′-bipyridine and water on the d.c. ploarogram suggests that the first three steps and other two steps observed at more negative potentials are different in nature from the same consideration as in the case with the reduction of the iron(II)[2] and the cobalt(II)[3] complexes. From all these results mentioned above, each of the first three steps of the manganese(II) complex is concluded to be a one-electron reduction of the complex itself as given by

$$[Mn(bipy)_3]^{2+} \underset{-e}{\overset{e}{\rightleftharpoons}} [Mn(bipy)_3]^{+} \underset{-e}{\overset{e}{\rightleftharpoons}}$$

$$[Mn(bipy)_3] \underset{-e}{\overset{e}{\rightleftharpoons}} [Mn(bipy)_3]^{-}$$

and the other two steps, the reduction of the ligand liberated from the complex. Kalousek polarograms show that the electrode process of each of the first three steps is reversible and also confirm the existence of low oxidation states such as $[Mn(bipy)_3]^+$, $[Mn(bipy)_3]$ and $[Mn(bipy)_3]^-$ at the electrode surface in acetonitrile.

The formation of tris(2,2′-bipyridine)manganese(I) state at the DME in ethanol was already reported by Vlcek,[1] though the compound seems not to be isolated. Herzog and Schmidt prepared tris(2,2′-bipyridine)manganese(0), $[Mn(bipy)_3]$,[6] and lithium tris(2,2′-bipyridine)manganate(−I), $Li[Mn(bipy)_3]\cdot 4THF$,[7] in tetrahydrofuran(THF). These facts confirm the above explanation for the first three steps of the reduction wave of the manganese(II) complex in acetonitrile. It may be concluded from the results obtained with the rotated platinum electrode that the anodic wave observed at +0.3 V is not the oxidation of manganese(II) to higher oxidation state but the oxidation of mercury to form mercury-bipyridine complexes, bipyridine being liberated from the manganese(II) complex at the electrode surface.

Polarographic and Spectroscopic Studies on the Ion-pair Formation of Trioxalatocobaltate(III) Ions with Cations in Aqueous Solutions

Nobuyuki TANAKA and Kazuo KOSEKI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 18, 1968)

The ion association between trioxalatocobaltate(III) anion and uni-, bi- and tervalent cations in aqueous solutions has been studied by polarographic and ultraviolet, visible and infrared spectroscopic methods. The association constants have been obtained by the measurement of the polarographic diffusion current of trioxalatocobaltate(III) ions in the presence of varied concentrations of cations at ionic strength 0.1 (NH_4NO_3) and 25°C. The influence of ammonium ion was taken into consideration in the treatment of polarographic data. The values obtained are 7.9 for $(CH_3)_4N^+[Co(ox)_3]^{3-}$, 3.7 ± 0.4 for $(C_2H_5)_4N^+[Co(ox)_3]^{3-}$, 22 ± 1 for $Na^+[Co(ox)_3]^{3-}$, 56 ± 6 for $Mg^{2+}[Co(ox)_3]^{3-}$, 55 ± 4 for $Ca^{2+}[Co(ox)_3]^{3-}$, 53 ± 3 for $Sr^{2+}[Co(ox)_3]^{3-}$, 55 ± 7 for $Ba^{2+}[Co(ox)_3]^{3-}$ and 118 ± 17 for $Al^{3+}[Co(ox)_3]^{3-}$. The association constant of $NH_4^+[Co(ox)_3]^{3-}$ was determined by the conductivity measurement to be 33.6 ($\log K=1.5_3$) at zero ionic strength. No change was observed in the visible, the ultraviolet and the infrared absorption spectra of trioxalatocobaltate(III) ions upon the addition of various cations even at the concentration at which the ion-pair formation is assumed to occur from the polarographic studies. These facts indicate that, in a sense of equilibrium study, there is no direct interaction between the complex anion and the cation, but one or more water molecules interpose between the two ions.

In recent years a number of investigations have been made of the ion-pair formation in solutions by many kinds of method. However, their results are not necessarily consistent with each other. The so-called "ion-pair" involves many different types, *e.g.*, a contact ion-pair, a solvent shared ion-pair and a solvent separated ion-pair.[1] Different types of ion-pairs are detected according to the characteristics of the methods used in the investigation. This may be a cause of the disagreement.

One of the purposes of this study is to determine the association constants between trioxalatocobaltate (III) anion and univalent, bivalent and tervalent cations using the polarographic method presented in a previous paper.[2] The other is to obtain some informations of the outer-sphere ion association from the comparison of the polarographic data with the visible, the ultraviolet and the infrared absorption spectra.

Experimental

Materials. Potassium trioxalatocobaltate(III) and ammonium trioxalatocobaltate(III) were prepared by the usual method.[3] The preparation of calcium, strontium and barium salts of trioxalatocobaltate(III) was made as follows. Calcium perchlorate which was prepared by the procedure of Smith and Koch[4] was added in excess to the solution of potassium trioxalatocobaltate(III) to precipitate potassium perchlorate. After filtration, calcium trioxalatocobaltate(III) was precipitated by the addition of ethanol. It was purified from aqueous solution by precipitating with ethanol. Strontium and barium trioxalatocobaltates(III) were prepared in the same way. Tetramethylammonium nitrate was prepared from $(CH_3)_4NBr$ and $AgNO_3$, and was recrystallized from water. Tetraethylammonium perchlorate was obtained according to Cokal and Wise.[5] All other chemicals used were of a guaranteed reagent grade.

Measurements. For the measurement of the limiting diffusion current, polarograms were recorded with a Shimadzu RP-2 polarograph in the solution of ionic strength 0.1 (adjusted with NH_4NO_3) containing 0.005% gelatin. The cell temperature was maintained at 25.0°C by means of a water thermostat. To avoid the effect of light, all the measurements were made with a brown-colored cell in a dark room. Since the trioxalatocobaltate(III) ions were reduced gradually to cobalt(II) in the presence of metallic mercury, the polarographic measurements were made as soon as possible after the dissolution of the complex and the removal of the dissolved oxygen in the solution.

The conductivity measurements were made in a glass cell equipped with platinized platinum electrodes using a Yokokawa BV-Z-103 B Wheatstone bridge. The cell constant was obtained to be 0.421 cm^{-1} by measuring

the conductivity of 0.1 M KCl solution. The conductivity water of a specific conductivity of 4.2×10^{-7} ohm^{-1} cm^{-1} was prepared by passing the redistilled water through the ion-exchange column. Its specific conductivity, however, raised to 1.36×10^{-6} ohm^{-1}cm^{-1} when it was shaked and kept in a flask for about one hour, and this value was used for the water conductivity correction. All the solutions used were kept at 25.0°C in a water thermostat.

The visible and ultraviolet spectra were obtained with a Hitachi EPS-3 spectrophotometer at room temperature. The ionic strength of the solution was adjusted to be 0.09. The infrared absorption spectra were measured with a Hitachi EPI-2G recording infrared spectrophotometer. Cells with windows of calcium fluoride were used when the measurements were made with solutions. Platinum foil of 0.05 mm thick was used for a spacer. The infrared absorption spectra of solid samples were obtained by the KBr disk method. The wave-length calibration was precisely made with water vapor and carbon dioxide.

Results

The Determination of the Association Constants Using the Polarographic Diffusion Current. In the investigation of the ion association, the addition of a certain salt is often required in order to adjust the ionic strength. In that case, the salt of the ions which seem not to associate with other ions must be chosen. However, in the case that the multivalent ions are involved in the system investigated, the association between the multivalent ions and the ion that is added in order to adjust the ionic strength cannot be sometimes ignored.

A modified equation of the equation which was presented in the previous paper[2] was derived for the determination of the association constant using the polarographic diffusion current. The influence of the ion which is added in order to adjust the ionic strength was taken into consideration in the treatment of polarographic data.

In the solution containing two different cations M^{m+} and $M'^{m'+}$ and complex anion X^{x-}, there exist the following equilibria

$$M^{m+} + X^{x-} \rightleftarrows M^{m+}X^{x-} \quad (1)$$

$$M'^{m'+} + X^{x-} \rightleftarrows M'^{m'+}X^{x-} \quad (2)$$

where $M^{m+}X^{x-}$ and $M'^{m'+}X^{x-}$ represent an ion-pair of M^{m+} with X^{x-} and that of $M'^{m'+}$ with X^{x-} respectively. Since the dissociation and the association of ion-pairs are very rapid, the apparent diffusion coefficient D is given by

$$D = \frac{D_X + D_{MX}K_{MX}C_M + D_{M'X}K_{M'X}C_{M'}}{1 + C_MK_{MX} + C_{M'}K_{M'X}} \quad (3)$$

where D_X, D_{MX} and $D_{M'X}$ are the diffusion coefficients of X^{x-}, $M^{m+}X^{x-}$ and $M'^{m'+}X^{x-}$, respectively, C_M and $C_{M'}$ are the concentrations of M^{m+} and $M'^{m'+}$ respectively, and K_{MX} and $K_{M'X}$ are the association constants of the corresponding ion-pairs expressed in concentration. When the ionic strength is kept constant, a relation given by the equation,

$$iC_M + jC_{M'} = a \quad (4)$$

holds for C_M and $C_{M'}$ where a is the ionic strength, i and j are the values calculated as follows. Assuming that M salt is of a u-v electrolyte, the value of i is given by $i=(vu^2+uv^2)/2v$. In a similar fashion, M' salt being u'-v' electrolyte, the value of j is given by $j=(v'u'^2+u'v'^2)/2v'$. Introducing $C_{M'}$ derived from Eq. (4) into Eq. (3), Eq. (5) is obtained, which is rearranged to Eq. (6).

$$D = \frac{D_X + \frac{a}{j}D_{M'X}K_{M'X} + \left(K_{MX}D_{MX} - \frac{i}{j}K_{M'X}D_{M'X}\right)C_M}{1 + \frac{a}{j}K_{M'X} + \left(K_{MX} - \frac{i}{j}K_{M'X}\right)C_M} \quad (5)$$

$$\frac{C_M}{\dfrac{D_X + \frac{a}{j}D_{M'X}K_{M'X}}{1 + \frac{a}{j}K_{M'X}} - D} = \frac{1 + \frac{a}{j}K_{M'X} + \left(K_{MX} - \frac{i}{j}K_{M'X}\right)C_M}{\dfrac{\left(D_X + \frac{a}{j}D_{M'X}K_{M'X}\right)\left(K_{MX} - \frac{i}{j}K_{M'X}\right)}{1 + \frac{a}{j}K_{M'X}} - \left(K_{MX}D_{MX} - \frac{i}{j}K_{M'X}D_{M'X}\right)} \quad (6)$$

The first term of the denominator of the left-hand side of Eq. (6) indicates the diffusion coefficient which is obtained in the absence of M^{m+}, that is, the expression which is obtained when C_M equals zero in Eq. (5).

The left-hand side of Eq. (6) can be obtained experimentally. If the left-hand side of Eq. (6) is plotted against C_M, a straight line must be obtained, and the ratio of the slope to the intercept gives

$$\frac{\text{Slope}}{\text{Intercept}} = \frac{K_{MX} - \frac{i}{j}K_{M'X}}{1 + \frac{a}{j}K_{M'X}} \quad (7)$$

When the value of either of K_{MX} and $K_{M'X}$ is known, that of the other can be calculated from Eq. (7). If the association between M' and X can be neglected, *i.e.*, $K_{M'X} \fallingdotseq 0$, Eq. (6) yields

$$\frac{C_M}{D_M - D} = \frac{1 + K_{MX}C_M}{(D_X - D_{MX})K_{MX}} \quad (8)$$

The association constant K_{MX} can be obtained directly from the ratio of the slope to the intercept. In the present investigation, M′ represents ammonium ion which is added in order to adjust the ionic strength, M represents other cations, and X, trioxalatocobaltate(III) anion.

Since it has been found that the ammonium ion forms ion-pair with trioxalatocobaltate(III) anion from the measurement of the conductivity of ammonium trioxalatocobaltate(III) solution, the results of the measurements of all systems investigated in the present study was treated with Eq. (6). The value of association constant of trioxalatocobaltate(III) ion with ammonium ion which is necessary to solve Eq. (7) was calculated from the conductivity of ammonium trioxalatocobaltate(III) solution. Figure 1 shows the experimental conductivity curve in which observed values of Λ are plotted against $C^{1/2}$. The equivalent conductivity at zero concentration Λ° was obtained from the extrapolation of the curve. The Λ_i° of trioxalatocobaltate(III) ion was obtained to be 91.4 Ω^{-1}cm^2 by subtracting Λ_i° of ammonium ion from Λ°. The association constant corresponding to the reaction,

$$NH_4^+ + [Co(ox)_3]^{3-} \rightleftharpoons NH_4^+[Co(ox)_3]^{3-}$$

was calculated according to the method of Jenkins and Monk.[6] The thermodynamic association constant was calculated to be 33.6 (log K=1.5$_3$) from the concentration association constants K_c obtained, using activity coefficients which were calculated by the Debye-Hückel equation. The concentration association constant $K_{M'X}$ at ionic strength 0.1 was calculated to be 7.9 from the thermodynamic association constant by using the activity coefficient. This value was employed to solve Eq. (7).

The change in current at -0.7 V *vs.* SCE was

measured with the increase of the cation concentration in neutral solution. Typical examples of these plots are given in Fig. 2. The diffusion coefficient was calculated by the Ilkovič equation from the mean diffusion current. The experimental values in Fig. 2 were treated with Eq. (6). The plots thus obtained are given in Fig. 3. The values of the ratio of slope to intercept were determined by a least square method with the plots in Fig. 3. The association constant K_{MX} was obtained by introducing the value of $K_{M'X}$ and that of the ratio of slope to intercept into Eq. (7), which is given in Table 1.*1 The thermodynamic association constants were calculated from those concentration association constants, using the activity coefficients which were calculated by the Debye-Hückel equation with the following ion-size parameters:[8] 4 Å for Na^+, 8Å for Mg^{2+}, 6Å for Ca^{2+}, 5 Å for Sr^{2+} and Ba^{2+}, 9Å for Al^{3+}, 6 Å for $[Co(ox)_3]^{3-}$ and 6.5 Å for all the ion-pairs $M^{m+}[Co(ox)_3]^{3-}$. The thermodynamic association constants are also given in Table 1.

The treatment with Eq. (6) was successfully extended to the systems containing tetraalkylammonium cations and trioxalatocobaltate(III) anions. The changes in diffusion coefficient with the increase in the concentrations of tetramethylammonium and tetraethylammonium ions are shown in Fig. 4, which are much different from those observed with the other systems. A similar experiment was carried out with the system containing hexamminecobalt(III) and tetraethylammonium cations in which no ion association is likely to take place. Although the addition of tetraethylammonium ion caused a slight decrease in the limiting current of hexamminecobalt(III), the decrease was confirmed to arise from the decrease in the drop time of the mercury electrode due to the surface-active properties of tetraethylammonium ions. These plots are also shown in Fig. 4 (3 in Fig. 4). The great change in current in the system containing $[Co(ox)_3]^{3-}$ anions and tetraalkylammonium cations cannot be accounted for by the decrease in drop time of mercury electrode. This may be attributed to ion-pair formation between $[Co(ox)_3]^{3-}$ anions and tetraalkylammonium cations. Equation (5) indicates that, when $K_{MX}/K_{M'X} \geqq 1 > D_{MX}/D_{M'X}$, plots of the diffusion coefficient D against C_M give curves similar to curves 1 and 2 in Fig. 4. The sign of equality gives a straight line similar to curve 1, while the sign of inequality gives a convex curve similar to curve 2. The experimental values in Fig. 4 corrected for the drop time of mercury electrode were treated with Eq. (6). The plots thus obtained are shown in Fig. 5. The association constants K_{MX} which were obtained with a procedure similar to other cases are given in the last two lines of Table 1.

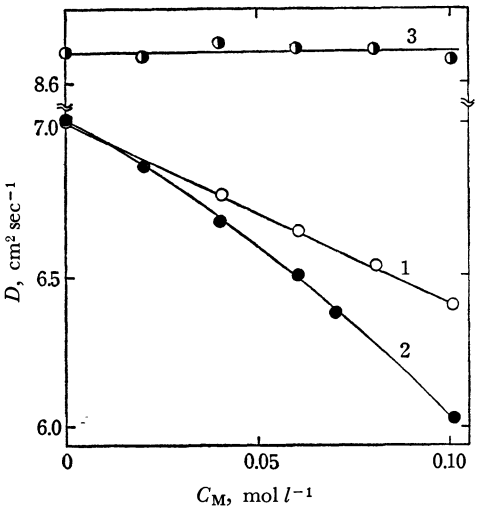

Fig. 4. Apparent diffusion coefficient (D) calculated from the reduction wave of cobalt complexes as a function of the concentration of tetraalkylammonium ions. The systems are: (1) $(CH_3)_4N^+$-$[Co(ox)_3]^{3-}$, (2) $(C_2H_5)_4N^+$-$[Co(ox)_3]^{3-}$ and (3) $(C_2H_5)_4N^+$-$[Co(NH_3)_6]^{3+}$. All the values are corrected for the drop time of DME.

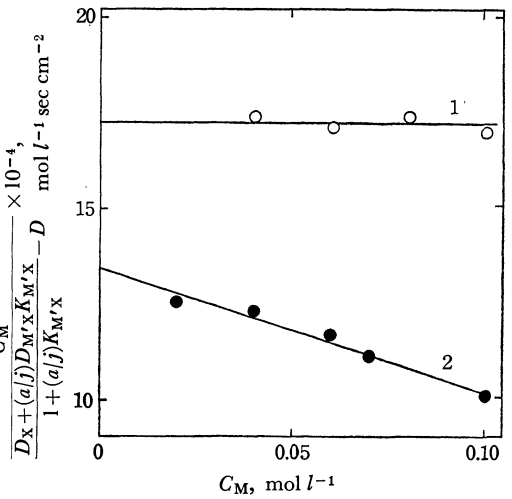

Fig. 5. Left-hand side of Eq. (6) as a function of concentrations of (1) tetramethylammonium and (2) tetraethylammonium ions.

*1 In the case of aluminum(III) ion, the association between aluminum(III) and nitrate ions seems not to be ignored. In this study, however, the correction for the effect of nitrate ions was not made, because no accurate value has been reported for the association constant of the ion-pair of these two ions. If it is assumed that the association constant of the ion-pair of aluminum with nitrate ions is the same with that of hexamminecobalt(III) with nitrate ions, which is, reported to be 1.6_3 in logarithmic unit at infinite dilution,[7] the association constant of $Al^{3+}[Co(ox)_3]^{3-}$ at ionic strength 0.1 is calculated to be 140 instead of 118 given in Table 1.

Visible and Ultraviolet Spectra. The visible and ultraviolet absorption spectra of trioxalatocobaltate(III) in aqueous solutions were measured in order to know what changes occur on the absorption spectra when an ion-pair $M^{m+}[Co(ox)_3]^{3-}$ is formed, where M^{m+} represents metal ions, such as Na^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+} and Al^{3+}. The solutions containing potassium trioxalatocobaltate and metal chloride were prepared as about 60—70% of trioxalatocobaltate ions exist in the form of ion-pair. The ion-pair formation gave no effect on the absorption spectra over the range of 210 mμ to 700 mμ.

Infrared Spectra. In order to investigate how the ion association affects the vibration of ligand, the infrared absorption due to $\nu_s(C\text{-}O)+\nu(C\text{-}C)$ was measured with the solution of potassium, magnesium, calcium and strontium trioxalatocobaltate(III). The solution of 0.02 M potassium trioxalatocobaltate(III) in which a great part of trioxalatocobaltate(III) ions seemed to exist in the form of free ions gave an absorption maximum due to $\nu_s(C\text{-}O)+\nu(C\text{-}C)$ at 1389 cm^{-1}. The solutions which contained 0.02 M potassium trioxalatocobaltate(III) and 0.15 M magnesium, calcium and strontium chloride gave also an absorption due to $\nu_s(C\text{-}O)+\nu(C\text{-}C)$ at 1389 cm^{-1}. From the value of the association constants obtained by the polarographic method it was estimated that 80—90% of trioxalatocobaltate-(III) ions were present in the form of ion-pair $M^{2+}[Co(ox)_3]^{3-}$ in these solutions. The absorption spectra of potassium, calcium, strontium and barium trioxalatocobaltate(III) in solid state were measured and compared with the spectra of the solutions mentioned above. They are given in Fig. 6.

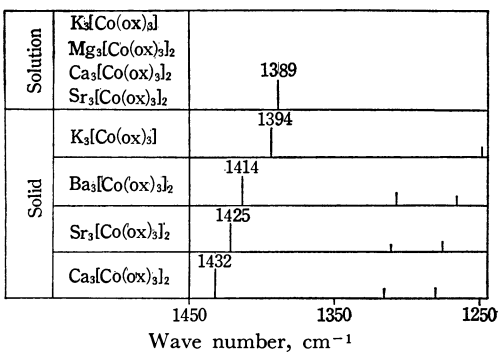

Fig. 6. Wave numbers of the absorption bands of trioxalatocobaltate(III) in aqueous solutions and in solid state.

Discussion

The association constants of trioxalatocobaltate-(III) anion with cations were compared with those of ferricyanide anion with cations and also those of hexamminecobalt(III) cation with anions (see Table 2). The values given for comparison in Table 2 are those of being determined from conductivity measurements, because the conductivity method seems to detect the same type of ion-pair as the polarographic method does. The association constants for the ion-pair $M^{m+}[Fe(CN)_6]^{3-}$ agree well with our results. The radii of $[Co(ox)_3]^{3-}$ and $[Fe(CN)_6]^{3-}$ ions are calculated to be 3.0Å and 2.8Å, respectively, by applying Stokes' law. That both complex anions have similar radii may be a cause of the good agreement. On the other hand, the association constants of hexamminecobalt(III) cation with anions are about five times larger than those of tervalent complex anion with cations except for the case of ion-pairs of 3-1 electrolytes, though the application of Stokes's law gives the radius of $[Co(NH_3)_6]^{3+}$ ion to be 2.8 Å, which is nearly equal to those of the complex anion described above. This great difference on association constant was, therefore, considered to arise from the difference in size between the ions paired with complex ions. The bi- and tervalent metal cations are strongly hydrated than the anions owing to their small sizes, so that the metal cations seem to associate with complex anions in a state of hydrated cations. Hence the apparent size of hydrated cation in a associated state appears to be larger than the size of hydrated anion. This may be a cuase of the great difference. The discussion for the results of spectroscopic study on ion association will lead some support to this consideration.

It would be expected that, if a trioxalatocobaltate(III) anion is associated with a cation, the complex anion is polarized and in consequence the change of absorption band in visible or ultraviolet

region occurs. However, any change was not observed on the absorption over the range of 210 mμ to 700 mμ. Moreover, if the ion-pair formation occurs, the decrease of the degree of degeneracy and the shift of the absorption band would be expected on the infrared absorption spectra. No changes, however, were observed in all the systems, although in solid state trioxalatocobaltates(III) of potassium and alkali earth metals gave the frequency shift. That is to say, the existence of ion-pairs could not be detected by the measurement of visible, ultraviolet and infrared absorption spectra. On the other hand, the existence of ion-pair was distinctly detected by the polarographic method. The explanation of this apparent discrepancy is that the complex anion has no direct interaction with metal ion, but one or more water molecules interpose between the two ions. The separation of the ions by several water molecules can greatly decrease the polarization effect of the complex anion, so that the absorption spectra show no indication of the ion-pair formation.

The consideration that the metal ion forms the ion-pair in a hydrated state was supported further by the discussion on the diffusion coefficient of ion-pair. The diffusion coefficients of the ion-pairs D_{MX} were obtained by substituting D_X, $D_{M'X}$, K_{MX} and $K_{M'X}$ into the slope of the plots of Eq. (6). D_X was calculated by the application of the Nernst equation to the limiting mobility of complex anion. $D_{M'X}$ was obtained with Eq. (3), when C_M equaled zero. The value of D_{MX} thus obtained are given in the first column of Table 3. The diffusion coefficients of ion-pairs decrease with increasing positive charges on the metal ion. This fact clearly demonstrates the influence of hydration of the cation. The increase in cation charge is accompanied by the increase in size of hydrated cation, and consequently give raise to the decrease in the diffusion coefficient of metal ion. The diffusion coefficients of the ion-pairs of trioxalatocobaltate(III) anion and alkali earth metal cations are further compared with those of the ion-pairs of tervalent complex cations and sulphate anion (see also Table 3). The diffusion coefficients of complex ions are also given in Table 3. It is seen from Table 3 that the diffusion coefficients of ion-pairs of complex anion and cation are smaller than those of complex cation and anion. Since the diffusion coefficient of complex anion is nearly equal to or somewhat larger than those of complex cation, the ions paired with complex ions seem to be responsible for the difference between these two sets of figures in Table 3.

The possibility of the existence of several water molecules between the complex anion and the metal cation was examined also by the estimation of the closest approach of the paired ions. The value of the closest approach was calculated in the same way as presented in the previous paper,[20] and was found to be in good agreement with the sum of Stokes' law radius of trioxalatocobaltate(III) ion and the radius of the hydrated metal ion. From these discussions it may be concluded that in a sense of equilibrium study a trioxalatocobaltate(III) anion and a metal cation has no direct interaction, but one or more water molecules interpose between the two ions.

The closest approach for ion-pair $R_4N^+[Co(ox)_3]^{3-}$ was also calculated. The values are 6.0 Å and 8.0 Å for $(CH_3)_4N^+[Co(ox)_3]^{3-}$ and $(C_2H_5)_4N^+$-$[Co(ox)_3]^{3-}$, respectively. They are in good agreement with the distance which were obtained by adding the crystallographic radius of R_4N^+ ion to the radius of $[Co(ox)_3]^{3-}$ ion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2073—2077 (1968)

Syntheses of *trans*-Isoflavan-4-ols

Shozo YAMAGUCHI, Shoei ITO, Ikuko SUZUKI and Naoto INOUE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received November 14, 1967)

The reaction of nitrous acid and three 4-aminoisoflavan hydrochlorides (III, IV, and V) obtained by the catalytic hydrogenation of isoflavanone oximes, and the hydroboration of three isoflavenes (XII, XIII, and VIII), were investigated in the hope of finding a general method of synthesizing *trans*-isoflavan-4-ols. The reaction of III and IV with nitrous acid afforded the corresponding *trans*-4-ols, though in a poor yield, but that of V produced no expected compound, the corresponding isoflavene (VIII) being obtained instead. The hydroboration of XII, XIII, and VIII afforded the corresponding *trans* alcohols (VI, VII, and XIV) in good yields. In addition, it became clear that 4-aminoisoflavans obtained by the catalytic reduction of the oximino compounds possess the 3,4-*cis* configuration.

Inoue obtained *cis*-7-methoxyisoflavan-4-ol (X) as a main product and *trans*-7-methoxyisoflavan-4-ol (VII) as a by-product by the reduction of 7-methoxyisoflavanone with sodium borohydride. However, the hydride reduction of isoflavanone and 4′,7-dimethoxyisoflavanone did not afford the *trans*-4-ols.[1,2] Later, the present authors[3] obtained VII by the reaction of 4-amino-7-methoxyisoflavan hydrochloride (IV) with nitrous acid, but we could not apply this reaction to other aminoisoflavans, since these amines had not yet been prepared in our laboratory.

In order to find out a general method of synthesizing *trans*-isoflavan-4-ols, we undertook the

** Unpublished results. The syntheses and the stereochemistry of these compounds will be reported elswhere.

synthesis of 4-aminoisoflavan (IIIa) and 4-amino-4',7-dimethoxyisoflavan (Va), and also the examination of their reaction with nitrous acid and of the hydroboration of isoflavenes. The results obtained will be presented in this paper.

4-Aminoisoflavans were synthesized according to the following reaction scheme. The catalytic hydrogenation of isoflavanone oxime (I) and 4',7-dimethoxyisoflavanone oxime (II) in acetic acid containing a small amount of perchloric acid in the presence of palladium on carbon produced the corresponding amines (IIIa and Va), which were then isolated as hydrochlorides (III and V), and the treatment of III and V with acetic anhydride and pyridine gave 4-acetamido derivatives (IIIb and Vb).

The stereochemistry of three 4-aminoisoflavans (IIIa, IVa, and Va) was determined on the basis of the NMR spectra. In the NMR spectra of these amines, the signals assigned to three protons of the 2- and 4- positions are observed around 4.0—4.9 ppm and overlap with each other. In the case of 4-acetamidoisoflavans (IIIb, IVb, and Vb), the proton signals of the 4-position shift to a lower field and appear quite broad. Therefore, it is difficult to determine the value of $J_{3H,4H}$ directly from the signals of the chroman-ring protons. As is shown in Table 1, the methyl proton signals of the acetyl group of 4-acetoxyflavan (*cis*, *trans*), 4-acetoxy-7-methoxyflavan (*cis*, *trans*), and *trans*-4-acetoxyisoflavans are observed at 2.02—2.07 ppm (Entries 1, 2, 3, 4, and 5). On the other hand, these signals of *cis*-4-acetoxyisoflavans shift to a field higher by approximately 0.19—0.22 ppm and appear at 1.83 ppm (Entries 3 and 4). In *cis*-4-acetoxyisoflavans, the acetyl group is above the plane of the adjacent phenyl group at the 3-position (Fig. 1): consequently, the acetyl group suffers the shielding effect of the C_8 phenyl group and shifts to a higher field. This upfield shift seems to be characteristic of 3,4-*cis*-isoflavans. A quite similar phenomenon is observed in the NMR spectra of the 4-acetamidoisoflavans (IIIb, IVb, and Vb). The methyl proton signals of the acetyl group of these acetamido compounds appear at 1.83 ppm (Entries 6, 7, and 8 in Table 1). A comparison of these values with those of *cis*-acetoxyisoflavans suggests the *cis* configuration of IIIb, IVb, and Vb.

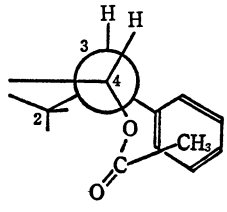

Fig. 1

The above inference is also supported by the stereochemistry of the catalytic hydrogenation of cyclohexanone oximes[4] and isoflavanones.[1-3] Furthermore, as will be shown in the Experimental part of this paper and as has been shown in a previous report,[3] in the reactions of 4-aminoisoflavan hydrochloride (III) and the 4-amino-7-methoxy derivative (IV) with nitrous acid, the yields of *trans*-isoflavan-4-ols (VI and VII) were as low as 26% and 15% respectively, and the 4-amino-4',7-dimethoxy derivative (V) gave only 4',7-dimethoxyisoflavene (VIII).[5] In view of the reported stereochemistry of the reaction of aminocyclohexanes with nitrous acid,[6] the results described above also support the *cis* configuration assigned to 4-aminoisoflavans.

The reaction of two 4-aminoisoflavan hydrochlorides (III and V) with nitrous acid was also carried out. From III, a compound with a mp of 97°C was obtained in a 26% yield; this compound had the molecular formula $C_{15}H_{14}O_2$, but it was not identical with *cis*-isoflavan-4-ol (IX).[1] Therefore, the compound may be supposed to be *trans* alcohol (VI). This was confirmed by comparing the NMR

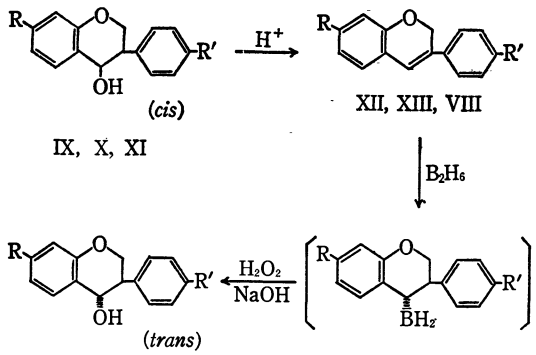
4',7-Dimethoxy-isoflavan-4-ol (XIV)	4.82	1 (4-H)	Quartet $J_{3,4}=7.9$	3(ax), 4(ax) trans
Acetate	6.06	1 (4-H)	Doublet $J_{3,4}=5.0$	3(ax), 4(ax) trans

spectra of VI and its acetate with those of *cis*-isoflavan-4-ol (Table 2). The reaction between V and nitrous acid at room temperature gave an olefinic compound with a mp of 161°C which was identified as VIII.[5] Even the reaction at a lower temperature (ice-cooling) gave no expected *trans*-4',7-dimethoxyisoflavan-4-ol (XIV); rather, the starting amine was recovered, together with VIII.

The synthesis of *trans*-isoflavan-4-ols by the hydroboration of isoflavenes was attempted next. The hydroboration of substituted double bonds and subsequent oxidation by hydrogen peroxide has been reported to lead to *cis*-type hydration, following the anti-Markownikoff rule.[7] Therefore, it was anticipated that the application of this reaction to isoflavenes would result in the formation of *trans*-isoflavan-4-ols. 7-Methoxyisoflavene (XIII) and



VI, IX, XII R=R'=H
VII, X, XIII R=OMe, R'=H
VIII, XI, XIV R=R'=OMe

Chart 2

VIII were prepared from the corresponding *cis* alcohols (X and XI) by heating in acetic acid. Isoflavene (XII) was prepared by refluxing a solution of the *cis* alcohol (IX) in acetic acid containing a small amount of concentrated hydrochloric acid.

A 1-mol equivalent of diborane (2.0 M equivalent in BH_3) and a 2.5 1-mol equivalent of XIII were allowed to react in tetrahydrofuran. At appropriate intervals of time, samples were withdrawn and analysed for remaining XIII by measuring the extinction at 333 mμ. The amounts of remaining unreacted XIII observed 30 min, 2 hr, and 17 hr after the beginning of the reaction were 65%, 35%, and 10% respectively. In order to transform the remaining XIII into the organoborane completely, a diborane-THF solution was then added until the molar ratio of XIII and diborane became 1.62 : 1. The XIII disappeared 70 min after the addition of the final diborane solution.

It has been reported[7] that, in the hydroboration of trisubstituted olefins such as α-pinene, the reaction proceeds rapidly to the dialkylborane stage. In our experiment, however, when the molar ratio of XIII (trisubstituted olefin) to diborane was 2.5 : 1, unreacted XIII was detected, but when the ratio was 1.62 : 1, no XIII was detected. The above experimental results indicate that the reaction proceeds predominantly to the monoalkylborane. After the usual treatment, a compound with a mp of 131°C was obtained in a 44% yield; this compound was identical with *trans*-7-methoxyisoflavan-4-ol (VII).[1-3] A similar reaction of XII gave *trans*-isoflavan-4-ol (VI) in a 73% yield. A compound (XIV) with a mp of 124°C was obtained in a 66% yield from VIII. It was different from *cis*-4',7-dimethoxyisoflavan-4-ol (XI)[1,2] and may, therefore, be supposed to be a *trans* modification. The NMR spectra of XIV and its acetate (Table 2) support the *trans* configuration.

In conclusion, the hydroboration of isoflavenes seems valuable as a general method of synthesizing *trans*-isoflavan-4-ols.

Experimental

The NMR spectra were determined with a Varian A-60 spectrometer at 60 MHz, using deuterochloroform as the solvent and tetramethylsilane as the internal reference.

4',7-Dimethoxyisoflavanone Oxime (II). A solution of 2.2 g of 4',7-dimethoxyisoflavanone[8] and 2.2 g of hydroxylamine hydrochloride in a mixture of 22 m*l* of pyridine and 22 m*l* of ethanol was refluxed for 10 hr. The reaction mixture was then poured into water to precipitate crystals. The recrystallization of the crystals from ethanol gave 1.7 g (74% yield) of crystals, mp 142—143°C.

Found: C, 68.47; H, 5.43; N, 4.65%. Calcd for $C_{17}H_{17}O_4N$: C, 68.21; H, 5.73; N, 4.68%.

4-Aminoisoflavan (IIIa). A solution of 3 g of isoflavanone oxime (I)[9] in 200 m*l* of acetic acid containing 0.5 m*l* of 70% perchloric acid was hydrogenated under atmospheric pressure in the presence of 3 g of 5% palladium on carbon.*1 After 2.43 mol of hydrogen had been absorbed at room temperature (18°C), the catalyst was filtered off. The acetic acid was removed under reduced pressure, and 6 N hydrochloric acid was added to the residue, thus affording crystals. Recrystallization from ethanol gave 2 g (64% yield) of 4-aminoisoflavan hydrochloride (III), mp 243—245°C (decomp.) ν_{N^+-H} 3200—2700 cm^{-1} (KBr). pK_a[10] 7.67(in H_2O); 7.25 (in 34% aqueous ethanol).

Found: C, 68.71; H, 5.98; N, 5.54%. Calcd for $C_{15}H_{16}ONCl$: C, 68.83; H, 6.16; N, 5.35%.

The crystals obtained by the neutralization of an aqueous solution of 300 mg of III with 5% sodium hydroxide were recrystallized from dilute methanol to give 150 mg of 4-aminoisoflavan (IIIa), mp 74—76°C.

Found: C, 79.69; H, 6.73; N, 6.01%. Calcd for $C_{15}H_{15}ON$: C, 79.97; H, 6.71; N, 6.22%.

4-Acetamidoisoflavan (IIIb). A solution of 100 mg of III in pyridine was acetylated with acetic anhydride by the usual method. Recrystallization from diluted ethanol then gave 70 mg of the acetate (IIIb), mp 182—183°C. ν_{NH} 3260 cm^{-1} (KBr), $\nu_{C=O}$ 1660 cm^{-1} (KBr).

Found: C, 76.74; H, 6.45; N, 5.13%. Calcd for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.41; N, 5.24%.

Reaction of 4-Aminoisoflavan Hydrochloride (III) with Nitrous Acid. To a swirling solution of 1 g of III in 80 m*l* of 50% acetic acid, there were added, drop by drop and under cooling with ice, 25 m*l* of an aqueous solution containing 700 mg of sodium nitrite. After the stirring had continued for 1 hr under cooling, and then a further 30 min at room temperature, the reaction mixture was poured into water, and subsequently extracted with ether. The extract was washed with a sodium hydrogen carbonate aqueous solution and with water, dried on sodium sulfate, and distilled. The recrystallization of the residue from petroleum ether gave *trans*-isoflavan-4-ol (VI), mp 96—97°C, in a 26% yield. The NMR spectrum of VI shows a signal of the C_4 proton at 4.92 ppm as a doublet, $J_{3H,4H}$ 8.0 Hz, ν_{OH} 3350 cm^{-1} (KBr).

Found: C, 76.32; H, 6.43%. Calcd for $C_{15}H_{14}O_2$: C, 76.62; H, 6.24%.

***trans*-4-Acetoxyisoflavan.** A solution of 100 mg of *trans*-isoflavan-4-ol (VI) in pyridine was acetylated with acetic anhydride by the usual method. The recrystallization of the crude product from diluted ethanol gave 70 mg of acetate, mp 72—73°C. $\nu_{C=O}$ 1739 cm^{-1}.

Found: C, 75.95; H, 6.24%. Calcd for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01%.

4-Acetamido-7-methoxyisoflavan (IVb). A solution of 100 mg of 4-amino-7-methoxyisoflavan hydrochloride[3] (pK_a 7.45 in 34% aqueous ethanol) in pyridine was acetylated with acetic anhydride by the usual method. The recrystallization of the product from ethanol gave 80 mg of acetate, mp 238—239°C. ν_{NH} 3250 cm^{-1} (KBr), $\nu_{C=O}$ 1640, 1665 cm^{-1} (KBr).

Found: C, 73.08; H, 6.66; N, 4.65%. Calcd for $C_{18}H_{19}O_3N$: C, 72.70; H, 6.44; N, 4.71%.

4-Amino-4',7-dimethoxyisoflavan (Va). A solution of 1.5 g of 4',7-dimethoxyisoflavanone oxime (II) in 250 m*l* of acetic acid containing 2 m*l* of 70% perchloric acid was hydrogenated in the presence of 1.5 g of 5% palladium on carbon under atmospheric pressure. After the solution had absorbed 2.20 mol of hydrogen at room temperature (17°C), the catalyst was filtered off and the solvent was removed under reduced pressure. To the residue, 6 N hydrochloric acid was added to give crystals. Recrystallization from ethanol gave 700 mg (45% yield) of 4-amino-4',7-dimethoxyisoflavan hydrochloride (V), mp 213—215°C (decomp.). ν_{N^+-H} 3200—2700 cm^{-1} (KBr). pK_a 7.50 in 34% aqueous ethanol.

Found: C, 63.62; H, 6.12; N, 4.13%. Calcd for $C_{17}H_{20}O_3NCl$: C, 63.41; H, 6.23; N, 4.35%.

The neutralization of an aqueous solution of 200 mg of the hydrochloride (V) with 5% sodium hydroxide afforded a crystalline material, which was then recrystallized from diluted ethanol to give 100 mg of 4-amino-4',7-dimethoxyisoflavan (Va), mp 89—90°C.

Found: C, 71.34; H, 6.79; N, 4.77%. Calcd for $C_{17}H_{19}O_3N$: C, 71.56; H, 6.71; N, 4.91%.

4-Acetamido-4',7-dimethoxyisoflavan (Vb). A solution of 100 mg of V in pyridine was acetylated with acetic anhydride in the usual manner. Recrystallization from ethanol gave 70 mg of acetate (Vb), mp 240—242°C. ν_{NH} 3250 cm^{-1} (KBr), $\nu_{C=O}$ 1643, 1665 cm^{-1} (KBr).

Found: C, 69.92; H, 6.35; N, 4.17%. Calcd for $C_{19}H_{21}O_4N$: C, 69.70; H, 6.47; N, 4.28%.

Reaction of 4-Amino-4',7-dimethoxyisoflavan Hydrochloride (V) with Nitrous Acid. To a swirling solution of 500 mg of the hydrochloride (V) in 60 m*l* of 50% acetic acid, there was added, drop by drop and under cooling with ice, a solution of 300 mg of sodium nitrite in 20 m*l* of water. After it had then been allowed to stand for 2 hr under the cooling and a further hour at room temperature, the reaction mixture was poured into water and subsequently extracted with ether. The extract was washed with a sodium hydrogen carbonate solution and with water, and dried on anhydrous sodium sulfate. The residue remaining after the removal of the ether was recrystallized from ethanol to yield 150 mg

10) K. Nakanishi, "Yuki Kagaku no Shinpo," Vol. 12, ed. by M. Murakami, Kyoritsu Shuppan, Tokyo, Japan (1957), p. 19.

(36% yield) of crystals, mp 160—161°C, which were identified as 4′,7-dimethoxyisoflavene (VIII). When V was treated with nitrous acid for 2 hr under milder reaction conditions (ice cooling), the expected *trans*-4′,7-dimethoxyisoflavan-4-ol (XIV) was not obtained, but 50 mg of VIII and 200 mg of unreacted V were recovered.

Isoflavene (XII). A solution of 1 g *cis*-isoflavan-4-ol (IX) in 30 m*l* of acetic acid containing 2 drops of concentrated hydrochloric acid was refluxed for 1 hr. After the removal of the acetic acid under reduced pressure, 50 m*l* of water were added. The crystals thus obtained were recrystallized from methanol to give 0.8 g of the crystals (XII), mp 90—91°C.

Found: C, 86.32; H, 5.92%. Calcd for $C_{15}H_{12}O$: C, 86.51; H, 5.81%.

Preparation of the Diborane-Tetrahydrofuran Solution[7]. All the reactions were carried out under a nitrogen atmosphere. To a swirling solution of 3 g of sodium borohydride in 18 m*l* of diglyme (dried on calcium hydride and then on lithium aluminum hydride, and subsequently distilled), there were added, drop by drop over a period of 30 min under cooling with ice, 15 m*l* of boronfluoride etherate (distilled under reduced pressure after adding anhydrous ethyl ether and calcium hydride). The stirring was then continued for 30 more min, after which the mixture was heated at 110°C for 1 hr for the complete generation of diborane. The generated diborane was cooled by dry ice - acetone to remove the ether, and then passed through 15 m*l* of THF (dried on lithium aluminum hydride and distilled) containing 0.2 g of sodium borohydride in order to remove the borontrifluoride. Then the diborane was introduced to 25 m*l* of THF in an absorption bottle cooled by ice water. The concentration of diborane in the diborane-THF solution was determined from the volume of the hydrogen generated by pouring a constant volume of the solution into a mixture of water-diglyme-THF.

***trans*-7-Methoxyisoflavan-4-ol (VII).** To a solution of 635 mg (2.67 mmol) of 7-methoxyisoflavene[3] (XIII) in 10 m*l* of THF, there were added 1.60 m*l* (1.06 mmol) of a diborane-THF solution (concentration 0.66 mol/*l*) with stirring and under cooling with ice. Every hour, a small portion of the solution was taken up in order to determine the unreacted XIII by means of the change in the absorption intensity at 333 mμ by reference to a previously-prepared calibration curve. The flask was permitted to remain for 2 hr at 0°C, and then kept for 15 hr at room temperature. After 17 hr, 0.9 m*l* (0.59 mmol) of the diborane-THF solution was added. After it had been confirmed that the unreacted XIII had disappeared after 70 min, 5 m*l* of THF and 0.5 m*l* of water were carefully added with stirring and under cooling with ice in order to decompose the excess diborane. To the above solution, there were then added, drop by drop, 1.25 m*l* of 3 N sodium hydroxide over a period of approximately 3 min and then 0.32 m*l* of 30% hydrogen peroxide over a period of about 2 min. The stirring was continued for 1 hr under cooling with ice, and then for 1 more hr at room temperature, after which the solution was poured into water and extracted with ether. In order to remove any phenolic substances, the extract was washed with 1 N sodium hydroxide and with water, dried on sodium sulfate, and distilled under reduced pressure. The residual oil was crystallized by the addition of ethanol, which afforded 300 mg (44% yield) of crystals, mp 130—131°C. The melting point of this compound was not depressed on admixture with authentic *trans*-7-methoxyisoflavan-4-ol.

***trans*-Isoflavan-4-ol (VI).** To a swirling solution of 1.0 g of isoflavene (XII) in 7 m*l* of THF, there were added 4.0 m*l* of the diborane-THF solution under cooling with ice. The reaction mixture was then worked up in a manner similar to that of Experiment XIII described above. After the ether had been removed, 5 m*l* of *n*-hexane were added to the residual oil, giving 0.8 g (73% yield) of crystals. Recrystallization from *n*-hexane - benzene afforded crystals, mp 97—97.5°C, which did not show any depression of melting point on admixture with authentic *trans*-isoflavan-4-ol.

***trans*-4′,7-Dimethoxyisoflavan-4-ol (XIV).** To a solution of 700 mg of 4′,7-dimethoxyisoflavene (VIII)[5] in 15 m*l* of THF, 2.2 m*l* of the diborane-THF solution were added under cooling with ice. The crystals obtained by the usual treatment were recrystallized from benzene to give 490 mg (66% yield) of crystals, mp 123.5—124°C. This compound (XIV) was not identical with the reduction product of 4′,7-dimethoxyisoflavanone. $J_{3H,4H}$ 7.9 Hz.

Found: C, 71.87; H, 6.44%. Calcd for $C_{17}H_{18}O_4$: C, 71.31; 6.34%.

By the usual manner, the acetate of XIV was prepared by reaction with pyridine - acetic anhydride, mp 131—132.5°C. $J_{3H,4H}$ 5.0 Hz.

Found: C, 69.77; H, 6.09%. Calcd for $C_{19}H_{20}O_5$: C, 69.50; H, 6.14%.

The authors wish to express their sincere thanks to Professor Yoshio Kitahara for his making convenient the NMR spectra measurements.

The Rearrangement of Isoflavanone Oximes with Lithium Aluminum Hydride

Naoto INOUE, Shozo YAMAGUCHI, Shoei ITO and Ikuko SUZUKI

College of General Education, Tohoku University, Kawauchi, Sendai

(Received December 19, 1967)

The reaction of isoflavanone oxime (III), 7-methoxyisoflavanone oxime (IV), and 4',7-dimethoxyisoflavanone oxime (V) with lithium aluminum hydride in ether for 20 hr under refluxing gave 3-phenyl-2,3,4,5-tetrahydro-1,5-benzoxazepine derivatives (XVII, XVIII and XIX) but not the expected 4-aminoisoflavans. When a similar reaction was carried out using flavanone oxime and 7-methoxyflavanone oxime, only 4-aminoflavans were obtained, and the rearrangement reaction observed in isoflavanone oximes did not occur. Therefore, it may be considered that, in the reaction of chromanone oximes and lithium aluminum hydride, the position (C_2 or C_3) and the size of the substituent exerts a remarkable influence on the rearrangement reaction, while the methoxyl group at the 7-position (*para* position to the oximino group) has little effect.

By the catalytic hydrogenation of flavanone oxime (I), Bognár and his co-workers[1] obtained 4-aminoflavan (II), which is an intermediate in the course of the synthesis of one of the stereoisomers of flavan-4-ol. They also reported that, in the reduction of I using diborane or lithium aluminum hydride or aluminum amalgam, II was always obtained. In the preceding paper[2] it was reported that the catalytic hydrogenation of isoflavanone oximes in the presence of palladium on carbon gave 4-aminoisoflavans, which are intermediates for the synthesis of *trans*-isoflavan-4-ols. In order to obtain 4-aminoisoflavans, an ether solution of isoflavanone oximes was reduced with lithium aluminum hydride. However, the expected 4-aminoisoflavans were not obtained; a different kind of compouds was isolated. This paper will describe the results of these reactions.

When an ether solution of isoflavanone oxime (III), 7-methoxyisoflavanone oxime (IV), and 4',7-dimethoxyisoflavanone oxime (V) was refluxed with lithium aluminum hydride for 20 hr and then treated with 6 N hydrochloric acid, hydrochlorides of unknown basic compounds, were obtained, IX mp 220°C, X mp 247°C, and XI mp 186°C respectively. These compounds (IX, X, and XI) are different from the hydrochlorides[2] of 4-aminoisoflavans (XII, XIII, and XIV), which are the catalytic hydrogenation products of III, IV, and V respectively. The IX, X, and XI compounds, show a broad ν_{N^+-H} band between 2800—2300 cm^{-1} in their infrared spectra, and may be assumed to be hydrochlorides of secondary amines in view of the infrared spectra[2] of XII, XIII, and XIV. In the infrared spectra of *N*-acetyl derivatives of the amines, no band corresponding to the N–H stretching vibration is observed, but one assigned to the carbonyl group of $N-COCH_3$ appears at 1640 cm^{-1}. The above data also support the idea that IX, X, and XI are secondary amine hydrochlorides. From the reactions of IX and X with nitrous acid, the nitroso compounds XV and XVI, possessing the characteristic absorption ($\nu_{N=O}$) of N–N=O at 1450 cm^{-1}, are obtained. These compounds are converted to the original amine hydrochlorides (IX and X), after catalytic hydrogenation with Raney Ni and subsequent treatment with hydrochloric acid. Therefore, it is clear that the reaction with nitrous acid and the successive catalytic hydrogenation does not change the skeletons of these compounds.

The molecular weights of the amines (XVIII and XIX) were determined to be 255 and 285 respectively by mass spectrometry; these values accord with those of 4-amino-7-methoxyisoflavan (VII) and 4-amino-4',7-dimethoxyisoflavan (VIII). The elemental analyses of XVIII and XIX agree with $C_{16}H_{17}ON$ and $C_{17}H_{19}O_3N$ respectively, which correspond to the molecular formulae of VII and VIII. In the mass spectra of 4-aminoisoflavans, the peaks of $M-NH_3$ and $M-NH_3-H$ are observed, while, in those of XVIII and XIX, no corresponding peaks are observed*1 (Fig. 2).

On the basis of these data, it may reasonably be concluded that the unknown compounds, IX, X, and XI, obtained by the lithium aluminum hydride reduction of isoflavanone oximes are secondary amine hydrochlorides isomeric with 4-aminoisoflavan hydrochlorides.

Fig 2.

Recently, a few examples of secondary amines being produced by rearrangement in the reduction of oximes with lithium aluminum hydride have been found. Smith and his co-workers[3] have reported that, in the reduction of oximes of aldehydes or ketones, the rearrangement products were obtained together with the corresponding normal reduction products. For example, the reduction of oximes of acetophenone and propiophenone afforded phenylethylamine (16%) and phenylpropylamine (14%), together with α-aminoethylbenzene and α-aminopropylbenzene, respectively.

Harfenist and Magniens[4] have reported that, in the lithium aluminum hydride reduction of oximes of six-membered ring ketones fused to phenothiazine, seven-membered cyclic amines (Table 1) were formed by ring enlargement. Graham and Williams[5] mentioned that, in the lithium aluminum

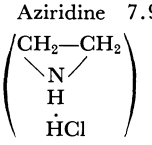
Aziridine 7.98[7]



hydride reduction of phenyl alkyl ketone oximes, bulky alkyl group increase the yields of secondary amines produced by rearrangement. On the other hand, Kitahonoki *et al.*[6] found that the reduction of ketoximes and aldoximes with lithium aluminum hydride in tetrahydrofuran causes a rearrangement affording azirizines.

The number of *aliphatic hydrocarbon protons* (4.67—3.08 ppm)*2 indicated by the NMR spectra of IX, X and XI is five,*3 this fact also supports the idea that these compounds are not azirizine derivatives (Fig. 3 (C).).

The pK_a values of azirizines are reported to be around 7.97[7]. However, as will be described later, those of IX, X, and XI are 4.05, 4.60, and 4.65 respectively (Table 1). In addition, azirizine compounds cause ring opening during catalytic reduction, affording primary amines. Since the *N*-nitroso derivatives of the compounds obtained in this experiment, as has been mentioned, gave the original secondary amines upon high-pressure hydrogenation, the formation of azirizine derivatives is also obviated.

Accordingly, it may be considered that the IX, X, and XI compounds possess the A- or B-type structure, as shown in Fig. 3, structures which are derived by the enlargement of the chromane ring, involving the rearrangment of the benzenoid carbon adjacent to the C_4 of isoflavanone oximes to the nitrogen atom of the oximino group.

Since A is a monoalkyl aniline derivative and B is a benzylamine derivative, there must be remarkable difference between their pK_a values. The pK_a values of IX, X, and XI were measured by the ultraviolet absorption method[8] using a Britton-Robinson buffer solution. These values were then compared with those of 4-aminoisoflavans reported in the preceding paper,[2] and with those[4] of the rearrangement products of oximes of phenothiazine derivatives (Table 1). From the data shown in Table 1, it may reasonably be concluded that the amines (XVII, XVIII, and XIX) obtained by the lithium aluminum hydride reduction of isoflavanone oximes possess the A-type structure.

Lyle and Troscianec[9] indicated that, in the lithium aluminum hydride reduction of oximes of acetophenone derivatives, the electron-releasing group at the *para* position gave more rearrangement products, and the electron-attracting group gave less. Different from Lyle's results, in this experiment the rearrangement product was obtained in a good yield (70—90%), irrespective of the presence or absence of the methoxyl group at the 7-position of isoflavanone oximes. It has been reported[1] that the reduction of flavanone oxime afforded only the normal reduction product even though lithium aluminum hydride was used. The present authors reinvestigated the reduction of flavanone oximes following the method of Bognár and found that the product was only 4-aminoflavan (*II*), identical with the product obtained by the catalytic hydrogenation of flavanone oxime. When a similar experiment was carried out using 7-methoxyflavanone oxime, only 4-amino-7-methoxyflavan (XX) was obtained, and the rearrangment product was not isolated. The pK_a values of hydrochlorides of II and XX are

6) K. Kitahonoki, K. Kodera, Y. Matsukawa, S. Miyazaki, T. Okuda, H. Takahashi and Y. Takano, *Tetrahedron Letters*, **1965**, 1059.

*2 The NMR spectra were determined with a Varian A-60 spectrometer, at 60 Mc, using deuterochloroform as the solvent and tetramethylsilane as the internal reference.

*3 If the secondary amines obtained in this experiment are aziridine derivatives, they must have three aliphatic hydrocarbon protons.

8) K. Nakanishi, "Yukikagaku no Shinpo," Vol. XII, ed. by M. Murakami, Kyoritsu Shuppan, Tokyo (1947), p. 19.

9) R. E. Lyle and H. J. Troscianec, *J. Org. Chem.*, **20**, 1757 (1955).

7.40 and 7.95 respectively; these values are close to those of 4-aminoisoflavans. Therefore, it may be considered that, in the reaction of chromanone oximes with lithium aluminum hydride, the position (C_2 or C_3) and the size of the substituent exerts a remarkable influence on the rearrangement reaction, but that the methoxyl group at the 7-position (the *para* position to the oximino group) has little effect. From a similar reaction using chromanone oximes substituted with various groups at the C_2 or C_3 position, the following conclusions were drawn: first, chromanone oximes without a C_2 substituent gave only the rearrangement products; second, chromanone oximes with a C_2 substituent gave a mixture of the normal reduction products (primary amines) and the rearrangement products (secondary amines); third, the more bulky substituents at C_2 gave the more normal reduction products and the fewer rearrangement products. This problem will be reported on later in more detail.

The mechanism concerning the rearrangement reaction of chromanone oxime with lithium aluminum hydride will be reported on by Kitahara and the present authors in the near future.

Experimental*4

Reduction of Isoflavanone Oxime (III) with $LiAlH_4$. To a swirling suspension of 1 g of $LiAlH_4$ in 80 m*l* of ether, there was added, drop by drop, a solution of 1 g of III in 70 m*l* of ether at room temperature. After having been allowed to reflux for 20 hr, the reaction mixture was decomposed with water under cooling with ice. The ether layer was washed with 1 N sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After the removal of the ether, 6 N hydrochloric acid was added, giving 0.8 g (80% yield) of crude crystals. Recrystallization from ethanol gave 0.6 g of 3-phenyl-2,3,4,5-tetrahydro-1,5-benzoxazepin hydrochloride (IX), mp 218—220°C. ν_{N^+-H} 2800—2300 cm^{-1}.

Found: C, 68.53; H, 6.02; N, 5.21%. Calcd for $C_{15}H_{16}ONCl$: C, 68.83; H, 6.16; N, 5.35%.

By the usual method, 200 mg of the hydrochloride (IX) was acetylated with pryidine-acetic anhydride, giving 150 mg of acetate, mp 190—191°C (from ethanol). ν_{COCH_3} 1653 cm^{-1}.

Found: C, 76.17; H, 6.49; N, 5.02%. Calcd for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.41; N, 5.24%.

A solution of 100 mg of the acetate in 5 m*l* of ethanol and 0.5 m*l* of concentrated hydrochloric acid was refluxed for 10 hr. The crystals obtained after the removal of the ethanol were recrystallized from ethanol to give the hydrochloride (IX). The neutralization of 100 mg of IX with 1 N sodium hydroxide gave an oily substance, which was extracted with ether and dried over anhydrous sodium sulfate; the solvent was then removed, but did not give crystals.

Reduction of 7-Methoxyisoflavanone Oxime (IV) with $LiAlH_4$. A solution of 2 g of IV in 120 m*l* of ether was added, drop by drop, to a swirling suspension of 2 g of $LiAlH_4$ in 80 m*l* of ether at room temperature. After it had been refluxed for 20 hr, the reaction mixture was decomposed with water under cooling with ice. The ether layer was washed with 1 N sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After the removal of the ether, 6 N hydrochloric acid was added to effect crystallization (1.8 g, 90% yield). Recrystallization from acetic acid gave 1.5 g of 3-phenyl-8-methoxy-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (X), mp 240—243°C. ν_{N^+-H} 2800—2300 cm^{-1}.

Found: C, 66.06; H, 6.18; N, 4.61%. Calcd for $C_{16}H_{18}O_2NCl$: C, 65.86; H, 6.22; N, 4.83%.

By the usual method, 200 mg of X was acetylated with pyridine - acetic anhydride, thus affording 170 mg of acetate, mp 142—143°C. ν_{CO} 1651 cm^{-1}.

Found: C, 73.09; H, 6.65; N, 4.64%. Calcd for $C_{18}H_{19}O_3N$: C, 72.70; H, 6.44; N, 4.71%.

The crystals obtained by the neutralization of 200 mg of X with 1 N sodium hydroxide were recrystallized from methanol, giving 100 mg of free amine (XVIII), mp 81—82°C. ν_{NH} 3350 cm^{-1}.

Found: C, 75.39; H, 6.64; N, 5.24%. Calcd for $C_{16}H_{17}O_2N$: C, 75.27; H, 6.71; N, 5.49%.

Reduction of 4',7-Dimethoxyisoflavanone Oxime (V) with $LiAlH_4$. A solution of 1.3 g of V in 60 m*l* of tetrahydrofuran was added, drop by drop, to a swirling suspension of 1.3 g of $LiAlH_4$ in 50 m*l* of ether at room temperature. After it had been refluxed for 24 hr, the reaction mixture was decomposed with water under cooling with ice. The ether layer was washed with 1 N sodium hydroxide and water, and then dried over anhydrous sodium sulfate. After the removal of the solvent, 6 N hydrochloric acid was added to give a solid, (0.97 g). Recrystallization from ethanol gave 0.5 g of 3-(4'-methoxyphenyl)-8-methoxy-2,3,4,5-tetrahydro-1,5-benzoxazepine hydrochloride (XI), mp 185—186°C. ν_{N^+-H} 2800—2300 cm^{-1}.

Found: C, 63.65; H, 6.14; N, 4.56%. Calcd for $C_{17}H_{20}O_3NCl$: C, 63.41; H, 6.23; N, 4.35%.

The acetylation of 100 mg of XI with pyridine-acetic anhydride by the general method gave 90 mg of acetate, mp 158—159°C. ν_{COCH_3} 1651 cm^{-1}.

Found: C, 69.52; H, 6.34; N, 4.07%. Calcd for $C_{19}H_{21}O_4N$: C, 69.70; H, 6.47; N, 4.28%.

The crystals obtained by the neutralization of 200 mg of XI with 1 N sodium hydroxide were recrystallized from ethanol, giving free amine (XIX), mp 83—84°C. ν_{NH} 3355 cm^{-1}.

Found: C, 71.31; H, 6.78; N, 4.97%. Calcd for $C_{17}H_{19}O_3N$: C, 71.56; H, 6.71; N, 4.91%.

Reaction of 3-Phenyl-2,3,4,5-tetrahydro-1,5-benzoxazepine Hydrochloride (IX) and Nitrous Acid. To a swirling solution of 700 mg of IX in 30 m*l* of 50% acetic acid, there was added, drop by drop, a solution of 600 mg of sodium nitrite in 30 m*l* of water under cooling with ice. After the solution had been stirred for 1 hr, the crystals produced were filtered and washed with water; 500 mg of crude crystals (mp 78—80°C) were thus obtained. Recrystallization from diluted methanol gave a *N*-nitroso compound (XV), mp 56—58°C. $\nu_{N=O}$ 1450 cm^{-1}.

Found: C, 71.02; H, 5.42; N, 10.92%. Calcd for $C_{15}H_{14}O_2N_2$: C, 70.85; H, 5.55; N, 11.02%.

Reaction of 3-Phenyl-8-methoxy-2,3,4,5-tetrahydro-1,5-benzoxazepine Hydrochloride (X) and Nitrous Acid. A solution of 0.8 g of sodium nitrite in

*4 All melting points are uncorrected. The ether used in these experiments was dried over $LiAlH_4$.

70 m*l* of water was added, drop by drop, to a swirling solution of 1.2 g of X in 250 m*l* of 50% acetic acid under cooling with ice. After the solution had been stirred for 1 hr, the crystals produced were filtered and washed with water; 1.1 g of crude crystals, mp 86—88°C, were thus obtained. Recrystallization from ethanol gave a *N*-nitroso compound (XVI), mp 64—66°C. $\nu_{N=O}$ 1450 cm^{-1}.

Found: C, 67.42; H, 5.34; N, 9.55%. Calcd for $C_{16}H_{16}O_3N_2$: C, 67.59; H, 5.67; N, 9.85%.

Catalytic Reduction of the 3-Phenyl-2,3,4,5-tetrahydro-1,5-benzoxazepine-*N*-nitroso Compound (XV) by Raney-Ni. A mixture of 100 mg of XV and 100 mg of Raney-Ni (W-4) in 30 m*l* of ethanol was submitted to hydrogenation in an autoclave (hydrogen pressure: 62 atm) at 65°C for one and a half hr. After the removal of the solvent, 6 N hydrochloric acid was added to crystallize the residue. Recrystallization from ethanol gave crystals, mp 218—219°C, whose mixed melting point with IX was undepressed.

Catalytic Reduction of the 3-Phenyl-8-methoxy-2,3,4,5-tetrahydro-1,5-benzoxazepine-*N*-nitroso Compound (XVI) by Raney-Ni. A mixture of 100 mg of XVI and 100 mg of Raney-Ni (W-4) in 50 m*l* of ethanol was submitted to hydrogenation in an autoclave (hydrogen pressure: 62 atm) at 60°C for 1.5 hr. After the removal of the solvent, 6 N hydrochloric acid was added to afford crystals. Recrystallization from acetic acid gave crystals of a mp of 240—242°C, which was undepressed on admixture with X.

Reduction of Flavanone Oxime (I) by $LiAlH_4$. A solution of 1 g of I in 70 m*l* of ether was added, drop by drop, to a swirling suspension of 1 g of $LiAlH_4$ in 80 m*l* of ether at room temperature. The mixture was refluxed for 20 hr, and then decomposed with water under cooling with ice and worked up as has been described above for III. The crystals obtained, 0.78 g, were recrystallized from ethanol, affording 4-aminoflavan hydrochloride, mp 267—270°C, which did not show any depression of melting point on admixture with the compound obtained by the catalytic reduction of I using palladium on carbon as a catalyst.

Reduction of 7-Methoxyflavanone Oxime by $LiAlH_4$. To a swirling suspension of 1 g of $LiAlH_4$ in 80 m*l* of ether, there was added, drop by drop, a solution of 1 g of 7-methoxyflavanone oxime in 100 m*l* of ether at room temperature. The mixture was then refluxed for 20 hr. By working up in the usual manner, 910 mg of crystals were obtained. Recrystallization from ethyl acetate gave 4-amino-7-methoxyflavan, mp 220°C (undepressed on admixture with the compound[10] obtained by the catalytic reduction of 7-methoxyflavanone oxime using palladium on carbon as a catalyst).

The authors wish to express their thanks to Mr. Hideji Abe for his measurement of the mass spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2082—2086 (1968)

Polar Conjugative Effect of Aryldithia Group on the Dissociation and Ultraviolet Spectra of Substituted Phenols[1]

Shigeru OAE and Masakuni YOSHIHARA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received October 2, 1967)

A few substituted aryldithiaphenols have been synthesized and their acid dissociations, NMR chemical shifts and UV spectra have been determined. The relatively stronger acidic nature of *p*-aryldithiaphenols over that of the meta-isomers is interpreted as being caused by the 3d-orbital resonance effect of the aryldithia group.

Some years ago, small blue shifts of UV spectra of dialkyl disulfides in the following order, *i.e.*, methyl, ethyl, isopropyl and *t*-butyl, were suggested to be due to the decrease of acidity of α-hydrogen in these dialkyl disulfides.[2] Meanwhile, the acidic nature of α-hydrogen in dialkyl disulfides has been demonstrated in several cases, where the disulfides have another electron-withdrawing group such as carboxyl or carboalkoxy group at α-carbon.[3-7] A typical example would be the alkaline cleavage of dithioglycolic acid, in which the initial step is presumed to be the removal of α-proton:

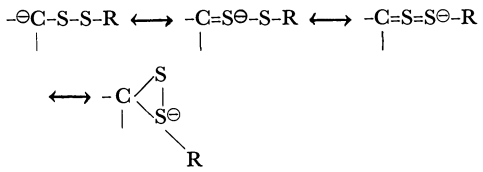
Although this apparent acidity is presumed to be due to the following 3d-orbital resonance of dithia group, there is no unambiguous evidence to support it.



Therefore it is desirable to have a set of quantitative data to illustrate the existence of 3d-orbital resonance of dithia group.

We have synthesized a few dithia-substituted phenols and measured their dissociation constants, chemical shifts and UV spectra. This paper will describe the results and their implications.

Experimental

Bis(4-hydroxyphenyl) Disulfide. Into 2 g of 4-hydroxythiophenol suspended in 30 m*l* of water was added a solution containing a little over an equivalent amount of ferric chloride. The mixture was warmed for 30 min, the resulting precipitate was collected and recrystallized from benzene-*n*-hexane mixture: 80% yield, mp 149—150°C, colorless needles. (Found: C, 57.87; H, 4.14%)

Bis(3-hydroxyphenyl) Disulfide. The reaction of 3-hydroxythiophenol with ferric chloride solution similarly gave bis(3-hydroxy-phenyl) disulfide in 80% yield: colorless needles, mp 94—95°C. (Found: C, 57.93; H, 4.15%. Calcd for $C_{12}H_{10}OS_2$: C, 57.58; H, 4.03%.)

4-Nitro-4'-hydroxydiphenyl Disulfide. 4-Nitrobenzenesulfenyl chloride prepared from bis(4-nitrophenyl) disulfide (4.9 g) and dry Cl_2 gas was dissolved in 30 m*l* of absolute ether. This solution was added dropwise into an absolute ether solution of 4-hydroxy-thiophenol (4 g) with cooling and stirring. After refluxing 10 min, the solvent was evaporated and the remaining product was recrystallized from aqueous ethanol; yellow needles, 8 g (90% yield), mp 118—120°C. (Found: C, 51.69; H, 3.47%. Calcd for $C_{12}H_9NO_3S_2$: C, 51.60; H, 3.25%.)

It is advisable that the refluxing should not be kept too long, since prolonged heating leads to a disproportionation to bis(4-nitro-phenyl) disulfide.

2-Nitro-4'-hydroxydiphenyl Disulfide. This compound was prepared in the same manner as in the case of 4-nitro-4'-hydroxy-diphenyl disulfide, from 4.9 g of bis(2-nitrophenyl) disulfide and 4 g of 4-hydroxythiophenol. Recrystallization from aqueous methanol gave yellow needles of mp 118—119°C, 70% yield. (Found: C, 51.60; H, 3.41%. Calcd for $C_{12}H_9NO_3Se$: C, 51.60; H, 3.25%.)

4-Nitro-3'-hydroxydiphenyl Disulfide. Into 50 m*l* of absolute ether solution containing 2 g of 3-hydroxythiophenol was added dropwise 4-nitrobenzenesulfenyl chloride dissolved in 50 m*l* of absolute ether under cooling and stirring. After stirring and cooling for 30 min, the solvent was removed *in vacuo*. The resulting oil was recrystallized from benzene-*n*-hexane mixture (without warming); 70% yield, mp 98—100°C. Found: C, 51.59; H, 3.41%. Calcd for $C_{12}H_9NO_3S_2$: C. 51.60; H, 3.25%.

Results and Discussion

Syntheses and Stabilities of Aryldithiaphenols. Symmetrical disulfides are relatively easy to prepare and quite stable. The unsymmetrical diaryl disulfides not bearing hydroxyl group are also quite stable even under refluxing in chloroform or carbon tetrachloride. However, unsymmetrical phenolic diaryl disulfides are rather unstable and disproportionate readily. Hence, the preparation and the recrystallization of unsymmetrical disulfides bearing a hydroxyl group have to be carried out rather quickly under the condition in which temperature is always kept below 40—50°C. Prolonged heating in ethanol, benzene, and chloroform always leads to the disproportionation. Many attempts to prepare 3- or 4-hydroxydiphenyl disulfide were all unsuccessful, though various conditions were applied changing the temperature, the reaction time, *etc.*

Acid Dissociations. The acid dissociation constants of all the aryldithiaphenols and the related compounds measured in 50 vol% aqueous ethanol solution are summarized in Table 1.

Table 1. Dissociation constants of several dithia-substituted phenols and the related compounds
(25°C, 0.001 M solns. in 50 vol% aqueous ethanol)[a]

Compound		pK_{a_1}	pK_{a_2}	ΔpK_a
	(I)	9.91		
	(II)	10.30		
	(III)	9.98		
	(IV)	10.08	10.68	0.60
	(V)	10.38	10.78	0.40
	(VI)	9.86		
	(VII)	10.35	11.0	0.65

a) pK_a values were estimated using 0.01 N KOH by a standard calculation (A. Albert and E. P. Serjeant, "Ionization Constants of Acids and Bases," Methuen and Co. (1962), p. 45).

It is interesting to note that the acidity of *p*-nitrophenyldithiaphenol (I) is stronger than that of the meta-isomer (II) by about 0.4 pK_a unit. These observations suggest strongly that the *p*-nitrophenyldithia group does operate an electron-accepting conjugation through benzene ring, involving the expansion of valence shell of the sulfur atoms of the dithia group in the dissociation of the *p*-substituted phenol, as shown below:

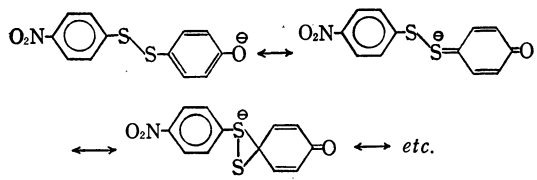


TABLE 2. COMPARATIVE σ-CONSTANTS

Group			$\Delta(\sigma_p-\sigma_m)$	Ref.
	m- *p*-	0.18 0.29	+0.11	8
	m- *p*-	0.16 0.03	−0.13	8
	*m*- *p*-	0.34 0.44	+0.10	8
	*m*- *p*-	0.31 0.19	−0.12	8
	*m*- *p*-	0.26 0.42	+0.16	This
	m- *p*-	0.52 0.71	+0.19	8

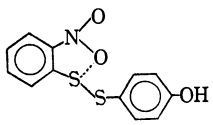
These values are calculated from the corresponding pK_a and the ρ-value of 2.50.

Hammett's σ-values of the dithia and the related groups in the dissociations of various substituted phenols are listed in Table 2. While only the inductive or π-inductive effect is transmitted through the benzene ring, the $\Delta(\sigma_p-\sigma_m)$ value becomes negative, as seen in the values of both phenoxy and *p*-nitrophenoxy substituted phenols, the positive values of $\Delta(\sigma_p-\sigma_m)$ for phenylthia and *p*-nitrophenylthia groups[8] and various other sulfur groups[9] have been taken to indicate the operation of the 3d-orbital resonance effect of these sulfur groups in the dissociations of the *p*-substituted phenols as shown below:

The $\Delta(\sigma_p-\sigma_m)$ value for *p*-nitrophenyldithia group (0.16) is even somewhat larger than that for the corresponding monothia group (0.10) and comes close to that for phenylsulfinyl group (0.19) which has been known to display 3d-orbital resonance effect both in the dissociation of the substituted phenols and the carbanion forming reactions.[10]

Though the *m*-hydroxyphenyl is not identical to *p*-hydroxyphenyl group, it is interesting to compare the acidities of the two isomers, IV and V, because the inductive effects of both groups are presumed not to be much different in view of our previous work on the dissociations of bis(hydroxyphenyl) sulfides, sulfoxides, sulfones and tris(hydroxyphenyl)sulfonium compounds.[11] The fact that the compound IV is a stronger acid than the compound V, apparently suggests that the 3d-orbital resonance effect is operating in the former compound.

The less acidic nature of *o*-nitrophenyldithiaphenol (III) as compared to the *p*-nitrophenyl isomer (I) is probably due to the non-bonding interaction of the following type which results in the decrease of



electronegativity of the sulfur atom attached nitrophenyl group, thus decreasing both the 3d-orbital resonance effect and electron-withdrawing inductive effect of the dithia group. A similar non-bonding interaction is already known from the X-ray structural determination of *o*-nitrobenzenesulfenic acid.[12]

NMR Spectra. The proton chemical shifts of OH groups of some aryldithiaphenols and the related compounds in 1,4-dioxane are summarized in Table 3.

Although only a few compounds are available for the study, apparently there are good correlations between the acid strength and the chemical shifts for both para- and meta- substituted dithiaphenols and monothiaphenols, whose slopes of chemical shifts (ppm) against pK_a values are found to be -1 (Fig. 1). These observations suggest that the chemical shifts are dependent on the molecular structures while the electron densities of hydroxyl

Ultraviolet Absorption Spectra. The ultraviolet absorption spectra of dithia- and monothiaphenols are taken in 50% ethanol and alkaline solution and summarized in Table 4 and Figs. 2 and 3.

One notices that the λ_{max} for 4-nitro-4'-hydroxydiphenyl disulfide (I), 335 mμ, is at a longer wavelength than that for the meta-isomer (II). Perhaps the chromophore, *p*-nitrophenyldithia group in this case, is perturbed by the *p*-hydroxyphenyl group due to the electron-donation than by the meta group which cannot come in conjugation with the chromophore. It is interesting to note that the λ_{max} (352 mμ) of 4-nitro-4'-hydroxydiphenyl sulfide is at a longer wavelength (17 mμ) than that of the corresponding dithia group (335 mμ), perhaps because of the easy transmission of the electron-withdrawing inductive effect of 4-nitrophenylmercapto group. A question arises as to the possibility through conjugation using 3d-orbitals with the expansion of outer shell of the sulfur atom. However, this possibility does not seem to appear in the ultraviolet absorption spectra. Thus, the λ_{max} of 4-nitro-4'-hydroxydiphenyl sulfide in 50% ethanol solution shifts only slightly to a longer wavelength in alkaline solution (4 mμ), while there are also no red shifts of λ_{max} from neutral to alkaline solutions in the case of the dithia-substituted phenols.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2086—2095 (1968)

Preparation and Oxidation of Dihydrothiophenes*1

Takao TAKAYA, Shigeo KOSAKA, Yoshio OTSUJI and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received November, 15, 1967)

The preparation and oxidation of 3,4-disubstituted 2,5- and 4,5-dihydrothiophenes are described. The oxidation of these dihydrothiophenes with 30% hydrogen peroxide in acetic acid gave the corresponding thiophene derivatives. However, the oxidation of the same compounds with perbenzoic acid in chloroform gave the corresponding sulfone derivatives. The mechanisms for these oxidation are discussed.

During the course of our studies of the chemistry of dihydrothiophenes, we happened to find that 2,5-dihydrothiophene-3,4-dicarboxylic acid (Ia_1, R=H)[1] is oxidized to thiophene-3,4-dicarboxylic acid (IIa_1, R=H)[1] by 30% hydrogen peroxide in acetic acid. This fact is not consistent with the previously-reported findings that the oxidation of 2,5-dihydrothiophene[2] and 2-methyl-4,5-dihydrothiophene-3-carboxylic acid[3] with the same reagent gives the corresponding sulfones. These observations prompted us to study the oxidation of

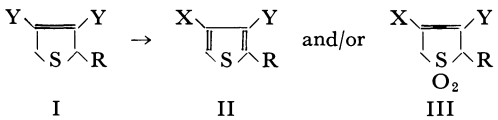
several 3,4-disubstituted 2,5- or 4,5-dihydrothiophenes in detail.

Results and Discussion

Oxidation of 3,4-Disubstituted 2,5-Dihydrothiophenes. When 3,4-disubstituted 2,5-dihydrothiophenes (I) were treated with 30% hydrogen peroxide in acetic acid, the corresponding thiophene (II) and/or sulfone derivatives (III) were obtained, depending on the nature of the substituents. The results are summarized in Chart 1 and in Table 1.



I II and/or III

These results suggest that: 1) when both of the two substituents are electron-withdrawing groups, the oxidation tends to produce the corresponding thiophene derivatives, II; 2) when one substituent is an electron-releasing group and the other is an electron-withdrawing group, the oxidation tends to produce the sulfone derivatives, III; and 3) 3,4-dimethoxycarbonyl-2,5-dihydrothiophene (Ic_1, R=H) and its 2-methyl derivative (Ic_2, R=CH_3) are exceptional. Upon oxidation the former produced a mixture of $IIIc_1$ and IIc_1 in an approximate molar ratio of 7 : 3, and the latter, a mixture of $IIIc_2$ and IIc_2 in an approximate molar ratio of 8 : 2.

The oxidation of 3,4-disubstituted 2,5-dihydrothiophenes, I, was also carried out with perbenzoic acid in chloroform. The products obtained in this oxidation are summarized in Table 1. The results show that the oxidation of 3,4-disubstituted 2,5-dihydrothiophenes with perbenzoic acid in chloroform produces the corresponding sulfone derivatives irrespective of the nature of the substituents, except that 2,5-dihydrothiophene-3,4-dicarboxylic acid, Ia_1, forms the corresponding sulfoxide (V). The exceptional formation of this compound may be due to its insolubility in chloroform. In fact, this compound precipitated out during the reaction.

The structure of the products obtained by the above oxidations was confirmed as follows. The thiophene derivatives were identified by comparison with the respective authentic samples which had been obtained by the oxidation of the corresponding dihydrothiophenes with chloranil. The sulfone derivatives were identified from the results of elemental analyses and from the presence of the absorption bands corresponding to the sulfone group in

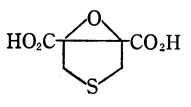
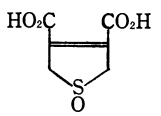
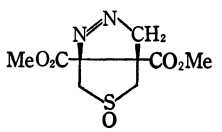
their infrared spectra. The structure of 3,4-dicarboxy-2,5-dihydrothiophene-1-oxide, V, was confirmed on the bases of the following observations: a) the elemental analysis, $C_6H_6O_5S$ (MW 189), shows that this compound contains one more oxygen atom than Ia_1, b) the infrared spectrum has no characteristic absorption bands in the sulfone and thiophene regions, and c) this compound produces the pyrazoline derivative (VI) when V is treated with diazomethane. The first two pieces of evidence, a) and b), suggest that either the sulfoxide V or the epoxide (IV) is a possible structure. However, the third piece of evidence, c), indicates that the most probable structure is the sulfoxide V. It is of interest to note here that when the sulfoxide V was heated for several minutes in a protic solvent such as aqueous ethanol or glacial acetic acid, it was converted into thiophene-3,4-dicarboxylic acid, IIa_1.[4]



IV

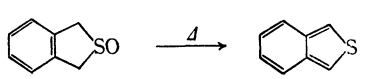


V



VI

A similar dehydration reaction has recently been found by Cava and Pollack[5] in 1,3-dihydrobenzo[*c*]-thiophene (VII); the pyrolysis of VII on neutral alumina afforded isothianaphthene (VIII) in a 94% yield.



VII VIII

4) This compound was kindly provided by Professor S. Oae.

5) M. P. Cava and N. M. Pollack, *J. Am. Chem. Soc.*, **88**, 4112 (1966).

These facts suggest that the transformation of dihydrothiophenes to the corresponding thiophene derivatives proceeds through the corresponding sulfoxide derivatives, even though attempts to isolate sulfoxides of 3,4-disubstituted dihydrothiophenes other than Ia_1 have been unsuccessful.

A probable mechanism for the transformation of the 2,5-dihydrothiophene Ia_1 to the thiophene IIa_1 *via* the sulfoxide V is illustrated in Chart 2. The

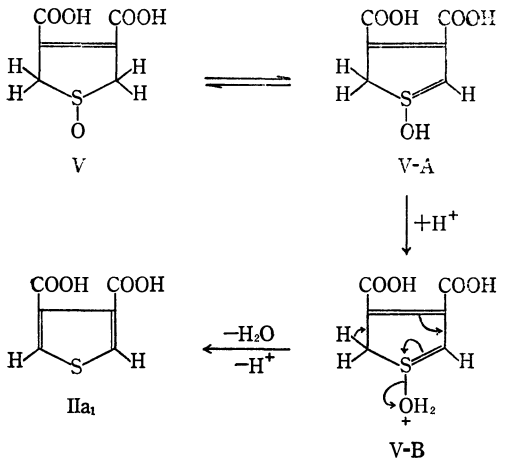


Chart 2

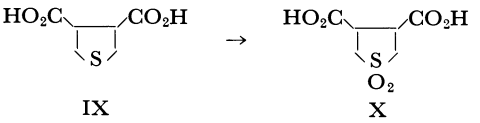
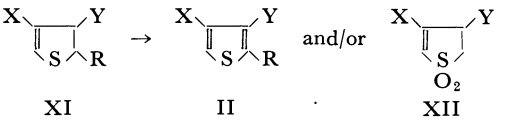
first step of this transformation is the oxidation of the sulfide to the sulfoxide. Since the hydrogen atom of the methylene group adjacent to the sulfoxide group is acidic, and since its acidity is also enhanced by two carboxyl groups, the electron-withdrawing groups at the 3- and 4-positions, the sulfoxide V may take a tautomeric form (V-A). The V-A tautomer would be dehydrated under acidic conditions to produce the thiophene derivative IIa_1 *via* V-B. A similar mechanism would hold for the other 2,5-dihydrothiophene which has electron-withdrawing groups at the 3- and 4- positions. In fact, in these cases the thiophene derivatives were produced. However, when one substituent is an electron-releasing group and the other is an electron-withdrawing group in 3,4-disubstituted 2,5-dihydrothiophenes, the hydrogen atom of the methylene group placed between the sulfoxide and the carbon atom bearing the electron-withdrawing group will not be acidic enough to be removed as a proton. In these cases a tautomeric equilibrium of the V⇌V-A type can not exist and the mechanism shown in Chart 2 can not be applied. As a result, the subsequent oxidation of the sulfoxide to the sulfone will take place. The proposed mechanism was further supported by the observation that tetrahydrothiophene-3,4-dicarboxylic acid (IX) afforded the corresponding sulfone (X) exclusively when IX was treated with 30% hydrogen peroxide in acetic acid.



In this case, the hydrogen atoms of the methylene group adjacent to the sulfur atom are not acidic enough to be removed as a proton. Consequently, the compound IX can not undergo the subsequent reaction indicated in Chart 2, and the sulfone derivative X is produced.

Oxidation of 3,4-disubstituted 4,5-Dihydrothiophenes. The oxidation of 3,4-disubstituted 4,5-dihydrothiophenes (XI) with 30% hydrogen peroxide or perbenzoic acid was carried out in a manner similar to that of 3,4-disubstituted 2,5-dihydrothiophenes I. The results are summarized in Table 2.



As may be seen in Table 2, 4,5-dihydrothiophene-3,4-dicarboxylic acid (XIa_1, R=H) and its 5-methyl derivative (XIa_2, R=CH_3) were, with 30% hydrogen peroxide in acetic acid, oxidized to the corresponding thiophene derivatives, IIa_1 and IIa_2. However,

Table 2. Oxidation of 4,5-dihydrothiophenes

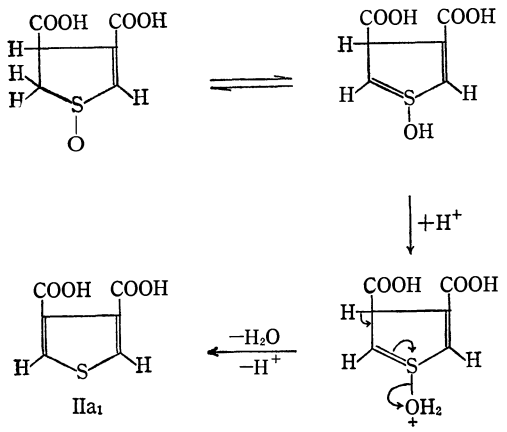

Chart 3

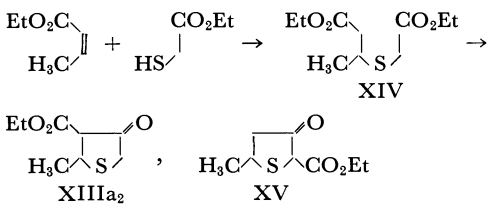
with the same reagent 2-methyl-4,5-dihydrothiophene-3-carboxylic acid[3] was not oxidized to the thiophene derivative, but to the corresponding sulfone derivative, in a 90% yield. These facts can probably be explained in terms of the mechanism outlined in Chart 3. Since the methylene group in XIa_1 is placed between an electron-withdrawing substituent and the sulfoxide group, one of the hydrogen atoms of the methylene group will be acidic enough to be removed as a proton*2 and the thiophene derivatives can be formed; otherwise, the dihydrothiophenes would be further oxidized to the corresponding sulfone derivatives.

The dissociation of the hydrogen atom of the methylene or methine group to a proton in the 3,4-disubstituted 2,5- or 4,5-dihydrothiophene would be much more favored in a protic solvent than in an aprotic solvent. This assumption would explain why the thiophene derivatives were produced in a protic solvent such as acetic acid, while sulfone derivatives were produced in an aprotic solvent such as chloroform. However, no explanation can be given of the fact that the oxidation of 3,4-dimethoxycarbonyl-2,5-dihydrothiophene, Ic_1, and its 2-methyl derivative, Ic_2, and 3,4-dimethoxycarbonyl-4,5-dihydrothiophene (XIb_1, R=H) with 30% hydrogen peroxide in a protic solvent such as acetic acid gave the corresponding sulfone derivative as the main product.

Preparation of Dihydrothiophenes. All of the dihydrothiophenes used in this paper, except for Ia_1, Ib_1, and XIa_1, were new compounds; they were synthesized by the following routes (see Chart 4). The starting compound ($XIIIa_2$, R=CH_3) was obtained by refluxing a solution of ethyl β-mercaptopropinate and ethyl crotonate in benzene in the presence of sodium ethoxide, ethyl β-ethoxycarbonylmethylmercaptobutyrate (XIV) was supposed to be an intermediate in this cyclization reaction. However, Larsson and Dahlström[6] have reported that, in contrast to our product, $XIIIa_2$, 2-ethoxycarbonyl-5-methyl-3-ketotetrahydrothiophene (XV) is produced by warming XIV in toluene in the presence of sodium ethoxide on a water bath. Although the reason for this inconsistency is not clear at the present time, it might be due to the differences in the reaction conditions employed.



The structures of the compounds $XIIIa_2$, Ib_2, Ia_2, Ic_2 and XIa_2 obtained in our experiments were confirmed by a comparison of their spectroscopic

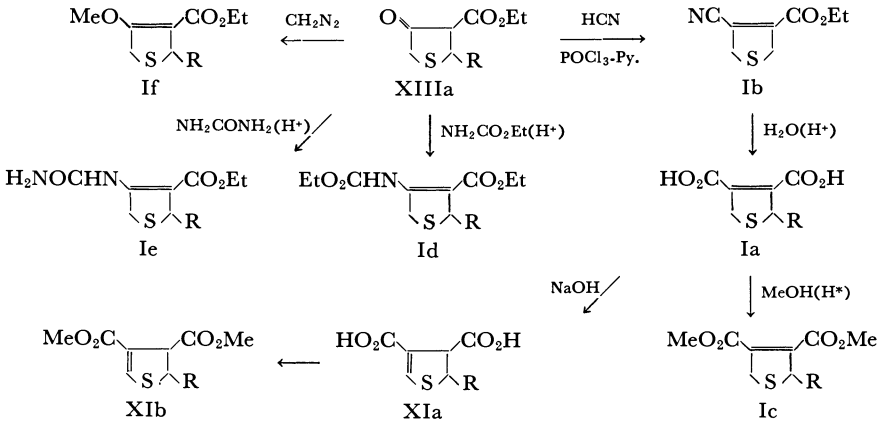


Chart 4

*2 In the case of the compound XIa_2, the hydrogen atom of the methine group to which the methyl group is attached will still be acidic enough to be removed as a proton. Thus, compound XIa_2 gave the IIa_2 thiophene upon oxidation.

TABLE 3. SPECTROSCOPIC DATA FOR 2-METHYL-3-ETHOXYCARBONYL-4-KETOTETRAHYDROTHIOPHENE AND ITS RELATED COMPOUNDS

		$XIIIa_1$***	Ib_1	Ia_1	Ic_1	XIa_1
UV* (mμ)	λ_{max}	249	228	223	212	293
	ε	2700	7600	10000	—	9900
IR** (cm^{-1})	$\nu_{C=C}$	1625	1635	1640	1655	1570
		$XIIIa_2$***	Ib_2	Ia_2	Ic_2	XIa_2
UV* (mμ)	λ_{max}	251	225	224	212	291
	ε	1900	7100	9000	8000	9200
IR** (cm^{-1})	$\nu_{C=C}$	1620	1630	1655	1660	1570

* Measured in 99% EtOH.

** Measured in CCl_4 for $XIIIa_1$, $XIIIa_2$, Ib_1, Ib_2, Ic_1, and Ic_2: measured in a KBr disk for Ia_1, Ia_2, XIa_1, and XIa_2.

*** The infrared spectra of $XIIIa_1$, and $XIIIa_2$ showed the following absorptions: $XIIIa_1$; 1760 (ester carbonyl), 1735 (ketone), 1670 (ester carbonyl after chelation to the enolic hydroxyl group), and 1625 cm^{-1} (C=C linkage); $XIIIa_2$; 1750 (ester carbonyl), 1730 (ketone), 1660 (ester carbonyl after chelation to the enolic hydroxyl group), and 1620 cm^{-1} (C=C linkage).

TABLE 4. THE COMPOUNDS OBTAINED BY THE OXIDATION OF 2,5- AND 4,5-DIHYDROTHIOPHENE DERIVATIVES

Compound	Mp (Bp, °C/mmHg)	Recryst. solvent	Formula	Analytical data					
				Calcd %			Found %		
				C	H	N	C	H	N
IIa_1	225—227[a]	Water							
IIa_2	204—205	10% Ethanol	$C_7H_6O_4S$	45.17	3.25		45.38	3.54	
IIb_1	96— 97	Cyclohexane	$C_8H_7O_2NS$	53.04	3.90	7.73	53.18	4.03	7.67
IIb_2	82— 83	Petroleum ether-chloroform	$C_9H_9O_2NS$	55.38	4.65	7.18	55.16	4.57	7.22

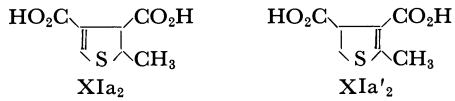
a) Lit. mp 230—231°C, J. Sice, *J. Org. Chem.*, **19**, 70 (1954).

b) Lit. mp 60—61°C, E. C. Kornfeld and R. G. Jones, *ibid.*, **19**, 1671 (1954).

properties with those of the related compounds. The spectroscopic data are summarized in Table 3.

First, note that the compounds Ib_1, Ia_1, Ic_1, and XIa_1 have been derived from $XIIIa_1$, and that the structures of all of these compounds have been confirmed. (Although Ic_1 was first obtained in our experiment, the structure of this compound should be correct since Ic_1 was prepared simply by the esterification of Ia_1.) In addition, note also that the compounds Ib_2, Ia_2, Ic_2, and XIa_2 were experimentally derived from $XIIIa_2$ by the same methods as those employed for the derivation of Ib_1, Ia_1 Ic_1, and XIa_1 from $XIIIa_1$. This means that Ib_2, Ia_2, Ic_2, and XIa_2 have structures corresponding to those of Ib_1, Ia_1, Ic_1, and XIa_1 respectively. An inspection of the spectroscopic data in Table 3 indicates that the compound XIa_1, in which the double bond in the ring is in conjugation with the sulfur atom, shows the absorption band at the longer-wavelength side both in the ultraviolet and the infrared ($\nu_{C=C}$) spectra as compared with those for the compounds Ib_1, Ia_1 and Ic_1, in which no such

a conjugation is involved. The similarity of the spectroscopic data of compounds $XIIIa_2$, Ib_2, Ia_2 Ic_2, and XIa_2 to those of the corresponding compounds, $XIIIa_1$, Ib_1, Ia_1, Ic_1 and XIa_1, strongly suggests that the structures for the compounds $XIIIa_2$, Ib_2, Ia_2, Ic_2, and XIa_2 shown in Chart 4 are all correct. For the compound XIa_2, the above arguments lead to the structure of either XIa_2 or XIa'_2. The NMR spectrum of the compound showed, however, that the XIa_2 structure is also correct (see Experimental Section).



XIa_2 XIa'_2

The preparation of the compounds which have an electron-releasing and an electron-withdrawing group in 3,4-disubstituted 2,5-dihydrothiophenes was carried out as follows. 3-Ethoxycarbonyl-4-ethoxycarbonylamino-2,5-dihydrothiophene (Id_1, R=H) and its 2-methyl derivative (Id_2, R=CH_3) were prepared by the condensation of $XIIIa_1$ or $XIIIa_2$ with urethan in the presence of *p*-toluenesulfonic acid. The position of the double bond in Id_1 was confirmed from the fact that the NMR spectrum of Id_1 showed two protons at C-2 and two protons at C-5. 3-Ethoxycarbonyl-4-ureido-2,5-dihydrothiophene (Ie_1, R=H) and its 2-methyl derivative (Ie_2, R=CH_3) were also synthesized by the condensation of $XIIIa_1$ or $XIIIa_2$ with urea. 3-Methoxy-4-ethoxycarbonyl-2,5-dihydrothiophene (If_1, R=H) was obtained by treating $XIIIa_1$ with an excess ethereal diazomethane by a method similar to that of Blake and his co-workers.[7]

Experimental

All the melting points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-S_2 infrared spectrophotometer. The ultraviolet spectra were obtained with a Hitachi EPS-20 recording spectrophotometer. The NMR spectra were obtained with a Nihondenshi JNM-3H-60 high-resolution nmr spectrometer in a 10% carbon tetrachloride solution of the samples, using a TMS reference at 22°C.

Materials. 3-Cyano-4-ethoxycarbonyl-2,5-dihydrothiophene Ib_1, 3,4-dicarboxy-2,5-dihydrothiophene Ia_1, and tetrahydrothiophene-3,4-dicarboxylic acid IX were prepared by the method of Baker and his co-workers from 3-ethoxycarbonyl-4-ketotetrahydrothiophene $XIIIa_1$.[8]

2-Methyl-3-ethoxycarbonyl-4-ketotetrahydrothiophene ($XIIIa_2$, R=CH_3). Eighty-seven grams of ethyl thioglycolate in 250 m*l* of dry benzene was added to dry sodium ethoxide prepared from 23 g of sodium and absolute ethanol. To the reaction mixture there was then added, drop by drop and with shaking, 82 g of ethyl crotonate over a period of 10 min. After being refluxed for 3 hr, the benzene solution was extracted with ice water. The aqueous layer was acidified with acetic acid and then extracted with benzene. The benzene extract was washed successively with water, dilute aqueous sodium bicarbonate, and water. The distillation of the benzene extract gave 5.1 g (41%) of $XIIIa_2$ boiling at 107—108°C/6 mmHg, n_D^{25} 1.497. This compound was used for the preparation of Ib_2 without further purification. The semicarbazone of $XIIIa_2$ was prepared by the usual method. Three recystallizations from aqueous ethanol gave an analytical sample, mp 149—150°C.

Found: C, 43.90; H, 6.01; N, 17.15%. Calcd for $C_9H_{15}N_3O_3S$: C, 44.08; H, 6.17; N, 17.14%.

2-Methyl-3-ethoxycarbonyl-4-cyano-2,5-dihydrothiophene (Ib_2, R=CH_3). This compound was prepared in a 70% yield from $XIIIa_2$ by applying the method of Baker and his co-workers,[8] who prepared Ib_1 from $XIIIa_1$, bp 106—108°C/1 mmHg.

Found: C, 54.74; H, 5.90%. Calcd for $C_9H_{11}NO_2S$: C, 54.82; H, 5.62%.

2-Methyl-2,5-dihydrothiophene-3,4-dicarboxylic Acid (Ia_2, R=CH_3). This compound was obtained in a 67% yield by the acid hydrolysis of Ib_2 according to the method of Baker and his co-workers,[8] mp 145—147°C (from acetone-benzene).

Found: C, 44.95; H, 4.43%. Calcd for $C_7H_8O_4S$: C, 44.70; H, 4.29%.

5-Methyl-4,5-dihydrothiophene-3,4-dicarboxylic Acid (XIa_2, R=CH_3). A solution of 1 g of Ia_2 in 5 m*l* of ethanol was refluxed for 5 hr with 1 g of potassium hydroxide in 5 m*l* of water. The solution was then acidified with dilute hydrochloric acid and extracted three times with ethyl acetate. The extracts were dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo*. The residue (0.4 g, mp 124—132°C) was recrystallized from acetone-benzene-petroleum ether to give 0.2 g (20%) of colorless crystals, mp 161—162°C. The infrared spectrum showed bands at 1570 cm^{-1} (double bond conjugated with a sulfur atom), 1705 cm^{-1} (carboxylic acid), 1660 cm^{-1} (α,β-unsaturated carboxylic acid) and 3050 cm^{-1} (olefinic proton), and the nmr spectrum of the dimethyl ester of XIa_2 showed a characteristic vinyl proton at 2, 6 τ (doublet, J=1.5 cps; a long-range coupling with a proton at C-3).

Found: C, 44.50; H, 4.32%. Calcd for $C_7H_8O_4S$: C, 44.69; H, 4.29%.

2-Methyl-3,4-dimethoxycarbonyl-2,5-dihydrothiophene (Ic_2, R=CH_3). A solution of 3.76 g of Ia_2 in dry ether containing a small amount of absolute methanol was treated with an excess of ethereal diazomethane. After the evaporation of the solvent, the distillation of the residue gave 3.1 g (70%) of a yellow liquid, bp 118—124°C/4 mmHg, n_D^{23} 1.502.

Found: C, 50.20; H, 5.34%. Calcd for $C_9H_{12}O_4S$: C, 50.00; H, 5.60%.

3,4-Dimethoxycarbonyl-2,5-dihydrothiophene (Ic_1, R=H). A mixture of 10.5 g of Ia_1, 1.0 g of *p*-toluenesulfonic acid, 80 m*l* of chloroform, and 60 m*l* of methanol was refluxed for 50 hr in a Soxhlet apparatus containing anhydrous sodium sulfate in a thimble. After the mixture had then been distilled through a Vigreux column at an atmospheric pressure in order to remove the solvent, the distillation of the residue gave 7.7 g (70%) of a colorless liquid, bp 130—131°C/3 mmHg, n_D^{23} 1.516.

Found: C, 47.68; H, 5.01%. Calcd for $C_8H_{10}O_4S$: C, 47.53; H, 4.99%.

7) J. Blacke, C. D. Willson and H. Rapoport, *J. Am. Chem. Soc.*, **86**, 5294 (1964).

8) B. R. Baker, M. V. Querry and A. F. Kadish, *J. Org. Chem.*, **13**, 123 (1948).

3,4-Dimethoxycarbonyl-4,5-dihydrothiophene (XIb$_1$, R=H). 4,5-Dihydrothiophene-3,4-dicarboxylic acid (XIa$_1$, R=H) was prepared by the method of Baker and his co-workers.[9] Recrystallization from acetone-benzene gave XIa$_1$, mp 180—181°C. A solution of 4.5 g of XIa$_1$ in dry ether containing a small amount of absolute methanol was terated with an excess of ethereal diazomethane. After the evaporation of the solvent, the residue was distilled to give 4.1 g (90%) of XIb$_1$, bp 122—124°C/3 mmHg, n_D^{30} 1.525. The infrared spectrum showed bands at 1730 cm^{-1} (ester C=O), 1700 cm^{-1} (α,β-unsaturated ester C=O), and 1575 cm^{-1} (double bond conjugated with a sulfur atom), and the nmr spectrum showed a characteristic vinyl proton at 2.55 τ (doublet, J=1.5 cps; a long-range coupling with a proton at C-3).

Found: C, 47.53; H, 4.99%. Calcd for $C_8H_{10}O_4S$: C, 47.65; H, 5.21%.

2-Methyl-3-ethoxycarbonyl-4-ethoxycarbonylamino-2,5-dihydrothiophene (Id$_2$, R=CH$_3$). A mixture of 11 g of the β-ketoester XIIIa$_2$, 6 g of urethane, 1 g of *p*-toluenesulfonic acid, and 200 m*l* of dry benzene was refluxed for 15 hr in a Soxhlet apparatus containing anhydrous sodium sulfate in a thimble. The mixture, was then washed thoroughly with water to remove the *p*-toluenesulfonic acid and the excess urethane. The evaporation of the solvent gave 14 g (93%) of the product, Id$_2$. This crude product was purified by chromatography using an alumina column and chloroform as an eluent, or by recrystallization from methanol-water, to give an analytical sample, mp 68—69.5°C.

Found: C, 50.72; H, 6.44; N, 5.17%. Calcd for $C_{11}H_{17}O_4NS$: C, 50.96; H, 6.61; N, 5.40%.

3-Ethoxycarbonylamino-4-ethoxycarbonyl-2,5-dihydrothiophene (Id$_1$, R=H). A mixture of 3.5 g of XIIIa$_1$, 1.8 g of urethane, 300 mg of *p*-toluenesulfonic acid, and 70 m*l* of dry benzene was refluxed for 15 hr in a Soxhlet apparatus. The mixture was then worked up in the manner described above to give 4.10 g (83%) of Id$_1$ (mp 70—71.5°C (from methanol-water)). The NMR spectrum of Id$_1$ ($CHCl_3$) showed a triplet at 8.7 τ (6H) (J=7.5 cps), a triplet at 6.3 τ (2H) (J=3 cps), a quartet at 4.85 τ(2H) (J=7.5 cps), a quartet at 5.75 τ(2H) (J=7.5 cps), a triplet at 5.6 τ(2H) (J=3 cps), and a singlet at 4.45 τ(1H).

Found: C, 49.13; H, 5.95; N, 5.53%. Calcd for $C_{10}H_{15}O_6NS$: C, 48.97; H, 6.17; N, 5.71%.

3-Ethoxycarbonyl-4-ureido-2,5-dihydrothiophene (Ie$_1$, R=H). A) A mixture of 5.0 g of finely-ground urea, 13 g of XIIIa$_1$, 1.5 m*l* of absolute ethanol, and three drops of concentrated hydrochloric acid was placed in an evaporating dish covered loosely with a watch glass, and then evacuated continuously by an aspirator in a desiccator containing concentrated sulfuric acid as a drying agent. After about a week, the dried mixure was recrystallized from 95% ethanol to give 12.9 g (80%) of Ie$_1$, mp 198—203°C. Repeated recrystallizations from 99% ethanol gave crystals melting at 201—203°C.

B) A mixture of 3.48 g of XIIIa$_1$, 1.20 g of urea, 40 m*l* of absolute ethanol, 90 m*l* of dry benzene, and 0.3g of *p*-toluenesulfonic acid was refluxed for 48 hr in a Soxhlet apparatus containing anhydrous sodium sulfate in a thimble. The mixture was then evaporated to dryness, and the residue was recrystallized from 95% ethanol to give 3.56 g (82%) of Ie$_1$, mp 201—203°C.

Found: C, 44.52; H, 5.27; N, 12.91%. Calcd for $C_8H_{12}O_3N_2S$: C, 44.44; H, 5.60; N, 12.96%.

2-Methyl-3-ethoxycarbonyl-4-ureido-2,5-dihydrothiophene (Ie$_2$, R=CH$_3$). By treating 4.70 g of XIIIa$_2$ and 1.65 g of urea such as has been described above in the case of Id$_1$ (method A), 3.0 g (78%) of crude Ie$_2$, mp 180—184°C, were obtained. Three recrystallizations from 95% ethanol gave pure Ie$_2$, mp 187—188.5°C.

Found: C, 47.20; H, 6.26; N, 12.18%. Calcd for $C_9H_{14}O_3N_2S$: C, 46.95; H, 6.13; N, 12.17%.

3-Ethoxycarbonyl-4-methoxy-2,5-dihydrothiophene (If$_1$, R=H). To a solution of 7 g of XIIIa$_1$ in dry ether there was added an excess of dry ethereal diazomethane. The resultant solution was kept in a refrigerator for 16 hr, and then evaporated; the residue was fractionally distilled to give 6 g of If$_1$, bp 118—120°C/5 mmHg.

Found: C, 50.95; H, 6.28%. Calcd for $C_8H_{12}O_3S$: C, 51.06; H, 6.43%.

Direct Conversion of Ia$_1$ to IIa$_1$. To a solution of 0.87 g of Ia$_1$ in 5 m*l* of acetone and 10 m*l* of acetic acid 1.5 m*l* of 30% hydrogen peroixde were added while the mixture was being cooled to prevent the temperature from rising above 50°C. The reaction mixture was then allowed to stand for 24 hr at 50°C. After the evaporation of the solvent under reduced pressure, the residue was recrystallized from water to give 585 mg (68%) of IIa$_1$.

Oxidation of the Cyanoester Ib$_1$ with 30% Hydrogen Peroxide in Acetic Acid (Procedure A). A mixture of 3.0 m*l* of 30% hydrogen peroxide and 20 m*l* of acetic acid was allowed to stand at 40°C for 3 hr. To the above cooled solution there was then added, in portions, a solution of 1.83 g of the Ib$_1$ cyanoester in 10 m*l* of acetone at a temperature below 25°C. The reaction mixture was allowed to stand for 38 hr at 25°C. The solvent was then removed under reduced pressure below 50°C. The residue was triturated with a mixture of petroleum ether and acetone to give 3-cyano-4-ethoxycarbonylthiophene (IIb$_1$, R=H).

Oxidation of Id$_1$, If$_1$, XIa$_1$ and XIa$_2$ with 30% Hydrogen Peroxide in Acetic Acid. This was carried out in a manner similar to that described for Ib$_1$.

Oxidation of the Cyanoester Ib$_2$ with 30% Hydrogen Peroxide in Acetic Acid. The oxidation of the Ib$_2$ cyanoester (1.970 g) in acetone (1.5 m*l*) with 30% hydrogen peroxide (3.0 m*l*) in acetic acid (20 m*l*) was carried out according to the procedure A. The reaction mixture was then worked up in a manner similar to that described for Ib$_1$, and the residue was chromatographed on alumina. The corresponding thiophene, IIb$_2$ (1.9 g), was eluted with a mixture of petroleum ether and chloroform (9 : 1), and a small amount of the corresponding sulfone, IIIb$_2$ (*ca.* 10 mg), was eluted with a mixture of petroleum ether and chloroform (4 : 6).

Oxidation of the Diester, Ic$_1$, Ic$_2$ and XIb$_1$ with 30% Hydrogen Peroxide in Acetic Acid. This oxidation was carried out in a manner similar to that described for Ib$_1$ (Procedure A). When the reaction mixture was worked up according to the procedure A, the residue gave a mixture of the corresponding thiophene and sulfone derivatives. The approximate molar ratio of the two derivatives in the mixture was estimated by a

9) G. B. Brown, B. R. Baker, S. Bernstein and S. R. Safir, *J. Org. Chem.*, **12**, 155 (1947).

comparison of the infrared spectra of the reaction mixture and those of a mixture of the authentic samples, IIc and IIIc, the relative concentrations of IIc and IIIc being varied correspondingly. The approximate molar ratio of the sulfone and the thiophene derivative in the oxidation products was : (70% $IIIc_1$: 30% IIc_1), (80% $IIIc_2$: 20% IIc_2), and (85% $XIIb_1$: 15% IIc_1), respectively. Attempts to separate the mixture completely by chromatography using an alumina or a silica gel column were unsuccessful.

Oxidation of Ie_1 and Ie_2 with 30% Hydrogen Peroxide in a Mixture of Acetic Acid and Acetic Anhydride. A mixture of 1.5 m*l* of 30% hydrogen peroxide, 4.5 m*l* of acetic anhydride, and 9.0 m*l* of acetic acid was allowed to stand at 45°C for 3 hr (or at 25°C for 12 hr). To the cooled solution there was then added, in portions, 1.08 g of Ie_1, with occasional cooling to prevent the temperature from rising above 45°C. Then the reaction mixture was kept at 45°C for 17 hr. After the evaporation of the solvent under reduced pressure below 45°C, the residue was recrystallized from 95% ethanol to give the product, mp 174—179°C. The infrared spectrum of the product showed a weak absorption band at 1020 cm^{-1} in the sulfoxide region. This product was presumed to be a mixture of the corresponding sulfoxide and sulfone derivative, but it was not separated by fractional recrystallizations. The product was refluxed with Raney nickel in ethanol for 1 hr, and the residue, after the evaporation of the solvent, was recrystallized to give 0.63 g (53%), of the $IIIe_1$ sulfone.

The 2-methyl derivative, Ie_2 was treated in a manner similar to that described for Ie_1 to give the corresponding sulfone, $IIIe_2$.

Oxidation of the Cyanoester Ib_1 with Perbenzoic Acid in Chloroform (Procedure B). To 46.8 m*l* (0.01 mol) of a solution of perbenzoic acid in dry chloroform there was added, portion by portion, a solution of 0.916 g (0.005 mol) of Ib_1 in 2 m*l* of acetone, while the temperature was maintained at 25°C. The mixture was then allowed to stand at 25°C for 24 hr. The reaction mixture was washed successively with two 15-m*l* portions of 5% sodium thiosulfate, with 10% aqueous sodium carbonate, and with three 20-m*l* portions of water, and then dried overnight over anhydrous sodium sulfate. After the removal of the solvent, 1.05 g of the corresponding sulfone, $IIIb_1$ was obtained. The characteristic infrared absorptions in the sulfone region were at 1343 and 1160 cm^{-1}.

Oxidation of the Cyanoester Ib_2 with Perbenzoic Acid in Chloroform. After a mixture of the Ib_2 cyanoester (591 mg, 3 mmol) and perbenzoic acid (6 mmol) in chloroform (23 m*l*) had been worked up as has been described for Ib_1 (Procedure B), the residue was chromatographed on alumina; a small amount of the corresponding thiophene, IIb_2 (*ca.* 20 mg), was eluted with a mixture of petroleum ether and chloroform (9 : 1), and 0.43 g of the corresponding sulfone, $IIIb_2$[10], with a (4 : 1) mixture of petroleum ether and chloroform.

Oxidation of Ic_1, Ic_2, Id_1, If_1, and XIb_1 with Perbenzoic Acid in Chloroform. This oxidation was carried out according to the procedure B to give the corresponding sulfones. The infrared spectra of these sulfone derivatives showed characteristic absorption bands in the sulfone region.

Oxidation of 2,5-Dihydrothiophene-3,4-dicarboxylic Acid Ia_2 to 2,5-Dihydrothiophene-3,4-dicarboxylic Acid-1-oxide (V). With 30% Hydrogen Peroxide-Acetic Acid. A mixture of 70 m*l* of acetic acid and 9.0 m*l* of 30% hydrogen peroxide was allowed to stand at 40°C for 3 hr. To this solution there was then added, portion by portion, 5.22 g of the Ia_1 diacid dissolved in 20 m*l* of acetone, while the temperature was maintained below 20°C; the reaction mixture was then kept at 20°C for 24 more hours. The colorless precipitate which was gradually formed was collected by filtration, washed with cold acetone, and then dried to give 4.70 g (83%) of the sulfoxide V, λ_{max}^{EtOH} 226 mμ ($\varepsilon = 11900$), ν_{max}^{KBr} 1870 w, 1710 s, 1674 s, 1645 s, 1295 s, 1225 s, 1010 s, 955 m and 730 cm^{-1} (m), neut. equiv. 190 (calcd 190). A second crop of the product (0.62 g) was obtained by the concentration of the mother liquor under reduced pressure. This minor product was identical in infrared and ultraviolet spectra with the authentic sample of thiophene-3,4-dicarboxylic acid.[4] The melting point of an admixture with the authentic sample was also undepressed.

With Perbenzoic Acid-Chloroform. To a solution of 4.4 g of perbenzoic acid in 10 m*l* of dry chloroform, there was added, portion by portion, a solution of 1.74 g of the Ia_1 diacid in 3 ml of acetone, while the temperature was kept below 25°C. A colorless precipitate soon appeared from the mixture. The reaction mixture was kept at 20°C for 24 hr. The precipitate was collected by filtration, washed with cold acetone, and dried to give 1.60 g (84%) of the sulfoxide V, which was identical in infrared and ultraviolet spectra with the product obtained by the treatment of Ia_1 with hydrogen peroxide-acetic acid.

Conversion of the Sulfoxide V to Thiophene-3,4-dicarboxylic Acid IIa_1. Two grams of the V sulfoxide were dissolved in 20 m*l* of water by warming the solution on a hot-plate. After the mixture had been cooled, long colorless, needles crystallized out. The crystals were collected by filtration and dried to give 1.6 g (89%) of IIa_1. Its mixed melting point with the authentic sample showed no depression. When acetic acid or aqueous ethanol was used as the solvent, the solvent was evaporated to dryness *in vacuo*, and then the residue was recrystallized from water.

Reaction of the Sulfoxide V with Diazomethane in Ether. A solution of 570 mg of the V sulfoxide in 1 m*l* of dry methanol was treated with an excess of diazomethane in ether. The reaction mixture, after standing for 24 hr at room temperature, was dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was recrystallized from benzene-chloroform to yield 390 mg (56%) of VI, mp 155—156°C. A characteristic infrared spectrum in the sulfoxide region was at 1045 cm^{-1}.

Found: C, 41.61; H, 4.65; N, 10.86%. Calcd for $C_9H_{12}O_5N_2S$: C, 41.54; H, 4.65; N, 10.77%.

Oxidation of Tetrahydrothiophene-3,4-dicarboxylic Acid (IX). Compound IX (0.82 g) was oxidized to X in a 80% yield, by a mixture consisting of 30% hydrogen peroxide (1.35 m*l*) and acetic acid (12 m*l*), in a manner similar to that described for Ib_1 except that the reaction was carried out at 50°C. The compound X had a mp of 201—203°C after recrystallization from acetic acid.

10) The structure of the sulfone $IIIb_2$ was confirmed by hydrolysis of $IIIb_2$ to $IIIa_2$ because of an unsuccessful purification of $IIIb_2$.

Found: C, 34.68; H, 3.74%. Calcd for $C_6H_8O_6S$: C, 34.62; H, 3.87%.

Dehydrogenation of the Ib_1 Cyanoester with Chloranil to the IIb_1 Thiophene. A mixture of 550 mg of the Ib_1 cyanoester and 787 mg of chloranil in 20 m*l* of dry toluene was refluxed for 6 hr. The mixture was then concentrated to a small volume under a stream of nitrogen. When the residue was diluted with 20 m*l* of dry chloroform, yellow crystals (chloranil) precipitated immediately. After filtration, the chloroform solution was concentrated to a small volume (*ca.* 5 m*l*), which was then chromatographed on alumina (20 g) using a mixture of chloroform and petroleum ether (5 : 1) as an eluent. After the evaporation of the solvent, the residue was triturated with petroleum ether to give 158 mg of the IIb_1 thiophene, which was identical in all respects (infrared, ultraviolet spectrum, and mixed melting point) with the prodct prepared from Ib_1 by the procedure A.

2-Methyl-3,4-dimethoxycarbonylthiophene (IIc_2, R=CH_3). Prepared by treating the IIa_2 diacid with diazomethane in ether, showed a bp of 123—124°C/3 mmHg, n_D^{15} 1.526.

Found: C, 50.70; H, 4.78%. Calcd for $C_9H_{10}O_4S$: C, 50.47; H, 4.71%.

Acid Hydrolysis of IIb_1 to IIa_1. A mixture of 180 mg of IIb_1, 1.5 m*l* of acetic acid, and 1 m*l* of concentrated hydrochloric acid was refluxed for 22 hr. The solvent was then evaporated to dryness *in vacuo*. Recrystallization from water gave 105 mg of IIa_1, mp 214—216°C, identical in all respects with thiophene-3,4-dicarboxylic acid, IIa_1.

Hydrolysis of $IIIc_1$ to 2,5-Dihydrothiophene-3,4-dicarboxylic Acid-1,1-dioxide ($IIIa_1$, R=H). A mixture of 2.0 g of $IIIc_1$ and 100 m*l* of saturated hydrobromic acid was stirred at 60°C for 20 hr. The reaction mixture was then concentrated to dryness under reduced pressure below 60°C. The residue was recrystallized from ether - petroleum ether to give 1.50 g (85%) of colorless crystals, mp 172—176°C. Found: C, 32.05; H, 3.58%. Calcd for $C_6H_6O_6S$: C, 32.15; H, 3.60%. The dehydration of the crystals over phosphorus pentoxide at 100°C *in vacuo* gave $IIIa_1$, mp 180—181°C.

Found: C, 34.94; H, 2.91%. Calcd for $C_6H_6O_6S$: C, 34.96; H, 2.93%.

Hydrolysis of $IIIc_2$ to 2-Methyl-2,5-dihydrothiophene-3,4-dicarboxylic Acid-1,1-dioxide ($IIIa_2$, R=CH_3). By refluxing a mixture of 592 mg of $IIIc_2$ and 10 m*l* of saturated hydrobromic acid in the manner described above for $IIIc_1$, 387 mg (72%) of $IIIa_2$ was obtained; mp 172—174°C (from ether-petroleum ether).

Found: C, 38.06; H, 3.68%. Calcd for $C_7H_8O_6S$: C, 38.19; H, 3.66%.

The authors are indebted to Dr. Syunichi Kawamura of the Radiation Center of Osaka Prefecture for the nmr measurements.

Synthesis and Properties of Nitrosoazulenes[1)]

Tetsuo NOZOE, Paw Wang YANG,[2a)] Hiroshi OGAWA[2b)] and Takashi TODA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received January 27, 1968)

Ethyl 2-amino-3-nitrosoazulene-1-carboxylate (II) was synthesized from ethyl 2-aminoazulene-1-carboxylate by treatment with isoamyl nitrite. The structure of the amino-nitrosoazulene was proved by the reductive acetylation of the azulene to give ethyl 2,3-diacetylaminoazulene-1-carboxylate. This nitrosation method was then applied to several azulenes possessing different substituents; it yielded some stable nitrosoazulene derivatives. The spectral properties of the nitrosoazulenes will be discussed. The condensation reactions of II with aromatic amines failed to give azo-dyes, but with diethyl malonate and malononitril they gave the corresponding pyrazinoazulene derivatives.

Although Hafner and his co-workers reported the formation of 1-nitrosoazulene in 1961,[3)] they could not succeed in isolating the pure substance. Kitahara and Kato obtained 2-amino-1-cyano-3-nitroso-7-isopropylazulene in a poor yield;[4)] however, its chemical and physical properties have not been investigated. The present authors have observed the formation of ethyl 2-amino-3-nitrosoazulene-1-carboxylate (II) in a fairly good yield[5)] accompanied

by the exchange of the tropyl group and the nitroso group when ethyl 2-amino-3-tropylazulene-1-carboxylate (I) was treated with isoamyl nitrite (IAN) in alcohol or benzene. It is very interesting that the deamination reaction of I did not take place and that II was obtained in a good yield even though the reaction was carried out in the presence of a reducing reagent such as alcohol. We applied this method to several azulenes and investigated the properties of the nitrosoazulenes thus obtained.

Although 1-nitrosoazulene has been reported to be very unstable and could not be isolated,[3] II is a

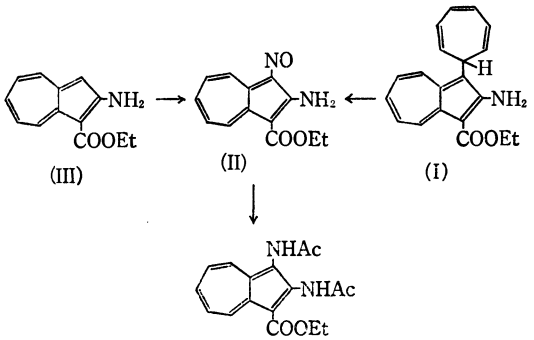
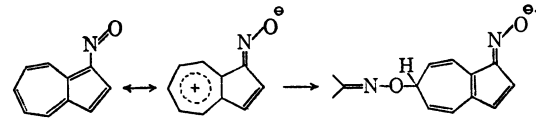
very stable entity. Therefore, ethyl 2-aminoazulene-1-carboxylate (III), which does not possess a tropyl group at the C-3 position, was treated with IAN in alcohol or benzene; II was thus obtained in a 95% yield. The addition of a trace amount of hydrogen chloride or concentrated sulfuric acid to the reaction mixture did not affected the yield of II. However, when III was treated with sodium nitrite together with a mineral acid in alcohol, II could not be isolated and intractable resinous substances were formed. Since I and III afforded the same product, II, the position of the introduced nitroso group should be C-3 position of the azulene ring. This was confirmed by the reductive acetylation of II, which yielded ethyl 2,3-diacetylaminoazulene-1-carboxylate (IV).[6]



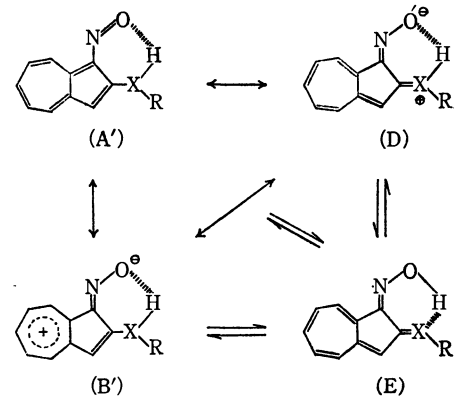
In order to investigate the effect of substituents on the nitrosation reaction, the reactions of several azulenes (V—XVII),[7] possessing different substituents, such as alkyl, alkylamino, ethoxycarbonyl, or hydroxyl groups, have been carried out under the same reaction conditions; the results obtained are shown in Table 1.

II and ethyl 2-methylamino-3-nitrosoazulene-1-carboxylate (XXII) are very stable, but 2-dimethylamino-, 2-acetylamino-, and 2-hydroxy-3-nitrosoazulene derivatives (XXIII, XIV, and XXV respectively) are not very stable and change to black, resinous substances when heated for a long time during the purification process or when stored for a long period. The products in other cases should be nitrosation products, according to their analytical data; however, they are very unstable and are obtained only as amorphous powders, accompanied by large amounts of tarry substances, and they could not be purified. The reductive acetylation of those substances (XVIII, XX, XXI, XXVI and XXVII) was then attempted. Although almost two equivalent moles of hydrogen were taken up in each case, only resinous products were obtained. On the other hand, XXV afforded ethyl 3-acetylamino-2-hydroxyazulene-1-carboxylate (XXVIII) in a good yield under the same conditions. XXVIII was also obtained by the same reductive acetylation of ethyl 3-(*p*-tolyl)azo-2-hydroxyazulene (XXIX), which had been obtained from XV.

The results presented above suggested that the nitrosation reaction of the azulenes takes place first, but the nitrosoazulenes formed are unstable, except for II, XXII XXV, *etc.*, and the polymerization and/or other reactions occur to give resinous materials. The molecular weights of XVIII, XIX, *etc.*, could not be measured because of their insolubility. It can reasonably be understood that 1-nitrosoazulenes can possess A- and B-type canonical formulae and that the self-condensation reactions occur to form C- and other-type polymers.



The nitrosoazulenes which have an amino or hydroxyl group at the C-2 position are stable entities. Therefore, one of the canonical formulae of those nitrosoazulenes is a D-type formula (and also A' and B'); this plays an important role in the stability of those nitrosoazulenes. D-type entities are able to tautomerize with E-type entities with an exchange of hydrogen atoms; this tautomerization may contribute to the stabilization of those nitrosoazulenes.



The nitrosation of azulenes with IAN may proceed by a radical mechanism. However, it is well-known that the cationoid substitution reactions of azulenes readily occur at C-1 and C-3 positions.[7a] The results shown in Table 1 indicate that azulenes which possess electron-releasing groups readily afford

6) M. Kobayashi, Master's thesis submitted to Tohoku University, March, 1961.

7) The methods of synthesizing known azulenes are described in the following articles and in the litratures cited therein: a) T. Nozoe and T. Asao, "Dai Yuki Kagaku, (Comprehensive Organic Chemistry)," Vol. 13, ed. by M. Kotake, Asakura Shoten, Tokyo (1960), pp. 439—534. b) T. Nozoe, S. Seto, K. Takase, S. Matsumura and T. Nakazawa, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **86**, 346 (1965).

nitroso derivatives, whereas azulenes which have electron-withdrowing groups do not give the corresponding nitrosoazulenes easily, but rather resulted in the recovery of the original azulenes under the same reaction conditions. Furthermore, I readily yielded II with the exchange of the tropyl group. In view of the above facts, it seems rather reasonable to say that the reaction proceeds through an ionic process.

Generally, the UV and visible spectra of azulenes show fine structures; however, the spectrum of II shows a fairly broad structure compared with that of III, as is shown in Fig. 1. The spectrum of azulene in concentrated sulfuric acid[8] and the spectrum of 1-ethoxycarbonylazulene-3-tropylium perchlorate[9] do not show such fine structures either. These facts suggest that the contribution of B- and D-type canonical formulae to II is fairly important.

—— II
---- III
— — 1-Ethoxycarbonylazulene-3-tropylium perchlorate

The IR spectrum of 5-nitrosotropolone, which is said to exist as a tropo-quinone oxime form,[10] shows strong bands at 1603 and 1325 cm^{-1}, a weak band at 1522 cm^{-1}, and a very weak band at 1439 cm^{-1}. On the other hand, the IR spectra of the nitrosoazulenes show several bands between 1530—1480 cm^{-1} as follows II, 1600 (s), 1570 (m), 1540 (m), 1515 (s), 1450 (m) and 1430 (s) cm^{-1}; XXII, 1605 (S), 1570 (m), 1525 (s), 1480 (w) and 1440 (s) cm^{-1}; XXIII, 1600 (s), 1570 (w), 1520 (s), 1480 (w) and 1430 (s) cm^{-1}; XXV, 1620 (m), 1580 (w), 1495 (v.s.), 1450 (v.s) and 1405 (w) cm^{-1}; XXVI, 1600 (m), 1545 (s), 1520 (s), 1475 (w), 1440 (s) and 1404 (s) cm^{-1}; and an ester carbonyl band near 1670 cm^{-1} in all the nitrosoazulenes above.[11] Although XXIII and XXVI do not have oxime-type tautomeric forms, they possess a strong band between 1525—1520 cm^{-1}. Therefore, the absorptions of the nitrosoazulenes are assigned to N=O stretching vibrations of the nitroso group this is in agreement with those of the nitroso group of aromatic compounds.[12] However, XXV does not show such a band in this region, but shows a very strong band at 1490 cm^{-1}. Presumably this is due to the contribution of the E-type canonical form; the band at 1700 cm^{-1} of XXV may be assigned to a C=O or C=N stretching vibration of the five-membered ring of D- or E-type entities of XXV, because no band is observed near 1700 cm^{-1} in other nitrosoazulenes.

Azulenes which possess a condensed imidazole ring fused to the C-1 and C-2 of the azulene nucleus have been synthesized.[6] The synthesis of the same type azulenes which possess an oxazole ring fused to C-1 and C-2 was attempted. XXV and XXIX were reduced over palladized charcoal in formic acid, providing ethyl 3-formamide-2-hydroxyazulene 1-carboxylate (XXX). However, the treatment of XXVIII and XXX in anhydrous formic acid and in acetic anhydride resulted in only the recovery of the starting substances and 3-diacetylamino-2-acetoxyazulene-1-carboxylate (XXXI) respectively. When the reactions were carried out with a small amount of concentrated sulfuric acid or under more drastic conditions, only tarry materials were formed. The treatment of XXXI with sodium hydroxide in alcohol regenerated XXVIII readily.

It is well known that the aromatic nitroso compounds afford azo-dyes and Shiff bases upon treatment with the corresponding amines and active methylene compounds respectively. The reaction of II with *p*-toluidine, *p*-nitroaniline, 2,4-dichloroaniline in benzene, pyridine or xylene resulted in the recovery of II under mild conditions; under more drastic conditions, only black, intractable, resinous substances were obtained. When the reaction was carried out in boiling aniline, red-violet needles were obtained. However, they were not identical with ethyl 2-amino-3-(phenylazo)azulene-1-carboxylate. The amount of this substances was insufficient for further investigation.

The treatment of II with diethyl malonate and malononitril gave diethyl 3(4*H*)-oxoazuleno[1,2-*b*]pyrazine-2,5-dicarboxylate (XXXII) and ethyl 2-cyano-3(4*H*)-oxoazuleno[1,2-*b*]pyrazine-5-carboxylate (XXXIII) respectively. They are hardly soluble in most organic solvents, and XXXIII could not be

Experimental[13]

Ethyl 2-Methylaminoazulene-1-carboxylate (XI). To a solution of 0.36 g of VII in 2 m*l* of dioxane, 0.50 g of 30% aqueous methylamine was added, and then the mixture was heated under reflux for 12 hr. The solvent was removed under reduced pressure, and the residue was dissolved in benzene. The benzene layer was washed with water, dried over sodium sulfate, filtered, and concentrated to give 0.365 g of a reddish-brown oil. The oil was chromatographed on alumina, and the cyclohexane eluate gave 50 mg of the recovered starting material, while the ether eluate gave 0.285 g of yellow needles of XI, mp 66—67°C. The recrystallisation of this from light petroleum raised its mp to 67.5—68°C; orange plates.

Found: C, 73.32; H, 6.52; N, 6.04%. Calcd for $C_{14}H_{15}O_2N$: C, 73.34; H, 6.59; N, 6.11%.

Ethyl 2-Diethylaminoazulene-1-carboxylate (XII). A solution of 0.80 g of VII and 0.83 g of 40% aqueous dimethylamine in 5 m*l* of alcohol was heated under reflux for 3 hr, and then the reaction mixture was treated as above. A brown oil, 0.835 g, was obtained and gave trinitrobenzoate (mp 159.5°C from alcohol) as reddish-brown needles.

13) All melting points are uncorrected.

Found: C, 55.79; H, 4.46; N, 11.89%. Calcd for $C_{21}H_{20}O_8N_4$: C, 55.26; H, 4.42; N, 12.28%.

Ethyl 2-Amino-6-bromoazulene-1-carboxylate (XIV). A solution of 0.427 g of diethyl 2-amino-6-bromoazulene-1,3-dicarboxylate[14] and 0.28 g of potassium hydroxide in 10 m*l* of alcohol was heated under reflux for 3 hr. The alcohol was then removed, and 8 m*l* of water was added to the reaction mixture to give 8.5 mg of the recovered starting material, which was separated by filtration. The water layer was acidified with N hydrochloric acid to form yellow precipitate. The separated precipitate was dried in a desiccator to give 0.38 g of a yellow-green powder. The powder was heated under reflux for 2.5 hr in 3 m*l* of pyridine and then concentrated. The residue was submitted to chromatography after having been dissolved in benzene, and then washed with water and dried over sodium sulfate. The benzene-ether (1: 1) eluate afforded 32 mg of 2-amino-6-bromoazulene, and the same mixed solvent (1: 4) gave 66 mg of brown micro needles of XIV, which did not show any clear melting point.

Found: C, 54.47; H, 3.80; N, 5.79%. Calcd for $C_{13}H_{12}O_2NBr$: C, 54.20; H, 3.48; N, 6.32%.

Ethyl 2-Acetoxyazulene-1-carboxylate (XVII). A solution of 0.454 g of XV in 3 m*l* of acetic anhydride was heated on a water bath for 5 min, and then the excess acetic anhydride was removed under reduced pressure to give 0.462 g of deep red needles of XVII, mp 62—63°C from alcohol.

Found: C, 69.50; H, 5.59%. Calcd for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46%.

Ethyl 2-Amino-3-nitrosoazulene-1-carboxylate (II). a) Into an ice-cold solution of 0.30 g of III in 9 m*l* of benzene, 0.216 g of IAN was stirred drop by drop; the solution was then allowed to stand overnight at room temperature. The solution was washed with water, dried over sodium sulfate, and concentrated to give 0.324 g of dark brown needles of II. The recrystallisation of crude II from benzene raised its mp to 177—178°C; brown needles.

Found: C, 63.61; H, 4.73; N, 11.25%. Calcd for $C_{13}H_{12}O_3N_2$: C, 63.92; H, 4.95; N, 11.47%.

When alcohol was used instead of benzene, the same results were obtained.

b) When benzene which had been saturated with dry hydrogen chloride or which contained a drop of conc. sulfuric acid was used and treated as above, 0.304 g of II was obtained from 0.30 g of III.

c) Into an ice-cold solution of 0.30 g of III in 10 m*l* of alcohol containning 0.4 m*l* of N hydrochloric acid, a solution of 0.22 g of sodium nitrite in 2 m*l* of water was stirred. After having been allowed to stand overnight at room temperature, the solution was neutralized with aqueous sodium bicarbonate, and then concentrated under reduced pressure to give a black residue, which failed to give a pure substance by means of column- or thinlayer-chromatography or other methods. When III was treated for a shorter period under the same conditions, the recovered III and some intractable gummy substances were obtained.

Ethyl 2-Methylamino-3-nitrosoazulene-1-carboxylate (XXII). By the same treatment as in the case of III, 50 mg of XI and 34 mg of IAN gave 59 mg of XXII as brown plates, mp 157°C from benzene.

14) T. Nozoe, S. Seto and S. Matsumura, This Bulletin, **35**, 1990 (1962).

Found: C, 65.47; H, 5.14; N, 10.45%. Calcd for $C_{14}H_{14}O_3N_2$: C, 65.10; H, 5.46; N, 10.85%.

Ethyl 2-Dimethylamino-3-nitrosoazulene-1-carboxylate (XXIII). From 0.30 g of XII and 0.30 g of IAN, 0.37 g of crude products was obtained; this was then submitted to chromatography. The benzene-ethyl acetate (1:1) eluate afforded 71 mg of the recovered substance, and the ethyl acetate eluate gave 0.193 g of a brown oil which did not give trinitrobenzolate, but a picrate as yellow-brown prism, mp 240—244°C from alcohol.

Found: N, 10.38%. Calcd for $C_{15}H_{16}O_3N_2$: N, 10.29%.

Found: C, 50.62; H, 4.07; N, 13.51%. Calcd for $C_{21}H_{19}O_{10}N_5$: C, 50.30; H, 3.82; N, 13.97%.

Ethyl 2-Hydroxy-3-nitrosoazulene-1-carboxylate (XXV). A solution of 0.60 g of XV in 18 m*l* of benzene and 0.36 g of IAN was treated as before. After the solution had been allowed overnight at room temperature, the formed precipitate was separated by filtration, and from the benzene layer a black powder was obtained. When the powder was recrystallized from benzene, acetone, or alcohol, this changed to an intractable gummy substance. The powder was washed with alcohol to give 0.522 g of XXV, mp 156°C (dec.).

Found: C, 61.85; H, 4.73; N, 5.27%. Calcd for $C_{13}H_{11}O_4N \cdot \frac{1}{2}H_2O$: C, 61.41; H, 4.76; N, 5.51%.

The ir spectrum of this shows a broad band at 3510 cm^{-1}.

Nitrosation of Other Azulenes. The other azulenes listed in Table 1 (V—XVII) were treated with IAN as above or with modified methods. However, the nitrosoazulenes formed were very unstable, and during the recrystallisation process they turned to intractable tarry or resinous substances. Some of them became resinified even when allowed to stand at room temperature or stored in an ice box. Therefore, the nitrosoazulenes obtained were washed with suitable organic solvents and submitted to analysis.

Reduction of II; Ethyl 2,3-Diacetylaminoazulene-1-carboxylate (IV). II (0.10 g) in 5 m*l* of acetic anhydride was reduced over 0.10 g of 10% palladised charcoal, and two equivalent moles of hydrogen was taken up. After the catalyst had been removed by filtration, the solution was concentrated and the residue was chromatographed on alumina. From the ethyl acetate eluate, pale violet crystals were obtained; the recrystallization of this from benzene afforded 43 mg of IV, mp 218—219°C, which failed to show any depression when mixed with an authentic sample of ethyl 2,3-diacetylaminoazulene-1-carboxylate.[6]

Ethyl 3-Acetylamino-2-hydroxyazulene-1-carboxylate (XXVIII). A solution of 0.12 g of XXV in 10 m*l* of acetic anhydride was treated as above over 0.12 g of 10% palladised charcoal. The residue obtained was recrystallized from alcohol to give 70 mg of XXVIII as reddish-brown micro needles, mp 220—220.5°C.

Found: C, 65.58; H, 5.62; N, 5.11%. Calcd for $C_{15}H_{15}O_4N$: C, 65.92; H, 5.53; N, 5.13%.

By the same method, 0.10 g of ethyl 3-(*p*-tolyl)azo-2-hydroxyazulene-1-carboxylate afforded 50 mg of XXVIII, and the mixed-melting-point measurement of XXVIII obtained from different starting substances did not show any depression.

Ethyl 3-(*p*-Tolyl)azo-2-hydroxyazulene-1-carboxylate (XXIX). A solution of 4.0 g of XV in 40 m*l* of pyridine was cooled in an ice bath, and into this *p*-tolyldiazonium chloride, prepared from 2.16 g *p*-toluidine in the usual way, was stirred drop by drop. After the mixture had been allowed to stand for a couple hours at room temperature, the precipitate formed was separated by filtration and recrystallized from alcohol to give 5.88 g of reddish-brown needles of XXIX, mp 146—147°C.

Found: C, 71.79; H, 5.64; N, 8.18%. Calcd for $C_{20}H_{18}O_3N_2$: C, 71.84; H, 5.43; N, 8.38%.

Ethyl 3-Formamide-2-hydroxyazulene-1-carboxylate (XXX). The catalytic reduction of 1.2 g of XXV over 0.20 g of 10% palladised charcoal in 15 m*l* of anhydrous formic acid caused the absorption of two moles of hydrogen. After the catalyst had been separated by filtration and the formic acid was removed, the residue was washed with water and dried in a desiccator; recrystallization from benzene then gave 1.05 g of reddish-brown micro needles of XXX, mp 187°C.

Found: C, 65.18; H, 5.34; N, 4.88%. Calcd for $C_{14}H_{13}O_4N$: C, 64.86; H, 5.05; N, 5.40%.

XXX was also obtained in a good yield by the catalytic reduction of XXIX in formic acid.

Cataltyic Reduction of Other Nitrosoazulenes. The catalytic reduction of XX,XXI, XXVI, and others over palladised charcoal was attempted. Although about two equivalent moles of hydrogen were taken up in every case, no pure substances could be obtained. Example: after reduction, 97 mg of brown powder were obtained from 0.15 g of crude XXVI and was submitted to chromatography. The benzene eluate was recrystallized from light petroleum-benzene to give 32 mg of a brown powder, mp 186°C, which did not give a correct analysis.

λ_{max}^{MeOH}, mμ; 238, 294, 305 and 275. IR in $CHCl_3$; 3450, 3000, 2950, 1680, 1430, 1370 and 1200 cm^{-1}.

Attempted Isooxazole-ring Formation. *a*) A solution of 0.10 g of XXX in 5 m*l* of anhydrous formic acid was heated under reflux for one hour; the formic acid was then removed under reduced pressure. The residue was washed with water and recrystallized from alcohol to give 85 mg of the recovered starting material. The addition of concentrated sulfuric acid or prolonged heating at an elevated temperature gave a black, intractable resinous substance.

b) Ethyl 3-Diacetylamine-2-acetoxyazulene-1-carboxylate (XXXI). A solution of 0.15 g of XXVIII in 10 m*l* of acetic anhydride was dissolved in benzene, washed with water, and dried over sodium sulfate, and the benzene was removed. The recrystallisation of the residue from alcohol-light petroleum afforded 0.14 g of pure XXXI as dark red prisms, mp 137.5—138.5°C.

Found: C, 63.41; H, 5.42; N, 3.88%. Calcd for $C_{19}H_{19}O_6N$: C, 63.86; H, 5.36; N, 3.92%.

Hydrolysis of XXXI. To a solution of 66 mg of XXXI in 2 m*l* of alcohol, 0.17 m*l* of N sodium hydroxide was added, and then the resulting solution was heated on a water bath for 2 hr. After the ethanol had been removed, water was added to the solution and the pH of the solution was adjusted to about 4 with N hydrochloric acid. The recrystallisation of the precipitate obtained above from alcohol gave 47 mg of micro needles, mp 219—220°C, which did not show any depression on admixture with the authentic sample of XXVIII.

Reaction of II with Aromatic Amines. A solution of 0.50 g of II in 10 m*l* of aniline was heated under

reflux for 2 hr, and then the excess aniline was removed under reduced pressure. The residue was dissolved in benzene, washed with water, dried over sodium sulfate, and chromatographed on alumina. The light petroleum eluate gave 88 mg of violet-brown needles, mp 232—234°C.

Found: C, 72.67; H, 5.49; N, 12.55%. λ_{max}^{MeOH}, mμ; 255, 320, 370 and 535; this is analogous to that of ethyl 2-amino-3-(phenylazo)azulene-1-carboxylate.

The condensation reactions of II with *p*-toluidine, *p*-nitroaniline, and 2,4-dichloroaniline in benzene, alcohol, xylene, or pyridine resulted in the recovery of II under milder conditions or in the formation of intractable tar under drastic conditions.

Ethyl 2-Amino-3-(phenylazo)azulene-1-carboxylate. Into a cold solution of 0.215 g of II in 5 m*l* of alcohol, 1 m*l* of phenyl diazonium chloride prepared from 0.15 g of aniline in an ordinary way was stirred drop by drop. The solution was then allowed to stand for 1 hr at room temperature. The precipitate formed was then separated by filtration and recrystallized from alcohol to give 0.275 g of violet needles, mp 136—137°C.

Found: N, 13.27%. Calcd for $C_{19}H_{17}O_2N_3$: N, 13.16%.

Diethyl 3(4*H*)-Oxoazuleno[1,2-*b*]pyrazine-2,5-dicarboxylate (XXXII). A solution of 0.25 g of II and 0.24 g of diethyl malonate in 3 m*l* of acetic anhydride was allowed to stand at room temperature for 4 hr with stirring, and then the excess acetic anhydride was removed under reduced pressure. The residue was dissolved in chloroform, washed with water, and dried over sodium sulfate; the concentration of the solution left a brown resinous substance which was submitted to chromatography. The ether - ethyl acetate (1 : 3) eluate afforded 28 mg of a violet-brown powder; the recrystallisation of this from light petroleum - benzene gave pale violet micro prisms of XXXII, mp 204—207°C.

Found: C, 62.43; H, 5.41; N, 8.09%. Calcd for $C_{18}H_{16}O_5N_2{\cdot}\frac{1}{2}H_2O$: C, 61.90; H, 4.90; N, 8.02%.

Ethyl 2-Cyano-3(4*H*)-oxoazuleno[1, 2-*b*]pyrazine-5-carboxylate (XXXIII). Into a solution of 0.25 g of II in 6 m*l* of anhydrous alcohol cooled in an ice bath, a solution prepared from 30 mg of sodium and 0.10 g of malononitril in 1 m*l* of anhydrous alcohol was stirred drop by drop; the reaction mixture was then stored in ice box overnight. The solvent was then removed under reduced pressure, and the residue was washed with water and dried in a desccator to give 0.16 g of a brown solid. The recrystallisation of this from methanol gave a dark violet powder of XXXIII, mp <250°C. Although the UV spectrum of XXXIII is very similar to that of XXXII, and although the IR spectrum of XXXIII agrees with the proposed structure (3300, 2180, 1670, 1600, 1540, 1470, 1440, 1430, 1255, 1110 and 860 cm^{-1}, KBr pellet), we failed to obtain analytically-pure substances.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2102—2111 (1968)

The Synthesis and Electrophilic and Nucleophilic Substitution Reactions of 6-Chloro-1-azaazulan-2-ones and 2,6-Dichloro-1-azaazulenes[1]

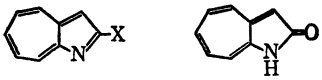
Takashi TODA, Shuichi SETO[2] and Tetsuo NOZOE

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received February 19, 1968)

6-Chloro-1-azaazulan-2-ones and 2,6-dichloro-1-azaazulenes have been synthesized from 2-amino-5-chlorotropone. By the investigation of their electrophilic and nucleophilic substitution reactions, it is proved that the electrophilic substitutions take place at the C-3 positions of those compounds, and that the nucleophilic substitutions occur at the C-6 positions and then at the C-2 positions. The tautomerism of 6-amino-2-chloro-1-azaazulene derivatives is discussed.

1-Azaazulenes and their 2-hydroxy derivatives (1-azaazulan-2-ones) are important and interesting substances not only as non-benzenoid analogues of indoles and isomers of quinolines, but also as heterocyclic azulene-type compounds. Several derivatives of 1-azaazulene (I) and 1-azaazulan-2-one (II) have been synthesized.[3-10] The electrophilic substitution reactions of those compounds[3a,8,10a] and the nucleophilic substitution reactions of 2-chloro-1-azaazulene (III)[3b,5b,7] have been investigated. However, 1-azaazulenes and those related compounds which possess functional groups other than alkyl groups in their seven-membered ring have not been known.[11] The purpose of the present paper is to synthesize 1-azaazulenes which possess halogen atoms in their five- and seven-membered rings, and to investigate the chemical properties of these synthesized 1-azaazulenes.



(I): X=H (II) (IV)
(III): X=Cl

It has long been known that abnormal substitutions take place during the nucleophilic reactions of halo-tropolones,[12] 2-halo-tropones,[13] and tropolone arylsulfonates,[14,15] and that abnormal ring formations occurd in the cases of azulenes,[4,15] 1-azaazulan-2-ones,[6] and 1-oxaazulan-2-one (IV) derivatives[14,15] obtained from 2-halo-tropones and tropolone arylsulfonates. Therefore, a method which is known to give a normal condensation product was employed: that is, the condensation reaction of 2-aminotropone derivatives with diethyl malonate.[6]

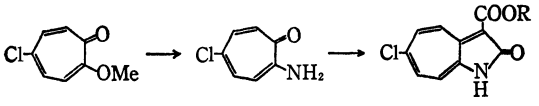
The Synthesis and Electrophilic Substitution Reactions of 6-Chloro-1-azaazulan-2-ones and 2,6-Dichloro-1-azaazulenes. 2-Amino-5-chlorotropone (V) was prepared by the action of liquid ammonia[16,17] on 5-chlorotropolone methyl ether (VI).[18] The reaction of V with diethyl malonate in the presence of sodium ethoxide afforded ethyl 6-chloro-1-azaazulan-2-on-3-carboxylate (VII) in *ca.* a 70% yield. The UV spectrum of VII is very similar to that of ethyl 1-azaazulan-2-on-3-carboxylate (VIII). The treatment of VII with aqueous alkali did not touch the chlorine atom, but gave a free carboxylic acid (VIIa).



(VI) (V) (VII): R=Et (VIIa): R=H

The hydrolysis of VII with concentrated hydrochloric acid also gave VIIa; the following decarboxylation reaction of VIIa in quinoline or collidine resulted in only tarry substances.

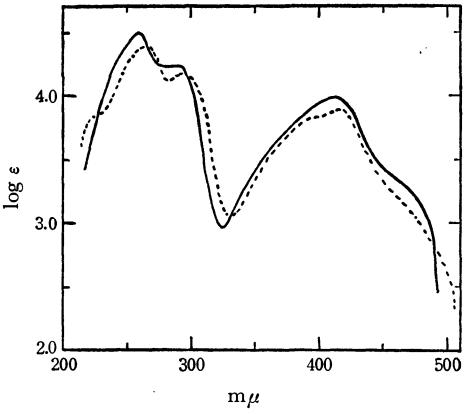


Fig. 1

—— II ---- IX

When VII was treated with concentrated hydrochloric acid in a sealed tube at about 130°C, 6-chloro-1-azaazulan-2-one (IX) was obtained by hydrolysis and by the decarboxylation of VII. On the other hand, the prolonged treatment of VII in concentrated hydrobromic acid under reflux afforded the 6-bromo derivative (X) with an exchange of halogen atoms, and the same treatment of X with concentrated hydrochloric acid gave back IX *vice versa.*

16) a) T. Nozoe, S. Seto, H. Takeda, S. Morosawa and K. Matsumoto, *Proc. Japan Acad.*, **27**, 556 (1951). b) *Sci. Repts. Tohoku Univ., Ser. I*, **36**, 126 (1952).

18) T. Sato, *Bulletin of the Chemical Research Institute of Non-Aqueous Solutions, Tohoku Univ.*, **8**, 47 (1959).

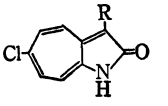
The catalytic reduction of IX and VIIa over palladized charcoal with alkali resulted in the formation of, respectively, the known 1-azaazulan-2-one (II)[3a] and its 3-carboxylic acid (VIIIa)[3a] in good yields. It is interesting and noteworthy to point out that 1-azaazulene and its derivatives, are readily reduced to give perhydro compounds by the catalytic reduction,[19] but not 1-azaazulan-2-one derivatives.

The electrophilic substitution reactions of 6-halo-1-azaazulan-2-ones were investigated.

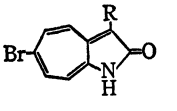
The bromination of IX in acetic acid afforded a monobromo compound (XI) in a good yield; this XI was also obtained from VIIa, with the evolution of carbon dioxide, by the same treatment. Since the bromination of 1-azaazulan-2-on-3-carboxylic acid (VIIIa) gave the 3-bromo-1-azaazulan-2-one,[3a] XI must be 3-bromo-6-chloro-1-azaazulan-2-one.

The nitration of IX and X in acetic acid with fuming nitric acid gave the corresponding nitro compounds (XII and XIII respectively). The reaction of X with *p*-tolyl diazonium chloride formed the 3-(*p*-tolyl)azo compound (XIV).

The catalytic reduction of XII and XIV over palladized charcoal gave the same 3-amino-6-chloro-1-azaazulan-2-one, which was very unstable and which could not be isolated in a free state, but which afforded a stable acetylamino derivative (XV) by the subsequent acetylation:



(IX): R=H
(XI): R=Br
(XII): R=NO_2
(XIV): R=*p*-tolylazo
(XV): R=NHAc



(X): R=H
(XIII): R=NO_2

The treatment of VII, VIIa, IX, X, and XI with acetic anhydride gave the respective corresponding acetates. The UV spectra of these acetates are similar to that of II,[3a] but not to that of I,[3b] and their IR spectra show two strong carbonyl bands, near 1720 and 1700 cm^{-1}. Therefore, they are *N*-acetyl derivatives of the original compounds. A careful examination, by means of chromatography and IR and UV spectroscopy, of the acetylation reaction mixtures and their mother layers after recrystallization did not show any evidence of the presence of *O*-acetyl derivatives.

Ethyl 2,6-dichloro-1-azaazulen-3-carboxylate (XVI) and 2,6-dichloro-1-azaazulene (XVII) were obtained by the treatment of VII and IX with phosphorus oxychloride, respectively. By the action of phosphorus tribromide, IX afforded 2,6-dibromo-1-azaazulene (XVIII), with an exchange of halogen atoms. The halogen atoms of XVII were

19) Unpublished observations made in the authors' laboratory.

exchanged by the treatment of hydrogen bromide in acetic acid to give XVIII, while, *vice versa*, those of XVIII were changed to XVII with the use of hydrogen chloride.

The bromination of XVII and XVIII in acetic acid proceeded readily and gave the corresponding trihalo derivatives (XIX and XX, respectively). XIX was also obtained by the bromination of 2,6-dichloro-1-azaazulen-3-carboxylic acid, which had been prepared from VIIa with phosphorus oxychloride. However, the rate of the bromination of 2,6-dichloro-1-azaazulen-3-carboxylic acid was not as fast as in the case of VIIa. The UV spectra of the obtained 2,6-dihalo-1-azaazulenes are similar to that of 2-chloro-1-azaazulene,[3b] as is shown in Fig. 2.

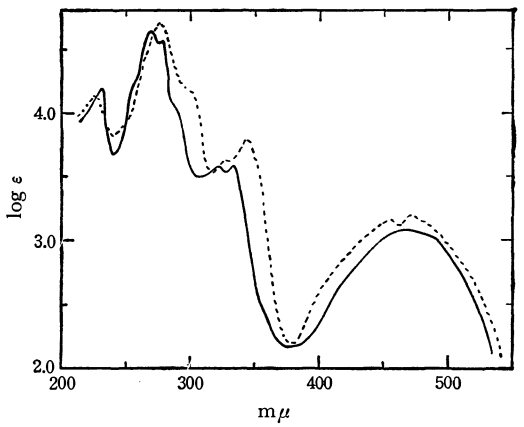


Fig. 2

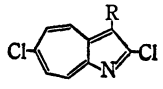
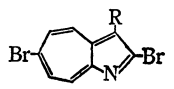
—— III ---- XVII

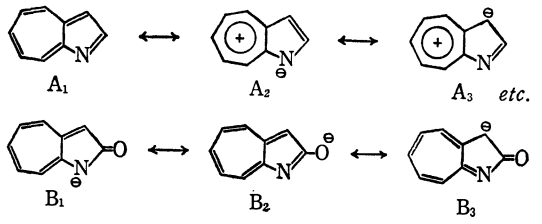




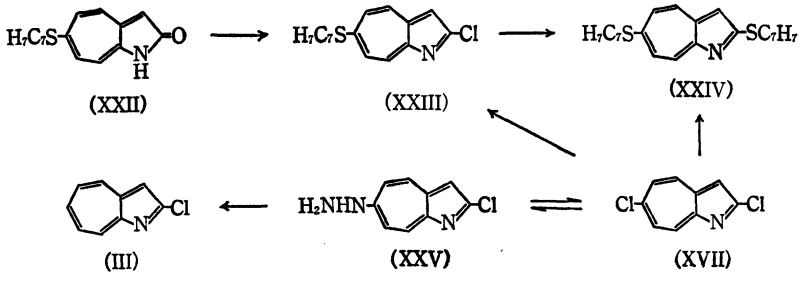
(XVI): R=COOEt (XVIII): R=H
(XVII): R=H (XX): R=Br
(XIX): R=Br
(XXI): R=COOH

The nitration and azo-coupling reactions of XVII resulted in the recovery of the starting substance.

The electron density of the 1-azaazulene nucleus is high at 1,3-positions because of the contributions of such resonance hybrids as A_1, A_2, and A_3.[3b,20] Therefore, the electrophilic substitution reactions take place easily at the C-3 position, especially if C-2 is replaced by an electron-donating group.[3] However, if an electronegative group is introduced into them, electrophilic substitution reactions might not be easy under milder conditions, such as azo-coupling, and/or under acidic conditions, such as nitration, because protonation occurs on the nitrogen atom (or the C-3 position), and this makes for a lower electron density of the 1-azaazulene nucleus. On the other hand, 1-azaazulan-2-one derivatives possess a hydrogen which can dissociate as a proton. Therefore, II forms an anion the canonical forms of which are such as B_1, B_2, B_3, *etc.*; electrophiles can readily attack the C-3 position of this type of anion, especially under basic conditions.



The Nucleophilic Substitution Reactions of 6-Chloro-1-azaazulan-2-one and 2,6-Dichloro-1-azaazulenes. The treatment of IX with excess aqueous potassium hydroxide, sodium methoxide, liquid ammonia, sodium cyanide, *p*-toluidine, *etc.* resulted in the recovery of the starting substance. With dimethylamine in methanol, IX afforded a very small amount of orange needles, but almost all of the IX was recovered. However, 6-(*p*-tolyl)thio-1-azaazulan-2-one (XXII) was obtained in a good yield when IX was treated with the sodium salt of *p*-thiocresol in methanol. The reaction of XXII with phosphorus oxychloride gave 2-chloro-6-(*p*-tolyl)thio-1-azaazulene (XXIII), which was also obtained from XVII with one equivalent mole of *p*-thiocresol. The further treatment of XXIII with *p*-thiocresol formed 2,6-di(*p*-tolyl)thio-1-azaazulene (XXIV), which was also obtained from XVII with an excess of *p*-thiocresol.

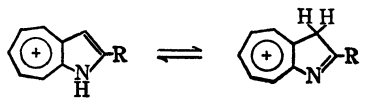


20) H. Kon, *Sci. Repts. Tohoku Univ., Ser. I*, **38**, 67 (1954).

The treatment of XVII with hydrazine hydrate in alcohol afforded a dark reddish-violet hydrazino compound (XXV) which was very unstable and which could not be isolated in a pure state. The decomposition reaction of this crude hydrazino compound with concentrated hydrochloric acid and cuprous sulfate, and with acetic acid and cuprous sulfate,[21,22] gave 2,6-dichloro-1-azaazulene, XVII, and 2-chloro-1-azaazulene, III, respectively. Therefore, the structure of XXV should be 2-chloro-6-hydrazino-1-azaazulene.

It has been predicted, on the basis of measurement of the dipole moment[23,24] and on the basis of theoretical considerations,[20,25] that the electron densities of azulenes and azaazulenes are lower in their seven-membered-ring part than in the five-membered-ring moiety. Thus, it was predicted that the nucleophilic substitution reactions of XVII would take place at the C-6 position first. The facts presented above prove this prediction from the point of view of the chemical reactivity of XVII.

On the other hand, 1-azaazulan-2-ones under the basic conditions are favoured to exist in their anion forms, such as B_1, B_2, *etc.*, as has been mentioned above. As a result of this, the nucleophilic substitution reactions of IX become difficult under the basic conditions. However, 1-azaazulenes and 1-azaazulan-2-ones can form tropyrium-type cations (C_1 and C_2) by protonation under acidic conditions. The nucleophiles readily attack such protonated species, such as in the halogen exchange reactions of IX and XVII described above. This is a phenomenon analogous to the halogen-exchange reaction of halo-tropones under acidic conditions.[26]



C_1 C_2

R=H or OH

The products obtained by the action of several nucleophilic reagents on XVII are shown in Table 1. The reaction of XVII with other nucleophiles than those listed in Table 1, such as sodium hydroxide, potassium cyanide, cuprous cyanide, and nitromethane, resulted in the recovery of the starting substance or did not give any clear-cut results.

* Two adjacent hydrogens in phenyl group.

After the substitution took place at C-6, no other substitution reaction occurred at C-2, even though excess reagents were used. Only a strong nucleophile such as the *p*-thiocresol anion[27] could afford the disubstituted product.

It has been shown that abnormal substitution reactions sometimes occur during the nucleophilic substitution reactions of troponoid compounds.[4,6,12-15] Therefore, the reactions described above might take place in such abnormal ways. To clarify this situation, the IR spectra of the nucleophilic substitution products were investigated. The fingerprint regions of the IR spectra of troponoid and azulenoid compounds show strong characteristic bands between 815—860 cm^{-1} and 770—820 cm^{-1} if they possess, respectively, two adjacent hydrogens and one hydrogen in their seven-membered ring.[28] The IR spectra of the 1-azaazulenes in Table 1 and of the 1-azaazulan-2-one derivatives in Table 2 show strong absorption bands between 815—850 cm^{-1}, but not between 770—820 cm^{-1} nor between 850—900 cm^{-1}. Thus, it is proved that the nucleophilic substitution reactions of XVII take place at the C-6 position in the normal way.

The IR spectrum of 6-amino-2-chloro-1-azaazulene (XXVIII) shows strong absorption bands at 1660 and 1602 cm^{-1} and bands at 3350, 3175, and 1585 cm^{-1} of a medium intensity. On the other hand, the 6-methylamino derivative (XXIX) possesses a strong band at 1598 cm^{-1} and medium bands at 3025, 1547 and 1502 cm^{-1}, while 6-dimethylamino compound (XXX) shows strong band at 1599 cm^{-1} and medium bands at 1588 and 1500 cm^{-1}. The assignment of these bands is rather difficult, because usually NH stretching appears between 3100—3500 cm^{-1}, NH deformation shows bands between 1550—1640 cm^{-1}, and the skeletal vibrations of aromatic compounds are between 1650—1480 cm^{-1}.[29] If the band of XXVIII at 1660 cm^{-1} is due to the imino C=N stretching, XXVIII has two tautomeric forms, such as D_1 and D_2. However, the UV spectra of XXVIII, XXIX

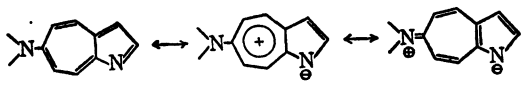
and XXX are very similar to each other, and XXX can not take the type-D_2 tautomeric form. Therefore, it is difficult to decide toward which form the equilibria of these compounds tend. Also, the UV and IR spectra were measured in very different states; the UV spectra were measured in highly-diluted solutions, and the IR spectra, in solid states. Therefore, the tautomeric forms may be different in the different states. As a rational explanation of those phenomena, the contribution of zwitter-ion structures, such as E_1 and E_2, to these three compounds is suggested. This would explain why the UV spectra of those three compounds, and also their IR spectra, show analogous figures.



E_1 E_2 *etc.*

Wheland has proposed the contributions of such zwitter-ion structures to 2-hydroxy- and 4-hydroxy-pyrimidines;[30] Tsubomura also pointed out the contributions of the same type of zwitter-ion structures to hydroxy- and amino-pyrimidines on the basis of a consideration of their IR and UV spectra.[31]

Experimental[32]

2-Amino-5-chlorotropone (V). In an ice-cold, sealed tube, 9.0 g of VI[18] were placed, and to this *ca.* 50 m*l* of liquid ammonia were introduced; then this mixture was allowed to stand at room temperature for 4 days. After the ammonia had then been removed, the residue was recrystallized from benzene-methanol to give 7.7 g of V, mp 157—159°C; further recrystallization from the same mixed solvents raised its mp to 159—159.5°C.

Found: C, 53.89; H, 3.45; N, 9.12%. Calcd for C_7H_6ONCl: C, 54.04; H, 3.89; N, 9.00%.

Ethyl 6-Chloro-1-azaazulan-2-on-3-carboxylate (VII). A mixture of 0.95 g of V in 5.0 m*l* of absolute alcohol and a solution of 3 m*l* of alcohol containing 0.3 g of sodium and 1.95 g of diethyl malonate in a sealed tube was heated at 100°C for 5 hr. After cooling, the alcohol was removed under reduced pressure, and water was added to the residue. The pH of the water layer was adjusted to *ca.* 4.5 with 1 N sulfuric acid, and then the precipitate formed was separated by filtration and dried in a desiccator. The recrystallization of the precipitate from ethyl acetate-alcohol gave 1.15 g of orange needles of VII; mp 227.5—228°C.

Found: C, 53.35; H, 4.52; N, 5.54%. Calcd for $C_{12}H_{10}O_3NCl \cdot H_2O$: C, 53.15; H, 4.79; N, 5.54%. λ_{max}^{MeOH} mμ (log ε); 225 (4.19), 283 (4.39) and 430 (4.18).

The mother layer of the recrystallization was chromatographed on alumina to give a further 0.12 g of VII, and 80 mg of V was recovered by the elution of the ethyl acetate.

31) H. Tsubomura, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan Pure Chem. Sect.*), **78**, 1528 (1957).
32) All melting points are uncorrected.

***N*-Acetate of VII.** A solution of 40 mg of VII in 0.5 m*l* of acetic anhydride was heated for reflux for 3 hr; then, after cooling, the precipitate formed was recrystallized from benzene-cyclohexane to give 40 mg of orange-yellow micro needles of the *N*-acetate of VII, mp 181°C.

Found: N, 5.13%. Calcd for $C_{14}H_{12}O_4NCl$; N, 4.77%. IR ($CHCl_3$); 1720 and 1705 cm^{-1}.

6-Chloro-1-azaazulan-2-on-3-carboxylic Acid (VIIa). A mixture of 0.25 g of VII, 1.0 g of pottassium hydroxide, 7 m*l* of water, and 20 m*l* of methanol was heated on a water bath for 2 hr. When the VII had dissolved completely, the pH of the solution was adjusted with 1 N sulfuric acid to *ca.* 3 to give the precipitate. The precipitate was separated by filtration, washed with water, and dried in a desiccator to give 0.21 g of yellow micro needles of VIIa. Recrystallization from alcohol afforded pure VIIa, mp 231—232°C (decomposed). The mother layer of the hydrolysis did not give any precipitate upon the addition of silver nitrate after the solution had been made acidic with nitric acid.

Found: C, 53.60; H, 2.72; N, 6.67%. Calcd for $C_{10}H_6O_3NCl$: C, 53.68; H, 2.70; N, 6.26%.

The *N*-acetate of VIIa was prepared by the same method as was used for the *N*-acetate of VII; yellow needles, mp 205—206°C (blacken).

Found: N, 5.31%. Calcd for $C_{12}H_8O_4NCl$: N, 5.27%. IR (KBr pellet); 1702 and 1685 cm^{-1}.

The Decarboxylated Bromination. a) *Bromination of 1-Azaazulan-2-on-3-carboxylic Acid.* The carboxylic acid (50 mg) was suspended in 1 m*l* of acetic acid and to this 50 mg of bromine was added. The acid was dissolved while carbon dioxide evolved, and the precipitate was formed after a while. The precipitate was then recrystallized twice from methanol to give 50 mg of orange needles mp 210—211°C which were found to be identical with 3-bromo-1-azaazulan-2-one by mixed-melting-point measurements.

b) *Bromination of VIIa.* VIIa (0.10 g) was treated with 80 mg of bromine in 2 m*l* of acetic acid as above to give 0.10 g of XI; orange silky needles from alcohol, mp 243—243.5°C.

Found: N, 5.62%. Calcd for $C_9H_5ONBrCl$: N, 5.41%.

N-Acetate of XI: orange-red needles, mp 190—191°C, from alcohol.

Found: N, 4.57%. Calcd for $C_{11}H_7O_2NBrCl$: N, 4.66%. IR ($CHCl_3$); 1723 and 1708 cm^{-1}.

6-Chloro-1-azaazulan-2-one (IX). A mixture of VII (0.80 g) and 8 m*l* of concentrated hydrochloric acid in a sealed tube was heated for 5 hr at 130°C. The hydrochloric acid was removed under reduced pressure, and then the residue was treated with aqueous bicarbonate to adjust its pH to *ca.* 8, washed with water, and dried in a desiccator. The precipitate was recrystallized from methanol to give yellow prisms of IX, mp 232—233°C; yield, 0.48 g.

Found: C, 59.79; H, 3.52; N, 7.49%. Calcd for C_9H_6ONCl: C, 60.19; H, 3.37; N, 7.79%. λ_{max}^{MeOH} mμ (log ε); 262 (4.38), 293 (4.15) and 410 (3.86).

N-Acetate of IX; yellow silky needles from ethyl acetate, mp 228—229°C.

Found: N, 6.42%. Calcd for $C_{11}H_8O_2NCl$: N, 6.32%. IR ($CHCl_3$); 1722 and 1705 cm^{-1}.

The Catalytic Reduction of VIIa and IX. a) In a solution of 50 mg of VIIa in 2 m*l* of 2 N sodium

hydroxide, 10 mg of 5% palladium on charcoal were suspended, and then the reduction was carried out in the usual way. The catalyst was removed by filtration, and the solution was acidified with 1 N sulfuric acid to give a yellow precipitate, the recrystallization of which from alcohol afforded yellow needles of VIIIa, mp 204°C (decompose); yield, 30 mg.

Found: N, 7.05%. Calcd for $C_{10}H_7O_3N$: N, 7.41%.

b) A solution of 0.10 g of IX and 50 mg of sodium acetate in 50 m*l* of methanol was reduced by means of palladised charcoal as above to give 60 mg of orange needles, mp 164—165°C after recrystallization from ethyl acetate; this melting point was identical with that of an authentic sample of II.[3a]

3-Bromo-6-chloro-1-azaazulan-2-one (XI). A solution of 0.10 g of IX in 2 m*l* of acetic acid was treated with 90 mg of bromine and then allowed to stand overnight at room temperature. After the acetic acid had been removed, the residue was washed with aqueous sodium bicarbonate and water, and recrystallized from alcohol to give orange silky needles of XI, mp 245°C; yield, 0.12 g. This was identical with the product of the decarboxylated bromination of VIIa.

Found: C, 41.47; H, 2.19; N, 5.75%. Calcd for $C_9H_5ONBrCl$: C, 41.81; H, 1.95; N, 5.41%.

6-Chloro-3-nitro-1-azaazulan-2-one (XII). To a solution of 0.20 g of IX in 5 m*l* of acetic acid, 0.3 m*l* of fumed nitric acid was added, and then the mixture was allowed to stand overnight at room temperature. The precipitate which formed was separated by filtration, washed with water and alcohol, and then recrystallized from a large amount of alcohol-dioxane to give greenish-brown scales of XII, mp >300°C; yield, 0.18 g.

Found: C, 47.53; H, 1.99; N, 12.20%. Calcd for $C_9H_5O_3N_2Cl$: C, 47.68; H, 2.24; N, 12.47%.

6-Chloro-3-(*p*-tolyl)azo-1-azaazulan-2-one (XIV). Into a solution of 0.10 g of IX in 5 m*l* of 50% of dioxane which had been cooled in an ice bath, *p*-toluene diazonium chloride prepared from 60 mg of *p*-toluidine in the ordinary way was added, drop by drop; the pH of the solution was then adjusted to *ca.* 8.5 with 5% aqueous sodium carbonate, after which the solution was allowed to stand overnight at room temperature. The precipitate formed was separated by filtration, washed with water, and dried in a desiccator to give 0.15 g of a red-purple powder. However, the purification of this powder by means of recrystallization or chromatography failed to produce an analytically-pure substance. The UV spectrum of this shows a figure analogous to that of 3-(*p*-tolyl)azo-1-azaazulan-2-one,[3a] but it shift to a longer wavelength. λ_{max}^{MeOH} mμ (log ε); 247 (4.21), 277 (4.22), 322 (4.13) and 480 (4.16).

3-Acetylamino-6-chloro-1-azaazulan-2-one (XV). a) *The Reduction of XII.* A suspension of XII in 100 m*l* of alcohol was reduced over 10 mg of 5% palladized charcoal in the usual way. The XII dissolved gradually. After 3 mol of hydrogen had been taken up, the catalyst was removed by filtration and the alcohol was concentrated. The residue turned to a black, resinous substances upon concentration. Acetic anhydride (2 m*l*) was added to the residue and the mixture was heated on a water bath. After the acetic anhydride had been removed under reduced pressure, the residue was recrystallized from acetone-methanol to give orange micro needles of XV; mp 276—277°C; yield, 40 mg.

Found: C, 55.57; H, 3.95; H, 11.51%. Calcd for $C_{11}H_9O_2N_2Cl$: C, 55.82; H, 3.83; N, 11.84%.

b) The Reduction of XIV. From 0.10 g of XIV, 40 mg of XV were obtained by the same procedure.

6-Bromo-1-azaazulan-2-one (X). In a sealed tube, 0.10 g of IX and 2 m*l* of acetic acid which had been saturated with dry hydrogen bromide were heated for 6 hr at 100°C. The acetic acid and hydrogen bromide were removed, and then the obtained residue was washed with aqueous sodium bicarbonate and water, and dried in a desiccator. The recrystallization of this solid from methanol gave 0.11 g of orange needles of X, mp 211—212°C. The mixed melting point of X with IX was 224—226°C.

Found: C, 48.59; H, 2.51; N, 6.59%. Calcd for C_9H_6ONBr: C, 48.24; H, 2.69; N, 6.25%.

By the same treatment of X in acetic acid saturated with hydrogen chloride, IX was obtained, mp 232°C. Found: N, 7.91%.

N-Acetate of X; mp 204—205°C. IR ($CHCl_3$); 1720 and 1700 cm^{-1}.

Found: N, 4.82%. Calcd for $C_{11}H_8O_2NBr$: N, 5.21%.

6-Bromo-3-nitro-1-azaazulan-2-one (XIII). By the same treatment as in the nitration of IX, 0.10 g of X afforded 80 mg of pale-greenish-brown leaflets of XIII, mp >300°C, from a large amount of dioxane.

Found: C, 40.58; H, 2.01; N, 10.96%. Calcd for $C_9H_5O_3N_2Br$: C, 40.17; H. 1.87; N, 10.41%.

Ethyl 2,6-Dichloro-1-azaazulen-3-carboxylate (XVI). In a sealed tube, 0.10 g of VII and 1.0 m*l* of phosphorus oxychloride were heated at 100°C for 3 hr, and then the phosphorus oxychloride was removed under reduced pressure. The residue was poured into crushed ice, and the pH of the water layer was adjusted to *ca.* 8.5 with sodium bicarbonate. The precipitate formed was separated by filtration, dried in a desiccator, and recrystallized from benzene to give 90 mg of yellow needles of XVI, mp 185—186°C.

Found: C, 53.05; H, 3.69; N, 5.51%. Calcd for $C_{12}H_9O_2NCl_2$: C, 53.36; H, 3.36; N, 5.19%.

2,6-Dichloro-1-azaazulene (XVII). a) From 8.0 g of IX and 50 m*l* of phosphorus oxychloride treated as above, 7.0 g of orange red needles of XVII were obtained; mp 183°C from cyclohexane. The second crop was 0.8 g, mp 177°C.

Found: C, 53.50; H, 2,87; N, 6.91%. Calcd for $C_9H_5NCl_2$: C, 53.56; H, 2.54; N, 7.07%. λ_{max}^{MeOH} mμ (log ε); 228 (4.16), 275 (4.71), 342 (3.84), 456 (3.19) and 464 (3.20).

b) By the same treatment of 0.10 g of X with 1 m*l* of phosphorus oxychloride, 0.10 g of IX was obtained. Found: N, 7.25%.

c) XVIII (0.10 g) was treated with 5 m*l* of acetic acid, which had been saturated with hydrogen chloride, for 5 hr at 140°C in a sealed tube. After cooling, the product was treated as above to give 80 mg of XVII, mp 181—182°C. Found: N, 7.11%.

2,6-Dichloro-1-azaazulen-3-carboxylic Acid (XXI). VIIa (0.20 g) in 1 m*l* of phosphorus oxychloride was treated as above, and then the pH of the water layer was adjusted to *ca.* 5 with sodium bicarbonate. The precipitate formed and the water-layer extracts obtained by means of benzene were combined, washed with water, and recrystallized from benzene to give 0.10 g of yellow needles of XXI, which did not have

a clear melting point.

Found: C, 49.20; H, 1.88; N, 5.63%. Calcd for $C_{10}H_5O_2NCl_2$: C, 49.64; H, 2.09; N, 5.79%.

2,6-Dibromo-1-azaazulene (XVIII). a) In a sealed tube, 0.10 g of IX and 1 m*l* of phosphorus tribromide were heated at 150°C for 3 hr; after cooling, the reaction mixture was treated as in the case of XVII. The crude XVIII was chromatographed on alumina, and the benzene eluate was recrystallized from benzene-cyclohexane to give orange-red needles of XVIII, mp 202—204°C; yield, 0.10 g.

Found: C, 37.61; H, 2.12; N, 5.24%. Calcd for $C_9H_5NBr_2$: C, 37.66; H, 1.76; N, 4.88%. λ_{max}^{MeOH} mμ (log ε); 230 (4.07), 280 (4.67), 331 (3.83), 347 (3.93) and 466 (3.23).

b) XVII (0.10 g) was heated in 5 ml of acetic acid which had been saturated with hydrogen bromide, for 5 hr at 140°C, and then treated as above to give 0.12 g of XVIII, mp 202.5—203.5°C. Found: N, 5.02%.

3-Bromo-2,6-dichloro-1-azaazulene (XIX). a) A solution of 50 mg of XXI in 1 m*l* of acetic acid was treated with 40 mg of bromine at room temperature. This oily substance formed gradually solidified. The reaction mixture was then allowed to stand for 3 hr, the acetic acid was removed under reduced pressure, and the pH of the residue was adjusted to *ca.* 8.5 with aqueous sodium bicarbonate. The precipitate which formed was then washed with water and dried in a desiccator, and the benzene solution of this was chromatographed on alumina. The benzene eluate was recrystallized from benzene to give 40 mg of reddish-carmine needles of XIX, mp 208—209°C.

Found: C, 39.14; H, 1.55; N, 5.58%. Calcd for $C_9H_4NBrCl_2$: C, 39.03; H, 1.45; N, 5.06%.

b) When 60 mg of XVII in 1 m*l* of chloroform were treated with 50 mg of bromine, the reaction proceeded exothermically and the precipitate formed immediately. The precipitate was then treated as above to give 80 mg of XIX, mp 208—209°C.

2,3,6-Tribromo-1-azaazulene (XX). To a mixture of 20 mg of XVIII and 5 mg of sodium carbonate in 2 m*l* of chloroform, 10 mg of bromine were added; the mixture was then allowed to stand at room temperature for 5 hr. The chloroform was removed, and the residue was washed with water, dried in a desiccator, and recrystallized from benzene - light petroleum to give 25 mg of reddish-carmine needles of XX, mp 215—216°C.

Found: C, 29.98; H, 0.86; N, 4.16%. Calcd for $C_9H_4NBr_3$: C, 29.54; H, 1.10; N, 3.83%.

An Attempted Nitration of XVII. To a solution of 50 mg of XVII in 1 m*l* of acetic acid, 0.2 m*l* of fumed nitric acid was added, after which the mixture was allowed to stand at room temperature overnight. After the acetic acid had then been removed under reduced pressure, the pH of the residue was adjusted to *ca.* 8 with aqueous sodium bicarbonate and the precipitate thus formed was washed with water and dried. The recrystallization of the residue from cyclohexane gave 40 mg of red needles, mp 180—182°C, which did not show any depression when the needles were mixed with the starting substance. The second crop was 5 mg. When the reaction mixture was heated on a water bath, no crystalline substances were obtained, and in concentrated sulfuric acid instead of acetic acid, the starting substance was recovered.

An Attempted Azocoupling Reaction of XVII. XVII (50 mg) was treated with 50 mg of diazotized toluidine in the ordinary way and then allowed to stand in a refrigerator overnight. The precipitate thus formed was then extracted with benzene, and the benzene layer was washed with water, dried over sodium sulfate, and chromatographed on alumina. The benzene eluate was recrystallized from cyclohexane to give 40 mg of orange-red needles, mp 182—183°C, which did not show any depression when the needles were mixed with the starting substance.

The Reaction of XVII with Hydrazine and the Decomposition of 2-Chloro-6-hydrazino-1-aza-azulene. a) A solution of 0.20 g of XVII and 80 mg of hydrazine hydrate in 2 m*l* of alcohol was warmed on a water bath for 30 min. The color of the solution changed from orange to dark orange, and then gradually to dark red. The alcohol was removed under reduced pressure and extracted with ethyl acetate. The ethyl acetate extracts were washed with water and dried over sodium sulfate, and the ethyl acetate was removed under reduced pressure to give 0.16 g of a red-violet powder, which decomposed *ca.* 210°C. The powder was unstable and could not be obtained in a pure state because when it was heated in a solvent the color of the powder changed and gave tarry substances.

A solution of 0.14 g of the crude XXV in 2 m*l* of acetic acid was poured all at once into a boiling solution of 0.70 g of cuprous sulfate in 2 m*l* of water. After cooling, the pH of the solution was adjusted to *ca.* 8 with sodium bicarbonate, and the solution was extracted with benzene; the combined benzene extracts were then dried over sodium sulfate and chromatographed on alumina. The benzene eluate was recrystallized from cyclohexane to give 50 mg of orange needles, mp 72°C, which did not show any depression when the needles were mixed with 2-chloro-1-azaazulene (III); the UV spectrum of the product was identical with that of III.

b) Freshly-prepared XXV (80 mg) was dissolved in 2 m*l* of concentrated hydrochloric acid, after which the solution was poured into a boiling solution of 0.60 g of cuprous sulfate in 2 m*l* of water. After cooling, the solution was treadted as above; 20 mg of orange needles were obtained; the mp of 182°C, did not show any depression when the needles were mixed with XVII.

6-(*p*-Tolyl)thio-1-azaazulan-2-one (XXII). IX (0.18 g) was added to a solution prepared from 0.20 g of *p*-thiocresol and 0.10 g of sodium methoxide in 10 m*l* of absolute methanol, and the mixture was heated in a sealed tube for 2 hr at 100°C. The methanol was then removed under reduced pressure, and the precipitate formed was washed with water, dried in a desiccator, and recrystallized from ether-alcohol to give brownish-red prisms of XXII, mp 220—220.5°C; yield, 0.23 g.

Found: C, 71.58; H, 5.36; N, 5.49%. Calcd for $C_{16}H_{13}ONS$: C, 71.90; H, 4.90; N, 5.24%. λ_{max}^{MeOH} mμ (log ε); 221 (4.31), 261 (4.50), 329 (4.21) and 416 (4.19).

2-Chloro-6-(*p*-tolyl)thio-1-azaazulene (XXIII). a) In a sealed tube, 80 mg of XXII in 1 m*l* of phosphorus oxychloride were heated for one hour. After the reaction, the product was treated as the ordinary way. The crude substances thus obtained were recrystallised from cyclohexane-benzene to give 70 mg of orange needles of XXIII, mp 128—129°C.

Found: C, 67.55; H, 4.01; N, 5.33%. Calcd for

$C_{16}H_{12}NSCl$: C, 67.25; H, 4.23; N, 4.90%.

b) To a solution of 60 mg of *p*-thiocresol and 30 mg of sodium methoxide in 5 m*l* of absolute methanol, 0.10 g of XVII was added, and then the mixture was heated under reflux for 15 min. The solution was concentrated under reduced pressure and extracted with benzene, and the benzene extracts were washed with water, dried with water, dried over sodium sulfate, and chromatographed on alumina. The benzene eluate was then recrystallized from cyclohexane-benzene to give orange prisms of XXIII, mp 127.5—129°C; yield, 0.12 g.

2,6-Di(*p*-tolylthio)-1-azaazulene (XXIV). a) A solution of 0.10 g of XVII in 3 m*l* of absolute methanol containing 0.14 g of *p*-thiocresol and 60 mg of sodium methoxide was heated under reflux for 15 min; after reaction, this mixture was treated as above. Orange prisms of XXIV were obtained, mp 189—190°C, yield, 0.16 g.

Found: C, 73.91; H, 5.21; N, 3.91%. Calcd for $C_{23}H_{19}NS_2$: C, 73.88; H, 5.13; N, 3.75%.

b) To a solution of 50 mg of *p*-thiocresol and 20 mg of sodium methoxide in 2 m*l* of absolute methanol, 0.10 g of XXIII was added; the mixture was heated under reflux for 20 min and then treated as above to give 0.12 g of orange prisms mp 189—190°C, which did not show any depression when the prisms were mixed with the XXIV obtained above.

2-Chloro-6-methoxy-1-azaazulene (XXVI). In 2 m*l* of absolute methanol containing 30 mg of sodium, 0.10 g of XVII was heated under reflux for 30 min; after cooling, the methanol was removed under reduced pressure. The precipitate thus formed was washed with water, dried in a desiccator, and recrystallized from benzene-cyclohexane to give 80 mg of yellow needles of XXVI, mp 103—104°C.

Found: C, 61.55; H, 4.29; N, 7.37%. Calcd for $C_{10}H_8ONCl$: C, 61.56; H, 4.16; N, 7.23%. Picrate, mp 206°C. Found: N, 13.18%. Calcd for $C_{16}H_{11}O_8N_4Cl$: N, 13.25%.

2-Chloro-6-ethoxy-1-azaazulene (XXVII). XVII (0.10 g) was treated as above in 2 m*l* of absolute alcohol, containing 30 mg of sodium, to give 0.10 g of yellow needles of XXVII, mp 117—118°C, from benzene-light petroleum.

Found: N, 6.97%. Calcd for $C_{11}H_{10}ONCl$: N, 6.75%.

The Reaction of XVII with Aqueous Alkali. To a solution of 60 mg of potassium hydroxide in 1 m*l* of water, 0.20 g of XVII was added, and the mixture was heated under reflux for 2 hr. The solvent was then removed, and the residue was washed with water and dried in a desiccator to give 0.18 g of yellow needles, mp 179—181°C, which did not show any depression when the needles were mixed with the original XVII. The silver nitrate test of the aqueous layer of the reaction mixture was negative.

The Reaction of XVII with Ammonia. *a) In Methanol.* A solution of 0.10 g of XVII in 15 m*l* of methanol was saturated with ammonia gas at 0°C and then allowed to stand at room temperature for 2 days. After the solvent and ammonia had been removed, the residue was extracted with benzene and chromatographed on alumina. The benzene eluate afforded 50 mg of yellow needles, mp 181—183°C, which did not show any depression when the needles were mixed with XVII.

The ethyl acetate eluate afforded 20 mg of yellow needles, mp 102°C, which did not show any depression when the needles were mixed with XXVI.

b) XVII (0.70 g) was dissolved in 50 m*l* of liquid ammonia which had been cooled in a sodium chloride-ice bath, and then the mixture was allowed to stand at room temperature for 4 days. After the ammonia had been removed the residue was washed with water, dried in a desiccator, and fractionally-recrystallized from benzene and acetone. From the benzene-soluble part, 0.15 g of XVII was recovered, and from the acetone-soluble part, 0.35 g of orange brown prisms of XXVIII, mp 218—220°C, was obtained.

Found: C, 54.60; H, 4.69; N, 13.83%. Calcd for $C_9H_7N_2Cl \cdot H_2O$: C, 54.97; H, 4.61; N, 14.25%.

2-Chloro-6-methylamino-1-azaazulene (XXIX). A solution of 0.10 g of XVII, 70 mg of methylamine hydrochloride, and 50 mg of sodium carbonate in 2 m*l* of methanol was heated in a sealed tube at 100°C for one hr, and then the methanol was removed. The residue was washed with water and recrystallized from acetone-methanol to give 70 mg of yellow-brown micro prisms of XXIX, mp 224—225°C.

Found: C, 62.05; H, 4.38; N, 14.11%. Calcd for $C_9H_7N_2Cl$: C, 62.34; H, 4.71; N, 14.54%.

2-Chloro-6-dimethylamino-1-azaazulene (XXX). A solution of 0.20 g of XVII and 0.5 m*l* of 40% of aqueous dimethylamine in 4 m*l* of methanol was heated under reflux for one hour, and then treated as above to give 0.19 g of pale brown XXX, mp 158—162°C. Recrystallization from benzene raised its mp to 194—195°C; yellow brown scales; yield, 0.16 g.

Found: C, 64.15; H, 5.32; N, 13.43%. Calcd for $C_{11}H_{11}N_2Cl$: C, 63.89; H, 5.36, N, 13.56%.

2-Chloro-6-ethylthio-1-azaazulene (XXXI). A solution of 0.10 g of XVII, 60 mg of sodium methoxide, and 70 mg of ethyl mercaptan in 2 m*l* of absolute methanol was heated under reflux for 15 min, and then the methanol was removed. The residue was dissolved in benzene, washed with water, dried over sodium sulfate, and chromatographed on alumina. The benzene eluate gave 90 mg of orange prisms of XXXI, mp 94°C, from benzene.

Found: C, 58.73; H, 4.46; N, 6.46%. Calcd for $C_{11}H_{10}NSCl$: C, 59.05; H, 4.51; N, 6.26%.

2-Chloro-6-nitro-1-azaazulene (XXXII). A solution of 0.10 g of XVII and 70 mg of sodium nitrite in 3 m*l* of methanol was heated under reflux for 2 hr, concentrated, and extracted with ethyl acetate. The combined ethyl acetate extracts were washed with water, dried over sodium sulfate, and chromatographed on alumina. The ethyl acetate eluate was then recrystallized from the same solvent to give silky, reddish-violet needles of XXXII, mp 220°C (decomp.); yield, 60 mg.

Found: C, 51.37; H, 2.57; N, 12.86%. Calcd for $C_9H_5O_2N_2Cl$: C, 51.82; H, 2.42; N, 13.43%.

Diethyl (2-Chloro-1-azaazulen-6-yl)malonate (XXXIII). To a solution of 50 mg of sodium in 3 m*l* of diethyl malonate, 0.20 g of XVII was added; the mixture was heated at 50°C for one hour, and then the diethyl malonate was removed under reduced pressure. The residue was poured into crushed ice, and the pH of the solution was adjusted to *ca.* 8 by the addition of acetic acid; this giving a precipitate. The precipitate was separated by filtration, washed with water, dried in a desiccator, and extracted with benzene. The benzene

extracts gave 20 mg of the starting substances. The benzene-insoluble solid was dissolved to ethyl acetate and chromatographed on alumina. The ethyl acetate eluate gave a resinous substance. The repeated recrystallization of this from ethyl acetate gave brown micro needles, mp 255°C (decomp. and gradually blacken about 220°C); yield, 40 mg.

Found: N, 3.97%. Calcd for $C_{16}H_{16}O_4NCl$: N, 4.35%.

When the reaction was carried out at room temperature, 90% of XVII was recovered, and the treatment of XVII in absolute methanol with diethyl malonate and sodium methoxide under reflux resulted in a 15% recovery of the XVII, a 20% recovery of the XXVI, and some intractable tar.

Ethyl 1-Cyano-1-(2-chloro-1-azaazulen-6-yl)acetate (XXXIV). To a solution which had been prepared from 0.24 g of ethyl cyanoacetate and 50 mg of sodium in 5 m*l* of benzene, 0.20 g of XVII was added, after which the mixture was heated at 70°C for 5 hr. After cooling, the reaction mixture was poured into crushed ice, and the pH of the water layer was adjusted to *ca.* 6.5 with acetic acid. The reaction mixture was then separated into a benzene-soluble part and an insoluble precipitate. The benzene layer afforded 0.10 g of the recovered XVII after concentration. The precipitate (0.10 g) was dissolved in ethyl acetate - alcohol (10: 1) and chromatographed on alumina three times. The recrystallization of the ethyl acetate - alcohol eluate gave 40 mg of yellow-brown micro prisms of XXXIV, mp 260°C (decomp., blacken *ca.* 200°C).

Found: C, 61.64; H, 4.15; N, 9.99%. Calcd for $C_{14}H_{11}O_2N_2Cl$: C, 61.21; H, 4.40; N, 10.19%.

2-Chloro-6-(*p*-tolyl)amino-1-azaazulene (XXXV). A solution of 50 mg of XVIII and 50 mg of *p*-toluidine in 3 m*l* of methanol was heated under reflux for one hour and then concentrated under reduced pressure; the precipitate thus formed was washed with aqueous sodium bicarbonate and then water. After having been dried in a desiccator, this was dissolved in benzene, and the benzene solution was chromatographed on alumina. The benzene eluate was recrystallized from cyclohexane -benzene to give 70 mg of reddish-brown micro prisms of XXXV, mp 200—201°C.

Found: N, 10.24%. Calcd for $C_{16}H_{13}N_2Cl$: N, 10.42%.

2-Chloro-6-(*p*-nitrophenyl)amino-1-azaazulene (XXXVI). A solution of 50 mg of XVII and 70 mg of *p*-nitroaniline in 4 m*l* of methanol was heated under reflux for one hour after which the methanol was removed under reduced pressure. The residue was washed with aqueous sodium bicarbonate and water, and recrystallized from acetone - methanol to give 60 mg of brown micro needles of XXXVI, mp 241—242°C.

Found: N, 14.07%. Calcd for $C_{15}H_{10}O_2N_3Cl$: N, 14.02%.

The support of this project by the Takasago Perfumery Co. is gratefully acknowledged.

The Formation and Reactions of α-Keto Sulfoxide

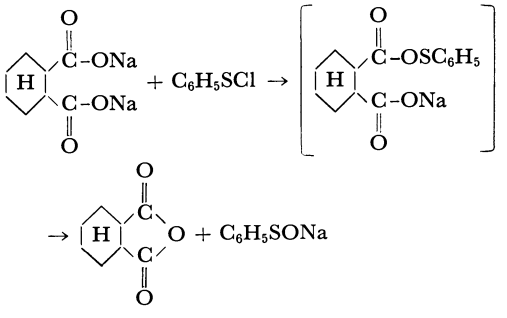
Takanobu KUMAMOTO and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 3, 1968)

The reactions of α-keto sulfoxide, produced by the oxidation of thiolester, were studied. It was established that the oxidation of *S*-ethyl thiobenzoate with *N*-bromosuccinimide and isopropyl alcohol afforded benzoyl ethyl sulfoxide. Similarly, butyryl ethyl sulfoxide was produced by the oxidation of *S*-ethyl thiobutyrate with iodosobenzene. α-Keto sulfoxide, produced by the above-mentioned oxidations, reacts with alcohols, phenols, amines or sodium carboxylates to afford acylated products such as esters, amides or carboxylic anhydrides in good yields.

It has been found that hexahydrophthalic anhydride is obtained in good yield by the reaction of sodium hexahydrophthalate with benzenesulfenyl chloride at room temperature. This result can be explained by assuming an initial formation of a condensation product, sodium benzenesulfenyl hexahydrophthalate, which in turn cyclizes to yield acid anhydride by the elimination of sodium benzenesulfenate.



Based on this finding, the oxidation of thiolesters was investigated with the assumption that α-keto

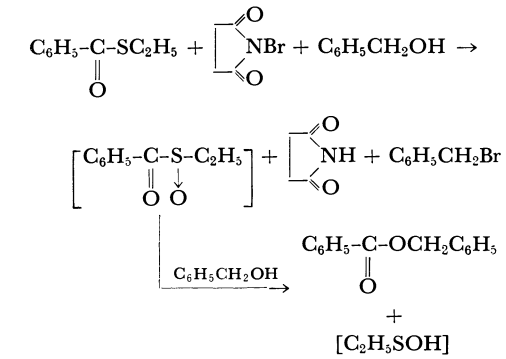
TABLE 1. THE REACTION OF 1 mol OF THIOLESTER WITH 1 mol OF *N*-BROMOSUCCINIMIDE AND 2 mol OF ALCOHOL

Thiol ester	Alcohol	Ester		Yield of succinimide
		Yield	Bp	
C_6H_5-C(=O)-SC_2H_5	C_2H_5OH	72%	88—91°C/12 mmHg	92%
C_6H_5-C(=O)-SC_2H_5	$C_6H_5CH_2OH$	61%	120—122°C/3 mmHg	99%
C_6H_5-C(=O)-SC_6H_5	C_2H_5OH	60%	96—100°C/20 mmHg	60%
C_6H_5-C(=O)-SC_6H_5	*n*-C_4H_9OH	65%	122—124°C/14 mmHg	84%

sulfoxide, an isomer of sulfenyl carboxylate, would be an active acylating reagent when it was treated with active hydrogen compounds.

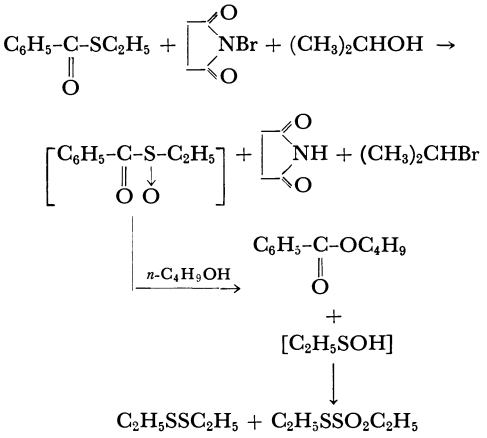
The oxidation of thiolester with either aqueous peracetic acid[1] or potassium permanganate[2] as an oxidant resulted in the formation of carboxylic acid, instead of the expected α-keto sulfoxide. In order to perform the above mentioned acylation reaction by the use of thiolester through α-keto sulfoxide, it is necessary to explore a convenient method for the oxidation of thiolester under anhydrous condition.

Recently, it has been reported that the treatment of *N*-bromosuccinimide with sulfide in hydrous dioxane at room temperature afforded sulfoxide.[3] In the present investigation, a modified oxidation of thiolester was tried by the use of alcohol instead of water in the above reaction as shown in the following equation. It was expected that oxidation by this procedure would be successfully carried out under anhydrous condition. Indeed, when 2 mol of benzyl alcohol was added to a mixture of 1 mol of *S*-ethyl thiobenzoate and 1 mol of *N*-bromosuccinimide, benzyl benzoate (61%), succinimide (99%) and benzyl bromide (64%) were obtained.



In a similar manner, various esters were obtained from the reaction of 1 mol each of thiolester and *N*-bromosuccinimide, and 2 mol of alcohols (see Table 1).

In order to extend this type of acylation to various active hydrogen compounds, such as amines or phenols, the oxidation of thiolester with equimolar amounts of *N*-bromosuccinimide and alcohol was investigated. The reaction of equimolar amounts of *S*-ethyl thiobenzoate, *N*-bromosuccinimide and isopropyl alcohol under ice-cooling, followed by the addition of butyl alcohol, resulted in the formation of butyl benzoate (93%), succinimide (88%), diethyl disulfide (68%) and *S*-ethyl thioethyl sulfonate (65%). Diethyl disulfide and *S*-ethyl thioethyl sulfonate would be the products resulted by the decomposition of ethanesulfenic acid formed. Of importance in this reaction is the fact that isopropyl benzoate, an undesirable by-product, was not obtained at all.



In a similar manner, various esters were obtained in good yields by the reactions of α-keto sulfoxide, produced from thiolester, *N*-bromosuccinimide and isopropyl alcohol, with various alcohols (see Table 2).

The existence of the α-keto sulfoxide, an intermediate, was confirmed by the infrared spectra of

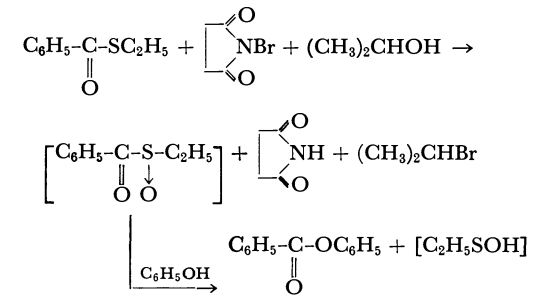
Table 3. The reaction of α-keto sulfoxide, produced by the oxidation of thiolester with iodosobenzene, with alcohols

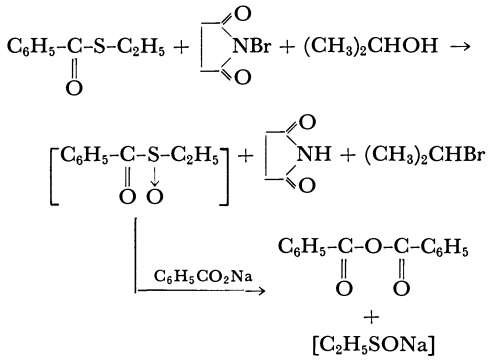
Thiol ester	Alcohol	Ester Yield	Ester Bp °C/mmHg	Yield of iodobenzene
C_3H_7-C(=O)-SC_2H_5	C_2H_5OH	72%	101—110/760	94
C_3H_7-C(=O)-SC_2H_5	i-C_3H_7OH	48%	110—115/760	80%
C_3H_7-C(=O)-SC_2H_5	n-$C_8H_{17}OH$	65%	120—126/24	—
C_6H_5-C(=O)-SC_2H_5	n-$C_8H_{17}OH$	37%	130—132/2	75%

the reaction mixture which was obtained from the reaction of the *S*-ethyl thiobenzoate, *N*-bromosuccinimide and isopropyl alcohol: 1720 cm^{-1}, 1780 cm^{-1} (>C=O), 1180 cm^{-1} (>S→O). This spectrum was identical with that of the reaction mixture which was obtained from the reaction of *S*-ethyl thiobenzoate and iodosobenzene mentioned below.

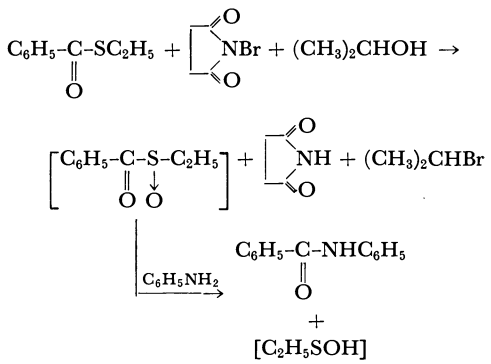
Next, α-keto sulfoxide, produced by the above mentioned procedure, was treated with phenol, phenyl benzoate (56%) and succinimide (87%) were obtained. The reactions of benzoyl ethyl sulfoxide with substituted phenol, such as *p*-chlorophenol and *p*-nitrophenol gave *p*-chlorophenyl benzoate and *p*-nitrophenyl benzoate in 34% and 10% yields, respectively along with a tarry product.



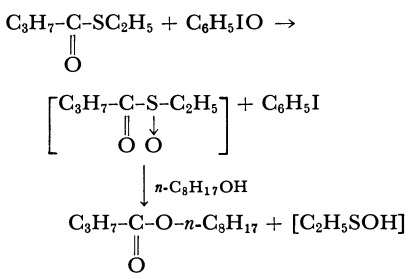
When benzoyl ethyl sulfoxide was allowed to react with benzoic acid, benzoic anhydride could not be obtained, while benzoic acid was recovered quantitatively along with unidentifiable tarry materials. However, when sodium benzoate was used instead of benzoic acid in the above reaction, benzoic anhydride was obtained in 65% yield.



In addition, benzoyl ethyl sulfoxide was found to react vigorously with aniline to afford benzanilide (70%) and succinimide (72%).



Then, the oxidation of thiolesters was tried by the use of iodosobenzene. When a mixture of *S*-ethyl thiobutyrate and iodosobenzene was refluxed in chloroform for 45 min, a precipitates of iodosobenzene disappeared. Successive addition of *n*-octyl alcohol to the reaction mixture at room temperature resulted in the formation of *n*-octyl butyrate in 65% yield.



Various esters were obtained in a similar manner by the reaction of thiolesters, iodosobenzene and alcohols (see Table 3).

Experimental

The Reaction of Sodium Hexahydrophthalate with Benzenesulfenyl Chloride. A mixture of sodium hexahydrophthalate (2.16 g, 0.01 mol) and benzenesulfenyl chloride (2.89 g, 0.02 mol) was stirred in tetrahydrofuran for 6 hr at room temperature. After the precipitates formed was removed by filtration, the residue was evapolated under reduced pressure. Distillation *in vacuo* gave hexahydrophthalic anhydride (1.00 g, 65%, bp 100—106°C/0.15 mmHg) with much amount of tarry product.

The Reaction of 1 mol of *S*-Ethyl Thiobenzoate with 1 mol of *N*-Bromosuccinimide and 2 mol of Benzyl Alcohol. Into a mixture of *S*-ethyl thiobenzoate (1.66 g, 0.01 mol) and *N*-bromosuccinimide (1.78 g, 0.01 mol) in carbon tetrachloride (20 m*l*), a solution of benzyl alcohol (2.16 g, 0.02 mol) in carbon tetrachloride (10 m*l*) was added drop by drop under stirring. After stirring had been continued for 3 hr, white precipitates were collected, washed with carbon tetrachloride; succinimide was obtained, 0.92 g (93%), mp 122—123°C. The filtrate was concentrated, and the distillation under reduced pressure gave a mixture of benzyl bromide and benzyl alcohol (bp 80—89°C/12 mmHg) and benzyl benzoate (bp 120—122°C/12 mmHg), 1.21 g (61%). The mixture of benzyl bromide and benzyl alcohol was refluxed with thiourea (1 g) in ether for 2 hr, and benzyl thioureyl bromide 1.53 g was obtained. From the weight of benzyl thioureyl bromide, the yield of benzyl bromide was estimated to be 1.06 g (62%).

Similarlly, various esters were obtained by the reaction of thiolesters and *N*-bromosuccinimide and alcohols. The results are listed in Table 1. All the esters were identified by the direct comparison of their IR spectra with those of corresponding authentic samples.

The Oxidation of *S*-Ethyl Thiobenzoate with *N*-Bromosuccinimide and Isopropyl Alcohol, and Reaction of Benzoyl Ethyl Sulfoxide, produced by the Oxidation, with Butyl Alcohol. Into a mixture of *S*-ethyl thiobenzoate (1.66 g, 0.01 mol) and *N*-bromosuccinimide (1.78 g, 0.01 mol) in carbon tetrachloride (10 m*l*), a solution of isopropyl alcohol (0.60 g, 0.01 mol) in carbon tetrachloride (10 m*l*) was added drop by drop under ice-cooling. After stirring for 2 hr, butyl alcohol (0.74 g, 0.01 mol) was added to the reaction mixture. The reaction mixture was stirred for 30 min. The succinimide, which precipitated, was filtered and was washed with carbon tetrachloride, 0.87 g (88%), mp 124—125°C. After removal of solvent, distillation under reduced pressure gave diethyl disulfide, (40—55°C/20 mmHg), 0.21 g (68%), *S*-ethyl thioethyl sulfonate, (90—100°C/20 mmHg), 0.25 g (65%) and butyl benzoate, (126—128°C/20 mmHg), 1.65 g (93%). Diethyl disulfide and butyl benzoate were identified by direct comparison of their IR spectra with those of corresponding authentic sample.

By a similar procedure, various esters were obtained by the reaction of benzoyl ethyl sulfoxide, produced by the reaction of *S*-ethyl thiobenzoate and *N*-bromosuccinimide and isopropyl alcohol, with various alcohols. The results are listed in Table 2. Butyl benzoate and benzyl benzoate were identified by direct comparison of their IR spectra with those of the authentic samples. The elemental analyses of octyl benzoate and cyclohexyl benzoate are as follows;

Found: C, 76.59; H, 9.43%. Calcd for $C_{15}H_{22}O_2$: ($C_6H_5CO_2$*n*-C_8H_{17}): C, 76.88; H, 9.46%.

Found: C, 76.34; H, 8.14%. Calcd for $C_{15}H_{16}O_2$ ($C_6H_5CO_2C_6H_{11}$): C, 76.44; H, 7.90%.

Reaction of Benzoyl Ethyl Sulfoxide with Sodium Benzoate. Sodium benzoate (1.44 g, 0.01 mol) was added to the carbon tetrachloride solution of benzoyl ethyl sulfoxide produced by the above mentioned procedure. After stirring for 30 min, white precipitates were collected. The solution was concentrated and distillation under reduced pressure gave benzoic anhydride (bp 140—142°C/1 mmHg) 1.46 g (65%).

Reaction of Benzoyl Ethyl Sulfoxide with Aniline. Similarly, *S*-ethyl thiobenzoate (1.66 g, 0.01 mol), *N*-bromosuccinimide (1.78 g, 0.01 mol) and isopropyl alcohol (0.60 g, 0.01 mol) were allowed to react under ice cooling. After removal of precipitated succinimide (0.70 g, 71% yield), excess amount of aniline (1.86 g, 0.02 mol) was added to the filtrate and a vigorous reaction took place in a short time. The reaction mixture was concentrated and the residue was washed with water and recrystallization from alcohol gave benzanilide, 1.38 g (70%), mp 162°C.

The Oxidation of *S*-Ethyl Thiobutyrate with Iodosobenzene and Reaction of Butyryl Ethyl Sulfoxide with Ethyl Alcohol. A mixture of *S*-ethyl thiobutyrate (1.32 g, 0.01 mol) and iodosobenzene (2.20 g, 0.01 mol) was refluxed in chloroform for 45 min. Ethyl alcohol (0.46 g, 0.01 mol) was added to the reaction mixture at room temperature. Distillation gave ethyl butyrate (bp 112—116°C/760 mmHg), 0.81 g (72%) and iodobenzene (bp 89—92°C/28 mmHg), 1.92 g (94%).

By a similar procedure, various esters were obtained by the reaction of butyryl ethyl sulfoxide, produced from thiolesters and iodosobenzene, with alcohols. Results are listed in Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2115—2117 (1968)

Stereochemical Studies of the 4-Hydroxyl Group of Polymethoxyflavan-3,4-diols

Shinzaburo HISHIDA, Misao UMEHARA, Fujiyuki KAYANUMA and Ryoichi MIYAZAKI

Department of Chemistry, Nihon University, Setagaya-ku, Tokyo

(Received February 17, 1968)

In the previous papers, it was suggested that the 4-hydroxyl group of flavan-3,4-*trans*-diols altered in configuration upon the formation of the isopropylidene derivatives. In order to confirm this suggestion, the isopropylidene derivatives were prepared by the reaction of 4-^{16}OH with acetone-^{18}O, and of 4-^{18}OH with acetone-^{16}O, and the contents of oxygen-18 were analyzed. The oxygen atom from acetone was found in the isopropylidene derivatives of *trans*-3′,4′,5,7-tetramethoxy-*cis*- and *trans*-3′,4′,5′,5,7-pentamethoxy-flavan-3,4-diols.

The formation of isopropylidene derivatives has frequently been used for the assignment of vicinal dihydroxyl groups in a cyclohexane ring to a cis configuration. However, it has been shown that this procedure is not diagnostic for a cis configuration in the case of 3,4-dihydroxyl groups of flavan-3,4-diols.[1] We have shown that identical isopropylidene derivatives were obtained from pairs of flavan-3,4-*cis*- and *trans*-diols which had methoxyl groups at the 5,7-position. Non-substituted flavan-3,4-*cis*-diol, its 4′-methoxy, and 7-methoxy derivatives gave the respective isopropylidene derivatives, but their trans isomers gave no isopropylidene derivatives by the reaction of flavan-3,4-diols with acetone in the presence of cupric sulfate.[2] In contrast to them, the trans isomers of 3′,4′,5,7-tetramethoxy- and 3′,4′,5′,5,7-pentamethoxyflavan-3,4-diol afforded the same isopropylidene derivatives as those from the respective cis isomers.[3] This anomaly may be explained by the benzylic character at the 4-position, which was enhanced by the presence of methoxyl groups at the 5,7-position and which then facilitated the formation of carbonium ions and the attack of the oxygen atom of acetone from the less strained site.[4]

We will report here the determination of the origin of the oxygen atom at the 4-position of the isopropylidene derivatives, whether it is from the 4-hydroxyl group or from acetone. The isopropylidene derivatives were prepared from 3′,4′,5,7-tetramethoxyflavan-3,4-*cis*- and *trans*-diol, which contained natural oxygen atoms, as a result of a reaction with acetone enriched with oxygen-18 in the presence of cupric sulfate, and from 3′,4′,5′,5,7-pentamethoxyflavan-3,4-*cis*- and *trans*-diol, which contained natural oxygen atoms, as a result of a reaction with enriched acetone. 3′,4′,5′,5,7-Pentamethoxyflavan-3,4-*cis*- and *trans*-diol, which were enriched at the 4-hydroxyl group with oxygen-18, were prepared by the reduction of the corresponding 3-hydroxyflavanone (ampelopsin pentamethyl ether), enriched with oxygen-18 at the 4-carbonyl oxygen atom, and submitted to a reaction with natural acetone.

Results and Discussion

The results of the measurements of the oxygen-18 contents are summarized in Table 1. The values of the oxygen-18 contents were calculated from the M+2/M ratio of the isopropylidene derivatives[5] and carbon dioxides,[6] which were obtained by the combustion of the samples, in the mass-spectra. It seems that the values from carbon dioxides are more appropriate, because in them the undesirable disturbance of contaminated deuterium atoms is excluded.

The cis and trans isomers of 3′,4′,5,7-tetramethoxyflavan-3,4-diols were readily separated through the formation of the boron complex of the cis isomer.

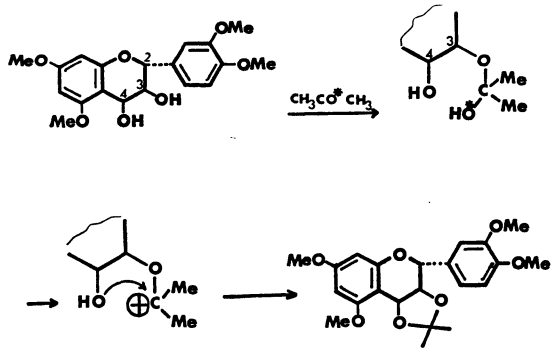
trans-diol	0.2(nat.)	1.45	1.4(1.7)
3′,4′,5′,5,7-$(OMe)_5$-			
cis-diol	0.2(nat.)	2.7	2.7(3.2)
	4.6(6.1)	0.2(nat.)	0.2(0.2)
trans-diol	0.2(nat.)	2.7	2.7(2.6)
	4.8(5.1)	0.2(nat.)	0.2(0.2)

The values were calculated from the M+2/M ratio of CO_2. The values in parenthesis were calculated from the M+2/M ratio of flavan-3,4-diols and isopropylidene derivatives.

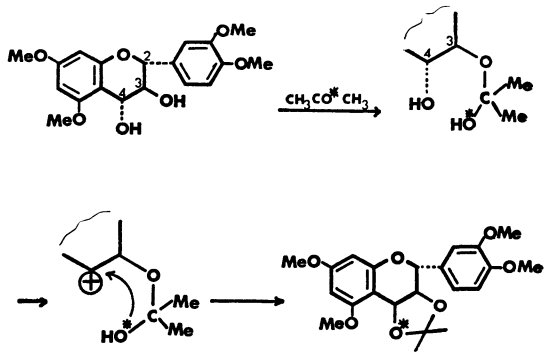
After the reduction of 3′,4′,5,7-tetramethoxy-3-hydroxyflavanone with sodium borohydride in boiling methanol, the reaction mixture was concentrated to a small volume and diluted with water; then the crystallization of the pure trans isomer took place. The aqueous solution which contained the boron complex of cis isomer gave the pure cis isomer on acidification with acetic acid. Their purities were checked by thin-layer chromatography. The distinct separation of the spots of the cis and trans isomers on a chromatogram was achieved by using silica gel treated with sodium borate. An incomplete separation of the cis and trans isomers was observed when 3′,4′,5′,5,7-pentamethoxy-3-hydroxyflavanone was reduced with sodium borohydride. According to the same procedure, the cis isomer obtained on the aqueous solution was found to be pure by thin layer chromatography, but the trans isomer proved to be contaminated with the cis isomer. The purification of the trans isomer was difficult, and the impure sample was submitted to the oxygen-18 experiment.

From Table 1, it is evident that the isopropylidene derivative from the cis isomer of tetramethoxyflavan-3,4-diol contained no oxygen-18 atom of acetone; it is supposed to be formed with a retention of the 4-hydroxyl group through the normal process (A).

The S_N1-type mechanism was postulated, because all the experimental results were covered by using the formation of carbonium ions. However, the S_N2-type and S_Ni-type mechanisms were valid in only a few cases.



However, it was found that the trans isomer readily formed the identical isopropylidene derivative incorporated with the oxygen-18 of acetone. This anomalous reaction may be explained as follows (process (B));



The formation of the dioxolane ring from the flavan-3,4-*trans*-diol through the process (A) requires more distortion of the pyran ring than that from the flavan-3,4-*cis*-diol. The dioxolane ring should be formed through the process that requires the less distortion. The enhanced benzylic character at the 4-carbon atom by the methoxyl groups facilitates the formation of carbonium ions, and the hydroxyl group of acetone hemiketal more readily attacks the carbonium ion from the less distorted site, the cis-direction, than from the trans-direction.

Both cis and trans isomers of pentamethoxyflavan-3,4-diol gave the same isopropylidene derivative, which was incorporated with acetone oxygen. Although the trans isomer was impure because of contamination with the cis isomer, the incorporation of acetone oxygen is not unexpected (*via* process (B)). However, the fact that the cis isomer incorporated acetone oxygen is very interesting and shows that the formation of carbonium ions at the 4-carbon atom and the reaction of the 4-carbonium ion with the hydroxyl group of acetone hemiketal (process (B)) exceeds the normal process (A).

The readiness of the formation of the 4-carbonium ion and of the attack of the hydroxyl group of

acetone hemiketal in the case of pentamethoxyflavan-3,4-diol, relative to the case of the tetramethoxy derivative, is not clearly explained by the resonance stabilization and the steric factors of the reaction process.

Experimental

3′,4′,5,7-Tetramethoxyflavan-3,4-diols. As has been described in the previous papers,[3] 3′,4′,5,7-tetramethoxy-3-hydroxyflavanone was reduced with sodium borohydride (in a large excess) in boiling methanol. The reaction mixture was concentrated to a small volume *in vacuo* and diluted with water. The pure trans isomer soon began to crystallize, and it separated from methanol as prisms, mp 205—206°C. On the acidification of the aqueous solution with acetic acid, the cis isomer was separated in a gelatinous form; it was changed to needles when shaken with ether, and was separated from methanol as needles, mp 165—166°C.

Thin-layer chromatography on silica-gel, using ethyl acetate saturated with water, showed that the cis and trans isomers were both pure. Silica-gel films were prepared as follows. Silica-gel (5 g) was suspended in a 2% aqueous solution of sodium borate (10 ml) and sprayed on glass plates (20 pieces 25 mm × 70 mm). Pink spots were developed by spraying of sulfuric acid and by gentle heating. The trans isomer is more mobile than the cis isomer.

3′,4′,5′,5,7-Pentamethoxyflavan-3,4-diols. The cis and trans isomers were prepared by the procedure described above. The cis isomer separated from methanol as needles, mp 195—196°C, and showed the one spot on a thin-layer chromatogram. However, the trans isomer, recrystallized repeatedly from methanol and benzene (as needles, mp 183—184°C), showed two spots. The lower spot corresponded to the spot of the cis isomer.

3′,4′,5′,5,7-Pentamethoxy-3-hydroxyflavanone-4-^{18}O. To a solution of 3-hydroxyflavanone (2.5 g) in 140 m*l* of dioxane there were added 10 m*l* of heavy water (^{18}O; 5.2%) and a trace of hydrochloric acid, and the solution was kept at 30°C for 2 days. After the removal of the solvent under reduced pressure, the remaining white crystals were separated from methanol as needles, mp 194.5—195.5°C, 2.0 g. The analysis of oxygen-18 showed an ^{18}O content of 5.1%, which was calculated from the M+2/M ratio of CO_2 (^{18}O; 5.4%, calculated from M+2/M ratio of the flavanone-4-^{18}O).

Analysis of Oxygen-18. The mass spectra of flavan-3,4-diols and isopropylidene derivatives were measured with a Hitachi RMU-6D mass spectrometer and a direct-inlet system, operating with an ionization energy of 70 eV. The M+2/M ratio was determined from the intensities of peaks by slow scanning and was corrected by considering the incorporated deuterium atoms.

To analyze oxygen-18 in the form of carbon dioxide, samples were decomposed with mercuric cyanide and mercuric chloride in a vacuum, according to the method of Rittenberg and Ponticorvo.[6]

The authors wish to thank Professor S. Oae and Dr. S. Kozuka of Osaka City University for their guidance in the analysis of oxygen-18.

Ring-butylamination of Toluquinone: Isolation of Products by TLC and an Observation of Their Reaction Course on the Basis of Molecular Reactivity Index

Ju KUMANOTANI, Fumio KAGAWA, Aizo HIKOSAKA and Kazuyuki SUGITA

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo

(Received February 20, 1968)

The ring-butylamination of toluquinone with *n*-butyl-amine was carried out in a chloroform or ethanolic solution at room temperature or at 25.0°C with various molar ratios of the quinone to the amine (designated as Q/A). For the successful separation of each product, TLC was applied, while polarography was used for following the change in the composition of the reacting mixture as well as for measuring the amount of the amino-quinone separated from the reacting mixture by TLC. In the butylamination of toluquinone with excess butylamine (Q/A: 1/5) for 10 hr, the major products were 3,6-bis-(*n*-butylamino)-toluquinone (32%) and 2,5-bis(*n*-butylamino)-*p*-benzoquinone (8%), accompanied by a relatively large amount of unknown by-products: with a Q/A of 2/1 for 2 hr, the major products were 3- and 4-*n*-butylamino-toluquinone (17% and 21%) and 3,6-bis(*n*-butylamino)-toluquinone (3.3%) together with toluhydroquinone (47%). The quantitative formation of 3,6-bis(*n*-butylamino)-toluquinone from 3-*n*-butylamino-toluquinone or the formation of 2,5-bis(*n*-butylamino)-*p*-benzoquinone (34%) and 3,6-bis-(*n*-butylamino)-toluquinone (1%) from 4-*n*-butylamino-toluquinone was also found (Q/A: 1/4, 3 hr or 13 hr), where a faster reaction was found for the 3-isomer than for the 4-isomer under the present conditions. The pathway of the formation of each product was discussed on the basis of the calculated reactivity index of toluquinone or its butylaminated toluquinone isomers toward the amine-attacking.

It is well known that the reactions of *p*-benzoquinone and its derivatives with amines can be classified into three types: (a) the nucleophilic 1,4-addition of an amine to a quinone to give an amino-quinol which, on oxidation, yields the corresponding amino-quinone,[1] (b) the amination of a substituted quinone by replacing the labile substituent (*e.g.*, halogen and alkoxyl) already present[2] and (c) the methylamination of the methylated quinones.[3] Among these reactions, the 1,4-addition reaction of an amine to a quinone was studied by Hofmann *et al.* with aromatic amines.[4] Regarding the reaction mechanism of the 1,4-addition of amines to quinones, however, few papers have been published, though this reaction seems to involve an interesting and attractive redox reaction system, judging from the standpoint of organic chemistry as well as from that of biochemistry. Moreover, the exact mechanism of the reaction of a quinone with an amine still remaines unsolved, since, for example, the amination of *p*-benzoquinone with an amine is so fast that its kinetic treatment is impossible by the usual analytical means.

The aim of this study, which has the ultimate purpose of revealing the quinone-amine reaction mechanism, is to find a quinone-amine reaction which proceeds at a rate measurable by conventional analytical means. Therefore, the system of toluquinone and *n*-butylamine was chosen and examined for the products made in a chloroform or ethanolic solution at room temperature or at 25.0°C, while the molar ratio of toluquinone to the amine was varied. Moreover, the concept of the reactivity index calculated by means of quantum chemistry was applied to the discussion of the product distribution of the amino-quinone formed in the quinone-amine reacting system.

Experimental

Materials. Toluquinone, mp 67.3—67.8°C, was prepared by the oxidation of toluidine by the method described in the literature.[5] The *n*-butylamine, obtained commercially, was of a chemically pure grade and was used without further purification.

TLC Analysis. TLC was carried out to separate each of the reaction products obtained in the reaction of

toluquinone with *n*-butylamine, prior to the identification or polarographic analysis of the products, by the ascending chromatographic technique. In this technique Silica Rider, a commercially-available silica-gel purchased from the Daiichi Pure Chemicals Co., Ltd., was used after its activation by heating at 110°C for 2 hr. The chromatography was conducted, in most cases, in a chloroform tank. In the TLC, chromatography was repeated twice in order to obtain sufficiently-separated zones.

Polarographic Study of the Butylamination of Quinone. *Polarographic Potential $E_{(1/2)}$ (vs. SCE).* This was measured at 25.0°C on a pure quinoid compound in a mixed solvent of isopropyl alcohol - aqueous phosphate buffer (pH 6.8) (1 : 1 by volume), using a Yanagimoto Polarograph PA-102. The $E_{(1/2)}$ thus measured can be used for deciding whether an alkylamino-quinoid compound is mono- or di-substituted, since, under the present quinoid system, $E_{(1/2)}$ is *ca.* −0.3 V for the mono-substituted quinone and *ca.* −0.5 V for the di-substituted quinone.

Polarographic Study of the Progress of the Alkylamination of Quinone. In the nucleophilic 1,4-addition of an amine to *p*-benzoquinone, the aminoquinol first formed yields the corresponding amino-quinone upon its oxidation with the parent quinone present in the reacting system; the latter may undergo a second amination in the same way to yield 2,5-bis(*n*-butylamino)-*p*-benzoquinone.[1] When the reaction is carried out in air, however, according to the different redox potentials of the quinone and the related amino-quinones that are participating in the reaction, there is a possibility of hydrogen abstraction with oxygen in air from the amino-hydroquinones formed in the course of the reaction. Therefore, in the polarographic studies of the reaction course of toluquinone and *n*-butylamine, the change in the composition of the reacting mixture *vs.* the reaction time was examined under various conditions for such products detectable by polarography as toluhydroquinone, toluquinone (−0.06 V), and mono- and di-butylaminated toluquinones, as well as hydrogen peroxide (−1.2 V). (None of the three possibly existing isomeric mono-butylaminated toluquinones could be detected in their mixture, nor could the di-butylaminated quinones be distinguished from each other under the present polarographic conditions.)

An example of polarographic analysis of the reacting mixture is as follows: To an ethanolic solution of toluquinone, which had been kept at 25.0°C in a water bath, was instantly added an ethanolic solution of *n*-butylamine, after which the reaction was continued under stirring for a certain time interval. During this reaction 0.1 m*l* portions of the reacting solution were pipetted out at certain time intervals and dissolved into 10.0 m*l* of an isopropyl alcohol solution; then 2.0 m*l* of the resultant solution, mixed with the same volume of the aqueous phosphate buffer (pH 6.0), was submitted to polarographic analysis.

Butylamination of Toluquinone with n-Butylamine. Derivation of 3,6-Bis(n-butylamino)-toluquinone and 2,5-Bis(n-butylamino)-p-benzoquinone by the Reaction of Toluquinone with Excess n-Butylamine. To a mixture of toluquinone (4.88 g, 40 mmol) in ethanol (100 m*l*) in an Erlenmeyer flask, *n*-butylamine (14.6 g, 200 mmol) was added drop by drop, over 30-min period at room temperature; after that the stiaring was continued for 5 hr, and the resultant solution was refrigerated for 2 days and filtered to remove violet crystals (3.4 g). This substance (1.0 g) was submitted to TLC, where the amount of the sample treated per plate (0.14×20×20 cm) was *ca.* 200 mg; a solution of this substance (200 mg) in chloroform (2 m*l*) was applied in line on the silica-gel layer and developed in a chloroform tank. After the solvent had reached the upper edge of the plate, the plate was dried in air for 30 min and then again developed with chloroform. The two separated zones (C′ and D′) were then scrapped from the plate and extracted with 10 m*l* of chloroform and then 10 m*l* of methanol; the extracts thus obtained were collected for C′ or D′, and evaporated to dryness under a reduced pressure of nitrogen to give violet crystals (C, 140 mg) and reddish crystals (D, 45 mg). These substances were recrystallizable from chloroform or ethanol.

Compound C; mp 119.7—120.7°C.

Found: C, 67.8; H, 9.3; N, 10.2%. Calcd for $C_{15}H_{24}O_2N_2$: C, 68.1; H, 9.1; N, 10.6%.

$E_{(1/2)}$, −0.53 V. R_f, 0.17.

IR in CCl_4[6]; 3355 and 3297 (m, ν_{N-H}), 1644 (m, $\nu_{C=C}$), 1613 and 1580 (s, $\nu_{C=O}$), 1502 cm^{-1} (s, amido II type).

NMR in $CDCl_3$ (see (1)): 9.05 and 8.95 τ (6 H_h), 8.50 τ (8 H_g), 7.93 τ (3 H_f), 6.87 τ (2 H_e, quartet coupled with H_g and H_a), 6.46 τ (2 H_d, quartet coupled with H_g and H_b), 4.80 τ (1 H_c) and 3.32 τ (1 H_a and 1 H_b, broadened).

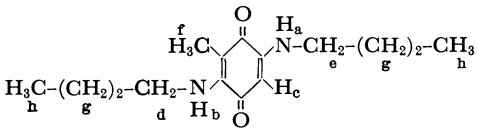
Compound D; mp 163.5—164.5°C.

Found: N, 11.2%. Calcd for $C_{14}H_{22}O_2N_2$: N, 11.2%.

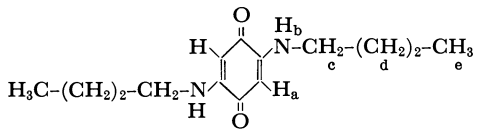
$E_{(1/2)}$, −0.57 V. R_f, 0.08.

IR in CCl_4[6]: 3355 (m, ν_{N-H}), 1650 (m, $\nu_{C=C}$), 1589 (s, $\nu_{C=O}$), 1503 cm^{-1} (s, amido II type).

NMR in $CDCl_3$ (see (2)): 9.07 and 8.96 τ (6 H_e), 8.44 τ (8 H_d), 6.84 τ (4 H_c, quartet coupled with H_d and H_b), 4.73 τ (2 H_a) and 3.36 τ (2 H_b, broadened).



(1)



(2)

From the above results, it was concluded that Compound C is 3,6-bis(*n*-butylamino)-toluquinone and that Compound D is 2,5-bis(*n*-butylamino)-*p*-benzoquinone.

The change in the composition of the reacting mixture *vs.* the reaction time was followed polarographically for a reaction carried out at a moderate reagent concentration in an ethanolic solution; it is shown in Fig. 1.

To determine the amount of each of the di-butylaminated quinones, 1.0 m*l* of the reacting solution obtained 10 hr after the beginning of the reaction was

6) Unpublished data; a paper on the spectral data of the amino-quinoid compound will be shortly submitted for publication.

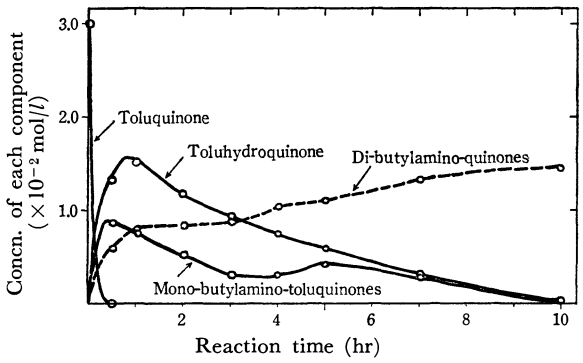


Fig. 1. Change of composition *vs.* reaction time in the reaction of toluquinone with excess *n*-butylamine (Q/A: 1/5); ethanolic solutions of toluquinone (36.6 mg, 0.3 mmol in 10 m*l*) and *n*-butylamine (1.0 m*l* of 15 vol%).

pipetted out, submitted to the TLC (thickness of the silica-gel layer: 0.6 mm), and chromatographed in a chloroform tank such as has already been described. The product (C or D) thus separated was dissolved in 5.0 m*l* or 10.0 m*l* of isopropyl alcohol to prepare a solution with a suitable concentration for the polarographic analysis; 2.0 m*l* of the resultant solution was mixed with the same volume of the aqueous phosphate buffer (pH 6.0) and submitted to the polarographic analysis. The product ratio of C to D was found to be 4/1.

Derivation of 3- and 4-n-Butylamino-toluquinone with a Q/A of 2:1. A solution of toluquinone (2.44 g, 20 mmol) in chloroform (10 m*l*) was instantly mixed with achloroform solution of *n*-butylamine (5 m*l* of 19.3 vol %) at room temperature in an Erlenmeyer flask and stirred magnetically for 1 hr, refrigerated for a day, and filtered to remove the precipitated crystals of toluhydroquinone. The resultant chloroform solution was submitted to the TLC in the same manner as has already been described, thus affording the crystals in yields of 450 mg (A′) and 290 mg (B′); 30 m*l* of dried ether were used for the extraction (200 mg of the sample were treated per plate).

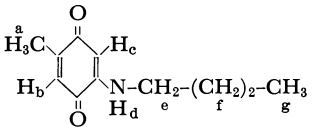
The A′ (20—30 mg), shown by its polarogram to consist of two components, A and C, was dissolved in a small amount of chloroform, applied on the silica-gel layer (thickness, 0.6 mm) and chromatographed with a mixed solvent of ethyl acetate - carbon tetrachloride (1 : 15 by volume). The chromatogram thus obtained was again developed in the same solvent tank to give pure A and C. The purity of the substance, A or C, was confirmed by a.c. polarography. A was isolated as a sublimate from its mixture with Compound C by heating the mixture under reduced pressure. B gave only one peak in its polarogram. The chemical and physical constants of the compounds, A and B, are shown below.

Compound A recrystallizable from *n*-hexane: mp 63.6—65.6°C.

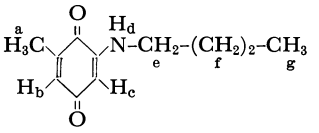
Found: N, 7.2%; mol wt (v.p.o.), 207. Calcd for $C_{11}H_{15}O_2N$: N, 7.3%; mol wt 193.

$E_{(1/2)}$, −0.30 V. R_f, 0.15.

UV: λ_{max}^{EtOH} 214 (ε 28200), 275 (ε 12200), 485 mμ (ε 2740).



(3)



(4)

NMR in $CDCl_3$ (see (3)); 9.05 and 8.95 τ(3 H_g), 8.42 τ(4 H_f), 7.95 τ(3 H_a, doublet coupled with H_b[7]), 6.90 τ(2 H_e, quartet coupled with H_d and H_f), 4.60 τ(H_c), 4.46 τ(H_d), broadened), 3.60 τ(H_b, quartet coupled with H_a).

Compound B recrystallizable from *n*-hexane: mp 72.2—73.3°C.

Found: C, 67.6; H, 7.8; N, 7.2%; mol wt (v.p.o.), 189. Calcd for $C_{11}H_{15}O_2N$: C, 68.4; H, 7.8; N, 7.3%; mol wt, 193.

$E_{(1/2)}$, −0.28 V. R_f, 0.07.

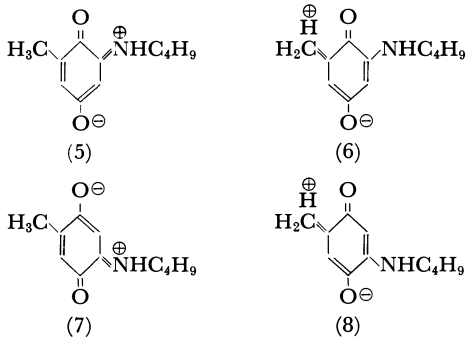
UV: λ_{max}^{EtOH} 218 (ε 22800), 278 (ε 9150), 485 mμ (ε 2940).

NMR in $CDCl_3$ (see (4)); 9.05 and 8.93 τ(3 H_g), 8.48 τ(4 H_f), 7.98 τ(3 H_a, doublet coupled with H_b), 6.88 τ(2 H_e, quartet coupled with H_d and H_f), 4.59 τ (H_c, doublet (J=2.5 cps) coupled with H_b[8]), 4.38 τ (H_d, broadened), 3.58 τ(H_b, quartet or quintet coupled with H_a and H_c).

Compound C: $E_{(1/2)}$, −0.53 V. Its infrared spectrum was in agreement with that of the authentic sample given in the preceding section.

According to the study made by Yates *et al.*[9] of the out-of-plane bending of the C-H of *p*-benzoquinone and its derivatives by infrared spectroscopy, it became evident that neither A nor B, each having a characteristic absorption band at 880 cm^{-1} or 894 cm^{-1} in CS_2 respectively, was identical with the 2,3-disubstituted *p*-benzoquinone isomer. Upon determining which compound, A or B was identical with one of the two possible isomers, 3- and 4-*n*-butylamino-toluquinone, we attempted to acertain the difference between the wave numbers of the two carbonyl groups within a molecule of each 3- and 4-*n*-butylaminotoluquinone. The results thus obtained were correlated with the expected $\Delta\nu_{C=O}$, originating from the different " aufrichtung " effect of the carbonyl group, which was given by the different hyperconjugation and the electron-donating effects of the existing methyl group or the different inductomeric effect of the *n*-butylamino group already present; (5) and (6) show 3-*n*-butylamino-toluquinone, and (7) and (8), 4-*n*-butylamino-toluquinone.

7) E. R. Wagner, R. D. Moss and R. M. Brooker, *Tetrahedron Letters*, **47**, 4236 (1965).
8) J. H. Day and A. Jaochim, *J. Org. Chem.*, **30**, 4108 (1965).
9) P. Yates, M. I. Ardao and L. F. Fieser, *J. Am. Chem. Soc.*, **78**, 652 (1956).



Thus, on the basis of a comparison between the observed facts that $\Delta\nu_{C=O}$ is 36 cm^{-1} for A and 47 cm^{-1} for B, it is concluded that Compound A is 4-*n*-butylamino-toluquinone and Compound B is 3-*n*-butylamino-toluquinone.

This is in agreement with the NMR spectra.

The change in the composition of the reacting mixture *vs.* the reaction time was followed polarographically (see Fig. 2).

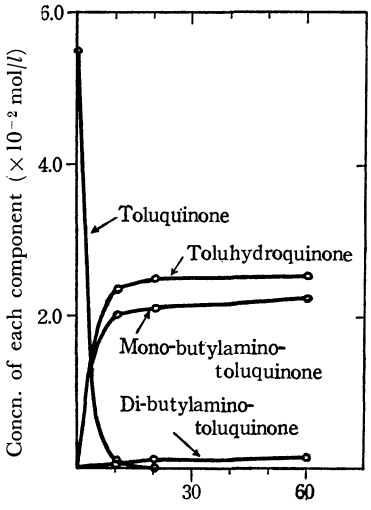


Fig. 2. Change of composition *vs.* reaction time in the reaction of toluquinone with *n*-butylamine-(Q/A: 2/1); a solution of toluquinone (36.6 mg, 0.3 mmol in ethanol (5.0 m*l*) was reacted with an ethanolic *n*-butylamine solution (0.5 m*l* of 3.0 vol%)

To determine the amount of each of the butylamino-toluquinones, 1.0 m*l* of the reacting solution obtained was, 2 hr after the beginning of the reaction, pipetted out and submitted to the TLC (thickness, 0.6 mm). Each of the substances, A′ and B′ extracted with 30 m*l* of ether, was submitted to polarographic analysis in the same way as has been described before; the A: B: C ratio was found to be 51 : 41 : 8.

Derivation of 3,6-Bis(n-butylamine)-toluquinone by the Reaction of 3-n-Butylamino-toluquinone and n-Butylamine with a Q/A of 1/4. A solution of 3-*n*-butylamino-toluquinone (63.7 mg, 0.33 mmol) in ethanol (10 m*l*) was instantly mixed with an ethanolic *n*-butylamine solution (1.0 m*l* of 12 vol%) at 25.0°C, stirred for 3 hr, and then submitted to the TLC on a silica-gel layer such as has been described for the mono-butylamination of toluquinone. The major separated zone was extracted with 5.0 m*l* of chloroform and then 5.0 m*l* of methanol; the extracts thus obtained were combined, and the solution was submitted to evaporation to dryness under reduced nitrogen pressure to give crystals as the residue; recrystallization from chloroform or ethanol gave violet crystals; mp 119.7—120.7°C; $E_{(1/2)}$, −0.53 V; R_f, 0.17; (Found: C, 68.2; H, 9.2; N, 10.3%). The identity of this compound with 3,6-bis(*n*-butylamino)-toluquinone was also established by its infrared spectral agreement with an authentic sample already prepared in the reaction of toluquinone with excess amine.

The relation obtained polarographically regarding the change in the reacting mixture *vs.* the reaction time is shown in Fig. 3.

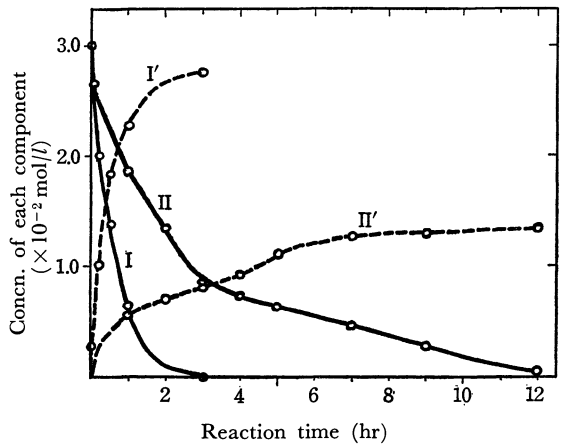

Fig. 3. Reaction of 3-*n*-butylamino-toluquinone (I) and 4-*n*-butylamino-toluquinone (II) with *n*-butylamine; (I) ethanolic solutions of 3-aminoquinone (63.7 mg, 0.33 mmol in 10 m*l*) and *n*-butylamine (1 m*l* of 12 vol%), (II) ethanolic solutions of 4-aminoquinone (28.9 mg, 0.15 mmol in 5 m*l*) and *n*-butylamine (0.5 m*l* of 12 vol%).

Upon the measurement of the yield, a 1.0 m*l* portion of the reacting solution pipetted out was submitted to TLC similar as that used in the preceding section; the yield of this substance was 95%.

Derivation of 2,5-Bis(n-butylamino)-p-benzoquinone and 3,6-Bis(n-butylamino)-toluquinone by the Reaction of 4-n-Butylamino-toluquinone with Excess n-Butylamine. A solution of 4-*n*-butylamino-toluquinone (28.9 mg, 0.15 mmol) in ethanol (5.0 m*l*) was reacted with an ethanolic *n*-butylamine solution (0.5 m*l* of 12 vol%) for 13 hr such as has already been described in connection with other reactions, and a half volume of the reacting solution was applied in line on the silica-gel layer (thickness: 0.6 mm) and chromatographed in the chloroform tank in the manner already described. Then, each of the violet- and pink-colored zones obtained was extracted with 5 m*l* of chloroform and then 5 m*l* of methanol. The extracts thus obtained gave violet- and pink-colored crystals after the removal of the solvent; the infrared spectra were identical with those of 3,6-bis-(*n*-butylamino)-toluquinone and 2,5-bis(*n*-butylamino)-*p*-benzoquinone respectively. The yield of each of these

products was measured by submitting a 1.0 ml portion of the remaining half volume of the reacting solution to an analysis combining TLC and polarography, as had already been used for the other cases; the yields of 3,6-bis-(*n*-butylamino)-toluquinone and 2,5-bis (*n*-butylamino)-*p*-benzoquinone were 1.0% and 34% respectively.

The change in the composition of the ethanolic reacting mixture *vs.* the reaction time was followed polarographically; it is plotted in Fig. 3.

Results and Discussion

Correlation of Each of the Butylaminated Quinones. In the reaction of toluquinone with an ethanolic solution of excess *n*-butylamine, the major butylaminated quinone derivatives were 3,6-bis(*n*-butylamino)-toluquinone (32% for the toluquinone used) and 2,5-bis(*n*-butylamino)-*p*-benzoquinone (8%), together with a relatively large amount of by-products. Upon the determination of the reaction course producing each of the butylaminated toluquinones, the reaction of toluquinone with the amine was carried out with a Q/A molar ratio of 2/1 ; as expected, this led to the formation of mono-butylaminated toluquinones, the products being toluhydroquinone (47%), 3- and 4-*n*-butylamino-toluquinone (17% and 21%), and 3,6-bis-(*n*-butylamino)-toluquinone (3.3%).

Among these products, 3,6-bis(*n*-butylamino)-toluquinone can be considered to be made through either 3- or 6-*n*-butylamino-toluquinone. It will be clearly explained below.

Further in the reaction of 3-*n*-butylamino-toluquinone with an ethanolic solution of *n*-butylamine (Q/A: 1/4), 3,6-bis(*n*-butylamino)-toluquinone was prepared approximately quantitatively, while, with 4-*n*-butylamino-toluquinone (Q/A: 1/4), 2,5-bis(*n*-butylamino)-*p*-benzoquinone (34%) and a trace of 3,6-bis(*n*-butylamino)-toluquinone were obtained, with a complete consumption of the amino-toluquinone. The former was, presumably, a result of the methylamination mechanism already proposed by Cameron *et al.*[3] for the methylamination of toluquinone with methylamine; the latter found by the TLC technique, was readily assumed to be produced by such a complex reaction as is illustrated by the formation of larger amounts of by-products, *e.g.*, through the redistribution of the butylamino-residue of the amino-quinones between the products existing in the reaction course.

Concerning the alkylamination of toluquinone or its derivation with alkylamine, the formation of 3,6-bis(methylamino)-toluquinone[3,10,11] from toluquinone and that of 2,5-bis(methylamino)-*p*-benzoquinone from 4-methoxyl-toluquinone[3,10] by reaction with methylamine have been reported. However, in the former case the pathway leading to the amino-quinone has not yet been established, and in the latter case 4-methylamino-toluquinone has been proposed as an intermediate on the basis of no evidence. The results obtained by the present authors for the reactions of *n*-butylamine and toluquinone or its amino-derivatives give exact evidence for the pathway of the alkylamination of toluquinone with an amine.

Polarographic Study of the Progress of the Reaction of Toluquinone with *n*-Butylamine. In the reaction of *n*-butylamine with toluquinone (Q/A: 2/1) it was revealed that the reaction was saturated within 20 min (see Fig. 2). The major products were mono-butylaminated toluquinones plus a minor quantity of dibutylaminated quinones; no detectable amount of hydrogen peroxide was found, indicating that the hydrogen-abstraction from the alkylamino-hydroquinone was made first with the parent quinone, not with oxygen in air.

With a Q/A of 3/2, due to the decrease in the amount of the mono-butylaminated toluquinone once formed through its further reaction, the reaction product obtained 2 hr after the beginning of the reaction was found to be contaminated with relatively large amounts of mono- and dibutylaminated quinones; this procedure is, then, unsuitable for the selective preparation of either mono- or di-butylaminated toluquinone in an excellent yield. Under the present conditions, the formation of hydrogen peroxide was detected by observing a polarographic wave corresponding to that of hydrogen peroxide at -1.2 V.

With a Q/A of 1/5, as may be seen from Fig. 1, the step-by-step butylamination of toluquinone to 3,6-bis(*n*-butylamino)-toluquinone through the well-known reaction course, the participation of toluquinone in the further reaction made through the air-oxidation of toluhydroquinone accumulated at the early stage of the reaction, and the saturation of the product distribution 10 hr after the beginning of the reaction can clearly be seen; the fact that the conversion curve observed on the rate of mono-butylaminated toluquinone shows two upward peaks indicates the complexity of the reaction. Of course, in this system the formation of hydrogen peroxide was also found polarographically.

An Observation of the Reactivity of Toluquinone toward *n*-Butylamine in Terms of the Reactivity Index Calculated. In the methylamination of *p*-benzoquinone leading to the formation of 2,5-bis(methylamino)-*p*-benzoquinone, it was proposed by Cameron *et al.*[3] that the first step is the nucleophilic 1,4-addition of the amine to the quinone, thus giving monomethylamino-hydroquinone. Then, as a parameter of the reactivity of toluquinone toward the attack by *n*-butylamine, the reactivity index was calculated for toluquinone and its mono-butylamino derivatives by utilizing the ω-technique in a simple linear combination of

TABLE 1. REACTIVITY INDEX FOR THE NUCLEOPHILIC SUBSTITUTION

Compound	Superdelocalizability $S_r^{(N)}$ (Formal charge Q_r) Position			
	1	3	4	6
Toluquinone	0.9724 (+0.087)	0.9614 (+0.064)	1.0202 (+0.070)	0.8825 (+0.043)
3-Alkylaminotoluquinone	0.9796 (+0.078)	0.9924 (+0.084)	0.8627 (+0.018)	1.0107 (+0.044)
6-Alkylaminotoluquinone	0.8848 (+0.041)	1.1817 (+0.067)	1.0910 (+0.059)	0.9790 (+0.064)
4-Alkylaminotoluquinone	1.1125 (+0.090)	0.8017 (+0.013)	1.0551 (+0.090)	0.8772 (+0.033)

the atomic orbital theory, using the Streitwieser heteroatom parameter.[12] (The calculations were performed on the HITAC 5020 Computer, in the Computer Center, The University of Tokyo; see Table 1.)

Ring Butylamination. The preferential attack at the 3 or 4 position of toluquinone with *n*-butylamine, and the subsequent amine-attack at the para-position of the first substituted amino group on the quinoid ring, can be readily predicted from their reactivity index, presented in Table 1. (The ring carbon to which the methyl or alkylamino group is linked is not considered, because of its steric effect toward the amine-attack.)

Moreover, it is obviously shown that a greater contribution by 3-*n*-butylamino-toluquinone than by the 6-isomer to the formation of 3,6-bis(*n*-butylamino)-toluquinone can be considered. The participation of 6-*n*-butylamino-toluquinone, of course, can not always be obviated, since, if this amino-quinoid compound were an intermediate in the present reaction course, the reactivity index of this compound toward butylamination would be relatively large.

Side-chain Butylamination. In order to elucidate the reactivity of the substituted methyl group on the quinoid ring toward the methyl-butylamination, the reactivity indices of the three possible monobutylaminated toluquinone isomers were compared; the formal charge or superdelocalizability calculated for the three isomers (at 1 position) shows that the carbon atom of the quinoid ring to which the methyl group is linked is most positive, causing the hydrogens of the methyl group to be more positive and then to undergo the formation of quinone methide readily, followed by methyl-butylamination.

In comparison with those reactivty indices (see Table 1) calculated for the three mono-alkylaminated toluquinone isomers, a larger reactivity for the methyl-butylamination can be predicted for the 4-alkylamino-toluquinone; this is in agreement with the experimental result of the preferential methyl-butylamination of 4-*n*-butylamino-toluquinone, whereas 3-*n*-butylamino-toluquinone could not be methyl-butylaminated and was converted quantitatively into 3,6-bis(*n*-butylamino)-toluquinone.

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received February 28, 1968)

N,N'-Dichlorobarbital (NDCB) reacted as a highly-reactive oxidizing or chlorinating reagent with ether, aldehyde, ketone, olefin and toluene. NDCB also showed a stereospecific chlorination of *d*-camphor, giving exclusively *exo*-3-chloro-*d*-camphor, and one of chloestanone, giving 2β-chlorocholestanone in part. The reactivities of a variety of *N*-halo compounds were compared and discussed in terms of the polarographic reduction potentials of the N-halogen bond in the compounds.

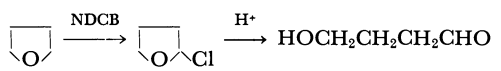
N-Halogenoimides have been known as effective halogenating or oxidizing reagents for olefins, alcohols and carbonyl compounds.[1] In the past, attention has been paid mostly to *N*-bromosuccinimide (NBS) because of its accessibility.[1] However, the usefulness of other *N*-halo compounds as reagents for organic syntheses seems to be open for further investigation.

During the course of our studies of the chemistry of barbital derivatives, we have found that *N,N'*-dichlorobarbital (NDCB) is a reactive reagent for organic compounds. NDCB has been synthesized by Ziegler *et al.* and found to be effective for the halogenation of olefins.[2] However, the other chemical properties of NDCB have not been much elucidated.

This paper will deal with the reactions of NDCB with a variety of organic compounds. A comparison of the reactivity of NDCB with those of other *N*-halo compounds will also be made in the light of the polarographic reduction potentials.

Results and Discussion

Reactions of NDCB with Organic Compounds. When NDCB was added to tetrahydrofuran at room temperature, a vigorous reaction took place. The product isolated after an acid-catalyzed hydrolysis was 3-hydroxybutyraldehyde.



A similar vigorous reaction was also observed in carbon tetrachloride at room temperature, but no reaction took place with NBS in carbon tetrachloride even at the reflux temperature.

NDCB reacted smoothly with toluene under reflux to give benzyl chloride in a high yield both in the absence of a solvent and in carbon tetrachloride. NBS did not react with toluene at all under these conditions. These results clearly demonstrate that NDCB is a reagent more reactive than NBS. The results are summarized in Table 1.

Benzaldehyde readily reacted with both NDCB and NBS to form benzoyl chloride and bromide reaspectively. The reaction of NDCB with excess butanol without a solvent afforded a mixture of *n*-butyraldehyde (47%) and *n*-butyric acid (16%), plus a trace of butyl butyrate, while the reaction in carbon tetrachloride yielded butyl butyrate as the main product, along with traces of butyraldehyde and butyric acid. With NBS, butyl butyrate was obtained as the main product irrespective of the presence or absence of carbon tetrachloride. Butyl butyrate would be obtained by the oxidation of the hemiacetal (**1**), which had been produced by the reaction of butyraldehyde and butanol, with *N*-halo compounds.

$$C_3H_7CHO + C_4H_9OH \rightarrow \underset{\mathbf{1}}{C_3H_7CH(OH)OC_4H_9}$$

$$\mathbf{1} + \text{NDCB or NBS} \rightarrow C_3H_7CO_2C_4H_9$$

Butyraldehyde, when oxidized with NDCB and NBS, usually gave butyric acid in a relatively high yield. However, when NDCB was allowed to react with butyraldehyde in the absence of a solvent at room temperature, a vigorous reaction took place to give a mixture of butyric acid and a condensation product, 2-ethyl-2-hexenylaldehyde, in a molar

TABLE 1. PRODUCTS OBTAINED BY THE REACTIONS OF NDCB AND NBS WITH ORGANIC COMPOUNDS

Compound	NDCB[a]			
	No Solvent	Yield (%)	In CCl_4	Yield (%)
Tetrahydrofuran	3-Hydroxybutyraldehyde	51	3-Hydroxybutyraldehyde	21
Toluene	Benzyl chloride	72	Benzyl chloride	—
Benzaldehyde	Benzoyl chloride	96	Benzoyl chloride	76
Butanol	Butyraldehyde	47	Butyraldehyde	trace
	Butyric acid	16	Butyric acid	trace
	Butyl butyrate	trace	Butyl butyrate	29
Butyraldehyde	Butyric acid	58	Butyric acid	74
	2-Ethyl-2-hexenylaldehyde	37		

Compound	NBS[b]			
	No Solvent	Yield (%)	In CCl_4	Yield (%)
Tetrahydrofuran	———		None[c]	
Toluene	None[c]		None[c]	
Benzaldehyde	Benzoyl bromide	—	Benzoyl bromide	—
Butanol	Butyraldehyde	7	Butyraldehyde	trace
	Butyric acid	trace		
	Butyl butyrate	44	Butyl butyrate	12
Butyraldehyde	Butyric acid	65	———	

a) The yield was calculated on the basis that two chlorine atoms in NDCB were paticipated in the reaction as active halogen atoms.
b) The yield was calculated on the basis that one bromine atom in NBS was participated in the reaction.
c) The starting material was recovered.

ratio of 3 : 2. A similar condensation was also observed in cyclohexanone; it will be described later.

These results suggest that NDCB reacts in two distinct ways, depending on the reaction medium. In heterogeneous media (in non-polar solvents such as carbon tetrachloride) the reaction chiefly proceeds in homolytic fashion, causing free radical halogenation. On the other hand, in homogeneous media (in polar solvents) the reaction proceeds in heterolytic fashion, the N–Cl bond reacting in the polarized form and behaving like a Lewis acid. A tendency of this kind, though to a lesser extent, has also been observed for NBS.[1]

Stereochemistry. The stereochemistry of halogenation with NDCB was studied, taking *d*-camphor and cholestanone as substrates. *d*-Camphor has been found to be halogenated with molecular chlorine to give *endo*-3-chloro-camphor (**2**)[3] exclusively. However, when an equimolar mixture of *d*-camphor and NDCB was heated at 140°C for 40 min, *exo*-3-chlorocamphor (**3**) was obtained in a 95% yield. The similar treatment of *d*-camphor with NBS gave *endo*-3-bromocamphor in an 80% yield.

	2	**3**
NDCB	0	95%
NBS	80%	0

An abnormal stereochemistry in the halogenation with NDCB was also found for cholestanone. The literature has shown that the chlorination of cholestanone can be carried out by passing chlorine gas into the solution of the compound in carbon tetrachloride or acetic acid, affording the 2α-chloro-derivative exclusively.[4] However, when a mixture of NDCB and cholestanone was heated at 140°C for 30 min, a mixture consisting of 3 parts of 2α-chloro- and 4 parts of 2β-chloro-derivatives was obtained in a total yield of 73%.

These products were nicely separated by column chromatography on alumina, using chloroform as an eluent, and were identified by the measurement of their melting points, infrared spectra, and optical rotations, which were all in satisfactory agreement

with the literature values. Unfortunately, we can not reasonably explain the abnormal stereochemistry observed in the reaction of NDCB.

Polarographic Reduction Potentials of *N*-Halo Compounds. There have been found many *N*-halo compounds which can potentially serve as halogenating or oxidizing reagents for organic compounds. The reactivities of these *N*-halo compounds can primarily be characterized by the polarity of the *N*-halogen bonds, which in turn determines the reductivity of those bonds. The polarographic half-wave potential seems to be a good index for the reductivity.

Very few polarographic data of *N*-halo compounds have been published. Recently, however, *N*-bromosuccinimide has been polarographically investigated in detail in water by Nagai and Matsuda.[5] The polarograms obtained have shown the appearance of complicated waves due to the hydrolysis of *N*-halo compounds. For this reason, we measured the half-wave potentials for *N*-halo compounds in dimethylformamide (DMF). Figure 1 shows the

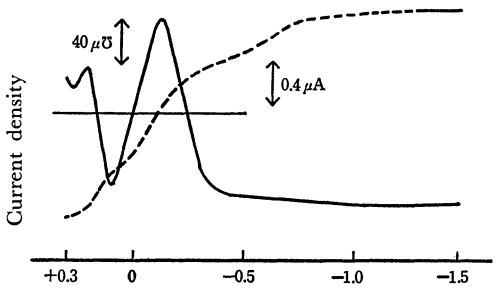

Fig. 1. Polarogram of *N,N'*-dichlorobarbital in DMF at 20°C.
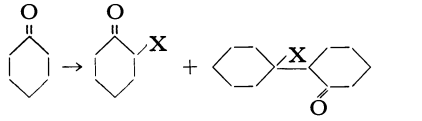
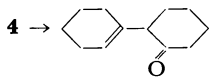
—— AC Polarogram
---- DC Polarogram

polarogram for NDCB. The peaks in the AC polarogram were in accordance with the $E_{1/2}$ values obtained by DC polarography, and the shape of the polarogram was reproducible in three experiments. These results indicate that the waves are attributable to the true electrochemical reduction. Barbital itself did not show the reduction waves above −1.5 V. The wave at −0.12 V would seem, therefore, to be the result of the reduction of the N–Cl bond. Other *N*-halo compounds behaved similarly. The $E_{1/2}$ values (V) measured at 20°C were as follows: *N,N',N''*-trichloroisocynanuric acid (−0.07), NDCB (−0.12), *N*-chlorophthalimide (−0.15), *N*-chlorosuccinimide (−0.21), and NBS (−0.26). These values indicate that the polarity of *N*-halo compounds decreases in the above order.

Correlation between the Reactivities of *N*-Halo Compounds and Their $E_{1/2}$ Values. *Rractions of Cyclohexanone with N-Halo Compounds.* It is reasonable to assume that, if the more polar N–halogen bond is contained in the *N*-halo compound, a much higher yield would be expected in the condensation product, since the condensation should be a polar reaction which could sometimes be catalyzed by Lewis acid.[6] On the basis of this assumption, the reactions of cyclohexanone with several *N*-halo compounds were studied. The treatment of cyclohexanone with the *N*-halo compounds in the absence of a solvent afforded 2-halogeno-cyclohexanone and 2-(1-halogenocyclohexyl)cyclohexanone (**4**) in yields depending on the *N*-halo compounds used, as is represented in Table 2.



4



5

The structure of **4** was established as follows: **4** was converted to 2-(1-cyclohexenyl)cyclohexanone (**5**) by treatment with pyridine. The properties of **5** thus obtained were identical with those of

Table 2. Products obtained by the reactions of *N*-halo compounds with cyclohexanone

N-Halo compound	Yield of the product (%) 2-Halogeno-cyclohexanone	2-(1-Halogeno-cyclohexyl)-cyclohexanone
N,N',N''-Trichloro-isocyanuric acid	39	61
N,N'-Dichlorobarbital	50	45
N-Bromosuccinimide	75	0

* The yield was calculated on the basis that three chlorine atoms in *N,N',N''*-trichloroisocyanuric acid, two chlorine atoms in NDCB, and one bromine atom in NBS were participated in the reactions.

5) T. Nagai and T. Matsuda, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **88**, 66 (1967).

6) J. Reese, *Ber.*, **75**, 384 (1942).

5 prepared by the method described in the literature.[7]

Table 2 shows that *N,N',N''*-trichloroisocyanuric acid, which contains the most polar N–Cl bond, produced the condensation product in the highest yield. The second highest yield of the condensation product was obtained with NDCB, which has less polarity in the N–Cl bond. The weakest polar compound, NBS, did not afford the condensation product in a detectable yield.

Halogenation of Cyclohexene. The halogenation of cyclohexene with *N*-halo compounds can be a good measure of the polarity of the N–halogen bond in the compounds. The compounds which contain more polar N–halogen bond would facilitate the addition of halogen to the double bond over an allylic halogenation which proceeds through a free radical mechanism. If the *N*-halo compound contains a less polar N–halogen bond, the allylic halogenation would be favored over the addition reaction. This expectation was verified by those of our experiments shown in Table 3. The reaction of NDCB with cyclohexene afforded a mixture of 3-chlorocyclohexene, the product due to the radical substitution and 1,2-dichlorocyclohexane, the product due to the polar addition, in the molar ratio of 53 : 14. However, with the less polar *N*-halo compound, NBS, the sole product isolated was 3-bromocyclohexene, which was the product due to the free radical substitution. Thus, we may suppose that the polarity of the N–halogen bond which could be estimated by the polarographic measurement, would provide a good method for the systematization of the reactivities of *N*-halo compounds.

Table 3. Products obtained by the reactions of *N*-halo compounds with cyclohexene

Product	Yield of product (%)*		
	NDCB	NCS	NBS
3-Chlorocyclohexene	53	42	—
3,6-Dichlorocyclohexene	trace	21	—
1,2-Dichlorocyclohexane	14	4	—
3-Bromocyclohexene	—	—	68
3,6-Dibromocyclohexene	—	—	17
1,2-Dibromocyclohexane	—	—	—

* The yield was calculated on the basis that two chlorine atoms in NDCB, one chlorine atom in NCS and one bromine atom in NBS were participated in the reactions.

Experimental

All melting points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-S_2 infrared spectrometer. The glc data were obtained using a Yanagimoto GCG-5 DH gas chromatograph. Microanalyses were performed with a Yanagimoto MT-1 CHN Corder. The optical rotations were measured with a Perkin-Elmer 141 Polarimeter.

Materials. *N*-Bromosuccinimide (NBS), mp 174—175°C,[1] *N*-chlorosuccinimide (NCS),[8] mp 148—149°C, *N*-chlorophthalimide, mp 183°C,[1] and *N,N',N''*-trichloroisocyanuric acid, mp 245°C (dec.),[9] were prepared by the methods described in the literature and were used after purification by recrystallization from benzene.

N,N'-Dichlorobarbital (NDCB) was prepared by passing chlorine gas into an aqueous solution of barbital at room temperature. After the chlorine had been saturated, the reaction mixture was cooled and filtered. The solid thus obtained was washed with water and recrystallized from benzene, mp 125—127°C. The yield was almost quantitative.

Found: C, 38.19; H, 3.64; N, 11.29%. Calcd for $C_8H_{10}O_3N_2Cl_2$: C, 37.97; H, 3.98; N, 11.07%

The other reagents were of a commercial grade and were used after purification by recrystallization or distillation.

Proof of Structure and Determination of Yields of Products. The reaction products were usually identified by a comparision of their infrared spectra with those of the respective authentic samples. For liquid products, the retention times in glc were compared with those of the authentic samples. For solid products, mixture-melting point examinations and microanalyses were also performed.

The yields of products were determined by glc analyses or by measurement of the weights of the products.

The glc analysis was used for toluene, tetrahydrofuran, butanol, cyclohexene, butyraldehyde and cyclohexanone.

In the cases of carbonyl compounds, they were also converted to their 2,4-dinitrophenylhydrazones and weighed.

Preparation of the Authentic Samples. Authentic samples of butyl butyrate,[10] 2-chlorocyclohexanone,[11] 2-bromocyclohexanone,[12] 3-chlorocyclohexene,[2] 3-bromocyclohexene,[2] 1,2-dichlorocyclohexane,[13] and 2-(1-cyclohexenyl)cyclohexanone[5] were prepared according to the procedures described in the literature. 2-Ethyl-2-hexenylaldehyde was kindly provided by the Kyowa Hakko Kogyo Co., Ltd.

General Procedure for Reactions with NDCB. *In the Absence of a Solvent.* To an excess organic compound (20—30 g) NDCB (5—10 g) was added at room temperature with shaking. The reaction usually proceeded smoothly and exothermally. The mixture was then warmed for 30 min, if necessary. After standing for 30 min, the mixture was cooled and then filtered to remove the precipitated barbital. The filtrate was distilled, and the distillate was subjected to analysis.

In Carbon Tetrachloride. A saturated solution of 10 g of NDCB in carbon tetrachloride was added to a solution of 10 g of an organic compound in 50 m*l* of the same

solvent at room temperature. The mixture was then usually heated at reflux for 1 hr and cooled. The precipitated barbital was separated by filtration, the filtrate was concentrated to remove the solvent, and then the residue was distilled. The distillate was subjected to analysis.

General Procedure for Reactions with NBS. *In the Absence of a Solvent.* To an excess organic compound (10—15 g) NBS (2 g) was added at room temperature with shaking, and then the mixture was refluxed for several hours under nitrogen. (In the reactions with NBS, much more severe reaction conditions were required for the completion of reactions than those used for the reactions with NDCB.) After the mixture had then been cooled, succinimide was separated as a solid and removed by filtration. The filtrate was distilled, and the distillate was subjected to analysis.

In Carbon Tetrachloride. A solution of 2 g of an organic compound in 10 m*l* of carbon tetrachloride was added to a solution of 2 g of NBS in 20 m*l* of carbon tetrachloride at room temperature. After the mixture had then been refluxed for several hours and cooled, the solvent was evaporated. The residue was distilled, and the distillate was subjected to analysis. Succinimide was usually recovered from the residue as a solid.

Reactions of Camphor. *With NDCB.* A mixture of 5 g of NDCB and 5 g of *d*-camphor was heated at 140°C for 40 min and then sublimed at 80°C/5 mmHg. Sublimation gave 5.8 g (95%) of *exo*-3-chlorocamphor, mp 117—118°C; $[\alpha]_D^{20}$ +47.7° (*c* 0.52, C_2H_5OH) (lit., mp 117°C,[3] $[\alpha]_D^{20}$ +35°[3] (*c* 10, C_2H_5OH)).

Found: C, 60.39; H, 8.05%. Calcd for $C_{10}H_{15}OCl$: C, 60.77; H, 7.81%.

With NBS. A mixture of 4 g of NBS and 4 g of *d*-camphor was treated in the manner described above. The sublimation of the mixture at 60—70°C/4 mmHg afforded 4.1 g (80%) of *endo*-3-chlorocamphor, mp 75—77°C, $[\alpha]_D^{18}$ +117.0° (*c* 0.52, benzene) (lit., mp 77°C,[3] $[\alpha]_D^{18}$ +117.1°[3] (*c* 10, benzene)).

Found: C, 51.98; H, 6.54%. Calcd for $C_{10}H_{15}OBr$: C, 52.01; H, 6.46%.

Reaction of Cholestanone with NDCB. A mixture of 1 g of NDCB and 2 g of cholestanone was heated at 150°C for 30 min. The reaction mixture was then chromatographed on a column of alumina, using chloroform as an eluent. One fraction contained 700 mg (32%) of 2β-chlorocholestanone, which, after recrystallization from ethanol - water, showed a mp of 119—121°C, $[\alpha]_D^{22}$ +120.6° (*c* 0.34, $CHCl_3$) (lit., mp 120°C,[14] $[\alpha]_D^{22}$ +124°[14] (EtOH)), $\nu_{C=O}$; 1715 cm^{-1}.

Found: C, 77.32; H, 11.19%. Calcd for $C_{27}H_{45}OCl$: C, 77.00; H, 10.79%.

The other fraction contained 900 mg (41%) of 2α-chlorocholestanone, which, after recrystallization from ethanol-water, showed a mp of 174—179°C, $[\alpha]_D^{20}$ +42° (*c* 0.67, EtOH) (lit., mp 182°C, $[\alpha]_D^{20}$ +41° (EtOH)), $\nu_{C=O}$; 1730 cm^{-1}.

Found: C, 77.27; H, 10.66%. Calcd for $C_{27}H_{45}OCl$: C, 77.00; H, 10.79%.

Polarographic Measurements. The polarographic data were obtained with a Yanagimoto Model PA-102 recording polarograph, using a H-cell equipped with a Hg reference electrode. The capillary characteristics were: $m=0.544$ mg/sec, $t=3.5$ sec/drop at 60 cm. Sample solutions were prepared by dissolving *N*-halo compounds in dry DMF at a concentration of 0.1 mol/*l*. Potassium perchlorate, 0.1 mol/*l* and a few drops of a solution of polyvinyl chloride in DMF were added to the sample solutions as a supporting electrolyte and as a maximum suppressor, respectively. Measurements were made at room temperature after bubbling nitrogen into the solutions for 30 min.

Reaction of Cyclohexanone with *N,N',N''*-Trichloroisocyanuric Acid. A mixture of 3 g of *N,N',N''*-trichloroisocyanuric acid and 10 g of cyclohexanone was refluxed for 1 hr and then cooled. Cyanuric acid, which was separated as a solid, was removed by filtration. The distillation of the filtrate under reduced pressure afforded 1.42 g (39%) of 2-chlorocyclohexanone, 94—96°C/14 mmHg and 2.23 g (61%) of 2-(1-chlorocyclohexyl)cyclohexanone, 108—110°C/4 mmHg.

Conversion of 2-(1-Chlorocyclohexyl)cyclohexanone to 2-(1-Cyclohexenyl)cyclohexanone. A solution of 1 g of 2-(1-chlorocyclohexyl)cyclohexanone in 10 m*l* of pyridine was refluxed for 1 hr. After cooling, the mixture was acidified with dilute hydrochloric acid and extracted with ether. The ether was then evaporated, and the residue was distilled under reduced pressure; bp 105—108°C/3 mmHg. The product was identical with the authentic sample of 2-(1-cyclohexenyl)-cyclohexanone in every respect.

Reaction of Cyclohexene with NCS. A mixture of 1.5 g of NCS and 10 m*l* of cyclohexene was refluxed for 1 hr, and then cooled. The precipitated succinimide was removed by filtration, and the filtrate was distilled under reduced pressure. The glc analysis of the distillate showed that the distillate consisted of 3-chlorocyclohexene (42%), 3,6-dichlorocyclohexene (21%) and 1,2-dichlorocyclohexane in the yields indicated in parentheses.

The authors wish to thank Dr. J. Nakaya for his suggestions concerning the polarographic measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2129—2134 (1968)

The Preparation and Cycloaddition Reactions of Pentafluoro-1,3-pentadienes

Hiroshige MURAMATSU, Kan INUKAI and Teruo UEDA

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received March 1, 1968)

3,4,5,5,5-Pentafluoro-1,3-pentadienes were prepared from 1 : 1 adducts of perfluoropropylene and alcohols by dehydration followed by dehydrofluorination. When 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene was heated at 130—220°C, an intramolecular cyclization occurred to give 1-methyl-2,3-difluoro-3-trifluoromethylcyclobutene in 73—87% yields. α-Trifluoromethyl-β-acetylacrylic acid and 1-trifluoromethyl-2-fluoro-3-methylenecyclobutene were synthesized from the cyclobutene by oxidation and dehydrofluorination, respectively. Several polyfluorocyclobutanes with a perfluoropropenyl group were prepared by the cross-cycloaddition of the pentafluoro-1,3-pentadienes with the fluoroolefins such as 1,1-difluoro-2,2-dichloroethylene, trifluorochloroethylene, and perfluoropropylene.

Though fluorine-containing 1,3-butadienes have been prepared by various methods,[1] only a few papers[2] dealt with the syntheses of the polyfluoro-1,3-pentadienes. As the (2-hydroperfluoropropyl)-alkylcarbinols were found to be prepared in an excellent yield by the addition of alcohols to perfluoropropylene under γ-irradiation,[3] these carbinols were considered to be suitable intermediates for the syntheses of pentafluoro-1,3-pentadienes. Accordingly, (2-hydroperfluoropropyl)dimethylcarbinol was treated with phosphorus pentoxide to yield 2-methyl-3,3,4,5,5,5-hexafluoro-1-pentene,[3] which was subsequently dehydrofluorinated with potassium hydroxide to give 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene.

$$CF_3CF{=}CF_2 + CH_3CHROH \xrightarrow{\gamma\text{-ray}}$$

$$CF_3CHFCF_2CR(CH_3)OH \xrightarrow{P_2O_5}$$

$$CF_3CHFCF_2CR{=}CH_2 \xrightarrow{KOH} CF_3CF{=}CFCR{=}CH_2$$

(Ia R=H; Ib R=CH_3)

The pentafluoro-1,3-pentadienes (Ia,b) consisted of *cis* and *trans* isomers, the former being predominant.[4] The ratio of *cis* to *trans* varied with the condition of dehydrofluorination. Whereas the *cis* isomer was formed almost exclusively in dehydrofluorination with solid potassium hydroxide in the absence of a solvent, the ratio of *cis* to *trans* was about 2 : 1 in the presence of methanol or ethanol.

The assignment of the isomers to *cis* and *trans* were made unambiguously on the basis of the coupling constants[5] between vicinal F and CF_3, and those between vicinal F and F in their ^{19}F NMR spectra, whose parameters are shown in Table 1. Both isomers of pentafluoro-1,3-pentadienes polymerized upon standing in air and the rates of polymerization of the *trans* isomers were much greater than those of the *cis* isomers. From the NMR spectra, the structures of the polymers were found to be $[-CF(CF_3)CF{=}CRCH_2-]_n$, formed through the 1,4-polymerization.

Several papers have reported on the intramolecular cyclization of polyfluoro-1,3-dienes. Perfluoro-,[6] 2,3-dichloro-1,1,4,4-tetrafluoro-,[7] and 1,4-dichloro-1,2,3,4-tetrafluoro-1,3-butadiene[8] have produced the corresponding perhalocyclobutenes upon heating. When 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene was heated at 130—220°C, an intramolecular cyclization took place to give 1-methyl-2,3-difluoro-3-trifluoromethylcyclobutene (II) in approximately 80% yield. The effect of reaction temperature on the yield was shown in

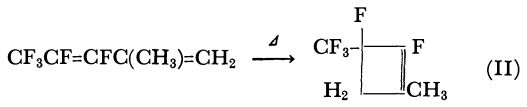
* Contained a small amount of the dimer of pentafluoropentadiene.

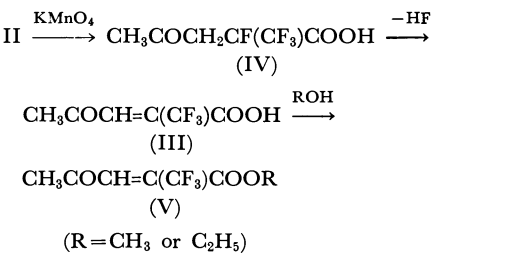
Table 2. The cyclization of 3,4,5,5,5-pentafluoro-1,3-pentadiene was unsuccessful due to polymerization to give viscous polymeric substance.



(II)

The structure of II was confirmed by elemental analysis, IR, and NMR spectra. In the ^{19}F NMR spectrum, a peak for the CF_3 group appeared as a doublet at 3.4 ppm caused by the splitting of a geminal fluorine ($J_{CF_3,F}$ 8.1 cps) and those for the =CF– and –CF– as a triplet and a multiplet at 37 and 100 ppm, respectively. The triplet may be due to a long range coupling with hydrogens of methylene group ($J_{F,H}$ 13.2 cps).[9]

The structure of II was further substantiated by the following reactions. Oxidation of II with potassium permanganate gave α-trifluoromethyl-β-acetylacrylic acid (III), which was obviously formed by dehydrofluorination of an intermediate, α-fluoro-α-trifluoromethyl-β-acetylpropionic acid (IV). Though two isomers of the disubstituted acrylic acid were possible, only the *trans* isomer was identified.

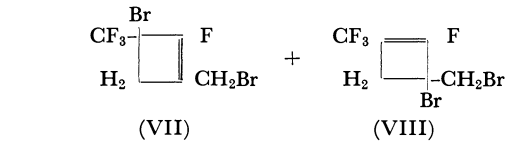


(R=CH_3 or C_2H_5)

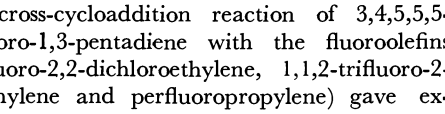
In esterification of III using *p*-toluenesulfonic acid as a catalyst, an isomerization took place to give a mixture of the *trans* and *cis* isomers, the *trans* ester being predominant (about 8 to 1 for R=CH_3; 6 to 1 for R=C_2H_5).

It has already been known[10] that carbonyl-containing groups in substituted olefins have long range deshielding effects on *cis*-β-hydrogen atoms and *cis*-β-methyl groups. The peak for the vinylic hydrogen of one isomer obtained in esterification appeared in a lower field by 0.7 ppm than that of the other isomer, but the peak for the methyl hydrogens in acetyl group of the former isomer appeared in a higher field by 0.6 ppm than that of the latter isomer. These chemical shifts of protons indicate the former to have the *trans* structure and the latter the *cis*. For the trifluoromethyl group, a deshielding effect of 0.6 ppm by the carbonyl group in the *cis* position was also observed in the ^{19}F NMR spectra. Table 3 gives the NMR parameters for methyl and ethyl α-trifluoromethyl-β-acetyl acrylates. It is seen that J^{cis}_{H,CF_3} is smaller than J^{trans}_{H,CF_3} in each of the esters.[11]

Treatment of II with potassium hydroxide produced 1-trifluoromethyl-2-fluoro-3-methylenecyclobutene (VI) through a 1,4-elimination. To a mixture of II and VI was added bromine under ultraviolet irradiation to yield the dibromocyclobutenes, (VII) and (VIII) in a ratio of 1 : 1.2. Debromination of VII and VIII gave the pure VI, which polymerized upon standing overnight, yielding a white solid polymer.

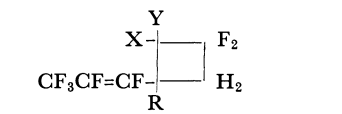


(VI)



(VII) (VIII)

The cross-cycloaddition reaction of 3,4,5,5,5-pentafluoro-1,3-pentadiene with the fluoroolefins (1,1-difluoro-2,2-dichloroethylene, 1,1,2-trifluoro-2-chloroethylene and perfluoropropylene) gave exclusively (perfluoropropenyl)cyclobutanes (IXa), no cyclohexenes being found.[12] In all the cases, the telomers of the pentadiene were formed as by-products. Similarly, 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene reacted with the fluoroolefins to give the (perfluoropropenyl)polyfluorocyclobutanes (IXb) together with II.



(IXa R=H; IXb R=CH_3)
(X, Y=Cl, F or CF_3)

Table 4 summarizes the yields based on the pentadienes added and the physical properties of polyfluorocyclobutanes containing a perfluoropropenyl group.

The cycloadducts IXa,b were identified by their NMR spectra and IR spectra ($\nu_{C=C}$ 1723—1729cm^{-1} for R=H, 1720—1726 cm^{-1} for R=CH_3). Further the 1-perfluoropropenyl-2-halo-3,3-difluorocyclobutenes (Xa,b) were synthesized by dehydrochlorination of the cycloadducts IXa. Xa was identical

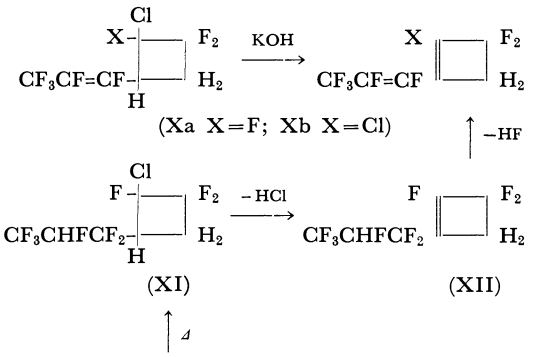
9) In some polyfluorocyclobutenes such as 1-phenyl-3,3,4-trifluoro-4-chlorocyclobutene and 1-phenyl-2,3,3-trifluorocyclobutene, the cross-ring couplings between H and F with $J_{H,F}$ of 8—12 cps were reported; C. M. Sharts and J. D. Roberts, *J. Am. Chem. Soc.*, **79**, 1008 (1957).

10) Ref. 5, p. 735.

11) For coupling constants between the vicinal F–F, F–CF_3, F–CH_3, or CF_3–CF_3 on the double bond in fluoroalkenes, it was found that $J^{cis}_{F,F}<J^{trans}_{F,F}$; $J^{cis}_{F,CF_3}>J^{trans}_{F,CF_3}$; $J^{cis}_{F,CH_3}<J^{trans}_{F,CH_3}$; $J^{cis}_{CF_3,CF_3}>J^{trans}_{CF_3,CF_3}$.

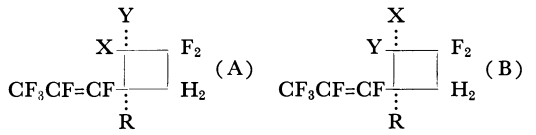
12) For a recent review on Diels-Alder reactions of organic fluorine compounds, see D. R. A. Perry, "Fluorine Chemistry Reviews," Vol. 1, P. Tarrant, ed., Marcel Dekker, Inc., New York (1967), p. 253.

with the product obtained in the dehydrohalogenation of the (2-hydroperfluoropropyl)polyhalocyclobutanes (XI), which was prepared by the cycloaddition of 3,3,4,5,5,5-hexafluoro-1-pentene and trifluorochloroethylene.



$CF_3CHFCF_2CH=CH_2 + CF_2=CFCl$

The cycloadducts formed in the cycloadditions of trifluorochloroethylene or perfluoropropylene with I were found from their ^{19}F NMR spectra to consist of the two isomers A and B in approximately equal amounts.



Experimental[13]

The NMR spectra were obtained using a JNM-C-60 high resolution spectrometer (60 Mc for ^1H and 56.4 Mc for ^{19}F). Tetramethylsilane was used for ^1H as an internal standard and trifluoroacetic acid for ^{19}F as an external standard.

3,4,5,5,5-Pentafluoro-1,3-pentadiene (Ia). 3,3,4,5,5,5-Hexafluoro-1-pentene was prepared as reported in a previous paper.[3] In a 200 m*l* flask equipped with a stirrer and a reflux condenser was placed 105 g (0.59 mol) of the hexafluoro-1-pentene. After powdered potassium hydroxide (30 g) was added, the mixture was heated at 65—75°C for 1 hr with stirring. A gas chromatogram of the reaction mixture indicated that about 20% of the reactant was dehydrofluorinated. Addition of potassium hydroxide (30 g) and heating of the reaction mixture (65—75°C, 1 hr) were repeated four times. Distillation of the mixture gave 81 g (0.51 mol, 86% yield) of 3,4,5,5,5-pentafluoro-1,3-pentadiene, bp 40—41°C, n_D^{20} 1.3372, d_4^{20} 1.266, $\nu_{C=C}$ 1696 and 1612 cm^{-1}. The gas chromatogram and ^{19}F NMR spectrum of the pentadiene indicated that it consisted of almost exclusively the *cis* form.

Found: C, 38.65; H, 2.90%. Calcd for $C_5H_3F_5$: C, 37.99; H, 3.19%

When the pentadiene was stored in air, it polymerized gradually to yield viscous polymer, whose structure was confirmed to be $[-CF(CF_3)CF=CHCH_2-]_n$ from its ^{19}F NMR spectrum. δ_{CF_3} 2.3 ppm, $\delta_{-CF=}$ 41 ppm (broad doublet, $J_{H,F}$ 30 cps), $\delta_{-\underset{|}{CF}-}$ 95 ppm.

2-Methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene (Ib). *a) Dehydrofluorination with Solid Potassium Hydroxide.* 2-Methyl-3,3,4,5,5,5-hexafluoro-1-pentene (86 g, 0.43 mol) prepared as reported[3] was treated with powdered potassium hydroxide (144 g) as mentioned above to give 63 g (0.37 mol, 86% yield) of 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene, bp 61—62°C, n_D^{20} 1.3357, d_4^{20} 1.211, $\nu_{C=C}$ 1719 and 1644 cm^{-1}. The gas chromatogram (DOP column, 2 m, 84°C, carrier gas He, 37 m*l*/min) of the pentadiene obtained showed two peaks, that of the *cis* isomer (retention time, 5.0 min) and of the *trans* isomer (6.7 min), in a ratio of 97: 3.

Found: C, 41.81; H, 2.95%. Calcd for $C_6H_5F_5$: C, 41.87; H, 2.93%.

b) Dehydrofluorination with Alcoholic Potassium Hydroxide Solution. In a 300 m*l* flask with a stirrer was placed 50.2 g (0.26 mol) of the 2-methylhexafluoro-1-pentene. A solution of 25 g (0.45 mol) of potassium hydroxide in 150 m*l* of ethanol was added drop by drop and the mixture was poured into water. The organic layer (39.5 g) was separated, dried and distilled to give 34.5 g (0.20 mol, 77% yield) of the 2-methylpentafluoro-1,3-pentadiene, whose gas chromatogram showed presence of the *cis* and *trans* isomers in a ratio of 7: 3.

A similar treatment of the 2-methylhexafluoro-1-pentene with potassium hydroxide in methanol gave the 2-methylpentafluoro-1,3-pentadiene in a yield of 45%. The ratio of *cis* and *trans* was 6: 4.

1-Methyl-2,3-difluoro-3-trifluoromethylcyclobutene (II). A 300 m*l* stainless-steel autoclave was charged with 93 g (0.54 mol) of 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene (*cis* : *trans* 97: 3) and 10 g of Terpene B. The mixture was kept at 150°C for 21 hr. The resultant mixture was distilled to give a fraction boiling at 78—82°C and a viscous residue (20 g), which was presumed to be a mixture of Terpene B and the telomer of the pentadiene. The distillate consisted of 3.6 g of the unchanged pentadiene and 74 g (0.43 mol, 80% yield) of 1-methyl-2,3-difluoro-3-trifluoromethylcyclobutene, which was redistilled to give the pure II, bp 79—80°C, n_D^{20} 1.3291, d_4^{20} 1.263, $\nu_{C=C}$ 1738 cm^{-1}.

Found: C, 42.09; H, 2.99%. Calcd for $C_6H_5F_5$: C, 41.87; H, 2.93%.

The effect of the reaction temperature on the yield was shown in Table 2, which indicates an optimum temperature to be in 140—200°C. Above 200°C, the yield decreased presumably because of the polymerization of the pentadiene.

α-Trifluoromethyl-β-acetylacrylic Acid (III). An aqueous solution of potassium permanganate (58 g, 0.37 mol) was added to 42 g (0.24 mol) of 1-methyl-2,3-difluoro-3-trifluoromethylcyclobutene in acetone. After removal of manganese dioxide by filtration, the filtrate was acidified with sulfuric acid and extracted with ether. Vacuum distillation of the extract gave 24 g (0.13 mol, 54% yield) of crude α-trifluoromethyl-β-acetyl acrylic acid, bp 106—107°C/7 mmHg, and a tarry residue (11 g). The crude acid containing a small amount of α-fluoro-α-trifluoromethyl-β-acetylpropionic acid, δ_{CF_3} 2.1 ppm (doublet), $J_{CF_3,F}$ 7.5 cps, $\delta_{-\underset{|}{CF}-}$ 87 ppm (multiplet), was recrystallized from benzene to give white needles, mp 70—71°C.

Found: C, 38.72; H, 2.65%; Neut. equiv. 180.

13) All temperature readings are uncorrected.

Calcd for $C_6H_5O_3F_3$: C, 39.57; H, 2.77%; Neut. equiv. 182.

Methyl and Ethyl α-Trifluoromethyl-β-acetylacrylate (V). A mixture of α-trifluoromethyl-β-acetylacrylic acid (9 g), methanol (50 ml), benzene (30 ml), and *p*-toluenesulfonic acid was refluxed for 6 hr and extracted with ether. Distillation of the extract gave 3.5 g of methyl α-trifluoromethyl-β-acetylacrylate (a mixture of *trans* and *cis* isomers), bp 90—92°C/18 mmHg, n_D^{20} 1.3992, d_4^{20} 1.305.

Found: C, 42.53; H, 2.65%. Calcd for $C_7H_7O_3F_3$: C, 42. 87; H, 3.60%.

The gas chromatogram (Silicone DC-550 column, 2 m, 167°C, carrier gas He, 58 ml/min) of the methyl ester showed two peaks of the *trans* isomer (retention time, 6.6 min) and the *cis* isomer (10.7 min) in an area ratio of 8: 1.

Ethyl α-trifluoromethyl-β-acetylacrylate (10 g) was prepared from the acrylic acid (9 g) in a similar way as described above. The gas chromatogram of the ethyl ester showed two peaks, that of the *trans* (8.8 min) and of thd *cis* (19.8 min) in a ratio of 6: 1. bp 95—99°C/18 mmHg, n_D^{20} 1.3998, d_4^{20} 1.248.

Found: C, 45.40; H, 4.25%. Calcd for $C_8H_9O_3F_3$: C, 45.72; H, 4.32%.

1-Fluoro-2-bromomethyl- 4 - bromo - 4 - trifluoromethylcyclobutene (VII) and 1-Fluoro-2-trifluoromethyl-4-bromo-4-bromomethyl-cyclobutene(VIII). A mixture of 130 g (0.76 mol) of 1-methyl-2,3-difluoro-3-trifluoromethylcyclobutene and 30 g of powdered potassium hydroxide was heated at about 110°C for 1 hr with stirring. Addition of potassium hydroxide (30 g) was repeated seven times and the gas chromatogram of the reaction mixture indicated the formation of 27 g (0.18 mol, 24% yield) of 1-trifluoromethyl-2-fluoro-3-methylenecyclobutene. To the reaction mixture, bromine (29 g, 0.18 mol) was added drop by drop under UV irradiation, and the distillation of the mixture gave a fraction boiling at 63—68°C/18.5 mmHg (43 g, 0.14 mol, 78% yield), which was a mixture of the dibromocyclobutenes, 1,4-adduct VII and 1,2-adduct VIII in a ratio of 1: 1.2. The dibromocyclobutenes were separated by a preparative gas chromatograph.

VII: n_D^{20} 1.4630, d_4^{20} 1.953, $\nu_{C=C}$ 1724 cm^{-1}, δ_{CF_3} −4.0 ppm (singlet), $\delta_{-CF=}$ 21 ppm (triplet), $J_{CH_2,F}$ 13 cps.

Found: C, 23.11; H, 1.37%. Calcd for $C_6H_4F_4Br_2$: C, 23.11; H, 1.29%.

VIII: n_D^{20} 1.4441, d_4^{20} 1.927, $\nu_{C=C}$ 1736 cm^{-1}, δ_{CF_3} −14.0 ppm (doublet), $\delta_{-CF=}$ 11 ppm (triplet of quartet), $J_{CF_3,F}$ 10 cps, $J_{CH_2,F}$ 13 cps.

Found: C, 22.71; H, 1.42%. Calcd for $C_6H_4F_4Br_2$: C, 23.11; H, 1.29%.

1-Trifluoromethyl - 2 - fluoro - 3 - methylenecyclobutene (VI). The dibromocyclobutenes described above was treated with zinc dust in hexanol to give quantitatively 1-trifluoromethyl-2-fluoro-3-methylenecyclobutene, bp 42—43°C, n_D^{20} 1.3640, d_4^{20} 1.191, $\nu_{C=C}$ 1720 and 1671 cm^{-1}, δ_{CF_3} −13.6 ppm (doublet), $\delta_{-CF=}$ 17 ppm (multiplet), $J_{CF_3,F}$ 12 cps.

Found: C, 42.37; H, 2.85%. Calcd for $C_6H_4F_4$: C, 42.61; H, 2.89%.

Preparations of the (Perfluoropropenyl)polyfluorocyclobutanes (IXa). A mixture of 136 g (0.86 mol) of 3,4,5,5,5-pentafluoro-1,3-pentadiene, 99 g (0.85 mol) of trifluorochloroethylene, and 10 g of Terpene B in a 300 ml autoclave was heated at 200°C for 21 hr. The content was poured into methanol to yield white polymers (48 g), which were separated by filtration. The filtrate was treated with water to remove methanol, and an organic layer was distilled to give the unchanged pentadiene, hexafluorodichlorocyclobutane (14.2 g), and 116 g (0.42 mol, 49% yield) of 1-(perfluoropropenyl)-2-chloro-2,3,3-trifluorocyclobutane, bp 119—120°C.

The cross-cycloaddition of 3,4,5,5,5-pentafluoro-1,3-pentadiene and other polyfluoroolefins was carried out under similar conditions.

Preparations of the (Perfluoropropenyl)methylpolyfluorocyclobutanes (IXb). A mixture of 85 g (0.49 mol) of 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene, 70 g (0.53 mol) of 1,1-difluoro-2,2-dichloroethylene, and 10 g of Terpene B was charged into an autoclave and heated at 202°C for 24 hr. The contents were poured into methanol to give dark colored polymers (27 g), which were then filtered. After the filtrate had been treated with water, the organic layer was separated, dried, and distilled to give a small amount of tetrafluorotetrachlorocyclobutane, 8 g (0.04 mol, 9% yield) of II, and 54 g (0.18 mol, 36% yield) of 1-methyl-1-perfluoropropenyl -2,2- dichloro - 3,3 - difluorocyclobutene, bp 90—92°C/64 mmHg.

The cross-cycloaddition of 2-methyl-3,4,5,5,5-pentafluoro-1,3-pentadiene and other polyfluoroolefins was carried out under similar conditions.

1-Perfluoropropenyl - 2, 3, 3 - trifluorocyclobutene (Xa). To 49 g (0.18 mol) of 1-perfluoropropenyl-2,3,3-trifluoro-2-chlorocyclobutane, 15 g (0.27 mol) of potassium hydroxide in 100 ml of ethanol were added drop by drop over a 1 hr period at room temperature. The mixture was stirred for 30 min and then poured into water. The organic layer (42 g) was separated, dried, and distilled to give 20 g (0.085 mol, 48% yield) of Xa, bp 80—81°C, n_D^{20} 1.3551, d_4^{20} 1.219, $\nu_{C=C}$ 1715 and 1663 cm^{-1}.

Found: C, 35.69; H, 1.19%. Calcd for $C_7H_2F_8$: C, 35.31; H, 0.85%.

1-Perfluoropropenyl-2-chloro - 3, 3 - difluorocyclobutene (Xb). 1-Perfluoropropenyl-2,2-dichloro-3,3-difluorocyclobutane (33 g, 0.11 mol) was treated with potassium hydroxide as mentioned above to give 19.4 g (0.076 mole, 67% yield) of Xb, bp 120—121°C, n_D^{20} 1.3958, d_4^{20} 1.561, $\nu_{C=C}$ 1687 and 1601 cm^{-1}.

Found: C, 32.03; H, 0.79; Cl, 13.2%. Calcd for $C_7H_2F_7Cl$; C, 31.18; H, 0.87; Cl, 13.9%.

1-Hexafluoropropyl-2-chloro - 2,3,3-trifluorocyclobutane (XI). A mixture of 117 g (0.65 mol) of 3,3,4,5,5,5-hexafluoro-1-pentene, 98 g (0.84 mol) of trifluorochloroethylene, and 5 g of Terpene B was charged into a 300 ml autoclave and heated at 200°C for 48.5 hr. Distillation yielded 32 g (0.11 mol, 17% yield) of 1-hexafluoropropyl-2-chloro-2,3,3-trifluorocyclobutane, bp 80—82°C/138 mmHg, n_D^{20} 1.3504, d_4^{20} 1.592.

Found: C, 28.54; H, 1.37%. Calcd for $C_7H_4F_9Cl$: C, 28.72; H, 1.24%.

1 - Hexafluoropropyl - 2,3,3 - trifluorocyclobutene (XII). To 28 g (0.094 mol) of XI, 6.3 g (0.11 mol) of potassium hydroxide in 50 ml of ethanol were added dropwise at room temperature. The mixture was poured into water and the organic layer (25 g) was separated and distilled to give 8.2 g (0.032 mole, 34% yield) of 1-hexafluoropropyl-2,3,3-trifluorocyclobutene, bp 93—96°C, n_D^{20} 1.3202, d_4^{20} 1.529, $\nu_{C=C}$ 1733 cm^{-1}.

Found: C, 32.57; H, 1.17%. Calcd for $C_7H_3F_9$: C, 32.01; H, 1.33%.

Treatment of XII with powdered potassium hydroxide produced (perfluoropropenyl)trifluorocyclobutene Xa in a yield of 50%.

The authors wish to thank Mr. H. Sugita of Government Industrial Research Institute, Tokyo, for the carbon and hydrogen analyses.

Studies on Separation of Amino Acids and Related Compounds. IV. Separation of Diastereomeric Tripeptides Containing Basic and Acidic Amino Acid Residue[1]

Masako MURAOKA, Norio YOSHIDA, Kosaku NODA and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received March 4, 1968)

Twelve pure tripeptides have been synthesized and the separation of each mixture composed of two diastereomeric tripeptides with an amino acid analyzer has been studied. Among six model systems of diastereomeric mixture studied, a mixture of the LL and LD isomers of glycyl-ornithyl-glutamic acid was separated most efficiently.

The several methods of measuring the extent of racemization of the step of the peptide bond formation have been reported in the literature.[2] Anderson *et al.*[3] found that benzyloxycarbonyl-glycyl-L-phenylalanyl-glycine ethyl ester can be separated from the racemate by fractional crystallization in which the less soluble racemate separates in the first crops; many investigators have used this Anderson's test for the study of racemization as a model system in different coupling procedures.[2] Williams *et al.* suggested the fractional crystallization of benzoyl-leucyl-glycine ethyl ester which is synthesized from benzoyl-L-leucine and glycine ethyl ester with a coupling procedure.[4] Clayton *et al.* indicated that a diastereomeric mixture of benzyloxycarbonyl-glycyl-alanyl-L-phenylalanyl-glycine can be separated by countercurrent distribution.[5] Weygand *et al.* have taken advantage of separating diastereomeric trifluoroacetyl-dipeptide methyl esters by gas chromatography for the study of racemization.[6] Taschner *et al.* were able to detect a small amount of the LD diastereomer in an LL dipeptide by paper chromatography; they have applied this technique in order to examine the degree of racemization caused by the activation of an acyl-dipeptide acid.[7] Halpern *et al.* have described the use of NMR procedure for detection of racemization.[8]

We have been attempting to find a convenient procedure of racemization-test with the application an of amino acid analyzer. A procedure which we have designed is as follows. When an acyl-dipeptide acid is condensed with an amino acid benzyl ester by an usual coupling method, an acyl-tripeptide benzyl ester will be obtained. The crude product is subjected directly to hydrogenolysis, and the hydrogenated material is submitted to an amino acid

$$\text{Z-Gly-L-A-OH} + \text{H-L-B-OBzl} \xrightarrow[\text{racemization of A residue)}]{\text{(with partial or complete}} \text{Z-Gly-A-B-OBzl (LL isomer + DL isomer)} \xrightarrow[H_2]{} \text{H-Gly-A-B-OH (LL isomer + DL isomer)}$$

analyzer (Fig. 1). In the present paper we describe the syntheses of several model peptides and the separation experiments of each mixture of diastereomeric peptides by the analyzer.

The literature survey on the separation of dipeptide diastereomers by an amino acid analyzer, has revealed that two groups reported the separation of a mixture of alanyl-alanines.[9] We also described in the previous paper the separation of leucyl-valine diastereomers.[1] Though the model dipeptides are not true diastereomers it would be of interest to note that Kornguth *et al.* have reported the complete separation of a mixture of ε-(α-L-glutamyl)-L-lysine and ε-(γ-L-glutamyl)-L-lysine.[10] A separation study of tripeptide diastereomers by an amino acid analyzer has not been performed to date as far as we recognize.

For model peptide, we chose tripeptide, which is composed of glycine, a basic and an acidic amino acid, with the surmise that a diastereomeric mixture of this polyfunctional neutral tripeptide might be efficiently separated under an appropriate condition. Each pure diastereomer of glycyl-lysyl-glutamic acid, glycyl-lysyl-aspartic acid, glycyl-ornithyl-glutamic acid and glycyl-ornithyl-aspartic acid were prepared in the conventional manner as the first step of the study. For example, glycyl-L-lysyl-L-glutamic acid was synthesized as shown in Fig. 2. Thus eight tripeptides (XXIII—XXX) of Gly-Lys-Glu type were obtained as hygroscopic crystals and their homogeneity was ascertained by paper and thin-layer chromatographies and electrophoresis.

As the control material for the experiment with the analyzer, several dipeptides (VII—X) of Lys-Glu type were also synthesized by the usual way.

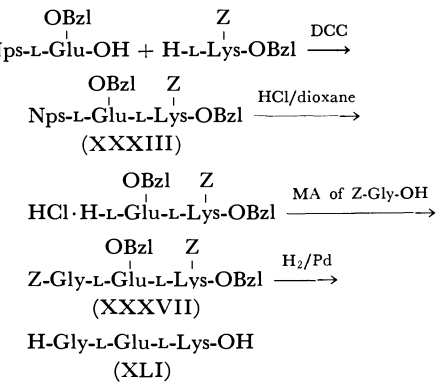

Fig. 3. Sequence of synthesis of tripeptide (XLI).
Nps-, *o*-nitrophenylsulfenyl; DCC, dicyclohexylcarbodiimide.

Since any mixture of diastereomeric tripeptides of Gly-Lys-Glu type was not separated completely by the analyzer as described later, syntheses of model tripeptides of Gly-Glu-Lys type were further attempted. Each pure diastereomer of glycyl-glutamyl-lysine and glycyl-aspartyl-lysine was prepared in the manner of the stepwise elongation to preclude racemization. For example, synthetic sequence of glycyl-L-glutamyl-L-lysine was noted in Fig. 3.

As a preliminary experiment, separation studies of mixture of diastereomeric peptides with paper chromatography and electrophoresis were performed. As noted in Table 1, it was observed that the mixture of dipeptide diastereomers was separated each other more efficiently in general than a mixture of tripeptides.

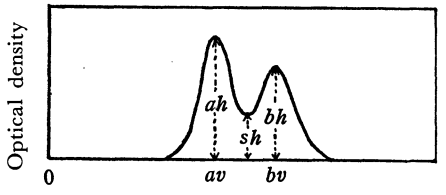

Fig. 4. Model elution pattern of a diastereomeric mixture.

A model elution pattern of a mixture composed of two diastereomers in the same amounts by an amino acid analyzer was indicated in Fig. 4. For the approximate expression of the efficiency of separation, we introduced the term rs, apparent ratio of separation; rs is calculated by the equation of $[sh/(ah+bh)\times 2]\times 100$.

Each mixture of the diastereomeric dipeptides or tripeptides was subjected to the analyzer. For the elution of columns three procedures were employed and the results obtained were summarized in Table 2. In procedure (i) the elution was carried out with a medium column (0.9×50 cm) and pH 5.28 buffer; any peptide mixture was found not to be

a) With medium column (0.9×50 cm) and 0.2 M sodium citrate buffer (pH 5.28).
b) With small column (0.6×10 cm) and 0.2 M sodium citrate buffer (pH 4.25).
c) With the small column, 0.2 M sodium citrate at pH 3.25 was applied until 360 m*l*, and then the system was changed to the pH 4.25 buffer.

separated. In scheme (ii) a smaller column (0.6 ×10 cm) was used and eluted with pH 4.25 buffer; any tripeptide system of Gly-Glu-Lys or Gly-Lys-Glu type was no separated though both dipeptide systems separated considerably. In scheme (iii) the elution was initiated with pH 3.25, and at fraction 360 m*l* the eluting solution was changed to pH 4.25 buffer. At first four systems of Gly-Lys-Glu type were studied; although separation of glycyl-ornithyl-glutamic acid diastereomers occurred most efficiently, the separation was not still completed (Fig. 7). Therefore, the analysis was further extended to two model systems of glycyl-glutamyl-lysine and glycyl-aspartyl-lysine; the results were

worse than that of the system of glycyl-ornithyl-glutamic acid. Several chromatographic patterns obtained were indicated in Figs. 5—7 for examples.

Though it appears that a reaction sequence to afford glycyl-ornithyl-glutamic acid from benzyloxycarbonyl-glycyl-δ-benzyloxycarbonyl-L-ornithine and L-glutamic acid dibenzyl ester can be used for the detection of racemization, the separation study of several dipeptide diastereomers, such as α-acetyl-lysyl-alanine, and tripeptide diastereomers is being continued in this laboratory in order to find a model system in better separation.

Experimental

The melting points were uncorrected. Optical rotations were determined with a Yanagimoto Photometric Polarimeter, OR-20 type.

D-Glutamic Acid Dibenzyl Ester *p*-Toluenesulfonate (I). This compound was obtained according to the procedure for the L-isomer.[11] Yield, 72%; mp 140—141°C; $[\alpha]_D^{20}$ −6.9° (*c* 2, methanol). Reported value for the L-isomer; mp 142°C; $[\alpha]_D$ +7.6° (methanol).[11]

D-Aspartic Acid Dibenzyl Ester *p*-Toluenesulfonate (II). This compound was obtained according to the procedure for the L-isomer.[11] Yield, 81%; mp 155—156°C; $[\alpha]_D^{20}$ +1.0° (*c* 2, methanol). Reported value for the L-isomer; mp 151—152°C; $[\alpha]_D^{20}$ +1.0° (methanol).[11,12]

Dibenzyloxycarbonyl-lysyl-glutamic Acid Dibenzyl Ester. *The LL Isomer (III).* A suspension of dibenzyloxycarbonyl-L-lysine dicyclohexylammonium salt[13] (1.78 g, 3 mmol) in ethyl acetate was stirred with 0.5 M citric acid (12 m*l*) during 1 hr. The ethyl acetate layer was separated and washed with water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo* and the residual oil (dibenzyloxycarbonyl-L-lysine) was dissolved in tetrahydrofuran (6 m*l*). The solution was treated with triethylamine (0.42 m*l*, 3 mmol) and isobutyl chloroformate (0.39 m*l*, 3 mmol) at −5°C.[14] After 15 min, a mixture of L-glutamic acid dibenzyl ester *p*-toluenesulfonate (1.50 g, 3 mmol) in chloroform (6 m*l*) and triethylamine (0.42 m*l*, 3 mmol) was added. The mixture was left to stand overnight at room temperature, and then evaporated *in vacuo*. The residue was dissolved in ethyl acetate (20 m*l*), then the solution was washed successively with 4% sodium bicarbonate, 2% hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*, and the oily residue was solidified by the addition of ether and petroleum ether. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 1.51 g (70%); mp 113°C; $[\alpha]_D^{25}$ −14.2° (*c* 1, dimethylformamide).

Found: C, 67.85; H, 6.42; N, 5.98%. Calcd for $C_{41}H_{45}N_3O_9$: C, 68.03; H, 6.27; N, 5.81%.

The LD Isomer (IV). This compound was obtained from dibenzyloxycarbonyl-L-lysine and I by the mixed anhydride method described above. Yield, 55%; mp 95°C; $[\alpha]_D^{20}$ +6.4° (*c* 1, dimethylformamide).

Found: C, 68.03; H, 6.32; N, 5.98%.

Dibenzyloxycarbonyl-lysyl-aspartic Acid Dibenzyl Ester. *The LL Isomer (V).* This compound was obtained from dibenzyloxycarbonyl-L-lysine and L-aspartic acid dibenzyl ester by the mixed anhydride method. Yield, 74%; mp 139—140°C; $[\alpha]_D^{25}$ −9.4° (*c* 1, dimethylformamide).

Found: C, 67.68; H, 6.11; N, 5.92%. Calcd for $C_{40}H_{43}N_3O_9$: C, 67.44; H, 6.52; N, 5.92%.

The LD Isomer (VI). This compound was obtained from dibenzyloxycarbonyl-L-lysine and II. Yield, 66%; mp 97—98°C; $[\alpha]_D^{20}$ +6.2° (*c* 1, dimethylformamide).

Found: C, 67.65; H, 6.19; N, 5.98%.

Lysyl-glutamic Acid (Lys-Glu). *The LL Isomer (VII).* A solution of III (0.72 g, 1 mmol) in a mixture of acetic acid (3 m*l*), methanol (1.2 m*l*) and water (0.6 m*l*) was treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* to dryness. The residual crystals were recrystallized from water - ethanol. Yield, 0.23 g (85%); mp 194—196°C (decomp.); $[\alpha]_D^{20}$ +20.1° (*c* 3.1, water) (Found as a hemihydrate: C, 46.34; H, 7.91; N, 14.49%). Bergmann *et al.*[15] reported the synthesis of this compound by hydrogenolysis of Z-L-Lys(ε-Z)-L-Glu-OH which was obtained through the saponification of Z-L-Lys(ε-Z)-L-Glu(γ-OEt)-OEt; mp 197°C; $[\alpha]_D^{19}$ +22.9° (water).

The LD Isomer (VIII). This compound was obtained by hydrogenolysis of IV as described above; yield, 96%; $[\alpha]_D^{20}$ +33.4° (*c* 1, water). The elemental analysis could not be performed because of its hygroscopic character compared with the LL isomer (VII), however the homogeneity of this compound VIII was confirmed by paper chromatography and electrophoresis.

Lysyl-aspartic Acid (Lys-Asp). *The LL Isomer (IX).* This compound was obtained by hydrogenolysis of V. Yield, 86%; $[\alpha]_D^{25}$ +25.3° (*c* 1.3, water) (Found as a monohydrate: C, 42.81; H, 7.73; N, 14.68%). Bergmann *et al.*[16] reported the synthesis of this compound by hydrogenolysis of Z-L-Lys(ε-Z)-L-Asp-OH; $[\alpha]_D^{25}$ +23° (water).

The LD Isomer (X). The compound VI was hydrogenated and the filtrate from the catalyst was evaporated to dryness. The residual crystals were collected with the aid of ethanol. Yield, 86%; mp 180—182°C (decomp.); $[\alpha]_D^{25}$ +30.6° (*c* 1, water).

Found: C, 42.66; H, 7.86; N, 14.68%. Calcd for $C_{10}H_{19}O_5N_3 \cdot H_2O$: C, 43.00; H, 7.58; N, 15.03%.

Benzyloxycarbonyl-glycyl-ε-benzyloxycarbonyl-L-lysine Ethyl Ester (XI). This compound was obtained from benzyloxycarbonyl-glycine and ε-benzyloxycarbonyl-L-lysine ethyl ester *p*-toluenesulfonate[17] by the mixed anhydride method as described for the preparation of III. Yield, 76%; mp 77—78°C; $[\alpha]_D^{21}$ +3.2° (*c* 1, ethyl acetate).

Found: C, 62.50; H, 6.66; N, 8.42%. Calcd for $C_{26}H_{33}O_7N_3$: C, 62.49; H, 6.87; N, 8.43%.

Benzyloxycarbonyl-glycyl-ε-benzyloxycarbonyl-L-lysine Hydrazide (XII). A solution of XI (4.99 g, 10 mmol) and hydrazine hydrate (1.21 ml, 25 mmol) in methanol was allowed to stand at 30°C for 48 hr. The excess hydrazine was evaporated *in vacuo*, and then water (50 ml) was added to the residue. The resulting crystals were collected by filtration and washed with water. Yield, 4.3 g (91%); mp 163—165°C; $[\alpha]_D^{25}$ −1.2° (*c* 1, dimethylformamide) (Found: C, 59.25; H, 6.31; N, 14.41%). Erlanger and Brand[18] reported the synthesis of this compound from Z-Gly-L-Lys(ε-Z)-OMe with hydrazine; mp 167°C.

Benzyloxycarbonyl-glycyl-δ-benzyloxycarbonyl-L-ornithine Ethyl Ester (XIII). This compound was obtained from benzyloxycarbonyl-glycine and δ-benzyloxycarbonyl-L-ornithine ethyl ester *p*-toluenesulfonate[19] by the mixed anhydride method as described for the preparation of III. Yield, 71%; mp 79—80°C; $[\alpha]_D^{20}$ −7.6° (*c* 1, dimethylformamide).

Found: C, 61.84; H, 6.44; N, 8.66%. Calcd for $C_{25}H_{31}O_7N_3$: C, 61.58; H, 6.32; N, 8.56%.

Benzyloxycarbonyl-glycyl-δ-benzyloxycarbonyl-L-ornithine Hydrazide (XIV). The compound XIII was converted to the hydrazide as described for the preparation of XII. Yield, 87%; mp 141—143°C; $[\alpha]_D^{20}$ +0.8° (*c* 1, dimethylformamide).

Found: C, 58.10; H, 6.25; N, 14.75%. Calcd for $C_{23}H_{29}O_6N_5$: C, 58.18; H, 6.24; N, 14.62%.

Benzyloxycarbonyl-glycyl-ε-benzyloxycarbonyl-lysyl-glutamic Acid Dibenzyl Ester. *The LL Isomer (XV).* To a chilled solution of XII (1.94 g, 4 mmol) in glacial acetic acid (40 ml) and 2 N hydrochloric acid (2.4 ml) was added sodium nitrite (0.32 g) with stirring. After the solution had been allowed to stand for 5 min at −5°C, it was diluted with cold water (100 ml), and the protected dipeptide azide was extracted three times with 50 ml portions of ethyl acetate. The combined ethyl acetate solution was washed with 4% sodium bicarbonate and water, dried over sodium sulfate, and then added to a cold solution of L-glutamic acid dibenzyl ester *p*-toluenesulfonate (2.00 g, 4 mmol) in triethylamine (0.56 ml, 4 mmol) and dimethylformamide (10 ml). After the mixture had been stirred for 3 days at 0°C and evaporated *in vacuo*, the residue was dissolved in ethyl acetate and washed successively with 4% sodium bicarbonate, 2% hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo* and the oily residue was solidified by the addition of ether and petroleum ether. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 2.17 g (69%); mp 117—118°C; $[\alpha]_D^{20}$ −10.8° (*c* 1, dimethylformamide). For the elemental analysis, a part of the crystals was purified further by column chromatography of Sephadex LH-20 (column size; 0.9×50 cm) using dioxane as a solvent.

Found: C, 65.82; H, 6.20; N, 7.28%. Calcd for $C_{43}H_{48}O_{10}N_4$: C, 66.14; H, 6.20; N, 7.18%.

The LD Isomer (XVI). This compound was obtained from XII and I by the azide method. Yield, 63%; mp 122°C; $[\alpha]_D^{20}$ +3.6° (*c* 1, dimethylformamide).

Found: C, 65.87; H, 6.26; N 7.38%.,

Benzyloxycarbonyl-glycyl-ε-benzyloxycarbonyl-lysyl-aspartic Acid Dibenzyl Ester. *The LL Isomer (XVII).* The protected tripeptide ester (XVII—XXII) were obtained in the same manner from the corresponding protected dipeptide hydrazide (XII or XIV) and the corresponding amino acid dibenzyl ester as described for the preparation of XV. Yield, 64%; mp 122—123°C; $[\alpha]_D^{20}$ −8.6° (*c* 1, dimethylformamide).

Found: C, 65.72; H, 6.10; N, 7.44%. Calcd for $C_{42}H_{46}O_{10}N_4$: C, 65.76; H, 6.05; N, 7.31%.

The LD Isomer (XVIII). Yield, 60%; mp 105—106°C; $[\alpha]_D^{20}$ +6.2° (*c* 1, dimethylformamide).

Found: C, 65.31; H, 6.15; N, 7.76%.

Benzyloxycarbonyl-glycyl-δ-benzyloxycarbonyl-ornithyl-glutamic Acid Dibenzyl Ester. *The LL Isomer (XIX).* Yield, 61%; mp 84°C; $[\alpha]_D^{20}$ −10.0° (*c* 1, dimethylformamide).

Found: C, 65.46; H, 6.05; N, 7.18%. Calcd for $C_{42}H_{46}O_{10}N_4$: C, 65.76; H, 6.05; N, 7.31%.

The LD Isomer (XX). Yield, 76%; mp 96°C; $[\alpha]_D^{20}$ +5.2° (*c* 1, dimethylformamaide).

Found: C, 65.37; H, 6.00; N, 7.33%.

Benzyloxycarbonyl-glycyl-δ-benzyloxycarbonyl-ornithyl-aspartic Acid Dibenzyl Ester. *The LL Isomer (XXI).* Yield, 64%; mp 127—129°C; $[\alpha]_D^{20}$ −8.0° (*c* 1, dimethylformamide).

Found: C, 65.03; H, 5.83; N, 7.84%. Calcd for $C_{41}H_{44}O_{10}N_4$: C, 65.41; H, 5.89; N, 7.44%.

The LD Isomer (XXII). Yield, 61%; mp 103—104°C; $[\alpha]_D^{20}$ +6.4° (*c* 1, dimethylformamide).

Found: C, 64.98; H, 5.83; N, 7.77%.

Glycyl-lysyl-glutamic Acid (Gly-Lys-Glu), LL Isomer (XXIII) and LD Isomer (XXIV); Gly-Lys-Asp, LL Isomer (XXV) and LD Isomer (XXVI); Gly-Orn-Glu, LL Isomer (XXVII) and LD Isomer (XXVIII); Gly-Orn-Asp, LL Isomer (XXIX) and DL Isomer (XXX). Each of benzyloxycarbonyl-tripeptide benzyl ester (XV—XXII) (2 mmol) obtained above was suspended in a solution (20 ml) of acetic acid, methanol and water (6:1:3), and the mixture was treated with hydrogen in the presence of palladium black. As the hydrogenolysis had proceeded the suspended material went into the solution. The catalyst was removed by filtration, and the filtrate was evaporated *in vacuo* to dryness. The residual oil become hygroscopic crystals upon treatment with ethanol. The yields were almost quantitative. The homogeneity of these peptides was established by paper chromatography and electrophoresis. Elemental analysis was not performed because of its highly hygroscopic character. Amiard and Goffinet[20] reported the synthesis of XXIII by saponification and detritylation of Tri-Gly-L-Lys(ε-Tri)-L-Glu(γ-OEt)-OEt.

***o*-Nitrophenylsulfenyl-γ-benzyl-D-glutamic Acid Dicyclohexylammonium Salt (XXXI).** This compound was obtained according to the procedure for the L isomer.[21] Yield, 66%; mp 167—168°C; $[\alpha]_D^{20}$ +33.7° (*c* 3.5, chloroform). Reported value for the L isomer,[21] mp 168°C; $[\alpha]_D^{20}$ −34.0° (chloroform).

o-Nitrophenylsulfenyl-β-benzyl-D-aspartic Acid Dicyclohexylammonium Salt (XXXII). This compound was obtained according to the procedure for the L isomer.[22] Yield, 59%; mp 165°C; $[\alpha]_D^{20}$ +41.0° (*c* 4, chloroform). Reported value for the L isomer;[22] mp 165—166°C; $[\alpha]_D^{20}$ −38.0° (chloroform).

o-Nitrophenylsulfenyl-γ-benzyl-glutamyl-ε-benzyloxycarbonyl-lysine Benzyl Ester. *The LL Isomer (XXXIII).* To a solution of o-nitrophenylsulfenyl-γ-benzyl-L-glutamic acid dicyclohexylammonium salt[21] (1.72 g, 3 mmol) and ε-benzyloxycarbonyl-L-lysine benzyl ester *p*-toluenesulfonate[23] (1.63 g, 3 mmol) in chloroform (12 m*l*) was added dicyclohexylcarbodiimide (0.62 g, 3 mmol) with stirring at −5°C. After 2 hr at −5°C, the stirring was continued at room temperature overnight. After the reaction mixture was evaporated *in vacuo*, the residue was treated with ethyl acetate (20 m*l*), and insoluble precipitate of dicyclohexylurea was removed by filtration. The filtrate was washed successively with 4% sodium bicarbonate, 0.5 M citric acid and water, dried over sodium sulfate and evaporated *in vacuo* yielding an oily residue. Yield of the oil, 2.01 g (90%). This oil did not crystallize on prolonged standing in a refrigerator.

The DL Isomer (XXXIV). This compound was obtained from XXXI and ε-benzyloxycarbonyl-L-lysine benzyl ester as described above. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 73%; mp 87—88°C; $[\alpha]_D^{20}$ +19.2° (*c* 1, chloroform).

Found: C, 63.07; H, 5.79; N, 7.59%. Calcd for $C_{39}H_{12}O_9N_4S$: C, 63.06; H, 5.70; N, 7.54%.

o-Nitrophenylsulfenyl-β-benzyl-aspartyl-ε-benzyloxycarbonyl-lysine Benzyl Ester. *The LL Isomer (XXXV).* This compound was obtained from o-nitrophenylsulfenyl-β-benzyl-L-aspartic acid dicyclohexylammonium salt[22] and ε-benzyloxycarbonyl-L-lysine benzyl ester as described above and recrystallized from ethyl acetate - ether - petroleum ether. Yield, 88%; mp 128—129°C; $[\alpha]_D^{20}$ −17.2° (*c* 1, dimethylformamide).

Found: C, 62.58; H, 5.51; N, 7.83%. Calcd for $C_{35}H_{40}O_9N_4S$: C, 62.62; H, 5.53; N, 7.69%.

The DL Isomer (XXXVI). This compound was obtained from XXXII and ε-benzyloxycarbonyl-L-lysine benzyl ester as described above. Yield, 82%; mp 118—119°C; $[\alpha]_D^{20}$ +11.8° (*c* 1, chloroform).

Found: C, 61.76; H, 5.40; N, 7.84%. Calcd for $C_{38}H_{40}O_9N_4S \cdot 1/2H_2O$: C, 61.86; H, 5.60; N, 7.60%.

Benzyloxycarbonyl-glycyl-γ-benzyl-glutamyl-ε-benzyloxycarbonyl-lysine Benzyl Ester. *The LL Isomer (XXXVII).* To a solution of the nitrophenylsulfenyl-dipeptide ester XXXIII (1.54 g 2 mmol) in dioxane (6 m*l*), 2 N hydrogen chloride in dioxane (4 m*l*) was added. After the solution was allowed to stand at room temperature for 30 min, it was evaporated *in vacuo*. The residual oil was washed several times with ether by the way of decantation; yield of the oily dipeptide ester monohydrochloride, 1.26 g (102%). Then the compound XXXVII was prepared from benzyloxycarbonyl-glycine (2 mmol) and the dipeptide ester monohydrochloride (1.26 g) obtained above by the mixed anhydride method as described for the preparation of III. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 1.11 g (71%); mp 97°C; $[\alpha]_D^{20}$ −9.0° (*c* 1, dimethylformamide).

Found: C, 66.23; H, 6.11; N, 7.21%. Calcd for $C_{43}H_{48}O_{10}N_4$: C, 66.14; H, 6.20; N, 7.18%.

The DL Isomer (XXXVIII). The crystalline dipeptide ester monohydrochloride (1.23 g) was obtained from the nitrophenylsulfenyl-dipeptide ester XXXIV (2 mmol) with the treatment of hydrogen chloride in dioxane as has been described above. Then, XXXVIII was prepared from benzyloxycarbonyl-glycine and the dipeptide ester monohydrochloride (1.23 g) by the mixed anhydride method. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 1.09 g (70%); mp 126°C; $[\alpha]_D^{20}$ −4.4° (*c* 1, dimethylformamide).

Found: C, 66.21; H, 6.13; N, 7.22%.

Benzyloxycarbonyl-glycyl-β-benzyl-aspartyl-ε-benzyloxycarbonyl-lysine Benzyl Ester. *The LL Isomer (XXXIX).* This compound was prepared from benzyloxycarbonyl-glycine and the crystalline dipeptide ester monohydrochloride which was obtained from XXXV with hydrogen chloride in dioxane. The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 61%; mp 117°C; $[\alpha]_D^{20}$ −18.6° (*c* 1, dimethylformamide).

Found: C, 65.76; H, 6.07; N, 7.27%. Calcd for $C_{42}H_{46}O_{10}N_4$: C, 65.76; H, 6.05; N, 7.31%.

The LD Isomer (XL). This compound was synthesized as described above from benzyloxycarbonyl-glycine and the crystalline dipeptide ester monohydrochloride which was obtained from XXXVI. Yield, 73%; mp 91°C; $[\alpha]_D^{20}$ +6.2° (*c* 1, dimethylformamide).

Found: C, 65.60; H, 6.08; N, 7.21%.

Glycyl-glutamyl-lysine (Gly-Glu-Lys). *The LL Isomer (XLI).* The compound XXXVII (0.78 g) was hydrogenated as has been described for the preparation of Lys-Glu (VII) and the filtrate from the catalyst was evaporated to dryness. The residual crystals were recrystallized from water-ethanol. Yield, 0.247 g (70%); $[\alpha]_D^{20}$ −22.4° (*c* 1, water).

Found: C, 44.28; H, 7.25; N, 15.66%. Calcd for $C_{13}H_{24}O_6N_4 \cdot H_2O$: C, 44.56; H, 7.48; N, 15.99%.

The DL Isomer (XLII). This was obtained by the

Paper Chromatography and Paper Electrophoresis. A paper chromatography was carried out with ascending technique using Toyo Roshi No. 52, and a peptide on the paper was revealed with ninhydrin. As shown in Table 2, it was observed that the diastereomers of several peptides were separated on the chromatogram. The electrophoresis was carried out under the following condition: 500 V/30 cm with formic acid - acetic acid - methanol - water solution and 300 V/30 cm with 0.2 M sodium citrate buffer. As indicated in Table 2, it appeared that the ability to separate a diasteremeric mixture was less than that in the paper chromatography.

Separation Studies with Amino Acid Analyzer. A mixture of 0.6 μmol each of the LL form and the LD (or DL) form of di- or tripeptides was analyzed by Hitachi amino acid analyzer with spherical resin (No 3105), model KLA-3B, under the following conditions: flow rate, 60 ml/hr and jacket temperature, 55°C. Three different analyses were performed for each diastereomeric mixture as follows: (i) with 0.9×50 cm column, 0.2 M sodium citrate buffer at pH 5.28 was used; (ii) with 0.6×10 cm column, 0.2 M sodium citrate at pH 4.25 was used; (iii) with 0.6×10 cm column, 0.2 M sodium citrate at pH 3.25 was applied for 6 hr (toltal effluent volume, 360 ml), and then the buffer system was changed to pH 4.25. The results obtained were summarized in Table 2. The several chromatographic patterns with the amino acid analyzer were indicated in Figs. 5—7.

The authors wish to express their thanks to Dr. Haruhiko Aoyagi, in this laboratory for his valuable discussions.

Studies on Pyrimidine Derivatives and Related Compounds. LVII.[1] Cyclization Mechanisms of Ethyl 2-(5-Pyrazolyl)aminoalkylidenecyanoacetates

Akira TAKAMIZAWA, Yoshio HAMASHIMA and Shoji SAKAI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received March 4, 1968)

It was found that the orientation of cyclization reaction of ethyl 2-(5-pyrazolyl)aminomethylenecyanoacetates (Va—c) and ethyl 1-cyano-2-(5-pyrazolyl)aminocrotonates (Xa—c) largely depends on the catalyst used: for example, the cyclization of Va by the acid catalyst results in only 7-amino derivative; on the other hand, the mixture of 7-amino derivative and 7-hydroxy derivative is obtained in the presence of the base catalyst. In order to clarify the mechanism of this reaction, we studied spectrophotometrically the behaviors of these compounds in basic solution, taking ethyl 2-(1,4-dimethylpyrazol-5-yl)aminomethylenecyanoacetate (XV), and ethyl 1-cyano-2-(1,4-dimethylpyrazol-5-yl)aminocrotonate (XVI) as model compounds. Consequently, it was found that the proton dissociation of the C_2-amino group is greatly disturbed by the methyl substitution on that carbon atom. This finding is used for explaining the fact that the base catalyzed cyclization of X is insensitive to the amount of catalyst used while that of V shows some dependency on the concentration of alkali.

Detailed investigation on the cyclization mechanism of 2-aminoalkylidenecyanoacetates has not yet been carried out. Recently, Midorikawa, *et al.*[2] reported that the condensation of methyl *cis*-1-cyano-2-methoxyacrylate and methyl *trans*-1-cyano-2-methoxycinnamate with hydrazine to pyrazole derivatives was mainly controlled by their geometric factors.

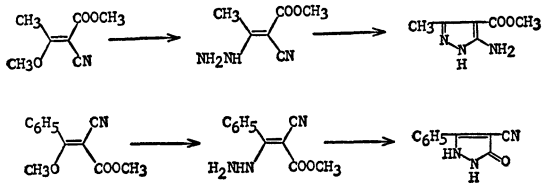

Chart 1

Previously,[3,4] it was suggested that the synthesis of 7-amino- or 7-hydroxypyrazolo[1,5-*a*]pyrimidine derivatives by the cyclization of ethyl 2-(5-pyrazolyl)-aminoalkylidenecyanoacetates was characteristically effected by acid or base catalysts, and, particularly in the latter case, was also effected by the amount of the catalyst used. This paper deals with the details of these reaction mechanisms.

Jones prepared ethyl ethoxymethylenecyanoacetate[5] (III) by the reaction of ethyl cyanoacetate (I), acetic anhydride, and ethyl orthoformate (II) and measured its NMR spectrum. He found a sharp singlet signal at τ 1.95 corresponding to the C_2 proton. We have prepared ethyl 2-(5-pyrazolyl)-aminomethylenecyanoacetates (Va—c) by the condensation of III with 5-aminopyrazoles (IVa—c) and have measured their NMR spectra with the results shown in Fig. 1. According to this figure, the NMR spectra of Va and Vc show the doublet signals of =CH-N< at τ 1.92 (J=13.8 cps) and at τ 1.86 (J=13.0 cps), respectively, each doublet being due to the coupling with adjacent NH proton. This indicates that Va and Vc consist of single ester, respectively. On the contrary, Vb shows the two doublet proton signals of =CH-N< at τ 1.72 (J=13.8 cps) and τ 2.00 (J=14.4 cps). From the intensities of these two doublet signals, the ratio of isomers is known to be approximately 1 : 1. Each doublet is converted into singlet by an addition of deuterium oxide. Jackman[6-8] and other several

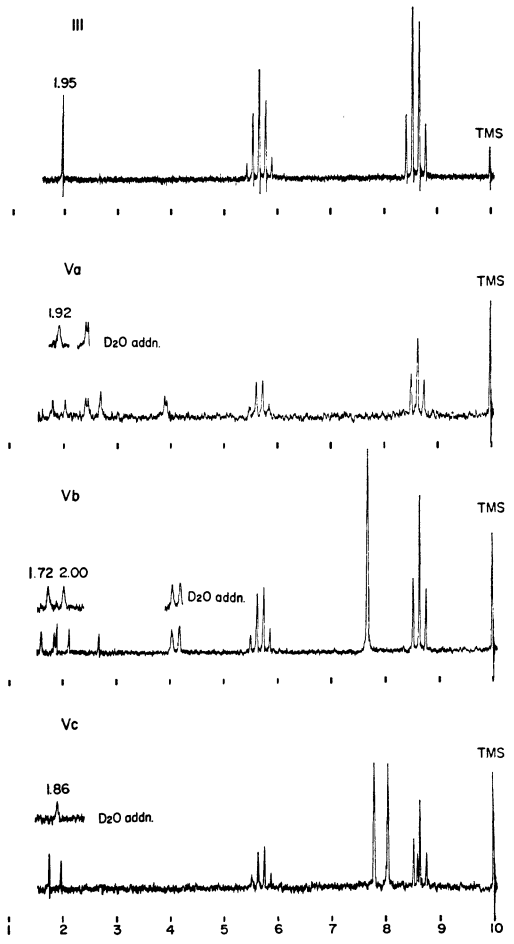

Fig. 1. The NMR spectra of III and Va—c at 60 Mc.

authors[9-12] demonstrated that, provided both isomers of a pair are available, NMR spectroscopy can be used to establish the geometric configurations of some α,β-unsaturated esters. This method is based on the fact that the protons of a *cis*-β-methyl group are more deshielded than those of a *trans*-β-methyl group. More recently, Hayashi, Hori, Baba and Midorikawa[13] and also McGreer *et al.*[14,15] reported that a *cis*-β-methyl group against the ester group of methyl 1-methoxyethylidenecyanoacetate is more

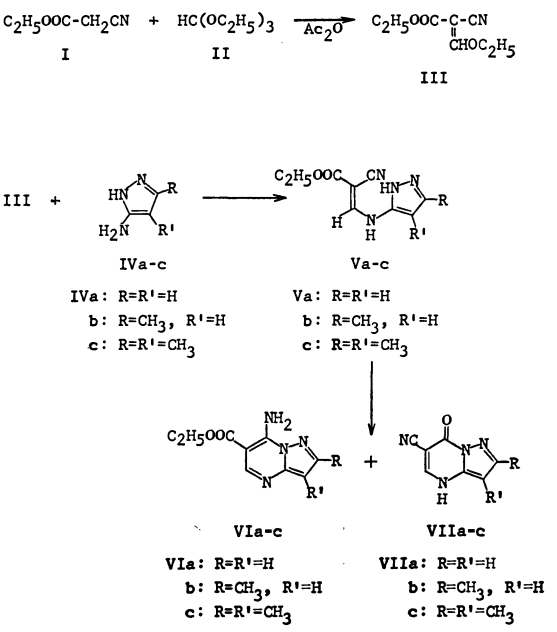

Chart 2

deshielded than that of *trans*-isomer, but the authors have no definite confidence for deciding the geometric configurations of Va—c from the data or NMR.

Now let us turn to the cyclization reaction of Va—c. The results obtained under various conditions are fairly systematic as is shown in Table 1a-d. The cyclization reaction of Va—c in the presence of acid catalysts gives only 7-amino derivatives (VIa—c). On the other hand, the reaction is rather complicated under base catalysts, and the mixture of VIa—c and 7-hydroxy derivatives (VIIa—c) can be obtained with

a) 40 m*l* of each solvent was used.
b) 1% $NaOC_2H_5$ in C_2H_5OH was used.
c) 3 m*l* of CH_3COOH was used as a solvent.
d) 10 m*l* of 5% NaOH solution was used as a solvent.

the general tendency that the proportion of VIa—c increases with the increasing amount of catalysts. Correlations of the ratios of the products with the amounts of catalysts are summarized in Fig. 2. The correlation curves for Va and Vb show the minimum ratios of VI to VII when an equimolar amount of catalyst is used.

Ethyl 1-cyano-2-ethoxycrotonate (IX) obtained by the reaction of I with ethyl orthoacetate (VIII) in acetic anhydride consists of the geometric isomers in the ratio of approximately 96 : 4. IX was used without further purification to prepare ethyl 1-cyano-2-(5-pyrazolyl)aminocrotonates (Xa—c), which were all decided by the NMR measurement to consist of a single component, respectively. The treatment of Xa—c with acid or alkali gives cyclization products in good yield. The results are given in Table 2. As is clearly seen in this table, only 7-hydroxy derivatives (XIIa—c) can be obtained under basic conditions regardless of the amount of the catalysts. On the other hand, the cyclization reaction of Xa—c under acidic conditions gives 7-amino- (XIa—c) and 7-hydroxy derivatives (XIIa—c) in the ratio of approximately 1 : 1.

From the above-mentioned results, it is clear that the orientation of cyclization reaction of Va—c is effected by the kind of catalyst used, namely, by acid or base catalyst used. Moreover, in the case of the base catalyzed cyclization, the reaction is sensitive to the amount of the catalyst. The similar situation concerning the dependence on the kind of catalyst was found for the reaction of Xa—c. In this

case, however, we could not observe the dependence upon an amount of base. In order to clarify the reason for the difference in the reaction between Va—c and Xa—c, their behaviors in alkaline medium have been studied by measuring ultraviolet absorption spectra of ethyl 2-(1,4-dimethylpyrazol-5-yl)-aminomethylenecyanoacetate (XV), and ethyl 1-cyano-2-(1,4-dimethylpyrazol-5-yl)aminocrotonate (XVI) which are similar in their structures to V and X, respectively, but cannot be expected to take pyrazolopyrimidine condensation because of the methylation on the N atom. In XV, as is shown in Fig. 3, the ultraviolet absorption maximum at 286 mμ shifts to 318 mμ by an addition of the base even in alcoholic medium, indicating the occurrence of deprotonation at the C_2-amino group.[16] The

16) Deprotonation may conceivably occur in the other groups. For example, the C_2-H of XV may dissociate proton in basic media. This possibility, however, is very likely excluded, because the C_2-H dissociation product is less stabilized by the resonance than the C_2-N-H dissociation product.

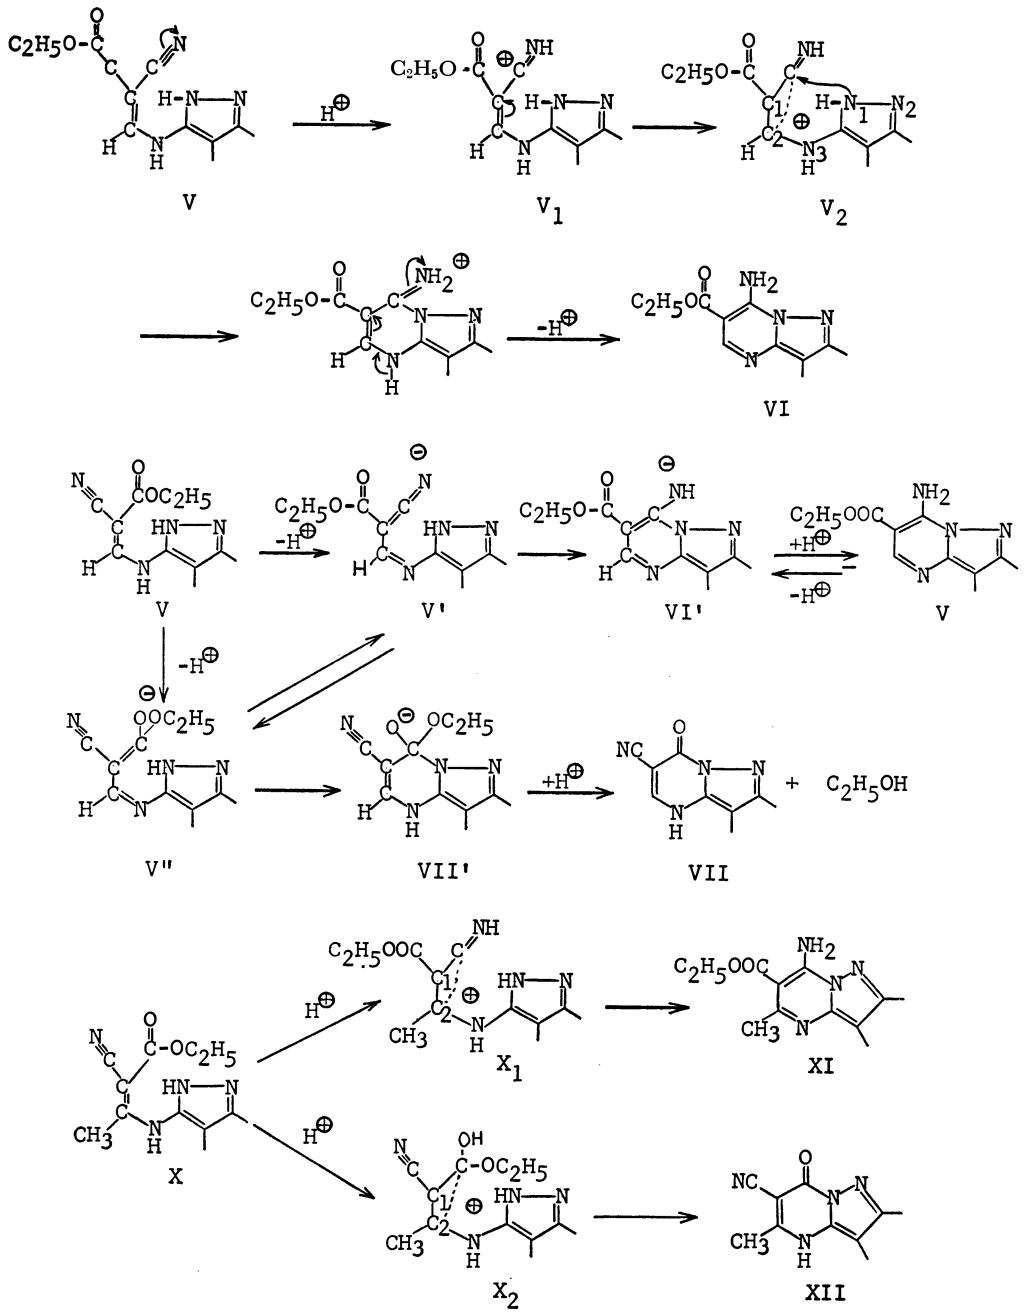

Chart 5

pK_a value of XV can be evaluated to be 8.45 by the aid of the usual equation.[17] In the presence of more than 5 equivalents of the base, the absorption curve becomes constant because of the complete dissociation. In XVI the dissociation hardly occurs in alcoholic medium, but by the addition to water, the dissociation may be thought to occur in view of the appearance of a new absorption maximum at 227.5 mμ (Fig. 4). This means that the methyl substitution at the C_2 position makes the dissociation more difficult.[18]

17) $pK_a = pH - \log((A-b)/(b-B))$ (A, B and b are the molecular extinction coefficients of the acidic form, the basic form and the equilibrium mixture of them, respectively, under the conditions that the total concentration of XV is constant).

18) The ultraviolet absorption spectra of ethyl 2-(1,4-dimethylpyrazol-3-yl)aminomethylenecyanoacetate (XVII) and ethyl 1-cyano-2-(1,4-dimethylpyrazol-3-yl)aminocrotonate (XVIII) were measured in solutions with various pH values. The results show that XVIII is dissociated with more difficulty than XVII is.

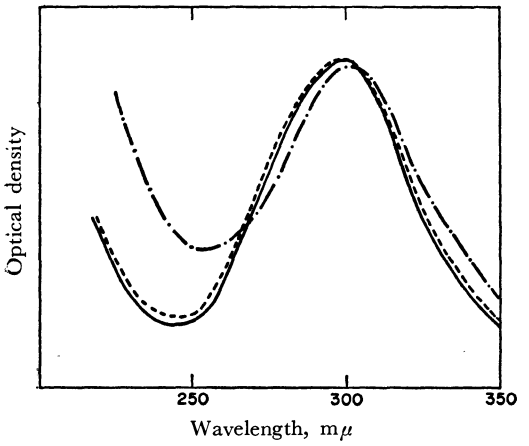

Fig. 6. Ultraviolet absorption curves of Xa under various conditions.
——: Neutral in C_2H_5OH (λ_{max} 298 mμ)
----: In the presence of $NaOC_2H_5$ (λ_{max} 298 mμ)
·—·: In the presence of excess of NaOH in H_2O (λ_{max} 303 mμ)

The same tendency was also observed in Va—c and Xa—c. For example, at room temperature dissociation of Vb in basic alcohol, which could hardly be expected to cause the cyclization reaction, was not detected, but the dissociation proceeded by the addition of water and the maximum at 318 mμ shifted to 327 mμ accompanied with an appearance of a new maximum at 239 mμ. On the contrary, as is shown in Fig. 6, dissociation was scarcely detected in Xa by the addition of excess of base in alcohol or even in water. From the above-mentioned experimental results of ultraviolet absorption spectra, it may be obvious that the dissociation of 2-(5-pyrazolyl)aminoalkylidenecyanoacetates in alkaline medium becomes difficult by the substitution of methyl group at the C_2 position. This seems to correspond to the fact that the cyclization of Va—c is more sensitive to the amount of alkali as catalyst than Xa—c.

As a whole, possible cyclization mechanisms of this series may be considered as follows: As is shown in Chart 5, protonation will occur in acidic medium at the cyano group[19] in V to give a carbonium ion intermediate such as V_2. In this intermediate cation, rotation may be possible around the C_1-C_2 bond, and the nucleophilic attack of pyrazole N_1 to the cyano group may preferentially give VI. With base catalyst, deprotonation from the N_3 amino group may easily give V′ or V″. The orientation of the reaction will be influenced by the stability of V′ and V″,[20] and the equilibrium (V′ ⇌V″) will be inclined towards V′ with the increasing amount of the base.

In X protonation occurs at the cyano or carbonyl group and the carbonium ions such as X_1 and X_2 are produced. In these ions rotation around the C_1-C_2 bond may be somewhat hindered sterically by the methyl group resulting in a mixture of 7-amino- (XI) and 7-oxo (XII) compounds. In the consideration of the base catalyzed cyclization of X, we must give attention to the spectrophotometric observation that deprotonation at the N_3 amino group is prohibited by the steric effect of the adjacent methyl group in addition to its hyperconjugation effect. From this it may be inferred that only 7-oxo compound (XII) is produced mainly because of its original geometric factor. In this series of reactions, the details of orientation mechanism may be thought to be controlled by various factors such as solvent effect, reaction temperature and so on. Further work on the reaction mechanisms for this series is in progress.

Experimental[21]

Cyclization Reactions of Va—c under Various Conditions. A. Vc (0.4685 g) was dissolved in 40 ml of ethanol by warming. After being cooled, the solution was mixed with 2 ml of ethanol containing 0.046 g of sodium, and stirred at room temperature for 68 hr. Evaporation of the mixture gave solids. To the residue was added water and the precipitated solids were filtered, washed and dried to give 0.268 g (56.3%) of VIc. The filtrate was made acidic by acid and the precipitated solids were filtered and dried. Recrystallization from methanol gave colorless needles, which were proved to be identical with an authentic sample. Yield, 34%.

B. Vb (0.44 g) was dissolved in 40 ml of ethanol by warming. After cooled, the solution was mixed with 1 ml of ethanol containing 0.023 g of sodium, and heated to reflux for 2 hr, and concentrated. To the residue was added water and the precipitated solids were collected and dried to give 0.2 g (45.5%) of VIb. From the mother liquid was obtained 0.146 g (42.0%) of VIIb neutralized by acetic acid.

C. To 10 ml of 5% sodium hydroxide in water was suspended 0.4124 g of Va, and the mixture was heated at 100°C for 20 min to become clear solution. After cooled, the solution was neutralized by acetic acid to give 0.261 g (81.6%) of VIIa as colorless prisms.

D. To 10 ml of 10% sodium carbonate in water was added 0.4685 g of Vc, and the mixture was heated on a steam bath for 1 hr resulting to obtain clear solution. After being cooled, the precipitated solids were collected and washed to give 0.103 g (27.4%) of VIc. The filtrate

19) The intermediate produced by protonation on the carbonyl oxygen atom can be considered. This intermediate, however, is disregarded for the cyclization of V, because the actual reaction does not occur through it.

20) In Chart 5, V′ and V″ are, respectively, represented by one of various resonance structures. In these intermediates, the negative charge may be considered to be delocalized all-around the molecule.

21) All NMR spectra were obtained on the Varian A-60 spectrometer in deuterio chloroform using tetramethylsilane (TMS) as an internal reference. The ultraviolet absorption spectra were recorded by Hitachi ELS-3 recording spectrophotometer.

was neutralized with acetic acid to precipitate a colorless solid, which was proved to be VIIc by the comparisons of infrared spectra. Yield, 0.246 g (52.6%).

E. To the suspension of 0.4124 g of Va in 40 m*l* of ethanol was added 0.42 g of conc. hydrochloric acid, and the mixture was heated to reflux on a steam bath for 2 hr. Evaporation of the solution resulted colorless residue, which was dissolved in water and neutralized with sodium carbonate to precipitate VIa as colorless needles, yield, 0.391 g (95%).

Cyclization Reactions of Xa—c under Various Conditions. A. To a solution of 0.4405 g of Xa in 40 m*l* of ethanol was added 0.42 g of conc. hydrochloric acid, and the mixture was heated to reflux for 2 hr and evaporated. The residues were dissolved in water and neutralized with sodium carbonate to obtain colorless solids, which were extracted with cold sodium hydroxide solution and filtered. The solid was proved to be identical with XIa by the comparisons of their infrared spectra. Yield, 0.137 g (39.4%). Sodium hydroxide solution was neutralized with acetic acid to obtain XIIa as colorless needles, yield, 0.208 g (47.2%).

B. To a solution of 0.4405 g of XIa in 40 m*l* of ethanol was added 0.092 g of sodium in ethanol (9 m*l*), and the mixture was heated to reflux on a steam bath for 2 hr. Evaporation of the solution gave colorless solid, which was dissolved in water and neutralized with acetic acid to give XIIa as colorless sticks, yield. 0.327 g (94%).

Ethyl 2-(1,4-Dimethylpyrazol-5-yl)aminomethylenecyanoacetate (XV). A solution of 1.7 g of III and 1.12 g of XIII in 30 m*l* of ethanol was heated to reflux for 3 hr, and concentrated. The residue was recrystallized from ethanol - ether to give XV as colorless sticks, mp 112—113°C, yield, 2.12 g (90.6%).

Found: C, 56.50; H, 6.35; N, 23.98%. Calcd for $C_{11}H_{14}O_2N_4$: C, 56.40; H, 6.02; N, 23.92%.

Ethyl 1-Cyano-2-(1,4-dimethylpyrazol-5-yl)aminocrotonate (XVI). A solution of 0.366 g of IX and 0.222 g of XIII in 3 m*l* of ethanol was heated to reflux for 10 hr, and concentrated to afford colorless residue, which was recrystallized from acetone - ether to give XVI as colorless rhombi, mp 142—144°C. Yield, 0.42 g (84.6%).

Found: C, 58.28; H, 6.32; N, 22.63%. Calcd for $C_{12}H_{16}O_2N_4$: C, 58.05; H, 6.50; N, 22.57%.

Ethyl 2-(1,4-Dimethylpyrazol-3-yl)aminomethylenecyanoacetate (XVII). A mixture of 0.85 g of III and 0.56 g of XIV in 20 m*l* of ethanol was heated on a steam bath for 5 hr, and concentrated to give colorless solid, which was recrystallized from ethanol to give XVII as colorless needles, mp 122—123°C. Yield, 1.02 g (87.2%).

Found: C, 56.50; H, 6.35; N, 23.98%. Calcd for $C_{11}H_{14}O_2N_4$: C, 56.40; H, 6.02; 23.92%.

Ethyl 1-Cyano-2-(1,4-dimethylpyrazol-3-yl)aminocrotonate (XVIII). A solution of 1.5 g of XIV and 2.6 g of IX in 10 m*l* of ethanol was stirred at room temperature for 30 min to give colorless solid, which was filtered and recrystallized from ether to obtain XVIII as colorless silky needles, mp 143°C. Yield, 2.3 g (71.7%).

Found: C, 58.36; H, 6.72; N, 22.83%. Calcd for $C_{12}H_{16}O_2N_4$: C, 58.05; H, 6.50; N, 22.57%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2148—2150 (1968)

Oxazolidone Derivatives of Hydroxyamino Acids. V.[1] New Synthesis of *threo*- and *erythro*-β-Hydroxy-DL-aspartic Acids*[1]

Toshishige INUI,*[2] Yoshimoto OHTA,*[3] Toshiaki UJIKE,*[4]
Hakuji KATSURA and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 8, 1968)

threo- and *erythro*-β-Hydroxy-DL-aspartic acids (VI and X) were synthesized by oxidation and subsequent hydrolysis of DL-*trans*- and DL-*cis*-5-furyl-2-oxo-oxazolidine-4-carboxylic acids (IV and VIII) derived from *threo*- and *erythro*-β-furyl-DL-serines (III and VII) respectively.

β-Hydroxyaspartic acids were first synthesized by Dakin.[2] Later, Kornguth[3] synthesized these amino acids by condensation of glyoxalic acid with copper glycinate. Recently, *threo*- and *erythro*-β-hydroxy-DL-aspartic acids were synthesized stereochemically by the reaction of *cis*- and DL-*trans*-epoxysuccinic acids with ammonia[4] or benzylamine[5] respectively.

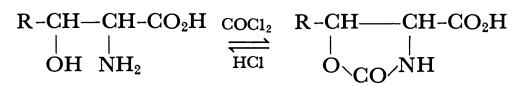
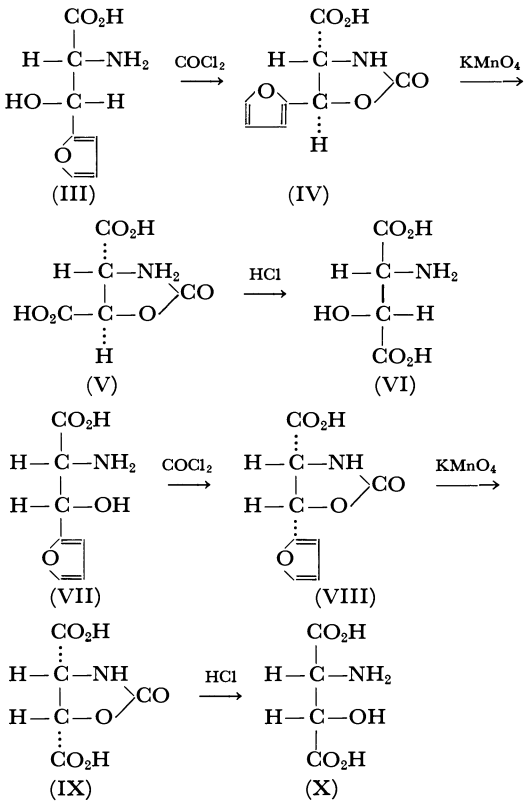
The present paper is concerned with another stereospecific synthesis of *threo-* and *erythro-*β-hydroxy-DL-aspartic acids from the corresponding β-furyl-DL-serines respectively.



(I) (II)

In the previous report,[6] hydroxyamino acids (I) such as threonine were easily cyclized with phosgene to the corresponding oxazolidone derivatives (II) without any configurational change at the either asymmetric center. If *trans-* and *cis-*furyloxazolidone-carboxylic acids (II, R = C_4H_3O) derived from *threo-* and *erythro-*β-furylserines (I, R = C_4H_3O) were oxidized to the corresponding oxazolidone-dicarboxylic acids (II, R = CO_2H), the dicarboxylic acids thus obtained would be hydrolyzed to *threo-* and *erythro-*β-hydroxyaspartic acids (I, R = CO_2H) maintaining the same configurations with those of the starting β-furylserines.

*threo-*β-Furyl-DL-serine (III) was prepared from furfural and glycine by the directions of Hayes.[7] On the other hand, *erythro-*β-furyl-DL-serine (VII)



(III) (IV) (V) (VI) (VII) (VIII) (IX) (X)

Table 1. R_f Values on paper chromatogram

threo-Isomer	R_f	*erythro*-Isomer	R_f
III	0.28	VII	0.18
threo-β-Phenyl-DL-serine	0.42	*erythro*-β-Phenyl-DL-serine	0.27
Threonine	0.18	Allothreonine	0.13

Solvent: *n*-Butanol-acetone-concentrated aqueous ammonia-water (8:1:1:6).[8]

was separated as its dioxane adduct from the mixture of III and VII, which was obtained by condensation of furfural with copper glycinate, by applying the method for separation of *erythro-*β-phenyl-DL-serine from its *threo-*isomer.[8] The R_f values of III and VII on paper chromatogram were compared with those of threonine, allothreonine and *threo-* and *erythro-*β-phenylserines (Table 1), and their structures were confirmed as the assigned ones. Then, III and VII were cyclized with phosgene to DL-*trans-* and DL-*cis-*5-furyl-2-oxo-oxazolidine-4-carboxylic acids (IV and VIII) respectively. Oxidation of IV with aqueous potassium permanganate solution provided DL-*trans-*2-oxo-oxazolidine-4,5-dicarboxylic acid (V) as a crystalline state in a yield of 30%, which was hydrolyzed with hydrochloric acid to *threo-*β-hydroxy-DL-aspartic acid (VI). However, oxidation and subsequent hydrolysis of IV without isolation of V gave VI in an overall yield of 40%. Similarly, *erythro-*β-hydroxy-DL-aspartic acid (X) was obtained by oxidation and subsequent hydrolysis of VIII in a yield of 39%. The properties tested of VI and X were identical with those of the corresponding authentic samples.

Experimental*5

***threo*-β-Furyl-DL-serine (III).** According to the directions of Hayes,[7] III was prepared by condensation of 293 g (3.05 mol) of furfural with 115 g (1.53 mol) of glycine in the presence of 170 g (3.03 mol) of potassium hydroxide in 1200 m*l* of ethanol. Yield, 126 g (48%), mp 197°C (decomp.) after recrystallization from water and ethanol.

Found: C, 49.47; H, 5.41; N, 8.28%. Calcd for $C_7H_9NO_4$: C, 49.12; H, 5.30; N, 8.18%.

***erythro*-β-Furyl-DL-serine (VII).** Using the method for preparation of threonine by Akabori,[9] a mixture of 10.2 g (0.106 mol) of furfural and 11.3 g (0.0534 mol) of copper glycinate in 200 m*l* of 1 N potassium hydroxide was stirred for 2 hr at 10—20°C. After it had been kept overnight at room temperature, undissolved material was filtered off and the filtrate was acidified with 20 m*l* of acetic acid. The acidic solution was washed with ether and bubbled with a stream of hydrogen sulfide to decompose the resulting copper complex. The filtrate from copper sulfide was evaporated *in vacuo* to a small

volume and diluted with ethanol to separate *threo*-isomer III (9.1 g; 50%), which was collected by filtration. The residue obtained by evaporation of solvent from the filtrate was dissolved into 30 m*l* of water and 30 m*l* of dioxane was added to the aqueous solution to precipitate VII as its dioxane adduct. Yield, 5.0 g (22%). Recrystallization from water-dioxane (1: 1) gave 3.3 g of chromatographically pure VII melting at 169°C (decomp.).

Found: C, 50.44; H, 6.06; N, 6.55%. Calcd for $C_7H_9NO_4 \cdot \frac{1}{2}C_4H_8O_2$: C, 50.23; H, 6.09; N, 6.51%.

DL-*trans*-5-Furyl-2-oxo-oxazolidine-4-carboxylic Acid (IV). To a solution of 29.0 g (0.168 mol) of III in 645 m*l* (0.645 mol) of 1 N potassium hydroxide, a solution of 20.2 g (0.204 mol) of phosgene in 80 m*l* of toluene was added dropwise over 30 min with stirring at 0—3°C and the reaction mixture was stirred for an additional 3 hr below 5°C. The aqueous layer separated from organic layer was acidified with 14 m*l* of concentrated hydrochloric acid to separate a crude product (28.0 g, mp 199—200°C (decomp.)), which was shown to be a mixture of IV and its potassium salt by detecting with flame test.

A stream of dry hydrogen chloride was passed through a suspension of the crude product in about 30 volumes of ethyl acetate and the resulting mixture was washed thoroughly with water. Evaporation of the dried solution provided IV as a pure state. Yield, 21.0 g (63%); mp 126—128°C (decomp.) after recrystallization from ethyl acetate - petroleum ether.

Found: C, 48.70; H, 3.64; N, 7.12%. Calcd for $C_8H_7NO_5$: C, 48.74; H, 3.58; N, 7.11%.

DL-*cis*-5-Furyl-2-oxo-oxazolidine-4-carboxylic Acid (VIII). In a similar way, a solution of 5.0 g (0.0232 mol) of dioxane adduct of VII in 50 m*l* (0.0891 mol) of 10% aqueous potassium hydroxide solution was treated with a solution of 2.8 g (0.0283 mol) of phosgene in 15 m*l* of toluene. The aqueous layer separated from organic layer was acidified with concentrated hydrochloric acid and the acidic solution was extracted with ethyl acetate. The dried extract was evaporated *in vacuo* leaving VIII as a crystalline solid. Yield, 2.8 g (61%); mp 143—144°C (decomp.) after recrystallization from ethyl acetate.

Found: C, 48.77; H, 3.71; N, 6.78%. Calcd for $C_8H_7NO_5$: C, 48.74; H, 3.58; N, 7.11%.

DL-*trans*-2-Oxo-oxazolidine-4, 5-dicarboxylic Acid (V). Three grams (0.0152 mol) of IV was dissolved into 200 m*l* of water and neutralized with 15 m*l* (0.0150 mol) of 1 N potassium hydroxide. The resulting solution was oxidized with 270 m*l* (0.0683 mol; 96% of required ammount) of 4% aqueous potassium permanganate solution for 2 hr at 15—20°C. After manganese dioxide precipitated had been removed, the aqueous solution was acidified with 10 m*l* of concentrated hydrochloric acid and evaporated to dryness *in vacuo*. The residue was extracted three times with 50-m*l* portions of hot dioxane and the combined extracts were evaporated *in vacuo* to give crystals. Yield, 0.8 g (30%); mp 159—160°C (decomp.) after recrystallization from ethyl acetate - petroleum ether.

Found: C, 34.90; H, 3.07; N, 7.95%; mol wt (titration with alkali), 177, 180. Calcd for $C_5H_5NO_6$: C, 34.29; H, 2.88; N, 8.00%, mol wt, 175.1.

The treatment of V with an ethereal diazomethane solution gave dimethyl DL-*trans*-2-oxo-oxazolidine-4,5-dicarboxylate melting at 97—99°C after recrystallization from benzene.

Found: C, 41.96; H, 4.54; N, 6.96%. Calcd for $C_7H_9NO_6$: C, 41.38; H, 4.47; N, 6.90%.

***threo*-β-Hydroxy-DL-aspartic Acid (VI).** *By Hydrolysis of V.* A solution of 1.0 g (0.0057 mol) of V in 20 m*l* of 6 N hydrochloric acid was refluxed for 6 hr and VI was isolated from the hydrolyzate in an usual way. Yield, 0.6 g (70%).

It was identified by comparing its physical properties such as infrared spectra with those of an authentic sample. Analytical sample was recrystallized from water and dried over phosphorus pentoxide in a vacuum desiccator.

Found: C, 32.53; H, 4.81; N, 9.55%. Calcd for $C_4H_7NO_5$: C, 32.22; H, 4.73; N, 9.41%.

By Oxidation and Subsequent Hydrolysis of IV. In the same way as the above, a neutralized solution of 5.0 g (0.0254 mol) of IV in 240 m*l* of water was oxidized with 475 m*l* (0.120 mol; 101% of required ammount) of 4% aqueous potassium permanganate solution. After manganese dioxide precipitated had been removed, the residue obtained from the filtrate was hydrolyzed with 30 m*l* of 6 N hydrochloric acid under refluxing for 6 hr. Yield, 1.5 g (40% based on IV).

***erythro*-β-Hydroxy-DL-aspartic Acid (X).** A neutralized solution of 3.0 g (0.0152 mol) of VIII in 200 m*l* of water was oxidized with 290 m*l* (0.0734 mol; 103% of required ammount) of 4% aqueous potassium permanganate solution. After removing manganese dioxide, the residue obtained from the filtrate by evaporation of the solvent was dissolved into 30 m*l* of 6 N hydrochloric acid and the resulting solution was refluxed for 6 hr. From the hydrolyzate, X was isolated as its hydrochloride in an usual way. Yield, 1.1 g (39%), mp 215°C (decomp.).

The properties tested of this compound such as infrared spectra were identical with those of an authentic sample.

Found: C, 25.86; H, 4.40; N, 7,66; Cl, 19.49%. Calcd for $C_4H_7NO_5 \cdot HCl$: C, 25.89; H, 4.35; N, 7.55; Cl, 19.11%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2151—2155 (1968)

Photochemical Rearrangement of Azoxybenzene to 2-Hydroxyazobenzene and *cis-trans* Isomerization

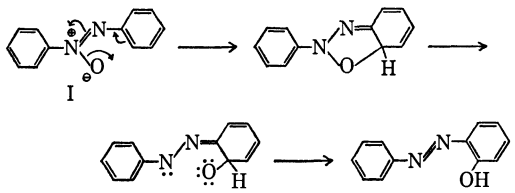
Rikuhei TANIKAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 11, 1968)

The photochemical oxygen migration and *cis-trans* isomerization of azoxybenzene have been investigated. The direct irradiation of *trans*-azoxybenzene leads to both rearrangement to 2-hydroxyazobenzene and *cis-trans* isomerization, whose rate is faster in a polar protic solvent and is never affected by a quencher. Direct irradiation does not afford any azobenzene formed from an excited triplet state of azoxybenzene. On the basis of these observations, the author proposes a mechanism in which 2-hydroxyazobenzene and *cis*-azoxybenzene are formed directly from an excited singlet state of *trans*-azoxybenzene. This mechanism is analogous to that for the photochemical rearrangement of nitrone to oxaziridine. Nitro- or dimethylamino-substituted azoxybenzene undergoes neither photochemical rearrangement nor *cis-trans* isomerization. Oxygen migration is not sterically hindered by a substituent in the 3-position of azoxybenzene.

The photochemical rearrangement of *trans*-azoxybenzene (I) to 2-hydroxyazobenzene (II) was first reported by Knipscheer,[1] and an intramolecular pathway was postulated by Badger *et al.*[2] because an oxygen atom was found to migrate from the azo-nitrogen atom, to which it was originally attached, to an ortho position of the aromatic nucleus adjoining the other azo-nitrogen atom.

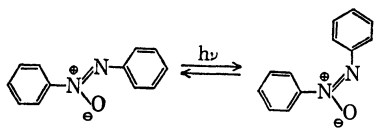


I

II

This intramolecular mechanism was confirmed by means of tracer methods.[3,4] Although it has not definitely been established whether or not an excited triplet state intermediate is involved, it may be suggested that II is formed directly from an excited singlet state of I, because an excited triplet state of I has been found to take a completely different course, *i.e.*, to undergo photochemical reduction to azobenzene.[5] Thus it is necessary to clarify this situation.

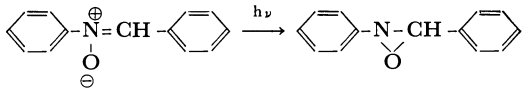
The photolysis of I affords *cis*-azoxybenzene (III) besides II,[6] but no effort has been made to discuss the rearrangement and the isomerization at the same time.



I III

A principal objective of this work is to propose a mechanism for these two photochemical reactions and to discuss the effect of solvents and substituents.

It is interesting to note that neither the photochemical rearrangement of *N*,α-diphenylnitrone (IV) to 2,3-diphenyl-oxaziridine (V)[7] nor the *cis-trans* isomerization of azobenzene[8] proceeds *via* its excited triplet state.



IV V

Results and Discussion

Reactive Intermediate. The photochemical rearrangement of *trans*-azoxybenzene (I) to 2-hydroxyazobenzene (II) was initiated with wavelengths longer than 300 mμ. The sole absorption

(λ_{max}^{EtOH}=323 mμ, ε_{max}=14700) above 300 mμ in the electronic spectrum of I is assigned to a $\pi\rightarrow\pi^*$ transition,[9,10] and $n\rightarrow\pi^*$ transition is assumed to be submerged under the high-intensity band of the $\pi\rightarrow\pi^*$ transition.[9] Therefore, the photochemical rearrangment of I probably starts from its $\pi\rightarrow\pi^*$ transition.

The irradiation of I in a solution or in a solid phase yielded II and *cis*-azoxybenzene (III). An example of the time dependencies of their yields is given in Fig. 1.

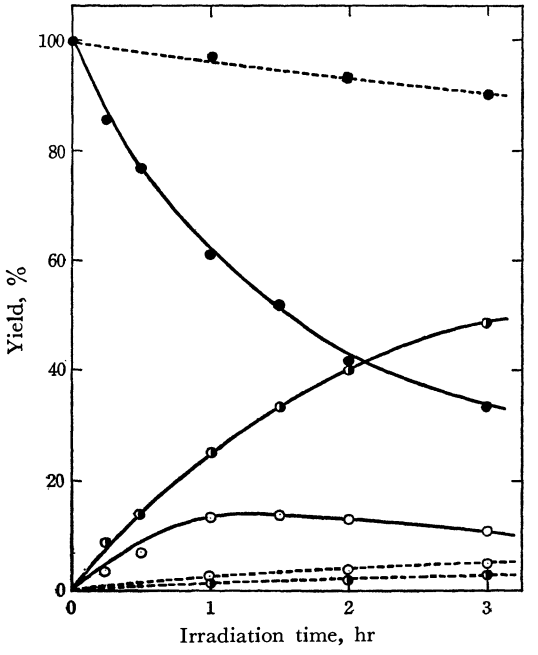

Fig. 1. Irradiation of azoxybenzene (10^{-2} M) at 25.0±0.1°C.
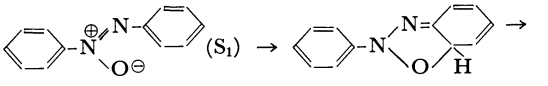
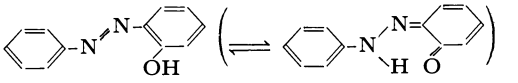
● *trans*-Azoxybenzene (I)
◑ 2-Hydroxyazobenzene (II)
○ *cis*-Azoxybenzene (III)
—— In ethanol ----- In *n*-hexane

Figure 1 shows the photostationary state of a *trans*-isomer I; a *cis*-isomer III was not established so easily. The thermal isomerization of III to I was slow under these experimental conditions.

Even if an oxygen-saturated or degassed solution of I containing naphthalene or iodine was irradiated, no difference from the results shown in Fig. 1 was found; that is to say, neither the rearrangement to II nor the isomerization to III was affected by a quencher. On the other hand, when a degassed solution of I with a sensitizer was irradiated, azobenzene was obtained as a major product. This photochemical reduction was thought to proceed *via* the excited triplet state of I.[5] However, the direct irradiation of I without a sensitizer never afforded azobenzene. These results show that the rearrangement to II probably occur directly from the excited singlet state, S_1, of I, not from its excited triplet state.



I

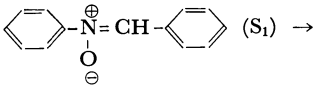


II

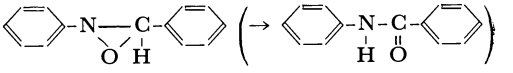
The driving force of cyclization may be attributed to the attack of an oxyanion, as has been implied by Badger *et al.*[2] Interestingly the excited singlet state S_1 of I is more basic than its ground state.[11]

II and III were obtained upon the irradiation of I in carbon tetrachloride or in a solid phase, while acetone was not formed upon the irradiation of I in isopropanol. These results are consistent with the above-mentioned mechanism, in which hydrogen abstraction is not expected to take place. On the other hand, the photochemical reduction of the excited triplet state of I is followed by hydrogen abstraction.[5]

The mechanism for the rearrangement of I to II is assumed to be similar to that for the photochemical rearrangement of *N*,α-diphenylnitrone (IV) to 2,3-diphenyl-oxaziridine (V).[7]



IV



V

The rearrangement of I to II is always accompanied by *cis-trans* isomerization. A *cis-trans* isomerization is often considered to involve an excited triplet state; indeed, the isomerization of IV is thought to proceed *via* the excited triplet state.[7] However, the *cis-trans* isomerization of I probably occur directly from the excited singlet state, not the triplet state for the reaction was not affected by a quencher, and azobenzene, which could be expected to be formed from the excited triplet state of I, was not obtained.

Solvent Effect. The results of the photolysis of I in various solvents using a Pyrex filter are given in Table 1.

The finding that the yield of II was higher in a polar protic solvent can be explained by an ionic

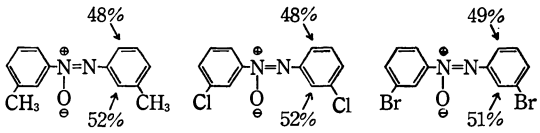
TABLE 1. IRRADIATION OF AZOXYBENZENE (10^{-2} M) FOR 2 HR AT 25.0±0.1°C

Solvent	Dielectric constant	Yield of Product (%)		
		I	II	III
EtOH	24.3	42.3	40.3	12.8
iso-PrOH	18.3	47.2	38.8	12.0
MeCN	37.5	58.3	11.7	12.8
Benzene	2.28	80.0	4.1	14.9
n-Hexane	1.89	93.0	2.0	4.3

mechanism containing the attack of an oxyanion. The solvent effect on the rearrangement and the isomerization of I is in contrast to the effect on the reduction, whose reactivity is controlled by the hydrogen-donating ability of the solvent used (for example, isopropanol>ethanol).[5] Photolysis for different times showed that the faster II was formed, the faster was the photostationary state of I and III established.

Substituent Effect. Although the irradiation of an ethanolic solution of 4,4′-dimethyl-, 4,4′-dichloro-, 4,4′-dibromo-, and 4,4′-dimethoxy-azoxybenzene gave the corresponding 2-hydroxyazobenzene and *cis*-azoxybenzene, 4,4′-dinitro- and 4,4′-bis-(dimethylamino)-azoxybenezene were photochemically unreactive. This is presumably the result of an excitation of a nitro- or dimethylamino-group, not an azoxy-group. It is interesting to note that both the rearrangement and the isomerization always take place at the same time.

Steric Effect. Cumming's report that the irradiation of an ethanolic solution of 3,3′-dimethyl-*azoxybenzene (VI) yielded only 2-hydroxy-3,3′*-dimethylazobenzene[12] is difficult to understand in view of the steric effect of a methyl group. In order to discuss whether or not a substituent at a 3-position of the aromatic nucleus hinders an oxygen atom from migrating to a 2-position, an ethanolic solution of VI, 3,3′-dichloroazoxybenzene (VII) or 3,3′-dibromoazoxybenzene (VIII), was irradiated. The ratios of the migration of an oxygen atom to the 2- and 6-positions were as follows:



VI VII VIII

A bulky substituent like a bromo-group had no steric effect on the rearrangement. This can be explained by the fact that a migrating group is a small oxyanion. The 2-hydroxy-3,3′-dimethylazobenzene obtained by Cumming *et al.* may have been a mixture of 2-hydroxy-3,3′-dimethyl-azobenzene and 6-hydroxy-3,3′-dimethylazobenzene.

Experimental

Materials. The azoxybenzenes were prepared by the reduction of the corresponding nitro compound (Method A) or nitroso compound (Method B), or by the oxidation of the corresponding azobenzene (Method C). They were purified by recrystallization or column chromatography until their thin-layer chromatography (TLC) showed only one spot (see Table 2).

Photolysis of Azoxybenzene (I). An irradiation source was a 100 W high-pressure mercury arc lamp fitted with a water-cooled immersion well (Eikosha Halos PIH 100). A degassed solution (10 m*l*) of I (10^{-2}M) was irradiated in a Pyrex tube (inner diameter, 15 mm) directly attached to the lamp, and was thermostated at 25.0±0.1°C. TLC (Merck silica gel G, *n*-hexane-benzene (2: 1)) showed two products, namely, 2-hydroxyazobenzene (II) and *cis*-azoxybenzene (III). The yield of the product was determined as follows. After irradiation, 2-hydroxy-4,4′-dichloroazobenzene (IX) was added to the solution as an internal standard. Each

component was separated by TLC on silica gel and extracted with chloroform. The yield was determined from the intensity of the maximum absorption of the extract in an electronic spectrum, whose extinction coefficient had previously been determined by means of an authentic sample. Before the absorption of the extract containing a *cis*-isomer III was measured, the extract had been left at *ca.* 35°C in the dark for 10 hr to transform it to a more thermally-stable *trans*-isomer. The extinction coefficients used in this work were: I $\varepsilon_{326\ m\mu}$= 14800, II $\varepsilon_{325\ m\mu}$=18000, and IX $\varepsilon_{339\ m\mu}$=19500 (in chloroform).

The time dependencies of the product composition are given in Fig. 1.

The results of the irradiation of I in various solvents for 2 hours are given in Table 1.

No change in the product ratio was detected from the irradiation of I with a quencher like oxygen (saturated), naphthalene (10^{-1}—1 M), or iodine (10^{-1} M).

A degassed isopropanolic solution of I (5×10^{-2}M) was irradiated for 20 hr as described above, and then analyzed by gas chromatography (Yanagimoto GCG-5DH, polyethylene glycol 20M 4.5 m, He), but no acetone was detected.

Photolysis of 4,4'-Disubstituted Azoxybenzene. A degassed ethanolic solution (10 m*l*) of 4,4'-disubstituted azoxybenzene (10^{-2}M) was irradiated in a Pyrex tube at 48.0±0.1°C for 3 hr. TLC on silica gel showed two products, namely, the corresponding 2-hydroxyazobenzene and *cis*-azoxybenzene. Their yields were determined as above. The results obtained are shown in Table 3.

Photolysis of 3,3'-Dimethylazoxybenzene (VI). *Qualitative Analysis of Products.* An ethanolic solution (200 m*l*) of VI (10^{-2}M) in a flask was irradiated with an unfiltered internal lamp for 100 hr. TLC on silica gel showed two products, which were supposed to be azobenzene derivatives from their color reactions with concentrated sulfuric acid on silica gel thin-layer chromatography. After the removal of the ethanol, the chromatography of the residue on a column of silica gel and elution with petroleum ether (bp 40—60°C) - benzene (2: 1) gave two compounds, A and B.

The first compound, A, was red crystals, mp 69°C (from ethanol).

Found: C, 74.49; H, 6.44; N, 12.11%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%.

The second compound, B, was red needles, mp 101°C (from ethanol).

Found: C, 74.45; H, 6.40; N, 12.32%. Calcd for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%.

From the results of elemental analysis and the usual example of the photochemical rearrangement of azoxybenzene, the two compounds, A and B, may be supposed to be 2-hydroxy-3,3'-dimethylazobenzene (X) and 6-hydroxy-3,3'-dimethylazobenzene (XI). On the other hand, the reaction products from diazotized *m*-toluidine and *o*-cresol were separated by TLC on silica gel to give a compound identical with Compound A in its melting point, R_f value, ultraviolet spectrum, and infrared spectrum; it did not give any Compound B. Hence Compound A was assigned to X. Similarly, the reaction of diazotized *m*-toluidine and *p*-cresol[19] gave Compound B, which was assigned to XI.

Quantitative Analysis of Products. A degassed ethanolic solution (10 m*l*) of VI (10^{-2}M) was irradiated in a Pyrex tube for 30 hr as has been described in discussing the photolysis of I. The products were separated by TLC, and their yields were determined from the absorption intensities in their electronic spectra in a manner described earlier. The extinction coefficients used were: X $\varepsilon_{332\ m\mu}$=19300 and XI $\varepsilon_{326\ m\mu}$=19000 (in chloroform). The product ratio of X to XI was 52 to 48.

Photolysis of 3,3'-Dichloroazoxybenzene (VII) and 3,3'-Dibromoazoxybenzene (VIII). *Qualitative Analysis of Products.* An ethanolic solution (200 m*l*) of VII or VIII (10^{-2}M) was irradiated for 100 hr. The products were separated by TLC (silica gel, *n*-hexane). Two products, C and D, were obtained from the photolysis of VII, and two others, E and F, from the photolysis of VIII. On the other hand, the reaction of diazotized *m*-chloroaniline and *p*-chlorophenol gave Compound C, and the reaction of diazotized *m*-bromoaniline and *p*-bromophenol gave Compound E. Thus Compound C was assigned to 6-hydroxy-3,3'-dichloroazobenzene(XII); D, to 2-hydroxy-3,3'-dichloroazobenzene (XIII); E, to 6-hydroxy-3,3'-dibromoazobenzene (XIV), and F, to 2-hydroxy-3,3'-dibromoazobenzene (XV).

XII was orange crystals, mp 158°C (from ethanol).

Found: C, 54.12; H, 3.26; N, 10.41; Cl, 26.57%. Calcd for $C_{12}H_8N_2OCl_2$: C, 53.97; H, 3.02; N, 10.49; Cl, 26.55%.

XIII was orange needles, mp 144°C (from ethanol).

Found: C, 54.21; H, 3.26; N, 10.72; Cl, 26.74%. Calcd for $C_{12}H_8N_2OCl_2$: C, 53.97; H, 3.02; N, 10.49; Cl, 26.55%.

XIV was reddish orange crystals, mp 171°C (from ethanol).

Found: C, 40.59; H, 2.49; N, 7.86; Br, 44.99%. Calcd for $C_{12}H_8N_2OBr_2$: C, 40.48; H, 2.27; N, 7.87; Br, 44.89%.

19) P. Jacobson and P. Piepenbrink, *ibid.*, **27**, 2703 (1894).

XV was reddish-brown crystals, mp 144°C (from ethanol).

Found: C, 40.76; H, 2.39; N, 7.79; Br, 45.11%. Calcd for $C_{12}H_8N_2OBr_2$: C, 40.48; H, 2.27; N. 7.87; Br, 44.89%.

Quantitative Analysis of Products. A degassed ethanolic solution (10 m*l*) of VII or VIII (10^{-2}M) was irradiated in a Pyrex tube for 30 hr as has been described in connection with the photolysis of I. The yields of the products were determined as has been described above. The extinction coefficients used were: XII $\varepsilon_{316\ m\mu}$=16700, XIII $\varepsilon_{330\ m\mu}$=18800, XIV $\varepsilon_{318m\mu}$=16400, and XV $\varepsilon_{332\ m\mu}$=19100 (in chloroform). The product ratio of XI to XII was 48 to 52, and that of XIV to XV was 49 to 51.

The author wishes to thank Professor Ryozo Goto for his helpful discussions and encouragement throughout the course of this work. He is also indebted to Professors Aritsune Kaji and Kazuhiro Maruyama for their valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2155—2161 (1968)

Selective Chemical Cleavage of Threonine Peptides[1)]

Takeo KANEKO, Shoichi KUSUMOTO,*1 Toshishige INUI*2 and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 13, 1968)

Threonine peptide was converted to an oxazolidone derivative *via* an *O*-chlorocarbonyl derivative by treatment with phosgene and dimethylaniline followed by refluxing in xylene, wherever the threonine residue was located in peptide chain, that is, either at amino or carboxyl terminal, or in the middle of the chain. When the oxazolidone peptide was treated with alkali at room temperature, the peptide bond of the original threonine residue of which the amino group participated was selectively cleaved giving a mixture of the carboxylic acid derived from the *N*-terminal amino acid or peptide, and 5-methyl-2-oxo-oxazolidine-4-carbonyl derivative, whereas other peptide bonds remained unchanged in this reaction. Several threonine peptides were synthesized and were subjected to the cleavage reaction. In all cases the expected cleavage occurred in a satisfactory yield.

Selective cleavage reaction of a peptide bond at the residue of β-hydroxy-α-amino acid by a strong acid such as sulfuric acid[2-5)] or hydrogen fluoride[6)] has been known. This cleavage is based on the N→O acyl migration. However, an entirely different principle can be applied to the same purpose. As already mentioned in the preliminary report,[1)] methyl *N*-benzoylthreoninate was found to be cyclized to *N*-benzoyloxazolidone derivative which was then hydrolyzed to 5-methyl-2-oxo-oxazolidine-4-carboxylic acid by sodium hydroxide under a mild condition accompanied with removal of the benzoyl group. This finding leads to an idea that the peptide bond in which the amino group of the hydroxyamino acid participated would be cleaved by cyclization to the oxazolidone derivative followed by hydrolysis with alkali as shown in Fig. 1, inasmuch as *N*-acyl

group attached to nitrogen atom in oxazolidone ring might be so labile to basic reagent as to cause the hydrolytic cleavage at the linkage between the acyl group and the ring nitrogen atom.

Actually *N*-protected serine peptide was cleaved selectively by this method to give the *N*-protected amino acid or peptide and the oxazolidone derivative as reported in the previous paper.[7] In this paper, the results obtained when threonine peptides were subjected to the similar reaction were presented.

All threonine peptides used in this study were synthesized mainly through the dicyclohexylcarbodiimide method by the usual precedure. Authentic 5-methyl-2-oxo-oxazolidine-4-carbonyl derivatives were prepared either from threonine itself or from threonyl peptide by treatment with phosgene and the base as shown below in the case of the cleavage reaction.

Di- or tripeptide in which the threonine residue was located at a *C*-terminal position, *e.g.*, *N*-benzyloxycarbonylalanylthreonine methyl ester (I, V), *N*-benzyloxycarbonylglycylthreonine methyl ester (VIII) or *N*-benzyloxycarbonylalanylalanylthreonine methyl ester (XI), was investigated as a first type of a model threonine peptide for the cleavage reaction. *N*-Benzyloxycarbonyl-DL-alanyl-DL-threonine methyl ester (I) or *N*-benzyloxycarbonyl-L-alanyl-L-threonine methyl ester (V) was converted to the *O*-chlorocarbonyl compound in almost quantitative yield according to the procedure by Skinner *et al.*[8] or by Bergel *et al.*[9] The *O*-chlorocarbonyl compound was then cyclized to an oxazolidone derivative by heating in xylene under reflux with evolution of hydrogen chloride. In this reaction, L-L compound V gave an oily oxazolidone derivative (VII) as the sole product, whereas DL-DL compound I afforded a mixture of crystalline and oily substances (IIIa and IIIb respectively). In the latter case, formation of the two substances may be due to a diastereoisomerism. When the compound V was treated with phosgene and pyridine under the condition which was used to prepare cyclic carbonic esters of vicinal glycol of sugars,[10] the oxazolidone derivative VII was obtained directly without isolation of the intermediate, the *O*-chlorocarbonyl compound. An infrared spectrum of this product was identical to that of the product of the stepwise synthesis as mentioned above.

The L-oxazolidone compound VII was treated with potassium hydroxide in methanol at room temperature to afford a mixture of *N*-benzyloxycarbonyl-L-alanine and L-*trans*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (L-IV) in yields of 71 and 60% respectively, while, in a similar reaction of the crystalline racemic oxazolidone compound IIIa, yields of the corresponding products were 87 and 90% respectively. Under the same condition of alkaline treatment, the original dipeptide, *i.e.*, *N*-benzyloxycarbonylalanylthreonine methyl ester (I or V) was only saponified and no cleavage of the peptide bond took place.

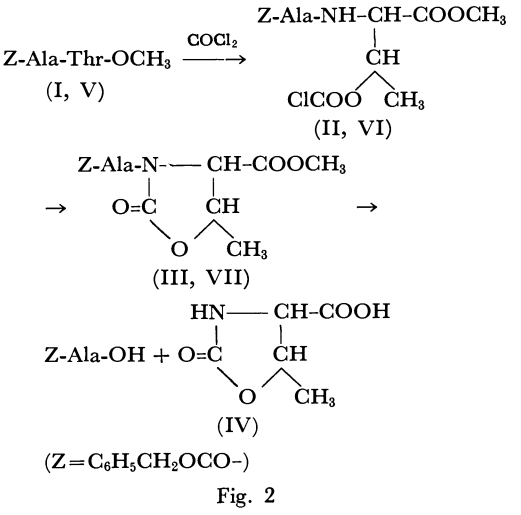

Fig. 2

Similar cleavage reactions also occurred on *N*-benzyloxycarbonylglycyl-DL-threonine methyl ester (VIII) and *N*-benzyloxycarbonyl-L-alanyl-L-alanyl-L-threonine methyl ester (XI), both giving fairly good yields of the corresponding degradation products as shown in Table 1. The reaction of the latter peptide ester XI with phosgene in benzene did not proceed well and only the starting material was recovered, while the reaction in dioxane gave the *O*-chlorocarbonyl compound (XII) in a good yield. From the results obtained above, it is now concluded that the cleavage reaction takes place selectively at the peptide linkage involving the amino group of the threonine residue without any effect on other peptide bonds, and all amino acid residues in the peptide are not subjected to racemization during the reaction.

In order to confirm the conclusion that the cleavage reaction occurs only at the linkage of the amino side of the threonine residue wherever threonine is located in the peptide chain, a reaction of *N*-benzyloxycarbonylglycyl-L-threonyl-L-phenylalanine methyl ester (XIX) was next investigated. In a similar way, the tripeptide XIX was converted to *N*-benzyloxycarbonylglycyl-L-5-methyl-2-oxo-oxazolidine-4-carbonyl-L-phenylalanine methyl ester (XXI) through a corresponding chlorocarbonyl compound (XX) as shown in Fig. 3. This oxazolidone peptide XXI was also cleaved by alkaline hydrolysis to give *N*-benzyloxycarbonylglycine and

TABLE 1. RESULTS OF SELECTIVE CLEAVAGE OF THREONINE PEPTIDES

Peptide	Oxazolidone derivative	Product isolated by cleavage reaction (yield)*	
I	IIIa	Z-Ala-OH (DL) (87%)	IV (DL) (90%)
I	IIIb	Z-Ala-OH (DL) (79%)	IV (DL) (67%)
V	VII	Z-Ala-OH (71%)	IV (60%)
VIII	X	Z-Gly-OH (71%)	IV (76%)
XI	XIII	Z-Ala-Ala-OH (86%)	IV (62%)
XIX	XXI	Z-Gly-OH (54%)	XVII (50%)

* Unless otherwise stated, the amino acid residue has an L-configuration.

L-5-methyl-2-oxo-oxazolidine-4-carbonyl-L-phenylalanine (XVII) in 54% and 50% yields respectively. The latter oxazolidone derivative XVII was crystallized as cyclohexylammonium salt and identified by comparison with the authentic compound which was obtained by treatment of L-threonyl-L-phenylalanine with phosgene and potassium carbonate.

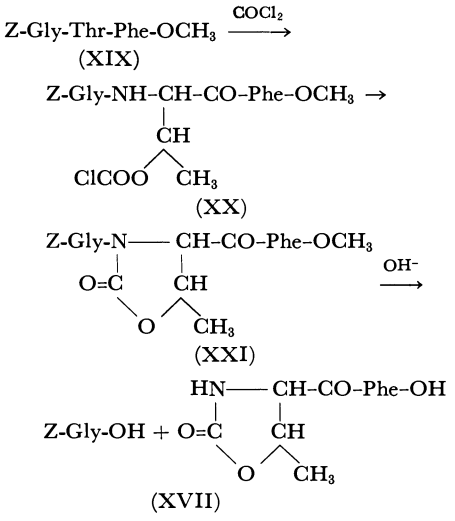

Fig. 3

In conclusion, it is ascertained that the peptide of β-hydroxy-α-amino acid, not only serine but threonine, can be cleaved selectively at the peptide linkage which involves an amino group of the hydroxyamino acid through formation of oxazolidone derivative without any racemization of amino acid residues and any cleavage of other peptide bonds.

Experimental*3

N-Benzyloxycarbonyl-DL-alanyl-O-chlorocarbonyl-DL-threonine Methyl Ester (II). Phosgene was passed through a suspension of 6.8 g (0.020 mol) of N-benzyloxycarbonyl-DL-alanyl-DL-threonine methyl ester[11] (I) in 80 m*l* of benzene at 8—11°C for 20 min after addition of 2.4 g (0.020 mol) of dimethylaniline until the solid was dissolved. The reaction mixture was stirred below 20°C for 2 hr and then allowed to stand overnight. Through the solution, carbon dioxide was passed to remove excess phosgene. The benzene solution was washed with water and dilute hydrochloric acid, and then dried. Evaporation *in vacuo* gave an oily substance which was readily crystallized; wt 7.8 g (97%). Recrystallization from benzene-petroleum ether gave pure crystals of II; mp 103.5—104.0°C.

Found: C, 51.12; H, 5.26; N, 6.91%. Calcd for $C_{17}H_{21}O_7N_2Cl$: C, 50.94; H, 5.28; N, 6.99%.

In order to confirm a structure of the *O*-chlorocarbonyl compound II, this was converted to *N*-benzyloxycarbonyl-DL-alanyl-*O*-(*N*-phenylcarbamoyl)-DL-threonine methyl ester by a reaction with aniline; mp 155—156°C.

Found: C, 60.38; H, 5.94; N, 9.22%. Calcd for $C_{23}H_{27}O_7N_3$: C, 60.38; H, 5.95; N, 9.19%.

Methyl DL-3-(*N*-Benzyloxycarbonyl-DL-alanyl)-5-methyl-2-oxo-oxazolidine-4-carboxylate (IIIa, b). A solution of 8.6 g of crude II in 80 m*l* of xylene was heated under reflux. An evolution of hydrogen chloride gas ceased after 1 hr. Upon concentration of the reaction mixture to about half a volume, a crystalline solid was formed. It was filtered off; wt 3.8 g (49%), and then recrystallized from ethyl acetate to give crystalline IIIa of mp 129.5—130.0°C; wt 2.8 g.

Found: C, 56.16; H, 5.52; N, 7.60%. Calcd for $C_{17}H_{20}O_7N_2$: C, 56.04; H, 5.53; N, 7.69%.

A mother liquor from the crystals was evaporated *in vacuo* to yield 4.5 g of an oily product IIIb.

Cleavage of IIIa and IIIb by Alkaline Hydrolysis. *a) Hydrolysis of Crystalline IIIa.* To a solution of 2.46 g (6.76 mmol) of IIIa in 38 m*l* of methanol, 1.51 m*l* of 0.90 N aqueous potassium hydroxide solution was added with stirring for 20 min. Stirring at room temperature was continued for an additional 1.5 hr. After evaporation *in vacuo*, water was added to the residue. Undissolved part was extracted with ethyl acetate. The aqueous layer was acidified with concentrated hydrochloric acid to pH 3 to deposit an oily substance which was then extracted with ethyl acetate. Evaporation of the solvent from the latter extract *in vacuo* after drying gave crystals; wt 1.32 g (87%), mp 113—114°C. It was recrystallized from ethyl acetate-petroleum ether; mp 113.5—114.0°C. The melting point and infrared spectrum of this compound were identical to those of authentic *N*-benzyloxycarbonyl-DL-alanine.

The aqueous layer of pH 3 which was separated from the ethyl acetate layer was further acidified to pH 1 by addition of concentrated hydrochloric acid, and evaporated *in vacuo*. The residue obtained was extracted with hot ethyl acetate three times. The ethyl acetate solution

*3 All melting points given are uncorrected.

11) Mp 103.5—105.0°C. This compound had been prepared by Th. Wieland, K. Freter and E. Gross, *Ann.*, **626**, 154 (1959) through the mixed anhydride method. In this study, the same compound was synthesized by the carbodiimide method in a similar way to that of the preparation of L-L-isomer (V) as shown below.

was concentrated after decolorization to give crystals; wt 0.89 g (90%), mp 117—119°C. Recrystallization from ethyl acetate - petroleum ether raised the melting point to 126.5—127.0°C. The melting point and the infrared spectrum of this crystals were identical to those of authentic DL-*trans*-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (DL-IV)[12].

b) *Hydrolysis of Oily IIIb.* In a way similar to the hydrolysis of IIIa, 4.5 g of IIIb was dissolved in 60 m*l* of methanol and treated with 27 m*l* of 1 N potassium hydroxide solution. As reaction products, 2.2 g (79%) of *N*-benzyloxycarbonyl-DL-alanine and 1.2 g (67%) of DL-5-methyl-2-oxo-oxazolidine-4-carboxylic acid (DL-IV) were obtained. Both compounds were identified by comparison with the authentic samples in their melting points and infrared spectra respectively.

N-Benzyloxycarbonyl-L-alanyl-L-threonine Methyl Ester (V). To a mixed solution of 22.3 g (0.10 mol) of *N*-benzyloxycarbonyl-L-alanine and methyl L-threoninate, prepared from 17.0 g (0.10 mol) of the hydrochloride and 10.2 g of triethylamine, in 180 m*l* of chloroform, a solution of 20.6 g (0.10 mol) of *N,N'*-dicyclohexylcarbodiimide in 50 m*l* of chloroform was added with stirring for 30 min. After standing overnight, *N,N'*-dicyclohexylurea formed was removed by filtration. The chloroform solution was washed with water, dilute hydrochloric acid, water, aqueous sodium hydrogen carbonate solution and water successively. Concentration of the solution after drying gave 29.5 g (87%) of a crude product which was then recrystallized from ethyl acetate to yield 22.9 g (68%) of V; mp 132.0—132.8°C, $[\alpha]_D^{16.5}$ −23.6° (*c* 2.88, methanol).

Found: C, 57.15; H, 6,63; N, 8.15%. Calcd for $C_{16}H_{22}O_6N_2$: C, 56.79; H, 6.55; N, 8.28%.

N-Benzyloxycarbonyl-L-alanyl-O-chlorocarbonyl-L-threonine Methyl Ester (VI). Phosgene was passed through a suspension of 6.8 g (0.020 mol) of V in 80 m*l* of benzene in the presence of 2.4 g (0.020 mol) of dimethylaniline at about 8°C for 30 min. The reaction mixture was treated in a manner similar to that in the preparation of DL-compound II to yield 8.0 g (100%) of crude crystals of VI. This was recrystallized from benzene-petroleum ether (1 : 1); mp 79.5—81.0°C, $[\alpha]_D^{13.5}$ +30.8° (*c* 3.05, benzene).

Found: C, 51.08; H, 5.15; N, 6.96; Cl. 8.48%. Calcd for $C_{17}H_{21}O_7N_2Cl$: C, 50.94; H, 5.28; N, 6.99; Cl, 8.85%.

Methyl L-3-(N-Benzyloxycarbonyl-L-alanyl)-5-methyl-2-oxo-oxazolidine-4-carboxylate (VII). *a*) *Stepwise Synthesis from VI.* A solution of 7.2 g of the crude VI in 60 m*l* of xylene was heated under reflux. A similar treatment of the reaction mixture to that in the preparation of DL-compound III gave 6.8 g of an oily product VII, $[\alpha]_D^{12}$ −58.8° (*c* 3.0, methanol).

b) *Direct Synthesis from V.* A mixture of 5.0 m*l* (0.062 mol) of pyridine and 12 m*l* of anhydrous benzene was added to 19.8 g of 10% phosgene solution in benzene at 2—4°C for 20 min with stirring. To this sticky half-frozen mixture, a solution of 3.2 g (9.4 mmol) of V in 50 m*l* of anhydrous dioxane was added dropwise at about 0°C for 40 min with stirring. Though the stirring became increasingly difficult, it was continued at this temperature for 1 hr, and then at room temperature for an additional 1 hr. After addition of 80 m*l* of ice-water, the reaction mixture was extracted with ethyl acetate several times. Combined organic layer was washed with 1 N hydrochloric acid, 5% aqueous sodium hydrogen carbonate solution and water successively, and dried with magnesium sulfate. After the solution had been evaporated *in vacuo*, 3.5 g of a pale brownish oil remained which was identified with authentic VII in infrared spectrum. This product seemed to be not so pure, because, on the cleavage reaction, it gave cyclohexylammonium salts of *N*-benzyloxycarbonylalanine and 5-methyl-2-oxo-oxazolidine-4-carboxylic acid in relatively poor yields of 42 and 26% respectively.

Cleavage of VII by Alkaline Hydrolysis. In a way similar to that in the cleavage of DL-compound III, hydrolysis of 3.11 g (8.54 mmol) of the crude VII in 80 m*l* of ethanol and 18 m*l* of 0.95 N potassium hydroxide solution was carried out. Extraction with ethyl acetate from an aqueous solution of pH 3 gave crude crystals of *N*-benzyloxycarbonyl-L-alanine of mp 72—76°C; wt 1.36 g (71%). It was recrystallized from chloroform-petroleum ether (1 : 1); wt 0.68 g, mp 86—87°C, $[\alpha]_D^{13.2}$ 13.8° (*c* 3.32, acetic acid). Further acidification of the remaining aqueous solution by hydrochloric acid gave 0.75 g (60%) of crude crystals of IV; mp 129—133°C. Recrystallization from ethyl acetate gave pure crystals of mp 139.0—139.8°C, $[\alpha]_D^{19.8}$ +40.7° (*c* 2.75, water). These physical constants as well as the infrared spectrum of this compound were all identical to those of authentic L-IV.[13]

N-Benzyloxycarbonylglycyl-DL-threonine Methyl Ester (VIII). A solution of 25.1 g (0.12 mol) of *N*-benzyloxycarbonylglycine in 260 m*l* of a mixture of chloroform and dioxane (1 : 1) was added to a solution of methyl DL-threoninate which was prepared from 20.4 g (0.12 mol) of the hydrochloride and 12.3 g (0.12 mol) of triethylamine, in 100 m*l* of chloroform. To the reaction mixture, a solution of 24.7 g (0.12 mol) of *N,N'*-dicyclohexylcarbodiimide in 50 m*l* of chloroform was added for 40 min with stirring. After stirring for 2 hr at room temperature, it was allowed to stand overnight. By the usual procedure, 37 g (95 %) of a crude product of VIII was obtained. It was recrystallized from ethyl acetate; wt 26.2 g (67%), mp 110.5—111.8°C.

Found: C, 55.57; H, 6.31; N, 8.87%. Calcd for $C_{15}H_{20}O_6N_2$: C, 55.55; H, 6.22; N, 8.64%.

Cleavage Reaction of VIII. *N*-Benzyloxycarbonylglycyl-*O*-chlorocarbonyl-DL-threonine methyl ester (IX) was obtained from 6.5 g (0.020 mol) of VIII by action of phosgene in the presence of 2.4 g of dimethylaniline in 80 m*l* of benzene at 5—8°C; wt 7.2 g (94%). Whole amount of the crude product IX thus obtained was cyclized by heating in 60 m*l* of xylene under reflux for 1 hr to yield 6.2 g of an oily substance (X) which was then dissolved in 80 m*l* of methanol and hydrolyzed by treatment with 35 m*l* of 1 N potassium hydroxide at room temperature for 1.5 hr. The reaction mixture was acidified to pH 3 by hydrochloric acid, and extracted with ethyl acetate to give crude *N*-benzyloxycarbonylglycine; wt 3.0 g (71% based on VIII). It was recrystallized from ethyl acetate - petroleum ether (4 : 1); mp 121.0—121.8°C. The remaining aqueous solution was acidified to pH 1 and treated by the usual procedure to

12) Lit.: T. Kaneko and T. Inui, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **82**, 1075 (1961); mp 127—128°C.

13) Lit.: T. Kaneko and T. Inui, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **82**, 1078 (1961); mp 139.5—140.5°C, $[\alpha]_D^{25}$ +41.2° (*c* 3.04, water).

give 2.2 g (76% based on VIII) of DL-IV. It was recrystallized from ethyl acetate - petroleum ether (4 : 1); mp 126.5—127.0°C. Both products were identified by comparison with the authentic samples.

N-Benzyloxycarbonyl-L-alanyl-L-alanyl-L-threonine Methyl Ester (XI). *a) Azide Method.* To a cold solution of 6.5 g (0.021 mol) of *N*-benzyloxycarbonyl-L-alanyl-L-alanine hydrazide[14] in a mixture of 43 m*l* of acetic acid, 21.5 m*l* of 5 N hydrochloric acid and 170 m*l* of water, there was added a cold solution of 18.0 m*l* of 10% aqueous sodium nitrite solution at −5°C. An oily product formed solidified immediately. The solid was extracted with a mixture of ethyl acetate and ether (1 : 1). The extract was washed with water, 3% aqueous sodium hydrogen carbonate solution and water successively in the cold, and then dried with sodium sulfate. On the other hand, 3.5 g (0.035 mol) of triethylamine was added to a suspension of 5.8 g (0.034 mol) of methyl L-threoninate hydrochloride in 40 m*l* of chloroform. After addition of 120 m*l* of anhydrous ether, triethylamine hydrochloride formed was filtered off. Free ester solution thus obtained was poured into the azide solution prepared above on ice-cooling. The reaction mixture was stirred for 3 hr and then kept in a refrigerator overnight. A crystalline product of XI was filtered; wt 5.9 g (69%), mp 179—180°C. It was recrystallized from methanol - ethyl acetate (3 : 1); wt 5.0 g, mp 181.0—181.5°C, $[\alpha]_D^{11}$ −56.5° (*c* 1.82, methanol).

Found: C, 55.87; H, 6.68; N, 10.26%. Calcd for $C_{19}H_{27}O_7N_3$: C, 55.73; H, 6.65; N, 10.26%.

b) Carbodiimide Method. A solution of 3.1 g (0.030 mol) of triethylamine and methyl L-threoninate prepared from 5.1 g (0.030 mol) of the hydrochloride, in 30 m*l* of chloroform was added to a solution of 8.8 g (0.030 mol) of *N*-benzyloxycarbonyl-L-alanyl-L-alanine in 40 m*l* of a mixture of dioxane and chloroform (1 : 1). To the mixture, a solution of 6.2 g (0.030 mol) of *N,N'*-dicyclohexylcarbodiimide in 15 m*l* of chloroform was added dropwise. The reaction mixture was stirred at room temperature for 4 hr and then allowed to stand overnight. A mixture of dicyclohexylurea and a condensed product was filtered off. This was heated in 80 m*l* of dioxane under reflux to dissolve the latter only, keeping the former insoluble. To the filtrate, 100 m*l* of petroleum ether was added to crystallize the product; wt 5.3 g (43%), mp 177—179°C. This was recrystallized from methanol-ethyl acetate (3 : 1); wt 3.6 g, mp 181.5—182.8°C, $[\alpha]_D^{12.5}$ −56.3° (*c* 1.83, methanol). All properties of these crystals were quite identical to those of the compound XI obtained by the azide method.

Found: C, 55.79; H, 6.64; N, 10.35%.

The organic layer separated from the solid product was washed with water, dilute hydrochloric acid, aqueous sodium hydrogen carbonate solution and water successively, and then concentrated *in vacuo* to give crystals; wt 3.5 g. It was recrystallized from ethyl acetate - petroleum ether (25 : 10); wt 2.5 g mp 141.5—142.5°C, $[\alpha]_D^{12.5}$ −5.4° (*c* 1.84, methanol).

Found: C, 56.27; H, 6.89; N, 9.91; H_2O, 2.53%. Calcd for $C_{33}H_{43}O_{11}N_5 \cdot H_2O$: C, 56.32; H, 6.45; N, 9.95; H_2O, 2.56%.

From the results of the elementary analysis and an infrared spectrum, a structure of this compound is presumed to be *O,N*-di-(*N*-benzyloxycarbonyl-L-alanyl-L-alanyl)-L-threonine methyl ester hydrate.

N-Benzyloxycarbonyl-L-alanyl-L-alanyl-O-chlorocarbonyl-L-threonine Methyl Ester (XII). Through a suspension of 4.1 g (0.01 mol) of XI in 40 m*l* of dioxane, phosgene was passed at 8—10°C for 45 min in the presence of 1.2 g (0.01 mol) of dimethylaniline. After stirring for 3.5 hr, the reaction mixture was allowed to stand overnight. After removal of excess phosgene by passage of carbon dioxide, the solution was concentrated *in vacuo* to give crystals. It was filtered, washed with water and then dried; wt 4.2 g (89%), mp 149—150°C (decomp.). Recrystallization from benzene gave 3.5 g of pure crystals; mp 150.5—151.°C (decomp.), $[\alpha]_D^{15}$ +8.6° (*c* 3.02, benzene).

Found: C, 50.87; H, 5.59; N, 8.81%. Calcd for $C_{20}H_{26}O_8N_3Cl$: C, 50.90; H, 5.55; N, 8.91%.

Methyl L-3-(N-Benzyloxycarbonyl-L-alanyl-L-alanyl)-5-methyl-2-oxo-oxazolidine-4-carboxylate (XIII). Heating of 3.1 g (0.066 mol) of XII in 30 m*l* of xylene under reflux for 75 min followed by evaporation *in vacuo* gave a product of a closed ring as a syrup; wt 2.8 g (98%), $[\alpha]_D^{15}$ −84.6° (*c* 3.6, methanol). This was used for the following cleavage reaction without further purification.

Cleavage of XIII by Alkaline Hydrolysis. Hydrolysis of 2.19 g (5.03 mmol) of XIII was carried out in 30 m*l* of methanol by addition of 11.1 m*l* of 0.9 N aqueous potassium hydroxide and keeping the solution at room temperature for 1.5 hr. After methanol had been evaporated *in vacuo*, water was added to the reaction mixture, pH of which was then adjusted to 3 by addition of hydrochloric acid. Extraction with ethyl acetate followed by evaporation of the solvent gave 1.27 g (86%) of crude crystals of mp 135.0—139.5°C. It was recrystallized from chloroform to yield a pure material; mp 149.0—150.0°C, $[\alpha]_D^{13.5}$ −32.5° (*c* 3.26, methanol), which was identified to be *N*-benzyloxycarbonyl-L-alanyl-L-alanine by comparison with the authentic sample.

On the other hand, the aqueous layer separated from the ethyl acetate extract was further acidified and evaporated *in vacuo* to give a residue. This was extracted with hot ethyl acetate and the solvent was removed by evaporation to give L-IV; wt 0.45 g (62%), mp 128—132°C. It was recrystallized from ethyl acetate; mp 138—140°C, $[\alpha]_D^{13.8}$ +41.8° (*c* 2.70, water). These were identical to those of the authentic sample.

N-Benzyloxycarbonyl-L-threonyl-L-phenylalanine Methyl Ester (XIV). To a mixed solution of 51 g (0.20 mol) of *N*-benzyloxycarbonyl-L-threonine in 400 m*l* of acetonitrile and methyl L-phenylalaninate, prepared from 48 g (0.22 mol) of the hydrochloride, in 60 m*l* of acetonitrile, a solution of 42 g (0.20 mol) of *N,N'*-dicyclohexylcarbodiimide in 100 m*l* of acetonitrile was added at room temperature with stirring. Stirring at room temperature was continued for 4 hr. After standing overnight, the urea derivative precipitated was filtered off, and the solvent was removed by evaporation *in vacuo*. Syrupy residue thus obtained was dissolved in ethyl acetate, washed with 5% aqueous potassium hydrogen carbonate solution, 0.5 N hydrochloric acid and water successively, and then dried with sodium sulfate. To a concentrated solution, petroleum ether was added to give

14) This compound was prepared from *N*-benzyloxycarbonyl-L-alanyl-L-alanine methyl ester by the usual procedure; mp 212—213°C, $[\alpha]_D^{7.3}$ −51.0° (*c* 1.92, methanol), $[\alpha]_D^{18}$ −67.4° (*c* 1.84, 0.5 N hydrochloric acid). Lit.: B. F. Erlanger and E. Brand, *J. Am. Chem. Soc.*, **73**, 3508 (1951).

crystals; wt 74 g (89%), mp 104—106°C. Repeated recrystallization from ethyl acetate - petroleum ether raised the melting point up to 108.5—109.0°C, $[\alpha]_D^{19}$ +3.9° (*c* 1.15, ethanol).

Found: C, 63.72; H, 6.36; N, 6.66%. Calcd for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N. 6.76%.

***N*-Benzyloxycarbonyl-L-threonyl-L-phenylalanine (XV).** To a solution of 1.03 g (2.5 mmol) of XIV in a mixture of 35 m*l* of dioxane and 5 m*l* of water, there was added 5.5 m*l* of 0.5 N aqueous sodium hydroxide solution dropwise for 8 hr with stirring. After standing overnight, 5.5 m*l* of 0.5 N hydrochloric acid was added, and the reaction mixture was evaporated *in vacuo* to dryness. The residue obtained was triturated with ethyl acetate to remove insoluble sodium chloride. Ethyl acetate solution was extracted with 5% sodium hydrogen carbonate solution. The aqueous extract was acidified with 2 N hydrochloric acid to yield crystals of XV; wt 0.51 g (51%), mp 152—154°C. It was recrystallized from ethyl acetate - petroleum ether; mp 156—157°C, $[\alpha]_D^{20}$ +23.2° (*c* 1.94, ethanol).

Found: C, 62.74; H, 6.04; N, 6.76%. Calcd for $C_{21}H_{24}O_6N_2$: C, 62.99; H, 6.04; N, 7.00%.

From the mother liquor of the first crystallization of the product, a considerable amount of XVII was obtained.

L-Threonyl-L-phenylalanine (XVI). Hydrogen gas was passed through a solution of 8.0 g (0.020 mol) of XV in a mixture of 150 m*l* of methanol and 20 m*l* of water at room temperature for 6 hr in the presence of palladium black. When a crystalline product was formed during the hydrogenation, water was added to dissolve it. The catalyst was removed by filtration and the filtrate was concentrated to a small volume. On addition of ethanol, crystals of dipeptide XVI were formed; wt 5.9 g (95%). It was recrystallized from water-ethanol; mp 251—253°C (decomp.), $[\alpha]_D^{21}$ +24.8° (*c* 2.02, water).

Found: C, 57.31; H, 7.77; N, 9.16%. Calcd for $C_{13}H_{18}O_4N_2 \cdot C_2H_6O$: C, 57.67; H, 7.74; N, 8.97%.

L-5-Methyl-2-oxo-oxazolidine-4-carbonyl-L-phenylalanine (XVII). To a solution of 3.1 g (0.01 mol) of XVI containing one mole of ethyl alcohol as crystallization solvent in 20 m*l* of water there were added 10 m*l* of 1 N aqueous potassium hydroxide solution and 2.8 g (0.02 mol) of solid potassium carbonate. To the mixture, 9.1 g of toluene solution containing 1.5 g (0.015 mol) of phosgene was added dropwise at 1—5°C for 20 min with vigorous stirring. The reaction mixture was stirred at the same temperature for 1.5 hr and then at room temperature for 40 min. An aqueous layer was separated, washed with ether and then acidified with 2 N hydrochloric acid to give crystals; wt 0.6 g. The filtrate was evaporated *in vacuo* to a residue, which was then triturated with ethyl acetate. To the concentrated ethyl acetate solution, petroleum ether was added to yield a second crop of the crystalline product; wt 2.3 g. Total yield, 2.9 g (99%). This was purified as cyclohexylammonium salt; mp 210.0—210.5°C, $[\alpha]_D^{20}$ +25.2° (*c* 1.27, water).

Found: C, 61.15; H, 7.53; N, 10.56%. Calcd for $C_{14}H_{16}O_5N_2 \cdot C_6H_{13}N$: C, 61.36; H, 7.47; N, 10.74%.

L-Threonyl-L-phenylalanine Methyl Ester Hydrochloride (XVIII). Hydrogen gas was passed through a solution of 8.3 g (0.020 mol) of XIV in 100 m*l* of methanol and 3.5 m*l* of concentrated hydrochloric acid in the presence of palladium black at room temperature for 20 hr. After removal of the catalyst by filtration, the solution was evaporated *in vacuo*. An oily residue thus obtained was dissolved in a small amount of methanol, and on addition of ether needles were obtained; wt 5.2 g (83%). It was recrystallized from methanol - ether; wt 4.4 g, mp 136—138°C.

Found: C, 53.10; H, 6.78; N, 8.67; Cl, 11.06%. Calcd for $C_{14}H_{21}O_4N_2Cl$: C, 53.08; H, 6.68; N, 8.84; Cl, 11.19%.

***N*-Benzyloxycarbonylglycyl-L-threonyl-L-phenylalanine Methyl Ester (XIX).** To a mixed solution of 4.2 g (0.020 mol) of *N*-benzyloxycarbonylglycine in 20 m*l* of tetrahydrofuran and 4.1 g (0.020 mol) of *N,N'*-dicyclohexylcarbodiimide in 20 m*l* of tetrahydrofuran, there was added a solution of a free dipeptide ester, prepared from 6.3 g (0.020 mol) of XVIII and an equivalent amount of triethylamine, in 80 m*l* of tetrahydrofuran. After the reaction mixture had been stirred at room temperature for 4 hr, it was allowed to stand overnight. A precipitate formed upon addition of acetic acid was filtered off and the filtrate was evaporated *in vacuo*. An oily residue obtained was crystallized from ethyl acetate; wt 6.9 g (73%), mp 146.0—148.5°C. It was recrystallized from ethyl acetate; mp 146.5—149.0°C, $[\alpha]_D^{22}$ −14.0° (*c* 2.0, chloroform).

Found: C, 61.25; H, 6.38; N, 8.78%. Calcd for $C_{24}H_{29}O_7N_3$: C, 61.13; H, 6.20; N, 8.91%.

***N*-Benzyloxycarbonylglycyl-*O*-chlorocarbonyl-L-threonyl-L-phenylalanine Methyl Ester (XX).** Phosgene was passed through a solution of 4.7 g (0.010 mol) of XIX and 1.2 g (0.010 mol) of dimethylaniline in 120 m*l* of anhydrous dioxane at 9—11°C 30 min. Stirring at this temperature was continued for 1.5 hr and then at room temperature for 1 hr. After standing overnight, the solvent was removed by evaporation *in vacuo*. A solution of the residue thus obtained in ethyl acetate was washed with 0.3 N hydrochloric acid and then dried with magnesium sulfate. Again, the solution was evaporated *in vacuo* to an oily residue, which was then crystallized from chloroform; wt 4.1 g (62%), mp 90—92°C (decomp.), $[\alpha]_D^{20}$ +36.3° (*c* 0.96, chloroform).

Found: C, 47.70; H, 4.50; N, 6.73; Cl, 21.56%. Calcd for $C_{25}H_{28}O_8N_3Cl \cdot CHCl_3$: C, 47.79; H, 4.48; N, 6.43; Cl, 21.71%.

3-(*N*-Benzyloxycarbonylglycyl)-L-5-methyl-2-oxo-oxazolidine-4-carbonyl-L-phenylalanine Methyl Ester (XXI). A solution of 9.1 g (0.014 mol) of XX in 90 m*l* of xylene was heated under reflux for 30 min. After evaporation *in vacuo*, a crystalline residue obtained was recrystallized from ethyl acetate - petroleum ether; wt 4.2 g (60%), mp 155.0—159.5°C. Repeated recrystallization gave a pure sample; mp 165.0—166.5°C, $[\alpha]_D^{20}$ +4.8° (*c* 1.05, ethanol).

Found: C, 60.05; H, 5.61; N, 8.32%. Calcd for $C_{25}H_{27}O_8N_3$: C, 60.35; H, 5.47; N, 8.45%.

Cleavage of XXI by Alkaline Hydrolysis. To a solution of 3.0 g (6.0 mmol) of XXI in 50 m*l* of methanol, there was added 14.4 m*l* of 1 N sodium hydroxide. After the reaction mixture had been stirred at room temperature for 2.5 hr, 2 N hydrochloric acid was added to pH 3. Methanol was removed by evaporation *in vacuo*. To a residue obtained, 1 N sodium hydroxide solution was added and extracted with ethyl acetate. The aqueous layer was separated and acidified to pH 3.2

with 1 N hydrochloric acid. An oily material formed was separated by decantation and the solution was further acidified to pH 2.5 to yield colorless crystals; wt 0.17 g, mp 122—123°C. Its infrared spectrum was identical to that of *N*-benzyloxycarbonylglycine. More amount of the same compound was obtained when the oily material was dissolved in ethyl acetate, extracted with 0.5 N sodium hydroxide solution and then the aqueous solution was acidified; wt 0.51 g. Total yield; 54%.

The aqueous solution of pH 2.5 was evaporated *in vacuo*. A residue thus obtained was treated with ethyl acetate. An oily residue obtained by evaporation of the solvent was then dissolved in ethanol. An addition of cyclohexylamine and ether to the solution gave colorless crystals of cyclohexylammonium salt; wt 1.17 g (50%), mp 199—201°C (decomp.). Its infrared spectrum was quite identical to that of cyclohexylammonium salt of XVII prepared from XVI by treatment with phosgene. Recrystallization from ethanol - ether gave a pure salt; mp 209—210°C (decomp.), $[\alpha]_D^{13}$ +24.9° (*c* 2.21, water).

The authors wish to express their thanks to Central Research Laboratories of Ajinomoto Co., Inc. for donation of amino acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2161—2164 (1968)

The Reaction between Hydrocarbon and Hydrogen Cyanide in Silent Electrical Discharge. II.[1] The Formation of Acrylonitrile from Ethylene and Hydrogen Cyanide*[1]

Kazuaki KAWAMOTO

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received March 14, 1968)

The present investigation was undertaken to examine the possibility of the direct introduction of a cyano radical into ethylene by means of a silent discharge. When a mixture of ethylene and hydrogen cyanide was discharged in an ozonizer under atmospheric pressure, the main liquid product was acrylonitrile, though the formation of telomers, such as ethyl cyanide, *n*-butyl cyanide and *n*-hexyl cyanide, was also observed. Besides these compounds, the reaction products were confirmed to consist of *s*-butyl, *n*-propyl, isopropyl, *n*-amyl, and isoamyl cyanides, and a gaseous product. The yield of acrylonitrile was affected by the temperature and voltage of the discharge. It has been found that the yields of the liquid products and the gaseous product increase with the rise in the temperature and voltage of the discharge, while the relative ratio of acrylonitrile to the other liquid product decreases. Judging from the relative concentration of each compound in the reaction products, it may be said that the vinyl radical and the cyano radical are the main intermediates in this reaction system.

Studies concerning the reaction of ethylene alone in electrical discharge have been reported by many investigators.[2] Moreover, in recent years, the reactions of ethylene and ammonia or oxygen under silent electrical discharge have been investigated by Sugino *et al.*[3] and by Tsutsumi *et al.*[4]

In a previous study,[1] it was found that, when a mixture of cyclohexane and hydrogen cyanide was discharged in an ozonizer, cyclohexyl cyanide could be prepared in one step, and that the relative amounts of this compound depended not only upon the discharge voltage, but also upon the discharge temperature.

The direct synthesis of acrylonitrile from ethylene and cyano-compounds has been established in several patents. (1) Acrylonitrile was obtained by the addition of cyanogen chloride or cyanogen bromide to ethylene in the presence of $AlCl_3$ and CH_3NO_2.[5] (2) It was found by Oberbacher[6] that

acrylonitrile could be prepared by the reaction of ethylene with cyanogen at 300—700°C at low pressures. (3) Porter and Nesty[7] and Sandner and Fierce[8] found that, in the absence of a catalyst, when ethylene was reacted with cyanogen or hydrogen cyanide at about 750—900°C it was transformed into acrylonitrile.

Francesconi and Ciurlo[9] reported that when a mixture of ethylene and hydrogen cyanide was subjected to the electrical discharge, ethyl cyanide and ethyl isocyanide were obtained.

In the present paper, the author wishes to report the direct formation of acrylonitrile in a reaction between ethylene and hydrogen cyanide in a silent discharge, and to establish, if possible, the most suitable conditions for the formation of acrylonitrile.

Experimental

Materials. The ethylene used in this experiment showed no impurity in gas-chromatographic analysis. (Columns of activated charcoal and dimethyl sulfolane were used.) The hydrogen cyanide was prepared according to Brauer's method.[10]

Apparatus and Procedure. The apparatus employed was similar to that used by the passing method in the previous paper.[1] The discharge tube used was a Pyrex tube 40 cm in effective length, 4 cm in outside diameter, and with a space gap of 0.25 cm. Ethylene and hydrogen cyanide vapor were passed through the discharge tube at a constant velocity for the period of the reaction. The amount of hydrogen cyanide used in each experiment was about a 2-mol. A 60-cycle alternating current was sent through a voltage regulator, and the voltage was stepped up by a transformer (Capacity: 15 kV) to give the required value. The products coming out of the discharge tube were removed by being passed through a condenser cooled with ice water, supplemented by two traps which were cooled with ice. The liquid products were analyzed by the method described below, while the noncondensable gas was analyzed by gas chromatography at intervals of 30 min.

Identification and Analysis of the Reaction Products. The reaction products were identified by comparing them with the authentic samples*2 by gas chromatography. (Columns of tricresyl phosphate, PEG-6000, and silicone DC 550 were used.) In addition, the reaction products were fractionally distilled in the presence of a small amount of hydroquinone, and the constituents of the cut were identified by the formation of the derivatives described below and by the infrared absorption.

The fraction boiling at 75—79°C was confirmed to consist mainly of acrylonitrile by transforming it into the *N-t*-butyl acrylamide,*3 mp 126—128°C, and the picrate of β-piperidinopropionitirle, *4 mp 160—161°C. They showed no depression in their melting points when mixed with authentic specimens. The infrared spectrum of this fraction agreed with that of authentic acrylonitrile. Besides acrylonitrile, the reaction products were identified by the methods described below.*5

The gaseous products, when analyzed by gas chromatography, were found to consist of ethane, acetylene, hydrogen, *n*-butane, 1-butene, 1,3-butadiene, methane, propane, and propylene. (Columns of activated charcoal, tricresyl phosphate, acetonylacetone, and dimethyl sulfolane were used.) The gaseous products could not be determined quantitatively. The liquid products were analyzed quantitatively by gas chromatography using a 5-m column of PEG-6000, a 3-m column of silicone DC 550, and a 3-m column of tricresyl phosphate at 140°C. Further, the content of acrylonitrile was also determined by the method of Beesing *et al.*[11] However, the difference between this method and gas-chromatographic analysis was less than 2 per cent.

Results and Discussion

By running ethylene with hydrogen cyanide only one time in an ozonizer under the conditions described in Table 1, a large number of compounds were obtained, along with acrylonitrile as the object substance. Among these, the identified compounds are summarized in Table 2. The compositions of the reaction products given in this table are reproducible within 1 per cent. In the presence of a small quantity of air, a solid brown deposit was formed on the glass wall. Accordingly, the air was completely removed from the reaction system. The liquid product absorbed oxygen from the air quite readily, and it was polymerized upon standing at room temperature.

Influences of the Discharge Temperatures and Voltages on the Reaction between Ethylene and Hydrogen Cyanide. As may be seen from

*2 *s*-Butyl, isoamyl, *n*-amyl, and *n*-hexyl cyanides were prepared according to the procedure of Jeffery and Vogel; G. H. Jeffery and A. I. Vogel, *J. Chem. Soc.*, **1948**, 679. Further, the following commercial chemicals were used for identification: acrylonitrile, ethyl cyanide, *n*-propyl cyanide, isopropyl cyanide and *n*-butyl cyanide.

*3 *N-t*-Butyl acrylamide was prepared according to the procedure of Plaut and Ritter; H. Plaut and J. J. Ritter, *J. Am. Chem. Soc.*, **73**, 4076 (1951).

*4 The picrate of β-piperidinopropionitrile was prepared by Brockway's method; C. E. Brockway, *Anal. Chem.*, **21**, 1207 (1949).

*5 (1) Ethyl cyanide was present in a fraction boiling at 92—97°C, and the ethyl 2,4,6-trihydroxyphenyl ketone, mp 175—176°C, was obtained. (2) *n*-Butyl cyanide was present in the fraction distilling at 136—141°C; this compound gave the *n*-butyl 2,4,6-trihydroxyphenyl ketone, mp 87—88°C. These alkyl (2,4,6-trihydroxyphenyl) ketones were prepared by the procedure of Howells and Little; H. P. Howells and J. G. Little, *J. Am. Chem. Soc.*, **54**, 2451 (1932). The infrared spectrum showed a strong absorption band at 2250 cm^{-1} (C≡N). (3) The other products were identified by comparing their retention times on the gas chromatography with those of authentic compounds.

T: Trace

Experiments Nos. 1 and 2 in Table 2, the conversion efficiency (grams of reaction product/grams of ethylene used×100) depends upon the temperature at which the discharge is carried out; it has been found that the yields of the liquid product and the gaseous product increase with a rise in the discharge temperature, and that, further, in the case of a high-temperature discharge, the proportion of acrylonitrile in the liquid product decreases and the yeilds of ethyl cyanide, *n*-butyl cyanide, and *s*-butyl cyanide increase. Thus, it may be said that a low temperature favors the formation of acrylonitrile. Ethyl, *n*-butyl, and *n*-hexyl cyanides seem to be formed by the telomerization between ethylene and hydrogen cyanide. However, the formation of *n*-octyl cyanide (1 : 4 telomer) and one-to-five or more products could not be observed by gas-chromatographic analysis. Further, the author could not find any dicyano-compounds and isocyano-compounds in the present research.

As may be seen from Experiments Nos. 3, 4 and 5 in Table 2, the yield of the reaction product was also affected by the discharge voltage; it has been found that increasing the voltage increases the yields of the liquid product and the gaseous product. Thus, the amount of ethylene reacted was at a maximum at the maximum voltage used in this experiment.

The Mechanism of the Formation of Acrylonitrile. It was reported by Egloff *et al.*[2] that the radical from ethylene in the electrical discharge was a vinyl radical, and that it was produced by breaking a carbon-hydrogen bond. Tsutsumi[12] reported that the vinyl radical was obtained by two molecular processes,*6 as is shown below.

12) S. Tsutsumi, *Chem. Ind.* (*Kagaku Kogyo*), **16**, 623 (1965).

*6 $CH_2=CH_2 + e^* \rightarrow CH_2=CH_2^* + e$

$CH_2=CH_2^* + CH_2=CH_2 \rightarrow$

$CH_2=\dot{C}H + CH_3-\dot{C}H_2$

The formation of acrylonitrile by the reaction of ethylene with hydrogen cyanide in a silent discharge may be represented as follows: The first step is the activation of the ethylene molecule and the hydrogen cyanide molecule by electron impact, while the second step consists of both (1) the reaction of the activated ethylene molecule with a normal ethylene molecule to give the vinyl radical and the ethyl radical, and (2) the decomposition of the activated molecules to give the vinyl radical, the cyano radical, and the hydrogen atom. Acrylonitrile may be formed by a combination of the vinyl radical and the cyano radical thus obtained. Further, the formation of acetylene, 1,3-butadiene, and 1-butene may show the existence of the vinyl radical.

The Reaction Occurring in the Silent Discharge. Although the reaction of ethylene with hydrogen cyanide in a silent discharge is somewhat complicated by a secondary reaction, the principal reaction can be interpreted as including the formation of the vinyl radical, the ethyl radical, the cyano radical, and the hydrogen atom and the combination of these radicals, telomerization, hydrogenation, and dehydrogenation.

Besides acrylonitrile, considerable quantities of one-to-one products and one-to-two products, such as ethyl cyanide and *n*-butyl cyanide, were produced. Since the investigated reaction is presumed to be a radical reaction, the mechanisms of these telomers may be described as below:

$$HCN + e^* \rightarrow HCN^* + e \rightarrow \cdot H + \cdot CN \quad (1)$$

$$CH_2{=}CH_2 + \cdot CN \rightarrow \cdot CH_2CH_2CN \quad (2)$$

$$\cdot CH_2CH_2CN + HCN \rightarrow CH_3CH_2CN + \cdot CN \quad (3)$$

$$\cdot CH_2CH_2CN + CH_2{=}CH_2 \rightarrow \cdot CH_2(CH_2)_3CN \quad (4)$$

$$\cdot CH_2(CH_2)_3CN + HCN \rightarrow CH_3(CH_2)_3CN + \cdot CN \quad (5)$$

$$\cdot CH_2(CH_2)_3CN + CH_2{=}CH_2 \rightarrow \cdot CH_2(CH_2)_5CN \quad (6)$$

$$\cdot CH_2(CH_2)_5CN + HCN \rightarrow CH_3(CH_2)_5CN + \cdot CN \quad (7)$$

The addition reaction of the $C_6H_{12}CN$ radical to ethylene in these reaction mechanisms need not be considered, since no products beyond *n*-hexyl cyanide were obtained. In addition, a part of the ethyl cyanide may be formed by the reaction between the ethyl radical obtained by two molecular processes*6 and the cyano radical. Further, it seems that ethane, *n*-butane, and 1-butene are obtained by the ethyl radical.

Beer and Besprozvannyi[13] found, from their data on the telomerization of ethylene in carbon tetrachloride and chloroform, that compounds ($ClCH_2(CH_2)_3CCl_3$ and $CH_3(CH_2)_3CCl_3$) with $n=2$ were formed over a wide range of ethylene concentration. They suggested that the predominance of telomers with $n=2$ resulted from the stabilization of the trichloroamyl radical by a "pseudo cyclic" configuration between the unpaired electron of the end CH_2 and the electrophilic CCl_3 groups. As may be seen from Table 2, the yield of the telomer (*n*-butyl cyanide) with $n=2$ was higher than that of the telomer (*n*-hexyl cyanide) with $n=3$. Accordingly, the existence of a pseudo cyclic arrangement may be supported in the reaction of ethylene with hydrogen cyanide under a silent discharge. The formation of *s*-butyl cyanide was also observed. This is presumably due to the isomerization of *n*-butyl cyanide to *s*-butyl cyanide.

The author wishes to express his hearty thanks to Professor S. Tsutsumi of Osaka University for his kind guidance and valuable suggestions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2165—2168 (1968)

The Effect of the ω-Cyano Group on the Reactivity of Secondary Bromides in the Formolysis Reaction and on the Reactivity of Primary Bromides in the Reaction with Silver Nitrate[1—4]

Peter S. STRILKO,[5a] Hiroyuki MORITA and Shigeru OAE[5b]

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received March 18, 1968)

Several ω-cyano-2-bromoalkanes have been synthesized and their formolysis rates were determined. The reactivity of these compounds was found to decrease with a decrease in chain length and have a parallerism with a chemical shift (>CH–, $-CH_3$) of NMR spectra. A similar sequence was observed in the reactivity of ω-cyano-1-bromoalkanes in the reaction with silver nitrate.

In the previous paper[6] of this series, rates of formolysis of several 5-substituted 2-bromopentanes were studied. While the 5-acetoxy and 5-bromo groups exhibited essentially no effect upon the reactivity, it was found that the methoxy group at the 5 position accelerated the formolysis by a factor of about thirty and that the cyano group at the same position caused nearly a five-fold retardation. The large accelerating effect of the methoxy group was ascribed to the five-membered ring neighboring group participation of the δ-methoxy group. This interpretation was confirmed later by Winstein and his co-workers.[7] As for the retarding effect of the ω-cyano group, the electrostatic attraction between the unshared electron pairs of covalently bonded bromine and the cyano group was suggested as a possible explanation, since the electron-withdrawing inductive effect is known to virtually disappear after being transmitted through more than three saturated methylene linkages in both S_N1 and S_N2 reactions[8,9] of primary organic halides. One way to test this assumption is to compare the reactivity of ω-cyanobromoalkanes of different methylene chain length, because direct electrostatic interactions of this nature should be quite insensitive to ring size. Therefore, the present investigation was undertaken to deal with the rates of formolysis of several 2-bromo-ω-cyanoalkanes, namely 2-bromo-3-cyanopropane, 2-bromo-4-cyanobutane, 2-bromo-5-cyanopentane and 2-bromo-6-cyanohexane. Contrary to our earlier expectation, the reactivity of 2-bromo-5-cyanopentane was much greater than that of 2-bromo-4-cyanobutane, which in turn, had remarkably greater reactivity than 3-cyano homolog, while the reactivity of 2-bromo-6-cyanohexane was found not to reach that of 2-bromobutane after being transmitted through four saturated methylene linkages, though it was greater than that of 2-bromo-5-cyanopentane.

The investigation has been extended to the kinetic study of the reaction of silver nitrate in absolute ethanol with 1-bromo-ω-cyanoalkanes, namely, 1-bromo-2-cyanoethane, 1-bromo-3-cyanopropane, 1-bromo-4-cyanobutane, 1-bromo-5-cyanopentane and 1-bromo-6-cyanohexane. Here again the reactivity was found to decrease as the cyano group more closely approached the reacting center and to be insensitive to the size of the chain length contrary to that expected from the assumption in the previous paper.[6]

Experimental

Materials. Commercially available extra pure 98% formic acid was diluted with distilled water to give a solution of specific gravity of 1.2086 at 20°C. This corresponds to 92.4% formic acid by weight. The purification of absolute ethanol and the preparation of a silver nitrate solution were discussed elsewhere.[10]

2-Bromo-6-cyanohexane was synthesized by a following method. Commercially available α-picoline was reduced to 2-methyl-piperidine by catalytic hydrogenation with Raney nickel at 200°C and 150 atm of hydrogen, and 2-methyl-piperidine thus prepared was converted to 1,5-dibromohexane by the von Braun reaction.[11] Equivalent amounts of 1,5-dibromohexane and sodium cyanide were refluxed in ethanol for 4 hr and 2-bromo-6-cyanohexane was obtained in a 25% yield. The fraction boiling at 103—103.5°C/2 mmHg was collected and used.

Found: C, 44.23; H, 6.37%. Calcd for $C_7H_{12}NBr$: C, 44.23; H, 6.03%. n_D^{30} 1.4784.

2-Bromo-5-cyanopentane was prepared by a procedure described.[6]

2-Bromo-4-cyanobutane was made similarly, starting from 1,3-dibromobutane and sodium cyanide. The fraction boiling at 86—86.5°C/8 mmHg was collected and used.

Found: C, 37.74; H, 5.08%. Calcd for C_5H_8NBr: C, 37.74; H, 4.98%. n_D^{30} 1.4692.

2-Bromo-3-cyanopropane was made similarly, starting from 1,2-dibromopropane and sodium cyanide. The fraction boiling at 65°C/75 mmHg was collected and used.

Found: C, 32.30; H, 4.16%. Calcd for C_4H_6NBr: C, 32.46; H, 4.16%. n_D^{30} 1.5147.

1-Bromo-2-cyanoethane was an Eastman white labeled product. 1-Bromo-3-cyanopropane, 1-bromo-4-cyanobutane, 1-bromo-5-cyanopentane and 1-bromo-6-cyanohexane were obtained from Aldrich Chemical Company. All were washed with diluted alkaline solutions, dried over anhydrous calcium chloride and carefully fractionated. Boiling points and refractive indices of the respective compounds are shown below. (Table. 1)

TABLE 1. PHYSICAL CONSTANTS OF ω-CYANO-1-BROMOALKANES

Compound	Boiling point	Refractive index
1-Bromo-2-cyanoethane	76.2—76.3°C/9 mmHg	1.4768
1-Bromo-3-cyanopropane	99.6—99.9°C/14 mmHg	1.4753
1-Bromo-4-cyanobutane	108.4—108.6°C/9.4 mmHg	1.4754
1-Bromo-5-cyanopentane	118.0—118.2°C/7 mmHg	1.4744
1-Bromo-6-cyanohexane	133.5—134.5°C/7.6 mmHg	1.4728

2-Bromobutane and 1-bromopentane were both Eastman white labeled products and were purified as in the previous work.[6,8]

Determination of Rate Constant. Kinetic measurements and rate calculations for the formolysis of secondary bromides were made by the same procedure previously used.[6] In this case, 5 m*l* portions were sealed in ampoules and the reaction was carried out at 85.00±0.01°C, 95.00±0.01°C and 105.00±0.01°C, respectively, while the titration was accomplished by Volhard's method, using ammonium alum as the indicator. First order rate constants were calculated according to the equation,

$$k = \frac{2.303}{t} \cdot \log \frac{a}{a-x}$$

The activation parameters were obtained graphically.

Isolation of Product in the Reaction of 2-Bromobutane with Formic Acid. A solution of 2-bromobutane in 90% formic acid was refluxed on a steam bath for 48 hr. This was poured into cold water and extracted with ether. The ethereal extracts were washed three times with water, three times with diluted sodium carbonate and three times again with water. They were dried over potassium carbonate and the solvent was distilled to give a pale yellow residue. This was found to have very similar index of refraction, infrared spectrum and identical retention time in the vapor phase chromatograph with an authentic sample of secondary butyl formate prepared by the method of Pickard, Kenyon and Hunter.[12]

Primary bromides are known to react with ethanolic silver nitrate to give the corresponding nitrate ester.[10] 1-Bromo-5-cyanopentane was treated in the same concentration solutions as those used for the kinetics, but allowed to reflux on a steam bath for several days. The silver bromide was filtered, followed by evaporation of the solvent, removal of any additional solid and distillation of the filtrate through a packed column. The yellow distillate, bp 113—114°C/15 mmHg, showed infrared bands at 1276 cm^{-1} and 1632 cm^{-1}, indicating the presence of nitrate ester and a strong aliphatic ether band at 1108 cm^{-1} in addition to those bands present in the starting material.[13]

Result and Discussion

The first-order rate constants, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of secondary bromides at 85.0°C, 95.0°C and 105.0°C are given in Table 2.

The results clearly indicate that low reactivity of 2-bromo-5-cyanopentane is not the unique phenomenon. In fact, the rate decreases with the decrease in chain length. However, when one plots the logarithms of the rates against *n*, one finds that 2-bromo-3-cyanopropane falls off the line while the others are in a fairly good correlationship (Fig. 1). Apparently the formolysis of this particular bromide proceeds through a different path. Indeed, both the enthalpy and entropy of activation of the reaction are vastly different from those of the other compounds. The strong electron-withdrawing inductive effect of ω-cyano group probably makes the S_N1 type heterolysis of C–Br bond so difficult that S_N2 type process, in which formolysis is assisted by the nucleophilic attack of formate, becomes predominant. As one expected, the NMR chemical shifts of methyne proton at 2 position of substitued

2-bromoalkanes can be correlated with the methylene chain lengths, while a rough linear correlationship is observed between the rates and the NMR chemical shifts of these organic bromides. (Fig. 2) A similar relationship between the chemical shifts and the electron-withdrawing properties has been reported in the case of ω-nitroalkanes,[14] however, in this case the inductive and/or field effects disappear rapidly after being transmitted through more than four methylene linkages. Perhaps in the case of nitro group, negative oxygen atoms display negative field effect and decrease the electron-withdrawing effect so markedly beyond more than two methylene groups away. While cyano group being uncharged yet electronegative and polarizable, may perturb the electrons further away, both directly and indirectly. From the NMR data, the transmission coefficient, ε, of cyano group is calculated to be 0.45–0.50. Transmission coefficient has been accepted to be nearly constant, *i.e.*, 0.35, in many reactions.[15] Therefore the value we obtained is somewhat larger than the ordinary one. In this case not only an inductive effect through methylene but also some field effect of highly electro-negative groups are in operation. To clarify this problem, $\rho\sigma^*$

treatment[16] was carried out in which σ^* values were calculated by using the transmission coefficient obtained in this experiment. A very good linear correlationship was found as in Fig. 3. This may mean that the formolysis of ω-cyano-2-bromoalkanes is controlled by the inductive effect alone.

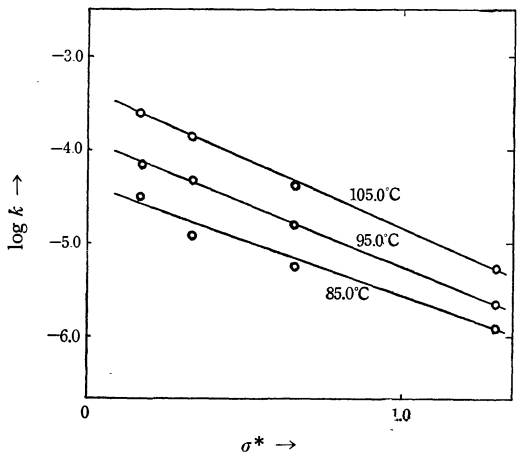

Fig. 3. Correlationship between the formolysis rates of $NC(CH_2)_nCHBrCH_3$ and σ^* of $-(CH_2)_n-CN$.

The second order rate constants for the reaction of the primary bromides with silver nitrates in absolute ethanol at 50.04±0.02°C are tabulated in Table 3.

There are numerous sources of evidence to support the fact that carbon-halogen bond fission is the rate determining step for the reaction between silver nitrate and alkyl halides. Therefore, one would expect that the slow reacting primary 1-bromo-ω-cyanoalkanes would show a similar sequence of reactivities in the reaction with silver nitrate. In fact, the cyano group was found to retard the reactivity considerably as it approaches closer to the reacting site. However, in this case the retarding effect of the cyano group virtually disappeared beyond three saturated methylene groups.

TABLE 3. SECOND-ORDER RATE CONSTANTS FOR THE REACTION OF PRIMARY BROMIDES WITH SILVER NITRATE IN ABSOLUTE ETHANOL AT 50.04±0.02°C

Compound	$k_2 \times 10^4$ $l\ mol^{-1}sec^{-1}$
1-Bromo-2-cyanoethane	2.98
1-Bromo-3-cyanopropane	5.01
1-Bromo-4-cyanobutane	14.0
1-Bromo-5-cyanopentane	23.4
1-Bromo-6-cyanohexane	21.6
1-Bromopentane	16.9

It is interesting to note that 1-bromo-5-cyanopentane and 1-bromo-6-cyanohexane were found to react faster than 1-bromo-pentane. This may be due to an altering of the electron-withdrawing ability of the cyano group by coordination with silver ion, as is known to occur in ũ bonded systems, or by some interaction with solvent such as hydrogen bonding.[17]

The presence of an ether in the product may be accounted for by a transition state model in which silver ion is exerting an attracting force on the halogen which results in partial carbonium ion character at the seat of reaction. Displacement could be effected by nitrate ion to give the expected product or by solvent with the subsequent loss of a proton to give rise to the ethoxy derivative.

We are indebted to Mr. Clyde Zault who checked some of the kinetic runs.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2169—2172 (1968)

Effect of Pressure on Graphitization of Carbon. IV. Abrupt Graphitization of Hard Carbon under 5 kbar

Kan-ichi KAMIYA, Michio INAGAKI, Masato MIZUTANI and Tokiti NODA*1

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 15, 1968)

A hard carbon, phenolformaldehyde resin char carbonized to 700°C, was heat-treated under a quasi-hydrostatic pressure of 5 kbar at various temperatures between 1100—1800°C for the residence times of 3, 20 and 60 min. The graphitization process of the hard carbon under pressure consisted of three stages. In the first stage of the graphitization, the profile of (002) diffraction line was symmetrical. It means that there is only one component A_H in the sample. In the second and third stages of graphitization, the (002) profile became composite. In the second stage, three components A_H, G'_H and G''_H coexisted in the sample. The sum of the contents of the components G'_H and G''_H was less than 20% and increased gradually with heat treatment temperature. In the third stage, two components A_H and G''_H coexisted. The content of the component G''_H increased abruptly up to more than 70% at about 1400, 1500 and 1700°C for the residence time of 60, 20 and 3 min, respectively. The components A_H and G''_H have the turbostratic and graphitic structures, respectively. The component G'_H seemed to have the intermediate structure between turbostratic and graphitic structures.

Hard carbons or non-graphitizing carbons are hardly graphitized even at very high temperatures such as 3000°C. So-called two- or three-phase graphitization was often observed for hard carbons at high temperatures of heat treatment.[1-4] Recently, Oberlin and Rousseaux gave a beautiful representation of two-phase graphitization of a sugar charcoal by means of dark field electron micrographs and electron microdiffraction.[5] On the other hand, soft carbons are easily graphitized under the same condition and multi-phase graphitization has never been observed. Under high pressure above 3 kbar, the graphitization of soft carbons was found to proceed very rapidly at relatively low temperatures as 1500°C and the phenomenon similar to the two-phase graphitization was observed.[6,7] It was found that even glassy carbon, a typical hard carbon, was graphitized around 1500°C under 10 kbar.[6] In the present work, phenolformaldehyde resin char, one of hard carbons, was heat-treated under the pressure of 5 kbar at various temperatures for three different residence times. The graphitization process of the sample was precisely followed by analyzing the profile of (002) diffraction line and was compared with that of soft carbon under the same pressure.

Experimental and Results

The sample used was a carbon prepared at 700°C from phenolformaldehyde resin, which was made by a conventional method using ammonium hydroxide as catalyst. The sample was a hard carbon and was

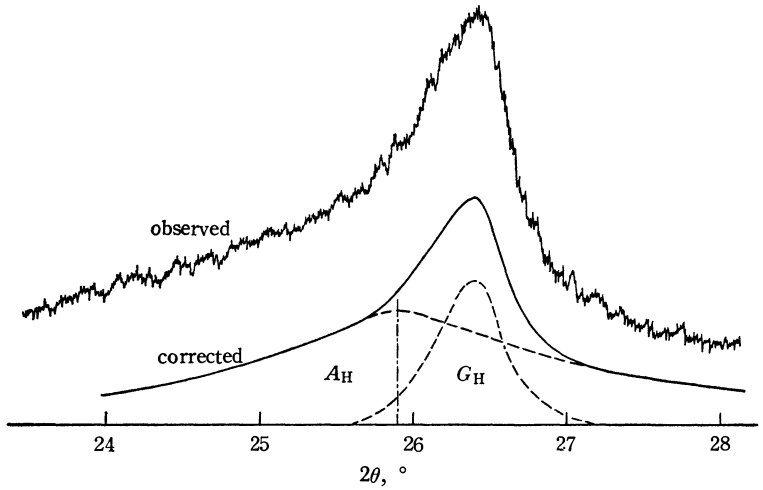

Fig. 2. Schema of separation of composite profile observed on the hard carbon.

named as PH-7 in order to make easy to distinguish from the sample of a soft carbon PV-7, which was used in the previous works.[6-9] The particle size of the sample was limited in the range of 0.1—0.4 mm. The used high pressure apparatus and the arrangement of specimen cell were the same as reported previously.[7] The heat treatments of the sample were performed under a quasi-hydrostatic pressure of 5 kbar at various temperatures between 1100—1800°C for residence times of 3, 20 and 60 min. The heat treatment temperature (HTT) was evaluated from the electric input power by using the relation between temperature and input power, which was determined beforehand for the same arrangement and sample. For the heat-treated sample, the profile of (002) diffraction line was measured by using Ni-filtered Cu$K\alpha$ radiation and a recording goniometer.

Change of (002) diffraction profile with HTT for the residence time of 60 min. is shown in Fig. 1. Above 1200°C, the profile appeared to be composite, consisting of at least two component profiles. Such a composite profile was separated into the component profiles by almost the same procedure as previously described.[7,8] In the present work, however, the profile on the low angle side is folded at the angular position where the tail of the folded profile coincides well with the tail of the composite profile on the high angle side (Fig. 2). When this profile on the low angle side is subtracted from the composite profile, the balance gives another component profile, which is on the high angle side. In the present work, these two components corresponding to the profiles on the low angle side and high angle side are designated as A_H and G_H, respectively.*2

For each separated profile, the c_0-spacing was measured by referring to the inner standard of silicon and the area under the profile was measured by using a planimeter. In order to obtain the content of the component G_H, the ratio of the area under the profile for the component G_H to the total area of the composite profile was obtained and then corrected for the preferred orientation of crystallite in the specimen by using the same calibration curve as reported previously.[8] Changes of c_0-spacing of two components with HTT are shown in Fig. 3 and the

change of content of the component G_H with HTT is shown in Fig. 4.

Discussion and Summary

On the graphitization process of the hard carbon PH-7 under 5 kbar, the profile of (002) diffraction line showed the composite one. Similar composite profiles of (00 *l*) diffraction line had been observed on the soft carbon PV-7 heat-treated under the same pressure.[6-9] The graphitization process of PH-7 under pressure seemed to be composed of two stages; in the early stage the (002) profile of the heat-treated sample being symmetrical and in the later stage it consisting of two component profiles A_H and G_H. However, the later stage could be divided into two more stages from the view points of c_0-spacing, symmetry of the profile and content of the component G_H, which will be described below. Therefore, the graphitization process of PH-7 under pressure was considered to consist of three stages. On the soft carbon PV-7, the graphitization process under the same pressure was divided into two stages.

In the first stage of the graphitization, the (002) profile is symmetrical though being very broad. It means that there is only one component A_H in the sample. The presence of the high angle component G_H was not indicated. The c_0-spacing of the component A_H decreases from the original value to 6.88 A with the increase in HTT.

In the second stage of graphitization (above 1200°C), the (002) profile becomes composite, consisting of the components A_H and G_H. The content of the component G_H increases gradually up to about 20% and its apparent c_0-spacing decreases from about 6.79 to 6.72 Å with the increase in HTT. The profile of the component G_H in this stage is not exactly symmetrical and therefore may consist of two components G'_H and G''_H. Assuming that the component G'_H has a relatively large c_0-spacing as 6.78 Å and the component G''_H has 6.72 Å and that the component G'_H transforms to G''_H, the gradual decrease of the apparent c_0-spacing and the lack of symmetry of profile of the component G_H may be explained. On the other hand, the component A_H becomes to have a constant c_0-spacing of 6.88 Å through this stage, though the angular position of this component profile has not been assumed as constant before the separation of the composite profile. On the soft carbon PV-7,[7] the component A_S on the low angle side had a little smaller c_0-spacing and its profile was much sharper than that of the compoent A_H observed on the hard carbon PH-7 in the present work.

In the third stage of graphitization, the content of the component G_H increases abruptly to more than 70% at about 1400, 1500 and 1700°C for the residence time of 60, 20 and 3 min, respectively. The profile of the component G_H is almost symmetrical

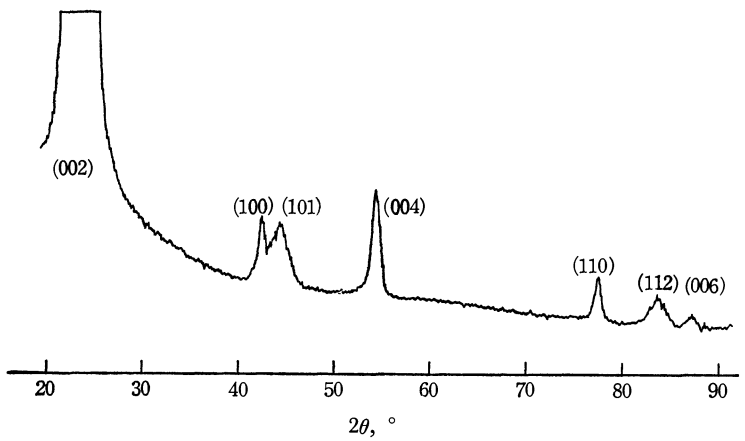

Fig. 5. Diffraction pattern of the hard carbon heat-treated at 1500°C for 60 min under 5 kbar.

and has the c_0-spacing of around 6.72 Å. Therefore, component G_H may consist of only one component the G''_H in this stage. The c_0-spacing of the component A_H is also constant at 6.88 Å through stage. The sample obtained in this stage (the content of G_H is more than 70%) was found to have the three-dimensional diffraction lines such as (101) and (112) lines (Fig. 5).

These experimental facts suggest the followings; The component A_H has turbostratic structure and its c_0-spacing in the second and third stages is the same as that has been assigned for this structure by others.[1,10] The component G_H is considered to consist of two components G'_H and G''_H. The component G''_H, which has the c_0-spacing of 6.72 Å and shows the three-dimensional diffraction lines, corresponds to graphitic structure and it may be the same as the component G_S observed on the soft cabon PV-7. The component G'_H, whose c_0-spacing is between 6.72 and 6.88 Å, corresponds to the intermediate structure between turbostratic and graphitic structures. The component G'_H is observed only in the second stage of graphitization and its content is much less than 20%. No component having such an intermediate structure as G'_H was observed on the soft carbon PV-7.

As shown in Fig. 4 (for the convenience of comparison the change of content of the component G_S in the soft carbon PV-7 are also shown), it is surprising that the hard carbon PH-7 is graphitized as abruptly as the soft carbon PV-7 at low temperature as 1500°C under 5 kbar. For the residence time of 3 min, the hard carbon PH-7 seems to be graphitized somewhat faster than the soft carbon PV-7.

From the results of the present work, it is deduced that the hard carbon heat-treated under pressure consists of two or three components, each of which has enough extent to produce the coherent X-ray scattering. Such a constitution of the structural components is very similar to that oberved on the soft carbon.[7]

The authors wish to thank Tokai Electrode Mfg. Co. for supplying the graphite materials used.

NOTES

Reaction of Triethylaluminum with Ketone

Yoshio BABA

Resources Research Institute, Kawaguchi, Saitama

(Received April 17, 1967)

It has been found that the reaction of alkylaluminum compounds with ketones involves normal addition, reduction and enolization reactions.[1-4]

Pasynkiewicz and Sliwa[5] have carried out studies of the reaction of triethylaluminum with diethyl ketone and diisopropyl ketone. As a result of these experiments, they concluded that the normal addition and reduction are affected by the mole ratio of ketone/$AlEt_3$ and by the reaction temperature, while the enolization reaction is not subject to such influences.

In the course of an investigation of the reactions of methyl ketones with triethylaluminum, the present author has been interested in the fact that, although the reactions of triethylaluminum and its diethyl ether adduct with ketones yield three kinds of products resulting from addition, reduction and enolization-condensation reactions, a considerable quantity of ethane has been obtained as a further product. The amount of this gaseous product was much greater than was to be expected from the amount of the enolization-condensation product.

The present investigation was undertaken to reveal the source of these gaseous products and the mechanism of the formation of the enolization-condensation product in the reaction of ketones with triethylaluminum and its diethyl ether adduct.

Experimental

All the melting points uncorrected.

Materials. Commercial acetone (bp 55°C), methylethyl ketone (bp 78°C), methyl *n*-propylketone (bp 101°C), methyl isopropyl ketone (bp 94°C), methyl *s*-butyl ketone (bp 116°C), methyl *t*-butyl ketone (bp 105°C) methyl *n*-amyl ketone (bp 148°C), methyl isoamyl ketone (bp 142°C), and acetophenone (bp 201°C) were purified by distillation. Triethylaluminum purchased from the Ethyl Corp. was used without further purification.

Solvent. Petroleum ether was distilled, and a fraction with a bp of 35—45°C was dried over metallic sodium.

Analytical Procedure. The amounts of recovered ketone and secondary alcohol were determined by the Iddles[6] and Verbeck[7] methods respectively. The tertiary alcohol content was calculated from the total amount of alcohol itself determined by the active hydrogen analysis, and from the secondary alcohol content. The amounts of the gaseous products were measured, and then their components were analyzed by gas chromatography using a Okura Gas Chromatograph, Model-4000 (dimethyl sulfolane 5 m; 20°C; hydrogen gas as carrier gas). The active hydrogen content of the condensation products was determined by the Niederl[8] method, based on the reaction with methylmagnesium iodide.

General Procedure. All the reactions were carried out in an atmosphere of dry nitrogen. A thirty-weight-percent solution of triethylaluminum or its diethyl ether adduct in dry petroleum ether, containing 0.1 mol of the aluminum compound, was added to a gently-refluxing 30 wt % solution of ketone (0.1 mol) in dry petroleum ether. A gaseous product which evolved during the addition of the aluminum compound solution was led through a gas meter to a gas receiver. The reaction solution was then refluxed for an additional 0.5 hr, by which time the gas evolution practically terminated. The reaction solution was cooled in an ice bath, and the aluminum compound was decomposed by adding diethyl ether containing a theoretical amount of water. After the addition of cracked ice, precipitated aluminum hydroxide was removed by filtration and the filter cake was washed thoroughly with ether. The organic layer was separated and dried over anhydrous magnesium sulfate. The solvent was removed by distillation using a Widmer column (30 cm), and the residue was then distilled. The components of the distillate were determined by the methods described in the "Analytical Procedure" section, while the residue of the distillation was weighed and its active hydrogen content determined.

Reaction of Acetone with Triethylaluminum. A rectification of the product obtained from the reaction

of acetone (5.8 g) with triethylaluminum yielded the following three fractions:

Fraction 1 bp 75—78°C, 0.6 g
Fraction 2 bp 95—98°C, 2.0 g
Fraction 3 bp 70—75°C/25 mmHg, 2.2 g

3,5-Dinitrobenzoates of Fraction 1 (mp 121—122°C, from ethanol) and Fraction 2 (mp 116—117°C, from ethanol) were identified as those of isopropyl alcohol and dimethylethylcarbinol, respectively, by mixed-melting-point determinations with the authentic substances. The Fraction 3 was converted into its 2,4-dinitrophenylhydrazone (mp 202—203°C, from ethanol, undepressed by admixture with the authentic hydrazone of diacetone-alcohol).

Reaction of Acetophenone with Triethylaluminum - diethyl ether Adduct. A crude product obtained from the reaction of acetophenone (8.2 g) with the triethylaluminum - diethyl ether adduct was separated by vacuum distillation into a low-boiling fraction (bp 85—95°C/5 mmHg, 6.5 g) and a high-boiling condensation product (bp 195—197°C/5 mmHg, 2.0 g). The low-boiling fraction, after its secondary alcohol content had been determined, was esterified by refluxing it with a solution of phthalic anhydride in dry pyridine containing a slightly excessive amount of anhydride. The tertiary alcohol fraction (3.8 g) was collected by the distillation of the reaction mixture, while the secondary alcohol (0.6 g) was recovered by the hydrolysis of the monoester of phthalic acid obtained as the residue of the distillation. No depression in the melting points of the 3,5-dinitrobenzoate of the secondary alcohol fraction (mp 94—95°C, from ethanol) or in the *p*-nitrobenzoate of the tertiary alcohol fraction (mp 99.0—99.5°C, from ethanol) was observed upon admixture with authentic derivatives of phenylmethylcarbinol and phenylmethylethylcarbinol respectively. The melting point of the semicarbazone (mp 150—151°C, from methanol) of the high-boiling condensation product (bp 195—197°C/5 mmHg) corresponded with that reported for the semicarbazone of dypnone.[9]

Results and Discussion

The results obtained in the reactions of ketones with triethylaluminum and its diethyl ether adduct are cited in Tables 1 and 2.

The reaction of methyl ketone with triethylaluminum with a ketone/$AlEt_3$ mole ratio of 1 and at the temperature of 50—60°C gave considerable quantities of condensation products. The yields of these condensation products in eight experiments, but not with pinacoline, were about 50 wt% based on the ketones used. These high-boiling products appear to be produced by the enolization condensation

reaction, as is shown in Eq. (1). In fact, in the experiments with acetone and acetophenone, diacetonealcohol and dypnone were obtained respectively. The amounts of ethane in the gaseous products nearly corresponded to that calculated from the active hydrogen content of the condensation products.

$$RCOCH_3 + \text{al-}C_2H_5 \rightarrow \underset{(I)}{RCOCH_2\text{al}} + C_2H_6$$

$$(I) + RCOCH_3 \rightarrow R\text{-}\underset{\displaystyle CH_2COR}{\overset{\displaystyle Oal}{\overset{|}{C}}}\text{-}CH_3 \xrightarrow{H_2O}$$

$$R\text{-}\underset{\displaystyle CH_2COR}{\overset{\displaystyle OH}{\overset{|}{C}}}\text{-}CH_3 \xrightarrow{\text{or } (-H_2O)} R\text{-}\overset{\displaystyle CH_3}{\overset{|}{C}}\text{=}CHCOR \qquad (1)$$

However, in the reaction of pinacoline with triethylaluminum, although considerable quantities of ethane were collected, neither the high-boiling product nor the recovered ketone were obtained; secondary and tertiary alcohols were obtained in yields of 39.1% and 59.3%, respectively. Such an inconsistency between the amount of ethane produced in the course of the reaction and the amount of active hydrogen in the high-boiling condensation product was markedly observed in the case of the reaction with the triethylaluminum diethyl ether adduct.

The reactions of ketone with an equimolar amount of triethylaluminum diethyl ether adduct differ from those with free triethylaluminum; the former afforded a smaller amount of condensation product than the latter. In the experiments with five methyl ketones, but not acetophenone, no ketones were recovered, while the amount of ethane evolved during the reaction was much greater than that obtained from the experiments with free triethylaluminum.

It may be concluded from the results of these experiments that the reaction of methyl ketone with triethylaluminum or its diethyl ether adduct proceeds through the courses indicated by Eqs. (2) and (3).

The enolate (II) produced by the reaction of ketone with free triethylaluminum appears to be so reactive as to react readily with the second molecule of the ketone and thus yield the condensation product. The enolate (III) formed by the reaction of ketone with the diethyl ether adduct of triethylaluminum, however, probably inhibits the condensation reaction because of the blocking effect of the coordinated diethyl ether.[10]

In the case of pinacoline, the reaction with free

$$RCOCH_3 + \text{al-Et} \begin{cases} \xrightarrow{\text{Addition}}\ \xrightarrow{(H_2O)}\ R\text{-}\overset{\displaystyle OH}{\overset{|}{C}}\text{-}CH_3 \\ \qquad\qquad\qquad\quad \underset{\displaystyle Et}{|} \\ \xrightarrow{\text{Reduction}}\ \xrightarrow{(H_2O)}\ R\text{-}\overset{\displaystyle H}{\overset{|}{C}}\text{-}CH_3 + C_2H_4 \\ \qquad\qquad\qquad\quad \underset{\displaystyle OH}{|} \\ \xrightarrow{\text{Enolization}}\ \underset{(II)}{RCOCH_2\text{al}} + C_2H_6 \end{cases} \qquad (2)$$

10) K. Ziegler, *Ann.*, **629**, 251 (1960).

triethylaluminum affords a sterically-hindered enolate comparable to those produced in the reaction of simple ketone with the triethylaluminum diethyl ether adduct; this is because of the accumulated methyl groups on the α-carbon atom of the carbonyl group. As a result of this steric effect, the addition of the second molecule of pinacoline to the enolate is completely suppressed; thus the reaction does not afford the condensation product.

The author wishes to thank Dr. J. Yoshimura, Professor of the Tokyo Institute of Technology, for many helpful discussions and suggestions made during this work.

Selective Deethoxycarbonylation of β-Ethoxycarbonylamino-α,β-Unsaturated Carboxylic Esters*[1]

Takao TAKAYA, Hataaki YOSHIMOTO and Eiji IMOTO

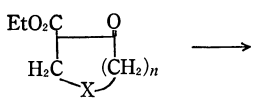
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received May 22, 1967)

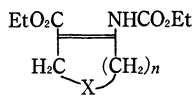
An ethoxycarbonyl group attached to a carbon atom is usually more easily hydrolysed in either an alkaline or an acidic medium than is an ethoxycarbonyl group attached to an amino group. We have, however, found that the hydrolysis of the compounds represented as having the general structure I with sodium ethoxide in ethanol occurs at different positions, depending on the nature of the group, G, intervening between ethoxycarbonyl and ethoxycarbonylamino groups.

$$EtO_2CNH\text{-}G\text{-}CO_2Et$$
(I)

When G was a group containing a double bond between the two functional groups, as in the compound III, the ethoxycarbonyl group attached to the amino group was selectively hydrolysed to give IV, in which the ethoxycarbonyl group attached to the carbon atom remained unchanged.

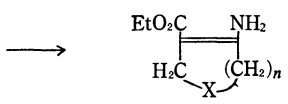


(II)



(III)

IIa_1: X=CH_2, n=1 $IIIa_1$: X=CH_2, n=1
IIa_2: X=CH_2, n=2 $IIIa_2$: X=CH_2, n=2
IIb_1: X=S, n=1 $IIIb_1$: X=S, n=1
IIb_2: X=S, n=2 $IIIb_2$: X=S, n=2

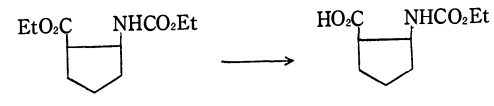


(IV)

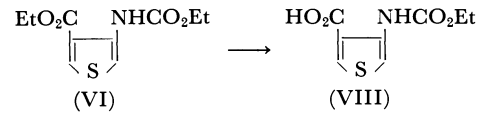
IVa_1: X=CH_2, n=1
IVa_2: X=CH_2, n=2
IVb_1: X=S, n=1
IVb_2: X=S, n=2

Although β-amino-α, β-unsaturated carboxylic esters, such as IVa_1 and IVa_2, were also obtained from the corresponding β-ketoester II and ammonia according to the method of Prelog and Szpilfogel,[1] a similar reaction of 3-ethoxycarbonyl-4-ketotetrahydrothiophene IIb_1 resulted in the complete recovery of the starting material. However, IVb_1 was obtained in only a moderate yield by the alkaline hydrolysis of 3-ethoxycarbonyl-4-ethoxycarbonylamino-2,5-dihydrothiophene $IIIb_1$.

On the contrary, when G was a group containing a single bond between the two functional groups, as in the compound V[2] or VI,[2] the ethoxycarbonyl group attached to the carbon atom was selectively hydrolysed with sodium ethoxide in ethanol to give VII or VIII, in which the ethoxycarbonyl group attached to the amino group remained unattacked. The acid hydrolysis of V and VI, as usual, gave VII and VIII, respectively.



(V) (VII)



(VI) (VIII)

The starting materials, β-ethoxycarbonylamino-α, β-unsaturated carboxylic esters, III, were prepared in good yields by refluxing the corresponding β-ketoester, II, and urethane in the presence of *p*-toluenesulfonic acid.

*1 Bp 40—60°C.
*2 Partly decomposed into 3-ethoxycarbonyltetrahydro-1,4-thiapyrone and ammonia.

Experimental[3]

β-Ketoester, II. Several β-ketoesters, 2-ethoxycarbonylcyclopentanone IIa_2,[4] 2-ethoxycabonylcyclohexanone (IIa_3),[5] 3-ethoxycabonyl-4-ketotetrahydrotiophene (IIb_1),[6] and 3-ethoxycarbonyltetrahydro-1,4-thiapyrone (IIb_2),[7] were sythesized by the methods given in the literature.

General Procedure for the Preparation of III. A mixture of 0.6 mol of II, 0.7 mol of urethane, and 1 g of *p*-toluenesulfonic acid dissolved in 100 m*l* of benzene was refluxed for 15 hr in a Soxhlet apparatus containing sodium sulfate in a thimble. The reaction mixture was then washed thoroughly with water to remove the *p*-toluenesulfonic acid and the excess urethane. After the evaporation of the solvent, a crude product was purified by chromatography using a column packed with alumina, plus chloroform - petroleum ether as an eluent, or by recrystallization from methanol-water (9: 1). The yield and properties for each compound are given in Table 1.

General Procedure for the Deethoxycarbonylation of III. A solution of 0.25 mol of sodium metal in 100 m*l* of ethanol containing 0.05 mol of III was refluxed for 17 hr. The cooled reaction mixture was diluted with water and then extracted with ether, after which the ethereal solution was treated with active charcoal and dried over sodium sulfate overnight. The solvent was removed, and the residue was recrystallized from an appropriate solvent or distilled under reduced pressure to give IV. The yield, properties, and recrystallizing solvent for IV are given in Table 2.

Hydrolysis of V or VI. After the treatment of 6 mmol of V or VI with 0.5 g of sodium metal in 50 m*l* of ethanol in the manner described above, the cooled reaction mixture was diluted with water, acidified with hydrochloric acid, and extracted with ether. The ethereal solution was then worked up in the usual manner and recrystallized from benzene. The products, VII and VIII, were obtained by refluxing V and VI respectively with 6 N hydrochloric acid for 8 hr. The analytical data and physical constants of VII and VIII are summarized in Table 2.

2) The preparation of V and VI will be described in another paper.
3) All melting points are uncorrected.

Syntheses of 3,3-Dimethyl-2-hydroxybutyric Acid and Tertiary Leucine and Their Optical Resolutions

Tadashi TANABE, Shinichi YAJIMA and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 8, 1967)

DL-3,3-Dimethyl-2-hydroxybutyric acid (I) was prepared by the reduction of trimethylpyruvic acid (II) with sodium amalgam[1] and by catalytic hydrogenation with palladium black.[2] The optical resolution of I has not yet been attempted, however.

DL-*t*-Leucine (III) was prepared by the reduction of trimethylpyruvic acid oxime[3] and resolved into its optical isomers by the treatment of the *N*-formyl derivative of III with brucine.[4] The absolute configuration of the (−) isomer (IIIa) was finally determined to be L by Izumiya *et al.*[5]

In the present work, I was prepared by the catalytic hydrogenation of II with a Raney nickel catalyst and was resolved into optically-active isomers with brucine and cinchonidine. The absolute configuration of the (+) isomer (Ia) was determined to be L_s by the deamination of L-(−)-*t*-leucine (IIIa) with nitrous acid to Ia.

III was prepared by the reductive amination of II with a Raney nickel catalyst and was converted into the *N*-acetyl derivative and the amide. The (−) isomer was obtained with cinchonidine from the former and with D-tartaric acid from the latter.

Experimental

Preparation of DL-3,3-Dimethyl-2-hydroxybutyric Acid (I). The ether extracts of the oxidized product of 120 g of pinacolone with pottasium permanganate[6] were concentrated, and then the residue was neutralized with 5 N sodium hydroxide. The resulting solution was hydrogenated at 50°C in the presence of a Raney nickel catalyst prepared from 5 g of alloy.[7] After the catalyst had been removed by filtration, the filtrate was passed through a column of sulfonic resin (H^+ form) and then concentrated to dryness *in vacuo* at below 50°C. Crude crystals were dissolved in a minimal volume of benzene, and then petroleum benzin was added. The crystals were collected to give 80 g of I. Mp 87—88°C.

Found: C, 54.36; H, 9.11%. Calcd for $C_6H_{12}O_3$: C, 54.53; H, 9.15%.

Optical Resolution of I into L-(+)-3,3-Dimethyl-2-hydroxybutyric Acid (Ia). Seventy-five grams of I and 224 g of brucine were dissolved in 1 *l* of water, and then the solution was concentrated to 500 m*l*. After the solution had been allowed to stand overnight in a refrigerator, the brucine salts were collected. Six recrystallizations of the salt from water yielded the pure brucine salt of Ia. Yield 22 g; mp 223—224°C (decomp.), $[\alpha]_D^{20}$ −31° (*c* 1, alcohol).

Found: N, 5.32 Calcd for $C_{29}H_{38}N_2O_7$: N, 5.33%.

Twenty grams of the salts were treated with 5 N sodium hydroxide, and the liberated brucine was removed by filtration. The filtrate was treated with sulfonic resin to remove a trace of brucine and sodium ions, and then concentrated to dryness under reduced pressure. The crystallization of the crude material from benzene-petroleum benzin gave optically-pure Ia. Yield 3.9 g; mp 51—52°C, $[\alpha]_D^{20}$ +4.5° (*c* 4, water). $[\alpha]_D^{20}$ −63° (*c* 1, water, 48.5 mg ammonium molybdate in 10 m*l*).

Found: C, 54.75; H, 9.30%.

Optical Resolution of I into D-(−)-3,3-Dimethyl-2-hydroxybutyric Acid (Ib). Thirty-five grams of cinchonidine and 15.8 g of I were dissolved in 100 m*l* of alcohol, and then the solution was allowed to stand overnight in a refrigerator to give 33 g of the cinchonidine salt. Five recrystallizations of the salt from alcohol gave pure cinchonidine salt of Ib. Yield 9 g; Mp 220—221°C, $[\alpha]_D^{20}$ −10.2° (*c* 1, alcohol).

Found: C, 69.46; H, 8.11; N, 6.24%. Calcd for $C_{25}H_{34}N_2O_4$: C, 70.09; H, 8.03; N, 6.57%.

Nine grams of the salt obtained were suspended in 100 m*l* of hot water, and then decomposed with 5 m*l* of 5 N sodium hydroxide under vigorous stirring for a day. After the removal of the cinchonidine by filtration, the filtrate yielded pure Ib when treated by the procedure described above. Yield 2.3 g; mp 50—51°C, $-[\alpha]_D^{20}$ −4.3° (*c* 4, water), $[\alpha]_D^{20}$ +65° (*c* 1, water, 51 mg of ammonium molybdate in 10 m*l*).

Found: C, 54.36; H, 9.38%.

Preparation of (+)-3,3-Dimethyl-2-hydroxybutyric Acid (Ia) from L-(−)-*t*-Leucine (IIIa). A solution of 0.77 g of sodium nitrite in 10 m*l* of water was added, drop by drop, to a solution of 1.4 g of L-(−)-*t*-leucine (IIIa) ($[\alpha]_D^{20}$ −8.5) in 10 m*l* of 2 N sulfuric acid. After the evolution of nitrogen had ceased, 5 m*l* of 2 N sulfuric acid was added and the product was extracted with ether. The ether extract was concentrated, and the residue was dissolved in 10 m*l* of water and decolorized with charcoal. After concentration *in vacuo*, the residual crude crystals were dissolved in a minimal volume of benzene, and then petroleum benzin was added. The resulting solution was cooled to give an acid (Ib). Yield, 70 mg; mp 43°C, $[\alpha]_D^{20}$ −58° (*c* 1, water, 50 mg of ammonium molybdate in 10 m*l*).

Preparation of DL-*t*-Leucine Hydrochloride (IV). Sodium trimethylpyruvate prepared from 62 g of II was subjected to reductive amination in 300 m*l* of concentrated aqueous ammonia (at 100 atm and 60°C) with a Raney nickel catalyst prepared from 3 g of alloy. The reaction mixture was then concentrated under reduced pressure. After the addition of sufficient 6 N hydrochloric acid to form the hydrochloride, the solution was evaporated to dryness and the IV was taken up with methanol. After the removal of the methanol, there remained 50 g of IV.

Preparation of *N*-Acetyl-DL-*t*-Leucine (V). III prepared from 50 g of IV by neutralization with 10 N sodium hydroxide was acetylated with a mixture of 90 m*l* of acetic anhydride and 20 m*l* of acetic acid at room temperature for 6 hr. The reaction mixture was then evaporated to dryness, and the product was taken up with alcohol. After the removal of the alcohol, the residual substance was recrystallized from alcohol. Yield 31.5 g; mp 229—231°C.

Found: C, 55.39; H, 8.59; N, 8.02%. Calcd for $C_6H_{14}NO_2Cl$: C, 55.47; H, 8.73; N, 8.39%.

Optical Resolution of V and Isolation of L-*t*-Leucine (IIIa). Sixty-five grams of V and 110 g of cinchonidine were dissolved in 200 m*l* of hot alcohol, after which the solution was allowed to stand overnight in a refrigerator. The crystalline precipitates were then collected. Six recrystallizations of the salt from alcohol gave 12 g of pure cinchonidine salt of IIIa. Twelve grams of the salt were decomposed with 1 N sodium hydroxide, and the liberated cinchonidine was filtered off. The filtrate was shaken with chloroform, acidified with 2 N hydrochloric acid, concentrated to 100 m*l* and extracted with ethyl acetate. The extract was evaporated to dryness, and the residue was recrystallized from a mixture of water and alcohol. 1.2 g of (−)-*N*-acetyl-*t*-leucine (VI) were obtained; mp 228—229°C, $[\alpha]_D^{20}$ −40° (*c* 1, water).

1.2 g of VI were hydrolyzed with hydrochloric acid, and then the hydrolysate was concentrated and the excess hydrochloric acid was removed by azeotropic distillation with water. The resulting crystals were dissolved in 20 m*l* of water and neutralized with diethylamine, and then 2 m*l* of alcohol were added. After the solution had stood overnight, IIIa was obtained. Yield 820 mg; mp 280°C (sublimed), $[\alpha]_D^{20}$ −9.5° (*c* 2, water).

Preparation of DL-*t*-Leucine Methylester Hydrochloride (VII). The product obtained from the reductive amination of 50 g of II was concentrated *in vacuo*, and the residue was extracted with 300 m*l* of methanol. Then to the extract there were added 100 m*l* of toluene, and the solution was evaporated to dryness under reduced pressure. The residue was dissolved in 300 m*l* of methanol, and the solution was saturated with hydrogen chloride, refluxed for 6 hr, and concentrated to dryness *in vacuo* at below 60 °C. A trace of water remaining in the residue was removed by azeotropic distillation with toluene; the subsequent addition of 5 m*l* of ether to the residue gave 27 g of VII. Mp 180—181°C.

Preparation and Optical Resolution of DL-*t*-Leucine Amide and Isolation of (−)-*t*-Leucine (III). Twenty-seven grams of VII were dissolved in 1 *l* of chloroform, and then dry ammonia was bubbled into the solution at 0°C. The ammonium chloride formed was filtered off, and the chloroform was removed under reduced pressure. The residual syrup was shaken with 200 m*l* of liquid ammonia in a 1-*l* autoclave for 12 hr at 55—60°C. After the ammonia had been evaporated off, the residue and 33.5 g of D-tartaric acid were dissolved in 45 m*l* of water. Storage overnight in a refrigerator gave 24.4 g of the salt. The salt was twice recrystallized from water to give 13.6 g of the pure D-tartrate of IIIa. $[\alpha]_D$ +0.88 (*c* 5, water).

13.6 g of the salt was hydrolyzed with 230 m*l* of 4 N hydrochloric acid for 6 hr, and the hydrolysate was concentrated to dryness. The residue was dissolved in 200 m*l* of water, and the solution was passed through a column of a weakly basic resin (Amberlite GC-45, OH^- form) to remove the tartaric acid and hydrochloric acid. *t*-Leucine was eluted with 400 m*l* of 0.5% aqueous acetic acid, after which to the eluate there was added 10 m*l* of concentrated hydrochloric acid. The resulting solution was concentrated to dryness. The residue was dissolved in a mixture of 9 m*l* of methanol and 4 m*l* of water, and the pH of the resulting solution was adjusted to 6.5 with diethylamine to yield 3 g of crude IVa, which was then recrystallized from a mixture of water and alcohol. Yield 1.7 g, $[\alpha]_D^{20}$ −9.0° (*c* 4, water). Found: C, 54.78; H, 10.09; N, 10.74%.

The authors wish to express their thanks to Professor Yoshiharu Izumi for his continuous guidance and help. They also wish to thank Miss Kiku Koike and Miss Nobuko Ohya for carrying out the elemental microanalyses.

The Cyanation of Ethylene with Cyanogen by a Silent Discharge

Tomiya ISSHIKI,*1 Noboru SONODA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 21, 1967)

There have been several patents[1-3] on the reaction of cyanogen with olefins. It has been shown that the reaction of cyanogen with ethylene over a nichrome wire coil above 815°C gives rise to succinonitrile,[1] whereas in the absence of a catalyst acrylonitrile was produced at 750—900°C,[2] or at 300—700°C under low pressure.[3] These facts show that the reaction of cyanogen with olefin may require high temperatures because of the high activation energy. In connection with our study on the reaction under an electrical discharge, a similar reaction was undertaken in a silent discharge, which seemed to resemble a high LET radiation process.[4] It was observed that the reaction proceeded smoothly at room temperature under atmospheric pressure.

The reaction of equimolar amounts of cyanogen and ethylene gave acrylonitrile as the main product in a yield of 40.0%, based on unrecovered ethylene, and propionitrile and valeronitrile were also formed in yields of 5.3 and 9.5%, respectively. A trace amount of adiponitrile was detected, and some undetectable solid, deposited on the surface of the discharge tube, was obtained. The gaseous products indentified were acetylene (7.6%), ethane (1.9%) and small amounts of butane, 1-butene, methane, hydrogen cyanide and hydrogen.

It was reported that acetylene was the main product of a silent discharge reaction with ethylene,[5] and that the reaction of cyanogen[6] in a silent discharge would give cyanoradical as an intermediate. Although little information was obtained about the reaction mechanism in the present experiment, acetylene may not be the precursor of acrylonitrile, because the addition of a small amount of acetylene to the reaction mixture did not cause any increase in the yield of the cyanated products.

Experimental

The silent discharge tube used was a Siemens type tube made of hard glass; discharge length, 24 cm; space gap, 3.5 mm; discharge space volume, 50 m*l*. The secondary voltage applied was 15 kV, and secondary current 1.0 mA at 60 cycles.

A gaseous mixture of 25.3 *l* of ethylene (0.503 mol) and cyanogen (0.503 mol) was circulated at the rate of 1.4 *l* min through the Siemens tube, and the effluent gas, before returning to the gas container, was passed through a cold trap at −20°C to collect condensable products.

After the discharge was continued for 7 hr, the components of the gaseous products were analyzed by v. p. c. using columns of activated charcoal and tricresyl phosphate: ethylene (0.293 mol), cyanogen (0.394 mol), acetylene (0.016 mol), ethane (0.004 mol), methane (0.001 mol), and trace amounts of 1-butene, butane, hydrogen, hydrogen cyanide and acrylonitrile were detected. To the condensed liquid products (8.2 g) was added a small amount of hydroquinone to prevent the polymerization of unsaturated products, and the resulting mixture was distilled under reduced pressure in a nitrogen atmosphere to give 5.7 g of a fraction boiling at 110°C/7 mmHg and 2.4 g of residue. Vapor phase chromatographic analysis of the fraction and the residue using a tricresyl phosphate column showed the presence of acrylonitrile (4.5 g), propionitrile (0.6 g), valeronitrile (0.8 g), adiponitrile (trace) and a small amount of unidentified products.

The acrylonitrile formed was also confirmed as its dibromo derivative; bromination of the liquid sample boiling at 76—78°C, obtained by redistillation of the above fraction, gave 2,3-dibromopropionitrile, which was identified by elementary analysis and the complete coincidence of the infrared spectrum with that of an authentic sample.

Found: C, 16.82; H, 1.56; N, 6.49; Br, 75.00%. Calcd for $C_3H_3NBr_2$: C, 16.93; H, 1.42; N, 6.58; Br, 75.04%.

Nitration of Phenylacetaldehyde

Yoshimori OMOTE, Naoaki FUKADA, Masakata HAYAKAWA and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received December 9, 1967)

There has been only one report about the direct nitration of phenylacetaldehyde (I); in that experiment Forrer[1] used concentrated nitric acid as a nitrating agent, but failed to obtain *o*-nitrophenylacetaldehyde (II). II is one of most important materials for preparing indole[2] and *N*-hydroxyindole,[3] but it is not convenient to synthesize II from *o*-nitrocinnamamide[2] or 1-chloro-4-(*o*-nitrophenyl)-2-butene.[4] We attempted to obtain II by the direct nitration of I with fuming nitric acid in acetic anhydride. The conditions were similar to those in the *o*-nitration with acetylnitrate.[5] Contrary to our expectations, however, II could not thus be obtained. Four compounds were isolated instead; they were identified as phenylacetaldehyde-diacetate (III), *p*-nitrophenylacetaldehyde-diacetate (IV), bis-(α-acetoxy-β-phenylethyl)-ether (V), and bis-(α-acetoxy-β-*o*-nitrophenylethyl)-ether (VI).

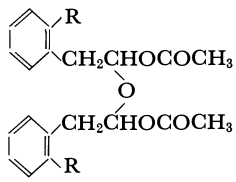
To an acetic anhydride solution of I, an equivalent amount of fuming nitric acid was added slowly at 0°C. An ether solution of the reaction mixture afforded an insoluble solid. The fractional distillation of the ether solution under reduced pressure gave two main fractions. The thin-layer chromatography of the yellow distillate, with a lower boiling point, showed that it contained the known compound III[6,7] as a main component. The orange distillate, with a higher boiling point, partly solidified upon cooling or standing for several days. After recrystallization, two crystalline compounds were isolated. One of them was identified with an authentic compound, V.[6,7] The structure of the other crystal (mp 102°C) was established to be IV by elemental analyses, and by a study of the IR, UV and NMR spectra. The NMR spectrum contained two symmetrical doublets with the same relative area centered at τ 1.82 and τ 2.59. The methine triplet was centered at τ 3.08.

The solid which was insoluble in the ether solution from the reaction mixture was recrystallized four times from acetone to afford colorless crystals (mp 196°C). The NMR spectrum showed an extensively split doublet (2 H) centered at τ 1.88 (the proton *ortho* to the nitro group) and a complex multiplet (6 H) with the strongest peak at τ 2.80 (the remaining three aromatic protons). The methine triplet was centered at τ 3.88. These data, as well as the results of elemental analyses and the IR and UV spectra of the crystal, were consistent with the structure of VI.

From a consideration of the reaction products, III, IV, V and VI, it seems reasonable to assume that direct nitration with fuming nitric acid in acetic anhydride cannot give II, but it can give III, from which IV and V are formed, and V can change into VI.

III, R=H

IV, R=NO_2



V, R=H

VI, R=NO_2

Experimental

All boiling points and melting points are uncorrected.

Nitration of Phenylacetaldehyde. To 100 g of phenylacetaldehyde (I) in 200 m*l* of acetic anhydride in a 500 m*l*, three-necked flask equipped with a mechanical stirrer, 53 g of fuming nitric acid (d 1.50) were added, drop by drop, over a period of 6 hr at 0°C. The liquid mixture was then stirred for 6 hr, during which the ice in the bath melted and the solution warmed to room temperature. The mixture was poured onto ice and left to stand overnight. The oily product was separated by decantation from the aqueous acidic solution, and washed with a sodium carbonate solution and water. By extraction with ether, the oily product was separated into two parts; part A was an oily solid, only slightly soluble in ether, while part B was readily soluble in ether.

Bis-(α-acetoxy-β-*o*-nitrophenylethyl)-ether (VI). Part A, a crude oily solid (about 10 g), was recrystallized four times from acetone to give colorless leaflets of VI, mp 196°C. NMR spectrum in deuterochloroform: τ 1.88 (doublet, 2 H), τ 2.80 (multiplet, 6 H), τ 3.88 (triplet, 2 H), τ 6.95 (doublet, 4 H) and τ 8.13 (singlet, 6 H). ν^{KBr} 2920, 2850, 1440, 1435 and 1375 (–CH_3 and –CH_2–); 1740 (CO); 3070, 1605 and 1495 (aromatic); 1510 and 1350 (NO_2); 1245 and 1230 (C–O–C) cm^{-1}.

Phenylacetaldehyde-diacetate (III). Part B was concentrated on a rotary evaporator, and then the residue was, under reduced pressure, distilled into three fractions, together with 30—50 g of a tarry residue. Fraction 1, 5 g of a yellow liquid, bp 50—125°C/2.5 mmHg; fraction 2, 26 g of a yellow liquid, bp 125°C/2.5 mmHg, and fraction 3, 27 g of an orange liquid, bp 125—175°C/2.5 mmHg. Most of the fraction 1 consisted of the starting material, I. Fraction 3 was redistilled to give two main fractions; fraction a, 17 g of a yellow liquid, bp 126°C/2.5 mmHg, and fraction b, 6 g of an orange liquid, bp 165—178°C/2.5 mmHg. Fraction 2 and fraction a were combined and redistilled to give a faint yellow liquid of III (35 g), bp 126°C/2.5 mmHg (lit. 146—148°C/10 mmHg[6,7]). NMR spectrum in carbon tetrachloride: τ 2.82 (multiplet, 5 H), τ 3.18 (triplet, 1 H), τ 6.98 (doublet, 2 H) and τ 8.04 (singlet, 6 H). ν 2950, 2850, 1455, 1435 and 1375 ($-CH_3$ and $-CH_2-$); 1760 (CO); 3050, 1605 and 1495 (aromatic); 1240 and 1200 (C-O-C) cm^{-1}. λ_{max}^{EtOH} 253 and 259 mμ. $\lambda_{max}^{0.1N\ NaOH\text{-}EtOH}$ 250 and 297 mμ.

***p*-Nitrophenylacetaldehyde-diacetate (IV).** Fraction b was partly solidified in the flask by cooling or standing for several days. Recrystallization several times from methanol afforded prisms of IV (3 g), mp 102°C. NMR spectrum in deuterochloroform: τ 1.82 and τ 2.59 (two symmetrical doublets with the same relative area, 4 H), τ 3.08 (triplet, 1 H), τ 6.78 (doublet, 2 H) and τ 7.92 (singlet, 6 H). ν^{KBr} 2950, 2850, 1440, 1430 and 1378 ($-CH_3$ and $-CH_2-$); 1750 (CO); 3080, 1608 and 1490 (aromatic); 1512 and 1350 (NO_2); 1240 and 1200 (C-O-C) cm^{-1}. λ_{max}^{EtOH} (log ε) 268 (4.02) mμ. $\lambda_{max}^{0.1N\ NaOH\text{-}EtOH}$ (log ε) 270 (4.03) and 471 (4.39) mμ.

Found: C, 54.18; H, 4.98; N, 5.10%. Calcd for $C_{12}H_{13}O_6N$: C, 53.93; H, 4.90; N, 5.24%.

Bis-(α-acetoxy-β-phenylethyl)-ether (V). The mother liquid of the recrystallization of IV was concentrated to give crude crystals, from which 0.05 g of V was obtained by recrystallization from ethanol, mp 126—127°C. The melting point was identical with that of an authentic sample.[7] ν^{KBr} 2930, 2850, 1455, 1435 and 1380 ($-CH_3$ and $-CH_2-$); 1740 (CO); 3050, 1605 and 1495 (aromatic); 1255 and 1240 (C-O-C) cm^{-1}. λ_{max}^{EtOH} 260 mμ. $\lambda_{max}^{0.1N\ NaOH\text{-}EtOH}$ 297 mμ.

Identification of Azulene Compounds in the Dehydrogenation Products of the Sesquiterpene Hydrocarbon Fraction of Camphor Oil

Shûichi HAYASHI, Shinji KUROKAWA and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received December 28, 1967)

In a previous investigation[1] of the colored matter in blue camphor oil,*1 in which S- and Se-guaiazulene (85 : 5 ratio) were identified, the authors pointed out that a mixture of azulene compounds obtained on the sulfur dehydrogenation of the sesquiterpene hydrocarbon fraction of the blue camphor oil behaved differently on thin-layer chromatography from a mixture extracted directly from the blue oil.

The present experiment was undertaken to clarify the structure of azulenes obtained from the sulfur dehydrogenation of the sesquiterpene hydrocarbon fraction of the blue camphor oil; the sesquiterpene hydrocarbon fraction was dehydrogenated with sulfur, and then a mixture of azulene compounds extracted from the reaction mixture was separated, by the use of silica gel - *n*-hexane chromatography, to yield S-guaiazulene (85%), vetivazulene (8%), and 3,5,8-trimethylazuleno[6,5-*b*]thiophene (7%).

This composition is remarkably different from the azulene composition in the blue camphor oil. The detection of vetivazulene was the first such case in the dehydrogenation products of camphor oil, and presented interesting information for the study of the constituents of camphor oil, because no constituent which may be considered to be a precursor has not been detected. 3,5,8-Trimethylazuleno[6,5-*b*]-thiophene may be a secondary reaction product of the S-guaiazulene produced in the dehydrogenation of camphor oil, for the azulenothiophene had also been produced in a similar yield in the high-temperature reaction of S-guaiazulene and sulfur.[2]

Experimental

Dehydrogenation of the Sesquiterpene Hydrocarbon Fraction. A high-boiling fraction of camphor oil,

*1 The high-boiling fraction of camphor oil containing sesquiterpene hydrocarbons and alcohols and other high-boiling constituents is called blue camphor oil, because of its color.

2) S. Hayashi, S. Kurokawa, M. Okano and T. Matsuura, *Tetrahedron Letters*, **1967**, 3443; *J. Sci. Hiroshima Univ., Ser. A-II*, **31**, 79 (1967).

obtained by distilling out a monoterpene fraction, bp above 215°C, d_4^{25} 0.9625, n_D^{25} 0.5057, $[\alpha]_D^{25}$ +40.0°, was fractionated through a Dixon-packed distillation column, and then the whole sesquiterpene hydrocarbon fraction, bp 104—120°C/9 mmHg, d_4^{25} 0.9289, n_D^{25} 1.5060, $[\alpha]_D^{25}$ +11.54°, was collected.

The fraction was dehydrogenated by heating it together with powdered sulfur at 180—240°C for 4 hr. The dehydrogenation products separated by distillation were then treated in the usual manner, phosphoric acid extraction and silica gel - benzene chromatography; a mixture of azulene compounds free from non-azulene products was thus obtained. This azulene mixture was then separated by chromatography on a silica-gel column using *n*-hexane. The results are shown in Table. 1

Table 1. Separation of azulene compounds produced in the dehydrogenation of the sesquiterpene hydrocarbon fraction

Eluting order	Appearance	Yield, g (%)
1	Blue, solidifiable	6.470 (84.9)
2	Violet, liquid	0.647 (8.3)
3	Dark violet, solid	0.517 (6.8)

Identification of the Azulene Compound. *S-Guaiazulene.* The blue azulene which was first eluted out from the column, solidified when stored. Its gas chromatogram (Chromosorb-W impregnated with 10% Silicone SE-30, Diasolid-L with 10% neopentyl glycol succinate, each column 1 m in length), IR,[3] UV,[4] visible[4] and NMR[5] spectra are in good agreement with those of S-guaiazulene. It gave the trinitrobenzoate,[6] mp 149—150°C, and the picrate,[6] mp 121—122°C, of S-guaiazulene (admixing).

Vetivazulene. The violet oil obtained from the second eluate was then purified by repeated phosphoric acid extraction and silica gel - *n*-hexane chromatography. The azulene oil thus obtained showed only one peak in gas chromatography, and its IR,[7] UV[8] and visible[4,8] absorption spectra agreed well with those of vetivazulene. The NMR and mass spectra of the oil can reasonably be explained by the structure of vetivazulene.

3,5,8-*Trimethylazuleno*[6,5-*b*]*thiophene.* From the third eluate, a dark violet crystalline mass, mp 95—107°C, was obtained after the solvent had been evaporated. It was further purified by repeated silica gel - *n*-hexane chromatography, and by subsequent recrystallization from methanol, to give dark violet needles melting at 116.0—116.5°C. A mixed-melting-point determination with 3,5,8-trimethylazuleno[6,5-*b*]thiophene[2] showed no depression. The NMR spectra of the compounds measured in chloroform and in trifluoroacetic acid both coincided with those of the azulenothiophene.[2] These findings were also supported by the IR and mass spectra.

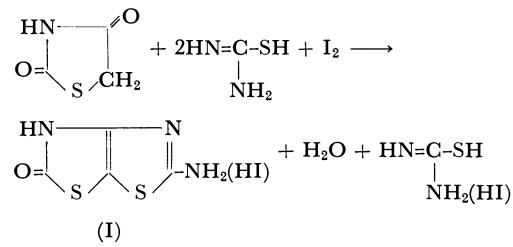
Studies of the Chemistry of Azole Derivatives. VII. *N*-Substituted-2-amino-5-ketothiazolidino[4,5-*d*]thiazoles

J. M. SINGH

School of Chemistry, Meerut College, Meerut, India

(Received January 6, 1968)

In extension to our previous work on thiazoles[2,3] the present communication deals with the study of reaction of compounds having $-\overset{O}{\overset{\|}{C}}-CH_2-$ function in cyclic structure with lodine and monosubstituted thioureas. Dodson[4] reported the preparation of 2-amino-4-methyl-5-carbethoxythiazole by the reaction of acetoacetic ester, iodine and thiourea. In order to extend the application of this reaction, 2,4-diketothiazolidine was condensed with thiourea and iodine (1 : 2 : 1). The reaction can be represented as given below.



(I)

On treatment with ammonium hydroxide (I) afforded the free base which could be diazotised using phosphoric acid and on acetylation it gave

monoacetylated derivative. These reactions, supported by analysis, confirmed the presence of an amino group.

Monosubstituted thioureas were prepared and condensed with 2,4-diketothiazolidine in presence of iodine (2 : 1 : 1) to give, *N*-substituted-2-amino-5-ketothiazolidino[4,5-*d*]thiazoles.

Experimental

Substituted thioureas were prepared following the method of De Clermont.[6]

2-Amino-5-ketothiazolidino[4,5-*d*]thiazole.

A mixture of 2,4-diketothiazolidine (0.1 mol), iodine (0.1 mol) and thiourea (0.2 mol) was heated on a water bath for 20 hr. The condenser was removed and heating was continued for another 12 hr. It was then kept in contact of ether for 12 hr. The excess of iodine was removed by sodium thiosulfate solution. 2-Amino-5-ketothiazolidino[4,5-*d*]thiazole hydroiodide thus formed was dissolved in water and neutralized with ammonium hydroxide solution to liberate the free base, recrystallized from alcohol, mp 175—177°C.

Found: N, 24.34; S, 36.35%. Calcd for $C_4H_3N_3S_2O$: N, 24.27; S, 36.99%.

The mono acetyl derivative melted at 220°C after recrystallization from benzene.

Found: N, 20.31; S, 30.31%. Calcd for $C_6H_5N_3S_2O_2$: N, 19.54; S, 29.76%.

Following this procedure other compounds were prepared.[7] Data of these products are listed in the table.

The author expresses sincere gratitude to the Head, Chemistry Department, Meerut College, Meerut, for providing necessary facilities.

Halogenation of Palladium(II) Complexes of β-Ketoamines

Akira KASAHARA and Takeo IZUMI

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received January 16, 1968)

Recenty, Collman has described electrophilic substitution reactions of chromium (III), cobalt (III), and rhodium (III) acetylacetonates[1]; furthermore, we have reported that divalent palladium acetylacetonate has a pseudo-aromatic nature and undergoes an electrophilic substitution at the central carbon of the chelate ring.[2] An investigation of the chemistry of the inert metal chelates of β-ketoamine, the mononitrogen analogs of acetylacetonates, seems a logical sequel to these earlier studies; along these lines, Collman and Kittleman[3] have reported on the bromination of the chromium (III) complexes of β-ketoamines. In the present work, the palladium(II) complexes (1) of β-ketoamines derived from aromatic amines (aniline, *p*-toluidine, and α-naphthylamine) and acetylacetone were found to undergo facile halogenation with *N*-halosuccinimides at the central carbon atom of the chelate ring in the manner of a quasi-aromatic system (*cf.* Fig. 1).

on alumina using dichlorometane. Recrystallization from benzene afforded 0.254 g (45% yield) of yellow crystals, mp 214—215°C (dec.). IR Spectrum (KBr): 1560, 1434, and 1380 cm^{-1}.

Table 1 summarizes the halogenated complexes that have been synthesized by this method. The yields of the purified complexes ranged from 30 to 50%.

Discussion

The infrared spectrum of bis(4-anilino-3-penten-2-one)palladium(II) (1, R=phenyl) exhibits strong and characteristic peaks at 1585 and 1512 cm^{-1}. This characteristic pattern of the infrared maxima is shown by all of the β-ketoamine complexes examined. The replacement of the hydrogen by the halogen at the central carbon atom resulted in the disappearance of the bands at 1585 and 1512 cm^{-1} and their replacement by a strong peak at 1560 cm^{-1}. This behavior is analogous to that of the spectra of the metal acetylacetonates. Dryden[6] observed that the replacement of the hydrogen by other groups at the central carbon of metal acetylacetonate rings caused the infrared doublet in the 1500—1600 cm^{-1} region to become a singlet at about 1550 cm^{-1}. An example of this empirical rule has also been observed in the series of the chromium(III) complexes of β-ketoamines.[3] Furthermore, bis(4-anilino-3-penten-2-one)palladium (II) (1, R=phenyl) shows a medium band at 1204 cm^{-1}, but there is no absorption peak at 1200 cm^{-1} in the spectra of the halogenated complexes. The medium band at 1199 cm^{-1} in the spectra of palladium acetylacetonate has previously been assigned to the bending mode of the hydrogen at the central carbon atom;[7] the absence of this peak is unequivocal evidence of the replacement at the central carbon of acetylacetonates.[8]

The nuclear magnetic resonance spectra summarized in Table 2 provide conclusive proof of the structure assigned to the halogenated complexes (2). The unhalogenated complex (1, R=phenyl) exhibits proton signals at 8.66, 8.37, 5.18, and 3.14—2.55 τ, with relative intensities of 3 : 3 : 1 : 5. These signals may be assigned to the methyl protons (a), methyl protons (b), the hydrogens on the center carbon, and the aromatic protons (*cf.* Fig. 1). On the other hand, the halogenated complex, bis(3-chloro-4-anilino-3-penten-2-one)palladium(II (2, R=phenyl, X=Cl), gives signals at 8.38, 8.13, and 3.22—2.65 τ, with relative intensities of 3 : 3 : 5. These signals may be assigned to the methyl protons (a), methyl protons (b), and the aromatic protons, respectively. The ultraviolet spectra of the palladium(II) complexes of β-ketoamines are summarized in Table 2. The introduction of the halogen into the chelate rings gives rise to a bathochromic shift in each of the ultraviolet maxima, suggesting an increased conjugated system.

Preliminary attempts to carry out the nitration and acetylation of this complex system were unsuccessful. Under the same conditions that had previously effected the nitration of palladium(II) acetylacetonate,[2] the β-ketoamine complexes were destroyed. The latter showed much less stability under acidic conditions.

Hydrogen Bonds between *p*-Chlorophenol and Alkylbenzenes

Masato IGARASHI and Tadatoshi WATABE

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Bunkyo-ku, Tokyo

(Received January 31, 1968)

Hydrogen bonds between organic hydroxy compounds and aromatic compounds, *i.e.*, the so-called π–H bonds, have been studied by many authors, for example, methyl alcohol - methylated benzene complexes were examined by Krueger and Mettee.[1)]

When *p*-chlorophenol was used instead of methyl alcohol, the shift of the OH-stretching frequency was greater than in the case of methyl alcohol. In this case *p*-chlorophenol was used as the proton donor, and methylated, ethylated and isopropylated benzenes were used as proton acceptors.

The OH-stretching frequency shifts, $\Delta\nu$, the enthalpy changes, $-\Delta H$, the entropy changes, $-\Delta S$, and the equilibrium constants, K, for π–H complexes formed in a carbon tetrachloride solution were obtained and compared with other findings on hydrogen-bonded complexes.

Experimental

The infrared absorption spectra were recorded with a Jasco Diffraction Grating Infrared Spectrophotometer, Model DG 201.

The concentrations of *p*-chlorophenol were regulated so as to have an order of magnitude of 0.001 mol/*l* and so as not to form hydrogen bonds among themselves, while those of alkylbenzenes were 0.5 mol/*l*, except for penta- and hexamethylbenzenes, which had a 0.2 mol/*l* concentration because of their low solubilities.

The temperatures of the solutions were altered by 10° stages from 15°C to 74°C in order to obtain $-\Delta H$ and $-\Delta S$ from the change in the absorption intensities of the free and hydrogen-bonded OH-stretching frequencies.

Results and Discussion

The observed values of $\Delta\nu$, $-\Delta H$, $-\Delta S$, and K are listed in Table 1. The frequency shift, $\Delta\nu$, seems to correlate extremely well with the number, n, of alkyl groups and little with their mutual configurations. The correlations are represented by a linear relation, *i.e.*, $\Delta\nu = an + 47$, shown in Fig. 1.

The gradients, a, were 9.0 in methylated benzenes, 7.9 in ethylated benzenes, and 9.7 in isopropylated benzenes, while the standard deviations were 0.3, 0.2, and 0.1 respectively.

The same linear correlation may be found from the table of methyl alcohol - methylated benzene complexes,[1)] where a is 8.7 ± 1.7 and where the 47 constant is replaced by 23. It is interesting to see that the gradients are nearly equal to each other irrespective of the species of alkyl groups in the proton acceptors and of the proton donors.

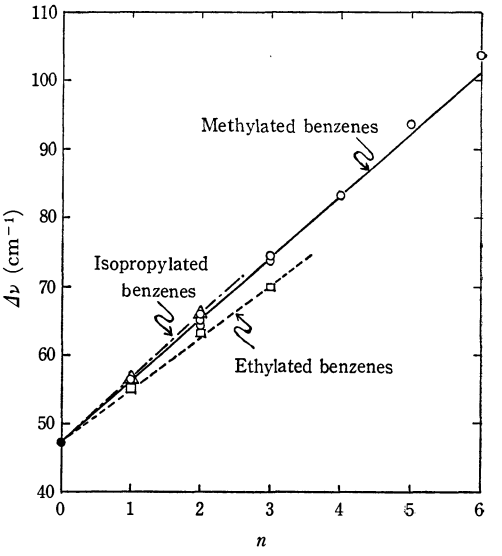

Fig. 1. The correlations between the OH frequency shifts $\Delta\nu$ of *p*-chlorophenol and the number n of alkyl groups in alkylbenzenes.

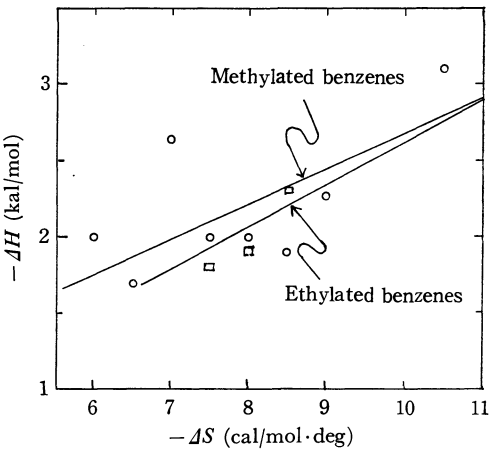

Fig. 2. The correlations between $-\Delta H$ and $-\Delta S$ of *p*-chlorophenol - alkylbenzene complxes.

The linear relationship between $\Delta\nu$ and ΔH (Badger-Bauer's rule) does not hold in this study

t-Butylbenzene	57.5	1.9	8	0.48

either, as Pimentel and McClellan have pointed out that it does not hold for many other examples of hydrogen-bonded complexes.[2)]

The ΔH *vs.* ΔS relation seems to be nearly linear, as in many other complexes,[1,2)] although the deviation from linearity is rather large (Fig. 2). The equilibrium constant, K, tends to increase monotonously as n increases. This trend is quite different from that of the methyl alcohol - methylated benzene series,[1)] which has shown the minimum value when $n=2$.

The authors wish to express their gratitude to Professor Keizo Suzuki for his kind encouragement throughout this study.

Reaction of Butadiene in the Presence of a Three-component Catalyst Consisting of Iron(III)acetylacetonate, a Phosphorus Compound, and Bis(diethylaluminum)sulfate

Masao IWAMOTO

Central Research Laboratories, Toyo Rayon Company, Ltd., Sonoyama, Otsu

(Received February 2, 1968)

It has been reported that a catalyst composed of iron(III)acetylacetonate and triethylaluminum is active in the reaction of butadiene with ethylene, yielding 1,4-hexadiene,[1] and also in the trimerization of butadiene, yielding *n*-dodeca 1,3,6,10-tetraene.[2] Hidai and his co-workers[3] studied the effect of adding triphenylphosphine as an electron donor to the catalyst system in the reaction of butadiene ; they found that the selectivity of the reaction was altered with an increase in the molar ratio of triphenylphosphine to iron(III)acetylacetonate. They obtained liquid polybutadiene as a by-product when the molar ratio was larger than five. On the other hand, we obtained a solid polymer composed of 1,2-addition sequences when three or four moles of triphenylphosphine per mole of iron(III)acetylacetonate were added to the catalyst system.[4]

In this note, the author will describe the characteristics of a three-component catalyst containing bis(diethylaluminum)sulfate as an organoaluminum compound. In a previous paper,[5] we reported on

the vinyl-polymerization of butadiene and isoprene in the presence of a catalyst composed of the cobalt thiocyanate - triphenylphosphine complex and bis-(diethylaluminum) sulfate. Bis(diethylaluminum)-sulfate has been found to act somewhat differently from triethylaluminum.

A mixture of butadiene linear dimers composed of 9.5 g of 3-methyl-1,4,6-heptatriene (MHT) and 12.7 g of 1,3,6-octatriene (OT) was obtained, along with 4 g of a by-product, in a reaction of butadine carried out at 50—60°C for 5 hr in the presence of a catalyst consisting of 0.5 mmol of iron(III)acetyl-acetonate, 2 mmol of triphenylphosphine, and 3.6 mmol of bis(diethylaluminum)sulfate. In this case, there was a selective formation of the linear dimers, and more 1,4-addition product, OT, than 1,2-addition product, MHT, was formed. The results obtained in the reaction of butadiene with a catalyst, using tributylphosphine as an electron donor, are summarized in Table 1. It was found that the amount of MHT in the dimer mixture was affected by the P/Fe molar ratio, and that the residue in the atmospheric distillation of the reaction mixture increased with an increase in the P/Fe molar ratio. As compared with the catalyst containing triphenylphosphine, the catalyst containing tributyl-phosphine tends to form more of the 1,2-addition product than of the 1,4-addition product, just as cobalt catalysts do.[6]

When diphenylphosphine was added to the catalyst system as an electron donor, a rubber-like polymer was obtained as the main product, together with a small amount of linear dimers. The infrared spectrum of the polymer shows strong absorption peaks at 910 and 955 cm^{-1}, suggesting a high content of the 1,2-addition sequence in the polymer chain. Triethylphosphite also promoted the polymerization of butadiene, yielding a colorless polymer mainly composed of the 1,2-addition sequence. When tributylphosphite or phosphorus oxychloride was added, the reaction proceeded less selectively to yield both the dimers and a polymeric substance.

It is considered that the catalytic formation of the oligomers is closely related to the vinyl-polymerization of butadiene, and these facts in turn suggest a similarity in the catalytically-active complex for both the reactions. The variation in the properties of the catalytic system is considered to depend on the physical and chemical characteristics of the electron donor added and may be explained in a way similar to that presented in a previous report.[3] Moreover, it has been found that the organoaluminum compound also affects the properties and the activity of the catalyst system.

The Acid-catalyzed S_N1-like Acylation of *l*-Menthol

Fuminori AKIYAMA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received February 8, 1968)

In a preceding paper[1] we reported that the propionylation of *l*-menthol in acetonitrile or liquid sulfur dioxide was a first-order-like reaction at a high initial concentration of *l*-menthol, even though the reaction was studied with equivalent amounts of *l*-menthol and propionyl chloride. This evidence will be studied in more detail in the present paper.

The second-order plot and the first-order plot in acetonitrile are visualized in Fig. 1 and Fig. 2. The slopes, k_1, of the apparent first-order plot were obtained at various concentrations of *l*-menthol, propionyl chloride, and *l*-menthyl propionate; they are shown in Table 1. The effect of the hydrogen chloride on the slope of the apparent first-order plot was also studied (*cf.* Fig. 3).

Table 1 and Fig. 3 indicate that the apparent first-order reaction is dependent on the concentrations of *l*-menthol and hydogen chloride, but not on the concentrations of propionyl chloride and *l*-menthyl propionate:

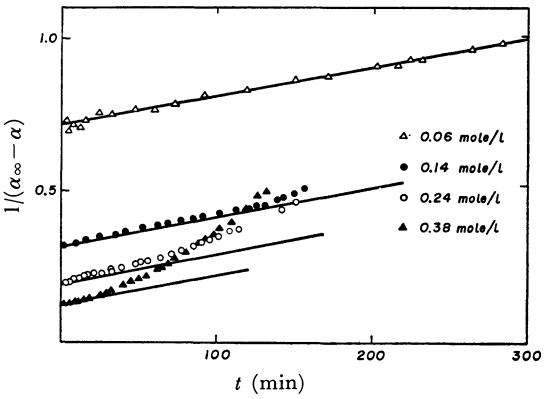

Fig. 1. Second-order plots in acetonitrile at 25°C.

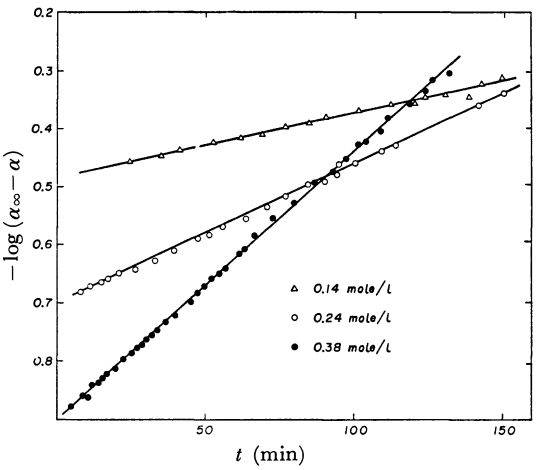

Fig. 2. First-order plots in acetonitrile at 25°C.

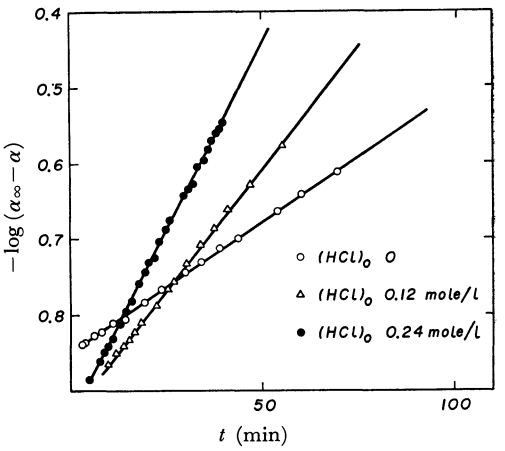

Fig. 3. Effect of hydrochloric acid on k_1 at 25°C. $(C_{10}H_{19}OH)_0$ 0.36 mol/*l*

1) F. Akiyama and N. Tokura, This Bullettin, **39**, 131 (1966).

Table 1. The effect of the initial concentrations of *l*-menthol, propionyl chloride and *l*-menthyl propionate on the first-order reaction rate in acetonitrile at 25°C

$(C_{10}H_{19}OH)$ mol/*l*	(CH_3CH_2COCl) mol/*l*	$(CH_3CH_2COOC_{10}H_{19})$ mol/*l*	k_1, sec^{-1}
0.14	0.14	0	3.85×10^{-5}
0.24	0.24	0	9.19×10^{-5}
0.24	0.24	0.25	8.75×10^{-5}
0.24	0.24	0.35	8.87×10^{-5}
0.36	0.24	0	1.43×10^{-4}
0.38	0.38	0	1.63×10^{-4}
0.38	0.19	0	1.53×10^{-4}
0.48	0.24	0	2.28×10^{-4}
0.67	0.38	0	3.11×10^{-4}

$$k_1 = k_1^\circ(C_{10}H_{19}OH) + k_1^\circ(HCl) \quad (1)$$

Therefore, the apparent first-order propionylation may not be an intrinsic first-order reaction. The effect of tetramethylammonium bromide and tetramethylammonium chloride on the apparent first-order propionylation was also studied; it is shown in Fig. 4.

This figure shows the acceleration of the reaction by tetramethylammonium bromide and the retardation of the reaction by tetramethylammonium chloride. Therefore, the apparent first-order propionylation may be assumed to contain a S_N1-like reaction. Perhaps the second term of Eq. (1), the propionylation catalyzed by hydrogen chloride, is the S_N1-like acylation:

$$CH_3CH_2COCl \xrightarrow{HCl} CH_3CH_2CO^+ + Cl^-\cdots HCl \quad (2)$$

The catalytic effect of hydrogen chloride is assumed to be that of a general acid catalysis. Other general acids, propionic acid and acetic acid, accelerate the apparent first-order reaction, as is shown in Fig. 5.

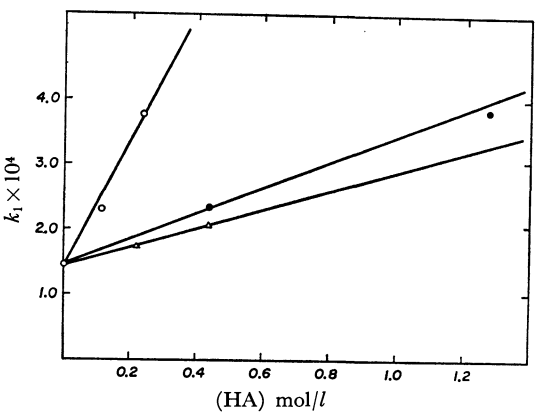

Fig. 5. The catalytic effect of hydrochloric acid, acetic acid and propionic acid. $(C_{10}H_{19}OH)_0$ 0.36 mol/*l*
○ hydrochloric acid+propionic acid
● acetic acid
△ propionic acid

Hydrogen chloride may have a retardation effect by means of the free chloride ion which is generated by the dissociation of hydrogen chloride, as well as an acceleration effect. Furthermore, hydrogen chloride may escape from the reaction solution partially. Therefore, an exact quantitative explanation of the effect of hydrogen chloride is difficult in the case of such a high concentration of hydrogen chloride.

However, the present authors can explain the propionylation of *l*-menthol at a high initial concentration of *l*-menthol as follows. In the initial stage of the reaction, a S_N2-type propionylation of *l*-menthol takes place. With the progress of the reaction, hydrogen chloride is generated and a S_N1 like propionylation, catalyzed by hydrogen chloride, takes place. As the decrease in the reaction rate with the consumption of *l*-menthol is compensated for by the acceleration of the reaction with the generation of hydrogen chloride, the propionylation is apparently a first-order reaction. At a low initial concentration of *l*-menthol, the propionylation of *l*-menthol is a second-order reaction, as is shown in Fig. 1. Perhaps the S_N1-like acylation does not take place without a general acid catalyst.

In a less polar solvent, benzene or chloroform no S_N1-like propionylation catalyzed by hydrogen chloride takes place, as has been shown in the preceding paper.[1] Because of the lack of the stabilization of the acylium ion in acyl halide in compared with that of the carbonium ion from the tertiary alkyl halide, the S_N1-like mechanism of acylation may require the aid of the acid catalyst in the polar solvent.

Experimental

Materials. Commercial extra-pure-grade *l*-menthol was used without further purification. Acetonitrile was dried with phosphorus pentoxide and distilled. The acetonitrile was distilled over potassium carbonate. Commercial propionyl chloride was distilled.

The Kinetic Procedure. The polarimetric procedure used for kinetic followings was described previously. A graphic representation of the apparatus was also found therein[1,2] The details of the kinetic procedure was also explained in a preceding paper.[1] Hydrogen chloride was generated by the following reaction:

$$CH_3COCl + H_2O \rightarrow CH_3COOH + HCl$$

After the addition of a definite amount of water, the effect of hydrogen chloride was studied.

Hydrogen Cyanide Formation in the Gas-phase Radiolysis of Mixtures of Nitrogen and Ethylene

Takefumi OKA, Ryo KATO, Shin SATO and Shoji SHIDA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 9, 1968)

Recently, several studies have been reported on the radiolytic isotopic exchange of nitrogen, in which the *G*-values of nitrogen atoms have been estimated to range from 9 to 19.[1-3] These values prompted us to investigate the radiolysis of gaseous mixtures of nitrogen and ethylene in an attempt to study the reactions of nitrogen atoms with ethylene molecules.

Experimental

Gaseous mixtures of nitrogen and ethylene in various pressures and ratios were irradiated with ^{60}Co γ-rays in sealed, 80-m*l* vessels made of Pyrex glass.

The nitrogen was purchased from the Takachiho Shoji Co. and was used without further purification. Gas chromatographic analysis showed that it contained 0.01% oxygen.

The dose rate was 1.25×10^6 R/hr; it was measured with a Fricke dosimeter, assuming that $G(Fe^{3+})=15.5$.

Products were analyzed by gas chromatography; for hydrocarbons, use was made of a column packed with silica gel, and for hydrogen cyanide, a column of dioctyl phthalate.

Results

The major products observed are shown in Fig. 1 as a function of the nitrogen pressure.

Since hydrogen cyanide was the only observed product containing nitrogen atoms, the *G*-values were measured under a variety of conditions.

1. Table 1 shows the irradiation-time dependence of *G*(HCN).*1

2. The pressure change of nitrogen from 250 to 750 Torr did not vary the value (0.5) of *G*(HCN), where the pressure of ethylene was 6 Torr and the irradiation time was 5 hr.

3. When the ethylene pressure was varied from 6 to 34 Torr, while the pressure of nitrogen (550 Torr) and the irradiation time (10 hr) were kept constant, *G*(HCN) was again found to be constant (0.4).

4. In the presence of sulfur hexafluoride (1 to

3) R. Shimozawa and K. Ooshima, Proceedings for the 10th Discussion Meeting of Radiation Chemistry, Hiroshima (October, 1967).

3 Torr), G(HCN) increased up to 0.8 from 0.4 (the latter value being obtained in the absence of sulfur hexafluoride), where the nitrogen was at 560 Torr, the ethylene was at 7 Torr, and the irradiation time was 10 hr.

5. When *trans*-2-butene (7 Torr) was used in place of ethylene, where the nitrogen was at 550 Torr and the irradiation time was 10 hr, practically no hydrogen cyanide formation was observed. When both ethylene (6 Torr) and *trans*-butene (7 Torr) were present, G(HCN) found was 0.1_7.

Discussion

Since G(HCN) does not vary with the change in the pressure of ethylene (result 3), it is obvious that hydrogen cyanide is formed by the reaction of active species from nitrogen with ethylene. By extrapolating the values in Table 1 to zero time, the initial G(HCN) value is estimated to be 0.8. The decrease in G(HCN) with the irradiation time may be due to the electron scavenging of the product, hydrogen cyanide,[4] followed by decomposition. The value of 0.8 is in agreement with that obtained in the presence of sulfur hexafluoride (result 4). Consequently, the G-value of active species responsible for the formation of hydrogen cyanide may be estimated to be 0.8.

The independency of G(HCN) of the pressure of nitrogen suggests that the active species are not excited nitrogen molecules. If excited nitrogen molecules are responsible for the formation of hydrogen cyanide, a decrease in G(HCN) should be observed with an increase in the pressure of nitrogen because of the deactivation. Moreover, it is generally accepted, in the study of active nitrogen produced by electric discharge, that the species responsible for the formation of hydrogen cyanide are nitrogen atoms, but not excited molecules.[5] Therefore, we can safely say that the active species leading to the formation of hydrogen cyanide in the present system are nitrogen atoms and/or nitrogen atom ions. The reaction may be as follows:

$$N \text{ (or } N^+) + C_2H_4 \rightarrow HCN + CH_3 \text{ (or } CH_3^+)$$

The methyl radical or ion formed here probably reacts with ethylene and yields propane as the final product.

When *trans*-2-butene was used in place of ethylene, we could not detect the formation of hydrogen cyanide, but in the presence of both olefins we found a small amount of hydrogen cyanide (result 5). This suggests that *trans*-butene reacts with active species produced from nitrogen, but does not yield hydrogen cyanide. Therefore, we carried out a careful search for products containing nitrogen atoms, but could not find any. One possibility is the interference of some impurity in *trans*-butene, although none could be detected.

Nitrogen atoms may be considered to be formed as follows:

$$N_2 \text{—} \sim\!\!\!\rightarrow N_2^+ + e \quad (1)$$

$$N_2 \text{—} \sim\!\!\!\rightarrow N + N^+ + e \text{ (or } N + N) \quad (2)$$

$$N_2^+ + e \rightarrow 2N \quad (3)$$

In the presence of ethylene, however, the reaction (3) competes with ion-molecule reactions, including the following reaction:

$$N_2^+ + C_2H_4 \rightarrow N_2 + C_2H_4^+ \quad (4)$$

The ions produced may decompose immediately or may react with other ethylene molecules. The rate of the reaction (4) will be more than 10^{-10} cc molecule^{-1} sec^{-1}, judging from a similar reaction in rare gases,[6] while the rate of the reaction (3) may be less than 10^{-6} cc molecule^{-1} sec^{-1}.[7] Under the conditions of the present experiment (a few Torr of ethylene and a dose rate of about 10^6 R/hr), the contribution of the reaction (3) to the formation of nitrogen atoms may be negligibly small.

According to a recent report on the electron impact of nitrogen,[8] a part of the ionization is dissociative. If we take 14% for the fraction of the dissociative ionization (this value corresponds to that obtained by the impact of 50 eV-electrons), the G-values of the nitrogen atoms and nitrogen atom ions estimated above can be interpreted well.

Hydrogenation and Hydrogenolysis. X. The Hydrogenation of Methoxy- and Ethoxyanilines with Rhodium Catalysts[1]

Shigeo NISHIMURA, Hiroshi UCHINO and Hisashi YOSHINO

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo

(Received February 26, 1968)

The catalytic hydrogenation of alkoxyanilines is usually accompanied by the hydrogenolysis of the alkoxyl group, which lowers the yields of corresponding alkoxycyclohexylamines.[2,3] Hydrogenolysis occurs most extensively in hydrogenation of methoxy- and ethoxyanilines. Freifelder and Stone hydrogenated various alkoxyanilines in methanol or ethanol at elevated temperature and pressure, using ruthenium dioxide, a catalyst that has proved useful in reduction of aromatic amines.[4] However, the yields of methoxy- and ethoxycyclohexylamines were rather low except in the case of *o*-ethoxyaniline where 2-ethoxycyclohexylamine was obtained in 78.7% yield. A low-pressure hydrogenation of alkoxyanilines over 5% rhodium-on-alumina in ethanol in the presence or absence of an equivalent of acetic acid was also reported.[3] Although hydrogenolysis occurred to a somewhat less extent under these conditions, it appears that, in most instances, rates of hydrogenation were small and considerable amounts of starting materials remained unchanged, even after a long reaction period with a 40% weight ratio of catalyst to alkoxyaniline. Thus, no satisfactory method for hydrogenation of alkoxyanilines, especially for methoxy- and ethoxyanilines, seems to have ever been described in the literature.

As reported in a previous paper,[5] decrease in the rate during the rhodium-catalyzed hydrogenation of aniline was considerably improved by the presence of a small amount of alkali which was added to or contained in the catalyst. Presence of alkali also depressed formation of secondary amine almost completely. Subsequently, we have studied the hydrogenation of alkoxyanilines with the alkali-promoted rhodium catalysts and found that the rhodium oxide prepared by fusion of rhodium chloride with lithium nitrate affords excellent yields of methoxy- and ethoxycyclohexylamines in hydrogenation of the corresponding methoxy- and ethoxyanilines. Over this catalyst, hydrogenolysis occurred only to a small extent (3.1—5.9%) and hydrogenation was completed within a few hours at 80—90°C under a high pressure of hydrogen with use of less than 2% weight ratio of catalyst to the substrate. Formation of secondary amines was also completely suppressed or only at a very low level over this catalyst. The results of the hydrogenation of isomeric methoxy- and ethoxyanilines are summarized in Table 1. The hydrogenation of ortho isomers was rather difficult to be completed at 80°C, but this difficulty was overcome at a higher reaction temperature. Approximate relative rates of hydrogenolysis, obtained on the basis of the amounts of cyclohexylamine formed during half-hydrogenation time, are also shown in the last column of Table 1, taking the rate for *o*-ethoxyaniline as unity. It will be seen that generally methoxyanilines hydrogenolyze more rapidly than do the corresponding ethoxyanilines, and that the rate of hydrogenolysis is in the order of ortho<meta<para isomers in both methoxy- and ethoxyanilines, although the proportion of hydrogenolysis is not always in the same order.[6]

Hydrogenation with the usual rhodium oxide, prepared by sodium nitrate fusion, was often inhibited at a later stage of reaction, although this oxide was as effective in hydrogenation of *p*-methoxyaniline as that by lithium nitrate fusion.[7] With rhodium hydroxide and lithium hydroxide, which was shown to be an effective catalyst system for hydrogenation of aniline,[5] *p*-methoxyaniline hydrogenated with a much smaller rate and gave a larger amount of hydrogenolysis product than with the rhodium oxide catalysts. The hydrogenation was strongly inhibited by the addition of sodium hydroxide. From these results, it will be probable that the hydrogenation of an alkoxyaniline is more easily inhibited by presence of a stronger alkali than in the case of aniline, and that the alkali contained in the oxide catalysts works as a weaker base than the corresponding alkali hydroxides. A similar difference in the action of alkali has also been observed in the rhodium-catalyzed hydrogenation of nitriles, where the reaction was retarded by addition of alkali in the order: LiOH<NaOH<KOH.[8]

Experimental

Catalysts. *The Rhodium Oxide Prepared by Lithium Nitrate Fusion.* A mixture of 3 g of rhodium chloride trihydrate and 45 g of lithium nitrate was fused in the same way as in the preparation of Adams platinum oxide.[9] After violent evolution of the oxides of nitrogen, the temperature was raised and kept at 420—460°C for about 15 min. After cooling, the solidified mass was rinsed in distilled water. The solid was collected, washed with 1—2% aqueous solution of lithium nitrate, and then dried over soda lime.

The Rhodium Oxide Prepared by Sodium Nitrate Fusion. This oxide was prepared according to the procedure described previously.[10]

Rhodium hydroxide. This was prepared from aqueous solutions of rhodium chloride and lithium hydroxide as described previously.[1]

Hydrogenation. The hydrogenation was carried out in a 200-m*l* autoclave of an electromagnetically-stirring type under the conditions described in Table 1. Isopropyl and *t*-butyl alcohols used as solvent were carefully dehydrated over calcium oxide, otherwise the hydrolysis products, alkoxycyclohexanols, were often produced during hydrogenation.

Analysis of Products. Products were analyzed by gas chromatography using a column of 10% PEG 6000-10% KOH on Chromosorb W (60—80 mesh). The gas chromatograms of alkoxycyclohexylamines were separated into two peaks except in the case of 2-methoxycyclohexylamine, where only one peak was obtained probably because of incomplete separation. The areas of the larger peaks, which probably correspond to the cis isomers, were 80.7, 69.2, 91.8, 85.3 and 74.1% for 3-methoxy, 4-methoxy-, 2-ethoxy-, 3-ethoxy- and 4-ethoxycyclohexylamine, respectively, in the experiments carried out at 80°C. Methoxy- and ethoxycyclohexylamines were further isolated by distillation at reduced pressure, after most of solvent had been distilled off at atmospheric pressure, with equipment of soda lime tubes.

This work was supported in part by the Mitsubishi Chemical Industries Co., Ltd., to which our thanks are due.

Electronic Structures of Methylenecyclopropene and Cyclopropenone

Akiyoshi WATANABE, Hiroyuki YAMAGUCHI, Yoshito AMAKO and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 11, 1968)

Recently, Saga[1] reported on the dipole moments and pK values of cyclopropenone derivatives. It seemed that it would be very interesting to compare his experimental data with the results of theoretical calculations. This report will describe an application of the semiempirical LCAO SCF MO method, including CI, to the electronic structures of these molecules.

In each iteration process of the SCF procedure, the values of the molecular integrals were recalculated by using the new bond distances, l_{rs}, obtained from the $l_{rs}=1.520-0.186\,p_{rs}$ relation,[2] where p_{rs} is the bond order between the two carbon atoms r and s obtained by the previous iteration process. However, the bond distance of C=O was kept constant throughout the calculation. One- and two-center Coulomb integrals were calculated by the usual approximation proposed by Parr and Pariser[3] and using the values of I_p and A given by Pritchard and Skinner[4] and the value of β obtained by Kon's formula.[5] In the CI calculation only the one-electron excitation configurations were taken into account. The final results may be tabulated as follows:

The calculated dipole moment of cyclopropenone, 4.428 D, seems to be reasonable when it is compared with the observed dipole moment of 3,4-diphenylcyclopropenone, 5.00 D.[1] The bond distances shown in the figures, which were obtained from the SCF p_{rs}'s, may serve to suggest the structures of these molecules. The formal negative charge at the oxygen atom of cyclopropenone seems to be too high to correspond to the pK value, −2.8 (25°C), of 3,4-diphenylcyclopropenone,[1] since the pK value of

the tropone molecule has been reported to be −1.02 (20°C) by Hosoya and Nagakura.[6] However, since the correspondence relation between the pK values and π electron densities should be limited within similar molecules, the reason for such a high negative formal charge at the oxygen atom as in cyclopropenone can be attributed to its special structure.

An Easy Conversion of 2,3,4,5,6-Pentamethylbenzyl Derivatives to Hexamethylbenzene by Catalysis of Sulfuric Acid[1)]

Hitomi SUZUKI and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 13, 1968)

In the acidic decomposition of 2,3,4,5,6-pentamethylbenzyl nitrate, an appreciable amount of hexamethylbenzene (HMB) was obtained as one of the main products.[2)] Since the intermolecular migration of the methyl group can hardly be possible under those mild conditions, HMB must have been formed by some other ways. Perhaps the most satisfactory interpretation is that the nitrate underwent the complex ionization to yield pentamethylbenzyl cation (PMB^+),[3)] which was then converted into HMB by the hydrogen atom abstraction.[4)]

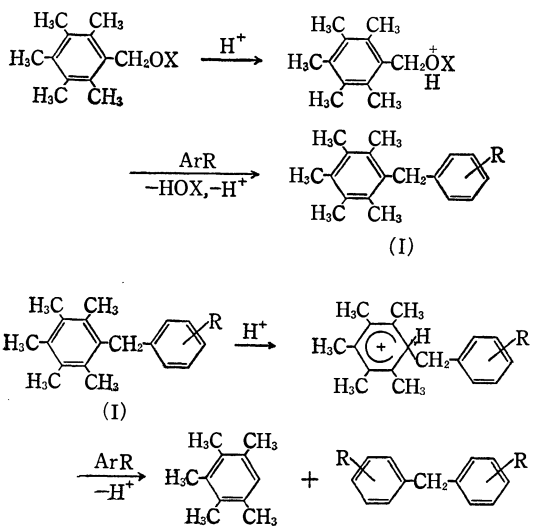
Cl	2.0	10	30 min at 13°C	0.53	64

* Calculated on the assumption that one mole of HMB was formed from two moles of the starting material.

With an intent to confirm this, some 2,3,4,5,6-pentamethylbenzyl derivatives were prepared and subjected to the action of sulfuric acid. All these compounds were found to be reduced with great ease to HMB, the yield of which could be increased considerably when the reaction was carried out in alkane medium. The characteristic color changes from purple-red into dark purple were observed during these transformations. Although the similar color change was observed by dissolving 2,3,4,5,6-pentamethylbenzyl alcohol in trifluoroacetic acid, the reduction was slow and incomplete at room temperature. However, PMR spectroscopy has revealed that the addition of small amounts of sulfuric acid to the solution can complete the reduction within a few minutes. Rather surprisingly, an attempted synthesis of bis(2,3,4,5,6-pentamethylbenzyl) ether by heating the alcohol with tosyl chloride in presence of pyridine also led to the formation of some HMB. The alcohol and its esters were especially subject to the easy reduction; even from the chloride HMB was slowly formed with continuous evolution of hydrogen chloride. The remarkable stability of PMB^+ has recently been established in strong acid system (SbF_5-SO_2),[5] but the present work has shown that PMB^+ is readily reduced to HMB under ordinary conditions. No pentamethylbenzene could be detected during these reactions.



In the medium of an aromatic hydrocarbon, the methylene group was transferred from PMB^+ to the solvent with the consequent formation of pentamethylbenzene and diphenylmethane derivatives. The process must be similar to those of the transcarbonylation,[6] the transbenzylation,[7] and the transsulfonation,[8] and may be explained in terms of steric crowdedness and strong electrophilic character of PMB^+.

Experimental

2,3,4,5,6-Pentamethylbenzyl derivatives were prepared as described in the literature: the alcohol (mp 160—161°C),[9] the nitrate (mp 95—97°C),[2] the acetate (mp 84.5—86.5°C),[9] and the chloride (mp 81—82°C).[10]

All these compounds dissolved readily in sulfuric acid to give a purple solution which was, after having stood for some time, diluted with excess of water. A solid precipitate was chromatographed on alumina using light petroleum to give HMB as an early eluate; it was spectroscopically identical with the authentic specimen, and showed no depression of the mixed melting point (mp 164—165°C).[11] A dark brown powder of no definite melting point (on heating, it turned to yellow with gradual decomposition) remained on the top of the column, and dissolevd readily in carbon tetrachloride to give a brown-red solution, the PMR spectrum of which showed a broad methyl absorption at around 7.8—8.0 τ. Thus it is a polymeric substance probably formed as a result of the hydrogen atom abstraction by PMB^+. Yields of HMB from various sources were recorded in Table 1.

2,3,4,5,6-Pentamethylbenzyl acetate (2.0 g) in methylcyclohexane (30 ml) was treated with sulfuric acid

(10 m*l*) under vigorous agitation at 13°C for 30 min. The mixture immediately turned into dark purple and some heat was evolved. Quenching with water, extraction by ether, and removal of the solvent under reduced pressure left a light brown solid, the chromatography of which on alumina using light petroleum gave HMB (mp 164—165°C, 0.86 g) as an early eluate.

A deep purple solution of 2,3,4,5,6-pentamethylbenzyl alcohol (0.5 g) in a large excess of trifluoroacetic acid was stirred at room temperature for 40 hr. Ordinary working-up and the subsequent chromatography on alumina gave HMB (0.03 g, 14%*) from the light petroleum eluates. Most products (mainly trifluoroacetate) remained on the top of the column.

The transfer of the methylene group of PMB^+ to another aromatic nucleus was realized by stirring a mixture of a pentamethylbenzyl derivative (2.0 g) with an aromatic hydrocarbon (40 m*l*) and sulfuric acid (15 m*l*) at 10°C for 1.5—2 hr. Products were analyzed by gas chromatography and identified by comparison with the authentic specimens; pentamethylbenzene and diphenylmenthane were formed nearly in equal quantity. Small amounts of another diphenylmethane compound (probably *unsym*-polymethyldiphenylmethane of the type I) were not further investigated.

A Facile Synthesis of 1,2 ; 5,6-Di-*O*-cyclohexylidene-α-D-allose*[1]

Masajiro KAWANA, Hiroshi OHRUI and Sakae EMOTO

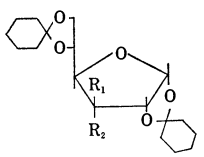
Rikagaku Kenkyusho (The Institute of Physical and Chemical Research), Yamato-machi, Kita-Adachi-gun, Saitama

(Received March 14, 1968)

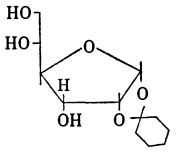
1,2;5,6-Di-*O*-cyclohexylidene-α-D-allose (III) is required for a study of asymmetric synthesis with sugar derivatives. It has been shown that 1,2 ; 5,6-di-*O*-cyclohexylidene-α-D-glucose (I) is more effective for some asymmetric reactions than the corresponding isopropylidene derivative.[1]

Sowa and Thomas[2] reported that 1,2; 5,6-di-*O*-isopropylidene-α-D-allose was prepared in a 62% yield from the corresponding glucose by oxidation with dimethyl sulfoxide - acetic anhydride (DMSO-Ac_2O), followed by reduction with sodium borohydride. This synthetic procedure, however, involves complicated manipulations, such as the removal of the excess DMSO-Ac_2O *in vacuo* at 35—40°C and the purification of the product by column chromatography.

The authors have found that the use of I,[3] which is more readily available than the corresponding isopropylidene derivative,[4] afforded a convenient method for preparing III and related compounds without the cumbersome treatment described above. The method, because of its simplicity, seems to be suitable for studies of allose chemistry.



I: R_1=OH, R_2=H
II: R_1, R_2=OH
III: R_1=H, R_2=OH



IV

The oxidation of I with DMSO-Ac_2O was carried out in the usual manner, and the reaction mixture was treated with aqueous potassium carbonate and ammonium hydroxide to give gummy materials, which were then reduced with sodium borohydride in a mixture of ether and methanol. The removal of the solvents provided crystalline products, which then gave pure III in a 50% yield after recrystallization. The relatively low yield of III was attributed to the formation of by-products, which presumably consist mainly of methylthiomethylene and acetyl derivatives of I formed in the oxidation step,[5] judging from the results of thin-layer chromatography. The *allo* configuration of III was confirmed by the conversion of the product into D-allose.

The selective cleavage of the 5,6-cyclohexylidene group of III was performed with aqueous acetic acid, affording 1,2-*O*-cyclohexylidene-α-D-allose (IV) in a 88% yield.

1,2;5,6-Di-*O*-cyclohexylidene-α-D-*ribo*-hexofuranos-3-ulose could also be easily obtained from the gummy

*1 In a journal which came to hand after this manuscript had been contributed to this Bulletin, K. James, A. R. Tatchell and P. K. Ray (*J. Chem. Soc.*, (*C*), **1967**, 2681) describe the synthesis of the title compound, but their techniques differ in some details.

materials as a crystalline mono hydrate (II), although in a low yield. The infrared spectrum of II in potassium bromide showed the presence of the hydroxyl group but no carbonyl group; however, the absorption band of the latter appeared in carbon tetrachloride, as in the case of the corresponding isopropylidene derivative.[6] The reduction of II with sodium borohydride yielded III stereospecifically under conditions similar to those of the reduction of the gummy materials.

Experimental

All melting points are uncorrected. The infrared spectra were measured with a Perkin-Elmer Model 521 grating infrared spectrophotometer. The optical rotations were determined with a Perkin-Elmer Model 141 photoelectric polarimeter in a 1-dm tube. The elemental analyses were performed by the Organic Analysis Laboratory of this Institute.

The thin-layer chromatography was performed by the ascending technique on a 250μ-layer of silica gel G (E. Merck, Darmstadt, Germany), activated for 2 hr at 120°C. The spray reagent was a mixture of methanol, sulfuric acid, and *p*-methoxybenzaldehyde (85: 10: 5, v/v).

1,2;5,6-Di-*O*-cyclohexylidene-α-D-allose (III). A mixture of 1,2;5,6-di-*O*-cyclohexylidene-α-D-glucose[3] (I; 3.4 g, 0.01 mol), dimethyl sulfoxide (15 m*l*), and acetic anhydride (10 m*l*) was allowed to stand at room temperature for 24 hr. A thin-layer chromatogram of the solution showed three main spots (one at R_f 0.43 due to the hydrate (II) of D-*ribo*-hexos-3-ulose, and those at 0.56 and 0.73 due to by-products) with benzene-ether (85 : 15, v/v). The reaction mixture was then stirred into an ice-water mixture (100 m*l*) containing potassium carbonate (15 g). After 30 min, 38% ammonium hydroxide (10 m*l*) was added, and the stirring was continued for 20 more min. The resulting gummy materials were washed with aqueous potassium carbonate and dissolved in ether (40 m*l*). The ethereal solution was washed with 10% aqueous potassium carbonate (10 m*l*) and then water (4×10 m*l*), and diluted with ether (5 m*l*) and methanol (10 m*l*).

To this solution there was added solid sodium borohydride (420 mg, 0.011 mol) under cooling in an ice-water bath; the mixture was stirred for 30 min, and then water (5 m*l*) was added. After the stirring had been continued for 5 min, the reaction mixture, now diluted with ether (20 m*l*), was washed with water (4×10 m*l*), and then the solution was dried over sodium sulfate. A thin-layer chromatogram of the solution showed four spots with benzene-ether (85 : 15, v/v) (R_f 0.25 due to III, 0.44 (faint) due to an unknown substance which was distinguishable from II by color, and 0.56 and 0.71 presumably due to by-products produced in the oxidative reaction). The evaporation of the solvents gave a crystalline product, which in turn provided III (1.7 g, 50%) after recrystallization from ligroin - ethyl acetate (9 : 1, v/v): mp 125—126°C; $[\alpha]_D^{25}$ +41.4° (*c* 0.65, ethanol); IR (KBr), 3495 cm^{-1}.

Found: C, 63.64; H, 8.02%. Calcd for $C_{18}H_{28}O_6$: C, 63.51; H, 8.29%.

A thin-layer chromatogram of III showed one spot (R_f 0.71) which could be distinguished from a spot (R_f 0.59) of I with chloroform-methanol (97 : 3, v/v).

A mixture of III (681 mg, 2.0 mmol) and Dowx 50W-X8 (H^+; 3 g (wet)) in dioxane (4 m*l*) and water (4 m*l*) was stirred as 80 °C for 45 min. The spots of the starting material and of 1,2-*O*-cyclohexylidene-α-D-allose (IV) on the thin-layer chromatograms almost completely disappeared; as solvent systems, chloroform-methanol (97: 3, v/v) and (85: 15, v/v) were employed respectively. The resin was filtered and washed with water, and the filtrate was extracted with chloroform (3×10 m*l*). The water layer was concentrated to dryness at 60°C in a rotary evaporator with the aid of a water aspirator, and the residue was crystallized from ethanol-water, affording analytically-pure D-allose (175 mg, 48.6%) (Found: C, 39.78; H, 6.61%): mp 127—131°C; $[\alpha]_D^{20}$ +2.1° (4 min) → +13.5° (20 hr) (*c* 1.46, water) (lit.[7] mp 128—128.5°C, $[\alpha]_D^{20\cdot1}$ +2.10° (4 min) → +14.41° (20 hr)). The X-ray powder diffraction patterns of the product were identical with those of an authentic sample.

The Hydrate of 1,2;5,6-Di-*O*-cyclohexylidene-α-D-*ribo*-hexofuranos-3-ulose (II). The oxidation of 1,2;5,6-di-*O*-cyclohexylidene-α-D-glucose (I; 3.4 g, 0.01 mol) was carried out in the same manner as has been described for the synthesis of the allose derivative (III). The ethereal solution of gummy materials was washed successively with aqueous potassium carbonate (10 m*l*) and water (40 m*l*), and then most of the ether was distilled out at 60°C under ordinary pressure and then at room temperature with the aid of a water aspirator. The oily residue gave, after the addition of *n*-hexane (15 m*l*), a crystalline product (1.3 g). Recrystallization from *n*-hexane - ethyl acetate (2 : 1, v/v) afforded II, which was then dried over phosphorus pentoxide at room temperature under reduced pressure (3 mmHg) for 2 hr. The yield of II was 0.9 g (25%): mp 119—121°C under rapid heating); $[\alpha]_D^{20}$ +40.0° (3 min) → +40.7° (5 min) → 41.8° (10 min) → +44.3° (30 min) → +44.3° (3 hr; constant) (*c* 0.28, 80% aqueous dioxane); IR, 3400 cm^{-1} (KBr), 1773 cm^{-1} (CCl_4, 40 min after solution).

Found: C, 60.87; H, 7.96%. Calcd for $C_{18}H_{28}O_7$: C, 60.66; H, 7.92%.

Solid sodium borohydride (57 mg, 1.5 mmol) was added to a solution of II (535 mg, 1.5 mmol) in a mixture of ether (16 m*l*) and methanol (4 m*l*) under cooling in an ice-water bath, and then the mixture was stirred for 30 min. Water (1 m*l*) was then added, after which the stirring was continued for 5 min. The resulting mixture, now diluted with ether (20 m*l*), was washed with water (4×5 m*l*), and the solution was dried over sodium sulfate. A thin-layer chromatogram of the solution showed only one spot due to III with chloroform-methanol (97: 3, v/v). The removal of the solvents gave analytically-pure III (483 mg, 94.5%) (Found: C, 63.60; H, 8.17%). Its melting point, specific rotation and infrared spectrum were identical with those of a sample prepared from the gummy materials.

1,2-*O*-Cyclohexylidene-α-D-allose (IV). The method reported by Gramera *et al.*,[8] but slightly modified,

6) O. Theander, *Acta Chem. Scand.*, **18**, 2209 (1964).

7) F. P. Phelps and F. Bates, *J. Am. Chem. Soc.*, **56**, 1250 (1934).

8) R. E. Gramera, A. Park and R. L. Whistler, *J. Org. Chem.*, **28**, 3230 (1963).

was used for this preparation. A solution of 1,2;5,6-di-*O*-cyclohexylidene-α-D-allose (III; 20 g, 0.059 mol) in acetic acid (210 m*l*) was diluted with water (90 m*l*). This solution was kept at 75°C for 35 min, and then poured into a shallow evaporating dish and allowed to evaporate to dryness in a hood at room temperature. The resulting crystalline mass was thoroughly dried by the repeated evaporation of its benzene solution (3× 100 m*l*) under reduced pressure at 60°C. The crude crystals (*ca.* 20 g) were recrystallized from ligroin - ethyl acetate (2: 1, v/v), yielding IV (13.5 g, 88%): mp 111—112°C; $[\alpha]_D^{25}$ +46.1° (*c* 0.56, ethanol); Fehling test, negative; IR (KBr), 3430 (shoulder), 3300, 3160 (shoulder) cm^{-1}.

Found: C, 55.60; H, 7.49%. Calcd for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75%.

The authors wish to thank Dr. Kiyoshi Isono of the Institute of Physical and Chemical Research for the X-ray powder diffraction data, and Dr. Hiroyoshi Kuzuhara of this Institute for his helpful suggestions.

The Heat of Dilution of Poly(vinyl acetate) in Benzene and Methyl Ethyl Ketone

Akihiro KAGEMOTO and Ryoichi FUJISHIRO

Department of Chemistry, Osaka Institute of Technology, Omiyakitano-cho, Asahi-ku, Osaka
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 15, 1968)

In our previous papers[1-4] we have measured the heats of dilution of atactic polystyrene,[1] *cis*-polybutadiene,[2] poly(ethylene oxide),[3] and polymethyl methacrylate[4] solutions; derived the interaction parameter between the polymer and solvent, and found that the interaction heat parameter, χ_H, is considerably dependent not only on the concentration of the polymer, but also on its molecular weight. In order to confirm this fact for other polymer solutions, the heats of dilution of poly(vinyl acetate) (PVAc) with the degrees of polymerization of 480, 1480, and 2450, and also the heat of mixing of the monomer of PVAc, were measured at 25.0±0.01°C using a twin micro-calorimeter, with methyl ethyl ketone (MEK) and benzene as solvents.

The heats of dilution of the polymer solutions were measured over the concentration range from 0.2 to 0.08 in the volume fraction of the polymer, by adding a successive of 10-m*l* and 30-m*l* portions of the solvent to a solution of a known concentration. The data obtained are shown in Table 1.

The benzene solution is endothermic, while the MEK solution is exothermic.

As has been shown in previously published paper,[1] the heats of dilution, $\Delta\overline{H}_d$, are related to the initial volume fraction of the polymer, ϕ_2, and the final one, ϕ_2', as follows:

$$\Delta\overline{H}_d = RT\chi_H\phi_2\phi_2'\Delta n_1 \quad (1)$$

when the interaction heat of parameter, χ_H, is not dependent on the concentration, or

$$\Delta\overline{H}_d/RT\phi_2\phi_2'\Delta n_1 = \chi_1 + \chi_2(\phi_2+\phi_2')/2 \quad (2)$$

when the χ_H parameter depends linearly on the concentration, according to the equation that $\chi_H=\chi_1+\chi_2\phi_2$.

In these equations Δn_1 is the number of moles of the solvent added.

By using the experimental data listed in Table 1 and Eq.(1), the interaction heat parameter, χ_H, has been obtained for each dilution process of each system; these parameters are given in the last column of Table 1.

According to Eq.(1), $\Delta\overline{H}_d$ must vary linearly with $\phi_2\phi_2'\Delta n_1$. However, these plots are not linear, as may be seen in Figs. 1 (a) and (b), indicating that χ_H depends on the concentration.

This tendency has been confirmed by plotting the $\Delta\overline{H}_d/\phi_2\phi_2'\Delta n_1$ against the average volume fraction $(\phi_2+\phi_2')/2$ for each system according to Eq. (2). In order to obtain the accurate values of χ_1 and χ_2, the least-squares treatment of the data was carried out according to Eq. (2); the results are shown in Table 2.

In a good solvent the χ_H parameter is considerably dependent on the concentration, while in the poor solvent, benzene, it is not.

Such a tendency can be explained according to the dilution theory of polymer solutions by Flory,[5] and

also according to the Huggins[6] theory. The Huggins theory, however, includes various factors characteristic of polymer solutions, so our results can not be quantitatively compared with those of this theory because of the lack of information concerning the chain configuration of the polymer molecules in the solution.

* $\overline{P}$: degree of polymerization.

Further, the value of χ_1, which is the interaction heat parameter in the dilute solution, decreases in absolute value as the molecular weight increases, as is shown in the first column in Table 2.

Such a dependence of the χ_1 parameter on the molecular weight has been found for other polymer solutions in previous papers.[3-4]

The dependence of the χ_1 parameter on the molecular weight has been theoretically derived by Huggins, who also explained it by using the dilute solution theory of polymers. For example, according to the theory the second virial coefficient can generally be given by the following equation:

$$A_2 = (\bar{u}_2^2/V_1)\phi_1(1-\theta/T)F(X)$$

where $F(X)$ is the complicated function of the molecular weight and the excluded volume (β); it decreases as the molecular weight increases.

The approximate treatment of the second virial coefficient gives the apparent interaction parameter, χ_1, as:

$$\chi_1 = (\psi_1\theta/T)F(X)$$

which is written as:

$$\chi_1 = \chi_1(X=0)F(X)$$

Since $F(X)$ decreases with an increase in the molecular weight, the apparent interaction parameter, χ_1, decreases with an increase in the molecular weight of the polymer.

Our results seem to be qualitatively in good agreement with the dilute solution theory of Flory.

Spin Correlation in Metal-Chelate-TCNQ Radical Salts

Mizuka SANO, Toshiaki OHTA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 16, 1968)

We have been interested in the paramagnetism of anion radical salts of 7,7,8,8-tetracyano-*p*-quinodimethan (TCNQ), and our study has been extended to the salts with metal-chelates. We synthesized a new kind of organo-metallic radical salts by the reaction between octahedral tris-dipyridyl (dip) metal-chelate compounds and TCNQ, and examined paramagnetic behavior of the salts as a function of temperature in the temperature region from 77 to 300°K, by a Faraday-type magnetic balance. The experimental procedure was the same as described in a previous paper.[1]

Preparation. $Fe(dip)_3(TCNQ)_2 \cdot 3H_2O$ (reddish black crystals), $Ni(dip)_3(TCNQ)_2 \cdot 3H_2O$ (greenish black crystals) and $Cu(dip)_3(TCNQ)_3Cl \cdot 4H_2O$ (black powder) were obtained by the reactions of $Fe(dip)_3Cl_2 \cdot 7H_2O$, $Ni(dip)_3Cl_2 \cdot 6H_2O$, and of $Cu(dip)_3Cl_2 \cdot 7H_2O$ with Li·TCNQ in methanol, respectively.

Results and Discussion

$Fe(dip)_3^{2+}(TCNQ^-)_2 \cdot 3H_2O$. The magnetic susceptibility decreased with decreasing temperature, although a small rise was observed in the lower temperature region. The curve (a) in Fig. 1 shows the temperature dependence of the paramagnetic susceptibility observed, after the correction was made for molecular diamagnetism of dipyridyl, TCNQ and H_2O, using the values determined experimentally and Pascal's constants. The curve (b) shows the susceptibility for $Fe(dip)_3Cl_2 \cdot 7H_2O$, after diamagnetism due to dipyridyl, Cl^- and H_2O was subtracted from the observed susceptibility. The corrected value showed a small paramagnetism of unknown character. The difference between (a) and (b), the curve (c), means the paramagnetic susceptibility resulted from the salt formation with TCNQ. If it is assumed that the rise in the lower temperature region originated from impurities, and that the susceptibility of impurities obeys Curie law as expressed by the curve (d), the difference between (c) and (d) could be attributed to the paramagnetism for TCNQ radicals in the salt, which is indicated by black circles in Fig. 1. The impurities would be TCNQ radicals which are improperly located in a lattice, as suggested by Kepler for other TCNQ salts.[2]

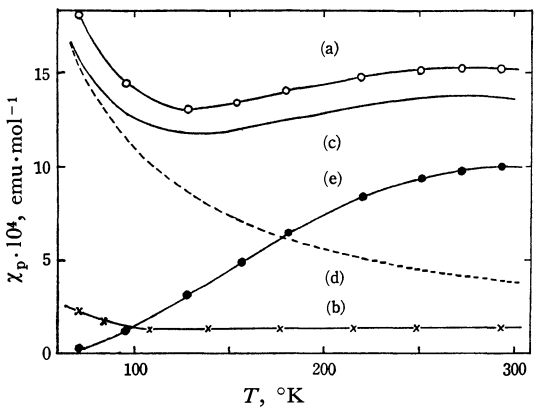

Fig. 1. Susceptibilities of (a) $Fe(dip)_3(TCNQ)_2 \cdot 3H_2O$, and (b) $Fe(dip)_3Cl_2 \cdot 7H_2O$, after correction for diamagnetism. (c) The difference between (a) and (b). (d) The assumed susceptibility for impurities. (e) The calculated, and ● the observed paramagnetic susceptibilities for TCNQ radicals in pairs.

According to the recent development in theoretical treatments of paramagnetism for organic free radicals, the paramagnetism can be reasonablv interpreted in terms of an exchange-coupled linear chain model.[3-5] For the case, in which spin correlation exists only in a pair of free radicals and gives rise to a ground singlet state and a thermally accessible triplet state (a singlet-triplet model), the paramagnetic susceptibility is expressed by

$$\chi_p = (2N'g^2\beta^2/kT) \cdot [3+\exp(\delta/kT)]^{-1},$$

where δ is the singlet-triplet energy separation, and N' is the number of spin pairs.

As can be seen in Fig. 1, the estimated susceptibility for TCNQ radicals finds a good fit to the value calculated from the singlet-triplet model, the curve (e), for which δ was taken to be 0.047 eV, and N', 5.17×10^{23}. The result reveals that the majority of anion radicals of TCNQ are pairing in the salt.

$Ni(dip)_3^{2+}(TCNQ^-)_2 \cdot 3H_2O$. The susceptibilities for this TCNQ salt and $Ni(dip)_3^{2+}Cl_2^- \cdot 6H_2O$ were both paramagnetic at room temperature, and increased with decreasing temperature. Figure 2 shows an appreciable amount of difference between

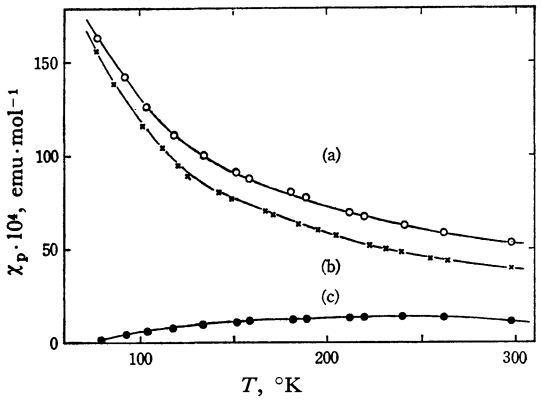

Fig. 2. Paramagnetic susceptibilities of (a) Ni(dip)$_3$(TCNQ)$_2 \cdot 3H_2O$, and (b) Ni(dip)$_3Cl_2 \cdot 6H_2O$. (c) The calculated, and ● the observed paramagnetic susceptibilities for TCNQ radicals in pairs.

the susceptibility values for these compounds. TCNQ radicals in the salt are thus found to contribute considerably to the observed paramagnetism. The temperature dependence of the susceptibility for the radicals in pairs could be explained on the basis of the singlet-triplet model for $\delta = 0.04$ eV, and $N' = 5.45 \times 10^{23}$.

This result indicates that the paramagnetism for the TCNQ salt could be explained without considering superexchange interaction between *d*-electrons in Ni(dip)$_3^{2+}$ and π-electrons in TCNQ radicals, and that spin correlation exists only in a pair of TCNQ anion radicals.

Cu(dip)$_3^{2+}$(TCNQ$^-$)(TCNQ)$_2$Cl$^- \cdot 4H_2O$. The paramagnetic susceptibility changed anomalously with the change in temperature. The susceptibility for TCNQ radicals, which was estimated tentatively from the difference between the value for the salt and that for Cu(dip)$_3^{2+}$Cl$_2^- \cdot 7H_2O$ is shown by the curve (c) in Fig. 3. It was nearly independent of temperature above 130°K, but it increased steeply

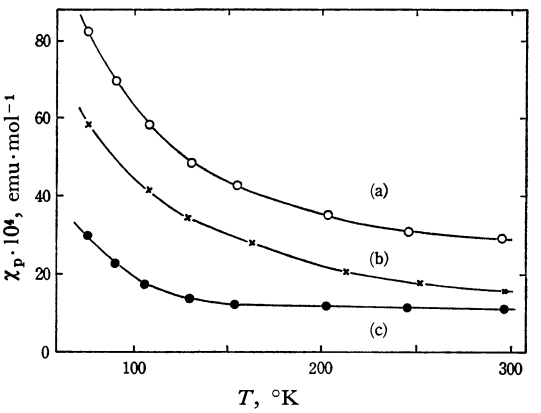

Fig. 3. Paramagnetic susceptibilities of (a) Cu(dip)$_3$(TCNQ)$_3$Cl$\cdot 4H_2O$, and (b) Cu(dip)$_3Cl_2 \cdot 7H_2O$. (c) The difference between (a) and (b).

in the temperature region below 130°K. The steep rise could not be fitted either to the values estimated by Curie law or by the Curie-Weiss law with a negative Weiss temperature. The electrical resistivity for this TCNQ salt was found to be as low as 270 Ω·cm at room temperature.

Ba^{2+}(TCNQ$^-$)$_2 \cdot 2H_2O$, Ni^{2+}(TCNQ$^-$)$_2 \cdot 3H_2O$, Fe^{2+}(TCNQ$^-$)$_2 \cdot 3H_2O$, and Cu$^+$(TCNQ$^-$)(TCNQ). The reciprocal values of paramagnetic susceptibility for the former three salts were plotted against temperature, as shown in Fig. 4, after

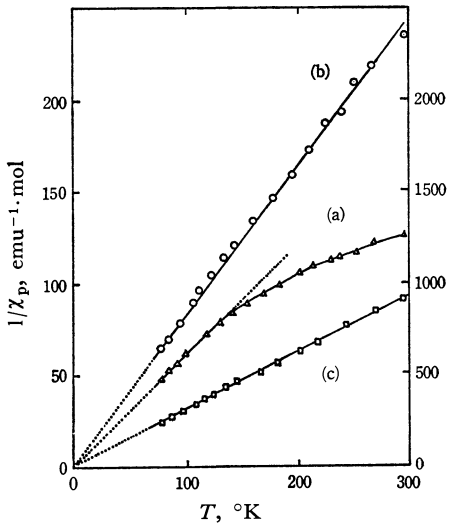

Fig. 4. Inverse paramagnetic susceptibilities of (a) Ba(TCNQ)$_2 \cdot 2H_2O$, (b) Ni(TCNQ)$_2 \cdot 3H_2O$, and (c) Fe(TCNQ)$_2 \cdot 3H_2O$. The scale for (a) is shown on right, while for (b) and (c) on left.

correction was made for their molecular diamagnetism. The paramagnetism of the nickel and ferrous salts was found to obey Curie law, and the value of the susceptibility agreed with the value expected on the basis of the cation alone. The same result has been reported by Kepler.[2)]

The plots for the barium salt, on the other hand, deviate from a straight line. Ba^{2+} itself is diamagnetic, so that the paramagnetism observed could be associated entirely with TCNQ radicals, and the deviation exhibits a strong spin exchange interaction between radicals. The temperature dependence of the susceptibility for the spin-paired radicals was explained by the singlet triplet model for which δ was taken to be 0.080 eV, and N', 4.77×10^{23}.

The product from metathesis of cupric sulfate with Li·TCNQ in methanol was found to have the composition of Cu(TCNQ)$_2$ by an elementary analysis. The inclusion of neutral TCNQ and its 1 : 1 ratio to TCNQ anion in the salt were determined by the measurement of an infrared absorption spectrum, which revealed that an electron transfer occurred from a TCNQ anion to Cu^{2+}, forming a diamagnetic Cu$^+$. The paramagnetic susceptibility of the salt

was low, 1.90×10^{-4} emu/mol at room temperature, and was independent of temperature.

Conclusion

The paramagnetic susceptibility for the TCNQ salts studied here, except for the copper salts, could be explained by a simple summation of the susceptibility value for the cation and that for anion radicals of TCNQ. The majority of the radicals in a salt are pairing in the sense of their spin exchange interaction, and the paramagnetism for the radicals in pairs is explained quantitatively on the basis of the singlet-triplet model. The singlet-triplet energy separation for the paired radicals in the metal-chelate-TCNQ salts is smaller than that in the simple metal-TCNQ salts.

Studies on Heteroaromaticity. XVI.[1] Further Studies on the Thermal 1,3-Dipolar Cycloaddition Reactions of Some Aromatic Hydroxamoyl Chlorides

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 8, 1968)

With a view of extending the synthetic utility of the thermal 1,3-dipolar cycloaddition reactions,[2] 5-nitro-2-furyl- (Ia), phenyl- (Ib), *p*-nitrophenyl- (Ic) and *m*-nitrophenylhydroxamoyl chloride (Id) were treated with i) triphenylphosphine, ii) benzonitrile or acetonitrile, iii) aromatic aldehydes, iv) quinones, v) anthranilate and vi) cyclic non-conjugated polyenes; each reaction proceeded smoothly with evolution of hydrogen chloride gas except when basic dipolarophiles were used. By this reaction, the yields of products were better than those *via* the routine nitrile oxide methods.

In the previous report,[2] the thermal 1,3-dipolar cycloaddition reactions of furyl- and 5-nitro-2-furylhydroxamoyl chloride with olefinic and acetylenic compounds was described and this paper deals with further experimental results carried out on several dipolarophiles with a view of extending the synthetic potentials of the thermal procedure. Reactions were carried out by using 5-nitro-2-furyl- (Ia), phenyl- (Ib), *p*-nitrophenyl- (Ic) and *m*-nitrophenylhydroxamoyl chloride (Id) and each reactivity was compared with those of the corresponding nitrile oxides, if possible.

Results and Discussion

Reaction with Triphenylphosphine. Stable aromatic nitrile oxides such as tri- and tetramethyl-substituted benzonitrile oxides are known to react with triphenylphosphine to afford the corresponding aromatic nitriles accompanied with the formation of triphenylphosphine oxide[3] but no description about the reaction of triphenylphosphine with benzonitrile oxide can be found. The corresponding nitrile oxides derived from Ia–d were treated with triphenylphosphine under the given reaction conditions[3] to afford the furoxane-type products instead of nitriles presumably because of strongly basic character of triphenylphosphine, but when Ia–d were directly heated in toluene with an equimolecular amount of triphenylphosphine for several hours, the corresponding nitriles, IIa–d, were obtained in good yields as shown in Table 1, also accompanied with the formation of triphenylphosphine oxide in almost quantitative yields. Such different yields might come from the different stability of each

Table 1. Nitriles (IIa—d)

Dipolar	Reflux hr	Yield %	Melting point, °C	IR (KBr) ν_{CN}, cm^{-1}
Ia	9	52	65—67[19]	2290
Ib	5	60	bp 190—192	2290
Ic	7	65	140—143[15]	2290
Id	9	71	119—118[16]	2290

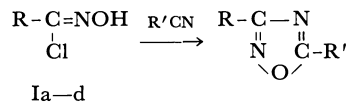
hydroxamoyl chloride, Ia—d, under the given creation conditions. It should be added that by this thermal procedure, no furoxane formation was observed as reported in the previous paper.[2]

Reaction with Benzonitrile or Acetonitrile. Benzonitrile oxide has been converted to oxadiazoles by the 1,3-dipolar cycloaddition reactions with both aromatic nitriles[4] and the nitriles activated by an electron-attracting substituent,[5] but the reaction with aliphatic nitriles was unsuccessful, though the catalytic action of boron trifluoride in the cycloaddition of benzonitrile oxide with nitriles and carbonyl compounds has been reported by Morrocchi, *et al.*[6]

Ia was heated in toluene with benzonitrile for 11 hr giving the corresponding oxadiazole IIIa in only 8% yield; the similar procedure in the presence of boron trifluoride etherate as a catalyst gave the same product in a 36% yield, while the reaction of 5-nitro-2-furocarbonitrile oxide with benzonitrile only afforded intractable tars. Ib also afforded IIb in a 65% yield even without the catalyst and almost quantitatively with the catalyst. IIIb has been prepared by the 1,3-dipolar cycloaddition of benzonitrile oxide with benzonitrile without a catalyst in a 55% yield.[7] These results obviously indicate that the presence of boron trifluoride can improve the yields of the thermal 1,3-dipolar cycloaddition products. The reaction of Ia with acetonitrile did not occur even in the presence of the catalyst and Ia was recovered, though Ib afforded IVb in a 35% yield under the similar reaction conditions. IVb has been prepared by the reaction of benzonitrile oxide with acetonitrile in the presence of the catalyst in a 35% yield.[6]



Ia—d

IIIa—d (R′: C_6H_5), IVb (R′: CH_3)

These results are summarized in Table 2 except IVb.

Reaction with Aromatic Aldehydes. Similar 1,3-dipolar cycloaddition reactions of benzonitrile oxide with such carbonyl compounds as aromatic

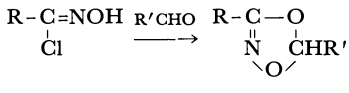
aldehydes, α-ketoesters and α-diketones have been reported to afford dioxazoles, but no reactions have been reported to occur with aliphatic aldehydes, acetophenone and aliphatic ketones in general.[5] Treatment of Ia with benzaldehyde, *p*-nitrobenzaldehyde and 5-nitro-2-furfural in the presence of the catalyst resulted in the formation of intractable tars, while Ib afforded with *p*-nitrobenzaldehyde and 5-nitro-2-furfural the corresponding dioxazoles, Vb, and VIb, respectively and similarly VId from Id and 5-nitro-2-furfural even in the absence of the catalyst. These results are summarized in Table 3.

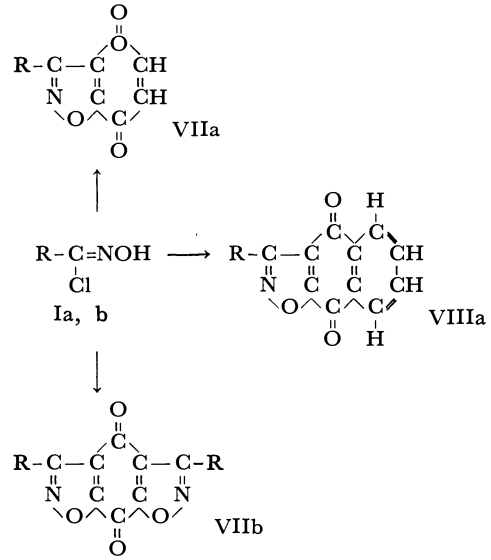
A role of such electrophilic catalyst as a Lewis acid in the thermal 1,3-dipolar cycloaddition reactions is uncertain at the present stage, but it could be said that the presence of boron trifluoride etherate might accelerate the removal of hydrogen chloride from hydroxamoyl chlorides and increase the polarization of a carbonyl group of dipolarophiles as predicted by Morrocchi, *et al.*[6]



Vb (R′: O_2N-C$_6$H$_4$-) VIb (R′: O_2N-furyl-) VId (R′: O_2N-furyl-)

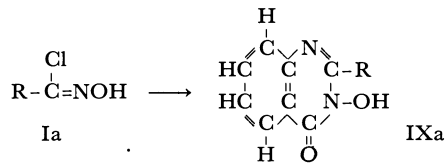
Reaction with Quinones. Benzonitrile oxide is also known to react with 1,4-benzoquinone and 1,4-naphthoquinone giving the corresponding 1 : 1 adducts, with subsequent oxidation to quinones having condensed benzene-isoxazole and naphthalene-isoxazole nuclei respectively.[8]

Ia was heated with 1,4-benzoquinone for 9 hr to afford VIa in a 31% yield: the structure was confirmed by the NMR spectrum in DMSO-d_6, showing a chemical shift at 2.90 τ (singlet, 2 H) attributable to two equivalent aromatic protons of benzoqinone. Similar treatment of Ia with 1,4-naphthoquinone afforded VIIa in a 25% yield and similarly, VIIb from Ib and 1,4-benzoquinone in a 36% yield. The structure of VIIa was confirmed from the elemental analysis and the NMR spectrum and furthermore, from the mass spectrum as described in Experimental, and the structure of VIIb was characterized as a 1 : 2 adduct from the elemental analysis and the NMR spectrum in DMSO-d_6, showing no aromatic proton originated from benzoquinone. It is noteworthy that the thermal procedure always afforded the products possessing an isoxazole structure instead of the simple adducts with an isoxazoline structure without any side-formation of furoxanes.[2]



VIIa, VIIIa, VIIb

Reaction with Anthranilate. Dornow and Fischer[9] have reported the formation of a quinazoline-type product from Ib and two equivalent amounts of methyl anthranilate on keeping the reaction mixture at room temperature. Similar treatment of Ia with methyl anthranilate also afforded IXa in a 60% yield; the structure was consistent with 3-hydroxy-4-oxo-2-(5′-nitro-2′-furyl)-3,4-dihydroquinazoline on the basis of the elemental analysis and the spectral data. The infrared spectrum (KBr disc) exhibited a strong absorption of ν_{CO} at 1695 and that of intramolecular hydrogen bonding at 2500 cm^{-1}, supporting its *N*-hydroxyl structure rather than its *N*-oxide.[10] In the ultraviolet spectrum in ethanol, the absorption maxima at 374 mμ (ε = 16700) and at 268 (18200) resembled to those of the known product IXb.[9]



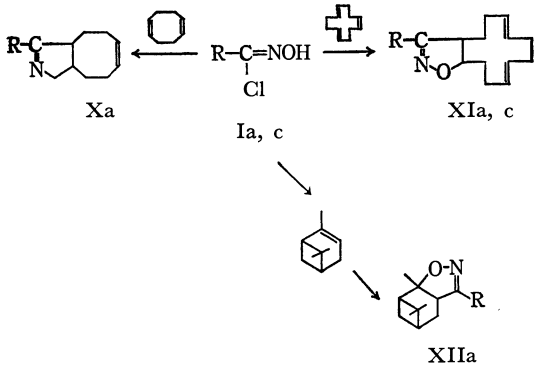
Ia → IXa

Reaction with Olefins. In addition to the previous report,[2] Ia was treated with non-conjugated cyclic polyenes like 1,5-cyclooctadiene and 1,5,9-cyclodecatriene to afford 1 : 1 adducts, Xa and XIa, in 55 and 70% yields, respectively. Ic also afforded a 1 : 1 adduct Xc in a 55% yield. However, the reactions of Ia with conjugated polyenes like 1,3-cyclooctadiene, myrcene and butadiene did not occur at all and the starting materials were

8) A. Quilico, C. Stagno and D'Alcontres, *Gazz. Chim. Ital.*, **80**, 140 (1950); *Chem. Abstr.*, **45**, 606c (1951). The yields of the products are very low and diphenylfuroxane and benzonitrile are always accompanied as the by-products.

9) A. Dornow and K. Fischer, *Chem. Ber.*, **99**, 72 (1966).

10) Similar phenomena have been observed in 2-hydroxypyridine *N*-oxide (E. Shaw, *J. Am. Chem. Soc.*, **71**, 67 (1949)) and 2-hydroxyquinoline *N*-oxide (K. G. Cunningham, G. T. Newbold, F. S. Spring and J. Sharp, *J. Chem. Soc.*, **1949**, 2091).



Xa Ia, c XIa, c XIIa

recovered, though benzonitrile oxide is known to react with conjugated dienes[11] or myrcene.[12]

As is pointed out in the previous paper,[2] cyclic monoolefins like cyclohexene, cyclooctene give good yields in the thermal 1,3-dipolar cycloaddition reactions; similarly, α-pinene underwent the same reaction with Ia giving a 1 : 1 adduct XIIa in a 90% yield.

As a conclusion, the thermal 1,3-dipolar cycloaddition reactions using hydroxamoyl chloride can be said to have more versatile applicability than those using the corresponding nitrile oxides; the reaction proceeds with evolution of hydrogen chloride gas which is a very convenient clue for determining the end-point of the reaction except when basic dipolarophiles are used. In the latter case, two equivalent amounts of bases are used and care should be paid to control the reaction temperature as low as possible enough to proceed the reaction. This is the case when basic dipolarophiles are readily decomposed by hydrogen chloride evolved, as is observed in the formation of IXa.

Experimental

The melting points were measured on a microhot stage and are not corrected. The microanalyses were carried out with a Yanagimoto C. H. N. Corder, Model MT-1 type. The infrared spectra were measured on a Nippon-Bunko IR-S type spectrophotometer and the ultraviolet spectra, on a Nippon-Bunko optical rotary dispersion recorder, Model ORD/UV-5. The NMR spectra were determined on a Varian A-60 spectrometer, with tetramethylsilane as an internal standard and the peak positions are expressed by τ-values. The mass spectrum was obtained with a Hitachi RMU-6D mass spectrometer with an energy of 70 eV.

Hydroxamoyl Chlorides. Ia,[12] Ib,[13] Ic[14] and Id[15] were prepared by the known procedures.

Reaction of Ia—d with Triphenylphosphine. A solution of 1.0 g (5 mmol) of Id and 1.3 g (5 mmol) of triphenylphosphine in 30 m*l* of dry toluene was refluxed at 140—150°C for 9 hr until evolution of hydrogen chloride gas had completely ceased. The solvent and surplus triphenylphosphine were removed under reduced pressue and the residue was dissolved in chloroform and chromatographed on a silica-gel (Mallinckrodt, 100 mesh) column, using chloroform as an eluent. From the first fraction, 0.57 g of *m*-nitrobenzonitrile was obtained. This was identified by the comparison with an authentic sample[16] spectroscopically (IR). From the second fraction, 1.4 g (96%) of triphenylphosphine oxide, mp 166°C (lit.,[17] mp 166°C) was obtained. Similar treatment of Ia—c with triphenylphosphine afforded the corresponding nitriles as shown in Table 1.

Reaction of Ia—d with Benzonitrile. A solution 0.75 g (5 mmol) of Ib and 0.55 g (5 mmol) of benzonitrile in 20 m*l* of dry toluene was refluxed at 140—150°C for 16 hr until evolution of hydrogen chloride gas had completely ceased. After removing toluene and surplus benzonitrile under reduced pressure, ethanol was added to the residue and the precipitated colorless needles were collected and recrystallized from ethanol-benzene to give 0.6 g of 3,5-diphenyl-1,2,4-oxadiazole, mp 110°C (lit.,[7] mp 109°C, no depression by the mixed melting point). Similar treatment of Ia—d with benzonitrile afforded the corresponding oxadiazoles as indicated in Table 2.

Reaction of Ib with Acetonitrile. A solution of 0.74 g (5 mmol) of Ib and 0.25 g (5 mmol) of acetonitrile in 25 m*l* of dry toluene was refluxed for 32 hr in the presence of a catalytic amount of boron trifluoride etherate. After the removal of distillable parts from the reaction mixture under reduced pressure, the residue was purified according to the procedure given by Tieman and Krueger[18] to afford 3-phenyl-5-methy-1,2,4-oxadiazole, mp 41°C (lit.,[18] mp 41°C) in a 35% yield.

Reaction with Aromatic Aldehydes. A solution of 0.72 g (5 mmol) of Ib and 0.73 g (5 mmol) of *p*-nitrobenzaldehyde in 20 m*l* of dry toluene was refluxed for 21 hr. After toluene was removed under reduced pressure, the residue was dissolved in chloroform and chromatographed on a silica-gel column, using chloroform as an eluent. The first fraction afforded 0.7 g of 3-phenyl-5-(*p*-nitrophenyl)-1,2,4-dioxazole (Vb). Similarly, 3-phenyl-5-(5′-nitro-2′-furyl)- (VIb) and 3-(*m*-nitrophenyl)-(5′-nitro-2′-furyl)-1,2,4-dioxazole (VId) were prepared from the corresponding components after 11 and 24 hrs' refluxing, respectively. These results are summarized in Table 3.

Reaction of Ia—b with Quinones. A solution of 0.9 g (5 mmol) of Ia and 1.0 g (10 mmol) of 1,4-benzoquinone in 30 m*l* of dry toluene was refluxed for 9 hr. The reaction mixture was filtered while hot and the filtrate was allowed to stand. The resulting precipitates were collected and recrystallized from ethanol-benzene to give 0.4 g of VIIa, mp 200—202°C. IR (KBr) cm^{-1}: 1690, 1670 (CO). UV λ_{max}^{EtOH} mμ (ε): 314 (13800), 246 (11600).

Found: C, 50.65; H, 1.40; N, 10.48%. Calcd for $C_{11}H_4O_6N_2$: C, 50.78; H, 1.54; N, 10.77%.

Similar treatment of Ib with 1,4-benzoquinone afforded VIIb, mp 264°C, after 22 hrs' refluxing.

presumable for this formula. If XIIa′ is assumed to be a correct structure, H_A' should be appeared in more lower magnetic field than the observed value, 6.55 τ, by the presence of a neighboring oxygen atom.

Studies on Heteroaromaticity. XVIII.[1] Reaction of Aromatic Hydroxamoyl Chlorides with Methyl Dithiocarbazinate

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 19, 1968)

Dornow and Fischer[2] have reported interesting reactions of aromatic hydroxamoyl chlorides with methyl dithiocarbazinate to give 2-substituted amino-5-methylmercapto-1,3,4-thiadiazoles; for example, 2-anilino-5-methylmercapto-1,3,4-thiadiazole, mp 126°C,[3] was obtained in 48% yield, from phenylhydroxamoyl chloride.

Since this kind of reactions is obviously involved in the thermal 1,3-dipolar cycloaddition reactions,[1,4] we attempted the similar reactions with 5-nitro-2-furyl- (I), *p*-nitrophenyl- (II), and *m*-nitrophenylhydroxamoyl chloride (III) and we wish to report on some interesting results.

I was refluxed in ethanol with two equivalent amounts of methyl dithiocarbazinate to afford a product in 50% yield, the structure of which was, however, characterized from the elemental analysis and the NMR measurement as 2-(5′-nitro-2′-furyl)-5-methylmercapto-1,3,4-thiadiazole, IV, instead of the expected 2-substituted amino-1,3,4-thiadiazole, IV′. The NMR spectrum of IV in DMSO-d_6 manifested a chemical shift at 7.14 τ (singlet, 3 H, $-SCH_3$) besides those due to nitrofuran ring protons.[5] Similar treatment of II afforded, however, a mixture of VI and VII in 45 and 27% yields respectively. The structural elucidation of both compounds was done from their elemental analyses and NMR sepctra and VI was confirmed to be 2-(*p*-nitroanilino)-5-methylmercapto-1,3,4-thiadiazole and VII, to be 2-(*p*-nitrophenyl)-5-methylmercapto-1,3,4-thiadiazole. Similarly, a mixture of the corresponding *m*-nitro compounds, VIII and IX, was obtained from III in 45 and 20% yields respectively. Treatment of I with two equivalent amounts of thiosemicarbazide under the similar reaction conditions resulted in the formation of intractable tars only, but when semicarbazide was used in place of thiosemicarbazide, normal substitution reaction had occurred between a chlorine atom of I and an amino group of semicarbazide affording X in 50% yield; the similar substitution has been observed in the reaction of I with some amino- and hydrazino compounds.[6]

About the mechanism of the formation of IV from I, VI and VII from II, and VIII and IX from III, we would propose here two competitive reactions, a) and b): in a), simple substitution reaction, followed by elimination of hydroxylamine afforded IV, VII and IX respectively; on the contrary, in b), thermal 1,3-dipolar cycloaddition might take place at first between hydroxamoyl chloride and carbon-sulfur double bond as shown in the usual nitrile oxide reactions[7] and this assumption seems to be reasonable from our previous findings on the parallel

reactivity between thermal 1,3-dipolar cycloaddition of hydroxamoyl chloride and the corresponding nitrile oxide cycloaddition.[1,4] As is suggested by Huisgen,[7] the intermediate thioisocyanate XII, produced by decomposition of the adduct XI *via* route b), seems to react with an equivalent amount of methyl dithiocarbazinate to give VI and VIII, which is the known procedure for preparing 2-anilino-5-methylmercapto-1,3,4-thiadiazole.[3] Other examples of the thermal 1,3-dipolar cycloaddition of hydroxamoyl chlorides with compounds possessing carbon-sulfur double bond are under investigation. The reason why phenylhydroxamoyl chloride affords exclusively 2-substituted amino compound through b)[2] and 1, giving 2-substituted IV through a), while the corresponding *p*- (II), and *m*-nitrophenylhydroxamoyl chloride (III) gave a mixture of the products through a) and b) at the same time, is uncertain at the present stage.

Experimental

Reaction of 5-Nitro-2-furylhydroxamoyl Chloride (I). A solution of 0.95 g (5 mmol) of I[1] and 1.15 g (11 mmol) of methyl dithiocarbazinate[8] in 40 m*l* of ethanol was refluxed for 12 hr. After removal of ethanol, the residue was digested with 20 m*l* of a ethanol-water mixture (1: 1). The resulting crystals were collected and recrystallized from ethanol to give 0.6 g of IV as yellow crystals, mp 180—181°C. UV λ_{max}^{EtOH} mμ (ε); 356 (14500), 282 (6300).

Found: C, 34.02; H, 1.76; N, 16.92%. Calcd for $C_7H_6O_3N_4S_2$: C, 34.58; H, 2.07; N, 17.28%.

Reaction of *p*-Nitrophenylhydroxamoyl Chloride (II). A solution of 0.6 g (3 mmol) of II[1] and 0.75 g (6 mmol) of methyl dithiocarbazinate[8] in 20 m*l* of ethanol was refluxed for 10 hr. The resulting crystals were collected after cooling and extracted with hot chloroform. The insoluble part was recrystallized several times from pyridine-ethanol to afford 0.36 g of yellow needles, VI, mp 270—271°C. IR (KBr) cm^{-1}; 3310, 3250 νNH). UV λ_{max}^{EtOH} mμ (ε); 354 (22800). NMR (DMSO-d_6) τ; 6.5 (broad, 1 H, -NH-), 7.25 (singlet, 3 H, -SCH$_3$).

Found: C, 41.13; H, 2.74; N, 20.57%. Calcd for $C_9H_8O_2N_4S_2$: C, 40.62; H, 3.01; N, 20.89%.

From the chloroform solution, 0.2 g of VII as colorless plates, mp 222—223°C, were obtained after removing chloroform, followed by recrystallization from benzene-ethanol. IR (KBr) cm^{-1}; no νNH. UV λ_{max}^{EtOH} mμ (ε); 335 (16300), 254 (8500). NMR (DMSO-d_6) τ; 7.14 (singlet, 3 H, -SCH$_3$).

Found: C, 42.13; H, 2.46; N, 16.72%. Calcd for $C_9H_7O_2N_3S_2$: C, 42.68; H, 2.74; N, 16.59%.

Reaction of *m*-Nitrophenylhydroxamoyl Chloride (III). Similar treatment of III[1] and work-up as above afforded VIII as yellow crystals, mp 234—236°C, in 45% and IX as colorless crystals, mp 172—173°C, in 20% yield.

VIII: IR (KBr) cm^{-1}; 3310, 3260 (νNH). UV λ_{max}^{EtOH} mμ (ε); 350 (2600, shoulder), 300 (24200), 245 (13400). NMR (DMSO-d_6)τ; 6.5 (broad, 1 H, -NH-) 7.25 (singlet, 3 H, -SCH$_3$).

Found: C, 40.43; H, 2.64; N, 20.59%. Calcd for $C_9H_8O_2N_4S_2$: C, 40.62; H, 3.01; N, 20.89%.

IX: IR (KBr) cm^{-1}; no νNH. UV $\lambda_{max}^{CHCl_3}$ mμ (ε); 306 (16600), 273 (12000). NMR (DMSO-d_6) τ; 7.15 (singlet, 3 H, -SCH$_3$).

Found: C, 42.68; H, 2.51; N, 16.21%. Calcd for $C_9H_7O_2N_3S_2$: C, 42.68; H, 2.78; N, 16. 59%.

Reaction of I with Semicarbazide. A solution of 0.93 g (5 mmol) of I[1] and 0.75 g (10 mmol) of semicarbazide in 10 m*l* of ethanol was refluxed for 1 hr. The resulting crystals were collected after cooling, washed with a small amount of water and recrystallized from water-ethanol-DMF to afford 0.5 g (44%) of X as pale yellow crystals, mp 195—197°C (decomp). IR (KBr) cm^{-1}; 3500, 3250 (νNH), 1660 (νCO).

Found: C, 31.00; H, 2.84; N, 29.94%. Calcd for $C_6H_7O_5N_5$: C, 31.45; H, 3.08; N, 30.56%.

Studies on Heteroaromaticity. XIX.[1] Direct 1,3-Dipolar Cycloaddition of Hydroxamoyl Chlorides with Enamines

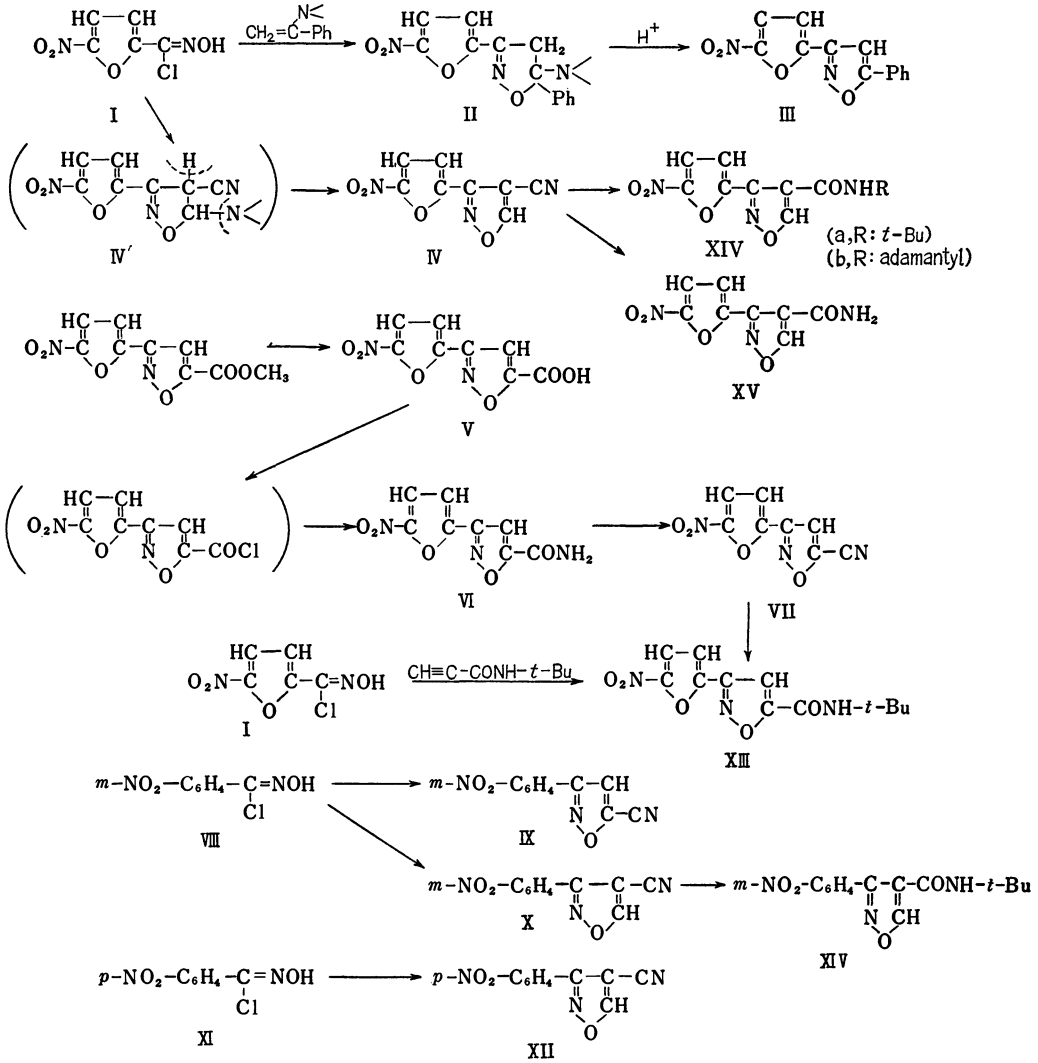
Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 26, 1968)

Minami and Matsumoto[2] have reported the 1,3-dipolar cycloaddition of 5-nitro-2-furonitrile oxide with a series of enamines, affording 1 : 1 adducts with a 5-amino-substituted isoxazoline structure and making for facile conversion to the corresponding isoxazoles by subsequent acid treatment. This paper will deal with our finding that the same products can be obtained directly from hydroxyamoyl chloride as from the corresponding nitrile oxide in better yields and by simpler procedures. Furthermore, we will report a novel one-step procedure for preparing isoxazole derivatives using enamines with

1) Part XVIII of this series: T. Sasaki and T. Yoshioka, This Bulletin, **41**, 2211 (1968).
2) S. Minami and J. Matsumoto, *Chem. Pharm. Bull. (Tokyo)*, **15**, 366 (1967).



a specific structure.

5-Nitro-2-furylhydroxamoyl chloride (I)[1] was treated with morpholino-1-phenylethylene in ether at room temperature to afford an adduct (1 : 1), II, in a 80% yield, though the same product was obtained from 5-nitro-2-furonitrile oxide[3] and the same enamine in but a 50% yield. This somewhat lower yield might be caused by the difficult solubility of the nitrile oxide in ether. From the fact that the acid hydrolysis of II supplied a known compound, 3-(5′-nitro-2′-furyl)-5-phenylisoxazole, III, with a mp of 209—210°C,[2] II was concluded to be 3-(5′-nitro-2′-furyl)-5-phenyl-5-morpholinoisoxazoline. When 1-morpholino-2-cyanoethylene[4] was used as a dipolarophilic enamine, one which has a strong electronegative cyano group instead of the electropositive alkyl or alicyclic group in general enamines such as the above-described 1-morpholino-1-phenylethylene, the product, IV, was proved to be 3-(5′-nitro-2′-furyl)-4-cyanoisoxazole as a result of the structural elucidation on the basis of the spectral data; the NMR spectrum in $CDCl_3$ manifested a chemical shift at 0.86 τ (singlet, 1 H, 5-C–H),[3] and the ultraviolet spectrum showed an absorption maximum at 309 mμ (ε=14100)[3] in ethanol.

It is noteworthy that IV has an isoxazole structure instead of the expected isoxazoline (IV′) structure after the spontaneous *cis*-elimination of a morpholine molecule from the latter,[5] presumably

3) T. Sasaki and T. Yoshioka, This Bulletin, **40**, 260 (1967).

4) T. Sasaki, unpublished data.

5) The NMR spectrum of 1-morpholino-2-cyanoethylene showed an AB-quartet about its olefinic protons. This compound was concluded to take a *trans*-configuration, considering that the coupling constant is 14 cps, causing a facile *cis*-elimination of a morpholine molecule. The same thing could be said about 1-pyrrolidino- and 1-piperidino-2-cyanoethylene.

by facile aromatization after removal of hydrogen cyanide on account of the strong tendency toward protonation of a hydrogen atom attached to a carbon bearing a cyano group. All attempts at the direct preparation of an isomer, VII, 3-(5'-nitro-2'-furyl)-5-cyanoisoxazole, were unsuccessful, whether the routine nitrile-oxide method or the direct treatment of I with cyanoacetylene was employed. This compound was finally prepared by the dehydration of 3-(5'-nitro-2'-furyl)-5-carbamidoisoxazole (VI); VI was prepared by the following sequence of reactions starting from a known 5-carbomethoxyisoxazole[3] →V→VI. VII was found to be hardly purified at all even by column chromatography; therefore, it was converted to the corresponding amide (XIII) by a Ritter reaction with *t*-butyl alcohol, which was compared with a product, XIV, derived from IV by the Ritter reaction. XIII and XIV showed similar ultraviolet spectral patterns, but they were quite different in their NMR spectra, as will be shown in the Experimental Section. IV was also prepared from 1-pyrrolidino-,[4,5] and 1-piperidino-2-cyanoethylene[4,5] under similar reaction conditions, indicating that this direct isoxazole-formation is a general characteristic of the above cyano-enamines. Similarly, *m*-nitrophenylhydroxazovl chloride (VIII) afforded the corresponding 5-cyano- (IX) and 4-cyanoisoxazole (X) by the reactions of the nitrile oxide with cyanoacetylene[6] and of VIII with 1-morpholino-2-cyanoethylene; IX and X were afforded in 30 and 70% yields respectively. On the other hand, from *p*-nitrophenylhydroxamoyl chloride (XI), only the 4-cyanoisoxazole (XII) could be isolated in a 80% yield by a reaction with 1-morpholino-2-cyanoethylene; X underwent a Ritter reaction to afford the corresponding amide (XIV). Acidic hydrolysis of the nitrile in IV was carried out and an almost quantitative yileld of the corresponding amide (XV) was obtained and its infrared spectrum was different from its 5-amide.[3]

Experimental[6]

Reaction of I with 1-Morpholino-1-phenylethylene. A solution of 0.95 g (5 mmol) of I[1] and 1.9 g (10 mmol) of 1-morpholino-1-phenylethylene[7] in 30 m*l* of dry ether was kept standing at room temperature for 1 month. The resulting crystals were collected and recrystallized three times from benzene to afford 1.5 g of II as pale yellow crystals, mp 215—216°C. UV λ_{max}^{EtOH} mμ (ε): 348 (13500), 253 (8600).

Found: C, 59.47; H, 4.88; N, 12.24%. Calcd for $C_{17}H_{17}O_5N_3$: C, 59.47; H, 4.99; N, 12.29%.

The nitrile oxide procedure[3] afforded II, but in only a 50% yield. With hydrochloric acid, II was readily converted to III[2] almost quantitatively.

Reaction of I with 1-Morpholino-2-cyanoethylene. A solution of 0.82 g (4.3 mmol) of I[1] and 1.3 g (10 mmol) of 1-morpholino-2-cyanoethylene[4] in 60 m*l* of dry ether was kept standing at room temperature for 1 month. After the ether had then been removed, the residual oil was digested with 30 m*l* of water; the resulting crystals were collected and recrystallized several times from ethanol to give 0.7 g (80%) of IV as pale yellow crystals, mp 130—132°C. IR (KBr) cm^{-1}: 2300 ($\nu_{C\equiv N}$).

Found: C, 46.90; H, 1.09; N, 20.32%. Cacld for $C_8H_3O_4N_3$: C, 46.87; H, 1.47; N, 20.49%.

The Ritter Reactions of IV. Into a solution of 0.15 g (0.8 mmol) of IV in 7 m*l* of *t*-butanol, there was stirred 0.7 m*l* of concentrated sulfuric acid at room temperature. An exothermic reaction occurred. After the reaction mixture had then been allowed to stand at room temperature for 1 day, it was poured into ice water and the resulting crystals were recrystallized from benzene - petroleum ether to give 0.15 g (70%) of XIVa, mp 169—171°C. IR (KBr) cm^{-1}: 3320 (ν_{NH}), 1665 (ν_{CO}). UV λ_{max}^{EtOH} mμ (ε): 319 (14000). NMR ($CDCl_3$) τ: 1.10 (singlet, 1 H, 5-C-H), 2.55 (singlet, 2 H, nitrofuran ring protons*[1]), 3.70 (broad, 1 H, NH), 8.51 (singlet, 9 H, t-Bu).

Found: C, 52.15; H, 4.79; N, 14.92%. Calcd for $C_{12}H_{13}O_5N_3$: C, 51.61; H, 4.69; N, 15.05%.

Similarly, from 0.22 g (1.1 mmol) of IV, 0.29 g (1.4 mmol) of adamantly bromide,[9] 10 m*l* of acetic acid and 1 m*l* of 98% sulfuric acid, 0.28 g (70%) of XIVb, mp 174—175°C, was obtined after purification by column chromatography*[2] and recrystallization from ethanol-petroleum ether. IR (KBr) cm^{-1}: 3410, 3380 (ν_{NH}), 1665 (ν_{CO}). UV λ_{max}^{MeOH} mμ (ε): 318 (8700).

Found: C, 60.28; H, 5.60; N, 11.05%. Calcd for $C_{18}H_{21}O_5N_3$: C, 60.16; H, 5.89; N, 11.69%.

Acidic Hydrolysis of IV. IV, 0.32 g (1.5 mmol), was dissolved in 4 m*l* of 98% sulfuric acid and this solution was kept standing at room temperature for 1 day and poured into ice water. The resulting crystals were collected and recrystallized from ethanol to give 0.31 g (95%) of XV, mp 271—272°C. IR (KBr) cm^{-1}: 3450, 3360, 3300 (ν_{NH}), 1690 (ν_{CO}). UV λ_{max}^{MeOH} mμ (ε): 315 (12700).

Found: C, 43.03; H, 2.30; N, 18.65%. Calcd for $C_7H_5O_5N_3$: C, 43.06; H, 2.26; N, 18.83%.

---

6) Melting points are uncorrected. The ultraviolet absorption spectra were recorded on a Nippon-Bunko optical rotary dispersion recorder, Model ORD/UV-5. The infrared spectra were obtained with a Nippon-Bunko IR-S spectrophotometer. Microanalyses were carried out with a Yanagimoto C. H. N. Corder MT-1 type. The NMR spectra were determined with a Varian A-60 spectrometer, using tetramethylsilane as the internal standard. The chemical shifts are recorded in τ-values.

8) S. Murahashi, S. Kurioka and S. Maikawa, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **77**, 1689 (1956).

*1 This is the first example of the appearance of a singlet of two nitrofuran-ring protons in 2,5-disubstituted furan derivatives. The reason is uncertain at present.

9) T. Sasaki, S. Eguchi and T. Toru, This Bulletin, **41**, 236 (1968).

*2 XIVb was obtained from the second fraction by silica-gel (Mallinckrodt, 100 mesh) chromatography, using chloroform as an eluent. From the third fraction, there was obtained 30 mg (10%) of 3-(5'-nitro-2'-furyl)-isoxazole-4-carbamide, mp 265—257°C, which was identical with XV.

Preparation of an Isomer, XIII. 3-(5′-Nitro-2′-furyl)-5-carbomethoxyisoxazole[3] was quantitatively hydrolyzed with hydrochloric acid to the corresponding acid, V (mp 222°C). IR (KBr) cm^{-1}: 1685 (ν_{CO}).

Found: C, 42.81; H, 1.63; N, 12.52%. Calcd for $C_8H_4O_6N_2$: C, 42.87; H, 1.80; N, 12.50%.

V was treated with thionyl chloride by the routine procedure to afford the corresponding acid chloride, which, without further purification, was then dissolved in benzene. Ammonia gas was introduced into this solution to give VI (mp 246—247°C) in a 92% yield.

Found: C, 43.16; H, 1.88; N, 19.25%. Calcd for $C_8H_5O_5N_3$: C, 43.06; H, 2.26; N, 18.83%.

VI was treated with thionyl chloride or phosphorus pentachloride, and the crude nitrile (its existence was demonstrated by the presence of the 2300 cm^{-1} absorption due to $\nu_{C\equiv N}$ in the IR spectrum) was treated with *t*-butanol in concentrated sulfuric acid, as has been described above, to afford XIII, which was also prepared in a 34% yield from the thermal 1,3-dipolar cycloaddition reaction of I with *N*-*t*-butylpropiolamide.[10] Mp 214—215°C. UV λ_{max}^{EtOH} mμ (ε): 318 (14000). NMR ($CDCl_3$) τ: 2.79 (singlet, 1 H, 4-C–H), 2.60 and 2.87 (each doublet, 1 H, J=3.8 cps, nitrofuran-ring protons), 3.50 (broad, 1 H, NH), 8.50 (singlet, 9 H, *t*-Bu).

Found: C, 51.87; H, 4.70; N, 15.00%. Calcd for $C_{12}H_{13}O_5N_3$: C, 51.61; H, 4.79; N, 15.05%.

3-(*m*-Nitrophenyl)-5-cyanoisoxazole (IX). VIII (0.61 g; 3.0 mmol) was dissolved in 100 m*l* of ether, and into this solution there was stirred an equivalent amount of 1% aqueous sodium hydroxide at room temperature. After 2 min, an ether layer was separated and dried; a solution of 0.3 g (3.0 mmol) of cyanoacetylene[8] was then added. The reaction mixture was kept standing at room temperature for 1 day, and then the residue, obtained after the removal of the ether, was chromatographed on a silica-gel column. From the second fraction there was obtained 0.20 g (30%) of IX, mp 122—123°C from ethanol. IR (KBr) cm^{-1}: 2300 (ν_{CN}). UV λ_{max}^{EtOH} mμ (ε): 248 (13200). NMR ($CDCl_3$) τ: 2.62 (singlet, 1 H, 4-C–H).

Found: C, 55.58; H, 2.01; N, 19.47%. Calcd for $C_{10}H_5O_3N_3$: C, 55.82; H, 2.34; N, 19.53%.

3-(*m*-Nitrophenyl)-4-cyanoisoxazole (X). VIII (0.61 g; 3.0 mmol) and 0.91 g (6.6 mmol) of 1-morpholino-2-cyanoethylene[4] were dissolved in 40 m*l* of ether, and then the reaction mixture was kept standing at room temperature for 1 month. The resulting crystals were recrystallized from ethanol to give 0.52 g (80%) of X, mp 101—103°C. IR (KBr) cm^{-1}: 2300 (ν_{CN}). UV λ_{max}^{EtOH} mμ (ε): 247 (13000). NMR ($CDCl_3$) τ: 0.82 (singlet, 1 H, 5-C–H).

Found: C, 55.99; H, 1.91; N, 19.53%. Calcd for $C_{10}H_5O_3N_3$: C, 55.82; H, 2.34; N, 19.53%.

The Ritter Reaction of X. X (0.2 g; 1 mmol) was dissolved in a mixture of 5 m*l* of *t*-butanol and 1 m*l* of concentrated sulfuric acid. The mixture was kept standing at room temperature for 6 days. It was poured into ice water and the resulting crystals were recrystallized from ethanol - petroleum ether to give 0.21 g (75%) of XIV, mp 141—143°C. IR (KBr) cm^{-1}: 3290 (ν_{NH}), 1650 (ν_{CO}). UV λ_{max}^{MeOH} mμ (ε): 252 (12600).

Found: C, 58.37; H, 5.21; N, 14.39%. Calcd for $C_{14}H_{15}O_4N_3$: C, 58.12; H, 5.23; N, 14.53%.

3-(*p*-Nitrophenyl)-4-cyanoisoxazole (XII). Much as above, XII was prepared from XI and 1-morpholino-2-cyanoethylene[4] in a 80% yield. Mp 165—167°C, from ethanol. IR (KBr) cm^{-1}: 2300 (ν_{CN}). UV λ_{max}^{EtOH} mμ (ε): 265 (14700). NMR ($CDCl_3$) τ: 0.87 (singlet, 1 H, 5-C–H).

Found: C, 55.63; H, 1.84; N, 20.00%. Calcd for $C_{10}H_5O_3N_3$: C, 55.82; H, 2.34; N, 19.53%.

Studies on Heteroaromaticity. XXII.[1] Bromination of 6-Substituted Uracils with NBS

Tadashi SASAKI and Moriyasu ANDO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 9, 1968)

N-bromosuccimide (NBS) is known to effect the side-chain bromination of aromatic hydrocarbons[2] and of 3-methylthiophene[3] and the allylic bromination.[4] Nishiwaki and Goto[5] have reported that 6-methyl- (Ia), 2-mercapto-6-methyl- and 2-amino-6-methyluracil are brominated with NBS in the presence of benzoyl peroxide (BPO) to afford the corresponding brominated products at the 5-position of a pyrimidine ring and from this fact, they have disclosed that the reactions proceed *via* an ionic mechanism by the electrophilic attacks of NBS at the 5-position, since the yields did not change even in the absence of BPO. However, the yield of the produced 5-bromo-6-methyluracil (IIa), for instance, is as low as 45%. We presumed that this

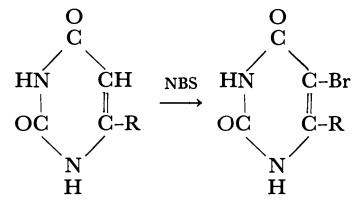
result is due to the poor solubility of Ia in carbon tetrachloride used as the solvent, though this solvent is commonly used in this type of reactions.[6] We changed the solvent from this non-polar carbon tetrachloride to polar ethanol, in which the solubility of uracil derivatives is larger than that in carbon tetrachloride. This increased solubility might favor the ionic reactions and as a result, the yield of IIa could be improved up to 85%. This note deals with the results of the similar procedure applied to other 6-substituted uracils. The structural elucidation of the products was done by the NMR spectra, since Nishiwaki and Goto[5] have demonstrated the site of the bromine atom to be at the 5-position by its characteristic reactivity[7] and by the chemical conversion to the known compounds. The NMR spectrum of IIa in DMSO-d_6, as an example, showed the presence of methyl protons and the absence of a C-5 proton, indicating IIa to be 5-bromo-6-methyluracil. The bromination is expected to proceed more readily as the electron-density at the 5-position of a pyrimidine ring increases by the stronger electron-donating nature of a 6-substituent R. Uracil[8] (Ib, R=H), 6-uracil acetate[9] (Ic, R=CH_2COOEt), orotaldehyde[10] (Id, R=CHO), and orotate[11] (Ie, R=COOEt) were treated with NBS and the considerable yields of the corresponding 5-



I a (R=CH_3) II a (R=CH_3)
b (R=H) b (R=H)
c (R=CH_2COOEt) c (R=CH_2COOEt)
d (R=CHO) d (R=$CH(OEt)_2$)
e (R=COOEt) e (R=COOEt)

bromo compounds were obtained, except the case when the bromination of Id afforded IId. The structure of IId was found to be the diethylacetal instead of the expected 5-bromoorotaldehyde from the elemental analysis and the spectral data; the NMR spectrum in DMSO-d_6 exhibited the chemical shifts at $-1.53\ \tau$ (s, -NH, disappeared on deuteration), -0.78 (s, -NH, disappeared on deuteration), 4.50 (s), 6.36 (q, J=6.8 cps) and 8.22 (t, J=6.8 cps) in the proton ratio of 1 : 1 : 1 : 4 : 6, among which a signal at $4.50\ \tau$ is assignable either to an acetal proton[12] or to a C-5 proton[13] and therefore, the ultraviolet spectrum was inspected. As shown in Table 2, an absorption maximum is

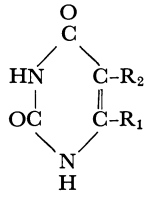
13) NMR of Ia (DMSO-d_6) τ: -0.85 (broad s, -NH, disappeared on deuteration), 4.65 (s, C-5-H), 7.95 (s, $-CH_3$).
It should be noted here that a broad signal due to NH protons was split into two sharp signals after bromination.

TABLE 2. UV ABSORPTION OF 6-SUBSTITUTED URACILS AND THEIR 5-BROMO DERIVATIVES



R_1	R_2=H		R_2=Br	
	λ_{max}^{MeOH} mμ	log ε	λ_{max}^{MeOH} mμ	log ε
H	258	3.80	270	3.90
CH_3	259	4.02	273	3.96
COOEt	286	3.87	290	3.82
CH_2COOEt	260	4.02	278	3.94
$CH(OEt)_2$*	260	3.90	278	3.93

* T. Sasaki, unpublished data.

located at 278 mμ, which is shifted 18 mμ bathochromically from that of 5-unsubstituted orotaldehyde diethylacetal and this is in good accordance with the general trend of other products as manifested in this table. From these facts, IId was concluded to be 5-bromoorotaldehyde diethylacetal. It should be mentioned as a conclusion that the yields decreased in the following sequence as the electron-donating nature decreased:

$$R = CH_3 \geq H \geq CH_2COOEt > CH(OEt)_2 > COOEt$$

Experimental[14]

5-Bromo-6-methyluracil (IIa). 0.6 g of 6-methyluracil (Ia)[13] and 1 g of NBS were suspended in 50 m*l* of ethanol and the reaction mixture was stirred at 55°C for 12 hr after addition of a catalytic amount of BPO. After the suspension dissolved, precipitation occurred again. Precipitated crystals were collected and recrystallized from ethanol. NMR (DMSO-d_6) τ: -1.40 (s, NH[13]), -1.28 (s, NH[13]), 7.80 (s, CH_3).

The above reaction without BPO afforded the same product in almost the same yield.

The yields, melting points and elemental analyses are summarized in Table 1 and the data on the ultraviolet analyses are summarized in Table 2, with those of other products.

14) The melting points were measured on a micro hot stage and were not corrected. The microanalyses were carried out with a Yanagimoto C. H. N. Corder, Model MT-1. The ultraviolet spectra were measured on a Nippon-Bunko optical rotary dispersion recorder, Model ORD/UV-5. The NMR spectra were taken on a Varian A-60 spectrometer, using tetramethylsilane as an internal standard and the chemical shifts are presented in terms of τ-values; where singlet is designated as s, doublet as d, triplet as t, quartet as q and multiplet as m.

SHORT COMMUNICATIONS

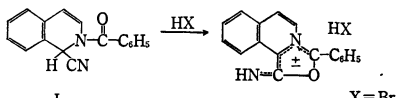
The Preparation of Mesoionic 5-Imino-3,5-dihydro-1,3-oxazole Derivatives

Shigeru SATO, Toshiyasu MASE*1 and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

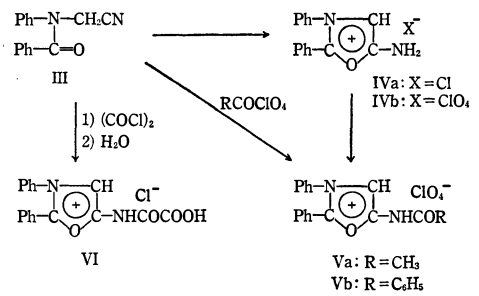
(Received May 30, 1968)

Of the mesoionic oxazoles with an exo-imino group, only fused ring compounds called Reissert-imine salts (II), have isolated and characterized as intermediates in the acid hydrolysis of Reissert compounds (I).[1,2]



I II X=Br X=ClO4

However, in the case of the acid hydrolysis of *N*-benzoylanilinoacetonitrile (III), the intermediacy of the mesoionic compound (IV) seemed to be unlikely, since III, in contrast with I, underwent normal hydrolysis to benzoic acid instead of to benzaldehyde.[3]



IVa: X=Cl IVb: X=ClO4

VI Va: R=CH3 Vb: R=C6H5

We wish to report here the successful preparation of IV (a and b) and exo-*N*-acyl derivatives (Va and Vb) from III.

Hydrogen chloride was introduced into a solution of III in methylene chloride until the saturation point had been reached. By adding ether to the resulting solution, 5-imino-2,3-diphenyl-3,5-dihydro-1,3-oxazole hydrochloride (IVa), mp 130—135°C (decomp.)[4] was separated out in an almost quantitative yield. The treatment of IVa with silver perchlorate in chloroform gave the hydroperchlorate (IVb), mp 200—202°C (decomp.). IVb was acetylated with acetic anhydride to give the exo-*N*-acetyl derivative (Va) in a 90% yield. Va was also obtained in an almost quantitative yield by the treatment of III with acetyl perchlorate in benzene. The *N*-benzoyl derivative of IV (Vb), mp 215—220°C (decomp.), was formed similarly in a 65% yield by the treatment of III with benzoyl perchlorate. The treatment of III with oxalyl chloride, followed by hydrolysis with water, gave VI, mp 180—185°C (decomp.).

The details of the present investigation will be present in a subsequent paper.

The Photoreaction of β-Acyl- and β-Aroyl-acrylic Acids

Noboru SUGIYAMA, Hiroshi KATAOKA and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

and Kazutoshi YAMADA

Departmet of Synthetic Chemistry, Chiba University, Yayoi-cho, Chiba

(Received June 4, 1968)

During the course of an investigation of the reaction of β-acyl- and β-aroyl-acrylic acids,[1,2] we have found that the methanol adduct, β-benzoyl-α-methoxypropionic acid (1d),[3] and *cis*-β-benzoylacrylic acid (1b) were obtained from *trans*-β-benzoylacrylic acid (1a) by irradiation in methanol.*1 We have studied the photoreaction of 1a in various solvents as well as the analogous photoreactions of β-acyl- and β-aroyl-acrylic acids and their esters (2a—8a).

Following three types of reaction were observed in the photoreaction listed in Table 1. a→b: *trans* to *cis* isomerization. a→c: isomerization to angelica lactones. a→d: alcohol addition to the olefinic double bond.

These reactions occurred complicatedly. For example, compound 1a in ether exclusively afforded the *cis*-isomer 1b, whereas that in methanol gave two products, the *cis*-isomer 1b and methanol adduct 1d. On the other hand, the irradiation of the methanol solution of 3a gave rise to both 3c and 3d. A methanol solution of 6a and 8a produced only the angelica lactone type compounds 6c and 8c. The details of these photoreactions will be reported elsewhere.

The d-d Bands of Hexachloroferrate(III) Ion

Hideo YAMATERA and Akemi KATO

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received June 13. 1968)

Spectra of finely powdered solid samples of hexacoordinated iron(III) chloride complexes were obtained in the visible and near infrared region with a Carl Zeiss PMQII spectrophotometer equipped with the reflectance attachment RA3.

The spectrum of $(NH_4)_4[FeCl_6][SbCl_6]$, which is representative of hexachloroferrate(III) spectra, is shown in Fig. 1. The bands associated with $[FeCl_6]^{3-}$ can easily be distinguished from those due to NH_4^+ vibrations by comparing the spectrum with that of $(NH_4)_2SnCl_6$, which is essentially isomorphous with $(NH_4)_4[FeCl_6][SbCl_6]$. The band at 12800 cm^{-1} corresponds to the first (lowest in wave number) band so far observed,[1-3] and the band at 8900 cm^{-1} has not been reported.

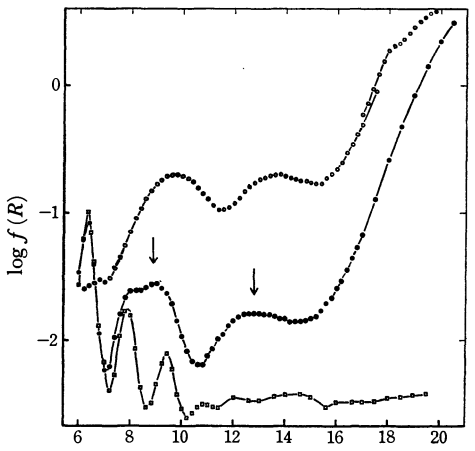

Fig. 1. Spectra* of $(NH_4)_4[FeCl_6][SbCl_6]$ (-●-), $Cs_3Fe_2Cl_9$ (-○-) and $(NH_4)_2[SnCl_6]$ (-□-).

The bands at 8900 cm^{-1} and 12800 cm^{-1} are assigned to the $^6A_{1g}\rightarrow{}^4T_{1g}(G)$ and $^6A_{1g}\rightarrow{}^4T_{2g}(G)$ transitions, respectively. With this assignment, a narrow band due to the $^6A_{1g}\rightarrow{}^4A_{1g}$, $^4E_g(G)$ transitions is expected to appear near 18000 cm^{-1}. Closer examination of the spectrum in this region disclosed a slight but discernible rise at about 18000 cm^{-1} on the slope of the intense charge transfer band. Moreover, the spectrum of $Cs_3Fe_2Cl_9$, which also contains $FeCl_6$ chromophores, clearly showed a shoulder at 17900 cm^{-1}, in addition to the two bands at 9800 cm^{-1} and 13600 cm^{-1}.

This assignment unfortunately disagrees with the assignment given by Hatfield *et al.*,[2] but it gives more reasonable values for the ligand field and interelectronic repulsion parameters: $\Delta=$ 11100 cm^{-1} and $B=605$ cm^{-1} (with the assumption $C=4B$). Jørgensen's estimation[4] of his spectrochemical and nephelauxetic functions, $f=$ 0.80 and $h=2.0$ for Cl^- and $g=1.4$kK and $k_{35}=$ 0.24 for Fe(III), leads to a prediction of $\Delta=$ 11200 cm^{-1} and $B=572$ cm^{-1}, if B for the free Fe^{3+} is assumed to be 1100 cm^{-1} by interpolation. Our result compares well with this prediction.

Full results and detailed discussions will be given elsewhere.

* $f(R)$ $[=(1-R)^2/2R$, where R represents the reflecting power] is nearly proportional to the absorption coefficient for finely powdered weakly absorbing substances. [See, for example, G. Kortüm and H. Schöttler, *Z. Electrochem.*, **57**, 253 (1953).]

Ionic Processes in the Radiolysis of Nitrous Oxide

Satoshi TAKAO, Shoji SHIDA, Yoshihiko HATANO and Hideo YAMAZAKI

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received June 14, 1968)

Although many studies have been made of the gas-phase radiolysis of nitrous oxide,[1] almost nothing definite has yet been established about its mechanism. In the present study SF_6 and CO_2 were used as electron scavengers, and various rare gases, as electron suppliers.

The irradiations were done with ^{60}Co-γ rays at 25°C to a total dose of 7.2×10^{20} eV·g^{-1}. The products, N_2 and O_2, were analyzed by gas chromatography, and the amounts of NO were calculated stoichiometrically.

The observed G-values of the products of the radiolysis of pure N_2O at 50—400 mmHg were $G(N_2)=10.1$, $G(O_2)=3.8$, and $G(NO)=5.1$, independent of the pressure. On the addition of only 0.01% SF_6 to the N_2O at 200 mmHg, these G-values all decreased rapidly, they then remained constant on the further addition of up to at least 0.3%. The decreases were $-\Delta G(N_2)=2.1$, $-\Delta G(O_2)=0.6$ and $-\Delta G(NO)=1.8$; accordingly, $-\Delta G(N_2O)=3.0$. The experiments with CO_2 gave similar results, except for a much slower leveling off of the G-values.

When increasing amounts (up to 600 mmHg) of rare gases were added to N_2O of a constant pressure of 60 mmHg, the amounts of N_2, O_2, and NO, all increased linearly in the case of He and Ne, while in the case of Ar, Kr, and Xe, although N_2 and O_2 increased linearly, NO did not appreciably increase at all. The increases in the G-values of the product by sensitization, G_{sens}, based on the energy absorbed by the rare gases, are shown in Table 1.

TABLE 1. G_{sens} FOR VARIOUS RARE GASES

	G_{sens}				
	He	Ne	Ar	Kr	Xe
N_2	7.3	6.3	3.0	2.9	3.8
O_2	2.8	2.4	1.5	1.6	1.8
NO	3.0	3.2	~0.0	~0.5	~0.5

If it is assumed that all electrons are scavenged by SF_6, and that SF_6^- does not contribute in any way to the decomposition of N_2O, one may infer from the above $-\Delta G$-values and with $W(N_2O)=33.0$ eV that one electron produced by the ionization of N_2O decomposes just one molecule of N_2O and yields 0.7 molecule of N_2. In the rare-gas experiments, the charge transfer from Xe^+ to N_2O is energetically impossible, and that from Kr^+ and Ar^+ appears not to occur either in spite of their higher ionization potentials than that of N_2O (12.9 eV), for their G_{sens} values are rather similar to those of Xe. As may be seen from the G_{sens} values, one excess (excess with respect to the positive ion produced by the ionization of N_2O) electron from these three rare gases, either as itself or through neutralization, decomposes one or less molecule of N_2O and yields one or less molecule of N_2. In the cases of He and Ne, the G_{sens} are remarkably higher than those for the other rare gases, and the ionization of N_2O by charge transfer and excitation transfer surely occurs. The fact that the formation of NO is not appreciably sensitized by Xe, Kr, and Ar indicates that N_2O^+ is necessary for the formation of NO. The results obtained here can not be accounted for by the often-assumed mechanism[2];

$$e^- + N_2O \rightarrow N_2 + O^-$$

$$O^- + N_2O \rightarrow N_2 + O_2^- \text{ and } NO + NO^-$$

because, according to this mechanism, more than one molecule of N_2 should be produced per electron. In order to explain the observed fact that one electron produces one or less molecule of N_2, one must assume the long-lived N_2O^- suggested by Freeman.[3] Recently Warman[4] has also obtained evidence for the initial formation of N_2O^- upon electron capture by N_2O. Thus, the major reaction may be tentatively described as follows:

$$e^- + N_2O \xrightarrow{M} N_2O^-$$

$$N_2O^- + N_2O^+ \rightarrow N_2 + O + N_2O$$

$$\text{and } N + NO + N_2O$$

followed by the combination of O and N to form O_2 and NO through NO_2. For the final conclusion to be attained, however, more supporting evidences are required.

Glass Transition in Dehydrated Amorphous Solid

Natsuo ONODERA, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 17, 1968)

Glass is considered as a kind of rigid, non-crystalline material. Usually glass is obtained by supercooling of liquid and therefore this condition is invariably adopted in its numerous definitions.

Non-crystalline solids can be, however, prepared by other unusual methods.[1] Dehydration process of some hydrated crystals also yields amorphous anhydrides.[2] Then a question arises as to whether these non-crystalline solids can be called glasses or not. One approach to this problem is to find out glass transition phenomena in these amorphous materials. This phenomenon is always accompanied with usual glass and characterizes boundary between glassy and supercooled liquid states.

Magnesium acetate tetrahydrate was dehydrated in solid state under vacuum (10^{-3} mmHg). The anhydride is known to give only one broad band in the low angle range of its X-ray diffraction pattern indicating an amorphous material, which transforms spontaneously into crystalline anhydride at about 250°C on heating.[3] About 20 mg of the anhydride was packed into an aluminum pan and mounted on sample holder of Perkin-Elmer DSC-1B scanning calorimeter. In order to keep a constant condition, sample was first heated up to 500°K, kept for a short time, and finally quenched to 400°K. Measurements were then carried out with heating rates between 1.25 and 80 deg·min^{-1}. The results are shown in Fig. 1.

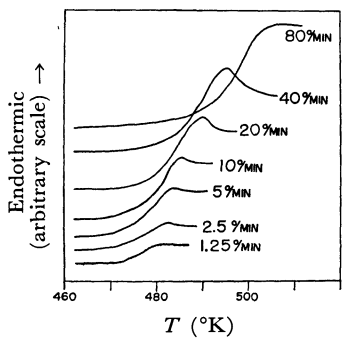

Fig. 1. DSC curve for the glass transition of magnesium acetate.

An endothermic anomaly always appears just before an exothermic effect due to crystallization. The shape and the temperature of the anomaly strongly depend on the heating rate employed. These results clearly show that the anomaly is due to glass transition phenomenon of the amorphous anhydride. Activation plot of the type developed by McMillan[4] is given in Fig. 2. From the slope of the bestfit straight line, apparent enthalpy of activation governing relaxation process becomes 131 ± 5 kcal·mol^{-1}.

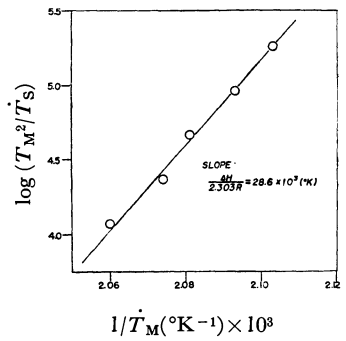

Fig. 2. Activation plot for the glass transition of magnesium acetate (T_M, inflection point; $\dot{T}_S$, heating rate).

We have discovered the first example of the non-crystalline solid prepared by dehydration exhibiting a glass transition phenomenon. This fact coincides with our previous observations[5] that the non-crystalline solid deposited on the chilled substrate from vapor state shows the same phenomenon. These observations lead to the conclusion that amorphous solids prepared by unusual methods other than supercooling of liquid can be firmly regarded as glasses. The details of the results will be given in due course.

Auto-correlation Function of the Maximum Wave Current in Polarography

Shizuo FUJIWARA, Yoshio UMEZAWA and Teruhiko KUGO*1

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 25, 1968)

Antweiler first reported noise-like fluctuations in the 1st kind maximum wave current of a polarographic *i-t* curve.[1] In connection with our series of investigations of the maximum wave current in polarography, we have recently obtained an auto-correlation function for these noise-like fluctuations with the use of a digitalized polarograph, where the mercury drop, voltage sweep and data sampling are synchronized.

The polarographic current of a drop of mercury at a constant voltage, *i. e.*, the *i-t* curve, is recorded automatically with the use of a digital computer (JEOL RA-5).

It is observed that the *i-t* curves are very smooth for the ordinary diffusion current, whereas, very noisy in the region of the maximum wave current. Fig. 1 a shows a typical example for a system of 2.5 mM copper(II) sulfate as depolarizer and 0.1 M potassium chloride as supporting electrolyte.

The result of analysis of the auto-correlation function for the noise-like current in Fig. 1a-(i) is as shown in Fig. 1b. The Fourier components of the auto-correlation function are shown in Fig. 1c. The 1st largest peak of the power spectrum of Fig. 1c refers to the direct current component, and the 4th peak refers to that of about 17 Hz. Accordingly, there exists a dominant hidden periodicity in the noise-like fluctuations in Fig. 1a-(i).

The details of the instrumentation and of the discussion of the results will be published in this journal. Further investigation is in progress.

Novel Isomers of the *trans*-(O–CN)-Cyanoaminoacidatodiethylenetriamine Cobalt(III) Complex Ion

Kuwako OHKAWA,*1 Shigenobu YANO and Junnosuke FUJITA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received June 26, 1968)

Recently we prepared many complexes containing the *trans*-(O–X)-[Co·X·am·dien]$^+$ type ions, (X=CN^-, Cl^-, NO_2^-, am=α-aminoacidato ion and dien=$NH_2CH_2CH_2NHCH_2CH_2NH_2$), and confirmed the geometrical structure of these ions from an analysis of their ultraviolet absorption spectra.[1] In these new complex ions, dien occupies the cis-trans (mer) position, and their NMR spectra (60 Mc) give the methylene signal of meridional dien ring in the same region as reported before.[2]

As Fig. 1-a shows, however, the NMR spectrum

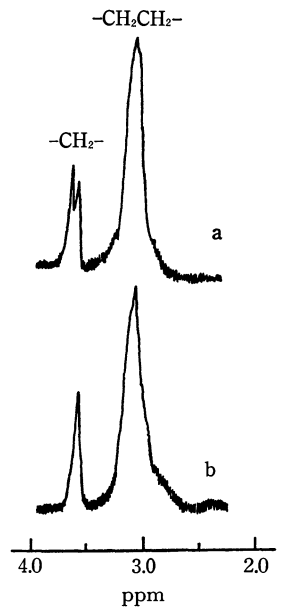

Fig. 1. The NMR spectra (60 Mc) of *trans*-(O–CN)-[Co(CN)gly·dien]$^+$ in D_2O.
a) Sample prepared from [Co(CN)$(SO_3)(NH_3)_4$]
b) Sample prepared from *trans*-(O–Cl)-[Co·Cl·gly·dien]$^+$
NaTMS was used as an internal reference.

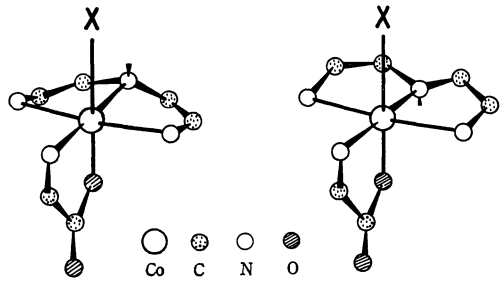

Fig. 2. Two isomers of *trans*-(O–X)-[Co·X·gly·dien]$^+$.

of the *trans*-(O–CN)-[Co(CN)gly·dien]$^+$ ion (gly=glycine), which was prepared from [Co(CN)$(SO_3)(NH_3)_4$] *via* Co(CN)dien$(OH_2)Br_2$, shows two kinds of methylene signal due to glycine ring at 210.5 and 213.5 cps. On the other hand, the corresponding chloro or nitro complex exhibits only one methylene signal at 216.3 and 213.4 cps, respectively. Such a difference was also observed in L-alaninate and α-aminoisobutyrate complexes.

The appearance of the two kinds of methylene signal in the cyanoglycinato complex would be due to existence of the two isomers shown in Fig. 2, or to any other reason coming from the coordination of CN^-. The latter reason, however, will be ruled out by the evidence that another sample of *trans*-(O–CN)-[Co(CN)gly·dien]$^+$, derived from the corresponding chloro complex by reaction of CN^- in DMSO, exhibits the same absorption spectrum with that prepared from [Co(CN)$(SO_3)(NH_3)_4$], but its NMR gives only one methylene signal (Fig. 1-b). This singlet signal coincides with one of the two signals mentioned above to support the existence of such an isomerism.

This isomerism would be attributed to the coordination of CN^- on either of the non-equivalent sides of the N_4 plane involving the puckered rings of dien. Hence such an isomerism cannot be substantiated in such complexes as [Co$(NO_2)_3$-dien],[3] in which both sides of the N_4 plane are occupied by two NO_2^- ions.

ESR Spectrum of Tropone Anion Radical

Yusaku IKEGAMI and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received July 4, 1968)

Tropone is a particularly interesting compound in which to compare experimentally and theoretically estimated pi-electron densities because it is a peculiar conjugate ring system. The Hückel MO treatment for tropone molecule results in that the unpaired electron in its anion radical does not distribute to the carbonyl group.[1] This fact is likely related to the instability of the anion radical. Treatment of tropone, for example, with alkali metal in degassed tetrahydrofuran or dimethoxyethane displays the immediate color change into reddish-violet solution, but it does not show any ESR signal. This paper reports the ESR spectrum of tropone anion radical prepared with the electrolytic technique, which have proven a valuable tool for the preparation of radical ions for ESR study.[2]

Tropone was thoroughly purified by distillation in a high-vaccum apparatus. The electrochemical reduction of the solution in degassed *N,N*-dimethylformamide (DMF) presented the spectrum shown in Fig. 1. Tetra-*n*-propylammonium perchlorate was used as the supporting electrolyte. The radical is not so stable that the signal strength decreased to one half during 15 min at room temperature after the current was shut off.

Hyperfine structure of the spectrum is analyzed with three splitting constants, which are reasonably assigned in consideration of the calculated spin densities, as given in Table 1. The calculations of unpaired spin densities (ρ_i^π) for tropone anion radical were carried out by Hückel and McLachlan's methods[3] on some cases changed Coulomb integral parameter (α_O) at oxygen atom and resonance integral parameter ($\beta_{C=O}$) of C=O bond. We neglected all other bond length variations. The parameters given for the carbonyl group do not affect so much on the spin densities of carbon atoms at 2-, 4-, 5- and 7-positions. A good results is shown in Table 1 in which the parameters, $\alpha_O=\alpha+1.8\,\beta$ and $\beta_{C=O}=1.4\,\beta$, were applied for the calculation.

TABLE 1. OBSERVED SPLITTING CONSTANTS AND CALCULATED SPIN DENSITIES FOR TROPONE ANION RADICAL

Isomerization Reactions of Dideuteroethylene and *cis*-2-Butene Photosensitized by $Zn(^3P_1)$

Shun-ichi HIROKAMI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 28, 1968)

Unimolecular isomerizations of monoolefins have extensively been used for the study of the photosensitizations in which the energies transferred from photosensitizers to reactants are less than the dissociation energies of any hydrocarbon bond.[1-4] More than twenty years ago, for instance, Steacie and his collaborators showed that excited zinc atoms were capable of sensitizing the reaction of ethylene.[5] Since then, however, no paper has appeared on zinc-photosensitization except a short note.[6]

A zinc lamp emits two resonance lines, one at 3076 Å, the other at 2139 Å. The latter is easily filtered out with a glass filter such as UV29 supplied by the Toshiba Denki Co. The lifetime of $Zn(^3P_1)$ has been reported to be 2×10^{-5} sec.[7] The energy transferred from $Zn(^3P_1)$ is 93.0 kcal, which is in between the values with $Cd(^3P_1)$ and $Hg(^3P_1)$.

Using the detecting method previously reported,[2] we examined the reaction of *trans*-dideuteroethylene photosensitized by $Zn(^3P_1)$ over the temperature range from 320 to 350°C in the expectation that the reactions could be explained by a mechanism similar to that of the photosensitization by $Cd(^3P_1)$.[3] However, unexpected results were obtained. The main reaction observed was *cis-trans* isomerization, the quantum yield of which increased with an increase in the pressure of the reactant, reaching more than twenty at the pressure of 40 mmHg. On the other hand, the isomerization to 1,1-dideuteroethylene, which is one of the main reactions in the Cd-photosensitization at low pressures,[3] was observed to occur very slowly.

With *cis*-2-butene as a reactant, slow *cis-trans* isomerizations were observed to occur both with and without the irradiation of the zinc resonance line at 3076 Å. The reaction with the irradiation was much slower than that of ethylene. When a small amount of acetylene was added to this system, however, the dark reaction was inhibited and the reaction photosensitized by $Zn(^3P_1)$ was much enhanced. The results are shown in Fig. 1.

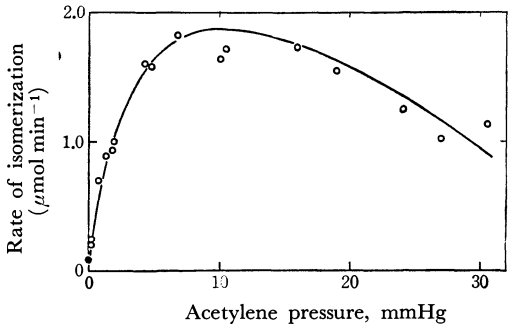

Fig. 1. Rate of the isomerization from *cis* to *trans*-2-butene photosensitized by $Zn(^3P_1)$ as a function of the pressure of acetylene added. (Initial pressure of *cis*-2-butene is 10 mmHg. Irradiation time is 2 min)

These results obviously show that excited zinc atoms react with ethylene or acetylene to produce catalyzers for the *cis-trans* isomerization of olefins. These catalyzers must be short-lived, because the isomerizations do not proceed after the termination of the irradiation. The mechanism of these reactions and the nature of the catalyzer are now being investigated.

Kinetic Studies of the Catalytic Ortho-Parahydrogen Conversion and Hydrogen-Deuterium Equilibration on γ-Alumina

Seigo OHNO and Iwao YASUMORI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 10, 1967)

Kinetic studies of the catalytic ortho-parahydrogen conversion and hydrogen-deuterium equilibration on highly purified γ-alumina were conducted in the range of temperature from 77 to 221°K and in the range of pressure from 10 to 120 mmHg. The rate equation obtained can be well explained by a mechanism which involves the reaction between an adsorbed atom and a molecule. The true activation energy, E, and the heat of adsorption of the reactive molecule, Q, were estimated as $E=0.51$—0.80 and $Q=0.51$—0.72 kcal/mol for the conversion (77—195°K), and $E=4.6$ and $Q=1.9$ kcal/mol for the equilibration (145—221°K). The conversion at temperatures below 90°K was found to proceed mostly *via* the magnetic mechanism. A thermal desorption study of adsorbed ethylene showed that there are three types of adsorption on γ-alumina with different activation energies of desorption, and that these species occupy a total of only a few hundredths of the surface. It was concluded that the most strongly-adsorbed ethylene blocks the reactions *via* the chemical mechanism, while the most weakly-adsorbed one retards the conversion *via* the magnetic mechanism. The nature of active sites for the reactions was discussed by taking the results of the ESR measurement into consideration.

During the past three decades, a number of investigations have been made in an attempt to ascertain the mechanisms of the ortho-parahydrogen conversion and of the hydrogen-deuterium equilibration on various solid surfaces, and several mechanisms have been proposed. Bonhoeffer and Farkas[1] proposed a dissociation-recombination mechanism of hydrogen on the surface. Later, Rideal[2] proposed an alternative mechanism, *i. e.*, the exchange of hydrogen atoms between an adsorbed hydrogen molecule and an atom, in order to account for the fact that the reaction rate is appreciable on some catalysts at which the rate of atomic recombination is extremely slow. Couper and Eley[3] have modified this mechanism by assuming the reaction of an adsorbed atom with a gaseous molecule. Further, Boreskov and Vassilevitch[4] proposed a mechanism in which the molecule, after the exchange, migrates to the site of weakest adsorption and then desorbs. A mechanism of bimolecular reaction between adsorbed molecules was proposed by Schwab and Killmann.[5,6]

Besides the chemical mechanisms expressed above, the interconversion between nuclear spin isomers, para- and orthohydrogen or ortho- and paradeuterium, proceeds physically by means of perturbations due to the inhomogeneous magnetic field of paramagnetic substances.

More detailed and accurate kinetic studies are needed in order to clarify which mechanism is operative and to determine whether adsorbed molecular hydrogen participates in the reactions. Only a few studies, however, have concerned themselves with these problems.

Among a number of active substances for these reactions, it has recently been reported[7,8] that evacuated or irradiated alumina is catalytically active to both the ortho-parahydrogen conversion*1 and the hydrogen-deuterium equilibration.*1 The fact that alumina, originally diamagnetic and a poor adsorbent of hydrogen, accelerates the conversion at such a low temperature as 77°K and the equilibration at higher temperatures suggests the existence of paramagnetic sites and of dissociatively-adsorbed hydrogen on the surface.

*1 Hereafter these will be called simply as conversion and equilibration.

The kinetics of the conversion and of the equilibration on the surface of highly-purified γ-alumina were examined in detail in the present experiment. In addition, studies of the effect of adsorbed ethylene on the reaction rates, on the thermal desorption of ethylene, and on ESR of γ-alumina were carried out in order to obtain some information on the nature of the active sites.

Experimental

Apparatus and Procedure. Kinetic studies of the conversion and of the equilibration on γ-alumina were carried out using an apparatus which consisted of a conventional high-vacuum system with a grease-free reaction vessel of about 950 m*l* combined with a circulation pump and arrangements for the preparation and storage of normal hydrogen, para-rich hydrogen, and deuterium. The reaction system was connected with a low-pressure-type gas chromatograph[8] *via* a greaseless valve and a trap cooled at 77°K.

The temperature of the catalyst vessel was maintained using the following cooling agents: liquid nitrogen (77°K), liquid oxygen (90°K), a mixture of *n*-propanol and methanol (100 : 30) cooled with liquid nitrogen (145°K), *n*-propanol cooled with liquid nitrogen (159°K), methanol cooled with solid carbon dioxide (195°K), and *n*-hexanol cooled with liquid nitrogen (221°K). The effective volume of the reaction vessel at each temperature was measured using hydrogen.

A measured amount of the reactant gas was introduced into the reaction vessel and left in contact with the catalyst for a given time; then about 1% of the gas was sampled for the gas-chromatographic analysis.

In case of the thermal desorption study, alumina was preliminally exposed to 5×10^{-2} mmHg of ethylene, at various temperatures, and then evacuated at the same temperature. The temperature of the alumina was then raised linearly with the time up to 350°C; the pressure change due to the desorption under pumping was simultaneously registered. The details of this apparatus will be reported later.

The amounts of irreversibly-adsorbed ethylene on γ-alumina were estimated as follows. Gamma-alumina in a small vessel was evacuated at 500°C. A known amount of ethylene was then introduced into the vessel at 195 or 298°K and left in contact with the alumina for 0.5 hr. The amount of ethylene remaining in the gas phase was then measured by collecting it into a side tube at the temperature of liquid nitrogen. The difference between the amounts of introduced ethylene and of collected one was equated with that of irreversibly-adsorbed ethylene.

The surface area of γ-alumina was determined by the BET method in a constant-volume system using nitrogen at 77°K.

The ESR spectra were measured at 9194 Mc/s on an X-band spectrometer (Japan Electron Optics Laboratory Co., JES-3B 365) using powdered γ-alumina placed in a quartz tube 4 mm in inside diameter. After calcination at 500°C, the samples were evacuated at various temperatures for 5 hr *via* a cold trap at 77°K and then sealed off prior to ESR measurements.

Materials. Cylinder hydrogen was purified by diffusing it through a heated thimble made of palladium-silver alloy. High-purity deuterium and ethylene from the Takachiho Chemical Co. were used without further purification. Cylinder helium was passed through a liquid-nitrogen trap, filled with Linde molecular sieve 13X, in order to remove the oxygen and other condensables.

Normal hydrogen was used as the reactant of the conversion at temperatures of 77 and 90°K, while para-rich hydrogen prepared by equilibrating it at 77°K was used in the temperature range from 145 to 195°K. In the case of equilibration, an equimolar mixture of hydrogen and deuterium was used as the reactant.

Aluminum oxide was prepared by the hydrolysis of aluminum isopropoxide which had been distilled three times under reduced pressure. The spectroscopic analysis of the oxide showed that the contents, as impurities, of iron, copper, magnesium, and manganese are all less than 1 ppm except for silicon (20 ppm). An X-ray diffraction study showed that the oxide, after having been calcined at 100 and 250°C, has the structure of pseude-böhmite, and that it changes to γ-alumina upon calcination at 500°C.

The γ-alumina catalyst finally adopted was calcined at 500°C for 10 hr in air, and then evacuated at the same temperature for 20 hr *in vacuo* at better than 1×10^{-6} mmHg. Prior to each run of reaction, the catalyst was evacuated at 500°C for 2 hr and cooled down to the reaction temperature by introducing about 10 mmHg of helium into the reaction vessel.

In some runs, the catalyst evacuated at 500°C was preliminarily brought into contact with 10 mmHg of ethylene for 1 hr at 195 or 298°K and then evacuated for 1 hr.

Results and Discussion

Experimental-rate Expression. It was verified that the diffusion through the catalyst pore has no influence on the rate; a calculation of the Thile modulus, by assuming a pore radius of 10 Å showed that the effectiveness factor of the surface was almost unity under the present reaction conditions.

As may be seen from the time course of the reaction under constant pressures (Fig. 1), the experimental-rate constants, k_e, of both conversion and equilibration were expressed as:

$$k_e = \frac{1}{t}\ln\frac{X_0-X_e}{X_t-X_e}\ \mathrm{min}^{-1} \qquad (1)$$

where X_0 is the initial mole fraction of the species which disappears with the progress of the reaction, and where X_t and X_e are those of the same species at the time t and the equilibrium at the experimental temperature, T, respectively. A specific rate, k_m, was calculated by the following equation:

$$k_m = n\frac{k_e}{60S} = \frac{k_ePV}{60SkT}\ \mathrm{molecules\cdot sec^{-1}cm^{-2}} \qquad (2)$$

whene n is the number of molecules in the reaction system; P, the total pressure of the reactant; V, the effective volume of the reaction

◐, 145°K; ○, 159°K; ◒, 195°K and ●, 221°K

system; S, the surface area of the catalyst, and k, the Boltzmann constant.

Figure 2 shows that the linear relationship holds between $1/k_m$ and $1/P$ for the conversion in the range of temperature from 77 to 195°K and in the range of pressure from 12.8 to 120.3 mmHg. Similar behavior can also be seen in Fig. 3 for the equilibration in the range of temperature from 145 to 221°K and in the range of pressure from 10.3 to 106.5 mmHg.

From these results, a rate expression which fits both the reactions may be given as:

$$-\frac{n}{S}\cdot\frac{dX_t}{dt}=k\frac{aP}{1+aP}(X_t-X_e)$$

molecules·sec^{-1}cm^{-2} (3)

where k corresponds to the value of k_m extrapolated to an infinite pressure. The Arrhenius plots of k shown in Fig. 4, may be expressed as:

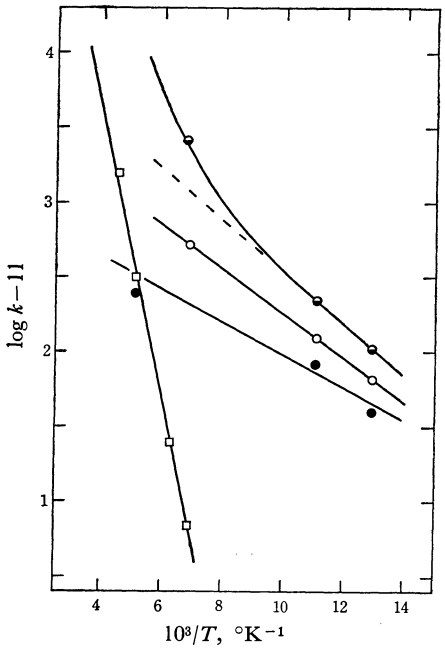

Fig. 4. Arrhenius plots of the extrapolated rate, k, in the conversion and the equilibration.
◒, conversion on unpoisoned γ-alumina; ○, conversion on γ-alumina poisoned by ethylene at 298°K and ●, at 195°K: □, equilibration on unpoisoned γ-alumina

$$k = A\exp(-E/\boldsymbol{R}T) \tag{4}$$

where A and E are constants.

The a parameter in Eq. (3) was determined from the slopes of the plots in Figs. 2 and 3. This parameter, as a function of the temperature, is shown in Fig. 5; it may be expressed as:

$$a = a_0\exp(\boldsymbol{Q}/\boldsymbol{R}T), \tag{5}$$

by taking two constants, a_0 and $\boldsymbol{Q}$. The estimated values of these constants are shown in Table 1.

It is found that the Arrhenius plot of k for the conversion deviates upward from a straight line with increasing temperatures and that it approaches that for the equilibration. This deviation does not, however, appear when the catalyst is preliminarily

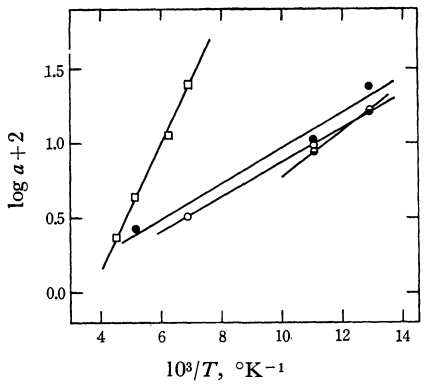

Fig. 5. Relationship between parameter, a, and temperature. Symbols are the same as those in Fig. 4.

treated by ethylene at 195 or 298°K. These results suggest that the reactions *via* a chemical mechanism are mostly retarded by adsorbed ethylene which remains on the surface of the catalyst evacuated at 298°K, while the low-temperature conversion is stopped by ethylene adsorbed at 195°K. It may, therefore, be concluded that the conversion at high temperatures proceeds *via* a mechanism similar to that of the equilibration, but that the reaction *via* another, probably physical, mechanism becomes predominant at low temperatures.

Mechanism of the Conversion. *Derivation of Rate Expression.* By assuming that the conversion takes place magnetically at low temperatures, the reaction may be described by the following scheme:

$$\begin{array}{ccc} o\text{-}H_2(g) & & p\text{-}H_2(g) \\ {\scriptstyle k_1}\big\downarrow\big\uparrow{\scriptstyle k_{-1}} & & {\scriptstyle k_2}\big\downarrow\big\uparrow{\scriptstyle k_{-2}} \\ o\text{-}H_2(a) & \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} & p\text{-}H_2(a) \\ \vdots & & \vdots \\ S_m & & S_m \end{array} \tag{I}$$

where S_m is a paramagnetic site on the surface. The rate equations for these steps may be written as:

$$\frac{dN_{go}}{dt} = \frac{V}{\boldsymbol{k}T}\cdot\frac{dP_o}{dt} = -k_1P_o(1-\theta)\sigma_1S + k_{-1}\theta_o\sigma_1S \tag{6}$$

Table 1. Kinetic constants in the conversion and the equilibration

Reaction	Catalyst treatment	E (kcal/mol)	Q (kcal/mol)	a_0 mmHg^{-1}	A molecules·sec^{-1}cm^{-2}
o-H_2=p-H_2	(A); evacuated at 500°C	0.80*	0.72*	1.7×10^{-3}	19×10^{14}

* Calculated from rates at 77 and 90°K.

$$\frac{dN_{gp}}{dt} = \frac{V}{kT}\cdot\frac{dP_p}{dt} = -k_2P_p(1-\theta)\sigma_1 S + k_{-2}\theta_p\sigma_1 S \quad (7)$$

$$\frac{d\theta_o}{dt} = k_1P_o(1-\theta) - k_{-1}\theta_o - k_3\theta_o + k_{-3}\theta_p \quad (8)$$

$$\frac{d\theta_p}{dt} = k_2P_p(1-\theta) - k_{-2}\theta_p + k_3\theta_o - k_{-3}\theta_p \quad (9)$$

where:

$$\theta = \theta_o + \theta_p$$

P_o and P_p are the partial pressures of ortho- and parahydrogen; N_{go} and N_{gp}, the numbers of the respective molecules in the gas phase; θ_o and θ_p, the surface coverages of these species, and σ_1, the number of active sites per unit area of the catalyst surface. At a steady state where $d\theta_o/dt = d\theta_p/dt = 0$, the expressions for the surface coverage are obtained as:

$$\theta_o = \frac{1}{D}\{k_1(k_{-2}+k_{-3})P_o + k_2k_{-3}P_p\} \quad (10)$$

$$\theta_p = \frac{1}{D}\{k_1k_3P_o + k_2(k_{-1}+k_3)P_p\} \quad (11)$$

where:

$$D = k_1(k_{-2}+k_3+k_{-3})P_o + k_2(k_{-1}+k_3+k_{-3})P_p + (k_{-1}k_{-2}+k_{-1}k_{-3}+k_{-2}k_{-3}).$$

By substituting these relations into Eqs. (6) and (7), we obtain the equations:

$$\frac{dP_o}{dt} = \frac{\rho}{D}(k_{-1}k_2k_{-3}P_p - k_1k_{-2}k_3P_o) \quad (12)$$

and

$$\frac{dP_p}{dt} = \frac{\rho}{D}(k_1k_{-2}k_3P_o - k_{-1}k_2k_{-3}P_p) \quad (13)$$

where:

$$\rho \equiv \sigma_1 S k T/V.$$

Assuming that there is no difference between the adsorption behavior of these isomers, *i. e.*, that $k_1=k_2$ and that $k_{-1}=k_{-2}$, Eq. (12) can be rewritten in the form:

$$-\frac{d(PX_o)}{dt} = \rho\frac{k_{-1}(k_3+k_{-3})}{k_{-1}+k_3+k_{-3}}\cdot\frac{(k_1/k_{-1})P}{1+(k_1/k_{-1})P}\times\left[X_o - \frac{1}{1+k_3/k_{-3}}\right] \quad (14)$$

where X_o is the mole fraction of orthohydrogen. This equation can easily be reduced to Eq. (3). The E and Q constants in Table 1 can, therefore, be expressed as:

$$E = -R\frac{d\ln\{k_{-1}(k_3+k_{-3})/(k_{-1}+k_3+k_{-3})\}}{d(1/T)} \quad (15)$$

$$Q = R\frac{d\ln(k_1/k_{-1})}{d(1/T)} = R\frac{d\ln a}{d(1/T)} \quad (16)$$

which have physical significance as the activation energy and the heat of adsorption, respectively.

Rate-determining Step of the Conversion. There are two extreme cases which depend on the relative order of the magnitude of rate constants, $k_{-1} \gg k_3$, k_{-3} and *vice versa*, corresponding to the cases where the rate is controlled by the surface conversion or by the desorption, respectively. In the former case, Eq. (14) can be simplified to:

$$-\frac{d(PX_o)}{dt} = \rho(k_3+k_{-3})\frac{(k_1/k_{-1})P}{1+(k_1/k_{-1})P}(X_o - X_e) \quad (17)$$

while in the latter case it can be simplified to the same equation except that k_{-1} replaces (k_3+k_{-3}) in Eq. (17).

The former case is preferable to the latter, as will be dicussed below. If the latter case were operative, the observed rate would correspond to the rate of desorption. On the basis of the activated complex theory, the rate of desorption is given as:

$$v = k_d n_{H_2(a)} = \frac{kT}{h}\exp(-E/RT)\sigma_1\theta_{H_2(a)} \text{ molecules}\cdot\text{sec}^{-1}\text{cm}^{-2} \quad (18)$$

The frequency factor, A, is equivalent to the $kT/h\cdot\sigma_1$ in Eq. (18). Hence, the observed value of A, 19×10^{14} molecules·sec^{-1}·cm^{-2}, in Table 1 results in the value of σ_1 of 1—3×10^3 sites·cm^{-2} at 77—90°K, a value which is too small to keep the rate of surface conversion faster than that of desorption.

Isotope Effect. As may be seen in Table 1, the activation energy of the conversion at temperatures below 90°K is smaller than that of the equilibration by about 4 kcal/mol. This difference is larger than that in the zero-point energies between gaseous hydrogen and deuterium, 1.8 kcal/mol. The latter should be the maximum difference in activation energy due to the isotope effect, as has been pointed out by Eley *et al.*[7] There ia a difference of 1.2 kcal/mol between the heats of adsorption determined from the kinetics of equilibration and of conversion. Moore and Ward[9] have estimated the heats of the molecular adsorption of para-, orthohydrogen, hydrogen deuteride, ortho-, and paradeuterium on alumina by gas chromatography. The obtained values, ranging from 1.40 (p-H_2) to 1.65 kcal/mol (p-D_2), lead to a maximum difference of 0.25 kcal/mol due to the isotope effect.

The above kinetic results can not be explained by the isotope effect only. The conversion at temperatures below 90°K, therefore, proceeds *via* a mechanism different from that of the equilibration.

9) W. R. Moore and H. R. Ward, *J. Phys. Chem.*, **64**, 832 (1960).

Mechanism of the Equilibration. The equilibration can only occur *via* a chemical mechanism. On the assumption that the Rideal mechanism is operative, the reaction scheme may be expressed as:

$$\begin{array}{ccccc} H_2(g) & & 2HD(g) & & D_2(g) \\ k_1' \downarrow\uparrow k'_{-1} & & k_2' \downarrow\uparrow k_{-2}' & & k_1'' \downarrow\uparrow k_{-1}'' \\ H_2(a) & & 2HD(a) & & D_2(a) \\ + & \underset{k_{-3}'}{\overset{k_3'}{\rightleftharpoons}} & + & \underset{k_{-3}''}{\overset{k_3''}{\rightleftharpoons}} & + \\ D(a) & & H(a)\ D(a) & & H(a) \end{array} \qquad \text{(II)}$$

By a treatment similar to the above, when the exchange of atoms is the rate-controlling step a rate equation may be derived as follows:

$$-\frac{d(PX)}{dt} = \rho'\theta_a(k_3'+2k_{-3}')\frac{(k_1'/k'_{-1})P}{1+(k_1'/k'_{-1})P} \times\left[X-\frac{1}{1+k_3'/2k'_{-3}}\right] \qquad (19)$$

with:

$$\rho' \equiv \sigma_2 S\boldsymbol{k}T/V,$$

where X is the sum of the mole fractions of hydrogen and deuterium in the gas phase and σ_2 is the number of active sites per unit area of the catalyst surface. The precise form of σ_2 is given in Eq. (20).

A thermal desorption study of hydrogen adsorbed on the alumina showed that no appreciable desorption occurred up to 250°K. Hence, by assuming that the surface coverage of the adsorbed hydrogen atom, θ_a, remains unaltered throughout the present experiment, it may be seen that Eq. (19) coincides with the experimental results, Eq. (3).

The heat of adsorption, 1.9 kcal/mol, estimated from the kinetic study is quite similar to those obtained by gas chromatography. To judge from these coincidences, it is probable that the equilibration proceeds mainly through a reaction of molecularly-adsorbed hydrogen with the adsorbed hydrogen atom.

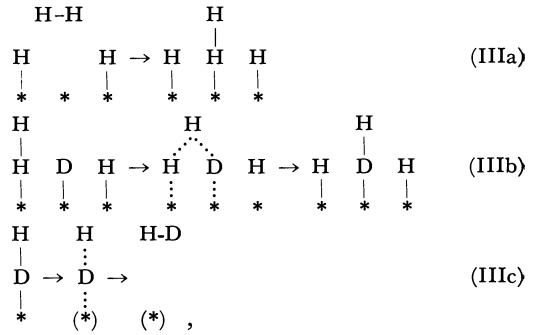
The application of the activated complex theory to this mechanism gives the following expression for the rate of the surface process:

$$v = \sigma_2 k_3'\theta_a\theta_m = \frac{z\sigma_a\sigma_m}{n_0} k_3'\theta_a\theta_m\ . \qquad (20)$$

The rate constant, k_3', has the form $k_3' = \boldsymbol{k}T/\boldsymbol{h}\cdot\exp(-E/\boldsymbol{R}T)$ if the ratio of partition functions, $f(X_\ddagger)/f(H(a))\cdot f(H_2(a))$, is unity. σ_a and σ_m are the number of sites which hold hydrogen atoms and molecules respectively. z is the number of nearest neighbors around the respective site; θ_m, the fraction of the surface covered by adsorbed hydrogen molecules, and n_0, the total number of active sites, $\sigma_a+\sigma_m$. This equation can be used to evaluate the number of adsorption sites on the present catalyst surface. Assuming that σ_a and σ_m are of the same order of magnitude, that $z=4$, and that $n_0=1\times10^{15}$ cm^{-2}, σ's can be evaluated as 0.5×10^{10} cm^{-2} from the observed value, 5.0×10^{18}, of A shown in Table 1.

A separate study of the poisoning effect of ethylene adsorbed at 298°K showed that the amount of adsorbed ethylene which completely blocks the reaction can be estimated to be 2×10^{12} molecules·cm^{-2} from the initial decrease in the equilibration rate. Dolidze *et al.*[10] have reported that γ-alumina, calcined at 500°C in air and evacuated at 320°C, can adsorb 3×10^{11} hydrogen atoms per unit area at 523°K under pressures below 10^{-2} mmHg. These values seem to be in satisfactory agreement with one another in view of the approximations made.

A rate equation similar to Eq. (19) can be derived on the basis of the Boreskov-Vassilevitch reaction scheme as:



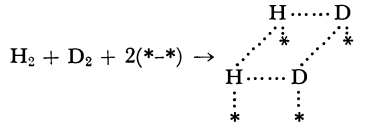
(IIIa)

(IIIb)

(IIIc)

provided that (IIIb) is the rate-controlling step, where * represents an active site and (*), the site for the weakest adsorption.

The Schwab-Killmann mechanism (IV).



(IV)

does not fit the observed kinetic equation. This mechanism results in the rate equation:

$$-\frac{d(PX)}{dt} = \rho''\left(\frac{aP}{1+aP}\right)^2\left[k_4\frac{X^2}{4} - k_{-4}(1-X)^2\right] \qquad (21)$$

where $\rho''\equiv\sigma_3^2 S\boldsymbol{k}T/2V$, where k_4 and k_{-4} are the rate constants of HD formation and its reverse on the surface respectively, and σ_3, the number of dual sites per unit area. This equation does not agree with Eq. (3) in two aspects, *i. e.*, the time-course characteristics and the pressure dependence.

Properties of Active Sites. It may be seen from Fig. 4 that the adsorbed ethylene affects the

10) G. M. Dolidze, Yu. A. Kobanovskii and L. S. Polak, *Kinetika i Kataliz*, **6**, 897 (1965).

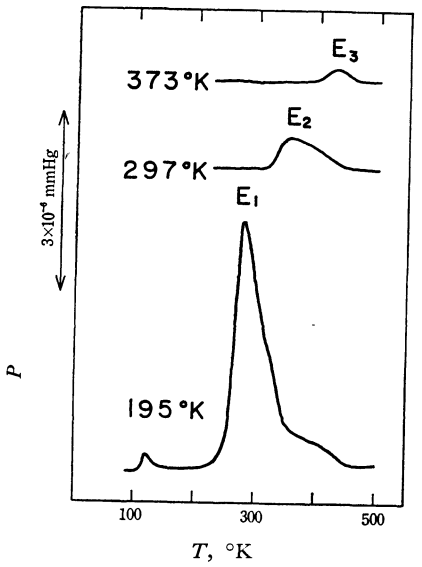


Fig. 6. Desorption spectra of adsorbed ethylene on γ-alumina.
Rate of temperature rise, 2.70°K/min

rate of conversion in different ways depending upon the reaction temperatures. Figure 6 shows the thermal desorption spectra of the adsorbed ethylene on the alumina preliminarily evacuated at 500°C. Irreversibly-adsorbed ethylene at 195°K gave a spectrum consisting of a small peak at 110°K, a large peak, E_1, with a maximum at 280°K, and a shoulder on the high-temperature side of E_1. With an adsorption sample at 297°K, an unsymmetrical peak, E_2, with a maximum at 355°K was obtained, but not the E_1 peak. Finally, a sample of adsorption at 373°K gave only a small, symmetrical peak, E_3. The relative areas of the peaks were estimated to be $16.3(E_1) : 3.3(E_2) : 1.0(E_3)$, and the activation energies of the desorption of the respective peaks were determined[11] to be $19(E_1)$, $25(E_2)$ and $31(E_3)$ kcal/mol on the assumption that the desorption obeys the first-order law. The peak at 110°K was attributed to the desorption of ethylene physically adsorbed on the alumina and/or the wall of the apparatus.

It was found, by a static measurement of the adsorption, that the fraction of the surface occupied by ethylene is quite small; the sum of the fractions of the surface covered by adsorbed ethylene which give the E_1, E_2, and E_3 peaks was 0.024, while that corresponding to E_2 and E_3 was 0.0021. The E_2 and E_3 peaks were found to coincide with those observed by Amenomiya and Cvetanović by a method of inert-gas flow.[11]

The γ-alumina in the present experiment gave a sharp, symmetrical ESR signal 12 oe wide, corresponding to $g=2.004$. The intensity of this signal changed with the evacuation temperatures, as is shown in Table 2. A similar signal with $g=2.003$ has been reported by Berger and Roth.[12]

Table 2. Changes in the intensity of ESR signal ($g=2.004$) of γ-alumina with evacuation

Evacuation	Intensity of ESR signal
30°C—5 hr	1.8×10^{14} spins/g
500°C—5 hr	0.75
550°C—5 hr	0.71
C_2H_4 adsorbed at 30°C after 550°C—5 hr	0.94

Provided that the conversion at low temperatures takes place only on these ESR active sites, its rate at 77°K is estimated to be 1×10^5 molecules·sec^{-1}·$spin^{-1}$ under a total pressure of 12.6 mmHg.

Eley *et al.*[7] have reported that there is a linear relationship between the rate of conversion and the number of unpaired electrons produced on α-alumina by γ-ray irradiation. On the basis of their findings, the rate of conversion at 77°K may be estimated as 2 molecules·sec^{-1}·$spin^{-1}$ under a total pressure of 4 mmHg provided that all these electrons are effective for the reaction. In the present study, the decrease in the conversion rate per ethylene molecule adsorbed at 195°K, which mostly retards the low-temperature conversion, is estimated as 0.5 under similar conditions. This value agrees in order of magnitude with the result reported by Eley *et al.* The ESR active sites do not, therefore, correspond to that for the low-temperature conversion.

This consideration leads to the following conclusions. There are two kinds of paramagnetic centers on or in evacuated γ-alumina; one gives an ESR signal, but has little effect on the low-temperature conversion, while the other gives no ESR signal, but accelerates the conversion. These active sites, including those for the equilibration, exist over only a small percentage of the whole surface. The most strongly-adsorbed ethylene retards the reaction *via* the chemical mechanism, while the most weakly-adsorbed one retards the conversion *via* the physical mechanism.

The authors wish to express their thanks to Professor Emeritus Yasuo Inamura of their Institute for his encouragement and to Mr. Tetsuo Maruyama of the Japan Electron Optics Laboratory Co. for his help in the ESR measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2234—2239 (1968)

Oxygen Oxidation of Ferrous Ions Induced by Chelation

Yoshimi KURIMURA,*1 Ryoji OCHIAI*2 and Niro MATSUURA

Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo

(Received November 20, 1967)

The oxidation of ferrous ions by dissolved oxygen in aqueous solutions in the presence of such chelating agents as EDTA, DTPA, EDTAOH, EDTP, CyDTA and NTA was studied spectrophotometrically. The rate equation for the oxidation reaction is:

$$d[Fe^{III}]/dt = 4k_p[Fe^{II}HZ][O_2] + 4k_n[Fe^{II}Z][O_2]$$

where k_p is the rate constant for the (1) reaction; k_n, the rate constant for the (2) reaction; $Fe^{II}HZ$, protonated chelate, and $Fe^{II}Z$, the normal chelate.

$$Fe^{II}HZ + O_2 \xrightarrow{k_p} Fe^{III}Z + HO_2 \quad (1)$$

$$Fe^{II}Z + O_2 \xrightarrow{k_n} Fe^{III}Z + O_2^- \quad (2)$$

The linear relationship between $\log k$ and $\log R_f$ shown by Eq. (3), was obtained from all the experimental results except for those on the EDTPA and CyDTA systems:

$$\log k = 0.92 + 0.13 \log R_f \quad (3)$$

In Eq. (3), k is $4k_p$ and R_f is $K_{Fe^{III}L}/K_{Fe^{II}HL}$ for the protonated chelate, while k is $4k_n$ and R_f is $K_{Fe^{III}L}/K_{Fe^{II}L}$ for the normal chelate. In the cases of the DTPA and CyDTA systems, a deviation from the straight line was observed. This can be explained by steric hindrance of the oxygen attack by these chelates.

The oxidation of ferrous ions by dissolved oxygen in aqueous solutions in the presence of simple anions, such as chloride,[1] sulfate,[2] perchlorate[3] and phosphate,[4] has been extensively investigated. The oxidation reaction has been found to be accelerated in the presence of pyrophosphate anions.[5-8] King and Davidson suggested that the oxidation rate of ferrous ions increases as the complexing affinity of the anion for ferric ions increases.[7] Thus, at a given pH, the rate can be found to decrease in the order of pyrophosphate, phosphate, chloride, sulfate, and perchlorate.

The oxidation reaction is also accelerated in the presence of such chelating agents as ethylenediaminetetraacetic acid (EDTA), nitritotriacetic acid (NTA), diethylenetriaminepentaacetic acid (DTPA), 1,2-cyclohexanediaminetetraacetic acid (CyDTA), *N*-Hydroxyethylenediamine-*N*,*N*',*N*'-triacetic acid (EDTAOH), and ethylenediaminetetrapropionic acid (EDTP). This acceleration may be ascribed to the stabilization of the oxidized form by the chelation. In this connection, a relationship between the oxidation rate of ferrous ions and the chelation of ferrous and ferric ions is expected. The rate and mechanism of the oxidation reaction of ferrous ions by dissolved oxygen were studied spectrophotometrically; the effect on the reaction rate of the chelation of ferrous and ferric ions will also be discussed.

Experimental

Materials. The ferrous ammonium sulfate, perchloric acid, and sodium hydroxide used were all commercially-available G. R.-grade reagents. Redistilled water was used in the preparation of the solutions.

Preparation of Samples. The hydrogen ion concentration in the chelating-agent solution containing sodium perchlorate was adjusted by the addition of dilute perchloric acid or a dilute sodium hydroxide

solution. A ferrous ion solution was prepared by mixing appropriate amounts of a ferrous ammonium sulfate solution, a sodium perchlorate solution, and water. The ionic strengths of these solutions were maintained at 0.1 by sodium perchlorate.

Measurement of Reaction Rate. The chelating agent and the ferrous ion solutions were kept in a thermostated bath at 25°C for about one hour. By the mixing of the air-saturated chelating-agent and the air-saturated ferrous ion solutions, the reaction was initiated. A portion of the reaction mixture was poured into a 1-cm quartz cell, and the variation in the optical density in the ultraviolet region due to the ferric chelate was recorded automatically on a Hitachi recording spectrophotometer. Thus, twelve seconds after the initiation of the reaction, reproducible results could be obtained. When the reaction proceeded at a moderate rate, the variation in the optical density was measured by using a Hitachi EPU-type spectrophotometer. The molar extinction coefficients used to determine the concentrations of the ferric chelates of EDTA, NTA, DTPA, CyDTA, EDTAOH, and EDTP were 9300 at 258 mμ, 7100 at 258 mμ, 9600 at 258 mμ 8200 at 260 mμ 7900 at 259 mμ, and 5600 at 258 mμ respectively. The variation in the molar extinction coefficients of these chelates under the present experimental conditions was within $\pm 3\%$ in each case.

The oxidation rates in the oxygen-saturated solutions were determined by the following procedure. A 20 m*l* test tube with two small pipes at the end of its was used. These pipes were used to bubble oxygen gas through the solution. One of the test tubes was used for the oxygenation of the ferrous-ion solution, and the other, for the oxygenation of the chelating agent solution. Oxygen bubbling was continued about two hours at 25°C. Then, one or two m*l* of the ferrous ion solution were pipetted into 10 m*l* of the chelating agent solution, in which oxygen bubbling was continued until the end of the measurements. A portion of the oxygen-saturated reaction mixture was poured into a 1 cm quartz cell equipped with a cap. The variation in the optical density was measured in the manner described above.

Results

Dependence of the Rate on the Concentrations of Ferrous Ions, Chelating Agent, and Oxygen. The variation in the ferric-ions concentration with the time at various concentrations of ferrous ions at a given pH and a given concentration of the chelating agent for the DTPA system is shown in Fig. 1. The initial oxidation rate was determined from the initial slope of the curve. The dependence of the rate on the concentration of Fe(II) for the DTPA system is shown in Fig. 2. A linear relationship between the rate and the concentration of Fe(II) was observed in this case. A linear relationship was also obtained between the rate and the concentration of the chelating agents, as Fig. 3 shows.

Under the present experimental conditions, the reaction was first-order with respect to the total concentrations of both ferrous ions and the chelating agent. However, this linear relationship was not observed in the relatively high pH region.

The oxidation reaction in these systems was also first-order with respect to the concentration of dissolved oxygen in the solution. This first order dependence was examined by comparing the specific rate in the air-saturated solution with that in the oxygen-saturated solution. The ratio of the concentrations of oxygen in the aerated and

oxygenated solutions was estimated to be about 1 to 4.7. This ratio was nearly equal to the ratio of the reaction rate in an aerated solution to that in the corresponding oxygenated solution, as is shown in Fig. 4 for the DTPA system.

The results suggested that the rate equation for Fe(II)-chelating agent-O_2 reaction system at a low pH is:

$$d[Fe(III)]/dt = k_a[Fe(II)]_t[Z]_t[O_2] \quad (1)$$

where k_a is the apparent rate constant; $[Fe(II)]_t$, the total concentration of the ferrous iron, and $[z]_t$, the total concentration of the chelating agent.

Dependence of the Rate on the pH. The variation in the rate with the pH in the DTPA, EDTA, CyDTA, and EDTAOH systems is shown in Figs. 5 and 6. The reaction rate in the EDTA system in the pH region from 3 to 5 under these experimental conditions could not be deterimned

because the rate was too rapid to determine its value. The oxidation rate in the DTPA system, as shown in Fig. 5, increases simply with an increase pH values of the solution under the conditions employed and reaches its maximum at pH 4. Then, with the increase in the pH, the rate begins to decrease, becoming nearly constant at pH values higher than 6.5. In the EDTA and the CyDTA systems, such a maximum in the reaction rate was also observed. On the other hand, under these experimental conditions the reaction rates in the NTA and the EDTAOH systems increase simply with an increase in the pH values and become nearly constant at higher pH values, without any distinctive maximum.

Discussion

The concentrations of Fe(II) chelate for the EDTA and the DTPA systems under the present experimental conditions can be calculated by using the formation constants of Fe(II) chelates and the acid dissociation constants of the chelating agents. The results of the calculation are shown in Fig. 5 for DTPA chelates. By comparing these two curves with the observed rate, it is made clear that the oxidation reaction of Fe(II) chelates proceeds

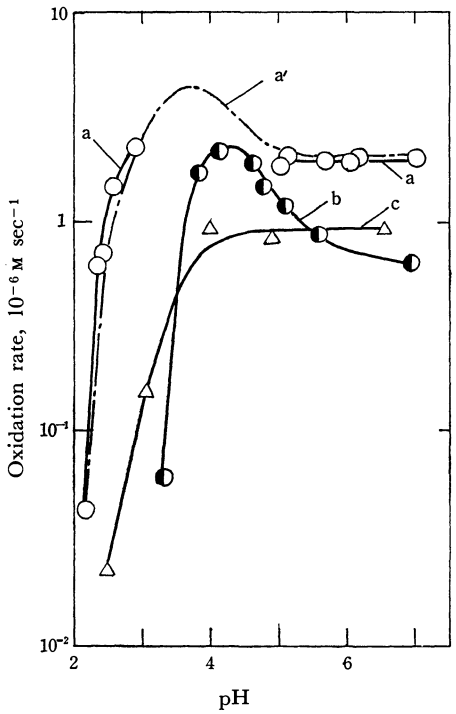

Fig. 6. Dependence of the oxidation rate on pH in the air saturated Fe(II)-chelating agent systems.
a EDTA system, 3.1×10^{-5} M EDTA
a' calculated curve for the EDTA system
b CyDTA system, 4.6×10^{-5} M CyDTA

through two simultaneous reaction paths, one of which involves the oxidation of the protonated chelate while the other involves the oxidation of the normal chelate. In a similar way, it may be suggested that the oxidation of Fe(II) in the EDTA system also preceeds through two simultaneous reaction paths. The maximum in the oxidation rate for the CyDTA system, shown in Fig. 6, indicates the presence of the protonated chelate in a low pH region, though the formation constant of the protonated chelate has not yet been reported. As is clear from the foregoing discussion, the rate equation (2) can be assumed for the oxidation of Fe(II) chelates discussed here:

$$d[Fe(III)]/dt = 4k_p[Fe^{II}HZ][O_2] + 4k_n[Fe^{II}Z][O_2] \quad (2)$$

In Eq. (2), k_p and k_n represent the rate constants of the two oxidation reactions, (3) and (4), respectively:

$$Fe^{II}HZ + O_2 \xrightarrow{k_p} Fe^{III}Z + HO_2 \quad (3)$$

$$Fe^{II}Z + O_2 \xrightarrow{k_n} Fe^{III}Z + O_2^- \quad (4)$$

The first term in the right-hand side of Eq. (2) corresponds to the oxidation of the protonated chelate, and the second, to that of the normal chelate. The k_n value for the oxidation of Fe(II) in the DTPA system can be determined from the reaction rate obtained in the high pH region and the concentration of the corresponding nornal chelate at the pH where the reaction rate is obtained.*3 Thus, using this k_n value, the rate obtained at a low pH, and the concentrations of the protonated and normal chelates, the value can be obtained. For the NTA and the EDTAOH systems, the first term of Eq. (2) can be neglected, so the k_n value can be obtained simply from a comparison of the oxidation rate with the concentration of the normal chelate at a given pH.

The rate-pH curves shown in Fig. 5 (curve a) for the DTPA and in Fig. 6 (curve a') for the EDTA system were calculated by using the k_p and k_n values for the corresponding systems. The agreement between the observed rates and the calculated curves confirms that the proposed rate equation is satisfactory. Such an agreement was also observed in the other systems.

Table 1. Rate constants for the oxidation of Fe(II) chelates and the formation constants of Fe(II) and Fe(III) chelates

Fe(II) chelate	(M^{-1} sec^{-1})	Logarithmic stability constant[9]		
		$K_{Fe^{II}HL}$	$K_{Fe^{II}L}$	$K_{Fe^{III}L}$
FeHEDTA	6.8×10^3	2.8		
FeEDTA	2.7×10^2		14.3	25.1
FeNTA	80		8.8	15.9
FeHDTPA	18	5.4		
FeDTPA	7.0		16.0	27.5
FeEDTAOH	1.0×10^2		12.2	19.8
FeEDTP	90		6.2	14.4
FeCyDTA	89		18.2	29.3

The values of the rate constants for several systems are listed in Table 1, along with the corresponding chelate formation constants for Fe(II) and Fe(III). It is interesting to note here that the rate constant for the oxidation of the normal chelate does not always increase with an increase in the corresponding formation constant of ferric chelate. This is contrary to the findings of King and Davidson for the oxidation of Fe(II)-simple anion systems.[7] The oxidation reaction

*3 The concentration of oxygen in the air-saturated solution in the pH region from 2 to 8 is estimated to be 2.4×10^{-4} M under the present experimental conditions.

9) J. Bjerrum, G. Schwarzenbach and L. G. Sillen, "Stability Constants," Chem. Soc., London (1956); A. Ringbom, "Complexation in Analytical Chemistry," John Wiely and Sons Inc., New York, N. Y. (1963).

of the protonated chelates always proceeds more rapidly than that of the corresponding normal chelates. For example, the rate constant for the oxidation reaction of the protonated Fe(II)-EDTA chelate is about thirty times greater than that of the normal chelate. This suggests that the addition of a proton to the normal chelate makes it liable to oxygen attack.

It may be suggested that the reaction mechanism for the oxidation of Fe(II) by oxygen in the presence of a chelating agent is as follows:

$$Fe^{2+} + HZ \rightleftharpoons Fe^{II}HZ \quad (a)$$

$$+H^+ \uparrow\downarrow -H^+$$

$$Fe^{2+} + Z \rightleftharpoons Fe^{II}Z \quad (b)$$

$$Fe^{II}HZ + O_2 \xrightarrow{k_p} Fe^{III}Z + HO_2 \quad (3)$$

$$Fe^{II}Z + O_2 \xrightarrow{k_n} Fe^{III}Z + O_2^- \quad (4)$$

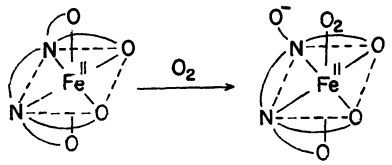
$$O_2^- + H^+ \rightarrow HO_2 \quad (5)$$

$$Fe(II) + HO_2 + H^+ \rightarrow Fe(III) + H_2O_2 \quad (6)$$

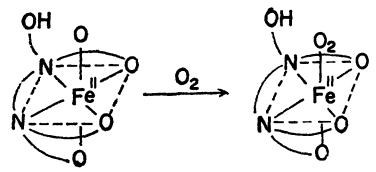
$$Fe(II) + H_2O_2 \rightarrow Fe(III) + OH^- + OH \quad (7)$$

$$Fe(II) + OH \rightarrow Fe(III) + OH^- \quad (8)$$

In these equation, Fe(III) and Fe(II) represent the ferric and ferrous iron species respectively. In the reaction of Fe(II)-EDTA chelates, the mechanism of reactions (3) and (4) may be represented as follows:



$$+ O_2^- \quad (9)$$



$$+ HO_2 \quad (10)$$

The reaction (9) corresponds to Eq. (4), and the reaction (10), to Eq. (3).

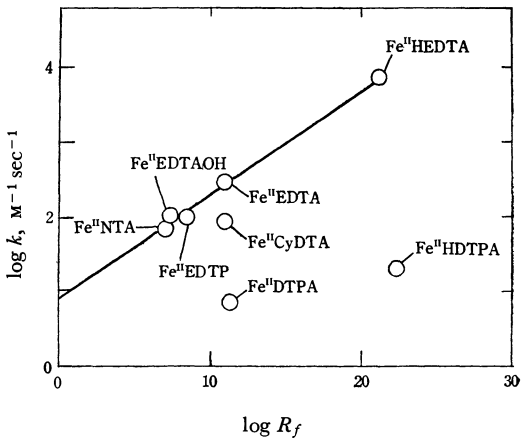


Fig. 7. Relation between log k and log R_f.
k: rate constant for the oxidation of Fe(II) chelate
R_f: $K_{Fe^{III}L}/K_{Fe^{II}L}$*4 for normal chelate
$K_{Fe^{III}L}/K_{Fe^{II}HL}$*4 for protonated chelate

If the relationship between the rate constant for the oxidation of Fe(II) and the formation constants of the chelates of Fe(II) and Fe(III) are examined, in all except a few cases a straight line is obtained, as shown in Fig. 7. Thus, the experimental equation (11) can be obtained from the straight line:

$$\log k = 0.92 + 0.13 \log R_f \quad (11)$$

Then:

$$\log k_x = 0.32 + 0.13 \log R_f \quad (12)$$

where k_x is k_p or k_n and where k is equal to $4k_n$ and R_f, to $K_{Fe^{III}L}/K_{Fe^{II}L}$ in the case of the normal chelate, and where k is equal to $4k_p$ and R_f, to $K_{Fe^{III}L}/K_{Fe^{II}HL}$ in the case of the protonated chelate. Daviation from the straight line is observed in the CyDTA and the DTPA systems. In view of the geometrical structure of these metal chelates, the oxygen attack on them might be restricted by steric hindrance.

If the activation entropies of these reactions are assumed to be identical with each other, a relationship between log k and log R_f can be obtained, as is described below. Equation (13) is obtained on the basis of the above assumption. It represents a linear relationship between standard free energy change, ΔG_0, and the corresponding standard free energy of activation, $\Delta G_0^{\neq}$, in the reactions.

$$\Delta G_0^{\neq} = \alpha + \beta \Delta G_0 \quad (13)$$

where α and β are the constants. The rate constant is given kinetically by the equation:

$$k_x = \frac{kT}{h} \exp(\Delta G_0^{\neq}/RT) \quad (14)$$

*4 $K_{Fe^{III}L}$, $K_{Fe^{II}L}$ and $K_{Fe^{II}HL}$ are the formation constants of normal Fe(III), normal Fe(II) and protonated Fe(II) chelates, respectively.

and the standard free energy change in the reaction is:

$$\Delta G_0 = -FE^0 + RT \ln R_f \quad (15)$$

where F is the Faraday constant and E^0, the standard oxidation potential of Reaction (16):

$$Fe^{2+} = Fe^{3+} + e^- \quad (E^0 = -0.77\ V)^{10)} \quad (16)$$

Combining Eqs. (13), (14), and (15) and by rewriting the resulting equation in logarithmic form, Eq. (17) is obtained:

$$\log k_x = \log \frac{kT}{h} + \frac{1}{2.303RT}\{\beta FE^0 - \alpha\} - \beta \log R_f \quad (17)$$

This equation represents the linear relationship between $\log k_x$ and $\log R_f$. By combining Eqs. (12) and (17), $\alpha = 16$ kcal mol^{-1} and $\beta = -0.13$ are obtained.

For the oxidation of the chelates described here, the straight line shown in Fig. 7 can be obtained, because the activation entropies are approximately identical with each other and because there is a compensation effect[11] between the activation enthalpy, $\Delta H^{\neq}$, and the activation entropy, $\Delta S^{\neq}$. Therefore, the principle of a linear-free energy relation (LFER) appears in the reactions. In the cases of DTPA and CyDTA, an exception is observed, as is shown in Fig. 7. This can be explained by lowering of the oxidation rate due to steric hidrance of the oxygen attack on these chelates.

The authors wish to express their thanks to Professor Yukichi Yoshino and Professor Mutsuo Kodama for their helpful discussions of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2239—2247 (1968)

An Energetic Consideration of the Monomer Reactivity in Catalytic Polymerization

Tsutomu KAGIYA, Yūzō SUMIDA and Tetsuya NAKATA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 29, 1967)

The elementary processes constituting the polymerization reaction are energetically considered, and the relation between the activation energy of each process and the structures of reagents or the kind of solvents is theoretically discussed. The solvation energy of ion has been evaluated with the ionization potential of anion or the electron affinity of cation, and the ionization potential or the electron affinity of the growing radical with that of the corresponding monomer. The energy of the highest occupied ($\varepsilon_{ho}=\alpha+\lambda_{ho}\beta$) or the lowest vacant ($\varepsilon_{lv}=\alpha-\eta_{lv}\beta$) π level of the monomer has been calculated, and the π bond dissociation energy has been evaluated with the summation ($\lambda_{ho}+\eta_{lv}$). On the basis of these considerations, the monomer reactivity in catalytic polymerization can be compared with the relative magnitude of the electronic natures of monomer and components of catalyst, *i. e.*, ionization potential or electron affinity.

In recent years, a number of experimental informations has been accumulated on the polymerization of vinyl compounds. On the basis of the data, Alfrey and Price[1,2] have systematically made a study of the correlations between the monomer reactivities in radical polymerization and the structural factors of vinyl monomers in terms of the empirical values of Q and e. Yonezawa, Fukui and their coworkers,[3-5] from the standpoint of the simple molecular orbital theory, have calculated the stabilization energy arising from π conjugation in the transition state in radical or ionic polymerization of vinyl monomer and the

localization energy indicating the facility of the initiation reaction in ionic polymerization, and have considered the relation between these characteristic values and the reactivities of monomers.

The latest experimental results, however, have indicated that the monomer reactivity is remarkably affected by the structure of catalyst[6,7] and the nature of solvent.[8,9] Hence it appears that these theories based on the free ion model are insufficient to explain the accumulated experimental data.

The purpose of the work is to study quantitatively the monomer reactivity in catalytic polymerization. The elementary processes constituting the polymerization reaction are energetically considered in connection with the electronic structures of the monomer and the catalyst. On the basis of the conclusion, the monomer reactivity in catalytic polymerization should be correlated with the electronic structures of a monomer and components of catalyst.

Theoretical

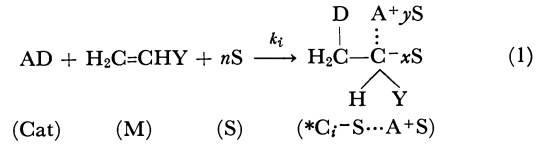
(I) The Overall Rate of Polymerization. It is generally assumed that the catalytic polymerization consists of the elementary processes of (i) the formation of the active ion-pair (the initiation), (ii) the monomer addition to the active ion-pair (the propagation), (iii) the formation of the polymer and the active ion-pair (the chain transfer) and (iv) the deactivation of the active ion-pair (the termination). In order to discuss theoretically the monomer reactivity in catalytic polymerization, an energetic consideration was forcused on the first two steps, that is, the initiation and the propagation. Then, the followings are postulated.

(i) The initiation process is that forms the solvated active ion-pair by the reaction of monomer and catalyst.

(ii) The propagation process consists of the formation reaction of the intermediate and its rearrangement reaction to make the chain growth. The former is that to form the complex in which the monomer co-ordinates to the solvated ion-pair nucleophilically and electrophilically. The latter is the unimolecular rearrangement reaction of the complex.

According to the above postulations, the elementary processes controlling the overall polymerization are illustrated by the following models for the anionic polymerization of the vinyl monomer as an example.

Initiation:

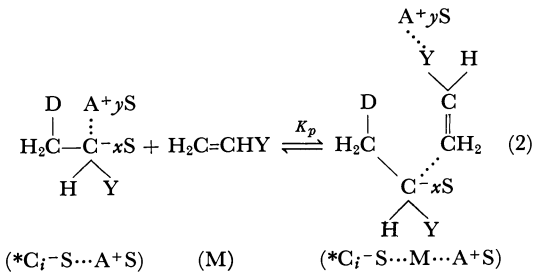


(1)

(Cat) (M) (S) ($*C_i$-S···A^+S)

Propagation:

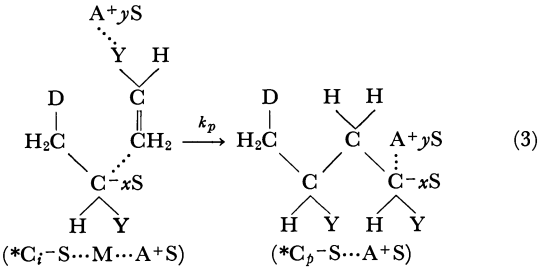
The formation of the intermediate complex:



(2)

($*C_i$-S···A^+S) (M) ($*C_i$-S···M···A^+S)

The rearrangement of the intermediate complex:



(3)

($*C_i$-S···M···A^+S) ($*C_p$-S···A^+S)

In the above models, AD represents a catalyst, and the conjugated component A is an electron acceptable group and D an electron donative group. The expression in ( ) indicates the abbreviation of the model compound. Where Cat: catalyst, M: monomer, S: solvent, $*C_i$-S···A^+S: initiating active ion-pair solvated, $*C_p$-S···A^+S: propagating active ion-pair solvated, $*C_t$-S···M···A^+S: intermediate complex, Y: electron donative group such as a carbonyl group in the monomer molecule, x and y: the number of solvent molecules solvating to the anion and the cation, and $x+y=n$. k_i and k_p are the rate constants of the initiation and the rearrangement reaction, and K_p the equilibrium constant of the intermediate formation.

Based on the assumption of the first order rate with respect to all components, the rate of consumption of the catalyst is

$$-\frac{d[Cat]}{dt} = k_i[S][M][Cat] \quad (4)$$

Since the concentration of the solvent and the monomer can be regarded as constant in the first stage of the polymerization, the remaining concentration of the catalyst is expressed by Eq. (5),

$$[Cat] = [Cat]_0 e^{-k_i[S][M]t} \quad (5)$$

where $[Cat]_0$ is the initial concentration of the catalyst. While, from the equilibrium reaction (2),

6) Y. Imanishi, T. Higashimura and S. Okamura, *Kobunshi Kagaku (Chemistry of High Polymers)*, **18**, 333 (1961).
7) T. Kagiya, T. Kondo and K. Fukui, This Bulletin, **41**, 2473 (1968).
8) T. Kagiya, T. Shimidzu and K. Fukui, *Shokubai (Catalyst)*, **5**, 304 (1963).
9) H. L. Hsieh, *J. Polymer Sci.*, **A3**, 153 (1965).

$$[*C_i\text{-}S\cdots M\cdots A^+S] = K_p[M] \times ([Cat]_0 - [Cat] - [*C_i\text{-}S\cdots M\cdots A^+S] - [*C_p\text{-}S\cdots A^+S]) \quad (6)$$

In the beginning of the polymerization, the polymer concentration $[*C_p\text{-}S\cdots A^+S] \approx 0$, hence

$$[*C_i\text{-}S\cdots M\cdots A^+S] = \frac{K_p[M][Cat]_0}{1+K_p[M]}(1-e^{-k_i[S][M]t}) \quad (7)$$

In the case of the first order propagation reaction with respect to the intermediate, the overall rate of polymerization is generally given as follows,

$$R = \frac{d[*C_p\text{-}S\cdots A^+S]}{dt} = k_p[*C_i\text{-}S\cdots M\cdots A^+S][M] = \frac{k_pK_p[M][Cat]_0}{1+K_p[M]}(1-e^{-k_i[S][M]t}) \quad (8)$$

It is apparent from Eq. (8) that the overall rate is simplified as follows by the relative magnitude of the K_p value, in both polymerization with the slow initiation ($k_i \ll 1$) and the rapid initiation ($k_i \gg 1$) defined by us previously,[10]

The polymerization with the slow initiation ($k_i \ll 1$):

$$K_p[M] \ll 1 \quad R = k_ik_pK_p[M]^2[S][Cat]_0t \quad (9)$$

$$K_p[M] \gg 1 \quad R = k_ik_p[M][S][Cat]_0t \quad (10)$$

The polymerization with the rapid initiation ($k_i \gg 1$):

$$K_p[M] \ll 1 \quad R = k_pK_p[M][Cat]_0 \quad (11)$$

$$K_p[M] \gg 1 \quad R = k_p[Cat]_0 \quad (12)$$

Equations (9) and (10) in the slow initiation system show that the polymerization rate in the early stage increases with the polymerization time.

Since the equilibrium constant K_p is considered to be small, the overall rate of polymerization can be generally discussed by Eq. (9). The observed specific rate k in the slow initiation system (9) involves that the equilibrium constant of the formation of the intermediate and both rate constants of the formation of the active ion-pair and the rearrangement reaction of the complex.

$$k = k_ik_pK_p \quad (13)$$

(II) An Energetic Study of the Catalytic Polymerization. Based on Eq. (13), the overall activation energy ΔE is given as follows by using each activation energy (ΔE_i, ΔE_p) and the Gibbs' free energy change (ΔG_p) of the reactions,

$$\Delta E = \Delta E_i + \Delta E_p + \Delta G_p \quad (14)$$

In order to evaluate quantitatively the activation energy and the Gibbs' free energy change of each reaction, an energetic study was made as follows.

(a) The Overall Activation Energy of the Initiation Reaction. As shown in Eq. (1), it has been considered in ionic polymerization whether the polymerization takes place by an anionic mechanism (the formation of the D-C covalent bond) or a cationic mechanism (the formation of the A-C covalent bond) is dependent on the relative electronic properties of the catalyst and the monomer.

In order to study energetically the rate of initiation, we assume the following elementary reactions of the initiation for an anionic polymerization as an example,

$$AD \rightarrow A\cdot + D\cdot \quad (i)$$

$$H_2C{=}CHY \rightarrow H_2\dot{C}{-}\dot{C}HY \quad (ii)$$

$$D\cdot + H_2\dot{C}{-}\dot{C}HY \rightarrow H_2C(D){-}\dot{C}HY \quad (iii)$$

$$H_2C(D){-}\dot{C}HY + e \rightarrow H_2C(D){-}C^-(H)(Y) \quad (iv)$$

$$A\cdot \rightarrow A^+ + e \quad (v)$$

$$H_2C(D){-}C^-(H)(Y) + xS \rightarrow H_2C(D){-}C^-(H)(Y)\,xS \quad (vi)$$

$$A^+ + yS \rightarrow A^+yS \quad (vii)$$

$$H_2C(D){-}C^-(H)(Y)\,xS + A^+yS \rightarrow H_2C(D){-}C^-(H)(Y)\,xS \quad (viii)$$

The reactions (i) and (ii) are the bond dissociation of the catalyst AD and the π bond dissociation of the vinyl monomer, and the component radical D· of catalyst combines with the monomer radical to give the polymer end (iii). The growing radical produced by the reaction (iii) and the other component radical A· of catalyst ionize ((iv), (v)) and form the corresponding solvated ions ((vi), (vii)). The two solvated ions having an opposite charge form a solvated ion-pair by an electrostatic force (viii).

According to Polanyi - Horiuchi - Semenov's empirical rule, the overall rate of the growing radical ($H_2DC\text{-}\dot{C}HY$) formation is considered to be large as both of the bond dissociation energy B(A-D) of the A-D bond and the π bond dissociation energy B(C=C) of the monomer are small or as B(D-C) of the $D\text{-}CH_2\dot{C}HY$ large. It is supposed that the reactions (iv) and (v) take place easily when the electron affinity $E_a(*C_i\cdot)$ of the radical $CH_2D\dot{C}HY$ indicated by $*C_i\cdot$ is large and the ionization potential $I_p(A\cdot)$ of a component A· is small, and that the reactions (vi) and (vii) occur facilely

10) T. Kagiya, M. Izu and K. Fukui, This Bulletin, **40**, 1045 (1967).

as the solvation energies, *i.e.*, $-\Delta G_s(*C_i^- \cdots S)$ and $-\Delta G_s(A^+ \cdots S)$, of the growing anion H_2-DCHYC$^-$ indicated by $*C_i^-$ and the counter cation A^+ are large. The two solvated ions having an opposite charge exist usually in the solution as a solvated ion-pair. It is, however, considered that the facility of the polymerization increases with a decrease in the electrostatic energy $-\Delta G_e(*C_i^- S \cdots A^+ S)$ arised between two solvated ions, because the rate of polymerization by a free ion mechanism is larger than that by an ion-pair mechanism.[11]

On the basis of the above considerations, it has been assumed that the activation energy (ΔE_i) of the initiation is expressed as follows, by the use of the free energy changes of these elementary reactions and the electronic natures of the catalyst components,

Anionic Polymerization;

$$\begin{aligned}\Delta E_{i(A)} = {} & c_1 B(\text{A-D}) + c_2 B(\text{C=C}) - c_3 B(\text{D-C}) \\ & + c_4[I_p(\text{A}\cdot) - E_a(*C_i\cdot)] \\ & + c_5[\Delta G_s(*C_i^- \cdots S) + \Delta G_s(A^+ \cdots S)] \\ & - c_6 \Delta G_e(*C_i^- S \cdots A^+ S) \end{aligned} \quad (15)$$

Cationic Polymerization;

$$\begin{aligned}\Delta E_{i(C)} = {} & c_1' B(\text{A-D}) + c_2' B(\text{C=C}) - c_3' B(\text{A-C}) \\ & + c_4'[I_p(*C_i\cdot) - E_a(\text{D}\cdot)] \\ & + c_5'[\Delta G_s(*C_i^+ \cdots S) + \Delta G_s(D^- \cdots S)] \\ & - c_6' \Delta G_e(*C_i^+ S \cdots D^- S) \end{aligned} \quad (16)$$

where $c_1, \cdots, c_6, c_1', \cdots, c_6'$ are the positive constants disregarding the kinds of monomer, catalyst and solvent.

(b) The Overall Activation Energy of the Propagation Reaction. As Eq. (2) shows, the formation reaction of the intermediate complex is that the monomer co-ordinates to the solvated ion-pair nucleophilically and electrophilically. Then, it is considered that the Gibbs' free energy of the co-ordination of the monomer to the growing chain and the counter ions can be estimated with the nucleophilic and electrophilic co-ordination energies and the electrostatic energy of the solvated ion-pair. Therefore, the Gibbs' free energy of the reaction is written as follows,

Anionic Polymerization;

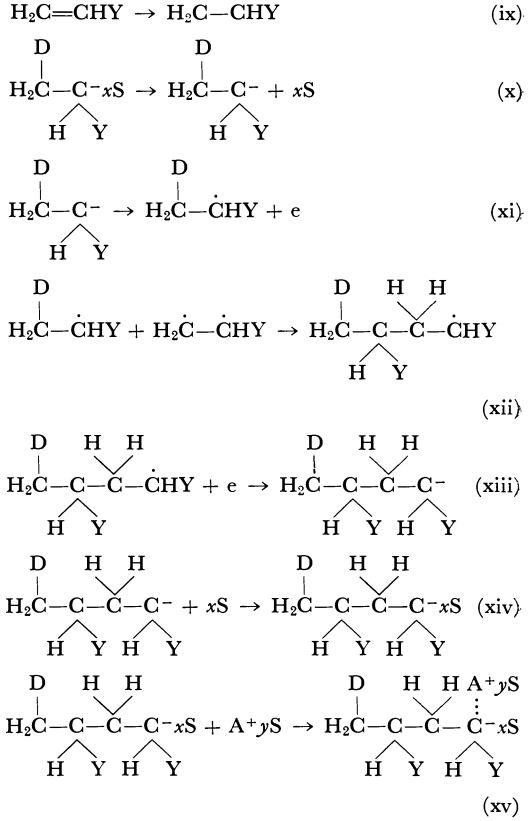
$$\begin{aligned}-\Delta G_{p(A)} = {} & -\Delta G_e(A^+ S \cdots M) \\ & - \Delta G_c(*C_i^- S \cdots M) + \Delta G_e(*C_i^- S \cdots A^+ S) \end{aligned} \quad (17)$$

Cationic Polymerization;

$$\begin{aligned}-\Delta G_{p(C)} = {} & -\Delta G_e(D^- S \cdots M) \\ & - \Delta G_c(*C_i^+ S \cdots M) + \Delta G_e(*C_i^+ S \cdots D^- S) \end{aligned} \quad (18)$$

where $-\Delta G_p$ represents the Gibbs' free energy of the formation reaction of the intermediate and $-\Delta G_c$ the co-ordination energy, and the abbreviation $*C_i^- S \cdots M$ or $*C_i^+ S \cdots M$ indicates the monomer co-ordinating to the solvated growing anion or cation and $A^+ S \cdots M$ or $D^- S \cdots M$ indicates the monomer co-ordinating to the counter cation or anion.

On the other hand, in a similar manner as the initiation reaction, the following elementary reactions of the chain growth reaction of the intermediate for an anionic polymerization as an example were assumed,



(ix) (x) (xi) (xii) (xiii) (xiv) (xv)

In the above elementary reactions, the reaction (ix) is the π bond dissociation to form the monomer radical, (x) and (xi) are the desolvation of the solvated growing ion and the formation of the growing radical, (xii) is the recombination of the growing radical with the monomer radical to make growth of the chain. The growing radical produced by the reaction (xii) ionizes (xiii) and forms the corresponding solvated ion (xiv), and the two solvated ions having an opposite charge form a solvated ion-pair by an electrostatic force (xv).

In the same way of the initiation reaction, the activation energy (ΔE_p) of the chain growth reaction may be considered to be small as the π bond dissociation energy B(C=C) of monomer is small and the bond dissociation energy B(*C-C) of the

11) D. N. Bhattacharyya, J. Smid and M. Szwarc, *J. Phys. Chem.*, **69**, 612, 624 (1965).

growing radical with the monomer radical large. It is supposed that the reactions (x) and (xi) are easily arised as the desolvation energy $-\Delta G_{ds}$ ($*C_i^- \cdots S$) of the solvated ion $H_2DCHYC^- \cdots xS$ indicated by $*C_i^- \cdots S$ and the ionization potential $I_p(*C_i^-)$ of the ion H_2DCHYC^- are small, and that the reactions (xiii) and (xiv) take place easily when the electron affinity $E_a(*C_p\cdot)$ of the radical $H_2DCHYCH_2CHYC\cdot$ indicated by $*C_p\cdot$ and the solvation energy $-\Delta G_s(*C_p^- \cdots S)$ of the propagating growing ion $H_2DCHYCH_2CHYC^-$ indicated by $*C_p^-$ are large. On the basis of the reason described in the initiation reaction, it is also considered that the rate of polymerization increases with a decrease in the electrostatic energy $-\Delta G_e$-($*C_p^- S \cdots A^+ S$) of (xv) arised between two solvated ions.

On the basis of the above considerations, it has been assumed that the activation energy of the chain growth reaction is expressed as follows,

Anionic Polymerization;

$$\begin{aligned}\Delta E_{p(A)} &= c_7 B(C{=}C) - c_8 B(*C\text{-}C) \\ &\quad - c_9[\Delta G_{ds}(*C_i^- \cdots S) - \Delta G_s(*C_p^- \cdots S)] \\ &\quad + c_{10}[I_p(*C_i^-) - E_a(*C_p\cdot)] \\ &\quad - c_{11}\Delta G_e(*C_p^- S \cdots A^+ S) \end{aligned} \tag{19}$$

Cationic Polymerization;

$$\begin{aligned}\Delta E_{p(C)} &= c_7' B(C{=}C) - c_8' B(*C\text{-}C) \\ &\quad - c_9'[\Delta G_{ds}(*C_i^+ \cdots S) - \Delta G_s(*C_p^+ \cdots S)] \\ &\quad + c_{10}'[I_p(*C_p\cdot) - E_a(*C_i^+)] \\ &\quad - c_{11}'\Delta G_e(*C_p^+ S \cdots D^- S) \end{aligned} \tag{20}$$

where $c_7, \cdots, c_{11}, c_7', \cdots, c_{11}'$ are the positive constants disregarding the kinds of monomer, catalyst and solvent. In Eqs. (19) and (20), the ionization potential $I_p(*C_i^-)$ or the electron affinity $E_a(*C_i^+)$ of the initiating anion or cation is approximately equal to the electron affinity $E_a(*C_p\cdot)$ or the ionization potential $I_p(*C_p\cdot)$ of the propagating radical, respectively. The desolvation energy $-\Delta G_{ds}$-($*C_i^- \cdots S$) or $-\Delta G_{ds}(*C_i^+ \cdots S)$ is also equal to the solvation energy $-\Delta G_s(*C_p^- \cdots S)$ or $-\Delta G_s$-($*C_p^+ \cdots S$). Equations (19) and (20) may, therefore, be written,

Anionic Polymerization;

$$\begin{aligned}\Delta E_{p(A)} &= c_7 B(C{=}C) - c_8 B(*C\text{-}C) \\ &\quad - c_{11}\Delta G_e(*C_p^- S \cdots A^+ S) \end{aligned} \tag{21}$$

Cationic Polymerization;

$$\begin{aligned}\Delta E_{p(C)} &= c_7' B(C{=}C) - c_8' B(*C\text{-}C) \\ &\quad - c_{11}'\Delta G_e(*C_p^+ S \cdots D^- S) \end{aligned} \tag{22}$$

(c) The Overall Activation Energy of the Polymerization. From a series of these energetic considerations, it seems reasonable to conclude that the overall activation energy, in any cases of the slow initiation and the rapid initiation,[10] is expressed as follows by using Eqs. (15)—(22),

The Slow Initiation System (9)

Anionic Polymerization;

$$\begin{aligned}\Delta E_{(A)} &= c_1 B(A\text{-}D) + (c_2 + c_7) B(C{=}C) \\ &\quad - c_3 B(D\text{-}C) - c_8 B(*C\text{-}C) \\ &\quad + c_4[I_p(A\cdot) - E_a(*C_i\cdot)] \\ &\quad + c_5[\Delta G_s(*C_i^- \cdots S) + \Delta G_s(A^+ \cdots S)] \\ &\quad + [\Delta G_c(A^+ S \cdots M) + \Delta G_c(*C_i^- S \cdots M)] \\ &\quad - (c_6 + 1 + c_{11})\Delta G_e(*C_i^- S \cdots A^+ S) \end{aligned} \tag{23}$$

Cationic Polymerization;

$$\begin{aligned}\Delta E_{(C)} &= c_1' B(A\text{-}D) + (c_2' + c_7') B(C{=}C) \\ &\quad - c_3' B(A\text{-}C) - c_8' B(*C\text{-}C) \\ &\quad + c_4'[I_p(*C_i\cdot) - E_a(D\cdot)] \\ &\quad + c_5'[\Delta G_s(*C_i^+ \cdots S) + \Delta G_s(D^- \cdots S)] \\ &\quad + [\Delta G_c(D^- S \cdots M) + \Delta G_c(*C_i^+ S \cdots M)] \\ &\quad - (c_6' + 1 + c_{11}')\Delta G_e(*C_i^+ S \cdots D^- S) \end{aligned} \tag{24}$$

The Rapid Initiation System (11)

Anionic Polymerization;

$$\begin{aligned}\Delta E_{(A)} &= c_7 B(C{=}C) - c_8 B(*C\text{-}C) \\ &\quad + [\Delta G_c(A^+ S \cdots M) + \Delta G_c(*C_i^- S \cdots M)] \\ &\quad - (1 + c_{11})\Delta G_e(*C_i^- S \cdots A^+ S) \end{aligned} \tag{25}$$

Cationic Polymerization;

$$\begin{aligned}\Delta E_{(C)} &= c_7' B(C{=}C) - c_8' B(*C\text{-}C) \\ &\quad + [\Delta G_c(D^- S \cdots M) + \Delta G_c(*C_i^+ S \cdots M)] \\ &\quad - (1 + c_{11}')\Delta G_e(*C_i^+ S \cdots D^- S) \end{aligned} \tag{26}$$

In the above Eqs. (23)—(26), we may regard the value of $B(*C\text{-}C)$ as a constant, because the dissociation energy of the *C-C bond is about 81 ± 3 kcal/mol. And $B(D\text{-}C)$ is constant (83 ± 4 kcal/mol) in the case of CH_3, OCH_3, NH_2 and OH as a component D, and $B(A\text{-}C)$ is constant because the hydrogen atom acts as a component A in the cationic polymerization. $B(A\text{-}D)$ is remarkably affected by the kind of catalyst (Table 1).[12,13] It is obvious in Table 1 that $B(A\text{-}D)$ varies more remarkably with the change in the electron affinity of component D than the ionization potential of component A. Then, it may be allowed that $B(A\text{-}D)$ is tentatively expressed as follows,

$$B(A\text{-}D) = c_{12} + c_{13}E_a(D) + c_{14}I_p(A) \qquad (c_{13} \gg c_{14} > 0) \tag{27}$$

where c_{12}, c_{13} and c_{14} are assumed to be the constants disregarding the kind of catalyst.

Subsequently, we tried to evaluate the solvation energy of ion with its electronic properties. Little information has, however, been reported on the

● metal cation, ○ halogen anion

solvation energies of ions determined in the various organic solvents all but water. Then, the plots of the hydration energies of ions[14] against the electron affinities of cations and the ionization potentials of anions were drawn in Fig. 1. In Fig. 1, as an electron affinity of divalent cation, the sum of the first and the second electron affinities was used, which is required to make the radical from the divalent cation. The hydration energy of the metal cation or the halogen anion has a linear relation through an origin with the electron affinity of cation or the ionization potential of anion. If there is a linear free energy relationship between the solvation energy in organic solvent and the hydration energy, the solvation energy of ion is generally expressed as follows,

$$-\Delta G_s(A^+\cdots S) = c_{15}E_a(A^+) + c_{16} \quad (c_{15} > 0) \qquad (28)$$

$$-\Delta G_s(D^-\cdots S) = c_{15}'I_p(D^-) + c_{16}' \quad (c_{15}' > 0) \qquad (29)$$

where c_{15}, c_{16}, c_{15}' and c_{16}' are the constants depending on the kind of solvents.

Moreover, it may be considered that the solvation energy of the polymer chain anion or cation is a constant in the same solvent system in consideration of the sufficient length of the polymer chain.

$$-\Delta G_s(*C_i^-\cdots S) = c_{17} \qquad (30)$$

$$-\Delta G_s(*C_i^+\cdots S) = c_{17}' \qquad (31)$$

On the other hand, it seems reasonable, from a point of quantum chemical view, that the nucleophilicity or the electrophilicity of monomer is approximately estimated by its ionization potential or electron affinity, respectively. That is, the nucleophilicity of monomer increases with a decrease in its ionization potential and the electrophilicity of monomer increases with an increase in its electron affinity. Hence, it is assumed that the co-ordination energy of monomer to ion and the electrostatic energy arised between two solvated ions are tentatively expressed as follows,

$$-\Delta G_c(A^+S\cdots M) = c_{18}E_a(A^+) - c_{19}I_p(M) + c_{20} \quad (c_{18}, c_{19} > 0) \qquad (32)$$

$$-\Delta G_c(D^-S\cdots M) = c_{18}'I_p(D^-) + c_{19}'E_a(M) + c_{20}' \quad (c_{18}', c_{19}' > 0) \qquad (33)$$

$$-\Delta G_c(*C_i^-S\cdots M) = c_{21}E_a(M) + c_{22} \quad (c_{21} > 0) \qquad (34)$$

$$-\Delta G_c(*C_i^+S\cdots M) = -c'_{21}I_p(M) + c_{22}' \quad (c_{21}' > 0) \qquad (35)$$

$$-\Delta G_e(*C_i^-S\cdots A^+S) = c_{23}E_a(A^+) - c_{24}I_p(*C_i^-) + c_{25} \quad (c_{23}, c_{24} > 0) \qquad (36)$$

$$-\Delta G_e(*C_i^+S\cdots D^-S) = -c_{23}'I_p(D^-) + c_{24}'E_a(*C_i^+) + c_{25}' \quad (c_{23}', c_{24}' > 0) \qquad (37)$$

where c_{18},$\cdots$, c_{25}, c_{18}',$\cdots$, c_{25}' are constants. And Eqs. (34) and (35) are simplified by using the relations (30) and (31).

The ionization potential and the electron affinity

14) J. D. Bernal and R. H. Fowler, *J. Chem. Phys.*, **1**, 515 (1933).

of the initiating growing radical can be considered in connection with the electronic porperties of the corresponding monomer. Although these values of all monomers are scarcely available up to the present, it is possible to evaluate those with the method of the molecular orbital theory or using some values relating to those. For instance, the ionization potential and the electron affinity are approximately expressed by the energies of the highest occupied ε_{ho} and the lowest vacant ε_{lv} π orbitals, respectively.

$$\varepsilon_{ho} = \alpha + \lambda_{ho}\beta = -I_p \tag{38}$$

$$\varepsilon_{lv} = \alpha - \eta_{lv}\beta = -E_a \tag{39}$$

(α, β: negative constants)

It is apparent from the above equations that the ionization potential is large as the λ_{ho} value is large, and that the electron affinity is large as the η_{lv} value is small.

The observed ionization potential[15] or the observed electron affinity[16] of the radical is plotted against the λ_{ho} or η_{lv} value of the corresponding monomer (in Figs. 2 and 3). Figure 4 shows the linear relation between the ionization potential of the radical and that of the monomer. From these figures, it is found that the ionization potential or the electron affinity of the initiating radical and

Lastly, we tried to evaluate the π bond dissociation energy B(C=C) of monomer H_2C=CHY with its characteristic values of the electronic structures. The observed values of B(C=C) have, however, been reported. Then, we estimated B(C=C) in term of the localization energy.[17]

$$H_2C{=}CHY \rightarrow H_2\dot{C}\text{-}\dot{C}HY \qquad \text{(ii)}$$

On the assumption that the two odd electrons of the product in the above reaction are the p-electrons, it is considered that B(C=C) may be expressed by the difference between the total energies of the radical and the monomer, as follows,

$$B(\text{C=C}) = \sum_i^{occ} \nu_i \varepsilon_{i(CH_2Y)} + \varepsilon_{(CH_3)} - \sum_j^{occ} \nu_j \varepsilon_{j(CH_2=CHY)} \qquad (42)$$

$$= \sum_i^{occ} \nu_i \lambda_i \beta_{(CH_2Y)} - \sum_j^{occ} \nu_j \lambda_j \beta_{(CH_2=CHY)} \qquad (43)$$

In Eq. (42), the first, the second and the third terms indicate the total energies of π electrons of the radicals CH_2Y and CH_3 and the monomer CH_2=CHY, respectively. Where $\sum^{occ}$ means a summation with respect to the occupied orbitals, ε_i is the π energy of the ith orbital, λ_i the coefficient of β_i in Eq. (38) and ν_i the number of π electron in the ith orbital.

It is found from the results that B(C=C) of monomer CH_2=CHY varies remarkably with the kind of substituent Y. In order to evaluate B(C=C) with its characteristic values, the plots of B(C=C) against the summation $(\lambda_{ho}+\eta_{lv})$ of the coefficinets of β in the highest occupied and the lowest vacant π orbitals of monomer were drawn in Fig. 5. From the linear relationship between B(C=C) and $(\lambda_{ho}+\eta_{lv})$, the π bond dissociation energy may be expressed as follows,

$$B(\text{C=C}) = c_{28}(\lambda_{ho}+\eta_{lv}) + c_{29} \quad (c_{28} > 0) \qquad (44)$$

$$= c_{30}(I_p(\text{M}) - E_a(\text{M})) + c_{31} \quad (c_{30} > 0) \qquad (45)$$

From a series of the above considerations (27)—(45), it is concluded that the overall activation energy of ionic polymerization may be expressed as follows,

The Slow Initiation System (9)
Anionic Polymerization;

$$\Delta E_{(A)} = k_1 + k_2 E_a(\text{D}) \pm k_3 I_p(\text{A}) - k_4 E_a(\text{M}) + k_5 I_p(\text{M}) \qquad (46)$$

Cationic Polymerization;

$$\Delta E_{(C)} = k_1' + k_2' I_p(\text{A}) - k_3' E_a(\text{D}) + k_4' I_p(\text{M}) - k_5' E_a(\text{M}) \qquad (47)$$

where $k_1,\cdots, k_5, k_1',\cdots, k_5'$ are the positive constants. The coefficient of I_p(A) in Eq. (46) represents the term, $(c_4+c_{23}+c_1c_{14}+c_6c_{23}+c_{11}c_{23})-(c_{18}+c_5c_{15})$, and might change in sign since the constants c_{15}, c_{18} and c_{23} are those to depend on the kind of solvent.

The Rapid Initiation System (11)
Anionic Polymerization;

$$\Delta E_{(A)} = k_6 \pm k_7 I_p(\text{A}) - k_8 E_a(\text{M}) + k_9 I_p(\text{M}) \qquad (48)$$

Cationic Polymerization;

$$\Delta E_{(C)} = k_6' - k_7' E_a(\text{D}) + k_8' I_p(\text{M}) - k_9' E_a(\text{M}) \qquad (49)$$

where $k_6,\cdots, k_9, k_6',\cdots, k_9'$ are the positive constants and the coefficient of I_p(A) in Eq. (48) might change in sign by the kind of solvent.

In the polymerization that the contribution to the activation energy of the monomer co-ordination to the growing ion is larger than that to the counter ion, these equations lead to the reasonable conclusion that the monomer reactivity in anionic polymerization increases as the electron affinity of the monomer increases, and that in cationic polymerization increases as the ionization potential of

17) G. W. Wheland, *J. Am. Chem. Soc.*, **64**, 900 (1942).

the monomer decreases.*1 On the attention to the catalyst in the polymerization of the same monomer, the catalytic activity in anionic polymerization increases as the electron affinity of component D decreases, whereas that in cationic polymerization increases as the electron affinity of D increases and as the ionization potential of A decreases.

On the basis of these energetic considerations, the monomer reactivity and the catalytic activity will be quantitatively discussed in the subsequent paper.

The authors are grateful to Professor Kenichi Fukui and Professor Teijiro Yonezawa for their valuable suggestions while carrying out this study.

*1 As Eq. (41) shows, $I_p(M)$ is positively proportional to $I_p(*C_i\cdot)$. It is found in a homologous series that there exists the positive linear relation between $I_p(*C_i\cdot)$ and $I_p(*C_i^-)$, *cf.*, $I_p(*C_i\cdot)$ and $I_p(*C_i^-)$ for the alkyl radicals are in units of eV 9.95 and 1.1 for methyl, 8.78 and 0.9 for ethyl, 8.69 and 0.8 for *n*-propyl, 8.64 and 0.65 for *n*-butyl, and 7.90 and 0.5 for isopropyl radical. According to this relation, the activation energy of the anionic polymerization is given as follows, $\Delta E_{(A)}=k_{10}-k_{11}E_a(M)+k_{12}I_p(*C_i^-)$. This equation indicates that the activation energy of the anionic polymerization decreases as the electron affinity of monomer is large and the ionization potential of the corresponding growing anion is small, in other words, that it is dominated with the energetic difference between the lowest vacant level of monomer and the highest occupied level of the growing anion. Similarly, the activation energy of the cationic polymerization is given as follows, $\Delta E_{(C)}=k_{10}'+k_{11}'I_p(M)-k_{12}'E_a(*C_i^+)$, and it is dominated with the energetic difference between the highest occupied level of monomer and the lowest vacant level of the growing cation. In words of the quantum chemical view, the concept that one may discuss the reactivity of monomer in ionic polymerization with the relative difference of the electronic states between the monomer and the growing ion, can be considered to correspond to the treatment of the zero-order perturbation.

A Structural Study on the Catalytic Activity in Ionic Polymerization

Tsutomu KAGIYA, Yūzō SUMIDA and Tetsuya NAKATA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 29, 1967)

According to the theoretical conclusion reported previously on the activation energy of the catalytic polymerization, the experimental results relating to the monomer reactivity and the catalytic activity in anionic or cationic polymerization were interpreted. The catalytic activity in ionic polymerization can be quantitatively compared with the relative magnitude of the ionization potential or the electron affinity of monomer and components (A, D) of catalyst (AD). As a measure of the ionization potential or the electron affinity of monomer, the energy of the highest occupied ($\varepsilon_{ho}=\alpha+\lambda_{ho}\beta$) or the lowest vacant ($\varepsilon_{lv}=\alpha-\eta_{lv}\beta$) π level of the monomer has been used, and as a measure of the electron affinity of component D, the pK_a of the acid HD or the σ_I value. In anionic polymerization, it was found that the polymerization by the catalyst with the same component A took place only in the combination of the monomer and the catalyst in which the η_{lv}/pK_a value was less than about 2.5×10^{-2}, and that the catalytic activity, with the same component D, depends on the kind of solvent. The results in cationic polymerization were also discussed in connection with the electron affinity of component D or co-catalyst. And the monomer reactivity in ionic polymerization with the same catalyst was quantitatively discussed with the η_{lv} or λ_{ho} value of monomer. From the accordance between the theoretical consideration and the experimental data, the present treatment was found to be useful for the purpose of the quantitative study of the catalytic activity and the monomer reactivity in ionic polymerization.

In the past ten years, many works on ionic polymerization have been accumulated. Little attention has, however, been paid to the relation between the catalytic activity and the structure of the catalyst.

In the previous paper,[1] the authors made a study on the energetic consideration of ionic polymerization and reported that the monomer reactivity could be compared with the relative magnitude of the electronic natures of monomer and catalyst components.

1) T. Kagiya, Y. Sumida and T. Nakata, This Bulletin, **41**, 2239 (1968).

The purpose of this paper is to determine the relation between the catalytic activity and the structure of the catalyst on the basis of the energetic study reported previously. It was found that the relative magnitude of the catalytic activity is closely related to the electronic structures of catalyst and monomer. The theoretical treatment was found to be useful for the purpose of a systematical interpretation of many kinds of experimental results.

Theoretical

As have been described in the previous paper,[1] the overall activation energy of ionic polymerization with the slow or the rapid initiation[2] is expressed as follows,

The Slow Inititation System
Anionic Polymerization;

$$\Delta E_{(A)} = k_1 + k_2 E_a(\mathrm{D}) \pm k_3 I_p(\mathrm{A}) - k_4 E_a(\mathrm{M}) + k_5 I_p(\mathrm{M}) \quad (1)$$

Cationic Polymerization;

$$\Delta E_{(C)} = k_1' - k_2' E_a(\mathrm{D}) + k_3' I_p(\mathrm{A}) + k_4' I_p(\mathrm{M}) - k_5' E_a(\mathrm{M}) \quad (2)$$

The Rapid Initiation System
Anionic Polymerization;

$$\Delta E_{(A)} = k_6 \pm k_7 I_p(\mathrm{A}) - k_8 E_a(\mathrm{M}) + k_5 I_p(\mathrm{M}) \quad (3)$$

Cationic Polymerization;

$$\Delta E_{(C)} = k_6' - k_7' E_a(\mathrm{D}) + k_8' I_p(\mathrm{M}) - k_5' E_a(\mathrm{M}) \quad (4)$$

where $k_1, \cdots, k_8, k_1', \cdots, k_8'$ are the positive constants. k_3 and k_7 depend on the kind of solvents. M: monomer, AD: catalyst, D: conjugated component acting as the electron donor, A: conjugated component acting as the electron acceptor. E_a and I_p are an electron affinity and an ionization potential, respectively. In the polymeriaztion that the contribution to the activation energy of the monomer co-ordination to the growing ion is larger than that to the counter ion, the last terms in these equations (1)—(4) contribute less to the change in the overall activation energy of the polymerization.

According to the energetic consideration of the catalytic polymerization, the catalyst give mainly an effect on the initiation and propagation reactions.[1,3] And, since the activation energy of the initiation reaction is larger than that of the propagation in the polymerization with the slow initiation, the overall catalytic activity can be discussed quantitatively with Eqs. (1) and (2). It is evident from Eqs. (1) and (2) that the overall activation energy of the anionic polymerization decreases as the electron affinity of D decreases, whereas that of the cationic polymerization decreases as that of D increases. The electron accepting component A of the catalyst is usually a metal or hydrogen atom, and the data of the ionization potentials of their compounds have been reported, while those of the electron affinities of D have not.

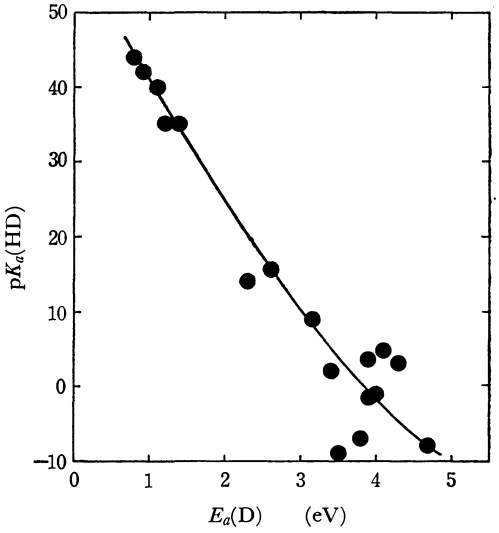

Fig. 1. Relation between the electron affinity of component D and the pK_a value of the conjugated acid HD.

In order to evaluate the electron affinity of D with the parameter corresponding to it, the relation between the E_a(D) value and the pK_a value of the conjugated acid HD[4,5] was investigated as shown in Fig. 1. E_a(D) can be approximately evaluated with pK_a(HD) as follows,

$$E_a(\mathrm{D}) = -k_9 \mathrm{p}K_a(\mathrm{HD}) + k_{10} \quad (k_9 > 0) \quad (5)$$

Therefore, the overall activation energy of the polymerization with the slow initiation by the catalyst with the same component A is given as follows, neglecting the last terms,

$$\Delta E_{(A)} = k_{11} - k_{12} \mathrm{p}K_a(\mathrm{HD}) - k_4 E_a(\mathrm{M}) \quad (6)$$

$$\Delta E_{(C)} = k_{11}' + k_{12}' \mathrm{p}K_a(\mathrm{HD}) + k_4' I_p(\mathrm{M}) \quad (7)$$

where k_{11}, k_{12}, k_{11}' and k_{12}' are constants.

Since the electron affinity of D is one of the measures of the electron withdrawing character of D, it is considered to be related to the inductive substituent constant σ_I. Figure 2 shows the relation between them. In a similar manner as described above, the overall activation energy can

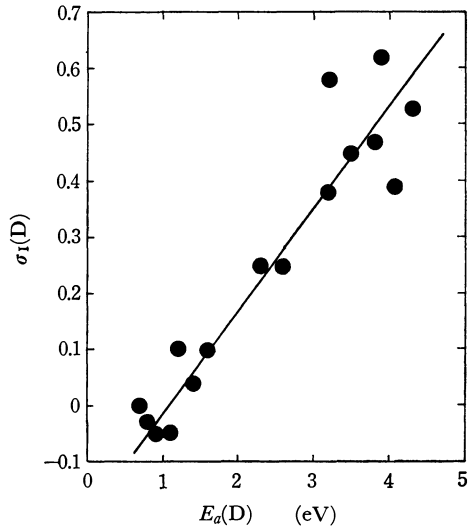

Fig. 2. Relation between the electron affinity of component D and the inductive substituent constant σ_I.

be expressed by the following equations, neglecting the last terms, instead of Eqs. (1) and (2),

$$\Delta E_{(A)} = k_{13} + k_{14}\sigma_I(D) - k_4 E_a(M) \quad (k_{14}>0) \tag{8}$$

$$\Delta E_{(C)} = k_{13}' - k_{14}'\sigma_I(D) + k_4' I_p(M) \quad (k_{14}'>0) \tag{9}$$

where k_{13}, k_{14}, k_{13}' and k_{14}' are constants.

The Eqs. (1)—(9) were used to discuss whether a certain compound in connection with the structures of catalyst and monomer has a catalytic activity or not.

Interpretation of Experimental Data

Monomer Reactivity and Catalytic Activity in Anionic Polymerization. As have been described in the preceding chapter, the monomer reactivity and the catalytic activity in anionic polymerization can be compared with the electron affinity of monomer and catalyst component D. Little information has, however, been reported on the electron affinities of various monomers except those of some components D. Then, as described in the previous paper,[1] the η_{lv} values of vinyl monomers were calculated as the parameter relating to the electron affinity and the results were summarized in Table 1 in the order of the smaller value. The observed half wave reduction potential[6] relating to the electron affinity is also tabulated in Table 1.

There is a general tendency that the monomer polymerizes more easily as its η_{lv} value is small, and that the order of the monomer reactivity is nearly in accordance with the empirical informations. In order to discuss quantitatively this fact, Fig. 3 was drawn. The half wave reduction potential was adopted as a measure of the electron affinity, and the reactivity[7] of monomer with the CH_3O^- or n-$C_{12}H_{25}S^-$ anion as its reactivity in anionic polymerization.

On the other hand, Higginson *et al.*[8] studied the reactivity of some vinyl monomers catalysed by the sodium salts of various weak acids and pointed out that the occurrence of the polymerization had some relations to the pK_a of the original acids and the color resulting from the addition of the catalyst into the monomer.

In Eq. (6), the overall activation energy of anionic polymerization with the same component A is given by the following equation,

$$\Delta E_{(A)} = k_{15} - k_{12}pK_a(HD) + k_{16}\eta_{lv}(M) \quad (k_{12},\ k_{16}>0) \quad (10)$$

In order to discuss the catalytic activity in connection with the property of monomer, it is necessary to claculate the value of $(-k_{12}pK_a(HD)+k_{16}\eta_{lv}(M))$. This value, however, cannot be calculated in practice. Then the η_{lv}/pK_a value was examined here and summarized in Table 2. Table 2 shows that the polymerization occurs in the combination of the monomer and the catalyst in which the η_{lv}/pK_a value is less than about 2.5×10^{-2}.

Tsuruta *et al.*[9] discussed the possibility of the anionic polymerization in connection with the structures of monomer and catalyst as shown in Table 3. In Table 3, (a) group of catalyst gives the polymer of the monomer in group (A), (B) and (C), (b) group (B) and (C) groups but not (A), and (c) group (C) group but not (A) and (B) groups. In order to study the result by using the above conclusion, the η_{lv}/pK_a values have been calculated. The results obtained also indicate that the polymerization takes place only in the combination of the catalyst and the monomer in which the η_{lv}/pK_a value is less than about 2.5×10^{-2}. It is concluded from the above facts that η_{lv}/pK_a value is an important parameter for evaluation of the catalytic activity in anionic polymerizations.

It is also considered that the analogous condition described above is preserved in the propagation reaction in anionic polymerization. In order to examine this inference, the η_{lv}/pK_a value was calculated as to the several vinyl monomers, where CH_3Y may be considered to be employed as the conjugated acid CH_2DCHY - CH_2CH_2Y of the propagating anion CH_2DCHY - CH_2C^-HY of the monomer CH_2=CHY. It is apparent in Table 4 that the η_{lv}/pK_a parameter is a good index to predict the occurrence of the anionic polymerizations.

Szwarc *et al.*[10] studied the anionic polymerization of styrene in tetrahydrofuran and in dioxane, and observed that the rate of propagation is dependent on the kind of counter ions and the nature of solvents. This result may be also discussed by Eq. (3). In the case of the same monomer and the

same conjugated component D of catalyst, Eq. (3) may be written as follows,

$$\log k = k_{17} \pm k_{18} I_p(\mathrm{A}) \quad (k_{18} > 0) \qquad (11)$$

where k is a rate constant of the propagation reaction, k_{17} and k_{18} are constants, and k_{18} depends on the kind of solvent. Figure 4 indicates that Eq. (11) can approximately express the change of the propagation rate with the counter metals.

Monomer Reactivity and Catalytic Activity in Cationic Polymerization. As the same manner, the λ_{ho} values of various vinyl monomers were calculated in the order of the smaller value as shown in Table 5. There is a general tendency that the monomer polymerizes more easily as its λ_{ho} value is smaller, and that the monomer whose ionization potential[11-14] is larger than about 10.2 eV occurs no longer a cationic polymerization. The order of the monomer reactivity is nearly in accordance with the empirical informations. Figure 5 shows the relation between the rate constant of propagation in the cationic polymerization of the styrene derivatives[15] and their ionization potentials.[11] These results also lead to the conclusion that the quantitative treatment in the previous paper[1] represents satisfactorily many experimental data on the monomer reactivity in the cationic polymerization.

On the other hand, Yokota *et al.*[16] studied the kinetics of the polymerization of formaldehyde by the various proton acids in liquid carbon dioxide, and reported that this polymerization belonged to a type of the stationary successive with the rapid initiation[2] and the catalytic activity was remarkably changed by the kind of counter anions. Substituting Eq. (5) into Eq. (4), it is expected that the following relation exists between the rate of polymerization and the pK_a value of the acid of the catalyst,

$$\log R = k_{19} - k_{20} \mathrm{p}K_a(\mathrm{HD}) \quad (k_{20} > 0) \qquad (12)$$

where R is a rate of polymerization, k_{19} and k_{20}

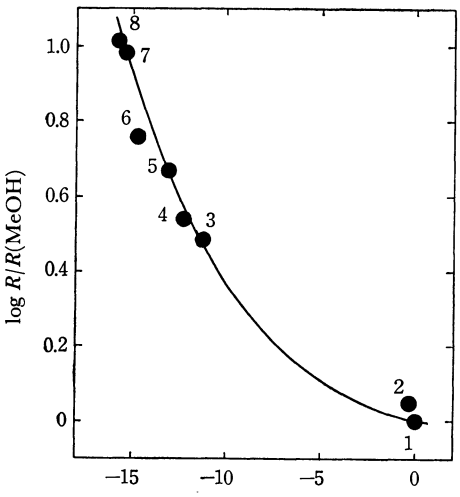

Fig. 6. Effect of the pK_a value of catalyst on the rate of cationic polymerization of formaldehyde. (1) Methanol, (2) Water, (3) Acetic acid, (4) Formic acid, (5) Monochloroacetic acid, (6) Dichloroacetic acid, (7) Trichloroacetic acid, (8) Trifluoroacetic acid.

are constants. As shown in Fig. 6, the relation (12), that is, Eq. (4) holds good in the cationic polymerization.

In both of the cationic polymerization of styrene catalysed by Lewis acids[17] and the racemization of 1-phenylethyl chloride,[18] the cationic activity of Lewis acids is in the order as follows,

$$\underset{(252)}{SbCl_5} \gg \underset{(175)}{TiCl_4} > \underset{(163)}{AlBr_3} > \underset{(133)}{SnCl_4} \gtrsim \underset{(141)}{FeCl_3} > \underset{(57)}{ZnCl_2} > \underset{(52)}{HgCl_2}$$

These Lewis acids react with the co-catalyst to form the counter anions of the growing chain end. Therefore, it is expected that an increase in the cationic activity of Lewis acid is arised from an increase in its acidity. Okamura *et al.*[17] employed the heat of solution of Lewis acid and ethyl acetate as a measure of the acidity of Lewis acid. Present authors used the shift of the characteristic band of the carbonyl group in the infrared spectrum of the Lewis acid-xanthone complex,[19] and reported[20] that an increase in the shift showed an increase in the acidity of Lewis acid. The values in parentheses in the above relation represent the magnitude of the carbonyl shift. There is a good correlation between the catalytic acitivity and the carbonyl shift in the Lewis acid-xanthone complex.

Similarly, the activity of co-catalysts in the polymerization system of the same monomer and the same Lewis acid catalyst, for example, in the cationic polymerization of isobutene catalysed by tin chloride,[21] decreases in the order,

$$\underset{(pK_a=0.64)}{CCl_3COOH} > \underset{(2.87)}{CH_2ClCOOH} > \underset{(4.76)}{CH_3COOH} > \underset{(9)}{CH_3CH_2NO_2} > \underset{(11)}{CH_3NO_2} > \underset{(10)}{C_6H_5OH} > \underset{(15)}{H_2O}$$

As the pK_a value of co-catalyst decreases, its activity increases, and Eq. (7) is satisfied.

As described above, in any cases of anionic and cationic polymerization the energetic treatment in the previous paper was found to be useful to explain quantitatively many kinds of experimental data.

The authors are grateful to Professor Kenichi Fukui and Professor Teijiro Yonezawa for their valuable suggestions while carrying out this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2254—2257 (1968)

SCFMO Parameters for Heteroatoms donating Lone Pairs

Kichisuke NISHIMOTO*1 and Leslie S. FORSTER

Department of Chemistry, University of Arizona, Tucson, Arizona, U.S.A.

(Received January 26, 1968)

The interrelationships between the semi-empirical parameters involved in SCFMO calculations have been considered. The calculated transition energies for molecules containing an atom that donates two electrons to the π-system are mainly dependent upon the first valence state ionization energy of the heteroatom, and the nearest-neighbor two center repulsion integrals.

The proliferation of semi-empirical SCFMO calculations has been accompanied by an ever widening array of parameter sets. This diversity is particularly evident in the parameters assigned to nitrogen and oxygen atoms donating two electrons to the π-system. Thus, good results have been obtained for the aniline spectrum when the nitrogen valence state ionization energy has been varied from 22.49 to 28.63 eV[1,2] and as an extreme cases, a successful calculation has been made with the nitrogen and carbon valence state ionization energies (V.S.I.E.) set equal.[3]

In addition to the V.S.I.E., I_μ, the parameters involved in SCFMO calculations in the Pariser-Parr-Pople approximation are the one and two center repuslion integrals, $\gamma_{\mu\mu}$ and $\gamma_{\mu\nu}$, and the core resonance integrals, $\beta_{\mu\nu}$. A number of systematic studies have been made on the effects of these parameters upon the electronic structure of aniline.[1,2,4,5] In some of this work, the interrelationships between the parameters have been implicit but insufficiently stressed. It is the purpose of the present note to focus attention on the more important aspects of the parameterization problem.

Method of Calculation

In the SCF variant of the Pariser-Parr-Pople method,[6] the $\boldsymbol{F}$ matrix is diagonalized, $\boldsymbol{F}\psi_i=\varepsilon_i\psi_i$. The eigenvalues, ε_i, and eigenvectors, $\psi_i=\sum C_{i\mu}\phi_\mu$, may then be used to compute the energies of an excited singlet configuration, χ_{i-j}, from the expression $E_{i-j}=\varepsilon_j-\varepsilon_i-(ii/jj)+2(ij/ij)$. Configuration interaction is then invoked. The off-diagonal elements of the CI matrix involve the repulsion integrals, $(kl/mn)=\int\psi_k(1)\psi_l(1)(1/r_{12})\cdot\psi_m(2)\psi_n(2)\mathrm{d}v$, that depend on the coefficients of the molecular orbitals. The elements of $\boldsymbol{F}$ are

$$F_{\mu\mu}=-I_\mu+\frac{1}{2}q_\mu\gamma_{\mu\mu}+\sum_{\nu\neq\mu}(q_\nu-n_\nu)\gamma_{\mu\nu} \quad (1)$$

$$F_{\mu\nu}=\beta_{\mu\nu}-\frac{1}{2}p_{\mu\nu}\gamma_{\mu\nu} \quad . \quad (2)$$

Where q_μ and $p_{\mu\nu}$ are the diagonal and off-diagonal elements, respectively, of the bond order-charge density matrix and n_ν is the number of electrons. 1 or 2, donated to the π-system by the νth atom.

The $\boldsymbol{F}$ matrix is then solved iteratively to self-consistency. The solutions are mainly dependent on the diagonal and nearest neighbor off-diagonal elements of $\boldsymbol{F}$.

Diagonal F Elements

For most of neutral molecules, $q_\nu-n_\nu$ is rather small and Eq. (1) can be written

$$F_{\mu\mu}\simeq-I_\nu+\frac{1}{2}q_\mu\gamma_{\mu\mu}$$

In the Pariser-Parr approximation, $\gamma_{\mu\mu}=I_\mu-A_\mu$. For $n_\mu=1$ and $q_\mu\simeq1$

$$F_{\mu\mu}\simeq-\frac{1}{2}I_\mu-\frac{1}{2}A_\mu$$

where A_μ, the electron affinity, is generally small. When $n_\mu=2$, $\gamma_{\mu\mu}=I_2-I_1$, the difference in the first and second V.S.I.E. For $q_\mu\simeq2$

$$F_{\mu\mu}\simeq-I_1=-I_\mu$$

Consequently, the diagonal elements of $\boldsymbol{F}$ are dependent principally upon the first V.S.I.E.

The validity of this approximation can be appreciated by reference to Table 1 and Fig. 1, wherein the computations of the aniline spectrum by a number of workers are summarized. With the exception of calculations 6, 9, and 10 which

\+ $I_N - I_C$ given
++ nearest neighbor $\gamma_{\mu\nu}$ reduced

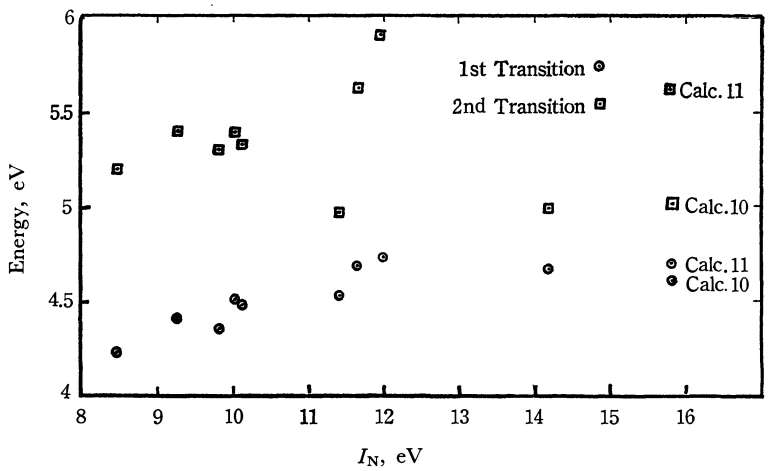

Fig. 1. Dependence of the two lowest aniline transition energies on $I_1 = I_2 - \gamma_{N-N}^{++}$. Parameters employed with each I_1 are listed in Table 1.

will be discussed below, the energies of the two lowest transitions lie close to a smooth curve, indicating a functional relationship depending only on the first V.S.I.E. of nitrogen.

This dependence upon I_1 is shown more graphically in Fig. 2 where only I_1 is varied for each curve. For the $-NH_2$ group, a constant β approximation ($\beta_{CC} = \beta_{CN} = -2.38$ eV) and the variable β approximation ($\beta_{CC} = -0.51p - 2.04$ eV and $\beta_{CN} = 0.53p - 2.24$ eV) yield the same curves. The repulsion integrals were claculated by the NM prescription[7];

$$\gamma_{\mu\nu} = 14.397/(a_{\mu\nu} + r_{\mu\nu}) \text{ eV}.$$

It is interesting to note that the phenol spectrum is well represented by the Fig. 2 curves. In the phenol calculation

$$I_O^+ - \gamma_{O-O}^{++} = 11.4 \text{ eV}$$

This leads to (Fig. 2) 4.67 and 5.75 eV which may be compared to 4.62 and 5.76 eV obtained from the usual variable β computation.[7] The aniline experimental transition energies are 4.34 and 5.29 eV and good results are obtained when $I_N^+ - \gamma_{N-N}^{++} \simeq 9$ eV.

Off-diagonal *F* Elements

Bloor, Daykin and Boltwood[5] have determined the effect of β_{CN} on the aniline transition energies and found that a variation from −2.00 to −2.75 eV leaves the lowest transition energy essentially unchanged, and produces only a 0.30 eV change in the second transition energy.

The nearest neighbor $\gamma_{\mu\nu}$ and $\beta_{\mu\nu}$ are interrelated by Eq. (2) and $F_{\mu\nu}$ would be but little affected by changes in $\gamma_{\mu\nu}$. Thus, the ***F*** matrix, and therefore

7) K. Nishimoto and L. S. Forster, *Theor. Chim. Acta*, **4**, 155 (1966).

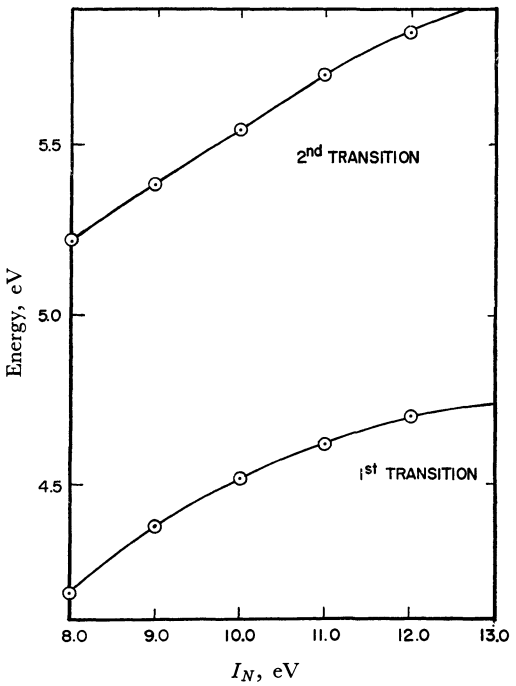

Fig. 2. Dependence of the two lowest aniline transition energies on I_1. Variable parameterization (NM integrals)[7] employed in all calculations.

the ground state charge distribution, are not very dependent on the repulsion integrals.

The statements in this section are applicable only to the systems with weakly interacting substituents, wherein, the spectrum of the parent molecule is not perturbed too greatly by the substituent(s). When many heteroatoms are incorporated into the π-system, *e. g.* uracil and isoalloxazine,[8] the off-diagonal $F_{\mu\nu}$ may be quite dependent upon the parameter choice.

Configurational Energies and Configuration Interaction

As noted above, neither the $\gamma_{\mu\mu}$ nor $\gamma_{\mu\nu}$ choice markedly affects the eigenvalues or the eigenvectors of the $\boldsymbol{F}$ matrix. Both the diagonal elements (configurational energies) and off-diagonal elements of the CI matrix depend upon the repulsion integrals over molecular orbitals, (kl/mn). These in turn are functions of the eigenvectors of the $\boldsymbol{F}$ matrix and the $\gamma_{\mu\mu}$ and $\gamma_{\mu\nu}$ integrals. The effect of nearest-neighbor $\gamma_{\mu\nu}$ is marked. In the Pariser-Parr calculation, $\gamma_{\mu\nu}$ were computed by a quadratic interpolation and the calculated energy of the 2nd benzene transition was 0.7 eV too small.[9] Reducing the nearest-neighbor $\gamma_{\mu\nu}$ rectifies this problem.[10,11] The drastic lowering or the second aniline transition in calculations 6, 9, and 10 can be ascribed to the larger $\gamma_{\mu\nu}$ employed.[1]

The use of the Nishimoto-Mataga technique for evaluating $\gamma_{\mu\nu}$[12] circumvents this difficulty.[1,3,7]

Core Charge Effect

In all of the calculations described in Table 1 and Figs. 1 and 2, N^{++} ($n_N=2$) was assumed. It should be possible by a suitable adjustment of the parameters to obtain appropriate $F_{CC}-F_{NN}$ differences (3—4 eV) when $n_N=1$, and we find that this is indeed the case. In contrast to the situation for transition energies where only the differences in diagonal F elements are imporatant, computation of ionization potentials from the orbital energies requires appropriate absolute values of the diagonal F elements. In this regard the N^+ core is quite unsuitable since very small (or even negative) ionization potentials are obtained with this assumption.

One Center Repulsion Integrals

Paolini[13] has suggested that $\gamma_{\mu\mu}$ is proportional to the Z_{eff} (computed from the Slater rules) of the neutral species. In the Pariser-Parr method:

$$\gamma^{+}_{N-N^{+}} = I_N - A_N$$

$$N[(sp^2)^4p_z, V_3] \rightarrow \overset{+}{N}[(sp^2)^4, V_2]: I_N$$

$$\bar{N}[(sp^2)^4p_z^2, V_2] \rightarrow N[(sp^2)^4p_z, V_3]: A_N$$

and

$$\gamma^{++}_{N-N^{++}} = I_2 - I_1$$

$$N[(sp^2)^3p_z^2, V_3] \rightarrow \overset{+}{N}[(sp^2)^3p_z, V_3]: I_1$$

$$\overset{+}{N}[(sp^2)^3p_z, V_4] \rightarrow \overset{++}{N}[(sp^2)^3, V_3]: I_2$$

Thus, $\gamma^{++}_{N-N^{++}}$ and $\gamma^{+}_{N-N^{+}}$ represent the repulsion between two p_z electrons in systems with different Z_{eff}. If we relate these quantities by

$$\gamma^{++}_{N-N^{++}}/\gamma^{+}_{N-N^{+}} = Z_{\text{neutral}}/Z_{\text{anion}} \qquad (3)$$

then $\gamma^{++}_{N-N^{++}}=1.1\gamma^{+}_{N-N^{+}}$. However, $\gamma_{\mu\mu}$ as used in Eq. (1) will depend upon the net charge on the μth atom. A large net positive charge will occur when $n_N=2$ and $\gamma^{++}_{N-N^{++}}$ should be larger than estimated by Eq. (3). The ratio of the two $\gamma_{\mu\mu}$ quantities used in our previous work is 1.4,[7] a reasonable value. In any event, whenever the

results are sensitive to $\gamma_{\mu\mu}$ choice, the $\gamma_{\mu\mu}$ magnitudes assigned to the $n=2$ and $n=1$ atoms should differ as indicated above.

Conclusion

If semi-empirical SCFMO calculations are used for spectral interpretations of systems with weakly interacting substituents, good results can be obtained by the appropriate choice of I_μ and nearest-neighbor $\gamma_{\mu\nu}$; the other parameters may be varied over a wide range with minor effect.

The experimental ionization potential for CH_3NH_2 is 9.26 eV,[14] a value suitable for I_1, in the calculation of the aniline transition energies. This suggests that the experimental ionization potentials for CH_3X can be used for I_1 whenever X is a substituent donating two electrons to the π-system. Consequently, the following I_1 quantities are recommended.

X	I_1 (eV)[14]
-OH	11.37
$-OCH_3$	10.52
$-NH_2$	9.26
$-NHCH_3$	8.53
$-N(CH_3)_2$	8.11

The nearest-neighbor off-diagonal F elements are approximately -4 eV. This corresponds to β in a Hückel calculation. Since $F_{NN}-F_{CC}\simeq-4$ eV, it is reasonable to express the Hückel coulomb parameter as $\alpha_N=\alpha+\beta$ for NH_2 group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2257—2263 (1968)

Changes in Catalytic Activity and Surface Properties of Nickel Oxide with Gamma-Irradiation

Toshiro YAMASHINA, Takaaki NAGAMATSUYA*1 and Masakatsu SANO

Faculty of Engineering, Hokkaido University, Sapporo

(Received January 27, 1968)

The nature of the active sites of nickel oxide has been studied by changing surface properties by means of γ-irradiation technique. Using powdered nickel oxide catalyst, catalytic activities, surface excess oxygen contents, electrical conductivity changes during thermal desorption of gases, and reactivities of the sample with CO_2, CO and H_2 were compared as a function of γ-ray dose of preirradiation. It has been found that the catalytic activity, the excess oxygen content and the conductivity change with the increase in the irradiation dose, and the change is remarkable when a total dose is greater than 1×10^8R. The catalytic activity for the decomposition of H_2O_2 was observed to increase, while that for the decomposition of i-C_3H_7OH vapor was observed to decrease with the irradiation dose. Measurements on the desorption of excess oxygen and the adsorption of CO_2 simultaneously with electrical conductivity have indicated that the adsorbed state of surface oxygen may be changed into a strong form by the irradiation, as $O^-_{(ad)} \rightsquigarrow O^{2-}_{(ad)}$. Discussions have been made on the correlation between the catalytic sites and surface properties of the irradiated nickel oxide.

Many studies have been made on the surface chemistry of nickel oxide as well as that of other transition-metal oxides, and particular interest is shown in the surface heterogeneity of the oxides. The surface heterogeneity of powdered nickel oxide has been investigated by various methods, including the determination of the distribution of surface excess oxygen,[1] isotopic exchange reaction technique,[2,3] electrical conductivity measurement during adsorption or desorption,[4] deactivation with CO_2 adsorption[5,6] and so on. However, there has been discrepancy among the results of

different workers. This may be due to the difference in the method of sample preparation or experimental procedures. Accordingly, many unresolved problems on active sites and the chemical reactivity of nickel oxide surface have been remained.

The present investigation was undertaken to obtain some informations as to the state of surface excess oxygen in connection with active sites and the surface reactivity of nickel oxide. By means of irradiation the surface state of the oxide could be changed selectively. Thus the surface state has been examined from many viewpoints such as catalytic activity, the nature of excess oxygen, electrical conductivity and adsorption of gases as a function of irradiation dose of γ-rays.

Some results on the nature of the irradiated nickel oxide, *i. e.*, on the catalytic activity for the decomposition of H_2O_2 solution[7] and the reduction kinetics by H_2,[8] have been reported previously by the present authors. The purpose of this report is to describe some additional results of the previous study and some preliminary results obtained by using an apparatus connected with a quadrupole mass spectrometer for the adsorption and the desorption of CO_2 and i-C_3H_7OH.

Experimental

Materials. NiO sample was obtained by decomposing and firing CP grade nitrate in air at 500°C for 5 hr after a gentle evaporation of the dilute solution of the nitrate. The oxide product was reduced to a granular form (100—200 mesh). The BET surface area of this sample measured by nitrogen adsorption was 9—10 m^2/g. Carbon monoxide (99.5%), carbon dioxide (99.95%) and isopropanol (spectro-grade) were obtained commercially. Hydrogen was purified by diffusing the crude gas through a palladium film.

Irradiation of sample was carried out in air at room temperature with Co-60 γ-rays, the intensity of which was 5.85×10^5 R/hr; total dose reached about 1×10^9 R.

Catalytic Activity. The catalytic activity of NiO was determined by using the decomposition of a 7.5% hydrogen peroxide solution as a model reaction. The rate of reaction was followed by measuring the volume of oxygen evolved per minute with the apparatus shown previously.[9] A 0.2 g catalyst sample was used for each run and the reaction temperature was 25—45°C. Before each run, the decomposition rate without catalyst was measured. Negligibly small amount of decomposition less than about 5% of that with catalyst was found to occur. The reproducibility in the determination of the catalytic activity was found to be better than 5%. The activity for the decomposition of i-C_3H_7OH was also measured by means of the apparatus described previously.[10]

Excess Oxygen Content and Electrical Conductivity Measurements. The quantity of excess oxygen in NiO was determined by an iodometric titration[9] and a gravimetric method with a vacuum microbalance. Chemical analysis by the iodometry was performed as follows: 0.5 g of KI, 50 m*l* of 35% HCl and 100 m*l* of H_2O were added to 0.5 g of catalyst sample and the sample was dissolved by heating gently. Under a nitrogen flow, the solution was cooled and allowed to stand in darkness, then the titration was made with a 0.01 N $Na_2S_2O_3$ solution as quickly as possible. Replicate titration experiments were made at least five times, the reproducibility in the determination being found to be better than 10%.

Electrical conductivity measurements were made by means of AC and DC potentiometric methods with a cell for powdered NiO shown in Fig. 1. An 1.0 g catalyst

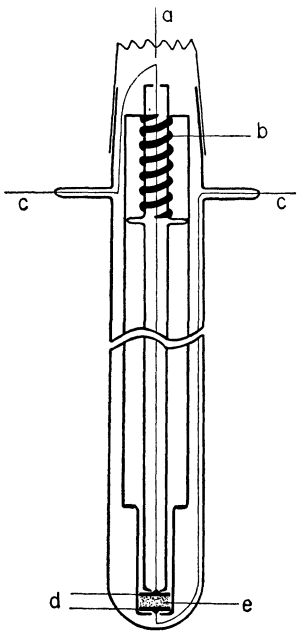

Fig. 1. Electrical conductivity cell.
a: to vacuum system, b: spring,
c: Pt leads for electrical measurements,
d: Pt disc, e: powdered sample

sample was inserted between two platinum plates (disc of 1 cm in diameter) and pressure of about 2 kg/cm^2 was applied with a steel spring. The closed end of a quartz tube containing the cell connected to a vacuum line was inserted into an electric furnace, then changes in the conductivity during the adsorption or the desorption of gases were measured. The resistivities of NiO were observed to be in the range from 10^5 to 10^8 Ω. Determinations both by the AC and DC methods gave nearly identical values of the resistance, and no polarization effect was observed in the measurement by the DC method. Accordingly, the following results in the present paper were obtained mainly by the DC method.

Adsorption and Desorption Measurements. Changes in the weight of catalyst samples during adsorption or desorption of gases were measured in an all

glass closed system of a Gulbransen type microbalance having the sensitivity of 7.21×10^{-7} g/div. (1 div.= 0.01 mm). The total volume of the system was about 1800 m*l*, and the system could be evacuated below 1×10^{-5} mmHg.

The rate of decomposition of i-C_3H_7OH adsorbed on nickel oxide was measured by using a vacuum apparatus having a mass spectrometer described previously.[10] The essential feature of the apparatus was the connection of the reaction vessel to a Mitsubishi MF1-T4 quadrupole mass filter by a variable leak (Granville-Phillips). Using the apparatus, the reaction mixture can be analyzed continuously throughout the course of the reaction.

Results

Effect of γ-Preirradiation on the Properties of NiO. Changes in the catalytic activity, the content of excess oxygen and the electrical conductivity of NiO were examined as a function of the preirradiation of γ-rays. The results are summarized in Fig. 2, in which the catalytic activity

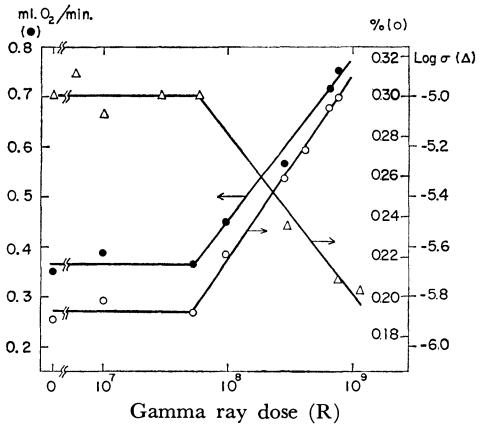

Fig. 2. Catalytic activity, excess oxygen and electrical conductivity of NiO as a function of γ-ray dose of preirradiation.
●: catalytic activity (40°C)
○: excess oxygen (iodometry)
△: electrical conductivity

is the decomposition rate of the H_2O_2 at 40°C. Each value was found to change with the increase of irradiation dose. The change is remarkable when a total dose is greater than about 1×10^8 R. No distinct changes due to the irradiation were observed in the BET surface area and the X-ray diffraction pattern. In Fig. 3, the catalytic activity and the conductivity are shown as a function of the amount of excess oxygen with the irradiation. Linear relationships are seen in both cases. It must be noted that the electrical conductivity of NiO, a p-type semiconductor, was observed to decrease in spite of an increase in the excess oxygen content with the irradiation.

Several properties of the non-irradiated and

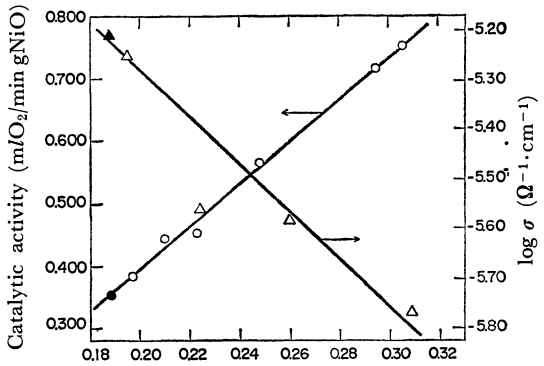

Fig. 3. Catalytic activity and conductivity *vs.* amount of excess oxygen with irradiation.

△: electrical conductivity
●▲: non-irradiated

irradiated (8.8×10^8 R) NiO are summarized in Table 1.

The anomaly observed in the relation between the conductivity and the excess oxygen content induced by the irradiation could be ascribed to the changes in the adsorption state of surface oxygen and the defect structure. The some properties of the excess oxygen have been compared on the non-irradiated NiO with the irradiated NiO; in the experiments described below, the authors have examined on two samples, NiO(I)-non-irradiated, NiO(II)-irradiated (8.8×10^8R).

Flash Desorption of Surface Oxygen. By means of a microbalance technique and by raising the temperature at a 1°C/min rate *in vacuo*, desorption curves of the oxygen from NiO(I) and from NiO(II) were obtained. The experimental results are shown in Fig. 4.

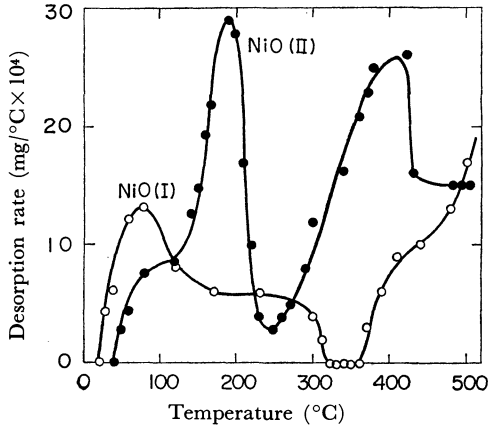

Fig. 5. Desorption rate of excess oxygen during raising temperature (1°C/min) *in vacuo*.

Further, the rates of oxygen desorption are plotted as a function of the desorption temperature in Fig. 5. As can be seen in these figures, the amount of oxygen desorbed from NiO(II) was less than that from NiO(I) in the temperature range below about 200°C, and the peaks of the desorption rate appeared at about 100°C for NiO(I) and about 200°C for NiO(II).

Changes in the electrical conductivity of the both samples during the desorption of excess oxygen are shown in Fig. 6, where $\log\sigma$ *versus* $1/T$ is plotted. As can be seen from the figure, NiO samples after irradiation have a lower conductivity than before, and when NiO(II) was heated up to higher temperatures *in vacuo*, a much different curve from that of NiO(I) was observed. Namely, an irregular "S" shaped change was observed for the NiO(II) in the temperature range 150—250°C. After heating up to 500°C NiO(II) became to behave like NiO(I). This fact seems to show a disappearence of the irradiation effect by the heating. The temperature of 200°C which gave the lowest conductivity in the irregular region corresponds with the temperature giving a high peak on the desorption rate curve in Fig. 5. The

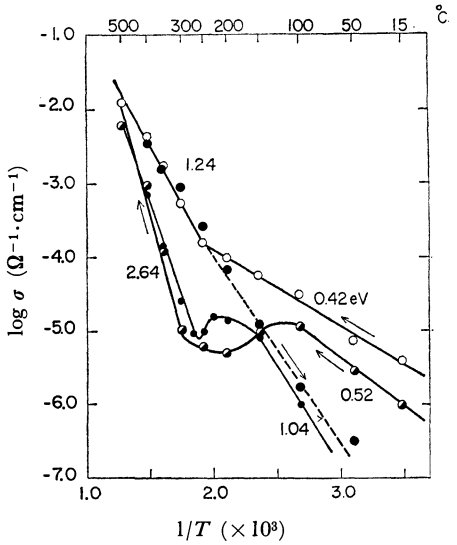

Fig. 6. Temperature dependence of electrical conductivity of NiO before and after irradiation, *in vacuo*.
○: non-irradiated sample (NiO(I))
◑: irradiated (8.8×10^8R) sample (NiO(II))
●: NiO(I) and NiO(II), cooled *in vacuo*
●: conductivity change of NiO in H_2 (2 mmHg), obtained by Dereń *et al.*[16]

irregular "S" shaped curve in the conductivity-temperature relationship is a characteristic feature for the irradiated samples, and the extent of the curvature becomes larger with increasing irradiation dose.

Adsorption of CO_2. Using the vacuum microbalance, adsorption measurements of CO_2 at room temperature were carried out on NiO(I) and NiO(II). Because the adsorption was a very rapid process, comparisons between NiO(I) and NiO(II) were not possible from the kinetics of adsorption. The amount of CO_2 adsorbed during 30 min at room temperature and under the pressure of 20 mmHg was shown in Table 2. It is to be noted that the amount of CO_2 adsorbed by

Table 2. Amount of CO_2 adsorbed by NiO CO_2: 20 mmHg, at 25°C

	NiO (I) non-irradiated	NiO (II) irradiated (8.8×10^8R)
Total amount of CO_2 adsorbed	0.0590(mg/0.1 g NiO)	0.0136
Amount of CO_2 desorbed by evacuation	0.0405	0.0063
Amount of CO_2 remained on NiO	0.0185	0.0073

NiO(II) is much less than the amount adsorbed by NiO(I). The process of electrical conductivity change during the adsorption of CO_2 at room temperature is given in Fig. 7, where the temperature at which the thermal treatments *in vacuo* were made is indicated along each curve. Conductivity changes resulted from adsorption were larger in NiO(I) than in NiO(II) in the cases of the pretreatment below 200°C.

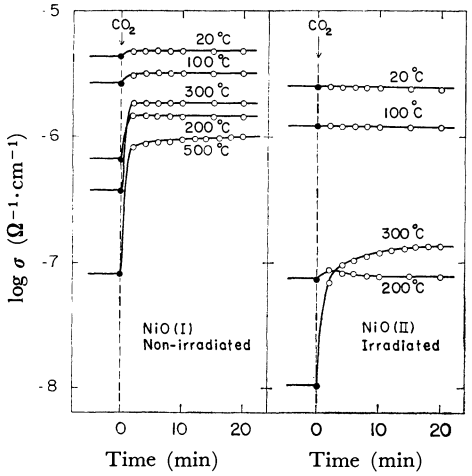

Fig. 7. Variation of electrical conductivity of NiO(I) and NiO(II) with adsorption of CO_2 (20 mmHg) at room temperature.
Sample was heated for one hour *in vacuo*, at the each temperature shown in figure, before CO_2 admission.

Decomposition of *i*-C_3H_7OH in Adsorbed Layer. To obtain another evidence on the reactivity of the irradiated oxide surface, the catalytic decomposition of *i*-C_3H_7OH by NiO(I) and NiO(II) has been examined. After *i*-C_3H_7OH was allowed to adsorb on the oxide at room temperature and under 30 mmHg pressure for 20 hr, the vapor of *i*-C_3H_7OH remained in the gas phase was removed by the evacuation at room temperature, then the strongly chemisorbed *i*-C_3H_7OH was desorbed by raising the temperature. The change in pressure of the system was read and the products were analyzed at every 50°C.

Results are presented in Fig. 8 and Fig. 9 where the relative intensities of main products, *i*-C_3H_7OH, $(CH_3)_2CO$, C_3H_6 and CO_2 are compared. With rise of desorption temperature, the

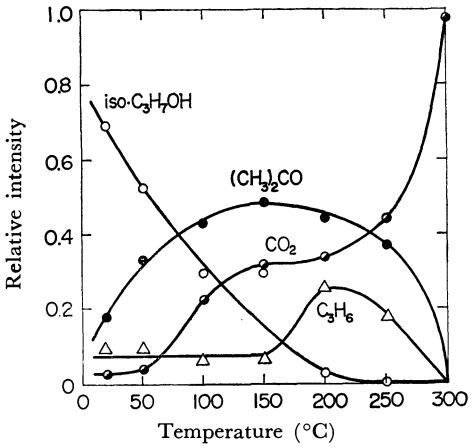

Fig. 8. Relative intensities of main products desorbed from adsorbed layer of *i*-C_3H_7OH, analysed by a quadrupole spectrometer; non-irradiated NiO (NiO(I)).

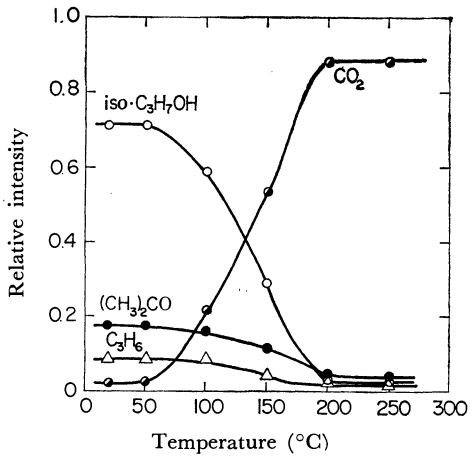

Fig. 9. Relative intensity of main products desorbed from adsorbed layer of *i*-C_3H_7OH, analysed by a quadrupole spectrometer; irradiated (8.8×10^8R) NiO (NiO(II)).

Table 3. Dehydrogenation of *i*-C_3H_7OH on irradiated NiO
(rising rate of temperature 1°C/min, analyzed by quadrupole spectrometer)

	Non-irradiated	Irradiated (6.7×10^8R)	Irradiated (8.8×10^8R)
Starting temperature of dehydrogenation of *i*-C_3H_7OH	115°C	140°C	210°C
Completion temperature of dehydrogenation of *i*-C_3H_7OH	250	280	330

composition of i-C_3H_7OH in the products decreased and that of CO_2 increased, on the other hand, $(CH_3)_2CO$ and C_3H_6 were observed to form only in the case of NiO(I) sample. The experimental results concerning the dehydrogenation of i-C_3H_7OH on NiO(I) and NiO(II) are summarized in Table 3. It can be seen that the reaction was retarded by the irradiation.

Reductive Properties of Irradiated NiO. Reduction rates of NiO(I) and NiO(II) by H_2 and CO were measured with the vacuum microbalance. Velocity curves for the reduction by H_2 (60 mmHg, at 190°C) and CO(70 mmHg, at 250°C) are presented in Fig. 10, where the reduction rate of NiO(II) is much lower than that of NiO(I).

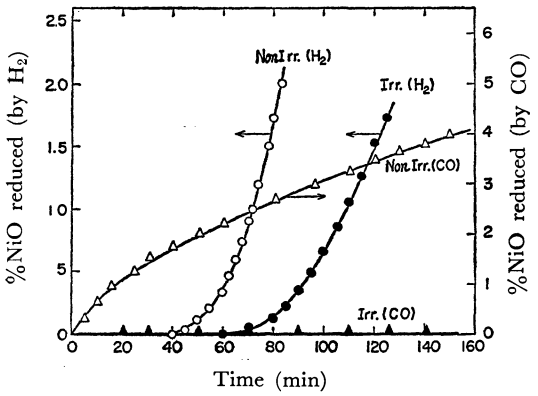

Fig. 10. Reduction curves of NiO samples by H_2 (60 mmHg, 190°C) and CO (70 mmHg, 250°C), ○△: non-irradiated, (NiO(I)) ●▲: irradiated (8.8×10^8R)(NiO(II).

Discussion

Measurements for the catalytic activity, the content of excess oxygen and the electrical conductivity of NiO as a function of γ-ray irradiation dose have shown abrupt changes when a total dose is greater than about 1×10^8 R. In the previous study on the hydrogen reduction of NiO with the irradiation,[8] the authors have found nearly the same phenomena as the present resulst. However, it is difficult at the present time to give full interpretation on the phenomena of the abrupt changes in terms of the irradiation.

In the present paper, discussion has been made on the surface state and the active sites of the irradiated NiO.

Surface State of the Irradiated NiO. Many works have been described on the surface properties of nickel oxide affected by nuclear irradiation.[11-13] Experiments by Charman and Dell[11] and Maxim and Braun[12] have shown that the amount of surface excess oxygen in NiO was increased by the reactor irradiation. The correlation between electrical properties and the content of excess oxygen of the reactor irradiated NiO has been investigated by Nachman *et al.*[13] They concluded that the complicated change in conductivity could be attributed to the radiation-induced defects in the lattice.

In the present study, the electrical conductivity was found to decrease and the amount of excess oxygen was found to increase as the irradiation dose was increased (Fig. 2). Such results can not be expected in ordinary p-type semiconductors. Therefore, the change in the conductivity seems to have no connection with the change in the excess oxygen content due to the irradiation. The descrease in the conductivity would be due to the decrease in the concentration of positive holes, *i. e.*, the charge-carriers, because the irradiation introduces deep trapping level on the vacant cation site as pointed out by several authors[13,14] in the study of nuclear radiation. According to the study by Young,[14] the conductivity of NiO was found to decrease after the nuclear irradiation *in vacuo* while to increase after the irradiation in oxygen. His results are much different from those of the present study which have shown the decrease in the conductivity after the γ-ray irradiation both *in vacuo* and in oxygen. The difference could be due to the conditions of irradiation and also the preparation of NiO samples, *i. e.*, Young prepared it by the complete oxidation of nickel foil at 1000°C.

Iodometric titration measurements with the partial dissolution method[9] have shown that the most of excess oxygen induced by the irradiation appeared to be near the surface of NiO particles. In view of the above facts, the most reasonable conclusion is that irradiation might cause two different effects against the surface properties of NiO: one is the induced chemisorption of oxygen and the other is the hole-trapping which makes to decrease in the concentration of charge-carrier. By the irradiation of γ-rays, surface excess oxygen may be converted to an adsorbed state bonding more strongly with the NiO lattice than the one before the irradiation, as

$$O^-_{(ads)} \rightsquigarrow O^{2-}_{(ads)}.$$

Changes in the electrical conductivity of NiO(II) during the CO_2 adsorption were much less than those of NiO(I) as shown in Fig. 7. The adsorption processes of CO_2 on the both samples could be considered as follows[3]:

11) H. B. Charman and R. M. Dell, *J. Phys. Chem. Solids*, **23**, 1967 (1962); *Trans. Faraday Soc.*, **59**, 470 (1963).

12) I. Maxim and T. Braun, *J. Phys. Chem. Solids*, **24**, 537 (1963).

13) M. Nachman, L. Cojocaru and L. Ribco, *Nukleonik*, **10**, 1 (1967).

14) D. A. Young, *Discussions Faraday Soc.*, **31**, 267 (1961).

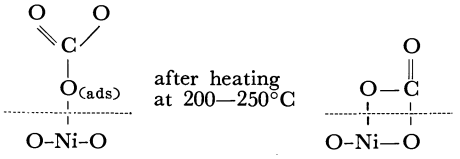
for NiO(I).

$$CO_2 + O^-_{(ads)} + Ni^{2+} = CO_3^{2-} + Ni^{3+} \quad (1)$$

and for NiO(II).

$$CO_2 + O^{2-}_{(ads)} + Ni^{2+} = CO_3^{2-} + Ni^{2+} \quad (2)$$

According to this mechanism, the concentration of Ni^{3+} ions in NiO(I) may be increased by the adsorption of CO_2, and the conductivity would be increased. Changes in the conductivity during the CO_2 adsorption was found to increase gradually as the pretreatment temperature was raised, and remarkable change was found above 200—250°C. This may be attributed to the change in the adsorbed state. Considering from the model proposed by Eischens *et al.*[15] and that proposed by Alexeyev *et al.*,[16] the change would be as follows:



This model requires that, after a heat treatment at higher temperature, CO_2 should become to adsorb on nickel ions which formed as a result of desorption of surface excess oxygen.

The irregular variation observed in the electrical conductivity of irradiated NiO when the temperature of sample was raised *in vacuo*, seems to be associated with the abrupt desorption of excess oxygen (Figs. 4 and 5) in nearly the same temperature range. It can be concluded that the strongly chemisorbed oxygen produced by the irradiation ($O^-_{(ads)} \rightsquigarrow O^{2-}_{(ads)}$) may start to desorb suddenly at 150°C. Consequently the concentration of charge-carriers (positive holes) diminished and it caused the decrease of conductivity. The phenomena of "S" shaped variation in $\log \sigma$ *vs.* $1/T$ curve have been found in the case of n-type semiconductors,[15] *e. g.*, ZnO, CdS, *etc.* Experiments carried out by Dereń *et al.*[16] on the conductivity of NiO have shown that the $\log \sigma$-$1/T$ curve in hydrogen (2 mmHg) was nearly the same as that found in the present study for the irradiated NiO (Fig. 5). The same experiments in this laboratory have given the same result as above.

The suggestion drawn from these experiments was that semiconducting property of the surface layer of NiO would be changeable from p-type to n-type. However, the clear explanation of these phenomena remains as a problem for the future.

Interpretaion of Catalytic Sites on Irradiated NiO. Many groups of workers have studied in recent years on the radiation effects on the catalytic activity of powdered catalysts. However their results have been rather conflicting and varied considerably with experimental systems and procedures. Consequently, it is very difficult to interpret the mutual relation between active sites and the surface structure changed in terms of irradiation. In the present study, the catalytic activity of NiO for decomposition of H_2O_2 was increased, while that for decomposition of i-C_3H_7OH was decreased by the irradiation. It can be concluded that active sites on NiO produced by irradiation should be different in each reaction. Considering the proportional relation between the amount of excess oxygen determined by the iodometric titration and the catalytic activity changed by the irradiation, it can be concluded that the active sites for decomposition of H_2O_2 correspond to the positive holes.

In his considerations regarding the mechanism of catalytic decomposition of H_2O_2 on NiO, Roginsky[17] has assumed that the positive holes produced by oxygen adsorption could be the acceptors of electrons from reactants. According to this assumption, the catalysts with higher concentration of positive holes would have the higher catalytic activity. The model proposed by Roginsky might be applied to the interpretation in the case of irradiated NiO.

On the other hand, the active sites for decomposition of i-C_3H_7OH, adsorption of CO_2 would not relate to the positive holes, but to the adsorption state of oxygen on irradiated NiO. Experiments on reductive properties of NiO, showed that reactivity of surface oxygen on irradiated NiO was much less than that on non-irradiated NiO.

The amount of CO_2 adsorbed by irradiated sample (NiO(II)) was only one-fourth of that by NiO(I). The nature of adsorption sites for CO_2 on NiO seems to be affected by the state of surface excess oxygen, *i. e.*, whether the surface excess oxygen is chemisorbed strongly or weakly. The adsorption measurements have shown that the ratio of the amount of i-C_3H_7OH adsorbed by the both samples at room temperature, was nearly the same as that of CO_2 at room temperature. From the above consideration, it seems to be most reasonable to conclude that the weakly chemisorbed oxygen ($O^-_{(ad)}$) might be more reactive than the strongly chemisorbed one ($O^{2-}_{(ad)}$) for decomposition reaction of i-C_3H_7OH. However, further clarification on the active sites produced on NiO by the irradiation must await more detailed studies.

UV and Visible Absorption Spectra of Monohalogenated Anthracenes. I. The First Absorption Bands

Isao OHNO

Department of Electronic Engineering, Faculty of Engineering, Tamagawa University, Machida, Tokyo

and Kaoru IGUCHI

Department of Chemistry, School of Science and Engineering, Waseda University, Nishiokubo, Tokyo

(Received February 3, 1968)

UV and visible absorption spectra of monohalogenated anthracenes are measured, and the first absorption band are reported. When anthracene is monohalogenated, the first absorption band slightly shifts toward red or does not shift in accordance with the change in the position and the species of the substituting halogen atom, but the vibrational structure remains unchanged. The sequence of magnitude of red shift due to the position is 9-halo>1-halo>2-halo-anthracene, while that due to the species is different depending on the substituted position: in the 9-position, it is monobromo>monochloro>monofluoro>monoiodo anthracene, and, in the 1 or 2-position, it is monochloro>monofluoro>monobromo≃monoiodo anthracene. For the sequence of red shift due to the species of the substituting halogen atom, there are similarities between the first absorption band of monohalogenated anthracenes and the K or B-band of monohalogenated benzenes. These results are discussed in terms of the simple LCAO MO perturbation treatment.

The effect of monohalogenation and other substitution of aromatic hydrocarbons on UV and visible absorption spectra has been studied by many authors,[1-5] where the shift and the intensity-variation of the absorption peaks have been examined. In polyacene, this effect of monohalogenation is so weak that the theoretical consideration may be treated with a perturbation theory containing some parameter determinations. The perturbation consists of two factors; the variation of 1) the steric configuration and 2) the electronic structure.

In UV and visible absorption spectra of anthracene, the first absorption band appears at near 380 mμ, and the second band at near 250 mμ. The first band has a prominent vibrational structure which is characteristic of polyacene, and the calculated energy[6] and the assignment of the transition, A_{1g}–B_{2u}, are well supported by many experimental data.[7] Since early, UV and visible absorption spectra of some of monochloro and monobromo anthracenes have been reported together with other simple substituted anthracenes.[8] Recently, the charge transfer band,[9] the excimer fluorescence and dimer absorption spectra[10] of these have been studied, but the complete systematic examination has never been reported.

For the extensive study of monohalogenated anthracenes, we have synthesized and purified all isomers of monofluoro, monochloro, monobromo and monoiodo anthracene. In this paper, we will report UV and visible absorption spectra corresponding to the first absorption band; wavelengths for O–O transition, the vibrational assignment and molar extinction coefficients of the first band. Also, these results are discussed systematically in terms of the simple LCAO MO perturbation treatment.

Experimental and Results

Samples were synthesized in the process as shown in Table 1, and purified by recrystallization from a suitable solvent, sublimation and column chromatography. The detail of sample preparation will be reported in another paper, (together with some of their properties and results of their elementary analysies). In this paper, the existence of halogen atoms except fluorine was confirmed qualitatively by Beilstein Method.

TABLE 1. PREPARATIONS OF MONOHALOGENATED ANTHRACENES

Halide	Starting material	Reaction	
9-Fluoro anthracene	Anthracene	*p*-Tolyliododifluoride →	
9-Chloro anthracene		Cl_2 →	
9-Bromo anthracene		Br_2 →	
9-Iodo anthracene	9-Bromo anthracene	Mg+I →	
1-Fluoro anthracene	1-Amino anthraquinone	The Schieman reaction	Reduction
1-Chloro anthracene		The Sandmeyer reaction	
1-Bromo anthracene			
1-Iodo anthracene			
2-Fluoro anthracene	2-Amino anthraquinone	Same as the above reaction	
2-Chloro anthracene			
2-Bromo anthracene			
2-Iodo anthracene			

The sample (*ca.* 1 mg) was dissolved in purified *n*-hexane (10 m*l*); then a definite volume (*ca.* 1 m*l*) of the solution was withdrawn and added to the same solvent (10 m*l*) in absorption cell. The absorption spectra were measured at room temperature with a Hitachi EPS-3 spectrophotometer in the range 290—410 mμ. They correspond to the first excitation band and are illustrated in Figs. 1—4. Wavelengths of absorption peaks, molar extinction coefficients*1 and the vibrational assignment are given in Table 2.

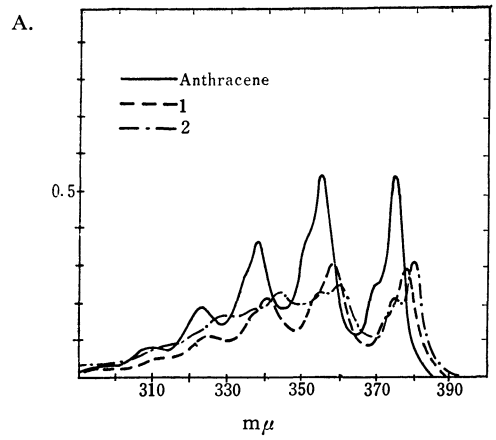

Fig. 1. The first absorption bands of anthracene and monofluoro anthracenes.
Concentration (10^{-5} mol/*l*)
$C_a=5.72$
$C_1=4.60$
$C_2=5.68$

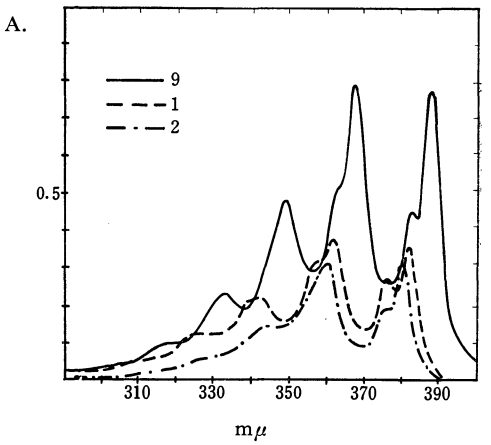

Fig. 2. The first absorption bands of monochloro anthracenes.
Concentration (10^{-5} mol/*l*)
$C_9=8.68$
$C_1=4.90$
$C_2=5.40$

The vibrational structure of the first absorption band of monohalogenated anthracene, two prominent vibrational progressions, appear clearly as those of anthracene. The wavelength of the absorption peak slightly shifts toward red or does not in accordance with the position and the species of the substituting halogen atom. The magnitude of shift is so small that the effect of monohalogenation on the electronic state of anthracene may be regarded as a perturbation, and so we will make a perturbation treatment in later section.

*1 We calculated the molar extinction coefficients by k=[absorbance]/[mole concentration]·[light path (cm)].

Though the monofluorination and the monochlorination have an influence on the first absorption band, the monobromination has an influence only when it is made at the 9-position, while the monoiodination has no influence. The sequence of red shift due to the atomic species is varied in accordance with the substituted position. In 9-position, it is monobromo > monochloro > (monofluoro)*2 > monoiodo anthracene, and in the 1 or 2-position, it is monochloro > monofluoro > monobromo > monoiodo anthracene. It is notable that the sequence of red shift due to the species of the substituting halogen atom in the 1 or 2-halo-anthracene is similar to that in the first absorption band, *i.e.*, B-band (A_{1g}–B_{2u}), of monohalogenated benzene, and the sequence in 9-halo-anthracene is almost similar to that in the second absorption band, *i.e.*, K-band (A_{1g}–B_{1u}).

Prominent vibrational frequencies are the same as those of anthracene; they are about 1400 cm^{-1} and about 400 cm^{-1}, which slightly depend on states of aggregation (gas, liquid, crystal phase or solvent used). The vibration of 1400 cm^{-1} is assigned to the stretching of carbon skeleton (Gamma Carbon Stretching) and another vibration is assigned to the skeletal bending.[7]

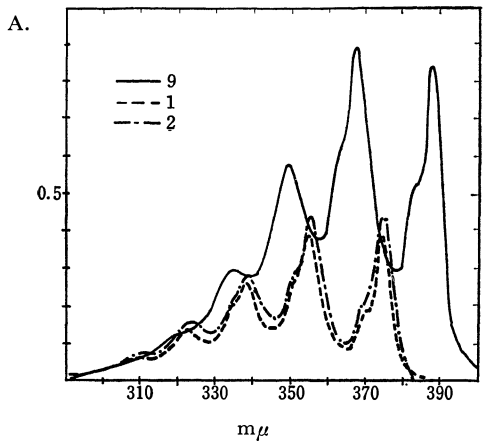

Fig. 3. The first absorption bands of monobromo anthracenes.
Concentration (10^{-5} mol/l)
C_9=9.03
C_1=4.93
C_2=4.49

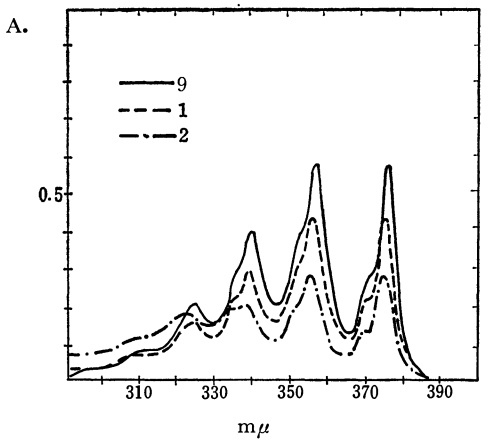

Fig. 4. The first absorption bands of monoiodo anthracenes.
Concentration (10^{-5} mol/l)
C_9=6.26
C_1=3.83
C_2=4.20

*2 Separation of 9-fluoro anthracene from unchanged anthracene was very difficult. We obtained the absorption peak at 386 mμ which is sure to be O-O transition of the first absorption band of 9-fluoro anthracene, but the other vibrational components could not be separated from those of the unchanged anthracene.

Discussion

Since early, experimental and theoretical studies of monosubstituted benzenes have accumulated a lot of information on electronic spectra of aromatic molecules.[1-4] These benzene derivatives are divided into two groups[4]: one has the substituents such as NO_2, NH_2 which interact strongly with the π-electron system of benzene, another has the substituents which interact weakly with it. Fluorine, chlorine and bromine atoms have a weak interaction with benzene, or more generally, with aromatic molecules. Iodine atom shows special effects, in which the Rydberg transition of iodine atom is mixed in the absorption spectra of benzene derivatives[4] and the steric effect appears in *p*-terphenyl derivatives,[5] but such special effects were not observed by us in the first absorption band of anthracene derivatives.

In spite of the simplicity, LCAO MO perturbation treatment gives many useful and intuitional informations. So this treatment has been used by many authors[2,3,5] since early to elucidate the effect of substitution on electronic spectra of aromatic molecules. Iguchi and his co-workers[5] applied the perturbation theory[11] to *p*-terphenyl derivatives, and obtained a good qualitative agreement between theory and experiment. Now, we intend to explain our experimental data with the same treatment.

It is known that a forbidden transition exists in the neighobrhood of this allowed transition (the first absorption band). In the Hückel approximation, however, both the highest occupied (No. 7) and lowest unoccupied (No. 7′) MO's, are well separated from other MO's. The first absorption corresponds principally to the transition No. 7—No. 7′ of MO's, and the forbidden transition to No. 7—No. 6′ (see Pariser[6]). Thus the effect

* denotes O–O transition

of forbidden transition is neglected in our treatment.

The effect of monohalogenation on electronic spectra of aromatic molecules may be divided into three types: 1) steric effect, 2) inductive effect and 3) resonance effect. Other types may not be considered for the first approximation. Type 1) may be neglected in polyacene because of the rigidity of the framework. while it is essential in polyphenyl such as *p*-terphenyl.[5] It is assumed that the inductive and resonance effects by the halogen atom are restricted to the AO of carbon atom to which the halogen is attached. So, when the anthracene molecule is monohalogenated, the change of energy of the ith MO is given by[12]:

$$\Delta \boldsymbol{e}_i = \boldsymbol{e}_i - \boldsymbol{e}_i^0 = (\boldsymbol{C}_t^i)^2\alpha^{(1)} + (\boldsymbol{C}_t^i)^2/[\boldsymbol{e}_i^0 + (\boldsymbol{C}_t^i)^2\alpha^{(1)} - \alpha_x]\cdot\gamma^2 \quad (1)$$

Where $\boldsymbol{e}_i^0$ and $\boldsymbol{C}_t^i$ are the energy and coefficient of the tth AO in the ith MO, respectively; t denotes the position of monohalogenation. Also, α_x designates the energy of the highest occupied orbital (p-orbital) of halogen atom, while γ is the resonance integral of the bond between halogen atom and anthracene, $\alpha^{(1)}$ is the change of core integral of carbon atom by the inductive effect of halogen atom. Here we may neglect the change of α_x (H_{77} in Matsen's notation) by the inductive effect of anthracene molecule.[2] In the estimation

12) K. Iguchi, *ibid.*, **30**, 319 (1959).

of the order of magnitude $(-\boldsymbol{e}_i^0)$ and $(-\underline{\alpha_x})$ may be regarded almost equal to ionization potentials of anthracene and methyl halides, respectively.[13] So, we have $(-\boldsymbol{e}_i^0) \simeq 7$ eV, $(-\alpha_x) \simeq 10$ eV, $(\boldsymbol{C}_t^i)^2 \lesssim 0.2$ and $\alpha^{(1)} \lesssim 3.3$ eV (see Table 3 and Fig. 5), then $(-\boldsymbol{e}_i^0)$ and $(-\alpha_x) \gg (\boldsymbol{C}_t^i)^2\alpha$.[1] Thus we may neglect the term $(\boldsymbol{C}_t^i)^2\alpha^{(1)}$ in denominator in Eq. (1). In alternant hydrocarbons the square of each AO coefficient is the same for both the highest occupied MO and the lowest unoccupied MO. Thus, the shift, δ, of the first absorption peak is expressed simply as

$$\Delta\boldsymbol{e}_{i'} - \Delta\boldsymbol{e}_i = \delta$$
$$= (\boldsymbol{C}_t^i)^2[1/(\alpha - k_t) - 1/(\alpha + k_t)]\cdot\gamma^2$$
$$\text{and} \qquad \alpha = \alpha_c^0 - \alpha_x,\ \boldsymbol{e}_i^0 = \alpha_c^0 + k_t \qquad (2)$$

Here α_c^0 is the core integral of carbon atom and k_t is the root of Hückel seqular equation.

Since $(\alpha - k_t)$ is larger than $(\alpha + k_t)$, δ is always negative. Thus, so far as the resonance effect is dominant, the red shift of absorption peak occures in anthracene derivatives, or more generally in alternant hydrocarbon derivatives. The magnitude of the red shift is determined by three factors: 1) $(\boldsymbol{C}_t^i)^2$, *i.e.*, the square of the coefficient of the tth AO in the ith MO, 2) the energy of the highest occupied orbital (p-orbital) of halogen atom and 3) the resonance integral between anthracene and halogen atom.

Now, let us consider the sequence of red shift. First, we consider the sequence due to the monohalogenated position. In this case, factor 2) and 3) are common for all position, so that the shift is determined by factor 1). From Fig. 5, giving the value of $(\boldsymbol{C}_t^i)^2$ calculated by Hückel approximation, the theoretical prediction of the sequence of red shift due to the position may be 9-halo > 1-halo > 2-halo-anthracene. This prediction is almost in harmony with our experimental data. Next, we consider the sequence of red shift due to the atomic species. In this case, factor 1) is common for all species, so that the sequence is determined by factor 2) and factor 3). Ionization potentials of halogenated methyls and the pure anthracene are listed in Table 3, and the sequence of its value is F > Cl > Br > I-methyls > anthracene. The evaluation of the resonance integral between halogen atom

and anthracene is one of the most important problem in discussion of the effect of substitution and will be discussed elsewhere. Here we will use semiempirical values determined by Nagakura[4] in electronic spectra of monohalogenated benzene. The sequence of magnitude is Br > Cl > I > F, as shown in Table 3. So, the theoretical prediction for the sequence of red shift of the absorption peak is monobromo > monochloro > monoiodo > monofluoro anthracene. The agreement between this prediction and our experimental data is not satisfactory; this prediction is only in harmony with the sequence of 9-bromo and 9-chloro anthracene, but does not the other monohalogenated anthracenes. And further the difference of the sequence due to the species in accordance with the substituted position cannot be explained by this treatment.

Some reasons for this disagreement will be thought as following. Essentially, the magnitude of the shift is too small to predict exactly with the simple LCAO MO perturbation treatment. Scince the density of π-electron in the highest occupied orbital and that in the lowest unoccupied orbital are largest at the 9-position, it may be allowed to neglect the resonance between halogen atom and carbon atoms to which the halogen atom is not attached, in the case of 9-halo-anthracenes. But in the cases of the other halogenated anthracenes,

it may not be allowed. We neglected the steric effect. If the substitution of the heavy atom such as bromine and iodine causes the distortion of the skeletal framework, it may affect the electronic structure. Our experimental fact is well explained if we assume that this distortion effect causes the blue shift and cancels out the red shift by the resonance effect in monohalogenated anthracene. However, there is no decisive evidence to support this assumption. On the contrary, it is reported that the distortion of skeletal framework causes red shift in substituted benzene.[14]

14) J. Dale, *Chem. Ber.*, **94**, 2821 (1961).

In this experiment it is found that the wavelengths of absorption peaks of monoiodo anthracenes and 1 or 2-bromo anthracene are not different from those of anthracene. This point will require a more detail examination. We are planning the elementary analysis and the measurement of infrared spectra to make sure the structure of monohalogenated anthracenes, and the results will be published in another paper.

One of the authors (I. O.) wishes to express his gratitude to Professor S. Aono of Kanazawa University for his continual encouragements, and also to Professor H. Miyazawa of Tamagawa University for his invaluable suggestion.

Nuclear Magnetic Double-resonance Study of the Hindered Internal Rotation in Formamide

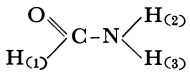
Hirotake KAMEI

Electrotechnical Laboratory, Tanashi, Tokyo

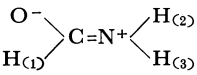
(Received February 13, 1968)

The nitrogen-14 quadrupole relaxation broadening effect on the proton spectrum of formamide was eliminated by a $^{1}H-\{^{14}N\}$ double resonance technique. The completely-decoupled proton spectra of formamide in the neat liquid and in acetone, dioxane, and water solutions were observed at several temperatures. The spectra observed at room temperature were analyzed on the basis of an ABC system, while the spectra at higher temperatures ($\sim$100°C) were analyzed on the basis of an AB_2 system. From the changes in the resonance lines of the formyl proton with the temperature, the values of the activation energy for the hindered internal rotation about the C-N bond, E_a^{rot}, and for the intermolecular proton exchange involving the amine protons, E_a^{ex}, were obtained. It has been found that the hydrogen-bond formation on the carbonyl oxygen of formamide increases the E_a^{rot} value and the magnitude of the vicinal coupling constants, while it decreases the magnitude of the geminal coupling constant.

The hindered internal rotation in amides has been attributed to the partial double-bond character in the C-N bond resulting from a contribution from a resonance form such as II.



I



II

The stability of the II resonance form must be affected by the nature of the intermolecular interactions between amide and the solvent molecule. One would predict a solvent effect on the activation energy for rotation about the C-N bond. Such solvent effect has been demonstrated for *N,N*-disubstituted amides[1,2] and thioamides[3] using a nuclear magnetic resoance technique. Effects due to protonation[4] and complex formation[5] have also been observed. Such solvent effects are also found for unsubstituted amides. However, the resonance lines of the protons bonded directly to nitrogen are broadened, and a complete analysis of the spectrum is usually not possible. The broad nature of the lines is derived from the quadrupole coupling of the ^{14}N nucleus. The quadrupole broadening can be eliminated by a technique of

nuclear magnetic double resonance[6] and also by the substitution of the isotope, ^{15}N. Sunners *et al.*[7] studied ^{15}N-substituted formamide and found the activation energy for rotation, E_a^{rot}, to be 18±3 kcal/mol for formamide in a 10 mol% acetone solution.

In the present work the quadrupole broadening was eliminated by the nuclear magnetic double-resonance technique. The completely-decoupled proton spectra of formamide were then obtained under different conditions. The values of E_a^{rot} have been determined in several solutions. The solvent effects on E_a^{rot} and NMR parameters will be discussed.

Experimental

Measurements. Double resonance experiments were carried out on a ^1H-{^{14}N} double resonance spectrometer which made possible the complete decoupling of the ^1H-^{14}N coupling by the irradiation of the large second radio-frequency field at about 2.9MHz and the observation of the proton resonance at 40MHz. Details of the spectrometer and associated equipments have been described elsewhere.[8]

Double-resonance proton spectra were obtained for each sample at several temperatures. The accuracy of the sample temperature determinations was about ±1°C. The frequency and width of each resonance line were determined by a method of sideband audio modulation, with an accuracy of ±(0.5%+0.05)Hz. In order to monitor the homogeneity of the field, the line width of cyclohexane, which was used as a reference, was measured in each measurement.

The measurements were made at a constant second radio-frequency field. The frequency was 2.88950 MHz, while the amplitude, H_2, was 4.3 gauss. The value of H_2 was determined from the Bloch-Siegert shift,[9] $\delta_B \sim \gamma^2 H_2^2/2\Delta\omega$, where $\Delta\omega$ is the frequency difference between the proton resonacne and the second radio-frequency field. Figure 1 shows typical spectrum

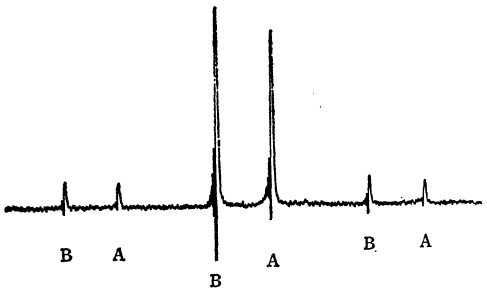

Fig. 1. Bloch-Siegert shift in cyclohexane resonance. A, normal resonance; B, H_2 supplied

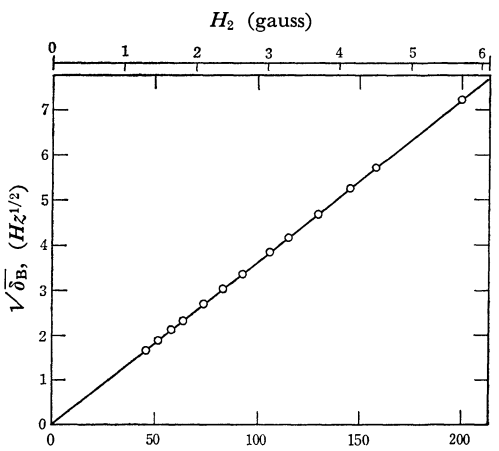

Fig. 2. Plot of $\sqrt{\delta_B}$ *vs.* the voltage of the second *r-f* field.

of cyclohexane with the bracketing side-band signals. When the second radio-frequency field is supplied, the resonance shifts to a lower field (from A to B). A plot of $\sqrt{\delta_B}$ *vs.* the voltage of second radio-frequency, to which H_2 is proportional, resulted in a straight line, as is shown in Fig. 2. Thus, H_2 can be determined precisely from the Bloch-Siegert shift in the hetero-nuclear double resonance.

Preparation of Samples. Formamide was purified as follows: With bromothymol blue as an indicator, reagent-grade formamide was neutralized with solid sodium hydroxide. Sodium formate was added to the neutral liquid, and formamide was fractionally distilled under reduced pressure by passing dry argon through. All the solvents were reagent-grade quality and were dried and doubly-distilled prior to use. The samples were degassed and sealed *in vacuo*. The compositions of the samples were determined by means of their weight.

Results and Discussion

Chemical Shifts and Coupling Constants at Room Temperature. The double-resonance proton spectra of formamide in the neat liquid and in water, acetone, and dioxane solutions at 27°C are shown in Fig. 3. The spectra can be assigned on the basis of three nonequivalent protons. This indicates that the rotation about the C–N bond is very slow at room temperature. The assignment of the spectra has been described previously.[10] The spectra have been analyzed on the basis of an ABC system, employing the Castellano-Waugh method.[11] Details of the method of spectrum analysis have been described elsewhere.[12]

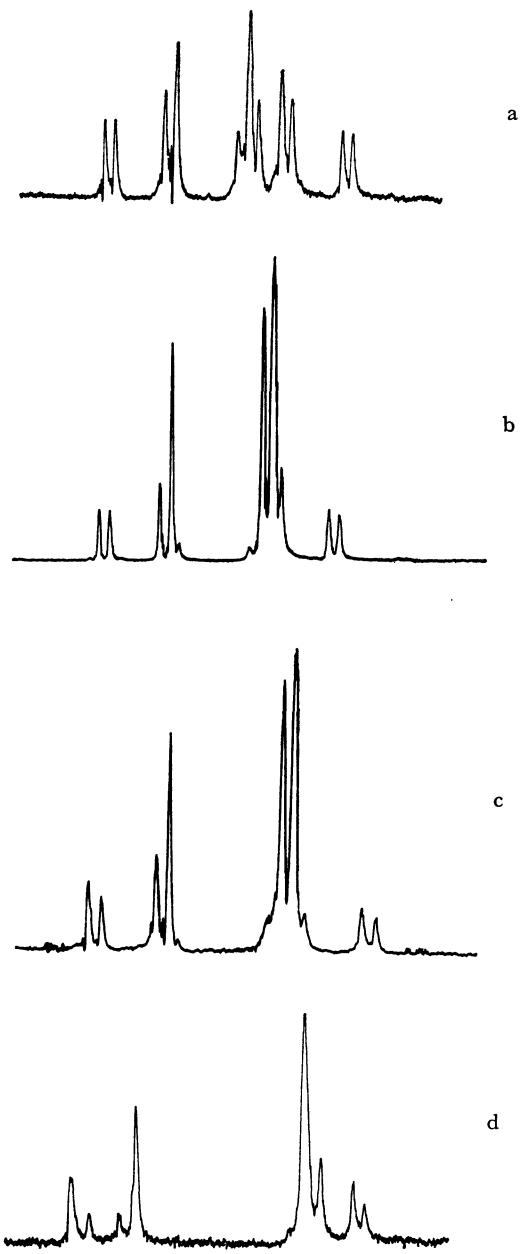

Fig. 3. ^{14}N decoupled proton spectra of formamide a) in the neat liquid, and in the solutions with b) water, c) acetone, and d) dioxane at 27°C.

The chemical shifts and coupling constants are given in Table 1. All the coupling constants have the same sign. The same results have been obtained for formamide-^{15}N by Bourn and Randall using a proton-proton double-resonance technqiue.[13]

A solvent effect on the chemical shift and the coupling constant is observed. This may arise from the different natures of the hydrogen-bond interactions in the different systems. Amine protons engage in the intermolecular hydrogen bond and the chemical shift is strongly dependent on the nature of the interactions with the solvent. No remarkable solvent dependence is found in the chemical shift of the formayl proton.

The coupling constant also shows a solvent dependence. This indicates that the molecular geometry or the electronic structure is affected by the intermolecular interactions.

Temperature Effects on the Spectrum. The spectra of formamide in the neat liquid at several temperatures are shown in Fig. 4. On raising the temperature, the rate of the hindered internal rotation about the C–N bond is increased,

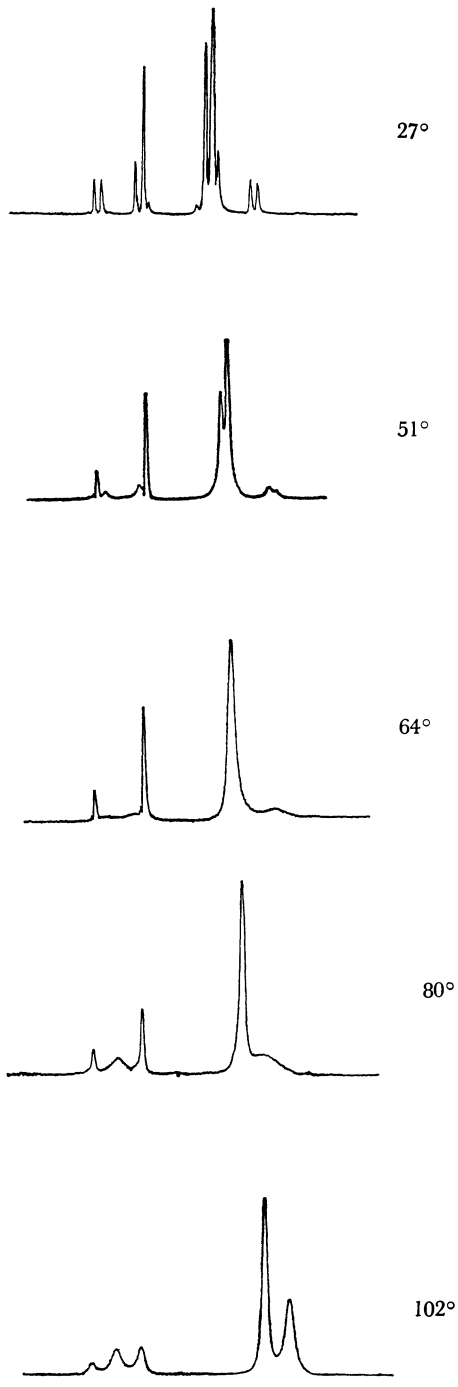

Fig. 4. ^{14}N decoupled proton spectra of formamide in the neat liquid at various temperatures.

and the spectrum is changed. At higher temperatures the rate of rotation becomes very rapid, so the amine protons are indistinguishable one from the other and the spectrum changes to an AB_2-type pattern. The coupling constants and the chemical shifts of the AB_2-type spectrum are given in Table 2, along with the average chemical shifts and the coupling constants at 27°C, $\bar{\delta}=(\delta_2^{27}+\delta_3^{27})/2$ and $\bar{J}=(J_{12}^{27}+J_{13}^{27})/2$. The signal of the amine protons is progressively shifted toward higher field with the increase in the temperature. This higher-field shift can be attributed to the increasing dissociation of the hydrogen bond involving these protons.

Hindered Internal Rotation and Intermolecular Proton Exchange. The signal shapes are influenced not only by the hindered internal rotation, but also by the intermolecular proton exchange involving the amine protons. As the temperature is raised, the rate of these rate processes increases and the lines broaden and coalesce. It is not possible to obtain the information concerning the hindered internal rotation separately from the information concerning changes in the signal of the amine protons. Although the formyl proton does not participate in the rate processes, its signal is affected by the rate processes through the spin-spin interaction. To the first-order approximation, the two outer lines of the $H_{(1)}$ quartet are unaffected by the internal rotation, and the line width and the separation between the two lines are not altered. Since the intermolecular proton exchange influences all the lines in the spectrum, the broadening of the two outer lines is attributable to the intermolecular proton exchange. The two inner lines broaden and ultimately coalesce. Changes in the separation between the two outer lines have not been observed up to 80°C.

The mean lifetime, 2τ, of the intermolecular proton exchange was evaluated from the broadening of the two outer lines in the $H_{(1)}$ quartet by employing the following relation:[14]

$$1/2\tau = \pi(\Delta' - \Delta) \qquad (1)$$

where Δ' (in Hz) is taken as the half-line width of the broadened line and where Δ is the line width in the absence of exchange. From 15°C to 30°C, changes in the line width have been lost in the experimental error. At lower temperatures a line broadening has been observed; this may arise from the increase in the viscosity of the sample. The line width at 27°C has been used as Δ. The values of the activation energy, E_a^{ex}, for the intermolecular proton exchange have been obtained from the plots of $\log 1/2\tau$ *vs.* $1/T$; the results are shown in Table 3. The value for the neat liquid is in good agreement with the value of 10 ± 3 kcal/mol reported by Sunners *et al.*[7] for formamide-^{15}N at higher temperatures, where internal rotation is already rapid.

In view of the above facts, it is possible to deal with the $H_{(1)}$ quartet by means of the approximation presented above.

TABLE 3. ACTIVATION ENERGY AND FREQUENCY FACTOR*

Solvent	Neat	Water	Acetone	Dioxane
Concentration mol%	100	22.8	22.2	24.6
E_a^{rot} (kcal/mol)	18.9±1.0	21.3±1.3	16.9±1.9	16.8±1.0
log A^{rot}	12.9±0.6	14.9±1.3	12.1±1.3	11.9±0.7
E_a^{ex} (kcal/mol)	12.1±2.5	14.5±5.5		11.7±1.3
log A^{ex}	7.6±1.5	9.3±3.5		7.1±0.8

* The errors quoted are 95% confidence limits.

At a given temperature the mean lifetime, 2τ, of the protons at the $H_{(2)}$ and $H_{(3)}$ positions was evaluated from the relation (1) (at lower temperatures) and the following relation[14] (at higher temperatures):

$$1/2\tau = \pi(\delta\nu)^2/2(\Delta' - \Delta) \qquad (2)$$

where $\delta\nu$ (in Hz) is the separation between two inner lines in the absence of rotation. The values of E_a^{rot} were obtained from the plots of log $1/2\,\tau$ *vs.* $1/T$. The results are given in Table 3, with the frequency factors.

The observed changes in E_a^{rot} with the solvent may be associated with the effects of the solvent on the partial double-bond character in the C–N bond. The predominant effect is a hydrogen-bonding effect. The hydrogen-bond formation on the carbonyl oxygen in the formamide molecule tends to favor the contribution of the II resonance form, and it increases the double bond character in the C–N bond. In acetone and dioxane solutions, the amine protons may be strongly bonded to the oxygen atoms in the acetone or dioxane molecule, while the carbonyl oxygen in the formamide molecule is left relatively free. Thus, the double-bond character in the C–N bond decreases and the activation energy is lowered compared to that in the neat liquid. In a water solution, the hydrogen bond between formamide and water is stronger than that of amide with itself, and a higher activation energy is found.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2274—2280 (1968)

Studies on the Radical Species in Solid Methylene Blue as Revealed from the ESR Spectra

Michio OKUDA, Takeo KOWATA, Yoshiharu USUI and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received February 19, 1968)

The ESR signals of polycrystalline methylene blue (MB) salts have been investigated in respect to a) temperature effect, b) anion effect, c) influence of the addition of donor and acceptor and d) response to visible light irradiation. a) The signal intensity in general increases with the rising temperature, but a sharp difference in the ESR behavior has been found above and below room temperature. Response to the temperature change at low temperature is reversible and the apparent activation energy is *ca.* 0.03 eV (L-type behavior) whereas the high temperature behavior has a marked tendency of irreversibility and the activation energy is at least one order larger (H-type behavior). b) No essential anion effect has been observed on *g*-value, line shape and spin concentration for chloride, iodide and phosphate. c) The addition of trinitrobenzene and paraphenylenediamine in 10 : 1 to MB chloride also had no essential effect. d) Corresponding to the L-type and H-type behavior observed in a), visible light irradiation has been found to cause a decrease or an increase in signal intensity respectively at low and high temperature. From these findings it has been concluded that there are at least two kinds of defect (L-type and H-type) and that the formation of radical species occurs only on such defect sites. Some suggestions have been made on the nature of these two types of defects and on the molecular processes occurring at or near these defect sites. The radical formation reaction is most likely to be connected with dye-dye interaction, $D^+ + D^+ \rightleftarrows D^{++} + D$.

The past work has shown that some kinds of dye give ESR signals in the solid state; various mechanisms have been proposed for their appearance, but they are not always amply established. Terenin *et al.*[1] have proposed a conduction electron theory for xanthene and triphenylmethan dyes, on the basis of the similar dependence of conductivity and of the ESR signal intensity upon the addition of water or oxygen. Nelson *et al.*[2] has claimed for the case of crystal violet, the occurrence of electron transfer between dye cation and its paired anion, because of great dependence of the features of the signal on the paired anion. Other mechanisms conceivable from relevant work are the biradical theory which has been mentioned by Simpson *et al.*,[3] and the defect theory suggested by Lagercrantz *et al.*[4] for methylene blue.

In the present paper attention is focused on the possibility of electron transfer between two dye cations. Since the occurrence of the analogous process has been well established by our group[5] and by Lindqvist[6] in the case of the photoreaction of some dyes in solution, it is quite natural to expect its occurrence also in the solid state where dye ions exist close with each other.

Choosing methylene blue, we have investigated the effect of temperature, of paired anions, of the addition of typical electron donor or acceptor and of the visible light illumination on the ESR signal of the polycrystalline sample. ESR in methylene blue was studied previously by Lagercrantz *et al.*[4] and by Simpson *et al.*[3] in the solid state but there is disagreement in many respects. On the other hand, ESR signals of methylene blue radical have been reported by Heineken *et al.*[7] and by Tuck *et al.*[8] in the acidic or alkaline solution.

Experimental

Materials. Methylene blue chloride, Merck G. R. grade was purified by two methods, by recrystallization from *n*-buthanol and by the method reported by Bergmann *et al.*[9] The latter is particularly effective

for removing a trace of trimethylthionine, which can be preferentially extracted from the aqueous 0.01 N ammonia-alkaline solution of methylene blue (0.1 g 100c) with benzene layer. Ten to twenty times extraction was necessary for the disappearance of the purple color of trimethylthionine in benzene layer. The solution of methylene blue purified, was concentrated under reduced pressure at room temperature and the obtained sample was dried below 40°C for 7 hr in an ampule at 10^{-5} mmHg.

s-Trinitrobenzene of Wakō G. R. grade was recrystallized from benzene at least three times. Paraphenylenediamine was purified by sublimation *in vacuo*.

The mixture of methylene blue with trinitrobenzene or paraphenylenediamine was prepared in the following way. The mixture at a desired composition was milled in a mortar and pressed at 4000 kg/cm^2 after degassing. The pressed sample was crashed to the size less than 1.5 mm and then desiccated in an ampule similarly as in the case of polycrystalline sample.

Procedure. All the samples dried in ampules were transferred to ESR sample tubes (5 mm in diameter) *in vacuo* and then sealed off. All the above procedures were performed in the dark. The ESR spectra were measured by a JEOL JESP-10 type ESR spectrometer (X-band, 100KC field modulation). The temperature was controlled over the range from 137°K to 373°K by passing a cold gas from liquid nitrogen or hot air through the inside of the cavity. The constancy was ±0.5°C. A light source was usually a projector incandescent lamp (Kondo 100V-500W, operated at 90V). Y2 cut off filter ($\lambda>470$ nm) and a $CuSO_4$ aq. solution filter were employed. For the investigation of the wavelength effect, Xe-arc lamp (Ushio UXL 500W) was used with a set of suitable interference filters. The light was focused on the sample tube with a condenser lens ($f\simeq1.8$). Intensity was not controlled in particular but was ascertained to be nearly the same.

Results and Discussion

To examine the possible effect of impurity, the samples purified by different methods have been compared at first. The samples recrystallized five times and eight times from *n*-buthanol showed the ESR signal of nearly equal intensity; it was always a single line of Lorentzian type with $\Delta H_{msl}=9.6$ and $g=2.0049$. Figure 1 shows one example. The spin concentration was respectively 1.3×10^{18} and 1.4×10^{18} per unit gram. The sample purified by Bergmann's method also gave the spin concentration of $\sim1\times10^{18}$ spins/g. These values are of the same order as the one reported by Simpson, 1.2×10^{18} spin/g and also are not very different from 10^{15}—10^{18} spin/g of Lagercrantz. On the basis of the above agreement irrespective of the different procedures in making samples, one may safely conclude that the signal is intrinsic for methylene blue.

Temperature Effect. As the first attempt to elucidate the origin of ESR signal, measurements were made at different temperatures from 143 to 343°K. Such studies are expected to be helpful to distinguish the defect theory, the conduction electron theory and the biradical theory.

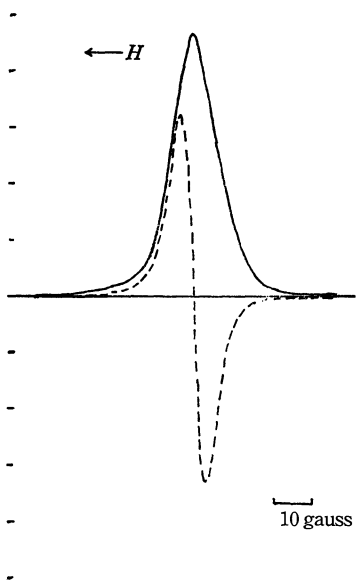

Fig. 1. ESR line shape of methylene blue chloride in the solid state.

Dotted line: Differential curve

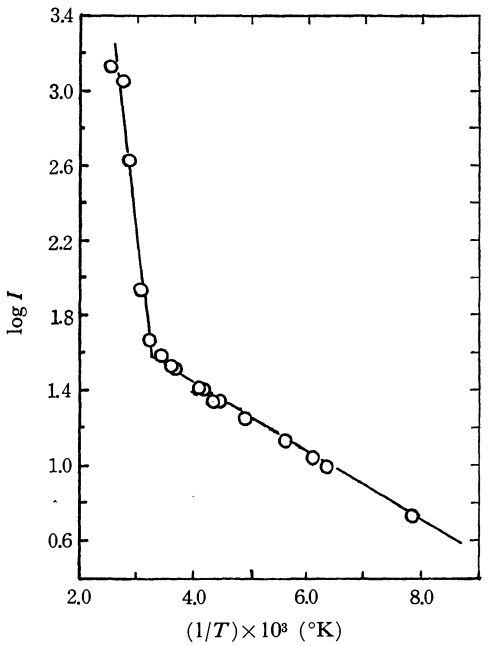

Fig. 2. Temperature dependence of the signal intensity of polycrystalline MB.

The essential features of the signal remain the same throughout the entire temperature region. The intensity increases monotonously with the rise of temperature. This agrees with Lagercrantz

at least qualtitatively, but not with Simpson. A notable finding is that in the response to temperature change, a clear difference exists above and below room temperature. Thus in the lower temperature region, the response is rather rapid and the change is reversible. At higher temperature, on the other hand, the response is very slow, requiring as long as several hours to get the final state at ~340°K. Around this temperature the equilibrium intensity is difficult to determine; the behavior appeared often to be even irreversible. The temperature dependence of the signal intensity (I) in the high and low temperature regions was found to be different in the order of magnitude. Figure 2 gives the plot of log I (corrected for Curie Law) against $1/T$. In the higher temperature region, the I-value at one to two hours after fixing temperature in heating experiments, was conventionally adopted. It is evident that the plot consists of two linear parts; from the slopes of the two linear lines, the energy difference between the two states with and without unpaired electron, was evaluated as 0.036 eV (ΔE^{L}) and 0.28 eV (ΔE^{H}) respectively for low and high temperature regions.

Although there is some ambiguity in the latter value, yet it is quite definite that ΔE^{L} is of the order of van der Waals energy and ΔE^{H} is more than one order larger.

If the electrons raised to the conduction band were the origin of the signal, as in the case of triphenylmethane and xanthene dyes,[1] the values of ΔE should be of the same order as the one evaluated from the temperature dependence of the electric conductivity. The latter value of Meier[10] is 1.36 eV and the value of Matsumoto is 1.6 eV[11] in the room temperature region; these values differ from the above ΔE values in the order of magnitude. Hence the conductive electron theory in a simple form may be rejected for the present sample. The biradical theory may also be ruled out from the similar reasoning, since the triplet level is expected to be located much higher than ΔE^{H} and ΔE^{L}.

On the other hand, the defect theory proposed by Lagercrantz[4] seems to be satisfactory if it is complemented by the following two assumptions. The first is that at low temperature, the radical formation reaction is in equilibrium only at certain defect sites, and the second is that at higher temperature, other type(s) of defect gradually come to play a dominant role. The first assumption is necessary, because the number of unpaired spins is less than 1% of the entire dye ions and yet the ΔE^{L} value is so small that quite an appreciable quantity of unpaired spin should exists in the equilibrium. Provided several % of the entire lattice sites exist as defects, the present result may be satisfactorily interpreted. The second assumption is less compulsive, but it is reasonable because an alternative assumption that two kinds of reaction occur at a single type of defect depending upon temperature, seems unlikely from the general theory of defect in solid state.

In the further investigations, emphasis was placed on the clarification of the process occurring at lower temperature, because the phenomena at lower temperature were thought to be more simple than at higher temperature.

Anion Effect and Donor, Acceptor Effect. Provided the electron transfer were occurring between dye cation and its paired anion, as has been established by Nelson *et al.*[2] for crystal violet, other salts than chloride would display quite different features in their ESR signals. Hence iodide and phosphate of methylene blue were investigated. Further, the effect of the addition of some inorganic salts and of a typical electron donor and acceptor was examined in a pressed form. The effect of pressing was also examined using polycrystalline methylene blue chloride.

ESR spectra of iodide and phosphate of methylene blue were measured at various temperatures from 143 to 293°K, quite similarly as in the case of chloride. The shapes of ESR spectra were essentially the same as the one of chloride. The data for the line width (ΔH_{msl}), the g-value, spin concentration at ordinary temperature and the values of ΔE^{L} are given in Table 1. It is seen that there is no significant difference in the three salts. Slight differences in the spin concentration and in

11) Private communication from S. Matsumoto.

ΔE^{L} are not compatible with the hypothesis of electron transfer between cation and anion. The pressed sample of methylene blue mixed with trinitrobenzene or paraphenylenediamine (TNB, PPD) (at the mole ratio, MB : TNB=1 : 10) as well as the similarly pressed sample of methylene blue alone gave essentially the similar signals. The ESR parameters such as line width, *g*-value and the ΔE^{L} value of these samples are given in Table 1. All of them are not different significantly from the values of the polycrystalline methylene blue unpressed. Furthermore it was found that the addition of sodium chloride, potassium bromide and pottassium iodide to chloride of methylene blue in the mole ratio of 2 : 1, do not essentially affect the characteristics of the signal.

All these findings support the afore-mentioned view that the formation of unpaired electron occurs at some defect points; because it is reasonable to consider that the added substances do not affect the nature of the defect so much as they may affect the average properties of the sample. Although the nature of the reaction related to the formation of unpaired electron is still unknown at this stage, it seems natural to consider the occurrence of reaction $D^{+}+D^{+}\rightleftharpoons D^{++}+D\cdot$ at defect sites, because the electron transfer between paired anion and cation has been ruled out and further because it is well-known that an analogous reaction, $D^{+}*+D^{+}\rightarrow D^{++}+D\cdot$ occurs photochemically in solutions.

Irradiation Effect. The investigation of the effect of light will give information on the nature of the molecular processes which may occur at normal and defect sites.

The effect of illuminating the polycrystalline methylene blue chloride by the visible light, has proved to be very unique in that it occurrs in the opposite direction at high and low temperature regions. At very low temperatures (<223°K) the signal intensity decreases upon irradiation, quite rapidly and reaches the steady value within a few minutes. When the illumination is stopped, the intensity recovers its initial value also in a few minutes. At higher temperatures ($\gtrsim 293$°K) the intensity increases, upon irradiation, but more slowly. When the light is off, the increase still continues for a few minutes and then begins to decrease. At an extremely high temperature of 373°K, this increase after the light being off, is not observable. At high temperatures, the recovery of the original intensity is very slow and in some cases seems to be even irreversible. Some examples of the intensity *vs.* time plot are shown in Fig. 3. It is evident that at 291°K and at 273°K, *i. e.*, in the medium temperature region, the plot can be interpreted as a superposition of the high and low temperature behaviors. Thus the slight increase observed when the light is off, is due to the existence of the low temperature type process. Although the intensity change upon irradiation is

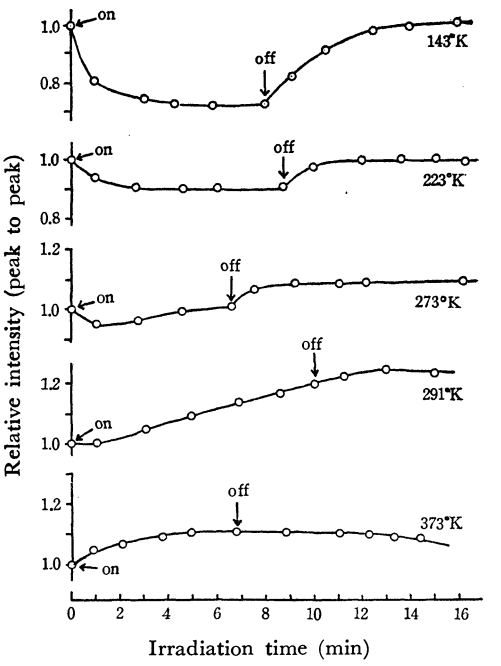

Fig. 3. Effect of photo-irradiation on the signal intensity of polycrystalline MB (measured by peak to peak distance of differential curve of ESR spectra).

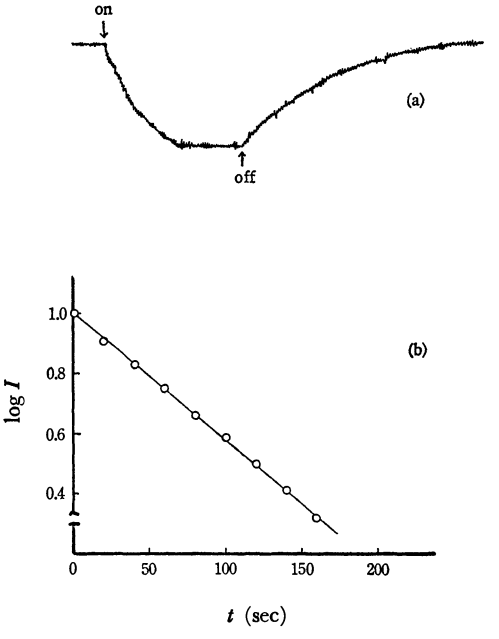

Fig. 4. Recovery processes of the signal intensity after the light is cut off. (at 183°K)
a: Recovery curve
d: Logarithmic plot of the amount of decrease of signal intensity *vs.* time.

quite remarkable, as stated above, there is no essential change in the signal shape as well as in

the line width and the g-value. The kinetics of the recovery at low temperatures could be investigated accurately by measuring the peak to peak distance in the differential curve of ESR signal. The recovery is satisfactorily exponential as is shown in Fig. 4. From the measurements at different temperatures, the apparent activation energy of 0.5 kcal/mol (0.02 eV) was obtained (ΔE_R).

All the above findings are consistent with the view which has been proposed; there are apparently two kinds of defect playing a dominant role respectively at high and low temperatures. The value of the activation energy for the recovery process (0.02 eV) at low temperature, which approximates the ΔE^L value, strongly suggests that the similar process as in the thermal one is occurring for the recovery.

Figure 5 gives the comparison of chloride, iodide and phosphate when they are irradiated at low temperatures. It is seen that the anion effect is

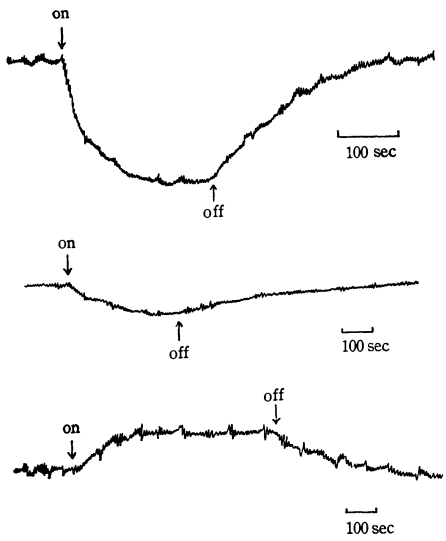

Fig. 5. Comparison of the effects of photo-irradiation on the signal intensity of different salts of MB. (from up to down)

remarkable. Thus the L-type behavior is very prominent in chloride, less in iodide whereas in phosphate the H-type one is notable even at 243°K.

It is to be noted that the H-type behavior in this case appears quite reversible. Careful inspection

Table 2. Kinetics of the photoresponse

Sample	1st order decay constant when the light is "ON" $\times 10^{-2}$sec^{-1} Temperature			Recovery process when the light is "OFF" (Half period several ten sec) Temperature

MB+PPD (1 : 10)	2.5		3.5	1st order		~2nd order

of the irradiation effect upon various samples leads to the suggestion that H-type defects in general consists of the reversible type and the other one(s) at which the ESR behavior is almost irreversible.

At any rate it seems plausible to attribute these differences in the three salts to the different contributions of the H-type defects in these salts, because the thermal behavior at L-type defects are so similar that it is difficult to attribute them to the L-type defect.

In the pressed methylene blue sample, the L-type behavior is quite prominent even at 290°K, as is shown in Fig. 6. The effect of the addition of donor or acceptor is not so pronounced but a general tendency is seen that the addition of TNB or PPD respectively enhances and suppresses the H-type behavior (when compared with the pressed methylene blue sample). This is clearly seen from Fig. 6(a)—(c). These results can be interpreted to be due to the opposite influence of a donor and an acceptor on the photochemical formation of radical species at H-type defects. Furthermore, the energy transfer by exciton mechanism is improbable, because if it really occurs, it would be greatly suppressed and consequently the photoeffect should be much reduced by the addition of donor and acceptor. Thus it may be concluded that most of the acts induced by illumination take place only in the close neighborhood of the defect sites.

Since the slow response when the light is on or off, suggests an appreciable structural change near defects, or mass transfer, some further kinetic studies were made in terms of the intensity change, when the light is on or off at low temperatures. The results are given in Table 2. It is seen that at low temperatures where the L-type defect plays a dominant role, the kinetic feature is essentially the same in all the samples. The second order process at 243°K suggests that the transient species produced by illumination, are two particles existing independently with each other. The activation energy for the disappearance reaction of radical species, as estimated from the data in Table 2 is 0.001—0.002 eV (ΔE_D).

Figure 7 shows the time dependence of the signal intensity when the pressed sample of methylene blue was irradiated by the light of narrow region at 18°C. The clear tendency is seen that the light of shorter wavelength enhances the H-type behavior. Since 660—670 nm and 625—630 nm correspond respectively to the main peak of methylene blue and the dimer absorption, it is tempting to consider that the dye ions at the H-type defects or in its close neighborhood take a dimer-like configuration.

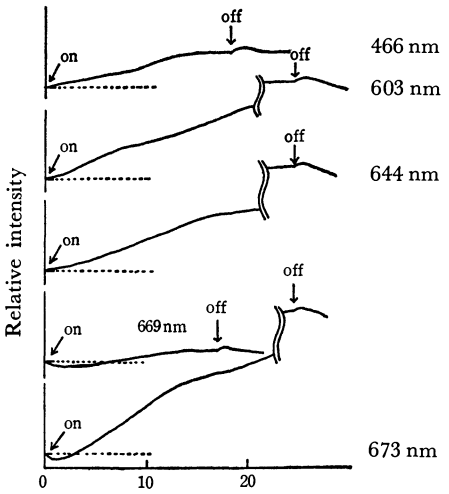

Fig. 7. Wavelength dependency of photo-irradiation effect on the signal intensity of pressed MB.

Summarized Discussion and a Possible Molecular Model

The existence of more than two types of defect, where unpaired electrons are located in the polycrystalline methylene blue chloride, have been verified from the temperature dependence of the signal intensity and the response to the irradiation. This has been further supported by the finding that the change from L-type to H-type behavior occurs

at about the same temperature in both phenomena. The formation of radical species is considered to occur mainly on these defect sites in both the illuminated and unilluminated conditions, on the basis that electron donor and acceptor of the high concentration does not essentially affect the signal intensity. The process occurring at L-type defects is mild and reversible and the one occurring at H-type defects is drastic. From the values of ΔE^{L}, ΔE_{D} and ΔE_{R}, the energy levels for the two states wth and without unpaired spin at L-type defects are given as Fig. 8.

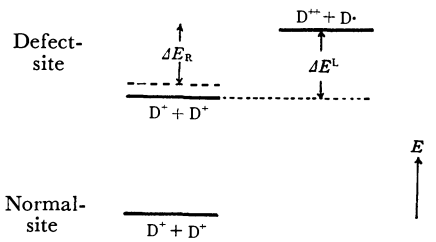

Fig. 8. Energy levels for the two states with and without unpaired spin at L-type defects.

It is particulary interesting that L-type defects show the decrease in signal intensity upon irradiation, while H-type defects show the increase. The magnitude of the contribution of L-type and H-type defects depends upon the kind of anion but at very low temperatures the L-type defect plays a dominant role irrespective of the salt type. Thus the characteristics of the signals in dark are not essentially affected by the anion. Sharp contrasts observed in the response to illumination in three salts, are concerned with the magnitude of the contribution of H-type defect, which is at most about 20% of the entire intensity at room temperature.

As to the molecular process occurring at L-type defects, the most plausible process is the electron transfer between two dye ions,

$$D^+ + D^+ \rightleftharpoons D^{++} + D\cdot \quad (\text{or } D^{++}\cdots D\cdot)$$

Although there is no strong evidence for this mechanism, all the other hypothesis cannot interpret the present results. Especially, the absence of a large anion effect on the features of the signal in dark, rules out the electron transfer between anion and cation.

The decrease in radical species upon irradiation may be due to the reaction of $(D^{++}\cdots D\cdot)$ with a near-by D^{+*} ion which may produce three ground state dye ions in a slightly different configuration, which is of course unstable. When the light is off, it returns to the original cofiguration and ultimately yield $D^{++}\cdots D\cdot$ to restore the equilibrium state. First order kinetics at very low temperatures justifies this view, in addition to the approximate agreement of ΔE^{L} and ΔE_{R}. However, with the rise of temperature, the process becomes more complicated as judged from the second order kinetics at 243°K. Further details of the process are quite unknown at the present stage.

Although detailed studies have not been attempted to elucidate the nature of the H-type defect, it is quite notable that the H-type response to illumination is brought about conspicuously by the wavelength corresponding to dimer absorption. This suggests the hypothesis that the dye ions exist as a dimer-like configuration at or around the H-type defects, and that the process occurring upon illumination is the reaction

$$(D^+\cdots D^+) \rightarrow D^{++} + D\cdot$$

In connection with this hypothesis, it is interesting that the phosphate of methylene blue displays the H-type behavior to a great extent, as has been shown in the H-type-response to illumination even at a low temperature of 243°K. This may be due to the circumstance that two dye ions attached to the bivalent anion are rather easy to take the dimer-like configuration. The results given in Table 1, seem to be interpreted along the similar reasoning. Thus a slightly higher spin concentration, narrowing of the linewidth and a slightly larger value of ΔE^{L} for the phosphate can be attributed to a larger contribution of the H-type defect in this salt.

The above discussion on the molecular process is of course still speculative. It will be interesting to extend the investigation to the salts involving other polyvalent anions and also to mixed dyes along the above picture.

The authors are grateful to Professor H. Kokubun for discussion.

The Reactions of Acetylene Photosensitized by Cd($^3P_1$)

Shigeru TSUNASHIMA and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 29, 1968)

The reactions of acetylene photosensitized by Cd($^3P_1$) have been investigated at 270±1°C. The main products were benzene and vinylacetylene. The formations of polymer and hydrogen were not observed. From the studies of the effects of pressures and foreign gases on the quantum yields, the product formations were successfully explained by the reactions of excited molecules. The investigation of the reaction of a mixture of hydrogen and acetylene photosensitized by Cd($^3P_1$) suggests that benzene is also formed from the reactions of hydrogen atoms and acetylene molecules.

Since Bates and Taylor investigated the reactions of acetylene photosensitized by mercury,[1] many investigations have been made of the reactions of this compound.[2-8] However, the mechanism of benzene formation has not yet been completely resolved. LeRoy has proposed a radical mechanism for the benzene formation,[7] while Shida and Tsukada have proposed a mechanism involving both free radicals and excited molecules.[8]

If benzene is formed only from the reaction of free radicals, its formation is not expected in the cadmium-photosensitization, because the dissociation energy of the C–H bond of the acetylene molecule (114 kcal)[9] is larger than the energy of triplet cadmium (87.7 kcal) even when the heat of the formation of cadmium hydride (15.5 kcal) is considered.

In the present paper, a detailed investigation of the reactions of acetylene photosensitized by cadmium will be reported.

Experimental

Acetylene, ethylene, isobutene, and *cis*-2-butene supplied by the Takachiho Shoji Co. were used after bulb-to-bulb distillations. The gas-chromatographic analysis showed that the impurities were less than 0.5%. Hydrogen supplied by the Suzuki Shokan Co. was used after it had been passed through a trap at the temperature of liquid nitrogen. Acetylene-d_2 was synthesized from calcium carbide and deuterium oxide. Mass-spectrometric analysis showed that the isotopic purity was larger than 98%.

The apparatus and the light source used were practically the same as have been described previously.[10]

The reaction products were analyzed by gas chromatography. The column used was packed with silicon DC-550 on celite (supplied by the Shimazu Co., 7 m long) and was operated at 60°C.

The intensity of the cadmium resonance line at 3261 Å was measured using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene under the assumption of the quantum yield being 0.5.[10]

Results and Discussion

Mechanism of Product Formations. In the reaction of acetylene photosensitized by cadmium at 270±1°C, the main products were identified as benzene and vinylacetylene by gas chromatography and by mass spectrometry. No hydrogen formation was observed; if present at all, the quantum yield is less than 10^{-5}.

Figure 1 shows the irradiation-time dependence of the products. A slight disappearance of acetylene was observed; the amount was almost equal to the sum of three times the amount of benzene and twice the amount of vinylacetylene. This fact suggests that the formation of polymers, such as cuprene, is negligibly small.

The isotopic hydrogen-atom distribution of benzene formed in the reaction of a mixture of acetylene-d_0 and -d_2 could not be determined, because intermolecular hydrogen-deuterium exchange reaction occurred rapidly, even in a dark reaction at 270±1°C.

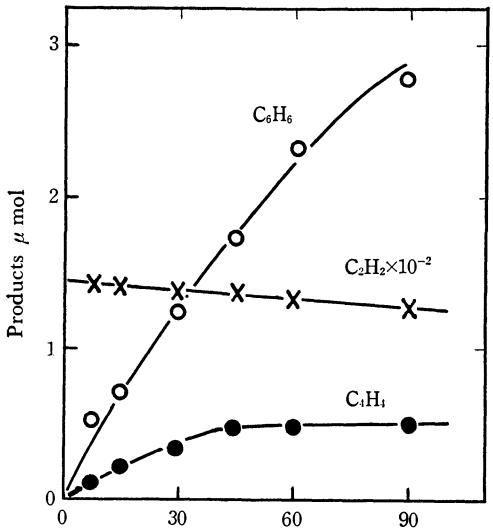

Fig. 1. Time dependence of the amounts of the products. (initial pressure, 36.6 mmHg)

Table 1 shows the quantum yields of the products formed in the reaction of acetylene at 80 mmHg, together with those in the presence of foreign gases.

The products of the cadmium-photosensitization are different from those of the mercury-photosensitization,[1-8] the direct photolysis,[11] and the radiolysis.[12] If benzene and vinylacetylene are formed from the reaction of free radicals, the formations of ethylene, 1,3-butadiene, and diacetylene can be expected, besides the formation of vinylacetylene. However, they were not observed in the cadmium-photosensitization. Furthermore, the energy available for the C-H-bond splitting in the cadmium-photosensitization is smaller than the dissociation energy of the C–H bond of the acetylene molecule. Benzene and vinylacetylene may be formed from the reaction of excited molecules. The energy levels of the excited singlet molecule are above the excitation energy of triplet cadmium.[13] The triplet state of the acetylene molecule is not known, although Bowman and Miller observed a peak at 2.0 eV in the electron-energy-loss spectrum of acetylene and tentatively surmised that the peak was caused by the triplet state of the acetylene molecule.[14]

Pressure-dependence of the Products. The quantum yields of benzene and vinylacetylene formations were measured over the pressure range from 10 to 330 mmHg (Fig. 2). Their maximum values were found at about 80 mmHg and at about 40 mmHg respectively. Even at the maximum values, the sum of their quantum yields is less than unity. That is, most of the energy absorbed by cadmium atoms is not used for the product formations. This fact can not be explained by the incomplete quenching of triplet cadmium atoms by acetylene, because the quenching efficiency of acetylene is almost equal to that of 2-butene[15] and the pressure range used here is the complete quenching region for 2-butene.[10]

To explain the pressure dependence of the quantum yields, the following reaction mechanism may be considered in terms of the excited molecules:

$$Cd(^3P_1) + A \rightarrow CdA^* \quad (1)$$
$$CdA^* \rightarrow Cd + A_1^* \quad (2)$$
$$CdA^* + A \rightarrow Cd + 2A \quad (3)$$
$$A_1^* + A \rightarrow A_2^* \quad (4)$$
$$\rightarrow 2A \quad (5)$$
$$A_2^* \rightarrow 2A \quad (6)$$
$$A_2^* + A \rightarrow A_3^* \quad (7)$$
$$A_3^* \rightarrow 3A \quad (8)$$
$$\rightarrow C_4H_4 + A \quad (9)$$
$$\rightarrow C_6H_6 \quad (10)$$
$$A_3^* + A \rightarrow C_6H_6 + A \quad (11)$$

where acetylene is denoted as A and where CdA* is the transient complex of a triplet cadmium atom and an acetylene molecule. The symbols A_1*, A_2*, and A_3* represent, respectively, an excited acetylene molecule (presumably, a triplet acetylene molecule), a transient dimer, and a transient trimer. The steady-state treatment derives the following relation:

$$\phi(C_6H_6)/\phi(C_4H_4) = k_{10}/k_9 + (k_{11}/k_9)[A] \qquad (I)$$

where $\phi(C_6H_6)$ and $\phi(C_4H_4)$ are the quantum yields of the benzene and vinylacetylene formations respectively. The plots of the $\phi(C_6H_6)/\phi(C_4H_4)$ ratio *vs.* the acetylene pressure are shown in Fig. 3. From the slopes and the intercepts, the k_{10}/k_9 and k_{11}/k_9 values are calculated by the method of least squares (Table 2).

TABLE 2. VALUES OF k_{10}/k_9 AND k_{11}/k_9

	k_{10}/k_9	k_{11}/k_9 (mmHg^{-1})
C_2H_2	1.2±0.3	4.6±0.4
C_2D_2	4.6±2.1	6.5±3.0

Effects of Ethylene and Isobutene. As is shown in Table 1, ethylene and isobutene inhibit the formations of benzene and vinylacetylene. Figure 4 shows the plots of ϕ_0/ϕ *vs.* the foreign gas

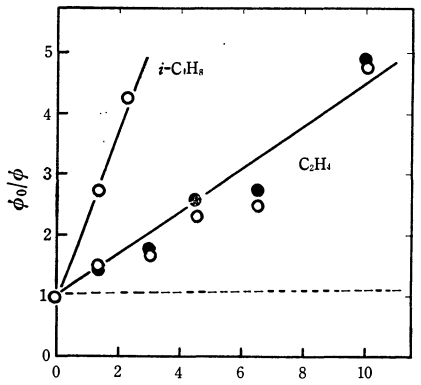

Fig. 4. Plots of ϕ_0/ϕ against the pressure of foreign gas.
(dotted line: expected curve from competitive quenching for Cd($^3P_1$) atoms, pressure of acetylene: 80 mmHg, ○: benzene, ●: vinylacetylene)

pressure in the reaction of acetylene at 80 mmHg. Here, ϕ_0 and ϕ are the quantum yields of benzene or vinylacetylene formations in the absence and in the presence of foreign gas respectively. The efficiency of isobutene for the inhibition is about five times that of ethylene. A similar trend has been reported in the efficiency of quenching

triplet benzene (about five times)[16,17] and triplet acetone (about four times),[18] and also in the efficiency of scavenging hydrogen atoms (about five times).[19]

The inhibition by ethylene or isobutene can not be explained by the competitive quenching for triplet cadmium atoms, since the observed $(\phi_0/\phi-1)$ values, as is shown in Fig. 4, are more than forty times as large as that calculated by assuming competitive quenching. The products expected by the addition of ethylene and isobutene were not detected in spite of careful research. The inhibition, therefore, may be explained by the quenching of excited molecules by foreign gases. Including the quenching reactions by foreign gases, the following relations are obtained:

$$(\phi_0/\phi)_{C_4H_4} = (1+k_{10}'[M]/(k_{10}+k_{11}[A]))(\phi_0/\phi)_{C_6H_6}$$
$$= (1+k_{11}'[M]/(k_8+k_9+k_{10}+k_{11}[A]))(1+k_7'[M]/(k_6+k_7[A]))(1+k_5'[M]/(k_4+k_5)[A])$$
$$\times (1+k_3'[M]/(k_2+k_3[A])) \quad \text{(II)}$$

Here, k_3', k_5', k_7', and k_{11}' represent, respectively, the rate constants of a foreign gas (M) for quenching CdA*, A_1*, A_2*, and A_3*.

As is shown in Fig. 4, the (ϕ_0/ϕ) value for vinylacetylene formation is almost equal to that for benzene formation; therefore, the $k_{11}'[M]/(k_{10}+k_{11}[A]) \ll 1$ relation holds under the conditions of this experiment. That is, the process of quenching A_3* by foreign gas is not effective for the inhibition of the formation of benzene and vinylacetylene. However, the linear relationship in Fig. 4 suggests that one of the quenching processes (reaction (3'), (5'), or (7')) is effective. However, no definite conclusion can be drawn as to which quenching process is the most effective on the basis of these experiments alone.

Isotope Effect. As is shown in Table 3, there are large isotope effects on the formations of benzene and vinylacetylene. In the mercury-photosensitization, no such large isotope effect has been observed on the formation of benzene.[8] The isotope effect can not be explained by the difference in the quenching efficiencies of acetylene-d_0 and -d_2.[15] The effect may result from the isotope effect on the rates of the reactions (9), (10), and (11), as is shown in Table 2.

Table 3. Isotope effects on the formations of benzene and vinylacetylene

Pressure mmHg	C_4H_4/C_4D_4	C_6H_6/C_6D_6
30	2.6	1.4
40	3.5	1.5
60	3.8	1.5
80	4.3	1.9
100	3.5	1.9

Effect of Hydrogen. As is shown in Table 1, the addition of an excess amount of hydrogen caused an increase in the quantum yield of benzene formation, together with those of ethylene and 1,3-butadiene formations. Cashion and LeRoy observed a similar effect of the addition of hydrogen in the mercury-photosensitization and proposed the importance of free radicals in the mechanism.[4] Benzene formed from the reaction of a mixture of acetylene-d_2 and hydrogen photosensitized by cadmium consisted of a mixture of C_6D_6(69.2%), C_6HD_5(26.6%), and $C_6H_2D_4$(3.5%). This suggests that a part of the benzene is formed by the reaction of hydrogen atoms. The reaction mechanism may be described as follows;

$$Cd(^3P_1) + H_2 \rightarrow CdH + H \quad (12)$$
$$H + C_2H_2 \rightarrow C_2H_3 \quad (13)$$
$$2\,C_2H_3 \rightarrow C_2H_2 + C_2H_4 \quad (14)$$
$$\rightarrow C_4H_6 \quad (15)$$
$$C_2H_2 + C_2H_2 \rightarrow C_4H_5 \quad (16)$$
$$2\,C_4H_5 \rightarrow C_4H_4 + C_4H_6 \quad (17)$$
$$\rightarrow \text{dimer} \quad (18)$$
$$C_4H_5 + C_2H_2 \rightarrow C_6H_7 \quad (19)$$
$$C_6H_7 \rightarrow C_6H_6 + H \quad (20)$$
$$\rightarrow \text{polymer} \quad (21)$$

This reaction mechanism interprets the formations of butadiene and ethylene as well as the formation of benzene. That is, benzene can also be formed from the reaction of free radicals.

The authors are indebted to Mr. H. Sakurai for the mass spectrometric analyses and to Mr. S. Hirokami for synthesizing acetylene-d_2.

Gel Filtration of Surfactants on Sephadex

Fumikatsu TOKIWA, Kenji OHKI and Isao KOKUBO

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received March 7, 1968)

An attempt has been made to apply gel filtration on Sephadex to micellar solutions of surfactants. The data on the gel filtration of surfactants were interpreted by taking into account the fact that there exist both micellized and unmicellized species in the solutions. A simple method for obtaining the retention volume of the micelle (V_M) of a surfactant directly from the elution curve was developed. Further, the relation between the values of V_M and the micellar molecular weights (MMW) was examined for various types of surfactants. A linear relation was found between V_M and log MMW, with the exception of a surfactant with a heterocyclic structure. It appears that gel filtration offers a convenient way for roughly estimating the MMW's of surfactants.

Gel filtration is a type of partition chromatography in which substances are separated largely on the basis of the molecular size. If a mixture of low-molecular-weight substances and high-molecular-weight substances moves through a gel column, the former are slowed down as a result of their penetration into the gel, enabling the latter to flow faster down through the column. The sizes of surfactant micelles are, in general, within the range to which this gel filtration is applicable. However, few studies have been made of the application of gel filtration to micellar solutions of surfactants.[1]

In the present work, an attempt has been made to apply gel filtration on Sephadex, a cross-linked dextran gel, to micellar solutions of surfactants, especially those of sodium dodecyl sulfate (SDS) and sodium tetradecyl sulfate (STS). The results were interpreted by taking into account the fact that micelles always exist in equilibrium with monomolecularly-dispersed species above the critical micelle concentration (CMC). Further, the relation between the retention volumes of micelles and their molecular weights was examined for various types of surfactants.

Experimental

Materials. Sephadex G-50 and G-75, with particle sizes of 20—80 and 40—120 micron respectively, and Blue Dextran 2000, with a molecular weight of 2×10^6, were obtained from Pharmacia, Sweden. The sodium decyl-, dodecyl-, and tetradecyl-sulfates were prepared from the respective alcohols by the method of Dreger *et al.*[2] and were purified by repeated recrystallizations from a mixture of isopropanol-water and by extraction with petroleum ether. The sodium decylbenzene sulfonate and sodium dodecyltrioxyethylene sulfate were the same samples as those used in previous works.[3,4] The sodium dodecane sulfonate was a product of Farbenfabrik Bayer, Germany. The dodecyl decaoxyethylene ether and octylphenyl decaoxyethylene ether were samples prepared and purified by a method described elsewhere.[4] The dodecylamine hydrochloride and hexadecyl pyridinium chloride were obtained from Tokyo Kasei and were purified by repeated recrystallizations from acetone. The oil-soluble dyes Yellow OB and Aniline Blue, which were used as solubilizates, were specially-prepared commercial samples.

Procedure. Sephadex G-50 or G-75 was allowed to swell in distilled water for at least 24 hr, and then decanted before being poured into a jacketed column, 1.3 cm in diameter $\times$38 cm in height, with a sintered glass plate at the bottom. After the column had then been filled with the Sephadex gel, a filter paper disk was placed on the top of the gel to prevent its disturbance when the sample solution was added. The column was maintained at 25 ± 0.1°C or 32 ± 0.1°C. The gel column was then washed with distilled water overnight. The void volume of the column, V_0, was checked on the first run of each freshly-packed column, and then on alternate runs, using Blue Dextran 2000.

The sample solution of a surfactant was applied continuously to the top of the column through a siphon connected to the sample reservoir. After about 30 m*l* of the sample solution had sunk into the gel, the eluant, which was the same solution as that which had previously filled the column, was allowed to flow down. An automatic fraction-collector was employed, and fractions of approximately 1 m*l* were collected. The electrical conductivity of each fraction was measured in

order to determine the retention volume of the surfactant.

An alternative procedure was employed to examine the relation between the retention volumes of the micelles and their molecular weights. A 1 m*l* portion of the sample solution in a concentration of 2.0 g/d*l*, which had been tagged by solubilized Yellow OB, was allowed to flow down, in the form of a sandwich (shown in Fig. 1) with two untagged 10 m*l* portions of the sample solution, through a column filled with the solution in a concentration of 0.5 g/d*l* of the same surfactant as that in the sample solution. This minimizes the widening of the sample band by diffusing the tagged micelles. The volume of the solution flowing down before and after the tagged sample solution was set at 10 m*l* after several examinations. The retention volume of the sample was determined with the naked eye.

Results and Discussion

Figure 2 shows the elution curves of SDS in water at various concentrations, using a Sephadex G-50 column. Below the CMC the retention volume obtained from the curve is independent of the concentration of the surfactant. Above the CMC, on the other hand, the retention volume decreases, at first rapidly and then more and more gradually, with an increase in the concentration. The surfactant solution, the concentration of which is higher than the CMC, contains both micellized and unmicellized (monomeric) species. The retention volume observed, V_{obs}, may, therefore, be separated into the retention volume of the monomer, V_m, and that of the micelle, V_M. The values of

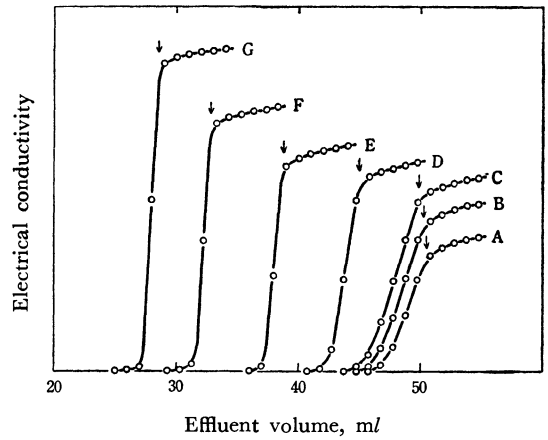

Fig. 2. Elution curves of sodium dodecyl sulfate in water at various concentrations with a Sephadex G-50 column at 32°C:
A 0.0030 M; B 0.0060 M; C 0.0080 M;
D 0.010 M; E 0.013 M; F 0.020 M;
G 0.040 M. The arrow indicates the retention volume of the surfactant at each concentration.

V_{obs}, V_m, and V_M are related by the expression:

$$V_{obs} = xV_m + (1-x)V_M$$
$$= V_M + x(V_m - V_M),\ x = C_m/C \qquad (1)$$

where C is the total concentration of the surfactant and C_m is the concentration of the monomer species. Below the CMC, $C_m=C$; therefore $V_{obs}=V_m$, since x is equal to unity. Above the CMC, C_m is nearly a constant ($C_m \simeq$CMC).[5] Thus, plots of V_{obs} *vs.* $1/C$ consist of two straight lines; one intersects the ordinate at V_M, and one is parallel to the abscissa at $V_{obs}=V_m$. These two lines intersect at $1/C=1/\text{CMC}$. Figure 3 shows the V_{obs}-*vs.*-$1/C$ plots for SDS and STS in water. The

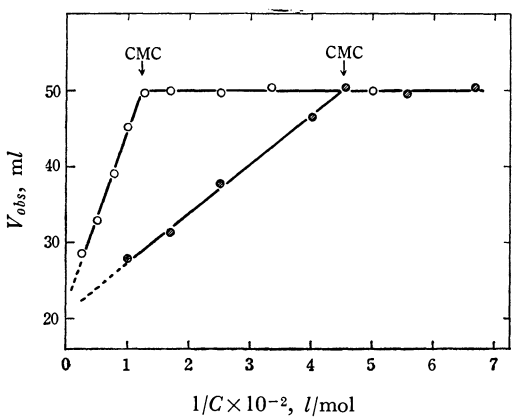

Fig. 3. Plots of V_{obs} *vs.* $1/C$ for sodium dodecyl sulfate (○) and sodium tetradecyl sulfate (◍) in water with a Sephadex G-50 column at 32°C.

5) E. Hutchinson, *Z. Physik. Chem. (Frankfurt)*, **21**, 38 (1959); E. Hutchinson, V. E. Sheaffer and F. Tokiwa, *J. Phys. Chem.*, **68**, 2818 (1964).

values of V_m for SDS and STS are almost the same, while the value of V_M for SDS is slightly larger than that for STS. The CMC values of SDS and STS obstained from the breakpoint of the V_{obs}-*vs.*-$1/C$ plots are in good agreement with their published values.[6,7]

If the gel column has previously been filled with the solution of the surfactant, which is the same as that in the sample solution, of a concentration of C_s, the x in Eq. (1) may be written in the following forms. When C_s is smaller than CMC:

$$x = (C_m - C_s)/(C - C_s)$$

When C_s is larger than CMC:

$$x = 0$$

Therefore, we have:

$$V_{obs} = V_M + \frac{C_m - C_s}{C - C_s}(V_m - V_M) \quad \text{for } C_s < \text{CMC} \qquad (2)$$

and:

$$V_{obs} = V_M \quad \text{for } C_s \geq \text{CMC} \qquad (3)$$

Figure 4 shows the V_{obs}-*vs.*-$1/(C-C_s)$ plots for SDS at different values of C_s. When $\text{CMC} > C > C_s$, $C_m = C$; therefore, the value of V_{obs} is again equal to V_m, and the plots of V_{obs} *vs.* $1/(C-C_s)$ in this region become straight lines parallel to the abscissa at $V_{obs} = V_m$. When $C \geq \text{CMC} > C_s$, C_m is nearly equal to the CMC and is independent of C, so the slope of the plots of V_{obs} *vs.* $1/(C-C_s)$ (*i. e.*, the value of $(C_m - C_s)\cdot(V_m - V_M)$) decreases with an increase in C_s and becomes zero at $C_s = C_m (\simeq \text{CMC})$, as may be expected from Eq. (2). When $C > C_s \geq$ CMC, the plots of V_{obs} *vs.* $1/(C-C_s)$ are straight lines parallel to the abscissa at $V_{obs} = V_M$, as described in Eq. (3). Thus, the value of V_M can easily be obtained from the retention volume observed, V_{obs}, at $C_s \geq$ CMC.

The retention volumes of substances have some relation with their molecular weights. In the field of biochemistry numerous attempts have been made to determine the molecular weights of proteins from their retention volumes.[8-10] It is

of interest and also of importance to learn whether there is any possibility of estimating the micellar molecular weights (MMW) of surfactants directly from their gel filtration data. For this purpose, the V_M values for various types of surfactants of known MMW were determined. In the present experiment the micellar solution of the surfactant examined, which was tagged with solubilized Yellow OB, was allowed to flow down in the form of a sandwhich, as has been described in the Experimental section, through a Sephadex G-75 column. The Sephadex G-75 was chosen after taking into account its fractionation range of molecular weight (3×10^3—6×10^4). The effect of oil-soluble dyes on the values of V_M was checked by using two different types of dyes, Yellow OB and Aniline Blue. It was confirmed that the retention volumes are not influenced by the addition of the dyes.

In Fig. 5, the MMW's of various types of surfactants are plotted against the V_M/V_0 ratios, where V_0 is the void volume of the column. There is a linear relation between log MMW and V_M/V_0 except in the cases of hexadecyl pyridinium chloride and octylphenyl decaoxyethylene ether, as may be seen in Fig. 5. The values of V_M for these surfactants deviate from the linear relation. Probably the derivation in the case of hexadecyl pyridinium chloride may be attributed to the interaction of the dextran gel with the pyridine ring in the surfactant molecule. Such interactions have been found in experiments with heterocyclic substances.[15] The reason for the deviation found in octylphenyl decaoxyethylene ether is not clear, because its MMW is outside the fractionation range of the gel used.

From the data presented above, it appears that gel filtration on Sephadex offers a convenient way of roughly estimating the MMW of a surfactant unless the surfactant has a heterocyclic structure.

The authors wish to express their thaks to Dr. H. Kita, Director of the Research Laboratories, for his encouragement and the permission to publish this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2288—2292 (1968)

Retardation of Polarographic Oxidation of Ethylenediaminetetraacetatocobaltate(II) by Mercury(I) Iodide Film Formation

Nobuyuki TANAKA, Setsuko YAMAMOTO and Yuichi SATO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 13, 1968)

The electrode process of ethylenediaminetetraacetatocobaltate(II) ($Co^{II}Y^{2-}$) at the dropping mercury electrode has been studied in the presence of iodide ions. It was found that polarographic anodic waves of $Co^{II}Y^{2-}$ were affected by the film of mercury(I) iodide which was formed electrolytically at the electrode surface. The measurement of current-time curves during the life of a mercury drop and the coulometric studies revealed that the electro-oxidation of $Co^{II}Y^{2-}$ was completely inhibited by the formation of monomolecular layer of mercury(I) iodide on the mercury surface.

The electrode processes of ethylenediaminetetraacetatocobaltates(II, III) at various kinds of electrodes have been studied by several investigators;[1-6] the polarographic behaviors of these complexes have been investigated in detail.[1-4] Anson[5] reported the effect of adsorbed halide ions on the electro-oxidation of ethylenediaminetetraacetatocobaltate(II) ($Co^{II}Y^{2-}$) at a platinum electrode. According to his paper, adsorbed halide ions act catalytically on the electro-oxidation of $Co^{II}Y^{2-}$ and inhibit the oxidation of the platinum electrode especially in acid solutions. Voltammetric and chronopotentiometric behaviors of the anodic oxidation of $Co^{II}Y^{2-}$ at a carbon paste electrode were reported by T. Kitagawa and S. Tsushima.[6] They found, however, that the adsorbable halide ions did not show any pronounced effect on the kinetics of the electrode reaction at the carbon paste electrode.

The present paper is concerned with the effect of iodide ions on the electro-oxidation of $Co^{II}Y^{2-}$ to $Co^{III}Y^{-}$ at the dropping mercury electrode (DME). Iodide ions depolarize the dropping mercury anode with the formation of slightly soluble merucry(I) iodide. In the presence of iodide ions, a direct current (d. c.) polarogram showed the decrease in anodic limiting current of $Co^{II}Y^{2-}$ and a current-time curve during the life of a mercury drop showed a peculiar shape. The influence of iodide ions on the polarogram and current-time curve of $Co^{II}Y^{2-}$ was explained as a result of the film formation of mercury(I) iodide on the electrode surface.

Experimental

A standard solution of cobalt(II) nitrate was obtained by the same procedure as reported previously.[7] Its concentration was determined with a standardized disodium dihydrogen ethylenediaminetetraacetate solution by amperometric titration. The concentration of iodide ions was determined by the Volhard method. All other chemicals used were of analytical reagent grade.

D.c. polarograms were recorded with a Yanagimoto Galvarecorder Model AP-1 with an automatic potential scanner. A Rikendenshi SP-J1 recorder with a Rikadenki DC-201 preamplifier was used to measure current-time curves. The dropping mercury electrode used had an m value of 1.397 mg/sec and a drop time t_d of 5.38 sec, being measured in an air-free 1 M potassium chloride solution containing 0.01% gelatin at 25°C and -0.5 V *vs.* SCE at a 70 cm height of the mercury reservoir. A saturated calomel electrode (SCE) was used as a reference electrode. All measurements were carried out in a thermostat of 25°C, and the dissolved oxygen in the solution was removed by passing pure nitrogen gas through the solution.

Current-potential and current-time curves presented in this paper are all corrected for residual currents. In the case of current-potential curves, the average current was measured and denoted by $\bar{i}$. The plus sign is given for the anodic current and the minus sign for the cathodic one according to the electrochemical nomenclature and definitions by CITCE. The quantity of electricity was calculated by weighing the area of current-time recording chart with a maximum relative error due to weighing of $\pm 1\%$.

Results and Discussion

Inhibition of the Electrode Reaction by Mercury(I) Iodide Film Formation. Cobalt(II)-EDTA anions gave a polarographic anodic wave as a result of the electrode reaction,

$$Co^{III}Y^{-} + e \rightleftarrows Co^{II}Y^{2-} \qquad (1)$$

Its half-wave potential $E_{1/2}$ was obtained at $+0.13_8$ V *vs.* SCE, independent of the ionic strength from 0.1 to 1.0 and of the concentration of gelatin from zero to 0.05%. This value of $E_{1/2}$ is in good agreement with that reported by Reilley *et al.*[1] independent of pH from 4.5 to 10.5. The limiting current of the oxidation wave was diffusion-controlled.

It is also well known that iodide ions give a polarographic anodic wave based on the electrode reaction,[8]

$$Hg_2I_2 + 2e \rightleftarrows 2Hg + 2I^{-} \qquad (2)$$

The wave showed a well-defined shape at a small concentration of iodide, but when the concentration of iodide was greater than about 5×10^{-4} M the limiting current showed irregular fluctuations. Accordingly, 0.05% gelatin was used in this experiment to improve the iodide limiting current.

The current-time curve of iodide ions showed a normal shape, provided that an appropriate concentration of gelatin was present in the solution. However, in the presence of iodide ions, polarograms of $Co^{II}Y^{2-}$ were found not to be diffusion-controlled and current-time curves of $Co^{II}Y^{2-}$ showed peculiar shapes. In Fig. 1 are shown

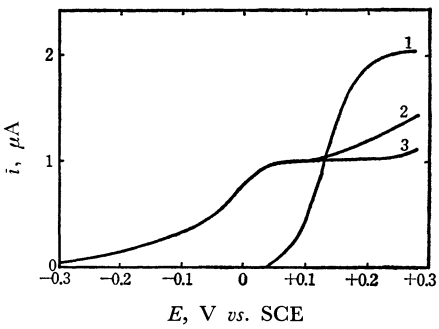

Fig. 1. Polarograms of 1.0 mM $Co^{II}Y^{2-}$ obtained in the solutions containing 0.1 M acetate buffer and 0.05% gelatin (1) in the absence and (2) in the presence of 3×10^{-4} M KI. Curve 3 is a polarogram of 3×10^{-4} M KI in 0.1 M acetate buffer containing 0.05% gelatin.

polarograms of 1.0 mM $Co^{II}Y^{2-}$ which were obtained in the solution containing 3×10^{-4} M potassium iodide, 0.1 M acetate buffer (pH 4.59) and 0.05% gelatin. Comparing curve 2 with curve 1, it is clear that the limiting current of $Co^{II}Y^{2-}$ is much smaller in the presence of iodide ions, whereas iodide ions yield a wave proportional to their concentration even in the presence of the complex. This phenomenon was also observed in the measurement of current-time curves.

Figure 2 presents the current-time curves during the life of a mercury drop measured at $+0.25$ V *vs.* SCE where the electrode reactions according to Eqs. (1) and (2) can take place. The abnormal

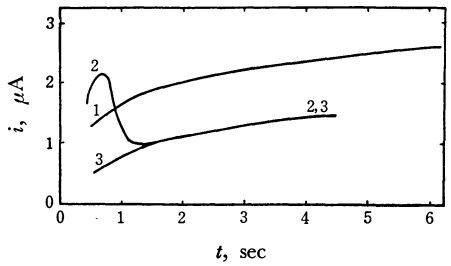

Fig. 2. Current-time curves obtained at +0.25 V *vs.* SCE with the same solutions as given in Fig. 1.

shape of current-time curve of $Co^{II}Y^{2-}$ was obtained in the presence of iodide ions (curve 2 in Fig. 2). During the earlier period of the growth of the mercury drop, the current-time curve (curve 2) follows the pattern of the normal diffusion-controlled current-time relationship, that is, the current observed is equal to the sum of the anodic current of $Co^{II}Y^{2-}$ (curve 1) and that of iodide (curve 3). Then, the current begins to decrease and at the end of the drop life it coincides exactly with the curve obtained in the solution containing only iodide ions. This suggests that mercury(I) iodide, which is the product of the electrode reaction according to Eq. (2), is adsorbed on the mercury surface and inhibits the electro-oxidation of $Co^{II}Y^{2-}$. In the earlier period of the drop life, the amount of adsorbed mercury(I) iodide is not enough to retard the electrode reaction of $Co^{II}Y^{2-}$, so that no deviation from the diffusion-controlled current occurs.

As the rate of mercury(I) iodide film formation is greater than the rate of the growth of the mercury drop, the ratio of the area occupied by the adsorbed mercury(I) iodide to the area of the mercury surface, *i. e.* the surface coverage θ, becomes larger with the time. This results in the retardation of the electro-oxidation of $Co^{II}Y^{2-}$ and the decrease in the current.

In Fig. 3 are shown the current-time curves obtained at various concentrations of iodide in the presence and the absence of $Co^{II}Y^{2-}$. These current-time curves demonstrate systematically the effect of adsorbed mercury(I) iodide on the oxidation of $Co^{II}Y^{2-}$ with increasing concentrations of iodide; the increase in the iodide concentration gradually changes the shape of the current-time curve. At a very low concentration of iodide such as 4×10^{-5} M, the current-time curve showed a normal shape during the whole life of the mercury drop (curve 1); this concentration of iodide is not sufficiently large enough to cause the retardation of the electro-oxidation of $Co^{II}Y^{2-}$. As the concentration of iodide increases, a remarkable change appears in the current-time curves (curves 2 and 3). When the concentration of iodide ions is equal to 1×10^{-3} M, the oxidation reaction of $Co^{II}Y^{2-}$ does

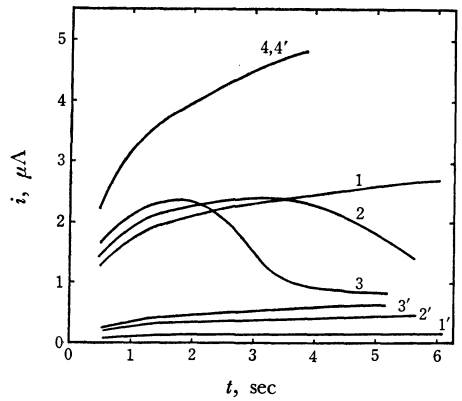

Fig. 3. Current-time curves of 1.0 mM $Co^{II}Y^{2-}$ obtained at +0.25 V *vs.* SCE in the solutions containing 0.1 M acetate buffer and 0.05% gelatin in the presence of (1) 4×10^{-5} M, (2) 1×10^{-4} M (3) 1.4×10^{-4} M and (4) 1×10^{-3} M KI. Curves 1' to 4' are current-time curves obtained in the same solutions as curves 1 to 4 but in the absence of $Co^{II}Y^{2-}$.

not occur even at the very beginning of the drop life; curves 4 and 4' are almost the same. In Fig. 4 are shown the d. c. polarograms which were obtained with the same solutions as shown in Fig. 3. Polarographic behaviors were found to be analogous to those of the current-time curves. With increasing concentrations of iodide, the anodic current of $Co^{II}Y^{2-}$ gradually decreases, until no difference could be seen between two polarograms of iodide ions with (curve 4) and without $Co^{II}Y^{2-}$ ions (curve 4').

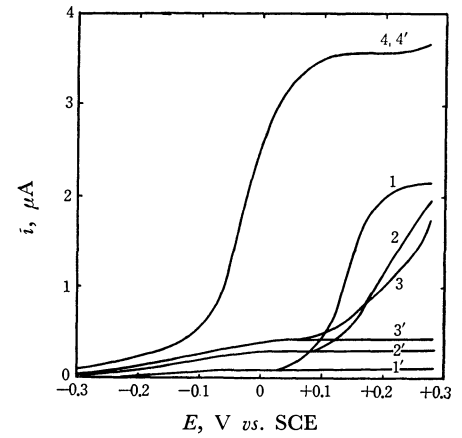

Fig. 4. Polarograms obtained with the same solutions as given in Fig. 3.

From the results mentioned above, it may be said that adsorbed mercury(I) iodide inhibits the electro-oxidation of $Co^{II}Y^{2-}$, but not that of mercury taking place in the presence of iodide ions. The electro-oxidation of mercury which took place in the presence of ethylenediaminetetraacetate

anion to form ethylenediaminetetraacetatomercurate(II) (HgY^{2-}) was also observed. It occurred at almost the same potentials as the electro-oxidation of $Co^{II}Y^{2-}$, but it was not so inhibited as $Co^{II}Y^{2-}$ in the presence of iodide ions.

Quantitative Evaluation of Adsorbed Mercury(I) Iodide. The inhibition of the electrode reaction of $Co^{II}Y^{2-}$ by mercury(I) iodide film formation at the surface of the dropping mercury electrode was investigated quantitatively in the following way. The quantity of electricity q which was consumed to form mercury(I) iodide (Hg_2I_2) at the electrode surface was measured from the area of the current-time curve of iodide ions. Let us denote the time when the current-time curve of $Co^{II}Y^{2-}$ began to decrease in the presence of iodide to be t_1, and the quantity of electricity consumed until t_1 to be q_1. The former was determined from the current-time curve which was prepared by subtracting the current-time curve obtained with the solution containing iodide only from that obtained with the solution containing $Co^{II}Y^{2-}$ and iodide. (See Fig. 5). The values of q were determined at various concentrations of iodide ions. Plots of q_1 *vs.* A_1 gave a straight line passing through the origin, where A_1 is the area of the electrode surface at time t_1 expressed in cm^2 ((1) in Fig. 6). Therefore it can be concluded that when the inhibition of the electro-oxidation of $Co^{II}Y^{2-}$ begins during the life of a mercury drop the extent of coverage of the electrode surface by mercury(I) iodide is constant irrespective of the iodide ion concentrations. A linear relationship between q_2 and A_2 was also obtained, as is shown by (2) in Fig. 6, where q_2 and A_2 mean the electricity consumed and the surface area, respectively, at time t_2 when the electro-oxidation of $Co^{II}Y^{2-}$ at the DME is completely inhibited.

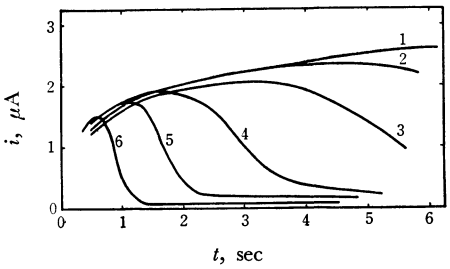

Fig. 5. Current-time curves of 1.0 mM $Co^{II}Y^{2-}$ at +0.25 V *vs.* SCE after correction for those of the corresponding concentration of iodide. The supporting electrolyte solutions contain 0.1 M acetate buffer and 0.05% gelatin. Concentrations of iodide ions are (1) none, (2) 8×10^{-5} M, (3) 1×10^{-4} M, (4) 1.4×10^{-4} M, (5) 2×10^{-4} M and (6) 3×10^{-4} M.

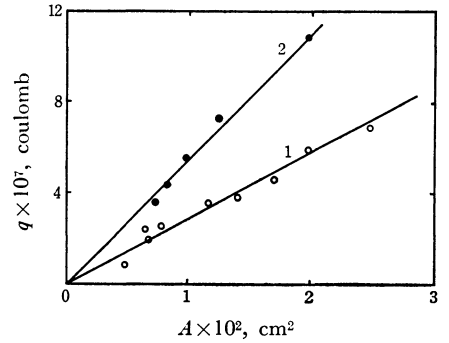

Fig. 6. The quantity of electricity versus the area of the DME (1) when inhibition of the electrode reaction begins and (2) when the electrode reaction is completely inhibited.

The surface coverage θ can be calculated with the equation,

$$\theta = \frac{n \times S}{A} \tag{3}$$

where n is the number of mercury(I) iodide molecules formed on the mercury surface, S is the area covered by one adsorbed molecule of mercury(I) iodide in cm^2, and A is the area of the electrode surface in cm^2. The value of n was calculated from the quantity of electricity consumed.

The crystal structure of mercury(I) iodide has been investigated by Havighurst.[9] If it is assumed that mercury(I) iodide forms a molecular film of the same structural arrangement as in the crystal, the effective area which one molecule of mercury(I) iodide occupies on the surface of mercury can be calculated with the aid of the structural parameters. When the amount of mercury(I) iodide produced by the electro-oxidation is less, the molecule is considered to be adsorbed in such a way that the c axis (the direction of I-Hg-Hg-I) is parallel with the surface of mercury. In this case, if the (110) plane is parallel with the surface, the effective area S is equal to 4.04×10^{-15} cm^2, while if the (100) plane is parallel with the surface, the value of S is equal to 5.71×10^{-15} cm^2.

On the other hand, if mercury(I) iodide is assumed to form a monomolecular film at time t_2 when the electro-oxidation of $Co^{II}Y^{2-}$ is completely inhibited, the effective area of one adsorbed molecule of mercury(I) iodide (Hg_2I_2) is calculated,

Table 1. Effective surface area S_2 of mercury(I) iodide at time t_2

$[I^-]\times10^4$ mol/l	t_2 sec	$q_2\times10^7$ coulomb	$A_2\times10^2$ cm^2	$S_2\times10^{15}$ cm^2

3.0	1.26	7.3	1.2	5.4
4.0	0.88	5.5	1.0	5.7
5.0	0.69	4.4	0.8	6.1
6.0	0.57	3.6	0.7	6.5
			Average	5.9×10^{-15} cm^2

9) R. T. Havighurst, *J. Am. Chem. Soc.*, **48**, 2113 (1926).

with the values of q_2 and A_2 obtained experimentally, to be approximately 5.9×10^{-15} cm^2 irrespective of the iodide concentration (see Table 1). This value is very close to the value of 5.71×10^{-15} cm^2 which was obtained with the assumption that the (100) plane of mercury(I) iodide covers the mercury surface.

As was mentioned above, the retardation of the electro-oxidation of $Co^{II}Y^{2-}$ begins at time t_1, when the mercury surface is covered by a smaller amount of mercury(I) iodide. The surface coverage θ_1 at time t_1 was calculated with the effective area of 5.71×10^{-15} cm^2 for mercury(I) iodide as given in Table 2, which seems to indicate

Table 2. Surface coverage θ_1 at time t_1

$[I^-] \times 10^4$ mol/l	t_1 sec	$q_1 \times 10^7$ coulomb	$A_1 \times 10^2$ cm^2	θ_1
0.8	3.53	6.9	2.5	0.5
1.0	2.52	5.9	2.0	0.5
1.2	2.02	4.6	1.7	0.5
1.4	1.51	3.8	1.4	0.5
2.0	1.13	3.6	1.2	0.6
3.0	0.63	2.6	0.8	0.6
4.0	0.50	1.9	0.7	0.5
5.0	0.47	2.4	0.7	0.7
6.0	0.32	0.8	0.5	0.3

that the retardation of the electro-oxidation of $Co^{II}Y^{2-}$ begins to occur when the fraction of the covered surface reaches nearly a half of the whole area of the electrode, again irrespective of the iodide concentration.

Conclusion. The electro-oxidation of ethylenediaminetetraacetatocobaltate(II) at the DME was found to be retarded and inhibited by the film formation of mercury(I) iodide. The effective area of one adsorbed molecule of mercury(I) iodide (Hg_2I_2) agreed with the area which one molecule of mercury(I) iodide covers if the (100) plane is considered to be parallel with the surface of mercury, being calculated with the aid of the structural parameters of the compound. It seems difficult, however, to decide at the present moment whether this agreement is fortuitous or not.

The film formation of mercury(I) iodide did not interfere with the electro-oxidation of mercury to form mercury(I) iodide, and less interfere with that of mercury to form ethylenediaminetetraacetatomercurate(II) under the conditions that the electro-oxidation of ethylenediaminetetraacetatocobaltate(II) is completely inhibited.

Silent Discharge Reactions in Aqueous Solutions. VIII. Effects of Discharge Gap Distance and Discharge Current on the Yield of Decomposition Products Formed from Water in Argon Atmosphere

Akira YOKOHATA, Katsuyuki HARAKON and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received March 14, 1968)

In order to elucidate the effects of discharge gap distance and discharge current on ${}^{s}G(H_2O_2)$, ${}^{s}G(OH)$ and ${}^{s}G(H)$, the study of this series was further made by using a new discharge apparatus. Both of acidic aqueous solutions of ferrous sulfate and ferrous sulfate-cupric sulfate have been selected as the reaction systems suitable for this purpose. Experiments were made in the range from 3 mm to 9 mm of discharge gap distance and from 0.2 mA to 0.5 mA of discharge current. Each ${}^{s}G$ value of H_2O_2, OH and H varied with gap distance (5→9 mm) and current (0.2 →0.5 mA) as follows; in the former, 1.0→1.2, 1.8→0.9 and 1.1→0.9: in the latter, 1.4→1.2, 0.6→ 0.9, 0.8→0.9. Based on the value of $Y(H_2O_2)/Y(H+OH)$, it was concluded that (1) the silent discharge reactions under a longer gap distance correspond to the radiolysis having a value of higher LET, that (2) although those under a lower current do also to a higher one, the effect of discharge current on the value of apparent LET is relatively small.

In the previous reports,[1] the authors have elucidated that in the silent discharge reactions of the aqueous solutions under the atmosphere of inert gas, the actions of the slow electrons generated in the gas phase to water molecules play a main

1) A. Yokohata and S. Tsuda, This Bulletin, **39**, 46, 53, 1636 (1966); **40**, 294, 1339, 2502, 2507 (1967).

role. In other words, the silent discharge reactions can be well interpreted in terms of an indirect effect: the primary one being the radiolysis of the water to give the intermediates like hydrogen atoms or hydroxyl radicals through the interaction of slow electrons with water molecules, in which the molecular products; hydrogen and hydrogen peroxide can also be obtained.

Each apparent G value (denoted by ${}^{s}G$) determined through the series of this study was as follows:

In argon; ${}^{s}G(\mathrm{H})=0.6$, ${}^{s}G(\mathrm{OH})=0.7$ and ${}^{s}G(\mathrm{H_2O_2})=1.5$

Of course, these values are meaningful only in the discharge tube used by us and not so universal as in the radiation chemistry. They appear to vary with the shape of discharge tube, the discharge gap distance and the discharge current, because the numbers and the mode of the streamers produced by discharge depend on them.

In order to get more informations on these points, a new discharge apparatus to make possible the variation of discharge gap distance was devised. The effect of electric discharge current has been also checked.

It is of interest and important to clear up these problems in the field of silent discharge. The aqueous solutions of ferrous ions and ferrous-cupric ions acidified with 0.4 N sulfuric acid were selected as the reaction systems suitable for this purpose.

Experimental

Apparatus. Figure 1 shows an experimental apparatus. It is composed of a discharge vessel having an electrode (A) of glass disk on which a tin foil (a) is wrapped and a gas washing bottle (B). A glass disk connected with glass holder (b) by adhesive is movable up and down through the wax-sealed part (c), which makes the variation of discharge gap distance possible. This disk was used as one electrode of the high tension side, and the tin foil part wrapped on the outer side (d) of vessel as another electrode (earth side).

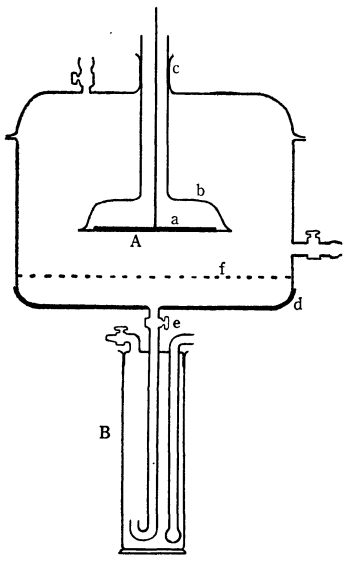

Fig. 1. Experimental apparatus.

After the sample solution deaerated previously by argon had been introduced into the vessel through the stopcock (e) of gas-washing bottle, the discharge was made by applying a high tension among those two electrodes, flowing argon gas through the vessel.

The discharge gap distance between the glass disk and the water surface was measured by the scale previously marked on the glass holder, while the level of the solution in the vessel was always kept constant (f).

The value of applied voltage was always calibrated by a static voltmeter. The electric discharge current was measured by the electric circuit shown in Fig. 2.

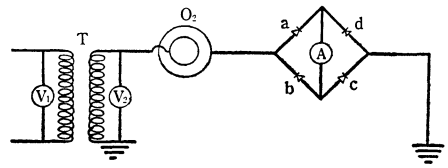

Fig. 2. Electric circuit.

V_1: Voltmeter V_2: Static electric voltmeter
a, b, c, d: Cu_2O rectifier A: Direct ammeter
Oz: Discharge tube T: Transformer

All experiments were made at room temperature, and at the constant solution volume of 100 m*l*. Flow velocity of argon gas was about 120 m*l*/min.

Materials. For the reliable performance, triple distilled water was always used throughout the work. All other materials were of reagent grade. Argon (purity$\gtrsim$99.998%) was used without further procedure.

Analysis. Ferric ion was determined from its optical density using a spectrophotometer at 304 mμ where $\varepsilon=2160\ \mathrm{M^{-1}cm^{-1}}$. Hydrogen peroxide was determined by the Ghormley method.[2]

Results

Figure 3 shows the relation between the applied voltage and electric current under each discharge gap distance of 5, 7 and 9 mm. As previously described, the discharge tube may be considered to be a sort of condenser having the capacitance C,[3] which consists of two parts, C_{die} and C_a; the former depends on the thickness and surface area of the glass disk and of the part covered by tin foil on the vessel, and the latter, on the gap distance among the glass disk and the water surface.

In Fig. 3, B, B', and B'' show respectively the firing voltage (V_1) for gap distance of 5, 7 and 9 mm. The AB, AB' and AB'' parts before discharge are

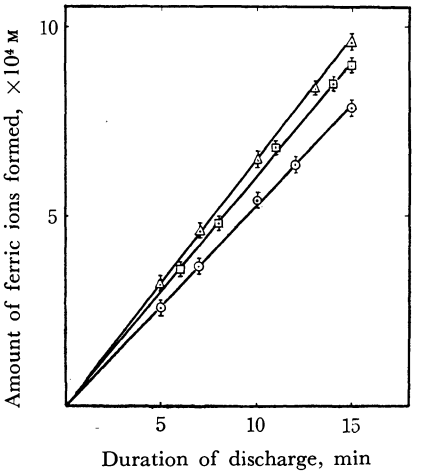

Fig. 6a

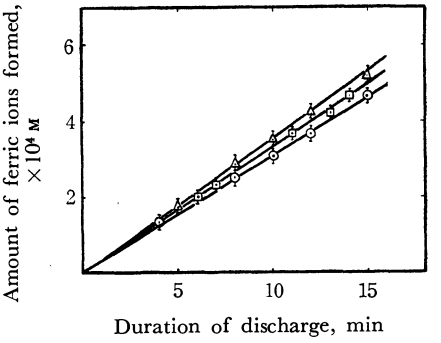

Fig. 6b

Fig. 6. Relation between amount of ferric ions formed and duration of discharge.
Discharge current: 0.5 mA
Dischrge gap distance:
⊙ 9 mm, ⊡ 7 mm, △ 5 mm
a Ferrous ion system: 2×10^{-3} M $FeSO_4$, 0.4 N H_2SO_4
b Ferrous-cupric ion system: 2×10^{-3} M $FeSO_4$—2×10^{-2} M $CuSO_4$, 0.4 N H_2SO_4

In the aqueous solution of 0.4 N sulfuric acid deaerated by argon, silent discharge leads to the formation of hydrogen peroxide.

Figure 4 shows the relation between the amount of hydrogen peroxide formed and the duration of discharge under the constant electric discharge current, 0.5 mA, where the discharge gap distance was changed in the range from 5 mm to 9 mm. In every case a good linearity has been found.

Figure 5 shows the relation between the amount of hydrogen peroxide formed and discharge current under a condition of discharge gap distance=9 mm and duration of discharge=10 min. In the experimental condition from 0.2 mA to 0.5 mA a good linearity was also found respectively.

As shown in the previous reports,[1] the silent discharge leads to the oxidation of ferrous ions to ferric ions. Then, the yield of ferric ions was independent of the concentration of ferrous ions in the range from 2×10^{-3} M to 4×10^{-1} M, and of the concentration of sulfuric acid in the range from 2×10^{-2} N to 1.5 N.

On the other hand, the addition of cupric ions reduces the yield of ferric ions because of the competition reaction of cupric ions and ferrous ions for the hydrogen atom. Then, it is also known that the existence of cupric ions of about 10 times as much as the ferrous ions is sufficient to scavenge the hydrogen atoms through the competition with ferrous ions.[1] In the ferrous ion system 2×10^{-3} M ferrous sulfate, and in the ferrous-cupric ion system 2×10^{-3} M ferrous sulfate and 2×10^{-2} M cupric sulfate were used respectively.

Figure 6 shows the relation between the amount of ferric ions formed and the duration of discharge (Fig. 6a for ferrous ion system and Fig. 6b for ferrous-cupric ion system), where the discharge current was 0.5 mA and the discharge gap distance was changed in the range from 5 mm to 9 mm. In all cases a good linearity has been found.

Figure 7 shows the relation between the amount of ferric ions formed and electric discharge current (Fig. 7a for ferrous ion system and Fig. 7b for ferrous-cupric ion system), where the discharge gap distance was 9 mm and the discharge current was changed in the range from 0.2 mA to 0.5 mA. In both cases a good linearity has been also found.

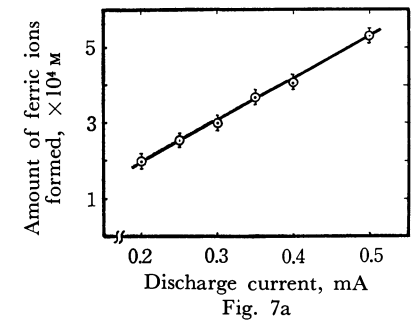

Fig. 7a

Discussion

On the basis of the well-known reaction mechanisms of the radiolysis of these systems, Eqs. (1) and (2) can be obtained. For the ferrous ion system,

$$G(Fe^{3+}) = 2G(H_2O_2) + G(OH) + G(H) \quad (1)$$

For the ferrous-cupric ions system,

$$G(Fe^{3+}) = 2G(H_2O_2) + G(OH) - G(H) \quad (2)$$

Since the silent discharge reactions correspond to ones induced by ionizing radiations of high LET (linear energy transfer), Eqs. (3) and (4) should be obtained respectively.[1]

$$Y(Fe^{3+}) = 2Y(H_2O_2) + Y(OH) + Y(H) \quad (3)$$

$$Y(Fe^{3+}) = 2Y(H_2O_2) + Y(OH) - Y(H) \quad (4)$$

where, Y shows respectively the yield of each product under a given discharge conditions. Thus, $Y(OH)$ and $Y(H)$ can be separately estimated from $Y(Fe^{3+})$ in the ferrous ion system, $Y(Fe^{3+})$ in the ferrous-cupric ion system, and $Y(H_2O_2)$ in the aqueous 0.4 N sulfuric acid.

Table 2. Relation between discharge gap distance and Y value

Gap distance mm	$Y(H_2O_2)$ $\times10^4$ M	$Y(H+OH)$ $\times10^4$ M	$Y(OH-H)$ $\times10^4$ M	$Y(H_2O_2)/Y(H+OH)$
5	1.3_6	3.7_8	0.8_1	0.36
7	1.4_7	3.1_1	0.4_0	0.47
9	1.5_5	2.2_4	0.0_6	0.69

By the same treatment as described in the previous report,[1] we can estimate $G(Fe^{3+})$ value from the value of apparent LET estimated on the basis of the relation between $G(H_2O_2)/G(H+OH)$ and LET. By combining $G(Fe^{3+})$ value estimated in this way with $Y(Fe^{3+})$, the absorbed dose can be determined. Of course, this means the dose determined by a chemical dosimeter; in other word, ones normalized to the scale of radiation chemistry. Let us call it "the apparent dose." The significance and the usefullness of this dose have been discussed in detail through the series of this study.

Effect of Discharge Gap Distance. Table 2 shows the respective value of $Y(H_2O_2)$, $Y(H+OH)$, $Y(OH-H)$ and $Y(H_2O_2)/Y(H+OH)$ under each discharge gap distance of 5, 7 and 9 mm, where discharge current=0.5 mA and duration of discharge=10 min. Thus, it can be understood that the silent discharge reactions of the aqueous solutions in argon atmosphere under each discharge gap distance of 5 mm, 7 mm and 9 mm correspond to the ones induced by the ionizing radiations having the value of LET of about 2, 4 and 6 (eV/Å).

By the use of each $G(Fe^{3+})$ value estimated from the value of LET,[4] the apparent dose rate can be respectively estimated to be 7.9×10^5 R/hr in 5 mm, 8.0×10^5 R/hr in 7 mm and 7.5×10^5 R/hr in 9 mm.

In general, the energy dissipated per second by the silent discharge is known to be expressed as follows:[5]

$$A=\frac{\left[f(C_{die}+C_a)(V_i+V_d)\{2E_m-(V_i+V_d)\{1+C_a/C_{die})\}\right]}{1+C_a/C_{die}} \qquad (5)$$

where V_i is correlated by the $V_i=V_1(C_{die}/(C_a+C_{die}))$ formula to the firing voltage, V_1. Table 3 shows the results of the calculation of A for each case of $V_d/V_i=0.2$ and 0.4.[1]

Since it is very difficult to determine exactly a value of firing voltage, the values calculated from Eq. (5) should be considered to be approximate ones.

Table 3. Calculated results of dissipated energy under each discharge gap distance of 5, 7 and 9 mm (normalized to the case of 5 mm)

Discharge gap distance mm	V_d/V_i	Dissipated energy
5		1
7	0.2	1.2
9		1.4
5		1
7	0.4	1.2
9		1.4

In spite of the fact that the dissipated energy increases with increasing discharge gap distance, the absorbed dose determined was almost the same. This finding suggests that the chemical utilization efficiency is rather better in a short discharge gap distance.

Table 4 shows each ${}^sG$ value of hydrogen peroxide, hydroxyl radical and hydrogen atom in relation to discharge gap distance. The increments of ${}^sG(H_2O_2)$ and the decrement of ${}^sG(OH)$ or ${}^sG(H)$ with the increasing discharge gap distance tend to confirm that the silent discharge reactions under a longer gap distance correspond to them induced by the ionizing radiations having a higher LET.

Table 4. Relation between discharge gap distance and ${}^sG$ value; discharge current=0.5 mA

Gap distance mm	${}^sG(H_2O_2)$	${}^sG(OH)$	${}^sG(H)$
5	1.0	1.8	1.1
7	1.1	1.3	1.0
9	1.2	0.9	0.9

In general, a higher applied voltage is needed for with an increasing discharge gap distance under

Table 5. Relations of the values of Y and apparent LET to each discharge current; discharge gap distance=9 mm

Discharge current, mA	$Y(H_2O_2)$ $\times10^4$ M	$Y(H+OH)$ $\times10^4$ M	$Y(OH-H)$ $\times10^4$ M	$\frac{Y(H_2O_2)}{Y(H+OH)}$	LET eV/Å
0.2	0.6_7	0.6_7	0.1_6	1.0	8
0.3	0.9_7	1.2	0.1_1	0.8	7
0.4	1.2_5	1.7	0.1_0	0.7	6
0.5	1.5_5	2.2	0.0_2	0.7	6

V_d: the stopping voltage

E_m: the maximum value of the applied voltage

a constant discharge current. A higher applied voltage would result in a localty of discharge which will induce the chemical reactions corresponding to them by a more densely ionizing radiations. The findings obtained support this interpretation.

Effect of Discharge Current. By the same procedure as above mentioned, the effect of discharge current was checked. Table 5 shows the respective value of $Y(H_2O_2)$, $Y(H+OH)$, $Y(OH-H)$, $Y(H_2O_2)/Y(H+OH)$ and apparent LET under each discharge current of 0.2, 0.3, 0.4 and 0.5 mA, where discharge gap distance= 9 mm and duration of discharge=10 min. From the value of apparent LET, the apparent dose rates under each discharge current of 0.2, 0.3, 0.4 and 0.5 mA were respectively estimated to be 2.9×10^5 R/hr, 4.4×10^5 R/hr, 6.0×10^5 R/hr and 7.5×10^5 R/hr. Table 6 shows the relation between each ${}^sG$ value of products and discharge current.

Table 6. Relation between discharge current and ${}^sG$ value; discharge gap distance=9 mm

Discharge current mA	${}^sG(H_2O_2)$	${}^sG(OH)$	${}^sG(H)$
0.2	1.4	0.6	0.8
0.3	1.3	0.8	0.9
0.4	1.3	0.8	0.8
0.5	1.2	0.9	0.9

These findings show that the silent discharge reactions under a lower current tend to correspond to the radiolysis having a value of higher LET. However, it can be concluded that the effect of discharge current on the value of apparent LET is relatively small.

Solvent Effect in NMR Spectroscopy. II. A Repulsive Interaction between the Benzene Solvent Molecule and the Nitrogen Lone-Pair, and the Effects Induced by the Addition of Protic Substances

Teijiro YONEZAWA, Isao MORISHIMA and Kazuhiko FUKUTA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 28, 1968)

The variations in the chemical shifts of proton resonances in imines, aziridines, and oximes, all of which have oriented nitrogen lone-pair electrons, on going from a carbon tetrachloride solution to a benzene solution ("benzene solvent shift") are determined. Also determined are the changes in the corresponding proton chemical shifts in a benzene solution when protic substances, such as methanol or trifluoroacetic acid, are added ("addition shift"). It is generally found that the upfield benzene-solvent shift is more sensitive to the protons *trans* to the oriented nitrogen lone-pair than to the *cis*. This observation indicates that the formation of a benzene-solute collisional complex is most likely to occur at a site as far as possible from the nitrogen lone-pair. The repelling of a benzene solvent molecule by the nitrogen lone-pair may occur due to the repulsive interaction between lone-pair electrons and benzene π-electrons. It is also found that the addition shift is upfield and is larger for the proton *trans* to the nitrogen lone-pair than for that *cis*. These general observations are of predictive value in the determination of the orientation of the nitrogen lone-pair electrons and in the assignment of the signals of proton groups in the vicinity of the nitrogen lone-pair.

A great number of studies of the specific solvent effects on the proton chemical shifts of polar solutes in aromatic solvents have been reported,[1,2] and the study of these effects has been proved to be a very powerful technique for use in structure elucidation and conformational analysis. For a complex molecule, the size and sign of the benzene-solvent shft (the difference in the chemical shift of a signal in a benzene solvent and in an inactive solvent) have been linked with the position of the protons relative to the polar functional groups.[2]

This benzene-induced chemical shift depends on the equilibrium formation of a stereospecific collisional complex between the solute and the benzene solvent.[2c] The orientation of the solvent molecule

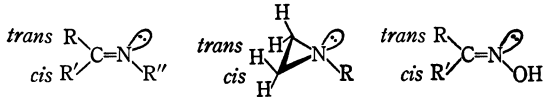
with respect to the dipolar functional groups is non-random. The ketones in a benzene solution form a solute-solvent collisional complex in which the π-electrons of the benzene ring interact with the partial positive charge on the carbonyl carbon atom in such a manner that the benzene ring locates as far as possible from the partial negative charge on oxygen.[2]

In addition to these benzene solvent shifts, we have found a solvent effect induced by the addition of protic substances, such as methanol or trifluoroacetic acid, to a benzene solution of several polar solute molecules.[1] In the previous paper,[1] we have pointed out that the addition of a protic substance to the benzene solution of the carbonyl compounds causes an upfield shift of the protons of the solute molecules. This effect is more pronounced on the protons lying in close proximity to the proton-accepting site of a solute molecule than on those remote from it. The use of this addition shift in structural analysis has been described.

Despite these abundant potential uses of the benzene-induced shift in solving structural and other physical problems, there have been few investigations aimed at elucidating the intrinsic nature of this stereospecific intereaction in aromatic solvents. In the present study we have tried to investigate the benzene-solvent effect of the nitrogen-containing molecules with oriented lone-pair electrons from two viewpoints. First, in order to make clear the nature of the repulsive interaction of the benzene solvent molecule with the negatively-charged site of the polar functional groups of a solute; a limiting case of this interaction between a benzene-solvent molecule and the nitrogen lone-pair electrons is studied. Second, the effect induced by the addition of a protic substance to the benzene solution is further examined for solute molecules with an oriented nitrogen lone-pair which is available as a proton-accepting site. In this work we have determined the benzene-solvent shift and the effect induced by the addition of protic substances on the protons of imines (I), aziridines (II), and oximes (III).



I II III

We now wish to propose the generalization that a benzene-solvent molecule is repelled by the nitrogen lone-pair and has a more remarkable shielding effect on the protons remote from the lone pair; this phenomenon to be of considerable predictive value in structural determination. The addition shift is also shown to have a definite tendency for various solute molecules.

Experimental

Materials. All the chemicals used in this study were obtained from commerical sources unless otherwise noted, and all were carefully purified by distillation before use. The aldimines and ketimines were prepared according to the procedure of Campbell *et al.*[3] To 29.5 g (0.5 mol) of *n*-propylamine, 29.0 g (0.5 mol) of acetone were added gradually over a period of two hours in a nitrogen atmosphere. Potassium hydroxide flakes were then added, and the mixture was allowed to stand in a refrigerator overnight. The dried material was distilled over a few pellets of potassium hydroxide. The *N*-phenylacetonimine was prepared by the condensation of the corresponding ketal[4] with aniline by the method of Hoch.[5] The 1-methyl- and 1-ethylaziridines were prepared from commercially-avaiable 2-methylaminoethanol and 2-ethylaminoethanol respectively by the method of Cairn.[6] The *O*-methylacetoxime ether was prepared by adding dimethylsulfate to a sodium hydroxide solution of acetoxime.[7]

NMR Measurements. Solutions for NMR measurements were prepared in such a way that the concentrations were 7.5 mol% in both the benzene and the carbon tetrachloride solutions. The details of the preparation of the samples for measuring the addition shift have been reported in a previous paper.[1] All the samples were run on a JEOL JNM-3H-60 spectrometer operation at 60 MHz, using an internally-locked field-frequency stabilization control system.[1] The chemical shifts were monitored by an electronic-frequency counter in Hz from an internal TMS.

Results and Discussion

Benzene-solvent Shift. Tables 1, 2, and 3 summarize the chemical shift, in benzene and carbon tetrachloride solutions, of protons of imines (Table 1), aziridines (Table 2), and oximes and oxime ether (Table 3). Before discussing the benzene-solvent shift, however, we wish to discuss briefly the signal assignment of the *cis* and *trans* proton groups for imines (I), aziridines (II), and oximes (III). The basis of the assignment of I is the proton-proton coupling constant between N-$CH_2(\alpha)$ and C-CH_3 protons. The lower-field methyl signal of *N-n*-propylacetonimine shows a splitting ($J=1.4$ Hz) by N-$CH_2(\alpha)$ protons, while the higher-field one gives $J=0.7$ Hz. For *N-n*-propylaldimine the corresponding coupling constant is 1.4 Hz. In light of the general trend, *trans* coupling constant > *cis* coupling constant, the lower-field methyl signal, resonating at about $\tau=8.1$, can be assigned to *trans* methyl protons. Accordingly, the NMR spectrum giving a single

methyl proton signal for *N*-*n*-propylaldimine shows the presence of a single *trans* isomer. These assignments correspond to results of recent work by Olah *et al.*[8] The assignment of the ring methylene proton signals for 1-methyl- and 1-ethylaziridine has been well established,[9] as have the facts that the higher-field one of the two separate ring proton signals belongs to the *cis* group, and the remaining one, the *trans*. For oximes, C-methyl protons when *cis* to the hydroxy group resonate at higher fields than when *trans*; both C-methylene and C-methine protons when *cis* to the hydroxyl group resonate at lower fields than when *trans*. These assignments are based upon the studies by Karabatsos[10] and Huitric.[11] The benzene-solvent shift, $\Delta\nu_{CCl_4}^{C_6H_6}$, is defined as the difference in the chemical shift of a signal between that in a benzene solution and in a carbon tetrachloride solution.

It can be seen from Table 1 that benzene causes a shielding of C-alkyl proton resonances relative to the carbon tetrachloride solution and a shielding or deshielding of N-alkyl protons for several imines. The benzene-solvent shift values, $\Delta\nu_{CCl_4}^{C_6C_6}$, for

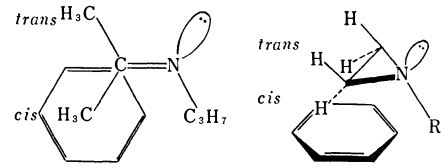

Fig. 1. Model representation of benzene-imine complex. Benzene solvent molecules are repelled by the nitrogen lone pair.

C-alkyl groups of *N*-*n*-propylacetonimine are very different for the *cis* and *trans* groups. A larger shift is observed for the *cis* methyl protons than for the *trans* ones; indeed, the difference is unexpectedly large. This observation makes one picture a benzene-imine stereospecific collisional complex in which the benzene-solvent molecule is repelled by the nitrogen lone-pair, as is shown in Fig. 1. This type of complex has a more effective shielding effect on the *cis* protons than on the *trans* ones. Table 1 also shows the results for *N*-*n*-propylacetaldimine. Contrary to the results for *N*-*n*-propylacetonimine, both C-alkyl and N-alkyl protons are shielded by the benzene solvent here. No shielding or deshielding effect by the benzene solvent for *n*-propyl protons of *N*-*n*-propylacetonimine and *N*-*n*-propylacetaldimine is yet clear in its origin. The larger value of the benzene-solvent shift for methine protons than for methyl protons on the C-alkyl group also indicates that aldimine exists in a single conformation with the C-alkyl group *trans* to the N-alkyl group. In the case of

e) The notation "*trans*" or "*cis*" is referred to the *N*-substituent.

the *N*-phenylacetonimine in Table 1, *cis* methyl protons are shifted more upfield by the benzene solvent than are *trans* methyl protons; this implies also that the benzene molecule is repelled by the nitrogen lone-pair and that it approaches the *cis* methyl group. The replacement of the *n*-propyl group by the phenyl group does not significantly affect this specific solvent shift.

This repulsive interaction between a benzene molecule and lone-pair electrons is further evident from the data for aziridine compounds compiled in Table 2. All the compounds in Table 2 perform a slow internal inversion at the nitrogen atom and show the *cis* and *trans* proton signals separately at room temperature. The $\Delta\nu_{CCl_4}^{C_6H_6}$ values are larger for *cis* methylene protons than for *trans* ones. This observation again indicates that the benzene-solvent molecule locates preferentially as far away as possible at the opposite side of the effective lone-pair (the nitrogen lone-pair) (Fig. 1). This repulsive interaction does not depend on the *N*-substituent alkyl group, as can be seen in Table 2, on passing from 1-methyl- to 1-ethylaziridine. Namely, for 1-ethylaziridine, which has the bulkier ethyl group, the $\Delta\nu_{CCl_4}^{C_6H_6}$ values are not significantly changed; this indicates that the benzene-solvent molecules lying at the *cis* ring methylene protons are not sterically repelled by the 1-substituent alkyl group. The difference in the solvent shift, $\Delta\nu_{CCl_4}^{C_6H_6}$, between the protons of the lone-pair side (the *trans* group) and the opposite side (*cis* group and 1-alkyl protons) is quite large, indicating that the benzene-solvent molecule locates preferentially on one side (the 1-alkyl side) of the three-membered-ring plane.

From these data and from our discussion of the benzene-solvent shift, it can now be concluded that the benzene π-electrons and the nitrogen lone-pair electrons interact repulsively and that this interaction causes a specific benzene-solvent effect on the nitrogen-containing solute molecules.

Oxime has two interaction sites with the benzene-solvent molecule; the nitrogen lone-pair and the hydroxyl group. The partial negative charge on the hydroxyl oxygen repels the benzene molecule and causes a more effective specific shielding of the *trans* C-alkyl protons than of the *cis*. This is analogous to the effect frequently encountered with the polar carbonyl group.[1,2] However, another repulsive site, the nitrogen lone-pair, is also active in benzene-oxime solvent interaction.

The observed benzene-solvent shift may result from the two competitive repulsive interactions between the benzene-hydroxyl group and the benzene-nitrogen lone-pair electrons. Although the benzene-solvent shifts for a few examples of oximes have been determined by Karabatsos,[10] we carried out further, extended studies in order to examine the above-mentioned type of competitive interaction. As is evident in Table 3, the difference in the $\Delta\nu_{CCl_4}^{C_6H_6}$ values for the *cis* and *trans* protons of acetoxime and cyclohexanone oxime is small compared with that between such protons of imines and aziridines (Tables 1 and 2), the value for the *trans* protons being only slightly larger. This observation may reflect the two competitive repulsive interactions mentioned above. Compared with the $\Delta\nu_{CCl_4}^{C_6H_6}$ values of imines with only one repulsive interaction site of the nitrogen lone-pair (Table 1), the reduced value of the difference in $\Delta\nu_{CCl_4}^{C_6H_6}$ for *cis* and *trans* protons of oximes supports the competitive repulsive interaction. This observation has also been encountered in a previous paper[1] regarding nitrosamine, which has two possible repulsive sites, the nitrogen lone-pair and the negatively-charged oxygen atom of the nitroso group.

For acetaldoxime and propionaldoxime, which are mixtures of the *syn* and *anti* isomers consisting of 67% and 45% *syn* isomers for the two aldoximes respectively, the repulsive interaction mentioned above can be expected. For acetaldoxime, the $\Delta\nu_{CCl_4}^{C_6H_6}$ value of the methyl protons is larger for the *syn* isomer than for the *anti*, while for the methine protons the situation is just the reverse. This observation also reflects the fact that the benzene-hydroxyl group repulsive interaction is stronger than the benzene-nitrogen lone-pair interaction. It should be noted that the difference in the $\Delta\nu_{CCl_4}^{C_6H_6}$ values for methyl and methine protons is quite a bit smaller for the case of the *anti* isomer of acetaldoxime compared with that of the *syn* isomer. A similar trend of the solvent shifts is also obtained for ethyl methyl ketoxime.

The last example is *O*-methyl acetoxime ether. In a carbon tetrachloride solution *cis* methyl protons (*cis* to the *O*-methyl group) resonate at a slightly lower field. The addition of benzene to this solution causes the signals to cross, and in the benzene solution the *cis* methyl protons resonate at a very slightly higher field, as may be seen in Table 3. Therefore, the value of $\Delta\nu_{CCl_4}^{C_6H_6}$ is larger for *trans* methyl protons than for *cis* methyl protons. This oxime ether also has two interaction centers with the benzene molecule, the nitrogen lone-pair and the oxygen lone-pair. From the above observation, it can also be said that the benzene-solvent molecule is repelled more effectively by the oxygen lone-pair electrons. This finding is compatible with the finding of Karabatsos and Hsi.[12]

Chemical Shifts Induced by the Addition of Protic Substances to Benzene Solutions. Tables 1—3 also present the chemical shifts for protons induced by the addition of portion of methanol (MeOH) or trifluoroacetic acid (TFA) to

12) G. J. Karabatsos and N. Hsi, *Tetrahedron*, **23**, 1079 (1967).

benzene solutions of imines, aziridines, oximes, and oxime ether. The addition shift, $\Delta\nu^{TFA}_{C_6H_6}$ or $\Delta\nu^{MeOH}_{C_6H_6}$ corresponds to the difference between the chemical shift induced by the addition of the protic substances to a benzene solution of the solute and the chemical shift induced by the addition of a protic substance to a carbon tetrachloride solution of the same solute.[1] This correction for the protonation shift is important for the solute molecules of the present case, which are sensitive to the protic additivities resulting from the hydrogen bonding interaction with the nitrogen lone-pair, causing downfield shifts of the protons in the vicinity of the nitrogen atom.

Figures 2—12 give the plots of the addition shift, $\Delta\nu^{TFA}_{C_6H_6}$ or $\Delta\nu^{MeOH}_{C_6H_6}$ *vs.* the concentration of the added protic substances. A considerable induced upfield shift for the protons in the vicinity of the nitrogen lone-pair is observed, as is to be expected from the various carbonyl compounds discussed in the previous work.[1] For *N*-*n*-propylacetonimine, the protons of the *n*-propyl group suffer larger upfield addition shifts in the groups closer to the nitrogen atom (Table 1 and Fig. 2). It may be seen in Fig. 2 that the aparent addition shift is enhanced by the increase in the concentration of added methanol, until the downfield shift induced by the OH···N hydrogen bond formation appears. For the methyl protons of the $N{=}C(CH_3)_2$ fragment, the relative value of the addition shift is in the order of the solvent shift for *cis* and *trans* methyl groups, and the general tendency of the addition shift does not hold, as was established for carbonyl compounds in the previous work.[1] In the case of carbonyl compounds, the order of the upfield addition shift is just the opposite of that of the solvent shift, and this addition shift is more sensitive to the protons lying in close proximity to the proton-accepting site of the solute molecule than to those remote from it.[1]

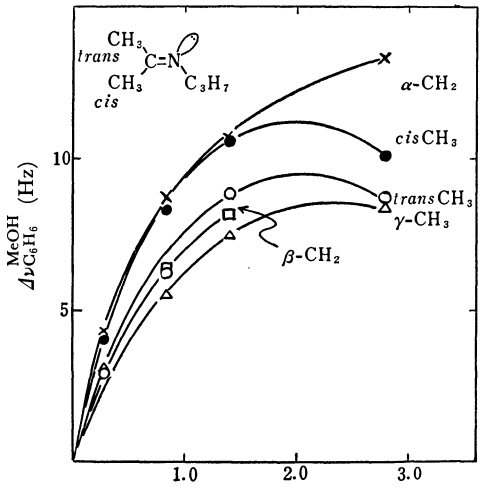

Fig. 2. Plots of $\Delta\nu^{MeOH}_{C_6H_6}$ *vs.* mol of added methanol for *N*-*n*-propylacetonimine.

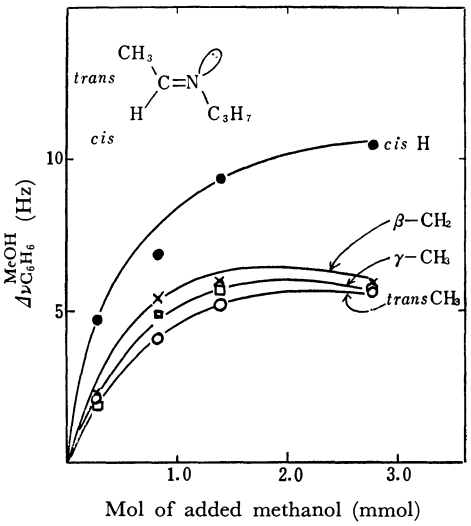

Fig. 3. Plots of $\Delta\nu^{MeOH}_{C_6H_6}$ *vs.* mol of added methanol for *N*-*n*-propylacetaldimine.

For *N*-*n*-propylacetaldimine, upfield addition shifts are observed for all the protons. It may be observed in Fig. 3 that this addition shift is more remarkable with the methine proton than with the methyl protons, which are *cis* to the nitrogen lone-pair. This addition shift has the same order as the solvent shift. The upfield addition shift increases with the concentration of added methanol, as is shown in Fig. 3. The upfield addition shift for the *N*-*n*-propyl proton is in the order of β-methylene $>\gamma$-methyl (the α-methylene signal is hidden in the methanol methyl proton signal). This

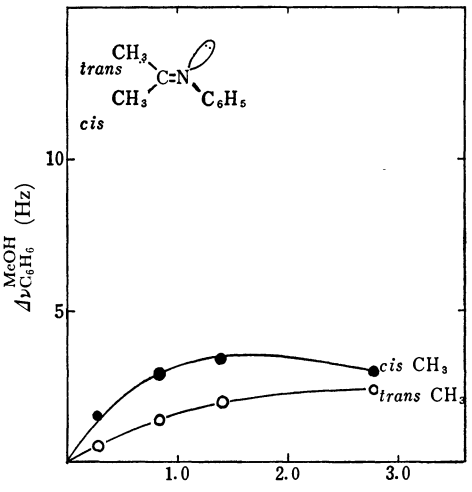

Fig. 4. Plots of $\Delta\nu^{MeOH}_{C_6H_6}$ *vs.* mol of added methanol for *N*-phenylacetonimine.

may also be seen for *N*-phenylacetonimine in Table 1 and Fig. 4 and for *N*-*n*-propylacetonimine in Fig. 2.

For 1-methyl- and 1-ethylaziridines, *cis* ring methylene protons undergo greater upfield addition shifts than do the *trans* protons, but the difference is very small (Figs. 5 and 6).

Oxime has two possible proton-accepting sites, the nitrogen lone-pair and the oxygen lone-pair of the hydroxyl group. Saito and Nukada[13] investigated the structure of oxime hydrochloride and showed that the protonation of the oximes occurs exclusively at the nitrogen lone-pair rather than at the hydroxyl oxygen atom. We will, therefore, in interpreting the addition shift for oximes, henceforth assume that, in solution with protic substances, the hydrogen-bonding interaction of oxime occurs exclusively at the nitrogen lone-pair. Judging from the addition shift for imines, the slightly larger value (Table 3 and Figs.

7—11) of $\Delta\nu^{TFA}_{C_6H_6}$ for the *cis* protons than for the *trans* protons of acetoxime and cyclohexanone oxime may reflect the fact that the hydrogen-bonding interaction preferentially occurs at the nitrogen lone-pair rather than at the hydroxyl oxygen. This will be verified in the discussion below of the results for *O*-methylacetoxime ether. It indicates that the generalization valid for the carbonyl compounds regarding the specific addition shift does not hold for oximes or for imines and aziridines.

As is shown in Table 3 and Fig. 9, the $\Delta\nu^{TFA}_{C_6H_6}$ values for methyl protons of acetaldoxime are larger for the *anti* isomer than for the *syn*. The $\Delta\nu^{TFA}_{C_6H_6}$ values of the methine proton are also larger for the *anti* isomer than for the *syn* isomer, as is also the case for $\Delta\nu^{TFA}_{C_6H_6}$ values. The same relation is observed for the methylene and methine protons of propionaldoxime. We interpreted this observation by assuming that the *anti* isomer is more subject to the hydrogen-bond interaction than the *syn* isomer, thus causing the greater upfield addition shift for the *anti* isomer than for the *syn*. The $\Delta\nu^{TFA}_{C_6H_6}$ value for the methyl protons of propionaldoxime is quite small and is slightly larger for the *syn* isomer than for the *anti* isomer, as is shown in Table 3 and Fig. 10. Ethyl methyl ketoxime gives results (Table 3 and Fig. 11) analogous to the case of propionaldoxime, as well as to that of the solvent shift.

Figure 12 shows the results for O-methylacetoxime ether. These results are anologous to those for acetoxime (see Fig. 8). The *cis* methyl group undergoes a larger upfield addition shift, $\Delta\nu^{TFA}_{C_6H_6}$, than does the *trans* methyl group when more methanol is added. The value of the addition shift, $\Delta\nu^{TFA}_{C_6H_6}$, for O-methyl protons is the smallest of those for the three methyl groups. These two observations imply that the hydrogen-bonding interaction preferentially occurs at the nitrogen lone-pair rather than at the oxygen lone-pair, as is the case with oximes. If the hydrogen-bonding interaction preferentially occurs at the oxygen lone-pair, the O-methyl group should undergo the largest upfield addition shift.

In conclusion, it is clear that, for compounds with a fixedly-oriented nitrogen lone-pair, the upfield addition shift is larger for the protons *trans* to the nitrogen lone-pair than for those *cis* to it. This tendency is different from the trend earlier established for the carbonyl compounds.[1] The origin of these conflicting observations is not clear at present; the problem will be investigated in the future.

However, it should be remarked that the present measurements of the benzene-solvent shift and the addition shift may themselves be useful in strucutal and stereochemical problems concerning the nitrogen lone-pair orientation.

The Crystal Structure of *l*-Cysteic Acid

Hideaki KONISHI,*1 Tamaichi ASHIDA and Masao KAKUDO

Institute for Protein Research, Osaka University, Joancho, Kita-ku, Osaka

(Received April 1, 1968)

The crystal structure of cysteic acid, $C_3H_7NO_5S$, has been determined. The crystal is orthorhombic with a space group of $P2_12_12_1$, and four molecules are in a unit cell with these dimensions: $a=8.35$, $b=10.16$, and $c=7.44$ Å. The molecule is a zwitter ion, $^-O_3SCH_2CH(NH_3^+)COOH$; its dimensions are generally similar to those found in other amino acids and sulfonic acids. The acidic groups occupy the trans positions with respect to the C_α–C_β bond, while the amino group is in a gauche position to the sulfonic group and forms an intramolecular hydrogen bond between them.

The X-ray crystal structure analysis of some α-amino acids and peptides has long been in progress in this Laboratory; the present work on cysteic acid was undertaken as part of this program. This amino acid is, in nature, found normally in sheep's fleece.

Recently, Hirota and Izumi[1] employed cysteic acid as a resolution reagent in the optical resolution of 2-amino-2'-nitro-6,6'-bitolyl; they obtained an optically highly pure compound. Izumi and others have also studied the asymmetric hydrogenation of methyl acetoacetate into methyl 2-hydroxybutyrate with catalysts modified with 2-amino acids or 2-hydroxy acids.[2] A characteristic result has been found in the asymmetric hydrogenation with the catalysts modified by cysteic acid.[3] In connection with the mechanisms of these resolutions and asymmetric reductions, it is worthwhile clarifying the ionic state of cysteic acid in the

crystal, since two types of zwitter ions are possible for this amino acid.

Experimental

Cysteic acid, $C_3H_7NO_5S$, prepared from cystine by treatment with aqueous bromine was supplied to the authors by Professor Yoshiharu Izumi. Colorless, transparent, and prism-like crystals were obtained by recrystallization from a methanol-water solution. They showed a pronounced cleavage perpendicular to the b axis. The lattice constants were obtained by oscillation and Weissenberg photographs taken around the b and c axes. More accurate values of the unit cell dimensions obtained on a single crystal diffractometer, using Mo$K\alpha$ radiation ($\lambda=0.7107$ Å), are: $a=8.35\pm0.01$, $b=10.16\pm0.01$, $c=7.44\pm0.01$ Å. The crystal belongs to the orthorhombic system; the absence of all ($h00$), ($0k0$), and ($00l$) reflections having odd values of h, k, and l respectively showed the space group to be $P2_12_12_1$. The observed density of the crystal obtained by the flotation method in a mixture of CH_3I and CCl_4 is 1.77 g cm^{-3}, while the calculated value is 1.77 g cm^{-3} (assuming four molecules in a unit cell).

The diffraction was measured on an AFC-model-1 (Automatic Four Circle) diffractometer made by Rigaku Denki Co., Ltd. The intensities in the $0<2\theta$(Mo$K\alpha$) $<55°$ range, which corresponds to the limiting sphere of Cu$K\alpha$ radiation, were collected. Zr-filtered Mo$K\alpha$ radiation was used with the pulse-height analyzer. The diffractometer was operated in an "open-loop" manner by a NEAC-2101 electronic computer. The $\omega/2\theta$-scan method was adopted for measuring the integrated intensities. The background was estimated from the measurements at the starting and end points of the scan. The programs designed by Tatzuo Ueki were used for the goniostat setting and the data processing.

The intensities were corrected only for Lorentz and polarization factors. In this way the integrated intensities of 1044 independent reflections were recorded, of which 121 (11.6%) were observed to be zero.

Structure Determination

The coordinates of the sulfur atom were deduced from the Patterson function. The first electron density map was synthesized by the use of the phases estimated from the coordinates of the S atom. Since the z parameters of S is nearly 1/4, the resulting map revealed the pseudo mirror plane on $z=1/4$. However, all the non-hydrogen atoms except for two carboxyl oxygen atoms could be located on the basis of the knowledge of the bond lengths and angles. In the succeeding Fourier map, all the non-hydrogen atoms of a

molecule were clearly defined. The final Fourier map is given in Fig. 1.

The positional and thermal parameters were refined by block-diagonal least-squares calculations, which minimize $\sum w(|F_o|-|F_c|)^2$. The weighting scheme was: $w=0$ when $F_o=0$ and $w=1$ when $F_o \neq 0$. The scattering factors for all the atoms were taken from "International Tables for X-Ray Crystallography (1959)". After several cycles of the least-squares calculation, the R index reached 15.6%. In the next calculation, all the hydrogen atoms were included. Their coordinates were assigned so that they are consistent with the tetrahedral bond angles and the optimum hydrogen bonding. Then, the maximum shift of the parameters (0.007 Å) became less than a half of the estimated standard deviation. It was, therefore, felt that further refinement would not improve the accuracy of the final parameters. The R index was 14.2% ($R=17.2\%$ with $F_o=0$). The mean value of the e.s.d.'s of the atomic coordinates of C, N, and O was 0.011 Å (0.009—0.014 Å). Difference-Fourier synthesis was carried out to confirm the hydrogen positions, but there still remained a little ambiguity about their positions, for there were many false peaks at other than the hydrogen atom positions. The atomic parameters are listed in Table 1, while the observed and calculated structure factors are listed in Table 2.

The computations were made on a NEAC 2200-model 500 in the computing center of this university. The program for the Patterson function was written by Noritake Yasuoka, and the others, by one of the authors (T. A).

Discussion

The bond distances and angles given in Fig. 2 are generally in good agreement with those previously reported for α-amino acids and sulfonic acids. The estimated standard deviations of the bond distances and angles are: 0.01 Å for S–O and S–C, 0.02 Å for other bonds, and 1.0° for the angles. In the molecule O(4)–S–C(3)–C(2)–C(1) possesses a trans-zigzag conformation, and N and S have a gauche form around the C(2)–C(3) methylene linkage (see Fig. 3).

The asymmetry about the C(1)–C(2) bond in the carboxyl group (C(2)–C(1)–O(1), 120°; C(2)–C(1)–O(2), 115°) is in good agreement with the foregoing findings. The two C–O distances, 1.22 and 1.28 Å, are significantly different from each other. The longer one is that of the oxygen atom with a hydrogen atom. The carboxyl group and C(2) are coplanar, and the equation for the best plane is;

$$0.2922X - 0.2990Y - 0.9061Z + 0.7324 = 0,$$

where X, Y, and Z are in the Å unit. The deviations of the individual atoms from the plane are:

O(1), 0.002; O(2), 0.001

C(1), −0.004; C(2), 0.001 Å.

The N atom also lies nearly on the plane, its deviation from the plane being −0.20 Å. The projection along the C(1)–C(2) bond is shown in Fig. 3.

The bond distances and angles of the sulfonic group are compared with those of other related compounds[4,5] in Table 3. The shape and size of the sulfonic group are substantially the same as in other compounds. The three S–O bonds seem to be nearly equivalent to each other, showing that there is no hydrogen atom bonded to this group.

Around the amino group there are four close N–O contacts (I, II, III, and V in Fig. 4) available for hydrogen-bond formations. Considering the configuration around N, the I, II, and III contacts are favorable for hydrogen bonds (see Table 4); of these, the I contact is an intramolecular hydrogen bond. Such a bond has also been found in taurine.[4] If V is assumed to be a hydrogen bond, an unfavorable conformation occurs around N. The three hydrogen atoms, H(7), H(6), and H(5), as refined by least-squares calculation, lie nearly on I, II, and III. These three are, therefore, favorable for hydrogen bonds. The cleavage perpendicular to the b axis can be well interpreted by taking V not to be a hydrogen bond. The fourth hydrogen bond (IV in Fig. 4) was found between O(2) of the carboxyl group and O(4) of the sulfonic group.

In the sulfonic group, each oxygen atom forms an NH–O hydrogen bond. In addition, O(4) accepts the OH–O hydrogen bond from the carboxyl group.

and sulfonic groups, together with the hydrogen-bond system in the crystal, the cysteic acid molecule can be said to have the zwitter ion form:

$$^{-}O_3SCH_2CH(NH_3^{+})COOH\,.$$

This could be expected from the difference between the dissociation constants of the carboxyl and the sulfonic groups. On the other hand, it has been expected, in the study of the optical resolution,[1] that cysteic acid is weaker than usual sulfonic acid. This seems reasonable if the molecule takes such a zwitter ion structure. It is also expected that, in an asymmetric hydrogenation,[3] this acid will be absorbed on the Raney nickel catalyst in a fairly different manner from common amino acids. This would explain the characteristic result obtained in the hydrogenation with the catalyst modified by this acid.

Fairly close van der Waals contacts are shown in Fig. 4(b). The molecules are at nearly $z=1/4$, and form a sheet parallel to the (010) plane by the three hydrogen bonds, II, III, and IV. No hydrogen bond seems to contribute to the contacts among these sheets.

The authors wish to express their deep thanks to Professor Yoshiharu Izumi for supplying material and for his continued interest, and to Drs. Tsunehiro Takano and Tatsuo Ueki for their kind cooperation. The authors' thanks are also due to the Matsunaga Science Foundation for its financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2312—2319 (1968)

Fluorescence Quenching and the Charge Transfer in the Excited State. III. Flash Photolytic Studies*[1]

Hiroshi YAMASHITA, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 1, 1968)

It has been established by the flash photolysis that the *N,N*-dimethyl β-naphthylamine (DMN) cation is produced by the interaction of excited DMN with dimethyl isophthalate (DMP). The assignment has been made by comparing the transient spectrum with that obtained by the γ-radiolysis of DMN in *s*-butyl chloride. The decay of the DMN cation is first order in acetone (DK, 20.7), ethanol (24.3) DMF (36.7), second order in formamide (109.5) and it is the superposition of first and second order in acetonitrile. This strongly suggests that the radical cation exists as the solvent-shared ion pair in medium polar solvents while as free species in highly polar solvents. The decay of the former has been found to be not essentially affected by oxygen. The finding that the transient spectrum is observed even in the aerated solution supports the view that it is produced at the singlet excited state. From the effect of [DMP] on the yield of triplet DMN, it has been inferred that the radiationless process occurring in the ex-CT complex is mainly internal conversion. The reactivity of the triplet DMN against DMP has been found very small as compared with that of the signlet excited state; the rate constant for $(DMN)^T + DMP \rightarrow DMN + DMP$ was $k_{10} \simeq 10^5\ M^{-1}\ sec^{-1}$. The erroneous discussion given in the previous paper has been corrected; the decrease both in the quenching constant (for normal fluorescence) and in the emissivity of the ex-CT emission with the solvent polarity (in slightly polar solvents) is most likely to be attributed to the solvent-solute interaction, the increase of which (with the increase in solvent polarity) is unfavorable both to the formation of the ex-CT complex and to the emissivity of the ex-CT emission.

In 1961 Weller *et al.*[1] discovered anomalous fluorescence in the system of perylene and aromatic amines dissolved in non polar solvents, the emission due to the charge transfer complex which is formed only in the excited state. At the same time, they also established by means of a flash technique, the formation of radical anions for the similar systems dissolved in polar solvents. These discoveries are the first confirmative evidence for charge transfer (CT) and electron transfer (ET) mechanisms for the quenching of fluorescence. Since then, extensive studies on the similar systems have been made by Mataga *et al.*[2-6] as well as Weller's group[7-9] and much information has been obtained in particular, on the behavior of excited CT (ex-CT) complexes.

In our previous papers,[10,11] one of the present authors (M. K.) with collaborators, has shown that the quenching action of methylbenzoate and dimethyl isophthalate (DMP) on the fluorescence of *N,N*-dimethyl β-naphthylamine (DMNA) can be interpreted satisfactorily by CT and ET mechanisms. Thus in support of CT mechanism, a new emission with a longer wavelength peak and with a large solvent effect, was observed in non polar or slightly polar solvents. ($DK < 10$), the emission which is most likely to be ascribed to ex-CT complex. In highly and medium polar solvents ($DK \gtrsim 20$) on the other hand, such an emission was absent and yet the quenching constant was very large and increased with the polarity of the solvent, in consistence with

ET mechanism. A difference between our system and Weller-Mataga's systems (W-M systems) are that the donor-acceptor relation is inversed, namely the fluorescer is a donor in our system while it is an acceptor in W-M systems.

The present paper is concerned with the flash photolytic studies on the system consisting of DMP and DMNA or β-napthyl ethyl ether (NEE) in various solvents. The principal purpose is of course, to detect the radical cation of fluorescer in highly or medium polar solvents in order to confirm definitely ET mechanism in our system. This has been verified in the case of DMNA; the transient spectrum observed, agreed satisfactorily with that of the radical cation obtained by the γ-radiolysis of DMNA in *s*-butyl chloride. In the case of NEE, the similar transient spectrum was observed but it did not agree with the one obtained by the γ-ray radiolysis. The conclusive assignment, therefore, must await further studies.

The second purpose of the present work, *i. e.*, the investigation of the behavior of the radical cation in various solvents, has been carried out, in view of the above results, mainly on the DMNA radical. It has been established that the free radical cation or the solvent-shared ion pair is formed depending on the polarity of the solvent.

The third purpose is to elucidate, in relation to the solvent effect, the radiationless processes occurring in the ex-CT complex. This has been done by examining the influence of quencher concentration on the yield of triplet DMNA. It has been found that the non radiative process in question is mainly the internal conversion to the ground state molecule. In connection with this investigation, the reactivity of triplet DMNA toward the quencher in various solvents has also been investigated. This has been found to be far less than that of the singlet excited state.

Finally comprehensive discussion has been given in which an erroneous discussion made in the previous paper[11] has been corrected.

Experimental

Materials. *N,N*-Dimethyl β-naphthylamine, *m*-dimethyl isophthalate, cyclohexane, benzene, isopropyl ether, ethyl ether, ethyl acetate, methyl acetate, ethyl benzoate and dimethyl formamide were purified in the same way as in a previous paper.[10]

β-Naphthyl ethyl ether was prepared according to reference.[12] The crude product was recrystallized four times from ethanol and finally sublimed *in vacuo*.

Phthalic anhydride of Kanto-Kagaku G. R. grade was recrystallized twice from benzene and was dried *in vacuo*.

Phthalonitrile of Wakojunyaku was recrystallized from the water-ethanol mixture (1 : 1 in volume) three times.

Liquid paraffin of Kanto-Kagaku G. R. grade was used without purification.

Bromobenzene of Wakojunyaku E. P. grade was fractionally distilled. Bp 155.0—155.5°C.

Ethanol of Wakojunyaku G. R. grade was distilled with a column of precision type. Bp 78.3°C.

Methanol of Wakojunyaku G. R. grade was treated with metallic magnesium and iodine, and then distilled. Bp 64.5°C.

Formamide of Wakojunyaku G. R. grade was purified by fractional solidification three times.

Apparatus and Procedure. The flash apparatus and the procedures were the usual ones.

Results and Discussion

Transient Spectra in the Presence and in the Absence of a Quencher. Figure 1 gives a transient spectrum obtained upon flashing the solution of DMNA in cyclohexane. This spectrum can safely be ascribed to T–T absorption on the ground of its short life time of about 60 μsec (first order decay, see below) and of the non-appearance in the aerated solution. A similar spectrum was obtained in liquid paraffin and in isopropyl ether*2 but was not in bromobenzene, ethyl acetate and ethyl benzoate, all of which belong to slightly polar solvent. This seems very curious and should be reinvestigated.

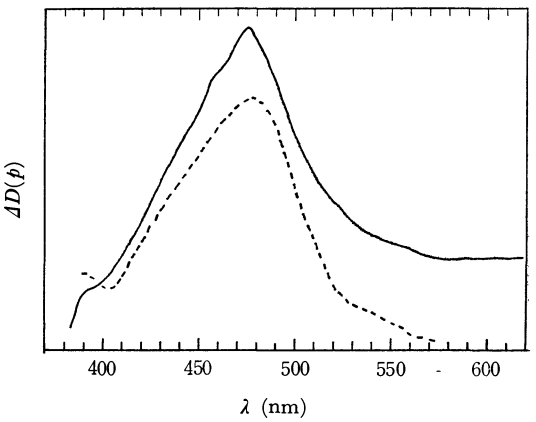

Fig. 1. T–T absorption spectra of DMNA in cyclohexane in the absence and in the presence of quencher.
30 μsec after flash
——: [DMNA] = 5×10^{-4} M, [DMP] = 0 M
– – –: [DMNA] = 5×10^{-4} M, [DMP] = 5×10^{-2} M

Upon addition of DMP as much as 5×10^{-2} M to the DMNA solution in cyclohexane, a similar T–T absorption was still observed although the intensity was somewhat weakened, and no new transient absorption was detected. This is just the result expected, since the ex-CT complex formed in nonpolar solvents, being very short-lived, cannot be observed by the usual flash technique.

12) W. A. Davis, *J. Chem. Soc.*, **77**, 33 (1900).

*2 The statement that no T–T absorption appeared in isopropylether, in the previous paper, should be corrected.

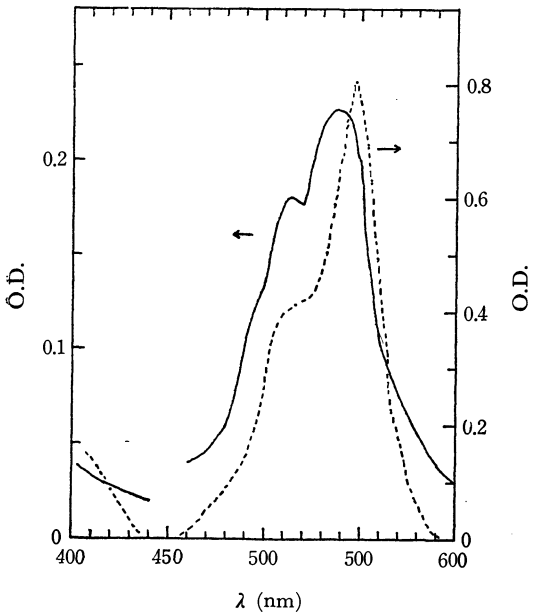

Fig. 2. Transient absorption of DMNA radical cation.
[DMNA] = 10^{-3} M, [DMP] 5×10^{-2} M
——: in DMF at room temp. by flash photolysis
- - -: in *s*-butylchloride at 77°K by γ-radiolysis

In highly or medium polar solvents (DK$\gtrsim$20) such as acetone, ethanol, acrylonitrile, dimethylformamide (DMF) and formamide, DMNA gave somewhat broadened T–T absorption.

Upon addition of $\gtrsim10^{-2}$ M DMP, a new absorption with a peak around 540 nm appeared in all the above solvents. Figure 2 shows as an example, a transient spectrum in the DMF solution. This is compared with the absorption spectrum of the DMNA cation obtained by the γ-ray radiolysis of the solution in *s*-butyl chloride at 77°K.*3 Fairly good agreement of the two spectra supports the assignment of our transient species as a radical cation.*4

Figure 3 gives the transient spectra in the acetone solutions. One can see the similar spectrum in the aerated solution. This indicates that the formation of radical cation occurs at the singlet excited state and that it is insensitive to oxygen, in agreement with the general behavior of radical cation.[13]

Furthermore, the usage of phthalic anhydride and phthalonitrile as quencher, gave the similar transient spectra.

*3 The authors are gratefull to Dr. T. Shida (*Inst. Phys. Chem. Research, Tokyo*) for having performed this experiment.

*4 Possibility that the absorption of radical cation and anion overlaps in the same region cannot altogether be denied (although not likely), since the latter could not be detected in the present work.

According to the unpublished results of our group, the fluorescent behavior of NEE-DMP system is similar to that of DMNA-DMP system in the points that it gives ex-CT emission in a slightly polar solvent but not in highly or medium polar solvents where high quenching is significant.

TABLE 1. THE DECAY CONSTANTS AND THE YIELDS OF THE DMNA RADICAL CATION IN VARIOUS CONDITIONS

Concentrations of		k (sec^{-1})		D_{540}	
DMNA, M	m-DMP, M	degassed	aerated	degassed	aerated
5×10^{-4}	10^{-2}	1.7×10^{4}	2.7×10^{4}	0.106	0.05
5×10^{-4}	5×10^{-2}	2.6×10^{4}	1.9×10^{4}	0.15	0.08
5×10^{-4}	10^{-1}	2.0×10^{4}	2.7×10^{4}	0.30	0.08
10^{-3}	5×10^{-2}	2.0×10^{4}	2.0×10^{4}	0.10	0.06
10^{-3}	10^{-1}	1.8×10^{4}	2.6×10^{4}	0.18	0.06

TABLE 2. THE HALF-LIFE PERIODS AND THE YIELDS OF THE DMNA RADICAL CATION IN ACETONITRILE

Concentration of		τ sec		D_{540}	
DMNA, M	m-DMP, M	degassed	aerated	degassed	aerated
5×10^{-4}	10^{-2}	3.4×10^{-4}	4.8×10^{-4}	0.097	0.064
5×10^{-4}	5×10^{-2}	4.1×10^{-4}	4.1×10^{-4}	0.098	0.086
5×10^{-4}	10^{-1}	4.4×10^{-4}	5.0×10^{-4}	0.11	0.084
10^{-3}	5×10^{-2}	3.3×10^{-4}	3.2×10^{-4}	0.084	0.074
10^{-3}	10^{-1}	4.7×10^{-4}	6.0×10^{-4}	0.093	0.075

Hence the similar flash experiments were performed on this compound.

Figure 4 gives a T-T absorption spectrum of NEE in cyclohexane, which agrees with the one reported by Porter and Windsor.[14] In the case of slightly polar solvents, the addition of $\sim10^{-2}$ M DMP gives essentially the similar transient spectrum.

In highly polar solvents such as DMF and acetonitrile, quite a different spectrum is observed as shown in Fig. 5. The spectra in these solvents are very similar to each other with two peaks around $\sim$540 and 500 nm and furthermore they resemble that of DMNA to some extent. It seems most likely to ascribe this spectrum to a radical cation of NEE, but the spectrum of the radical cation obtained by the γ-radiolysis in s-butyl chloride was quite different and the conclusive assignment should await further sutdies.

The Behavior of DMNA Radical Cation in Various Polar Solvents. In DMF, the decay rate and the yield of the radical cation immediately after flashing (measured by the optical density at 540 nm) were investigated in various conditions. The results are listed in Table 1. The decay was first order.

One can say that the first order rate constant is essentially the same for both aerated and deaerated solutions. The yield in the degassed solution increases evidently with the increase in the concentration of DMP. The yield in the aerated solution is less than half that in the degassed solution. This may be due to the competitive deactivation reaction of the singlet excited DMNA by oxygen. All the above results support the view that the radical cation is produced at the singlet excited state.

In the case of acetone and ethanol used as solvents, the decay obeys first order in the degassed solution. The rate constants is $4.1\times10^{3}\,sec^{-1}$ for ethanol, and $7.5\times10^{3}\,sec^{-1}$ for acetone. In the aerated solution, the yield is negligible in the case of ethanol and very small for acetone.

In acetonitrile, the decay is always the superposition of the first and the second order processes. Table 2 gives the yield as measured at the maximum of the optical density at 540 nm and the half life period (τ) (not very accurate) as evaluated from the decay curves.

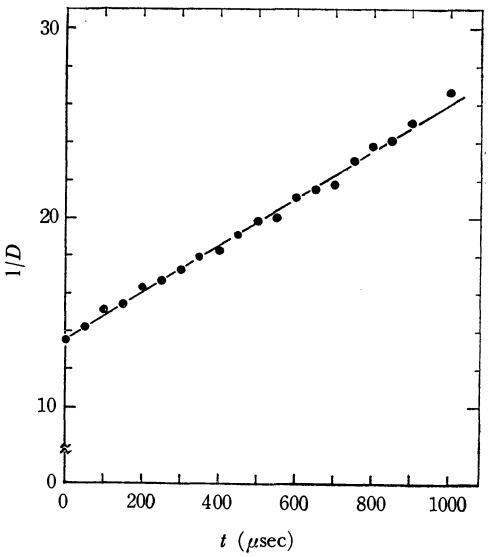

Fig. 6. Second order decay of DMNA radical cation in formamide.
[DMNA] = 1×10^{-3} M, [DMP] = 5×10^{-2} M

14) G. Porter and M. W. Windsor, *Proc. Roy. Soc.*, **A245**, 238 (1958).

TABLE 3. THE RATE CONSTANTS AND THE YIELD OF THE DMNA RADICAL CATION IN FORMAMIDE (PA, phthalic anhydride)

Concentration of			k (M^{-1} sec^{-1})		D_{540}
DMNA, M	DMP, M	PA, M	(degassed)	(aerated)	(degassed)
1.5×10^{-3}	5×10^{-2}	—	1.35×10^{5}	1.0×10^{5}	0.264
1.5×10^{-3}	—	5×10^{-2}	4.3×10^{4}	7×10^{4}	0.305

TABLE 4. HALF-LIFE VALUES AND THE YIELDS OF THE DMNA RADICAL ION

Solvent		[DMNA], M	Acceptor, M	τ sec	D_{540}
Acetone		5×10^{-4}	5×10^{-2} (DMP)	1.3×10^{-4}	0.116
	Aerated	5×10^{-4}	5×10^{-2}	3.3×10^{-4}	0.056
Ethanol		5×10^{-4}	5×10^{-2}	2.5×10^{-4}	0.115
DMF		5×10^{-4}	5×10^{-2}	3.8×10^{-5}	0.047
	Aerated	5×10^{-4}	5×10^{-2}	5.3×10^{-5}	0.036
		5×10^{-4}	5×10^{-2} (PA)	2.6×10^{-5}	0.056
Acetonitrile		5×10^{-4}	5×10^{-2} (DMP)	4.1×10^{-4}	0.098
	Aerated	5×10^{-5}	5×10^{-2}	4.1×10^{-4}	0.086
Formamide		1.5×10^{-3}	5×10^{-2}	5.4×10^{-4}	0.264
		1.5×10^{-3}	5×10^{-2} (PA)	7.7×10^{-4}	0.305
		1.0×10^{-3}	5×10^{-2} (DMP)	1×10^{-3}	0.074

In this case the yield in the aerated solution is not so different from that for the degassed solution.

In the case of formamide, the decay of the DMNA radical cation is second order as is shown in Fig. 6. The similar result was obtained when phthalic anhydride was used instead of DMP. The results are listed in Table 3.

Summarizing the behavior of the radical cation of DMNA in various solvents, the notable finding is that the radical cation decays according to first order in the solvents of medium polarity (acetone (DK=20.7), ethanol (24.3) and DMF (36.7)) while in a solvent of high polarity (formamide (DK=109.5)), it is second order and in acetonitrile (intermediate in the above two groups), the decay is a superposition of the first and second order. In view of the quite similar absorption spectra observed in all the cases, there seems to be no other interpretation than the following. In the medium polar solvents, the radical cations and anions exist as solvent-shared ion pairs which reconvert to the stable species by a unimolecular process, while in the highly polar solvents the free radical ions exist as two separate species and recombined bimolecularly. In acetonitrile, the separated radical species and the ion pairs may coexist.

In Table 4, half-life values and the yields of the DMNA radical ion in various solvents are summarized.

The result that the half-life in DMF is one order smaller than in formamide despite the several ten times smaller yield in the former, reconfirms that the radical cation exists as ion pair in the former and further it indicates that the ion pair in DMF is rather unstable. The order in the τ-values (DMF<ethanol, acetone<acetonitrile) suggests that the ion pair becomes more stable in this order.

Interaction between Triplet DMNA and DMP in Nonpolar Solvents. It is interesting to examine the influence of the addition of DMP on the yield of triplet DMNA and on its decay. The former is expected to afford the information as to the radiationless processes for the ex-CT complex while the latter will enable us to compare the reactivity of singlet and triplet excited states against the acceptor-type quencher. Cyclohexane is the most suitable solvent because the yield of ex-CT complex is very high and accordingly the quenching constant is also very high (K=65) in this solvent.

Before describing the results, it is convenient to list up the usuful relations which can be derived on the basis of the following plausible scheme.

$F + h\nu \rightarrow {}^1F^*$	I_{ab}	
${}^1F^* \rightarrow F + h\nu$	k_1	free fluorescer molecule
${}^1F^* \rightarrow F$	k_2	
${}^1F^* \rightarrow {}^3F$	k_3	
${}^1F^* + Q \rightarrow {}^1F^*\cdots Q$	k_4	encounter complex
${}^1F^* \cdots Q \rightarrow {}^1F^* + Q$	k_{-4}	
${}^1F^* \cdots Q \rightarrow (F^+\cdots Q^-)^*$	k_5	
$(F^+\cdots Q^-)^* \rightarrow F + Q + h\nu_{CT}$	k_6	ex-CT complex
$(F^+\cdots Q^-)^* \rightarrow F + Q$	k_7	
$(F^+\cdots Q^-)^* \rightarrow {}^3F + Q$	k_8	

The above scheme is essentially the same as the one proposed in the previous paper;[11] small

differences are 1) discrimination of the internal conversion and intersystem crossing processes (k_2, k_3 and k_7, k_8) and 2) neglect of any kinds of deactivation process, such as $(^1F^*\cdots Q)\rightarrow F+Q$ or $(^1F^*\cdots Q)\rightarrow {}^3F+Q$, for the encounter-complex. The former is necessary to treat the triplet yield. The latter neglect may be permitted since in the present system, the formation of ex-CT complex is considered to be a principal process for quenching. It is to be added that the ex-CT complex is assumed to behave irreversibly.

On the basis of the above scheme, the application of the steady method leads to the following formulas straighforwardly.

$$D_T/D_{T_0} = \frac{1+\frac{k_4k_8}{k_3}\gamma\tau_2[Q]}{1+\gamma k_4\tau_1[Q]} \quad (1)$$

$$I_F/I_{F_0} = \frac{1}{1+k_4\tau_1\gamma[Q]} \quad (2)$$

$$I_{F,CT} = \frac{k_4k_6\gamma\tau_1\tau_2[Q]I_{ab}}{1+k_4\tau_1\gamma[Q]} \quad (3)$$

where

$$\gamma = k_5/(k_{-4}+k_5),\ \tau_1 = 1/(k_1+k_2+k_3)$$
$$\tau_2 = 1/(k_6+k_7+k_8)$$

From the above equations and by using the relations

$$K = k_4\gamma\tau_1 \quad (4)$$
$$\Phi_{CT} = k_6\tau_2 \quad (5)$$
$$\Phi_0 = k_1\tau_1 \quad (6)$$

where K is a quenching constant and Φ_{CT} is a probability of CT emission, the follwoing relations can easily be obtained.

$$I_{F,CT} = \frac{K\phi_{CT}[Q]}{1+K[Q]} \quad (7)$$

$$I_{F,CT}/I_F = \frac{I_F}{I_{F_0}}k_4k_6\gamma\tau_1\tau_2[Q]I_{ab} = \frac{k_4k_6\gamma\tau_2[Q]}{k_1} = \frac{K\Phi_{CT}[Q]}{\Phi_0} \quad (8)$$

$$\frac{D_T}{D_{T_0}} = \frac{I_F}{I_{F_0}}\left(1+\frac{k_4k_8}{k_3}\gamma\tau_2[Q]\right) = \frac{I_F}{I_{F_0}}\left(1+\frac{k_8\tau_2}{k_3\tau_1}K[Q]\right) \quad (9)$$

Turning to the experimental results, examples of the decay for triplet DMNA are shown in Fig. 7. From such decay curves the triplet yields and the apparent first order rate constants were evaluated for several concentrations of DMP. From the latter values, the following values were obtained as the genuine rate constants for the processes,

$$F^T \xrightarrow{k_9} F$$

$$F^T + Q \xrightarrow{k_{10}} F + Q$$

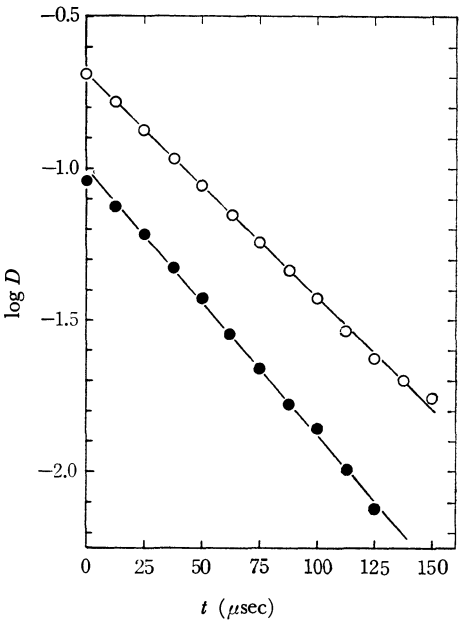

Fig. 7. First order decay of DMNA triplet in cyclohexane in the absence and in the presence of quencher.
○ [DMP]=0 M
● [DMP]=5×10⁻² M
[DMNA]=5×10⁻⁴ M

$$k_9 = 1.68\times10^4\ \text{sec}^{-1} \quad k_{10} \simeq 10^5\ \text{M}^{-1}\,\text{sec}^{-1}$$

It can be concluded from the above k_{10}-value that the reactivity of the triplet DMNA toward DMP is very small as compared with that of the singlet excited state.

Table 5 gives the relative yields of the triplet state $[F^T]/[F^T]_0$ (suffix 0 denotes the absence of Q) as evaluated from the optical densities at 480 nm, and the relative fluorescence intensities obtained from the data given in previous paper.[11]

Although the data are rather scanty, the ratio $[F^T]/[F^T]_0$ is larger than I_F/I_{F_0} only by less than 10% or so. From Eq. (9) it may be concluded that $k_8\tau_2$ is several times smaller than $k_3\tau_1$.

Table 5. Relative yields of triplet and relative fluorescence intensities

[Q], M	$[F^T]/[F^T]_0$	I_F/I_{F_0}	$K[Q]$
0	1	1	0
5×10^{-3}	0.80	0.75	0.33
10^{-2}	0.65	0.6	0.65
5×10^{-2}	(0.59)	0.23	3.3

Summary and Comprehensive Discussion

The present investigation has demonstrated clearly that the electron transfer occurs from the excited DMNA molecule to DMP in polar solvents.

The evidence for the view that the radical ions do not always exist as free ions but exist as solvent-shared ion pair, is afforded by the finding that the transient species in medium polar and in highly polar solvents, give essentially the similar spectrum and yet the decay feature in the former is first order whereas the latter is second order.

In nonpolar or slightly polar solvents, the ex-CT complexing has already been amply demonstrated in the previous paper, and some additional information has been obtained by the present flash studies. Since some papers dealing with the ex-CT complex appeared last year at about the same time as Part II of the present series, and since a part of the discussion given in the previous paper,[11] has been found to be improper, the authors would like to take up some of the previous results as well as the present ones and generally discuss them, referring also the results of other workers.

In the previous paper it was shown that the relative quenching efficiencies $(a\gamma)_i/(a\gamma)_2$ (2; cyclohexane) and the relative emissivity of ex-CT complex $(\phi_{0,CT})_i/(\phi_{0,CT})_2$ in slightly polar solvents, ($\phi_{0,CT}$; a ratio of the acts of an emitting process to those of the effective quenching process for normal fluorescence) decrease with the polarity of the solvent in somewhat similar manner. The result itself is correct, but the interpretation was erroneous. Thus the statement*5 "... one common process for CT emission and the quenching process, *i. e.*, the process of formation of the ex-CT complex essentially affects both CT emission and the quenching process ... and that this perhaps the main reason why ϕ_{CT} and $a\gamma$ decreases with the solvent polarity." is not correct. As is clear from the definition, ϕ_{CT} should reflect the emissivity of ex-CT complex itself. As long as the CT mechanism prevails, the decrease in $a\gamma$ naturally causes the decrease in the quantum yield of ex-CT emission, but the parallel decrease in ϕ_{CT} and $a\gamma$ should be interpreted to indicate that the more difficult the formation of ex-CT complex becomes, the less emitting the ex-CT complex becomes. This is very plausible on the basis of solvent-solute interaction, because as the solvent becomes more polar, the reorientation of solvent molecules becomes more and more difficult and at the same time, the interaction between the pdrouced ex-CT complex and solvent molecules becomes also larger, and this will cause the decrease in emissivity of ex-CT complex.

The previous results reinterpreted in this way is quite consistent with other workers' results. Thus Mataga *et al.*[5] showed that in the ex-CT complex of pyrene and dimethylaniline, the rate constant for emission, k_f', decreases while that for radiationless process, k_i' increases and that the quantum yield, Q_F', largely decreases with the polarity of the solvent. Weller *et al.*[8] also found that in the anthracen-diethylaniline system, the relative intensity of the ex-CT complex decreases with the solvent polarity and decreases far more than the lifetime of ex-CT emission. This is because, they interpreted, the former depends on the tendency with which the ex-CT complex is formed and also on the emissivity of the ex-CT complex, while the latter is concerned with the ex-CT complex itself.

As to the molecular processes which cause the decrease in the emissivity of the ex-CT complex with the solvent polarity, Mataga stressed the interaction between fluoresent species and solvent molecules which affect not only the molecular configurations (the configuration of the ex-CT complex and that of the surrounding solvent molecules) but also the electronic state of the ex-CT complex. Weller on the other hand considered that the increase in the solvent polarity enhances the process

$$(A^-\cdots D^+) \xrightarrow{k_{IP}} A_S^-\cdots D_S^+ \qquad (a)$$

where $A_S^-\cdots D_S^+$ is nonfluorescent. Furthermore he attributed the decrease in the probability of ex-CT complexing with the increase of solvent polarity, to the competition of the following two processes,

$$A^* + D \rightarrow (A^-\cdots D^+) \qquad (b)$$

$$A^* + D \rightarrow (A_S^-\cdots D_S^+) \rightarrow A + D \qquad (c)$$

of which the latter prevails over the former as the solvent becomes more polar.

Although there is no doubt that such processes must generally be taken into consideration, the authors are inclined that Mataga's picture fits better to our system at least in slightly polar solvents. Because in slightly polar solvents ($DK \lesssim 10$) the formation of the ion pair was not observed. More strong evidence is, as reported in the previous paper, that the addition of a small quantity of the highly polar solvent to the DMNA solution in nonpolar solvents causes a decrease of $a\gamma$ itself. This result can never be interpreted if only the competition between Process (b) and (c) is essential for quenching phenomena. That reorientation of solvent molecules is necessary for the ex-CT complexing was also clearly demonstrated by Mataga *et al.*[6] by comparing the fluorescent spectra of aromatic hydrocarbons dissolved in aromatic dimethyl amines at low and high temperatures.

As to the radiationless processes occurring in the ex-CT complex, the authors, in the present paper, have demonstrated fairly clearly that in our system it is the internal conversion to the ground state molecule and not the intersystem crossing. This is somewhat similar to Mataga's result,[5] that pyrene in acetonitrile involving dimethylamine gives no T-T absorption, but is contrary to Weller's result for the perylene-aromatic amine system.[1]

*5 p. 2262 in Part II, Ref. 11.

The finding that the reactivity of triplet DMNA toward DMP is much smaller than that of singlet state agrees with the current view that the triplet state generally resembles the ground state rather than the singlet excited state and it is of radical nature rather than ionic. Similar results have been reported also by Mataga *et al.*;[6] they found that the phosphorescent spectra of some hydrocarbons in dimethylaniline are practically the same as those in *n*-hexane and that the phosphorescent decay times are also the same in the both solvents.

Studies on the Electronic Spectra of the Semiquinones of Anthracene and Its Related Heterocycles. I

Hiroshi MASUHARA, Michio OKUDA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 1, 1968)

Electronic absorption spectra of two types of half reduced acridine, *i. e.*, C-radical (unpaired electron on 9-C-atom) and N-radical (unpaired electron on N-atom), of half-reduced anthracene and of xanthene deprived of one hydrogen atom, are measured in several rigid solvents at 77°K. It has been established that these radicals can be produced conveniently by irradiating the rigid solutions of the reduced forms, by a medium high pressure mercury lamp. It has been found that the absorption spectra of these radical species are generally classified into three groups, a) ~250 nm (4.9 eV), b) ~350 nm (3.5 eV) and c) visible (2.3—2.8 eV). Peculiar features for each radical species are; i) anthracene radical has no visible absorption, ii) acridine N-radical has no absorption at ~250 nm, and iii) acridine C-radical has a prominent sharp peak at 281 nm. Flash photolytic and ESR studies have also been performed on the radical species produced upon irradiation of dihydroanthracene and xanthene; the results obtained have substantiated the assignment of the intermediates observed in rigid solvents.

Our group has long been engaged in the studies of the primary processes of the photoreduction of some typical dyes and also of acridine.[1-5] Further studies on the photoreduction in relation to acridine are now being extended to phenazine and anthracene. Under such circumstances, it is highly desirable to measure the accurate electronic absorption spectra of the semiquinones of anthracene and its related heterocycles and also to investigate theoretically their electronic structures. Such studies are considered also to be important as the basic information of dye photochemistry, since the foregoing types of compound are the skeletones of various dyes.

From such a view point, accurate measurement of the absorption spectra of semiquinones of anthracene, acridine and xanthene were made in rigid solvents, and the open shell SCF calculation including CI was attempted to discuss the electronic structures of these semiquinones. The present paper is mainly concerned with the experimental results, deferring the theoretical ones to the next paper.

It has been found that these types of semiquinone can be produced most conveniently by the photochemical dehydrogenation of the reduced forms (acridan, dihydroanthracene, xanthene). Since they have no absorption below 300 nm and since they were almost completely converted to semiquinones by irradiation, reliable measurement could be performed throughout the region from 230 to 1000 nm.

It has been established that the absorption spectra of these semiquinones are well correlated with each other as is expected from the resemblance of the absorption spectra of the oxidized form (except xanthene) apart from minor differences. ESR and flash experiments have also been performed to confirm the assignment of the intermediate species in question.

Experimental

Materials. 9,10-Dihydroanthracene and xanthene of G. R. grade were purified by repeated recrystallization from ethanol. Acridan was synthesized by reducing acridine with sodium amalgum.

Solvents used for Low Temperature Spectroscopy. Ethanol (99.5 vol%) of G. R. grade was used without any treatment, while the one of E. P. grade was purified by distillation. Isopentane and ethyl ether were dried over sodium and then distilled. Methylcyclohexane was treated with fuming sulfuric acid several times, washed with alkaline aqueous solution and then with water, shaken with alkaline $KMnO_4$ solution, rewashed with water, desciccated over $CaCl_2$ and silica gel and finally distilled with a fractionating column. All the solvents purified were checked by UV spectra. No absorption was observed above 210 nm for isopentane and above 220 nm for methylcyclohexane.

Solvents used for ESR Measurements. Poly-trifluorochloroethylene (Daiflon) was used without any purification. Tetrahydrofuran of First Grade from Wako-junyaku was refluxed with sodium for several hours, and then distilled.

Degassing of the samples was performed by at least five cycles of freeze-pump-thaw or by distillation method, both on a vacuum line.

Apparatus and Procedure. *Low Temperature Spectroscopy.* After having tried various types of apparatus, the final and most satisfactory one which is shown in Fig. 1, was manufactured.

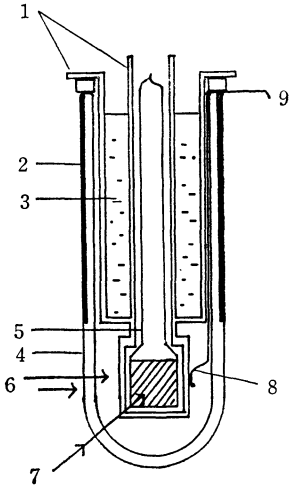

Fig. 1. (1) cell-holder of copper, (2) plated with silver, (3) liquid nitrogen, (4) quartz Dewar vessel, (5) quartz cell, (6) analysing beam, (7) exciting beam, (8) copper-constantan thermopile, (9) to microampere-meter

A quartz cell (5) settled in a copper cell-holder (1) was cooled slowly by pouring liquid nitrogen into the cell-holder. The apparatus was mechanically stable. A constant and sufficient low temperature of 77°K was attained in about ten minutes. There was no fear of the depression of the meniscus below the center of the cell, which would have interfered with an accurate measurement. After being kept at 77°K for more than twenty minutes, the sample was irradiated by a medium pressure mercury lamp (Toshiba Chokoatsu SHLUV, with a cover glass removed) with no filter.

All the absorption spectra were measured by a Hitachi EPS-3 spectrophotometer. Temperature was measured by a copper-constantan thermopile (8), the tip of which was fixed on the cell-holder (1) near the quartz cell.

The solvents used were

1) isopentane and methylcyclohexane mixture (1 : 1 — 1 : 4)

2) EPA (5 : 5 : 2 — 5 : 2 : 3)

3) ethanol. When not evacuated, a little water (6 vol%) was sometimes added; this procedure was very efficient for preventing cracking of rigid matrix. This was unnecessary for the evacuated ethanol solution.

Flash Apparatus. Same one as has been described in previous papers.[1,4]

ESR Spectra. A Nippon Denshi (Japan Electron Optics) P-10-type ESR spectrometer (X-band) with 100 kc field modulation, was used. As solvents, benzene, tertiary butanol, tetrahydrofuran and Daiflon were used; good ESR signals were obtained in the last two solvents. The reason for not having used the usual rigid solvents is that they often give rise to some free radicals of their own origin and complicate the ESR signals;[6] all the foregoing solvents have no easily detachable hydrogen atoms. Although the solutions when cooled to a low temperature of 77°K, assume the polycrystalline state, it was expected from the previous work,[6] that they would give the ESR spectra originating from only the solute species. 500 W medium pressure mercury lamp was used as a light source. The light was passed through a water layer 1 cm thick and focused on the quartz cell by means of a lens.

Results and Discussion

Anthracene Semiquinone. When the solutions of dihydroanthracene 1.0×10^{-4} M in rigid solvents were illuminated by a mercury lamp at 77°K, they always colored slightly yellow. At

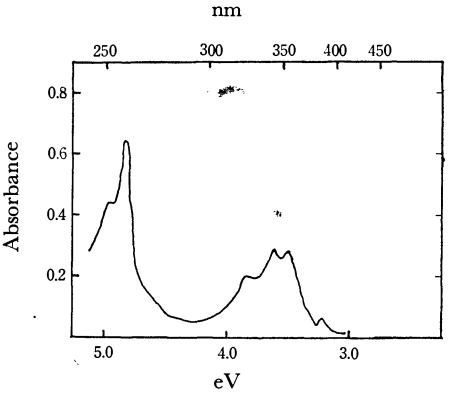

Fig. 2. The electronic spectrum of anthracene semiquinone obtained by irradiating MP (9 : 3) solution of 9,10-dihydroanthracene, 1.0×10^{-4} M at 77°K.

6) S. Niizuma and M. Koizumi, This Bulletin, **41**, 1090 (1968).

this temperature, the color remained unaltered for more than an hour when the light was off. Figure 2 gives the absorption spectrum in MP (9 : 3). Prominent peaks are seen around 250 and 340 nm regions. When the sample was warmed to room temperature, the major part of these bands disappeared and the absorption spectra of the resulting solution clearly showed that a small quantity of anthracene was produced. Hence it is most likely to attribute the above absorption bands to anthracene semiquinone, which is produced during the dehydrogenation reaction of 9,10-dihydroanthracene. It is, however, worthy noticing that the spectral shape of 340 nm region resembles closely that of anthracene, apart from a slight blue shift and the non-existence of 380 nm peak of anthracene. As to the assignment, therefore, the authors at first conceived of the possibility of the detachment of two hydrogen atoms in one act, yielding a certain anthracene-like intermediate such as distorted anthracene stabilized in rigid solvents. But such a view has proved to be ruled out; the assertion that the spectrum in question is really to be ascribed to semiquinone, has been substantiated from the following flash photolytic and ESR investigations.

Figure 3 gives the transient absorption spectrum obtained when the solution of dihydroanthracene 5×10^{-4} M, in ethanol was illuminated by the flash. The absorption in the region around 425 nm is most likely to be ascribed to the triplet state, while the one in the region 305—360 nm, to semiquinone, because the former decays as the superposition of the first and second order processes with a half life of 60 μsec and the latter, on the other hand, decays in second order with a much longer life of 370 μsec. Evidently the asorption around 305—360 nm corresponds to the one in rigid solvents. No transient absorption spectrum was detected in the aerated solution. The finding that the absorption in question decays as of second order and with a large half-value period can never be reconciled with the view of the distorted anthracene.

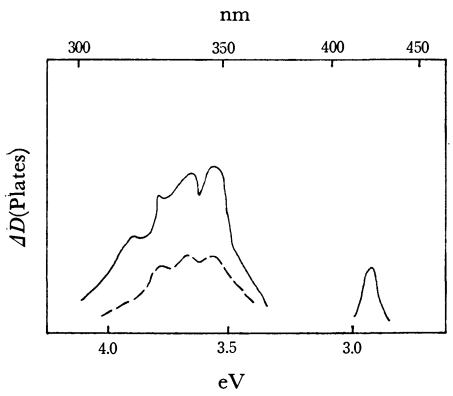

Fig. 3. The transient absorption spectra from the ethanol solution of 9,10-dihydroanthracene, degassed and 5.0×10^{-4} M at room temperature.

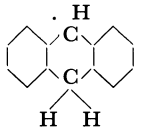
a) contains a little water (6 vol%)
b) obtained from the flash photolysis

ESR studies were performed by using the solution of dihydroanthracene 5×10^{-2} M in Daiflon and tetrahydrofuran. When irradiated by a mercury lamp at 77°K, the sample colored yellow and gave good ESR signals. Some parameters of the signals are listed in Table 2.

Table 2. Parameters of ESR signals of anthracene semiquinone

Solvent	g-Value	ΔH_{msl}(geuss)
Daiflon	2.0029	20.4
Tetrahydrofuran	2.0028	32.5

Somewhat larger value of ΔH_{msl} for tetrahydrofuran will be discussed later. From the g-value and the value of ΔH_{msl} there is scarcely any doubt that the signal is due to a π-radical, which in the present case is most likely to have the following structure.



Although the media for the spectral and ESR studies are different, it is reasonable to consider, from the similar coloration, that the same reaction is occurring in the two cases.

One more point to be worthy noticing in respect to the feature of UV spectrum is that anthracene semiquinone has no absorption in the visible region, in sharp contradistinction to other semiquinones investigated in the present investigation.

Acridine Semiquinone. When solutions of acridan in rigid solvents were irradiated by mercury lamp at 77°K, the solution always colored brown. The color remained for more than an hour after the light was off, but it disappeared upon warming the sample to room temperature. Two examples of the absorption spectrum are shown in Fig. 4, a and b. The bands in three wavelength regions

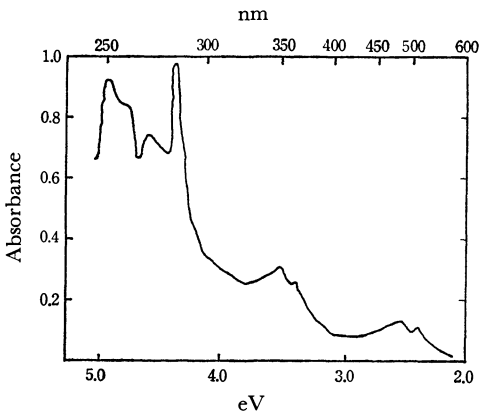


Fig. 4a. The electronic spectrum of acridine semiquinone obtained by irradiating aerated EPA (4:4:2) solution of acridan, 3.6×10^{-5} M at 77°K.

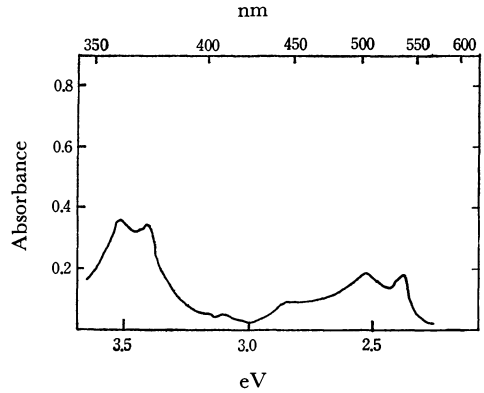

Fig. 4b. The electronic spectrum of acridine-C semiquinone obtained by irradiation of the degassed MP (4:1) solution of acridan, 3×10^{-4} M at 77°K.

are distinguished, the prominent peaks being (253, 281 nm*1) (365 nm) (480, 520 nm). In the flash experiment[1] using ethanol solution of acridine, the region around 365 nm had escaped the observation because of the superposition of the acridine absorption. The peaks at 281, 480 and 522 nm mentioned above, agree fairly well with the ones published before as well as with the ones obtained by the photolysis of diacridan.[6] Hence the above spectrum is safely assigned to a C-radical (see Fig. 6). The values of molar absorbance evaluated under the assumption that the entire acridan is converted to semiquinone, are given in Table 3.

Besides the aforementioned peaks, a broad absorption extending from 500 to 700 nm was observed in EPA and in ethanol. This may be due to solvated electrons but there is no definite evidence at present.

*1 According to theory, the appearance of this only in this case, is peculiar.

TABLE 3. ESTIMATED MOLAR ABSORBANCE OF ACRIDINE C-RADICAL

Solvent	365 nm	488 nm	523 nm
MP	0.9×10^{4}	4.0×10^{3}	3.5×10^{3}

b) by Kira[1]

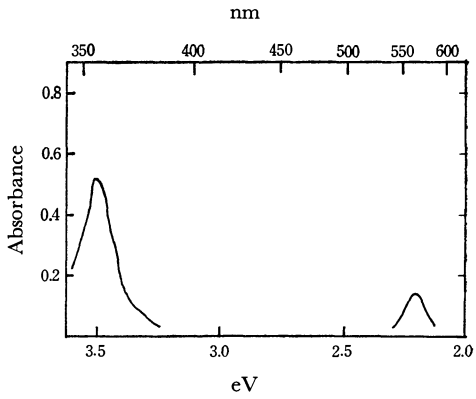

Fig. 5. The electronic spectrum of acridine-N semiquinone obtained by irradiating the aerated ethanol solution of acridan, 1.0×10^{-4} M at 77°K. This ethanol solution included a little water (6%).

Figure 5 gives the absorption spectrum of the intermediate produced by the irradiation of the aerated ethanol solution of acridan at 77°K. This spectrum is quite different from the ones shown in Fig. 4. At the time when the above results were obtained, it was a puzzling matter how to interpret these differences, because Kira and Koizumi's work[7] was not yet commenced at that time. Now that strong evidence has been given for the formation of C-radical and N-radical according to the experimental conditions, the absorption spectrum given in Fig. 5 can safely be

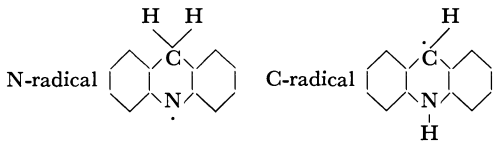

Fig. 6.

ascribed to N-radical from the agreement of the peak positions. Although there seems to be no doubt as to the assignment, a problem still remains why the N-radical is formed in the aerated ethanol solution whereas only the C-radical is formed in the

a) From the flash data

aerated EPA solution as well as in the degassed MP solution. The problem awaits further studies, together with the ESR studies which are now in progress. Table 4 gives the solvent effect on the absorption spectrum of C-radical.

From the absence of the solvent effect, all the absorption may safely be attributed to the π-π^* transition.

Xanthene Semiquinone. When the xanthene solutions in ethanol or MP were irradiated, the solutions became yellow in color. As shown in Fig. 7, the absorption spectrum displays peaks at 255 nm (with a shoulder near 270 nm), 340 nm, 580 nm and a broad absorption band extending from 370 to 400 nm. When the sample was warmed up to room temperature, the shoulder at 270 nm and the last broad band still remained to exist while the other bands disappeared completely. This implies that along with a radical

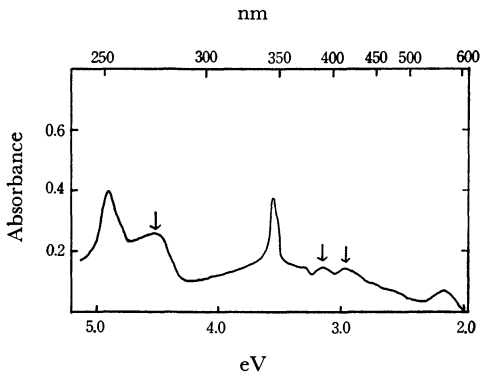

Fig. 7. The electronic spectrum of xanthene semiquinone obtained by the irradiation of the degassed ethanol solution, 1.2×10^{-4} M at 77°K. This spectrum includes the absorption of the photoproduct (↓), which is not separated from semiquinone.

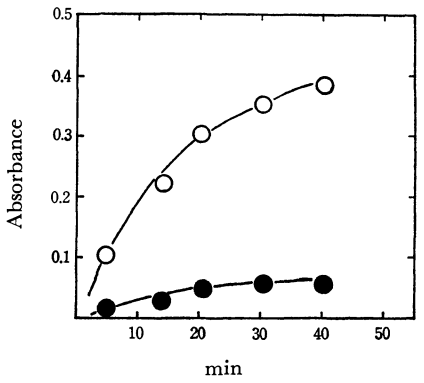

Fig. 8. A build-up of xanthene semiquinone (○ 343 nm) and that of photoproducts (● 390 nm). 8×10^{-5} M ethanol solution of xanthene.

species, some stable compound was produced simultaneously. Judging from the build-up curves shown in Fig. 8, the formation of the radical species and the stable compound in question, appears to proceed as two independent reactions. It is to be noted that the absorption bands at 252 and 270 nm were interfered with the bands of the original compound. Further, it is likely that most of xanthene semiquinone reconverts to xanthene by regaining a hydrogen atom when the solvent is melted, because the amount of xanthene was found to be almost the same as that before irradiation. The solvent effects are given in Table 5.

Good ESR signals were obtained when 5×10^{-2} M of xanthene in tetrahydrofuran or Daiflon was irradiated. The sample became yellow upon irradiation. The ESR spectrum in the case of tetrahydrofuran medium, as shown in Fig. 9, is somewhat asymmetric and broad, similarly as in the case of anthracene semiquinone in the same medium.

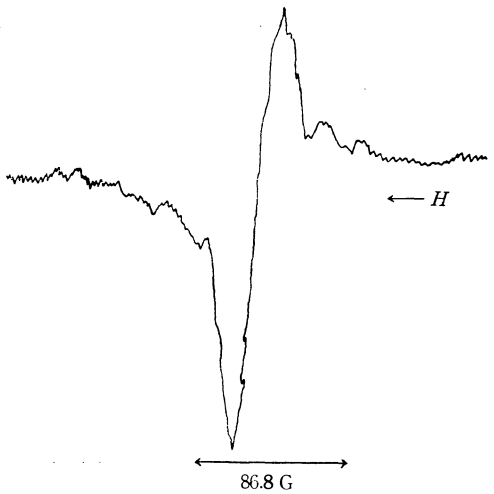

Fig. 9. ESR spectra obtained by the irradiation of tetrahydrofuran solution of xanthene, 5×10^{-2} M.

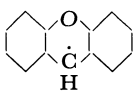
This is perhaps due to the coexistence of the tetrahydrofuran radical, which was produced through a secondary reaction between xanthene semiquinone and tetrahydrofuran molecules.[8] ESR parameters are given in Table 6.

TABLE 6. ESR PARAMETERS OF XANTHENE SEMIQUINONE

Solvent	g-Value	ΔH_{msl}(gauss)
Diflon	2.0043	16.2
Tetrahydrofuran	2.0046	26.0

From the g-value and the value of ΔH_{msl}, there is no doubt that the radical is a π-radical with the following structure:



8) S. Niizuma and M. Koizumi, to be published. T. Maruyama *et al.*, the 19th Annual Meeting of the Chemical Society of Japan, Tokyo, 1966.

In the flash experiments, two transient absorptions were observed around 340 nm and 420 nm of which the latter was attributed to the triplet state, because of its short decay rate. That no absorption was detected in the vicinity of 580 nm, may be due to a very small absorbance of 580 nm as is evident from Fig. 7. The absorption around 340 nm evidently corresponds to the one in rigid solvents and is acribed to xanthene semiquinone.

Comprehensive Discussion

The present investigation has established that the absorption spectra of semiquinones in question, are classified into three groups, ~250 nm (4.9 eV), ~350 nm (3.5 eV) and visible (2.3—2.8 eV).

According to an open shell SCF-CI calculation (Longuet-Higgins-and-Pople-type) the details of which will be reported in the next paper, one obtains the similar classification except for some shifts (toward shorter wavelength), *i. e.*, ~1 eV, ~0.6 eV and ~0.5 eV respectively for 4.9 eV group, 3.5 eV group and for a visible group. This correspondence between theory and experiment is considered to be an additional evidence for the assignment of the intermediates as semiquinones. As to the peculiarities of the spectrum of each semiquinone, the most significant findings are;

a) Acridine C-radical has a prominent sharp peak at 281 nm.

b) For acridine N-radical, the band around 250 nm is very weak.

c) Anthracene semiquinone has no visible absorption.

As to these three characteristics, reasonable interpretations will be given in the theoretical part. Finally, it will be added that the difference in reactivity toward oxygen, between acridine C- and N-radicals, may be attributed to the energy difference of the half occupied molecular orbitals of the two species. This will also be discussed in the next paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2325—2330 (1968)

The Rectification Effects Using the Ices Doped with Electrolytes

Kuniyoshi SHIMIZU, Yoshiaki YOSHIDA, Manabu SENŌ and Hiroshi NOZAKI

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received April 2, 1968)

The rectifying properties of the combined systems of two crystals, one being doped with a proton donor (poly(styrene sulfonic acid) or hydrogen fluoride) and the other being doped with a proton acceptor (poly(2-vinyl-*N*-*n*-butylpyridinium bromide), poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide) or lithium hydroxide) are examined and discussed. In the case of the combination of the ices doped with poly(styrene sulfonic acid) and poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide) or poly(2-vinyl-*N*-*n*-butylpyridinium bromide), the current *versus* voltage curves have the hysteresis loops and the rectification ratio defined as the ratio of the forward current to the backward current is low. The dynamic rectification effect is slightly observed. In the case of the combination of the ices doped with lithium hydroxide and hydrogen fluoride, the rectification ratios exceed 100 and the rectification mechanism is presumed to be the same as in the system of the aqueous solutions. The dynamic characteristics depend on the frequencies; the rectification phenomena are not observed when the alternating voltages with frequencies higher than 30 kc are applied.

Reiss and Fuller[1] pointed out that the proton excess and the proton defficiency in an aqueous solution exert a similar function to the electron excess and the electron defficiency in a usual semiconductor, respectively. In the previous paper,[2] the rectification effect on the liquid junction of the aqueous solution of poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide) and the aqueous solution of poly(styrene sulfonic acid) was investigated. The rectification effect was also found by some authors[3] on the composite membrane consisting of cation- and anion-exchange membrane. On the basis of the mobility of the charge carriers, the electron in a semiconductor is more analogous to the proton in ice than the proton in an aqueous solution. As a matter of fact, Eigen and de Maeyer[4] suggested the possibility of rectification effect on the ices doped with LiOH and HF.

In the present investigation, the rectifying properties are examined and discussed on the combined systems of two ices, one being doped with a proton donor (poly(styrene sulfonic acid) or HF) and the other being doped with a proton acceptor (poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide), poly(2-vinyl-*N*-*n*-butylpyridinium bromide) or LiOH).

Experimental

Materials. Poly(styrene sulfonic acid) (PVSA), molecular weight, 100000, was prepared by the same method as in the literature.[5] One molecule of PVSA has 450 sulfonic groups. Poly (2-vinyl-*N*-*n*-butylpyridinium bromide) (NBPB), molecular weight, 15000, was prepared by the method in the literature.[6]

Found: N, 8.0; Br. 21.2%. Calcd for complete quarternarization: N, 5.8; Br, 33.0%.

Poly(2-vinyl-*N*-*n*-butylpyridinium hydroxide) (NBOH) was prepared by the same method as in the previous paper.[2] Lithium hydroxide and hydrogen fluoride of reagent grade were used without further purification. Water used was treated as follows. The deionized water was distilled in a pyrex cell still containing a small amount of $KMnO_4$ and was collected in a polyethylene vessel. Then the distilled water was degassed by using the apparatus reported in the literature.[7] The specific conductivity was of the order, 10^{-7} ohm^{-1} cm^{-1}.

Apparatus and Procedure for Measurements. For measurements of the static conductivity of the ices doped with electrolytes, the electrolyte solutions in the silica tube (Fig. 1) were frozen in a dry-ice - methanol bath while nitrogen gas was flowed through the silica tube. The measurements were started at five hours after the electrolytes solution was poured into the silica tube (diameter: 4.0 cm). For the investigation of the rectification effect using the ices doped with electrolytes, the procedure of solidification of electrolyte solutions was conducted as follows. At first, the solution of NBOH (or NBPB, LiOH) was transferred into the silica tube maintained at −10°C in an alcohol bath and was

frozen therein. After three hours, the solution of PVSA (or HF) which was supercooled at a few degrees below 0°C was poured above the NBOH (or NBPB, LiOH)-doped ice in the silica tube and was solidified in the alcohol bath for three hours. Then, the electric current was read at 30 sec after the voltage was applied. A constant voltage was supplied by a battery, and an alternating voltage was supplied by an ultra-low frequency oscillator (10^{-3}—10^{6} sec).

Results

I. The D. C. Electric Conductivity of Ice Doped with Polyelectrolyte. The d. c. electric conductivities of ices doped with PVSA, NBPB or NBOH were measured by using the apparatus as shown in Fig. 1. In Figs. 2, 3 and 4, the dependence of the electric conductivity (σ) of the ices doped with polyelectrolytes on temperature is shown, where the concentrations of polyelectrolytes are 1.36×10^{-2} and 0.68×10^{-2} equiv/l. Although an irregular change was observed near the freezing point, the Arrhenius-type relationship holds in a range of sufficiently low temperatures. From the straight line portions in Figs. 2, 3 and 4, we obtained the following relations.

$$\sigma_p = \sigma_{p,o}\exp(-8.23\times10^3/\boldsymbol{R}T) \quad (1)$$

$$\sigma_h = \sigma_{h,o}\exp(-13.94\times10^3/\boldsymbol{R}T) \quad (2)$$

$$\sigma_{h'} = \sigma_{h',o}\exp(-13.94\times10^3/\boldsymbol{R}T) \quad (3)$$

where the indeces p, h and h' refer to the ices doped with PVSA, NBOH and NBPB, respectively.

The dependence of the electric conductivity of the ices doped with polyelectrolytes on the concentrations of the polyelectrolytes at -10°C is shown in Fig. 5.

II. The Rectification Phenomena Using the Ices Doped with Electrolytes. Making the solid junction of two ices, one doped with a

electrode is placed in the region of ice doped with a proton donor, the system exhibits a greater electric resistance than the case when the voltages with the reverse polarity were applied. The typical curves of the static current *versus* voltage are shown in Figs. 6 and 7. The data given in Figs. 6 and 7 were read at 30 sec after the voltages were applied. From these figures we can see that the curves have the hysteresis loops in both the NBOH-PVSA and the NBPB-PVSA systems.

The dynamic characteristics of rectification phenomena were remarkable when the alternating voltages of ultra-low frequencies were applied to the systems. The rectification effect was slightly observed even when the alternating voltage of 10 kc was applied. An example is shown in Fig. 8.

LiOH-HF System. The static and dynamic rectification phenomena of this system are more remarkable than those of NBOH-PVSA and NBPB-PVSA systems. The static characteristics are shown in Figs. 9 and 10. The curves in Fig. 9 were measured under the condition where the concentration of LiOH was maintained at 0.1 equiv/l and the concentration of HF was varied from 0.0097 to 0.0776 equiv/l. The curves in

Fig. 10 were obtained under the condition where the concentration of HF was maintained at 0.0388 equiv/l and the concentration of LiOH was varied from 0.025 to 0.3 equiv/l. A dynamic characteristic is shown in Fig. 11. The rectification ratio (the ratio of the forward current to the backward one) strongly depends on the frequency of the applied voltage and an example is shown in Fig. 12. The rectification phenomena were slightly observed even when the alternating voltage of 30 kc was applied.

Discussion

The d. c. electrical conductivity of the pure ice measured by Johnstone,[8] Bradley[9] and Granicher[10] was about 10^{-9} ohm^{-1}cm^{-1} at -10°C and the activation energy was 13.8 kcal/mol (by Granicher[10]). In the ice crystal, each oxygen atom is surrounded tetrahedrally by four hydroxyl ions at a distance of 2.76 Å. The pure ice is a good example of a protonic conductor. The mobility of a proton is ten times higher than a hydroxyl ion in ices (the mobilities of hydroxyl ion and proton are $\leq 5\times10^{-2}$ cm^{2}V^{-1}sec^{-1} and 0.1 to 0.5 cm^{2}V^{-1}sec^{-1}, respectively). The results in Figs. 2, 3 and 4 may be understood on this basis. Furthermore, the activation energy observed in the pure ice would reflect one for a protonic conduction, and the activation energy for a hydroxyl ion conduction should be greater. The activation energies of the electrical conduction of the ices doped with PVSA, NBPB and NBOH were measured to be 8.23, 13.94 and 13.94 kcal/mol, respectively. From these observations, it can be said that the inclusion of the linear polymers would contribute to the increase in the electrical conduction, owing to an increase in carrier concentrations and a lowering in activation energies caused by the generation of the structural defect in ices. The similarity in the conductivities of ices doped with NBPB and NBOH suggests that the charge carrier in both ices is the same one (OH^-).

Form the above consideration, it should be clear that the charge carriers of the ices doped with electrolytes are protons in the case of addition of PVSA and HF, and hydroxyl ions in the case of addition of NBOH, NBPB and LiOH. Then, by making the solid junction of two ices, one doped with a proton donor and the other with a proton acceptor, the rectification effect could be observed, such as in a *p-n* junction of a semiconductor.

In the case of the liquid junction analogous to a *p-n* junction,[2] the following equations were proposed for the rectification effect; when the forward bias voltages are applied;

$$J = e(D_pC_p/L_p+D_hC_h/L_h)\{\exp(\alpha eV/kT)-1\} \quad (4)$$

when the backward bias voltages are applied;

$$J = eg[\exp(\beta eV/kT)-\exp\{-(1-\beta)eV/kT\}] \quad (5)$$

where J is the electric current, e is the elementary charge, D_p and D_h are the diffusion coefficients of proton and hydroxyl ion, respectively, C_p and C_h are the concentrations of electrolytes in the proton excess region and the proton defficiency region, respectively, L_p and L_h are the mean distances by which proton and hydroxyl ion proceed in the proton defficient and proton excess regions until their disappearance, α is the coefficient showing the effective portion of the applied voltage, β is the transfer number for the neutralization reaction, g is the exchange velocity at the dissociation equilibrium of H_2O, k is the Boltzmann constant and V is the applied voltage. Equation (4) was derived under the assumption that the rate of electrical conduction is controlled by the diffusion of charge carriers in the transition region. On the other hand, Eq. (5) was derived under the assumption that the dissociation reaction of H_2O is the rate-determining step in the electrical conduction mechanism and from this equation the backward currents are shown to be independent of the concentrations of the charge carriers.

In the case of NBPB-PVSA and NBOH-PVSA systems, the recitification effects were observed as expected, but the static characteristics are not explained by Eqs. (4) and (5), and, moreover, the hysteresis is observed in the current *versus* voltage curves even in the forward direction (Figs. 6 and 7). The rectification effects were also slightly

observed when the ultra-low frequency a.c. ($\leq$10 kc) was applied. The causes of the hysteresis, which is a principal discrepancy from the theoretical prediction, are considered to be due to the capacitance of the system, the space charge effect or the polarization effect. The capacitance of the system would play a more significant role, as the concentrations of charge carriers becomes lower. The polarization effects are caused by the electrode effects and by the difference in mobilities between the charge carriers in the bulk of ices. The polarization connected with the electrode processes can be neglected at sufficiently high voltages.

In the case of LiOH-HF systems, the rectification curves as shown in Figs. 9 and 10 are well reproduced by Eqs. (4) and (5). The backward currents are almost independent of the concentrations of charge carriers, although the values are higher than in the pure ice. The constancy of the backward currents is well explained by the dissociation controlled mechanism, as derived for the liquid junction. The dynamic characteristics are remarkable when the alternating voltage with frequencies ranged to 30 kc was applied. This could be expected from the higher mobilities of H^+ and OH^- in ice. It is not possible to give detailed discussions here, for the uniform distribution of the doped electrolytes is not confirmed in the present investigation. It may be noticed, however, that the rectification effect observed in the HF-LiOH system is the most excellent of the junction diodes with the ionic conduction mechanism reported up to the present.

Dilute Solution Properties of Monodisperse Poly(α-methyl styrene). I. Sedimentation Coefficient in Theta Solvent

Mitsuo ABE,*1 Kuniaki SAKATO, Takashi KAGEYAMA, the late Masaaki FUKATSU and Michio KURATA*2

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received April 5, 1968)

The sedimentation behavior of anionically polymerized poly(α-methyl styrene) has been studied as a function of molecular weight, concentration and speed of centrifugation under the theta condition of solvent and temperature, *i. e.*, in cyclohexane at 39°C. Analysis of the data was made by use of Fujita's equation for the pressure- and concentration-dependent sedimentation. It was found that the sedimentation coefficient at zero concentration and one atmosphere was given as $s_0^0=2.00\times10^{-15}M^{1/2}$ sec, where M is molecular weight. The concentration dependence coefficient k and the pressure dependence coefficient μ appearing in the Fujita equation were obtained as $k=6.2\times10^{-4}M^{1/2}$ dl/g, and $\mu=1.6\times10^{-9}$ cm²/dyne, respectively. The intrinsic viscosity in the theta solvent was also determined as $[\eta]_\theta=7.60\times10^{-4}M^{1/2}$ dl/g.

The purpose of this series is to present the results of systematic measurements carried out on the dilute solution properties of anionically prepared poly(α-methyl styrene). This polymer was taken as working material since its molecular weight distribution had been reported to be extremely sharp compared with other species of anionically prepared polymers.[1] Studies along the same line as the present have been published recently by Bywater and associates,[2] and by Nagasawa and associates.[3] They studied the behavior of intrinsic viscosity, sedimentation coefficient and polymer coil dimensions as functions of molecular weight and solvent nature, and compared the results with the current theories. However, no extensive measurement on the viscoelastic properties of dilute solutions of monodisperse polymer has been

published yet but some preliminary measurements.[4,5] Thus, in this series, we intend to investigate not only the viscosity and sedimentation behavior but also the viscoelastic behavior of dilute solutions under varying conditions of molecular weight, concentration and solvent nature.

In this paper, we present a series of velocity sedimentation data obtained for the monodisperse poly(α-methyl styrene) in a theta solvent. The sedimentation coefficient at zero concentration and one atmosphere is determined as a function of molecular weight using Fujita's equation for the pressure- and concentration-dependent sedimentation.[6]

The Fujita equation for the apparent sedimentation coefficient s_{app} is written in the form that

$$s_{app} = \frac{\ln(r/r_m)}{\omega^2(t-t_0)} = s_c^0\left\{1 + K\left[\left(\frac{r}{r_m}\right)^2 - 1\right]\right\} \quad (1)$$

with

$$s_c^0 = s_0^0/(1 + kc) \quad (2)$$

$$K = \frac{kc - m(1 + kc)}{2(1 + kc)} \quad (3)$$

$$m = \frac{1}{2}\mu\omega^2\rho_0^0 r_m^2 . \quad (4)$$

Here r is the radial distance of the boundary from the axis of rotation, r_m is the radial distance of the meniscus, ω is the angular velocity, t is the time measured from the moment the acceleration of the rotor commenced, t_0 is the zero-time correction for the acceleration period, and ρ_0^0 is the density of solvent at one atmosphere. s_c^0 and s_0^0 represent values of the sedimentation coefficient at initial concentration c of the solution and at infinite dilution, respectively: the both are referred to one atmosphere of the pressure. k and μ are constants characteristic of the polymer-solvent system: the former is called the concentration dependence coefficient and the latter is called the pressure dependence coefficient.

An experimental test of Eq. (1) has been made by Billick using anionically polymerized polystyrene.[7] He has shown that the pressure and concentration dependence effects of the sedimentation velocity can be treated adequately by Eq. (1) in both poor and good solvents. However, as was noted by Blair and Williams,[8] the evaluation of the pressure dependence coefficient μ and also of the concentration dependence coefficient k is very sensitive to the zero-time correction t_0 applied for the acceleration period, and accordingly it is subjected to a rather large experimental error. In fact, Billick[7] has reported rather scattering values, $\mu = 1.2—3.4\times10^{-9}$ cm²/dyne; while Blair-Williams[8] and Wales-Rehfeld[9] have reported $(1.6\pm0.2)\times10^{-9}$ and 2.2×10^{-9}, respectively, for the system polystyrene in cyclohexane.

In view of the existing uncertainty in the value of μ, we found it worthwhile to remeasure the pressure-dependent sedimentation rate using monodisperse polymer samples. After the present work was completed, Noda *et al.*[3] published velocity sedimentation data on the same polymer-solvent system as the present, though their measurements were less extensive with respect to the variation of speed of centrifugation than ours. They reported $\mu = 2.3\times10^{-9}$ for the system poly(α-methyl styrene) in cyclohexane.

Experimental

Polymer Samples and Their Molecular Weights. Nine samples of poly(α-methyl styrene) with narrow distribution of the molecular weight were prepared in our laboratory by the anionic polymerization technique.[1,10] The initiator used was *n*-butyl lithium for BH-1 and seven samples of BB series, and sodium naphthalene for sample A-1. The terminator used was *n*-butanol for the BB and A series, and water for the BH series. The polymerization was carried out at −78°C in a purified water-free tetrahydrofuran as solvent. All polymers were fractionated in a large-scale Desreux column at 25°C by using benzene-ethanol mixtures, and the middle fraction of each polymer was utilized for measurements. These polymers were then freed from solvents by freeze-drying from benzene solutions followed by evacuation for about 24 hr at 60°C, and were sealed into ampules under argon atmosphere or at 10^{-6} mmHg pressure. More details of the sample preparation will be described elsewhere.[11]

The weight-average molecular weights M_w were determined by light scattering in benzene at 30°C and in cyclohexane at 39°C using a Brice type photoelectric photometer. The refractive index increments in these two solvents were 0.134 and 0.200 ml/g, respectively, for the light of 436 mμ wavelength. The number-average molecular weights M_n were determined by osmometry for samples BB-4, 6, 8, BH-1, and A-1 in toluene at 37°C. Details of these measurements will be described in Part II of this series, but a part of the results is given in Table 1.

The ratios M_w/M_n of our samples were in the range 0.93—1.07 if they were evaluated directly from the values of M_w and M_n. This ratio M_w/M_n, however, can be evaluated with a higher accuracy from the

a) Determined in both benzene and cyclohexane.
b) Determined in benzene. c) determined in cyclohexane.

sedimentation boundary curve obtained in theta solvent.[12] The results of such measurements indicated that M_w/M_n were less than 1.01 for the samples BB-4, 5, 6, BH-1 and A-1. It is clear from these measurements that all our samples have an extremely narrow molecular weight distribution.

Theta Solvent and Temperature. Reagent grade cyclohexane was dried over a molecular sieve of 4A after the removal of a trace of benzene by a silica gel column, and was fractionally distilled with metallic sodium. The theta temperature was 38.6°C in cyclohexane as determined by the light-scattering second virial coefficient A_2. Figure 1 shows the A_2 *versus* temperature relationship obtained for sample A-1.

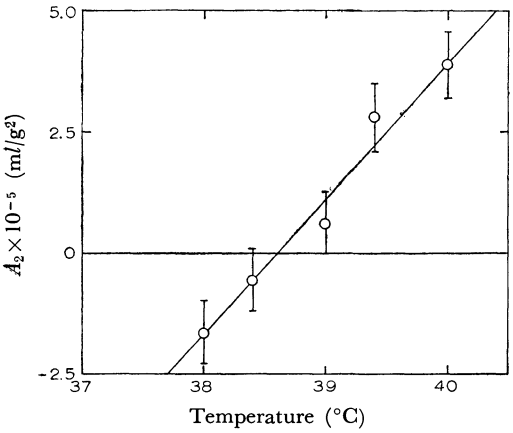

Fig. 1. Variation of the light-scattering second virial coefficient with temperature of sample A-1 in cyclohexane.

Sedimentation Velocity. Sedimentation velocity measurements were carried out in a Spinco model E ultracentrifuge equipped with an RTIC temperature control unit. In all experiments, the temperature was controlled at 39.0±0.1°C. A double sector cell of 12 mm long was used, and measurements were made at four rotor speeds, *i. e.*, 59780, 50740, 42040 and 29500 rpm, and at three or four initial concentrations of about 0.03 to 0.25 g/dl. Schlieren diagrams were read on a' 'Universal" contour projector (made by Nihon Kogaku Co., Ltd., Tokyo, Japan) to the accuracy of some 0.005 mm. The boundary position r in Eq. (1) was determined from the maximum of the refractive index gradient, since the schlieren diagrams were of good gaussian distribution curves.

Partial Specific Volume. A measuring-cylinder pycnometer of the Lipkin type was used to determine solution densities. The volume was approximately 10 ml. The density ρ_0 of cyclohexane was 0.7598 at 39°C. The partial specific volume v of poly(α-methyl styrene) was found to be 0.882 ml/g in this solvent.

Intrinsic Viscosity. Viscosity measurements were carried out in cyclohexane at 39°C using dilution viscometers of the Ubbelohde type. The corrections for the kinetic energy and shear rate effect were both negligible under the experimental conditions. The intrinsic viscosity $[\eta]_\theta$ and the Huggins coefficient k' determined are given in Table 1. The solvent viscosity η_0 was 0.730 centi-poise at 39°C.

Results

Zero-time Correction for Sedimentation. Among several methods so far proposed for the evaluation of the zero-time correction t_0 in sedimentation experiments, the so-called "best-fit" method of Blair and Williams[8] was found to be most appropriate for analysis of the present measurements. In this method, the value of t^0 is determined so as to minimize the "standard deviation" σ which is defined by

$$\sigma = [(1/n)\sum_{i=1}^{n} R_i^2]^{1/2} \tag{5}$$

with

$$R = s_c^0\omega^2(t-t_0) + s_c^0K\omega^2(t-t_0)[(r/r_m)^2-1] - \ln(r/r_m) \tag{6}$$

Here n denotes the number of observation in a given run of experiments. Figure 2 illustrates

12) T. Homma, K. Kawahara, H. Fujita and M. Ueda, *Makromol. Chem.*, **67**, 132 (1963).

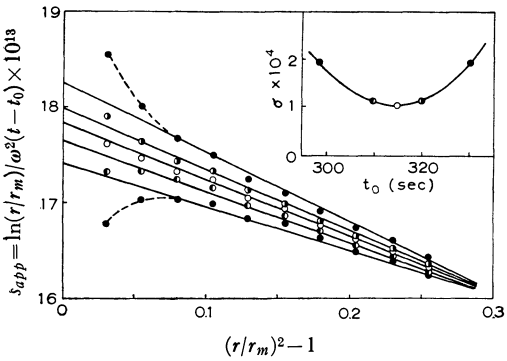

Fig. 2. Determination of the zero-time correction t_0 by the " best-fit " method of Blair and Williams. The five lines and different marks show the apparent sedimentation coefficients plotted against the quantity $(r/r_m)^2-1$ with five different choices of t_0 value. The insert shows variation of the standard deviation σ with the assumed values of t_0. Sample, A-1; rotor speed, 50740 rpm; concentration, 0.131 g/dl.

the procedure for the determination of t_0, in which the apparent sedimentation coefficients s_{app} obtained for various assumed values of t_0 are plotted against the quantity $(r/r_m)^2-1$. With aid of the best-fit line to each set of experimental points, a pair of values of s_c^0 and K can be determined, and then the standard deviation σ can be calculated using Eqs. (5) and (6). The values of σ thus obtained are shown in the insert of Fig. 2 as a function of t_0, and the "best-fit" value of t_0 is determined to be 315 sec. This value of t_0 was considerably larger than the time, 260 sec in this example, required for the so-called "2/3-acceleration".[7,13]

Pressure- and Concentration-dependence Coefficients. The values of s_c^0 and K corresponding to the best-fit value of t_0 were determined for samples BB-4, 5, 6, BH-1 and A-1 under various conditions of the concentration and the speed of centrifugation. The results are summarized in Table 2. For illustration, the values of s_c^0 of sample BB-5 thus determined are plotted in Fig. 3 against the concentration c. No systematic effect of the speed of centrifugation is observed in these s_c^0 *versus* c plots, and we can evaluate the concentration dependence coefficient k within an accuracy of about ten or twenty percent. The values of k thus obtained are listed in Table 1, and are plotted against the square-root of the molecular weight in Fig. 4. This plot suggests the relationship,

$$k = 6.2\times10^{-4}\,M^{1/2}\ \text{dl/g}.$$

The pressure dependence coefficient μ can be readily evaluated by substituting the values of K and k into Eqs. (3) and (4). The results are

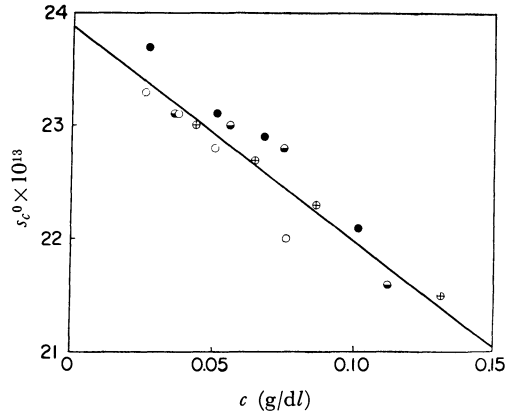

Fig. 3. Variation of sedimentation coefficient s_c^0 with the concentration c of sample BB-5 in cyclohexane at 39°C. Rotor speeds: ○, 59780; ⊕, 50740; ◒, 42040; ●, 29500 rpm.

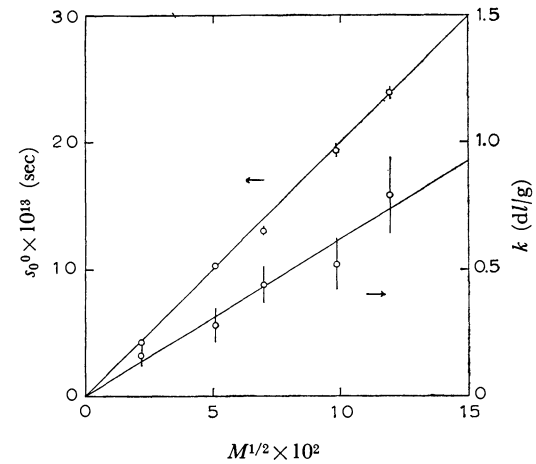

Fig. 4. The sedimentation coefficient s_0^0 and its concentration dependence coefficient k as functions of the molecular weight M.

tabulated in Table 2. No systematic variation of the μ values with the polymer molecular weight nor concentration is observed, and the averaging of these sixty four values of μ yields

$$\mu = (1.6 \pm 0.2)\times10^{-9}\ \text{cm}^2/\text{dyn}. \qquad (8)$$

Sedimentation Coefficient at Infinite Dilution. The sedimentation coefficient s_0^0 at zero concentration of the polymer and at one atmosphere are listed in Table 1. As shown in Fig. 4, this quantity s_0^0 is proportional to the square root of the molecular weight:

$$s_0^0 = (2.00 \pm 0.03)\times10^{-15}\,M^{1/2}\ \text{sec}. \qquad (9)$$

Intrinsic Viscosity. The intrinsic viscosities given in Table 1 are also proportional to the square root of the molecular weight:

$$[\eta]_\theta = (7.60 \pm 0.07)\times10^{-4}\,M^{1/2}\ \text{dl/g}. \qquad (10)$$

Discussion

The present measurements indicate that the concentration dependence of the sedimentation coefficient does not vanish at the theta temperature. According to Pyun and Fixman,[14] the concentration dependence coefficient k, as expressed in units of dl/g, is given as:

$$k = k^{\varphi}(4/300)(M/N_A\pi)^2[(1-v\rho_0)^2/6\eta_0 s_0^0]^3 \quad (11)$$

where N_A is the Avogadro number, and ρ_0 and η_0 are the density and viscosity of solvent. k^{φ} denotes the value of the concentration dependence coefficient when the concentration is expressed in the volume fraction. The Pyun and Fixman theory shows that k^{φ} depends on the thermodynamic interaction between polymer segmants and that it takes a value between 2 and 3 at the theta point. The substitution of the present results, Eqs. (7) and (9), into Eq. (11) yields $k^{\varphi}=3.08$. This value is favorably compared with the above theoretical estimate, especially with the value, $k^{\varphi}=2.96$, which is derived by their "spherocylinder" approximation.[14]

As for the pressure dependence coefficient μ of the sedimentation coefficient, Noda *et al.* have reported the value, $\mu=2.3\times10^{-9}$, for the same polymer-solvent system as the present.[3] They referred to the agreement of this value with the theoretical value, $\mu=2.0\times10^{-9}$, which is calculated from the pressure-dependence coefficient λ of the solvent viscosity using the relationship,[15]

$$\mu = \lambda + [v\rho_0/(1-v\rho_0)]\kappa. \quad (12)$$

Here κ is the isothermal compressibility of the solution. The value of λ, however, is known only roughly in the case of cyclohexane,[15] and therefore the above comparison of μ values will not be given a much significance. The present estimate of μ given in Eq. (8) is in good agreement with the values which were obtained for polystyrene in cyclohexane by Blair-Williams,[8] Billick,*3 and Cowie-Bywater.[16] Thus, we prefer the present estimate $\mu=1.6\times10^{-9}$, and conclude that μ is primarily independent of polymer species but characteristic of solvent.

In spite of the above discrepancy in μ values, no discrepancy is observed in the values of s_0^0 between the measurements by Noda *et al.*[3] and ours. This can be demonstrated by plotting s_0^0 against $[\eta]_\theta$. As shown in Fig. 5, the two series of data support the single correlation line:

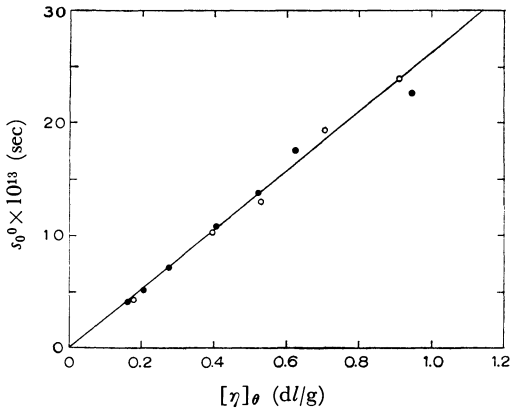

Fig. 5. Relationship between the sedimentation coefficient and the intrinsic viscosity. White circles, the present data; black circles, the data of Noda, Saito, Fujimoto and Nagasawa.[3]

$$s_0^0 = 2.63 \times 10^{-12}[\eta]_\theta. \quad (13)$$

This is probably due to the fact that in measurements of Noda *et al.*, the rotor speed was chosen as slow as possible to reduce the pressure effect. At such a low speed of centrifugation, the estimation of the pressure coefficient μ is subjected to a rather large experimental error, but the determination of s_0^0 itself can be performed with a sufficient accuracy.

The sedimentation coefficient *vs.* molecular weight relationship, Eq. (9), is slightly different from the relationship presented by Noda *et al.*:[3]

$$s_0^0 = 2.04 \times 10^{-15} M^{1/2}$$
(in cyclohexane at 39°C). (14)

The intrinsic viscosity *vs.* molecular weight relationship, Eq. (10), is also different from the relationships,

$$[\eta]_\theta = 7.13 \times 10^{-4} M^{0.51}$$
(in cyclohexane at 39°C) (15)

$$[\eta]_\theta = 7.80 \times 10^{-4} M^{0.50}$$
(in cyclohexane at 37°C) (16)

which were presented by Noda *et al.*[3] and Cowie *et al.*,[2] respectively. These discrepancies seem to arize from small but systematic errors involved in the molecular weight determination in these three laboratories. With the present data, we obtain from Eqs. (9) and (10)

$$\beta = \frac{s_0^0[\eta]_\theta^{1/3}\eta_0 N_A}{(1-v\rho_0)M^{2/3}} = \Phi^{1/3}P^{-1}$$
$$= (2.41 \pm 0.07) \times 10^6, \quad (17)$$

where P and Φ are the Flory universal constants for the sedimentation coefficient and the intrinsic viscosity, respectively. This value of the Scherage-Mandelkern constant β is slightly lower than the value $(2.5—2.6)\times10^6$ which is predicted by the

current theories. It is, however, difficult to decide whether this discrepancy is attributed to underestimate of M in our light scattering measurements or to overestimate of Φ in the current theories.

(Received April 11, 1968)

The electronic structures of bicyclo(1.1.0)butane, tricyclo(3.1.0.0)hexane, tricyclo(2.1.0.0)-pentane, tricyclo(1.1.0.0)butane, prismane, and spiro(2.2)pentane are studied by the extended Hückel method. The calculated total energies of bicyclo(1.1.0)butanes with various dihedral angles, θ, and bridgehead C–C–H angles, α, show that the most stable configuration of bicyclobutane is at $\alpha=135°$ and $\theta=115$—$120°$. It is made clear that the s-nature of the carbon atoms of the $C\text{–}H_{axial}$ and $C\text{–}H_{equatorial}$ depends greatly on the dihedral angle of the two cyclopropane rings. The double-bond character between the bridgehead carbon atoms in the bicyclobutane and its homologues is pointed out. The stabilities of the C–C bonds of prismane are shown to be largely dependent on the angle between the C–H bond and the four-membered-ring plane. The electronic structures of some configurations of spiropentane with different dihedral angles are discussed. The physico-chemical properties of these compounds are briefly investigated.

It is well known that the cyclopropane ring has a small C–C–C bond angle of 60° and exhibits aromaticity and peculiar reactivities in most reactions.[1-3] Therefore, it is interesting to examine the physico-chemical properties of the following compounds: bicyclo(1.1.0)butane (I) in which two cyclopropane rings are fused with each other, with one C–C bond in common, and its homologues: tricyclo(3.1.0.0)-hexane (II), tricyclo(2.1.0.0)pentane (III) and tricylo(1.1.0.0)butane (IV), prismane (V), and spiro(2.2)pentane (VI), in which two cyclopropane rings hold a carbon atom in common.

Spiro(2.2)pentane (VI) was synthesized by Murray and Stevenson[4] about twenty years ago. The other compounds have, however, been prepared quite recently. The preparation of bicyclo(1.1.0)-butane (I) has been reported by Lemal *et al.*[5] and Srinivasan[6] independently. Tricyclo(3.1.0.0)-hexane and tricyclo(2.1.0.0)pentane derivatives were prepared by Meinwald[7] and by Masamune.[8] The preparation of tricyclo(1.1.0.0)butane, the structure of which seems to be tetrahedron, has not been reported as yet. Prismane derivatives have been synthesized by Viehe *et al.*,[9] and the properties of these small cage compounds have recently been reported on by Wiberg *et al.*[10]

As for theoretical investigations, Weltner[11] suggested that tricyclo(1.1.0.0)butane (IV) consists of "acetylenic" sp hybridized carbon atoms and

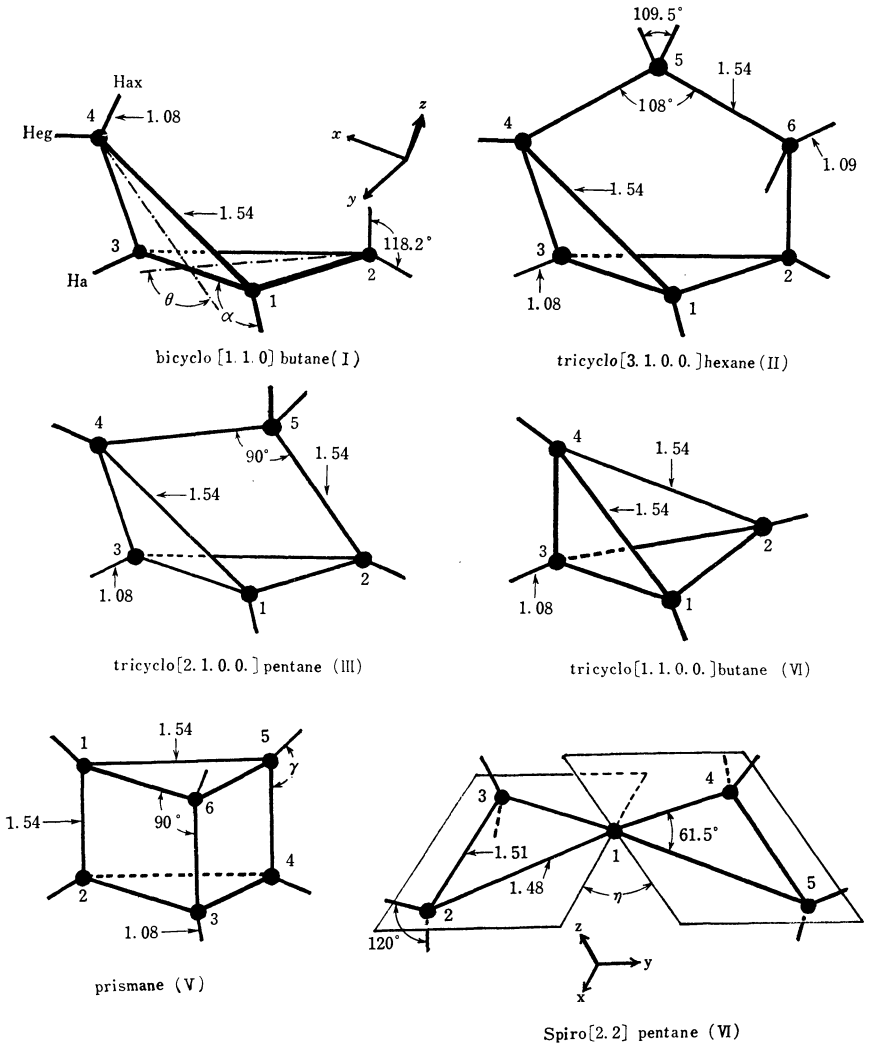

Fig. 1. Molecular structures of polycyclo compounds.

pointed out the large s-nature of the carbon atom in the C–H bond, basing his observations on the maximum overlap method.[12] Maksić *et al.*[13] calculated the electronic structure of bicyclobutane (I) by the same method and indicated the remarkable s-nature of bridgehead carbon atoms. Pomerantz *et al.*[14] suggested qualitatively that the central bond has an olefinic π-character.

Quite recently, Baird and Dewar[15] have calculated the strain energies of many cyclopropanes and cyclopropenes by means of the NDDO method[16] and be established that tricyclobutane (IV) would have very large strain energies (150.5 kcal/mol).

In the present paper, the correlation between the electronic structures and the dihedral angle of bicyclobutane will be studied first. Then, we will discuss how the electronic structures change for a series of bicyclobutane homologues: tricyclohexane (II), tricyclopentane (III), and tricyclobutane (IV). Secondly, the electronic structures of two possible configurations of prismane (V) will be investigated in relation to their stabilities. Finally, the stabilities of spiropentane (VI) with several dihedral angles will be discussed in comparison with that of 1,1-dimethylcyclopropane.

The extended Hückel method[17] is used for the

calculation. The parameters used in the present paper are identical with those previously reported.[17,18]

For all the compounds mentioned above except for spiro(2.2)pentane (VI)[19] the bond lengths and bond angles have never been reported. We assume them by referring to the observed values of cycloalkanes,[20] shown in Fig. 1.

Electronic Structures of Various Configurations of Bicyclo(1.1.0)butane and Its Homologues. *Stable Configuration of Bicyclo(1.1.0)-butane I.* The relation between the dihedral angle, θ, and the total electronic energies of bicyclobutane with the constant value of $\alpha=180°$ is shown in Fig. 2. The calculated results indicate that the total electronic energy reaches a minimum at the dihedral angle, θ, of 115—120°, while the bicyclobutane seems to be bent more than cyclobutane, which has the dihedral angle of 160°.

Next, the calculations were carried out, changing the value of the bridgehead C–C–H angle, α, in the range of 90—180° but keeping the constant dihedral angle of 120°, which corresponds to a local minimum of total electronic energy. In Fig. 3 the total electronic energy of bicyclobutane is plotted against the value of α. It is found that the total electronic energy has a minimum at an α value of about 135°.

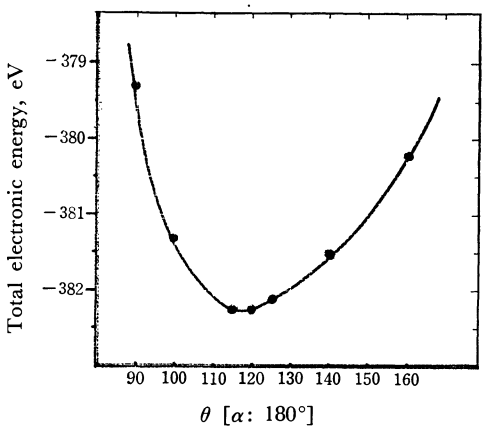

Fig. 2. Total electronic energies of various configurations of bicyclobutane.

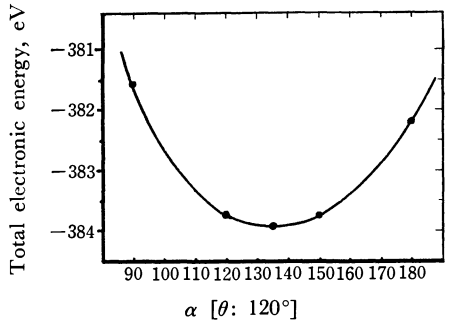

Fig. 3. Total electronic energies of various configurations of bicyclobutane.

As to the molecular structure of bicyclobutane, Haller and Srinivasan[21] suggested the following on the basis of their IR spectral data: $\theta=126°$, $\alpha=163°$, $\angle HCH=118°$, C_1–C_2; 1.53 Å, C_1–C_3; 1.54 Å and C–H; 1.08 Å.

On the other hand, Harmony and Cox[22] have recently reported the following values, based on their microwave spectroscopic data: $\theta=121°$, $\alpha=130°$, $\angle HCH=116°$, C_1–C_2; 1.51 Å, C_1–C_3; 1.49 Å and C–H; 1.08 Å. Our results seem to support the structure reported by Harmony and Cox.

Stability of Bicyclo(1.1.0)butane and Its Homologues. Tricyclo(3.1.0.0)hexane (II), tricyclo(2.1.0.0)-pentane (III), and tricyclo(1.1.0.0)butane (IV)*2 are considered to be cage molecules which are constructed by connecting perihedral secondary carbon atoms (*i. e.*, C_2 and C_4 in Fig. 1) with a ethylenic group, with a methylenic group, and directly.

Table 1 shows the dihedral angle, θ; the bridgehead C–C–H angle, α*3; the highest occupied HO orbital energy; the lowest vacant LV orbital energy, and the gap energy between these energies. The HO orbital energies of these compounds are about −11——12 eV, as is shown in Table 1; they are higher by 1—2 eV than that of cyclopropane, whose HO orbital energy is −13.052 eV. The ionization potentials for these compounds seem to be smaller than that of cyclopropane. The LV orbital energies for these compounds are much lower than those for acyclic saturated hydrocarbons (*n*-butane, 2.492 eV; isobutane, 1.374 eV; neopentane, 0.837 eV); thus, the electron affinities of these compounds may be very large. These levels of bicyclobutane and its homologues, however, are higher than those of acyclic unsaturated hydrocarbons (*e. g.*, ethylene; −8.253 eV); therefore, the LV energy levels of these compounds are located midway between those for common saturated hydrocarbons and unsaturated hydrocarbons. The energy gaps between the HO and LV orbital energies for these compounds are 4—7 eV, much

$n=2,1,0$

less than that for cyclopropane (8.709 eV). It is well known that cyclopropane has its UV absorption spectra near the wavelength of 190 mμ.[23] Therefore, the absorption spectra of present compounds exist in rather a longer wavelength region than those of cyclopropane, and their conjugative abilities may be large. The conjugative property will be discussed below.

Nature of the Central Bond of Bicyclo(1.1.0)-butane and Its Homologues. In this section the double-bond character of the central bonds (C_1–C_3 bonds in Fig. 1) of bicyclobutane and its homologues will be elucidated.

The AO coefficients of the HO and LV orbitals of the bicyclobutane with the most stable configuration and its homologues are cited in Table 2. They mainly consist of the $2p_Z$ and $2p_X$ of C_1, C_2, C_3 and C_4; other, very small AO coefficients are neglected.

These results indicated that a π-type interaction takes place between two p_Z AO's of the carbon atoms in the central bonds of these compounds. Further, the HO and LV orbitals are respectively, the bonding and the antibonding orbital with respect to the p_Z–p_Z bond. The natures of the two orbitals of these compounds resemble those of the π-orbitals of mono-olefins.

Wiberg *et al.*[10] have reported that the reaction of bicyclobutane-1-methanol with a dilute acid occurs almost instantaneously, accompanying the cleavage of the central bond, and that 1-hydroxycyclobutanemethanol is obtained. It is known that this addition reaction follows the Markownikoff rule.[10]

In addition, peculiar properties have been

23) H. Weitkamp, U. Hasserodt and F. Korte, *Chem. Ber.*, **95**, 2280 (1962).

observed in bicyclobutane, such as that the absorption spectra of methyl-3-methylbicyclobutane-1-carboxylate appears at 210 mμ (ε: 7000), just as in the corresponding α,β-unsaturated ester,[10] and that the addition of iodine to bicyclobutane proceeds *via* an intermediate such as a benzene-iodine complex.[10] Further, the derivatives of tricyclohexane (II) and tricyclopentane (III) with conjugative substituents on carbon atoms, C_1 and C_3, show their UV absorption spectra in rather a longer-wavelength region.[8,24]

Our present conclusion, indicating the existence of the π-type conjugation in the central bond, is compatible with the suggestion of Pomerantz *et al.*,[14] and it explains fairly well the above peculiar properties.

s-Nature of the C-H Bonds of Bicyclo(1.1.0)butane and Its Homologues. The s-nature of the bonds of bicyclobutane and its homologues has been studied in terms of Y_{CH}, which was difined in a previous paper[18] as representing the contribution of the 2s AO of the carbon atom to the C-H bond:

$$Y_{CH} = \frac{N_{C(S)H(S)}}{M_{CH}} \times 100\%$$

where the notation C(S) implies the 2s AO of a carbon atom.

The relation between the values of Y_{CH} and the dihedral angle, θ, of bicyclobutane is shown in Fig. 4.

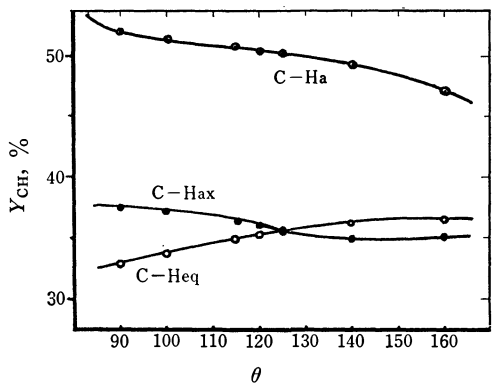

Fig. 4. Values of Y_{CH} of various configurations of bicyclobutane.

The value of Y_{CH_a} decreases with the increase in θ. However, the value of Y_{CH_a} is much larger than those of $Y_{CH_{axial}}$ and $Y_{CH_{equatorial}}$. Hence, the s-nature of the carbon-hybridized orbital of the C-H_a bond may be expected to be large. The value of $Y_{CH_{axial}}$ decreases with the increase in $Y_{CH_{equatorial}}$ the two curves cross at the value of $\theta = 125°$.

The observed ^{13}C-H coupling constants,[8,10,25,26] the fractional s-character of the carbon hybrid atomic orbital for the C-H bond estimated by experiments or from the values calculated by Weltner[11] and Maksić *et al.*,[13] the values of Y_{CH}, and the squares of the bond order, $(P_{CsHs})^2$, are given in Table 3, where P_{CsHs} in dicates the bond order between the 2s orbital of the carbon atom and the ls orbital of the hydrogen atom in a C-H bond.

It may be seen in Table 3 that these theoretical indices run approximately parallel to the magnitude of the s-nature estimated and the ^{13}C-H coupling constants. However, for C-H axial and C-H equatorial bonds in bicyclobutane, the calculated results contradict the ^{13}C-H coupling constants.

However, it may be noted that, as has been stated above, the s-natures of these two C-H bonds very sensitively with the change in the dihedral angle and the two Y_{CH} curves cross at 125°, which is very close to the dihedral angle, 120°, adopted in the present calculations. If, for the dihedral angle, the value of 126° reported by Haller and Srinivasan is adopted, our results agree with the experimental results. This point should be checked further both experimentally and theoretically with regard to the reliability of the extended Hückel approximation.

As to tricyclobutane (IV), the value of Y_{CH} for its four equivalent C-H bonds amounts to 50%. This indicates the fractional s-character of the carbon hybrid AO in this compound is very large and that the C-H bond is markedly polar.

Electronic Structures of Prismane (V). Two structures of prismane were studied; one is a rather hypothetical configuration (V'), which consists of two interacting cyclopropenyl radicals, as is shown in Fig. 5. The other is a more real configuration

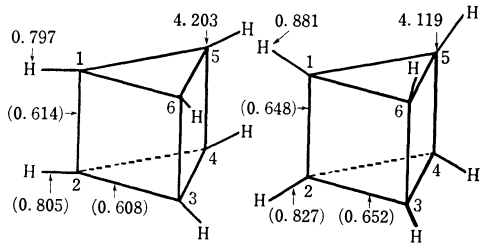

Fig. 5. Atomic populations and atomic bond populations of two configurations of prismane.
( ): atomic bond population

(V), where the C-H bonds of the cyclopropenyl radicals are bent to the outside. In Table 4 the total electronic energies and the energies of the highest occupied and lowest vacant orbitals of the two configurations of prismane (C_6H_6) are given,

	$\eta=45°$	$-\{0.2723C_{1X}-0.4800(C_{2}-C_{3Y})\} + \{0.6574C_{1Z}-0.4800(C_{5Y}-C_{4Y})\}$
	$\eta=0°$	$0.5761\{(C_{2Y}-C_{3Y})-(C_{5Y}-C_{4Y})\}$

together with those of benzene for comparison. The present calculations show that these two configurations of prismane are less stable than benzene and that the V configuration is more stable than the V′. Therefore, it may be concluded that the value of the C–C–H angle, γ, plays an important role in determining the stability of prismane. The highest occupied orbitals for both configurations are higher than that for benzene; the energy levels of the lowest vacant orbital for both configurations are higher by about 2 eV than that for benzene, but are markedly lower than those for ordinary saturated hydrocarbons (*e. g.*, *n*-butane, 2.492 eV) and for cyclopropane (−4.244 eV).

The atomic population and the atomic bond population of both configurations of prismane are given in Fig. 5.*4

Photodecomposition of Prismane (V). Breslow *et al.*[27] proposed a reaction mechanism for the photodecomposition of prismane, where bicyclo(2.2.0)-hexa-1,5-diene is produced at first with cleavages of the C_1–C_5 and C_2–C_4 bonds, not of the C_1–C_2 bond, followed by isomerization to benzene. We assume this reaction in the following mechanism: the irradiation of light first causes the excitation of one electron from the HO orbital to the LV orbital, while in the next stage the cleavage of the weakest bond takes place. For this singlyexcited state, the values of $M_{C_1C_2}$ and $M_{C_1C_5}$ are obtained as 0.814 and 0.419 respectively. This implies that the cleavage of C_1–C_5 bond may occur more easily. These calculated results support the reaction mechanism proposed by Breslow *et al.*

Electronic Structures of Spiro(2.2)pentane (VI). As to spiro(2.2)pentane (VI), the dihedral angle, η, is experimentally known to be 90°. In the present treatment, the electronic structures for three configurations, with η=90, 45 and 0°, were investigated in order to reveal the correlation between the dihedral angle and the stability of spiro pentane. They were compared with the electronic structure of 1,1-dimethylcyclopropane, which is considered to be derived from spiropentane by opening one cyclopropane ring.

Spiropentane is the most stable at η=90° (−488.38 eV) (this is in accordance with the experimental result) and gradually becomes more unstable as η decreases from 90 (−486.90 eV) to 0° (−484.09 eV). The HO orbital energy for spiropentane with the configuration of η=90° (−12.551 eV) is lower than that for 1,1-dimethylcyclopropane (−12.325 eV), but higher than those for methylcyclopropane (−12.612 eV) and for cyclopropane (−13.052 eV).

The AO coefficients of the HO and LV orbitals for spiropentane and dimethylcyclopropane are given in Table 5. In spiropentane with η=90° both orbitals are doubly degenerated, and each orbital consists of the carbon 2p orbitals of a cyclopropane ring. The LV and HO orbitals at η=45° are nearly equal to a linear combination of the corresponding doubly degenerated orbitals at η=90°. At the value of η=0°, the HO orbital is exclusively made of the $2p_Z$ AO of the carbon atom C_1, just as is a lone-pair orbital, further, the LV orbital is constructed only from the $2p_Y$AO's of the four carbon atoms, C_4, C_5, C_2 and C_3. Therefore, spiropentane of this configuration has extremely peculiar electron distribution.

An the basis of a comparison of the atomic bond populations, the C_2–C_3 bond for spiropentane ($M_{C_2C_3}$=0.592) may be expected to be weaker than those for 1,1-dimethylcyclopropane (M_{C_2C},= 0.611) and cyclopropane (M_{CC}=0.628). In fact, in the hydrogenation which accompanies the ring-opening reaction, the heat of formation, ΔH, for spiropentane is −42.0 kcal/mol, which seems to be required for the cleavage of the C_2–C_3 bond; on the other hand, the ΔH for cyclopropane is −37.6 kcal/mol.[28]

These experimental results indicate that the cleavage of the C_2–C_3 bond occurs more easily in spiropentane than in cyclopropane; this is in accordance with our calculated results.

The calculations were carried out on the HITAC 5020 Computer at the University of Tokyo.

*4 As prismane of the V′ configuration is transformed into the V configuration, all the atom bond populations increase and the value of M_{cc} for a three-member ring becomes larger than that of cyclopropane, 0.629. This fact may also indicate that the bending of C-H bonds is closely correlated with the stabilization of prismane.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2343—2349 (1968)

Photochemistry of Acetanilide. I. Quantum Yields of the Rearrangement and Benzene Photosensitized Reaction

Haruo SHIZUKA[1] and Ikuzo TANAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

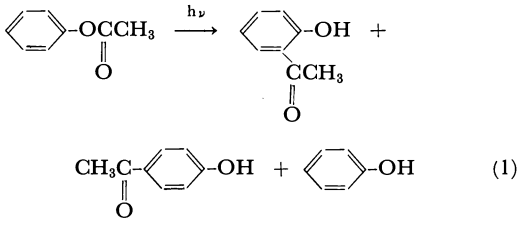
(Received April 12, 1968)

The photochemical rearrangement of acetanilide under 2537 Å irradiation has been studied by spectrophotometry. The quantum yield of the rearrangement in cyclohexane solution was independent of the irradiation time, concentration of acetanilide, presence of oxygen and light intensity. It was found that electronic energy transfer from the electronically excited benzene to acetanilide occurred in the mixed solution, and the transfer mechanism was explained by singlet-singlet nonradiative energy transfer. It was observed that the energy transfer rate constant was about 22 times greater than that predicted by diffusion theory (the transfer rate constant, $k_3=1.45\times10^{11}\ l\cdot mol^{-1}\cdot sec^{-1}$). From these studies, it is proposed that the rearrangement of acetanilide is an introamolecular reaction and does not occur from the triplet state but from the lowest singlet excited state.

It is known that organic carbonyl compounds give rise photochemically to many interesting reactions; abstraction, rearrangement, addition, dimerization and decomposition.

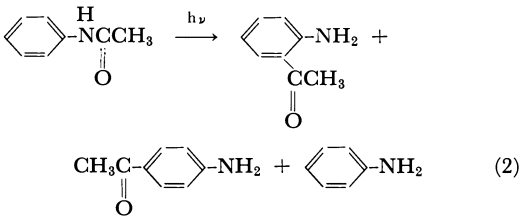
The photochemical reactions of phenyl esters in solution yield products of rearrangement similar to those of the Fries reaction. Hence, this rearrangment is termed the photo-Fries-rearrangement.

Anderson and Reese[2] reproted that phenyl esters rearrange to yield *ortho*-hydroxyl aryl ketones as well as *para* isomers by irradiation with UV light, as indicated by Eq. (1).



(1)

Kobsa[3] and Finnegan *et al.*[4] reported similar findings. Elad and coworkers reported the photochemical reaction of anilide, another carbonyl derivative.[5]



(2)

Kobsa suggested a mechanism for the photo-Fries-reaction involving homolysis of the phenyl ester into a free-radical pair, held together in a solvent cage, with subsequent rearrangement.[3] However, little mechanistic work on the photo-Fries-rearrangement has been reported.

On the other hand, a molecular-orbital calculation has been carried out to determine the π-electronic structure of acetanilide.[6] The subject of electronic energy transfer between unlike molecules in solution through a resonance interaction has received considerable interest.[7-15] The study of electronic energy transfer is very useful for investigating the role of excited states in photochemical

reactions. It is very interesting to elucidate the correlation between the photochemical reaction and the electronically excited state for acetanilide through photosensitization by benzene in the liquid phase. The photosensitizations by benzene have been studied in the gas phase.[16-19]

This paper reports measurements of quantum yields under various conditions and the mechanism of electronic energy transfer from the excited benzene to acetanilide, in order to make clear the mechanism of the photo-Fries-rearrangement.

Experimental

Materials. Acetanilide was a Tokyo Kasei Co. G. R. grade product and was purified by repeated recrystallization from water. *o*-Amino acetophenone, *p*-amino acetophenone and piperylene were Tokyo Kasei Co. G. R. grade products. Benzene was a Kokusan Chemical Works Ltd. G. R. grade product and was purified by vapor-phase chromatography. Cyclohexane was a Nichiri Co. reagent grade product and was purified by passage through silicagel and by distillation.

Light Source. A low pressure mercury resonance lamp containing neon was used as the 2537 Å radiation source with a Vycor glass filter.

Light Intensity Measurement. Actinometry was carried out in a reaction cell (quartz) using a ferric oxalate actinometer solution. The light intensity at 2537 Å was determined by the difference in light intensities with and without the benzene solution filter which cut off the wavelengths below 2700 Å. In the case of benzene photosensitization, a reaction cell of 1 cm length was used and the light intensity (I_0) at 2537 Å was 9.7×10^{14} photons·sec^{-1}·cm^{-2}.

Analysis. The amounts of *o*-amino acetophenone and *p*-amino acetophenone produced by the photochemical reaction were determined spectrophotometrically. Ultraviolet absorption spectra at room temperature were taken with Hitachi 139 and Hitachi EPS 2 spectrophotometers.

Results and Discussion

Reaction Products. The spectrum of the solution of acetanilide changed markedly upon irradiation with 2537 Å light as shown in Fig. 1. Absorption Band II (240 mμ) of acetanilide decreased and new bands with maxima at 225, 287 and 355 mμ appeared as the irradiation time increased, with two isosbestic points at 233 and 255 mμ. The reaction products corresponded to *o*-amino acetophenone (absorption peaks 225 and 355 mμ) and *p*-amino acetophenone (absorption peaks 224 and 287 mμ) as shown in Table 1.

Therefore, quantum yields of *o*-amino acetophenone, *p*-amino acetophenone and the disappearance of acetanilide were measured spectrophotometrically. The samll amount of aniline which was produced from the primary process of the photochemical reaction for acetanilide[5] could not be directly determined by means of the

spectrophotometric method, because of the overlapping acetanilide, *o*-amino acetophenone and *p*-amino acetophenone spectra.

Effect of Irradiation Time, Concentration, Oxygen, and Light Intensity on Quantum Yields. Quantum yields were obtained under various conditions (Fig. 2). The quantum yields of the rearrangement in cyclohexane did not change with variation in irradiation time, concentration of acetanilide and light intensity (Fig. 2 a, b and d). The effect of oxygen dissolved in the solution on the quantum yield was probably absent because there was no difference in quantum yields between an aerated solution and one deaerated by flushing with nitrogen at room temperature (Fig. 2c) The quantum yields of *o*-amino acetophenone and *p*-amino acetophenone in cyclohexane solution at 20°C were 0.07 and 0.06, respectively. The quantum yield of the disappearance of acetanilide was about 0.15. The addition of piperylene as a triplet quencher (E_T ~2.48 eV)[20] did not affect the quantum yield of this isomerization in a concentration range 10^{-4} to 10^{-2} mol/*l* (Fig. 2e).

(e) On addition of piperylene
○···Φ of *o*-amino acetophenone
●···Φ of *p*-amino acetophenone

From these results, it is assumed that acetanilide does not react from the triplet state $T_1(\pi-\pi^*)$. The photochemical rearrangement of acetanilide may be an intramolecular reaction in dilute solutions ($<\sim 10^{-3}$ mol/*l*) as suggested for phenyl acetate by Anderson and Reese.[2] However, it has been reported that an intermolecular reaction occurred in the rearrangement of acetanilide.[5a] It is though that the intermolecular reaction occurs at high concentrations.

Energy Transfer from the Electronically Excited Benzene to Acetanilide. The photosensitization has been studied quantitatively in a cyclohexane solution at room temperature through a determination of the relative rate R/R_0 of product formation, varying the concentrations of benzene and acetanilide, where R and R_0 are the reaction rates with and without benzene in acetanilide solution, respectively. The reaction rates of the

product formations (*o*-amino acetophenone and *p*-amino acetophenone) were measured spectrophotometrically. Figure 3 shows the dependences of the relative rates R/R_0 on the concentration of benzene in aerated or deaerated cyclohexane solutions. An effect of dissolved oxygen ($\sim 10^{-3}$ mol/*l*) was not observed within the experimental error as shown in Fig. 3. An increase in the rate of rearrangement could not be detected even in a carefully degassed solution. This could be explained by the fact that the maximum rate of the quenching reaction by dissolved oxygen of 10^{-3} mol/*l* was about one tenth of the overall deactivation rate of the excited singlet benzene ($^1B_{2u}$), considering it to be diffusion controlled, as is discussed later. Figure 4 shows the dependence of the relative rate R/R_0 on the concentration of acetanilide. The

energy transfer efficiency γ from the excited benzene to acetanilide was calculated from the following equation;

$$\gamma = \frac{I_\Sigma - I_A}{I_B} \tag{3}$$

where

$$I_\Sigma = \frac{R}{R_0} I_{A0} \tag{4}$$

and I_{A0} is the light intensity absorbed by acetanilide in the absence of benzene, which was determined experimentally, I_A and I_B are the light intensities absorbed by acetanilide and by benzene in the mixed solution, respectively, which have been calculated using Beer's law. Figure 5(a) or 6(a) shows the transfer efficiency γ as a function of the concentration of benzene (donor) or of acetanilide (acceptor), respectively. It seems that the excited state of benzene for this energy transfer should be the lowest singlet excited state ($^1B_{2u}$) since the effect of dissolved oxygen on the photo-

●···*p*-amino acetophenone}

sensitization was absent as shown in Fig. 5(a). If the energy transfer had occurred from the triplet state of benzene ($^3B_{1u}$), the reaction rate of an aerated solution would be small in comparison with that in a deaerated solution.

The characteristics of the lower excited state of benzene and acetanilide are summarized in Table 2. If energy considerations are kept in mind, the following reactions may occur when benzene molecules absorb radiation at 2537 Å in the mixed solution;

$$\begin{array}{ccccc} B^* & \xrightarrow{k_3} & A^* & \xrightarrow{\phi} & \text{Reaction product} \\ & & (+A) & & \\ & & (+B) & & \\ h\nu \uparrow & \downarrow k_1 & \downarrow k_2 & & \\ B & & & & \end{array} \qquad k_1 = k_B^c + k_B^s + k_B^f$$

$$B \xrightarrow{h\nu} B^* \tag{5}$$

TABLE 2. ENERGIES, OSCILLATOR STRENGTHS AND WAVE FUNCTIONS FOR LOWER EXCITED STATES OF BENZENE AND ACETANILIDE

	Symmetry	Observed excitation energy, eV	Observed oscillator strength	Wave function	Band assignment
Benzene[a)]	$^1B_{2u}(D_{6h})$	4.88	0.0014	$1/2(V_{24}-V_{35})$	I
Acetanilide[b)]	$^1B_2(C_{2v})$	4.53_2	0.01	$0.481V_{24}$ $-0.875V_{35}$	I
	$^1A_1(C_{2v})$	5.18_3	0.28	V_{34}	II

a) See Ref. 21.
b) See Ref. 6.

$$B^* \xrightarrow{k_{B^c}} B_T \quad (6)$$

$$B^* \xrightarrow{k_{B^a}} B \quad (7)$$

$$B^* \xrightarrow{k_{B^f}} B + h\nu' \quad (8)$$

$$B^* + B \xrightarrow{k_2} 2B \quad (9)$$

$$B^* + A \xrightarrow{k_3} B + A^* \quad (10)$$

where B and A are the ground states of benzene and acetanilide, respectively, B* is the excited singlet state of benzene ($^1B_{2u}$), B_T the lowest triplet state of benzene ($^3B_{1u}$), A* the lowest singlet excited state of acetanilide ($^1B_2$) and Φ the quantum yield of the product. Then, using a steady-state treatment, the following equations are obtained.

$$[B^*] = \frac{I_B}{k_1 + k_2[B] + k_3[A]} \quad (11)$$

$$\gamma = \frac{k_3[B^*][A]}{I_B} = \frac{k_3[A]}{k_1 + k_2[B] + k_3[A]} \quad (12)$$

The transfer efficiency γ decreased as the concentration of benzene increased (Fig. 5(a) and Eq. (12)), due to self-quenching (Eq. (9)). On the other hand, γ increased when the concentration of the acceptor (acetanilide) increased, as shown in Fig. 6(a) and Eq. (12).

Equation (13) is derived from Eq. (12),

$$\frac{1}{\gamma} = \frac{k_1 + k_2[B]}{k_3[A]} + 1 \quad (13)$$

Figure 5(b) shows that the results corresponding to Eq. (13) are well represented by a linear plot of $1/\gamma$ *vs.* [B], where $[A]=5.22\times10^{-5}$ mol/*l*. From the slope and intercept of the plot shown in Fig. 5(b), k_2 and k_3 can be obtained.

$$\frac{k_2}{k_3[A]} = 2.3\times10^2\ l/\text{mol}$$

$$\frac{k_1}{k_3[A]} + 1 = 6.1$$

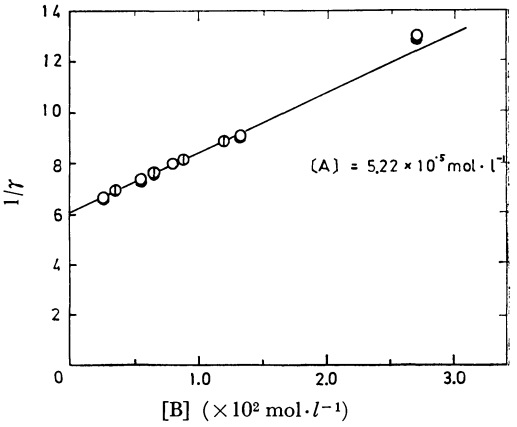

Fig. 5(b). Plot of $1/\gamma$ against the concentration of benzene.

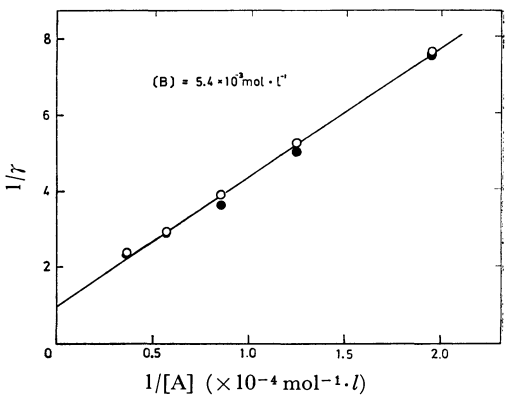

Fig. 6(b). Plot of $1/\gamma$ against the reciprocal of acetanilide concentration.

$$k_2 = 4.51 \times 10\ \ k_1\ l/\text{mol} \quad (14)$$

$$k_3 = 3.76 \times 10^3\ k_1\ l/\text{mol} \quad (15)$$

Figure 6(b) shows that the results corresponding to Eq. (13) give also good linearity of $1/\gamma$ *vs.* 1/[A], where $[B]=5.4\times10^{-3}$ mol/*l*. The slope of the plot in Fig. 6(b)

$$\frac{k_1+k_2[B]}{k_3} = 3.35 \times 10^{-4}\ \text{mol}/l \quad (16)$$

21) H. B. Klevens and J. R. Platt, Tech. Rept., Laboratory of Molecular Structure and Spectra, University of Chicago, Part 1, p. 145 (1953—1954).

From Eqs. (14) and (15), Eq. (17) is derived

$$\frac{k_1+k_2[\mathrm{B}]}{k_3} = \frac{k_1+4.51\times 10k_1\times 5.4\times 10^{-3}}{3.76\times 10^3\times k_1}$$

$$= 3.32\times 10^{-4}\ \mathrm{mol}/l \qquad (17)$$

These two values of the slope which are derived in different ways are in good agreement.

From the work of Ivanova *et al.*,[22] the lifetime of the benzene singlet excited state ($^1B_{2u}$) in the absence of acetanilide is given by

$$\tau_B = \frac{1}{k_1} = 2.6\times 10^{-8}\ \mathrm{sec}$$

$$k_1 = 3.85\times 10^7\ \mathrm{sec}^{-1} \qquad (18)$$

Therefore, the self-quenching rate constant k_2 and the energy transfer rate constant k_3 are calculated from Eqs. (14) and (15), respectively.

$$k_2 = 1.74\times 10^9\ l\cdot\mathrm{mol}^{-1}\,\mathrm{sec}^{-1} \qquad (14')$$

$$k_3 = 1.45\times 10^{11}\ l\cdot\mathrm{mol}^{-1}\,\mathrm{sec}^{-1} \qquad (15')$$

It is interesting to note that the value of k_3 in this experiment is close to the 1.4—$2.5\times 10^{11}\ l\cdot\mathrm{mol}^{-1}\cdot\mathrm{sec}^{-1}$ obtained by Bowen and Livingston[12] for the mixture of anthracene derivatives and perylene (or rubrene) at room temperature in various solvents.

The rate constant of a diffusion-controlled bimolecular reaction is represented approximately by the modified Debye equation.[23,24]

$$k_D = \frac{8RT}{3000\eta} \qquad (19)$$

where k_D is in units of $l\mathrm{mol}^{-1}\mathrm{sec}^{-1}$ when η, the viscosity of the solvent, is in units of poise.

The value of k_D corresponding to cyclohexane at 20°C is $6.6\times 10^9\ l\cdot\mathrm{mol}^{-1}\cdot\mathrm{sec}^{-1}$.[25] The empirical value of the rate constant k_2 corresponding to the self-quenching of benzene might not exceed the value of k_D. In contrast to this, the energy transfer rate constant k_3 is about 22 times greater than the value of k_D.

The possibility that complex formation between benzene and acetanilide is responsible for this energy transfer was shown to be unlikely by the fact that the spectral intensities and the positions of the mixed solution were identical with those of the separate solutions as shown in Fig. 7.

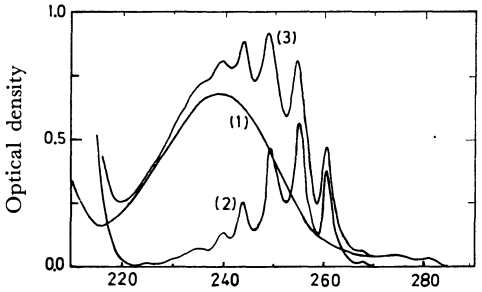

Fig. 7. Absorption curves of CH soln's of acetanilide, benzene and their mixture.
(1) Acetanilide $5.0\times 10^{-5}\ \mathrm{mol}\cdot l^{-1}$
(2) Benzene $2.6\times 10^{-3}\ \mathrm{mol}\cdot l^{-1}$
(3) Acetanilide $5.0\times 10^{-5}\ \mathrm{mol}\cdot l^{-1}$, benzene $2.6\times 10^{-3}\ \mathrm{mol}\cdot l^{-1}$

The critical transfer distance R_0 is given by[7,8]

$$R_0^6 = \frac{9000\ln 10\ \chi^2\varphi_s^0}{128\pi^6 n^4 N}\int_0^\infty f_s(\bar{\nu})\varepsilon_A(\bar{\nu})\frac{d\bar{\nu}}{\bar{\nu}^4} \qquad (20)$$

where $\bar{\nu}$ is the wave number, $\varepsilon_A(\bar{\nu})$ the molar extinction coefficient of the acceptor, $f_s(\bar{\nu})$ the spectral distribution of fluorescence of the sensitizer (measured in quanta and normalized to unity on a wave number scale), N Avogadro's number,

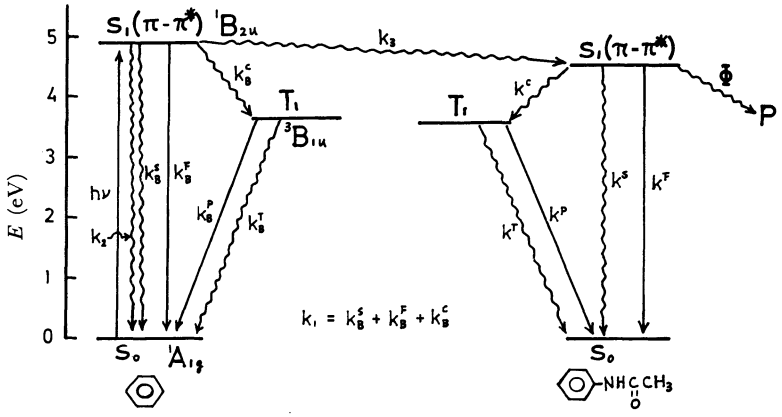

Fig. 8. Energy state diagram for energy transfer between benzene and acetanilide.

22) T. V. Ivanova, P. I. Kudryashov and B. Ya. Sveshnikov, *Doklad. Akad. Nauk. SSSR*, **138**, 572 (1961).
23) P. Debye, *Trans. Electrochem. Soc.*, **82**, 265 (1942).
24) E. J. Bowen, *Trans. Faraday Soc.*, **50**, 97 (1954).
25) J. G. Calvert and J. N. Pitts, Jr., "Photochemistry," John Wiley and Sons, New York (1966), p. 627.

χ^2 an orientation factor equal to 2/3, n the index of refraction of the solvent and φ_s^0 the fluorescence efficiency of the sensitizer for [A]=0. The integral was evaluated graphically (6.72×10^{-14}). φ_s^0 was obtained from the work of Ivanova *et al.*[22] (0.1). Then,

$$R_0 \approx 26\ \text{Å}$$

Though the $^1B_{2u}\leftarrow{}^1A_{1g}$ transition in benzene is a symmetry forbidden transition, the Förster equation (20) might be applied to this energy transfer because the overlap integral (6.72×10^{-14}) is not so small.

Considering the magnitude of the energy transfer rate constant k_3, it is thought that the transfer from the electronically excited benzene to acetanilide is singlet-singlet nonradiative energy transfer; a resonance transfer for a weak interaction.

Figure 8 shows the energy level diagram for the energy transfer between benzene and acetanilide

$$B^*(^1B_{2u}) + A(^1A_1) \xrightarrow{k_3} B(^1A_{1g}) + A^*(^1B_2) \quad (21)$$

In conclusion, it is said that acetanilide does not react from the triplet state, but *via* the lowest singlet excited state formed by the benzene-photosensitized reaction.

The authors are greatly indebted to Associate Professor Yuji Mori of the Tokyo Institute of Technology for his generous and very helpful discussions concerning this paper.

Bond Distances of Cyanogen as Determined by Gas Electron Diffraction

Yonezo MORINO, Kozo KUCHITSU, Yasurō HORI*1 and Mitsutoshi TANIMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 18, 1968)

The internuclear distances of cyanogen were determined by gas electron diffraction to be $r_g(C\equiv N)=1.163_4\pm0.001_9$ Å and $r_g(C-C)=1.392_5\pm0.002_2$ Å. The average moment of inertia calculated from this structure agreed with Maki's infrared results as corrected for rotation-vibration interaction. The spectroscopic moment of inertia obtained by Maki was used for calibrating the electron-diffraction scale factor, and the zero-point average distances, with their limits of error, were obtained as $r_z(C\equiv N)=1.155_2\pm0.001_3$ Å and $r_z(C-C)=1.387_1\pm0.001_4$ Å.

It has long been known that the length of a CC single bond depends on its environment. A carbon-carbon single bond adjacent to multiple bonds is found to be appreciably shorter than one in normal hydrocarbons, and the shortening is most conspicuous when the single bond is located between triple bonds.[1] Cyanogen, C_2N_2, is one of the simplest molecules of this category. Earlier electron-diffraction measurements of this molecule by Pauling, Springall and Palmer[2] and by Langseth and Mφller[3] gave $r(C\equiv N)=1.16\pm0.02$ and 1.15 ± 0.02 Å, and $r(C-C)=1.37\pm0.02$ and 1.38 ± 0.02 Å, respectively. The precise rotational constants, B_0, for two isotopic species, $^{12}C_2{}^{14}N_2$ and $^{12}C_2{}^{15}N_2$, have been obtained by Maki[4] from his rotational analysis of the infrared spectra. The resulting bond distances are $r_0(C\equiv N)=1.15_4\pm0.017$ Å and $r_0(C-C)=1.38_9\pm0.030$ Å.

On the basis of more recent developments in experiment and theory, a reliable average structure can be determined by the use of a combination of rotational constants obtained from high-resolution spectroscopy and internuclear distances obtained from electron diffraction.[5] The present study aims to apply this method to determining the average structure of cyanogen in the ground vibrational state.

Experimental

A sample of cyanogen, which contained 0.6% carbon dioxide and 0.4% air, was kindly offered by Dr. Shizuo Nakamura of the Sagami Chemical Research Center. It was purified before use by pumping off any impurities from the sample while it was held at dry ice temperature.

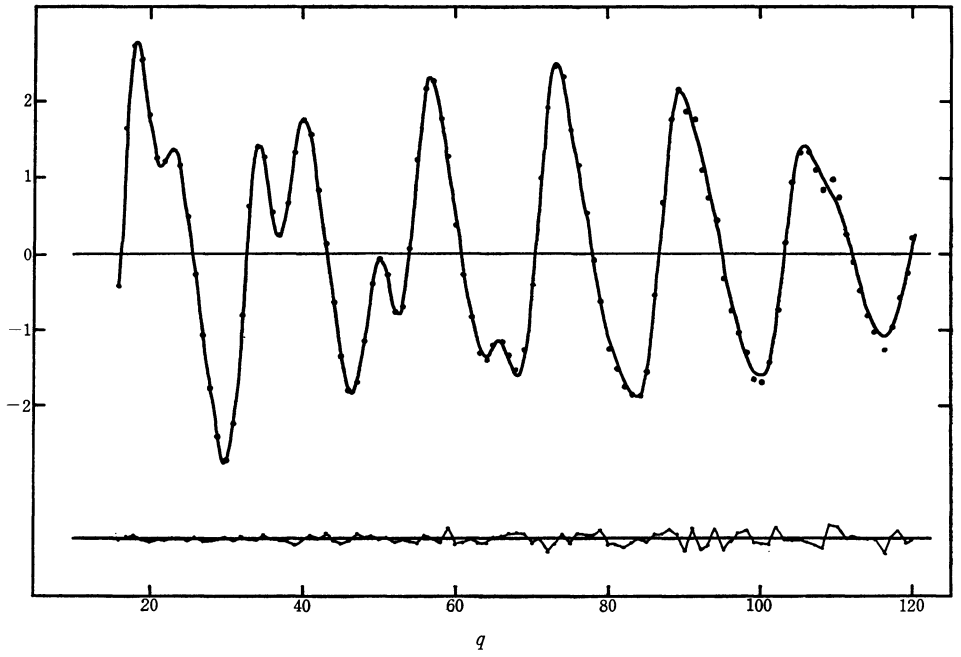

Fig. 1. Reduced molecular intensity curves (dots for observed values and the solid curve calculated from the best-fit model) and the residuals (below).

A diffraction apparatus with an r^3-sector previously reported[5] was used for the present study. The camera distances were measured as 243.22±0.02 and 107.78± 0.02 mm. The accelerating voltage (about 40 kV) was stabilized within 0.1%. The wavelength of the electron beam was calibrated to 0.15% with reference to the r_a(C=O) bond distance (1.164$_6$ Å) of carbon dioxide measured under the same experimental conditions. The gas, stored in a 2-*l* flask with a pressure of about 50 mmHg at 293°K, was led into the apparatus through a nozzle 0.2 mm in diameter. The pressure in the apparatus was less than 1×10^{-4} mmHg during photographic exposure. The beam current was about 0.16 μA. Diffraction photographs were recorded on Fuji Process Hard plates.

Four photographs from each camera distance were traced with a microphotometer, and the optical densities were measured by an integrating digital voltmeter, TR-65A15.[6] Photographs were taken so as to keep the optical densities in the region proportional to the electron intensities.

Analysis

The electron intensity was analyzed by a standard least-squares method[7] after correction for small extraneous scattering. The calculations were made by using the HITAC 5020E at the Computation Center of the University of Tokyo. The experimental reduced molecular intensity, $qM(q)$, for q values of 16 to 120 was fitted to the theoretical expression by an estimated weight function:

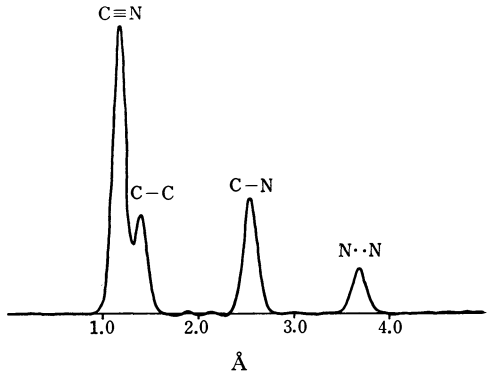

Fig. 2. Radial distribution curve for cyanogen.

$$qM(q) = k\sum c_{ij}\exp\left[-\frac{1}{2}l_{ij}^2\left(\frac{\pi}{10}\right)^2q^2\right] \times \sin\frac{\pi}{10}q\left[r_{aij}-\kappa_{ij}\left(\frac{\pi}{10}\right)^2q^2\right]\Big/r_{aij} \quad (1)$$

The asymmetry parameters, κ, were fixed at their estimated values,[8] κ(C≡N)$=5.5\times10^{-7}$ Å^3 and κ(C–C)$=12.0\times10^{-7}$ Å^3. The κ parameters for nonbonded atom pairs were assumed to be zero. Figure 1 shows some typical reduced molecular intensities (experimental and best-fit) and the difference between the observed and the calculated values from the best-fit parameters. The r_a distances and the mean amplitudes obtained from the above analysis are listed in Table 1, along with their limits of error, which were estimated from

Table 1. Internuclear distances, mean amplitudes and shrinkages of cyanogen (in Å units)

	r_a	l_{obs}	l_{calc}
C≡N	$1.162_3 \pm 0.001_9$	$0.035_3 \pm 0.000_8$	0.0347
C-C	$1.391_3 \pm 0.002_2$	$0.041_6 \pm 0.002_6$	0.0428
C·N	$2.542_3 \pm 0.003_5$	$0.050_8 \pm 0.001_3$	0.0470
N··N	$3.695_9 \pm 0.005_8$	$0.056_3 \pm 0.004_0$	0.0515

	r_g	δ_{obs}	δ_{calc}
C≡N	1.163_4	—	—
C-C	1.392_5	—	—
C·N	2.543_3	$0.012_6 \pm 0.004_5$	0.011
N··N	3.696_7	$0.022_6 \pm 0.006_8$	0.024

the internal consistency and the reproducibility of the results from four sets of electron intensities. The last column of Table 1 gives the values of the mean amplitudes calculated by the use of quadratic force constants. The F_{11}, F_{12}, and F_{22} force constants were calculated from the ν_1 and ν_2 for $^{12}C_2{}^{14}N_2$ and from the ν_1 for $^{12}C_2{}^{15}N_2$, which was estimated from the $\nu_1+\nu_5$ for this isotopic species by the use of the ν_5 and x_{55} for the normal species;[4] they were found to be $F_{11}=16.78$, $F_{12}=0.42$, and $F_{22}=6.71$ md/Å. The other force constants were determined uniquely from the vibrational frequencies, since the secular equations are all one-dimensional: $F_{33}=17.73$, $F_{44}=0.18$, and $F_{55}=0.17$ md/Å. The observed shrinkage effects, δ_g, agree with the calculated values reported by Cyvin and Meisingseth,[9] and are shown in Table 1.

Average Distances

With the force constants obtained above, the zero-point average distance, $r_\alpha{}^0$, was derived from r_α in three steps:[5] (i) The thermal average of the instantaneous internuclear distance was calculated by:

$$r_g = r_a + l^2/r_a \qquad (2)$$

(ii) The r_g distance was converted to the absolute-zero temperature:

$$r_g(0°K) = \lim(T \to 0°K) r_g \qquad (3)$$

(iii) The average distance, $r_\alpha{}^0$, was obtained by the subtraction of the centrifugal correction and the perpendicular contribution:

$$r_\alpha{}^0 = r_g(0°K) - (\langle \Delta x^2 \rangle_0 + \langle \Delta y^2 \rangle_0)/2r_e - \delta r \qquad (4)$$

In the second step the parameters characterizing the anharmonicity of the bond-stretching vibrations were assumed to be equal to those of the corresponding diatomic molecules. The anharmonic term, $\langle \Delta z \rangle$, which is latent in the expression of r_g, was estimated for bonded atom pairs in a way described elsewhere.[5] Those for nonbonded atom pairs were calculated by the summation of the linear terms for the constituent bonded pairs. The mean-square perpendicular and parallel amplitudes of vibration, $\langle \Delta x^2 \rangle$, $\langle \Delta y^2 \rangle$ and $\langle \Delta z^2 \rangle$ were calculated by the general formulas given by Morino and Hirota.[10]

The $r_\alpha{}^0$ distances determined in this way, listed in Table 2, are essentially equivalent to the spectroscopic distances, r_z, between the average positions of the atoms in the ground vibrational state.

Table 2. Zero-point average distances from electron diffraction (in Å units)

	$r_\alpha{}^0$		$r_\alpha{}^0$
C≡N	$1.156_6 \pm 0.002_0$	C·N	$2.544_3 \pm 0.003_5$
C-C	$1.388_8 \pm 0.002_2$	N··N	$3.707_0 \pm 0.005_8$

Table 3. Average moments of inertia for $^{12}C_2{}^{14}N_2$ and $^{12}C_2{}^{15}N_2$ (in amu Å^2 units)

	$^{12}C_2{}^{14}N_2$	$^{12}C_2{}^{15}N_2$	
$I_\alpha{}^0$(ED)	107.53 ± 0.35	114.36 ± 0.38	
I_z(IR)	107.27 ± 0.03	114.09 ± 0.03	set A[a]
	107.31 ± 0.03	114.12 ± 0.03	set B[a]

a) See Ref. 4.

The average distances are shown to be additive:

$$r_\alpha{}^0(C\cdot\cdot N) - r_\alpha{}^0(C\text{-}C) - r_\alpha{}^0(C\equiv N) = -0.001_1 \pm 0.004_6 \text{ Å}$$

and:

$$r_\alpha{}^0(N\cdot\cdot N) - 2r_\alpha{}^0(C\equiv N) - r_\alpha{}^0(C\text{-}C) = 0.005_0 \pm 0.006_8 \text{ Å}$$

The linearity of the molecule has thus been confirmed by the present study of gas electron diffraction. The moments of inertia, $I_\alpha{}^0$, of $^{12}C_2{}^{14}N_2$ and $^{12}C_2{}^{15}N_2$ corresponding to the $r_\alpha{}^0$ distances are listed in Table 3.

Average Moment of Inertia as Detemined by Infrared Spectrocopy

The moment of inertia, I_z, for the average configuration was calculated from the effective rotational constant for the ground vibrational state, B_0, by[11]:

9) S. J. Cyvin and E. Meisingseth, *Acta Chem. Scand.*, **15**, 1289 (1961).

10) Y. Morino and E. Hirota, *J. Chem. Phys.*, **23**, 737 (1955).

11) V. W. Laurie and D. R. Herschbach, *ibid.*, **37**, 1687 (1962).

$$I_z = \frac{h}{8\pi^2 B_0} - \frac{h}{8\pi^2} \times \left[\frac{1}{\omega_1} + \frac{1}{\omega_2} + \frac{1}{\omega_3} + \frac{1}{\omega_4} + \frac{1}{\omega_5} - \frac{4}{\omega_3+\omega_5} - 4(\zeta_{14})^2\left(\frac{1}{\omega_2} + \frac{1}{\omega_1+\omega_4}\right) - 4(\zeta_{24})^2\left(\frac{1}{\omega_1} + \frac{1}{\omega_2+\omega_4}\right)\right] \quad (5)$$

The correction term was calculated to be -0.012 amu Å^2. The average moments of inertia are listed in Table 3.

Average Structure of Cyanogen

The average moments of inertia obtained from electron diffraction and from infrared spectroscopy agree well with each other, differing only about 0.24%. The difference is within the limit of error of the electron-diffraction experiment. Infrared spectroscopy gives moments of inertia more accurate than those of electron diffraction. On the other hand, uncertainties in the spectroscopic bond distances are still a few hundredths of an angstrom, as assigned by Maki.[4] The principal reasons for this are that the distances derived from the isotopic moments of inertia are sensitive to small errors in the moments (as is illustrated in Fig. 3) and that the dependence of the average bond distances on isotopic substitution is uncertain. On the other hand, the essential part of the above-mentioned discrepancy in the moments of inertia can be ascribed to the systematic error of 0.12% in the measurement of the electron wavelength. Such being the circumstances, the scale factor was calibrated by the spectroscopic moments of inertia (Maki's set A); the corrected average bond distances turned out to be:

$$r_z(\text{C}\equiv\text{N}) = 1.155_2 \pm 0.001_3 \text{ Å}$$

and:

$$r_z(\text{C-C}) = 1.387_1 \pm 0.001_4 \text{ Å}$$

The use of his alternative set, B, which was regarded by Maki as less plausible, led to an increase of 0.0002 Å in both distances. The r_z structure obtained above is, accidentally, close to the effective r_0 structure reported by Maki.

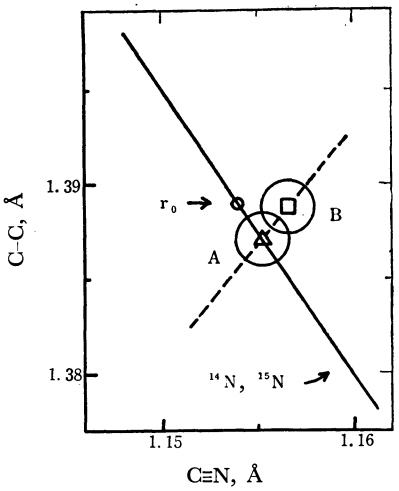

Fig. 3. Plot of the C-C distance *versus* the C-N distance in cyanogen. The solid line represents the relationship between the distances r(C-C) and r(C≡N). Two lines for $^{12}C_2{}^{14}N_2$ and $^{12}C_2{}^{15}N_2$ are virtually indistinguishable in the region shown in the figure. The broken line is a locus of the most probable distances as the electron-diffraction scale factor is varied. The square corresponds to the $r_\alpha{}^0$ distances observed by electron diffraction, while the triangle represents the average distances r_z. The circles indicate the limits of random error in electron-diffraction experiment. The limits of uncertainties of the r_z parameters are set by the crossings of the solid lines and the circle A. The limits of error of the r_0 distances reported by Maki (± 0.030 Å for C-C and ± 0.017 Å for C-N) are outside the illustrated region.

The CC bond length determined above is about 0.01 Å longer than the value expected from the empirical rule proposed by Stoicheff,[12] r(C-C≡) $= 1.299 + 0.040 \times 2 = 1.379$ Å. This slight discrepancy can be explained, at least qualitatively, in terms of the difference in bond order. The details will be published in a forthcoming paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2353—2356 (1968)

Infrared Spectra and Conformations of Succinonitrile in Silver and Copper Complexes

Masako SUZUKI and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 22, 1968)

Succinonitrile silver nitrate $[Ag(NCCH_2CH_2CN)]NO_3$ and succinonitrile disilver nitrate $[Ag(NCCH_2CH_2CN)Ag](NO_3)_2$ were prepared and the infrared spectra down to 60 cm^{-1} were measured. It was shown that the ligand molecule takes only the trans form in these complexes. The far infrared spectra were also measured for the free succinonitrile ligand at room and liquid nitrogen temperatures and for the copper complex. The assignments of bands for the nitrate ion and the trans and the gauche forms of succinonitrile were given.

Vibrational spectra of succinonitrile show that this molecule takes both the trans and gauche forms in the solid state at room temperature and only the latter form remains at low temperature.[1,2] As for the crystal of bis(succinonitrile)copper(I) nitrate, $[Cu(NCCH_2CH_2CN)_2]NO_3$, infrared spectra,[3] and X-ray analysis[4] show that the ligand succinonitrle takes the gauche form.

We have succeeded in preparing two kinds of silver complexes, succinonitrile silver nitrate $[Ag(NCCH_2CH_2CN)]NO_3$ and succinonitrile disilver nitrate $[Ag(NCCH_2CH_2CN)Ag](NO_3)_2$. We have measured the infrared spectra of these complexes down to 60 cm^{-1} and found that the ligand succinonitrile molecule takes only the trans form in these complexes. This fact has been confirmed for the disilver nitrate by the X-ray analysis as reported by Nomura and Saito.[5] In the present paper the results of the infrared spectra of silver nitrate and disilver nitrate complexes are reported. The fact that we have only the trans form in the silver complexes and only the gauche form in the copper complex enables us to obtain the spectra of the two conformations separately. Accordingly, the spectra of the copper complex and the free succinonitrile ligand have also been measured down to 60 cm^{-1} and the assignments of bands have been reinvestigated.

Experimental

Silver complexes were prepared from succinonitrile and silver nitrate. Succinonitrile (bp 158—160°C/20 mmHg) was melted at about 60°C and silver nitrate powder was added. The excess nitrile was extracted by an alcohol-ether mixture. The complexes were recrystallized from ethanol and colorless needle-like crystals were obtained. Microscopic investigation showed that two kinds of crystals exist. One was transparent and of regular shapes and the other was opaque and of irregular shape. These two kinds of crystals were separated manually. The following elementary analysis showed that the former kind is succinonitrile disilver nitrate and the latter is succinonitrile silver nitrate.

Found: C, 11.80; H, 0.84; N, 13.32%. Calcd for $[Ag(NCCH_2CH_2CN)Ag](NO_3)_2$: C, 11.44; H, 0.96; N, 13.34%.

Found: C, 19.57; H, 1.77; N, 16.91%. Calcd for $[Ag(NCCH_2CH_2CN)]NO_3$: C, 19.22; H, 1.61; N, 16.80%.

The copper complex was prepared according to the method given by Morgan.[6]

The infrared spectra were recorded by the following grating spectrometers: Hitachi EPI-2 and Perkin-Elmer 112G (4000—650 cm^{-1}), Japan Spectroscopic Co. 401G (700—300 cm^{-1}) and Hitachi FIS-1 (500—60 cm^{-1}). Nujol mull and HCB mull were used except in the far infrared region, where the samples mixed with paraffin were used. The copper complex in a KBr disk or in contact with alkali halide windows was reported to decompose gradually.[3] For the present complexes the same phenomena were observed. In order to avoid the decomposition, thin polyethylene films were inserted between the alkali halide windows and the sample. Sometimes the sample was purposely put in contact with the KBr window, since the changes in spectra were useful for discriminating the nitrate ion bands from those belonging to the ligand molecule. Succinonitrile was melted and solidified between the KBr plates in the 4000—500 cm^{-1} region or between the silicon plates in the 500—60 cm^{-1} region and was used for the measurement at room temperature and at liquid nitrogen temperature. The spectra are shown in Fig. 1.

Result and Discussion

The complexes dealt with in the present study contain nitrate ions and the absorption bands

due to this ion are discussed first. Figure 2 shows the modes of normal vibrations, their selection rule in infrared and Raman spectra and the frequencies which these vibrational modes are expected to have. The spectra given in Fig. 1 were compared with those of some inorganic nitrate salts and the bands asterisked in Fig. 1 are assigned to the nitrate ion vibrations. The totally symmetric vibration, ν_1, is infrared inactive. However, a weak band appears near 1035 cm^{-1} for the three complexes and is assigned to this mode which becomes infrared active owing to the crystalline field effect. The out-of-plane vibration, ν_2, is infrared active and appears near 820 cm^{-1} as a sharp band. The degenerate N-O stretching vibration, ν_3, appears very strongly in the region 1250—1450 cm^{-1}.

* Ag(i), and Ag(ii) and Cu denote succinonitrile silver nitrate, disilver nitrate, and copper nitrate, respectively.

For the copper complex only one peak appears at 1352 cm^{-1}. For the silver complexes three bands appear in this region as shown in Fig. 1. When the sample was fresh, the central peak at 1351 cm^{-1} for silver nitrate and at 1335 cm^{-1} for disilver nitrate appeared strongly. The intensities of the two bands near 1410 cm^{-1} and 1280 cm^{-1} relative to that of the central peak increased when the sample was in contact with alkali halide plates. We did not investigate the spectral changes in

detail, since they were not related with the problem dealt with in the present study. The degenerate ONO deformation vibration, ν_4, appears as a doublet near 725 and 704 cm^{-1}, the splitting being caused by the crystalline field effect. In addition to the fundamental bands discussed above two peaks appear at 1764 and 1739 cm^{-1} for silver nitrate. These peaks are assigned to the combination bands, 1037+725 and 1037+704 in cm^{-1}. For the disilver nitrate and copper complexes the doublets near 1750 cm^{-1} are interpreted similarly. The results are summarized in Table 1.

As for the free ligand, the spectra of succinonitrile are interpreted as the overlap of the trans and gauche bands.[1,2] In the present measurement the spectrum was extended down to 60 cm^{-1} and three very broad bands were found at 186, 138 and 102 cm^{-1} and a sharp band at 237 cm^{-1} at room temperature. In this region the CCN deformation vibration (b_u) and the CC torsion (a_u) of the trans form and the CCN deformation vibration (a) and the CC torsion (a) of the gauche form are expected to appear. In order to make the situation clear, the spectrum at liquid nitrogen temperature was measured and is shown as a dotted line in Fig. 1. The spectrum above 300 cm^{-1} shows that only the gauche form exists at liquid nitrogen temperature and, accordingly, the four bands at 237, 186, 138 and 102 cm^{-1} should be assigned to the gauche form. The frequencies of the 237 and 186 cm^{-1} bands are compared with the calculated[2] and are assigned to the two CCN deformation bands. The remaining two bands at 138 and 102 cm^{-1} are tentatively assigned to CC torsion and an intermolecular vibration, since for the nitrile group a considerably strong intermolecular interaction is expected. The results are summarized in Table 2 and Fig. 1, where the trans and gauche forms are denoted by T and G, respectively.

The spectrum of the copper complex shown in Fig. 1 supports the conclusion obtained by Matsubara[3] and Kinoshita, Matsubara and Saito[4] that only the gauche form exists. As shown in Table 2 almost all the bands are assigned to those of the gauche form. There are some very weak bands, such as those at 837 and 748 cm^{-1}, which are not given in the table. They are assigned to the combination bands. In the region lower than 400 cm^{-1} metal-ligand vibrations are also expected. They may be coupled with the low frequency vibrations of the ligand gauche molecule. In fact, six bands appear below 300 cm^{-1} instead of the four bands of the free ligand gauche form. They are tentatively assigned as shown in Table 2, although they may be strongly coupled with each other.

The spectra of silver nitrate and disilver nitrate are of interest, when they are compared with those of the free ligand and copper complex. It is surprising that all the bands assigned to the gauche form disappear and only those assigned to the trans form remain. From these spectra we can conclude undoubtfully that the ligand molecule takes the trans form in the silver nitrate and disilver nitrate complexes. This conclusion was confirmed by the X-ray analysis by Nomura and Saito.[5] The detail of the assignments are given in Table II. The gauche bands at 962, 604, 480, 358, 237, 186 and 138 cm^{-1} disappear. Silver nitrate has two bands at 929 and 530 cm^{-1} and disilver nitrate has two bands at 933 and 512 cm^{-1}. They definitely correspond to the 917 and 529 cm^{-1} bands of the trans form of free ligand. As for the region below 300 cm^{-1}, silver nitrate has two bands at 171 and 105 cm^{-1} and disilver nitrate has three bands at 170, 130 and 72 cm^{-1}. In this region, CCN deformation (b_u), CC torsion (a_u), and metal ligand vibrations are expected to appear. The band at 170 cm^{-1} is very broad and is interpreted to be the overlapped band. Tentative assignments are given in Table 2, although three vibrations are strongly coupled with each other.

Certain Interactions between Transition Metal Ions and the NCS Group in Chromium(III) Isothiocyanato Complexes. I. Reinecke's Salt Type Complexes Involving Cobalt(II) and Copper(II) Ions*1

Hisaya OKI, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 21, 1967)

Cobalt(II) tetraisothiocyanatochromate(III), $Co[Cr(NCS)_4(NH_3)_2]_2$, was prepared from cobalt(II) chloride and Reinecke's salt in an aqueous solution. The absorption spectrum gave evidence that the so-called "cobalt-salt" dissociated into cobalt(II) cation and Reineck's anion in aqueous solution. The reflection spectrum showed a remarkably strong absorption band at $14.08 \times 10^{13}\,sec^{-1}$, which might be assigned to bonding between cobalt(II) and sulfur in an NCS^- ligand. The three absorption peaks observed at 2158, 2095 and 2065 cm^{-1} in the IR spectrum due to C-N stretching vibrations also emphasized the strong interaction between cobalt and sulfur. The effective magnetic moment estimated was 4.58 B. M. at 18.3°C. The corresponding copper(II) salt, $Cu(OH)[Cr(NCS)_4(NH_3)_2]$, was obtained from an aqueous solution of copper(II) sulfate and Reinecke's salt as a yellow powder. It was a sparingly soluble in water. In the reflection spectrum, the red-shifted band covered much of the first band region of Reinecke's salt and in the IR spectrum, the C-N band had only a small splitting. The magnetic moment was found to be 3.84 B. M. at 16.0°C, which is close to the predicted value in the complex when copper is reduced, becoming univalent. X-Ray diffraction analysis also showed a relatively stronger contraction of the unit cell in the copper salt than in the cobalt salt. On the basis of the above points, it was proposed that in the copper salt there is considerable π-bonding between copper and the two adjacent isothiocyanate groups.

It has already been reported[1] that the so-called "cobalt(II) salt" prepared from cobalt(II) chloride and Reinecke's salt exhibited a gradual color change from reddish-purple to grayish-green when it was exposed to dry air, and the color changed back to the original purple upon absorption of water, while the corresponding "copper(II) salt" gave a yellow color quite different from Reinecke's salt, when it was prepared from copper-(II) sulfate and Reinecke's salt. However, no further attempts to obtain information on the structures of these salts has been made.[1]

The green color in the cobalt(II) salt in the dry, solid state and the yellow color in the copper(II) salt suggest the presence of a certain interaction between cobalt or copper ion and Reinecke's anion. Our interest lies particularly in investigating such color changes in the cobalt and copper salts in relation to a structural discussion based on the spectra, magnetic behavior and measurements of chemical properties.

Experimental

Preparation of Compounds. *Cobalt(II) Tetraisothiocyanatochromate(III)* (called "Co-salt"). To a solution of Reinecke's salt (8 g/800 m*l* of H_2O) at 60°C, a solution of cobalt(II) chloride hexahydrate (225 g/700 m*l* of H_2O) at 5°C was added. Being kept in a refrigerator over night, reddish-purple scale-like crystals precipitated out. After filtration, the crystals were washed with a small amount of ether, and when dried over sulfuric acid *in vacuo*, their color changed to grayish-green.

Found: Cr, 14.39; Co, 8.47; N, 23.64%. Calcd for $Co[Cr(NCS)_4(NH_3)_2]_2$, Cr, 14.94; Co, 8.47; N, 24.16%.

In reverse, the color changed back to the original upon washing with water.

Copper(III) Tetraisothiocyanatochromate(III). (called "Cu-salt"). To a solution of Reinecke's salt at 60°C, a solution of copper(II) sulfate pentahydrate was added in a stoichiometric ratio (1 : 1). As soon as both solutions were mixed together, a yellow powder was obtained. The color does not change in a dry or moist atmosphere. The crystal was insoluble in water, alcohol, ether, dioxane and several organic solvents.

When the solids of Reinecke's salt and copper(II) sulfate hydrate were mixed in a motar, the same salt was also obtained.

Found: Cr, 13.05; Cu, 15.84; N, 21.57; C, 12.27; H, 1.70%. Calcd for $Cu(OH)[Cr(NCS)_4(NH_3)]_2$: Cr, 13.03; Cu, 15.94; N, 21.07; C, 12.29; H, 1.75%.

Apparatus for Measurement. Molar conductivity, electronic and reflection spectra, IR and far-infrared absorption spectra, magnetic suceptibility and

X-ray diffraction were measured with a Yokogawa Universal Bridge BV-Z-13A, a Hitachi EPU-2A spectrophotometer with a standard reflection attachement, a Nippon Bunko IR Spectrometer DS-301 and a Hitachi ERI-101 Grating IR Spectrometer, a Gouy balance and a Rigaku-denki Geigerflex X-ray Analyser, respectively.

Results and Discussion

Conductivity and pH Measurements. The value of the molar conductivity of the "Co-salt" was 196.4 $cm^2ohm^{-1}(1\times10^{-2}$ mol/l) at 25°C and that of Reinecke's salt 103.1 cm^2ohm^{-1} (2×10^{-2} mol/l). This suggests that the Co-salt is a 1 : 2 valency type salt, being capable of dissociating into a cobalt cation and Reinecke's anion in aqueous solution according to the following equation,

$$Co[Cr(NCS)_4(NH_3)_2]_2 \rightarrow Co^{2+} + 2[Cr(NCS)_4(NH_3)_2]^-.$$

For the corresponding Cu-salt, the conductivity could not be measured because of its insolubility in water. Christensen[1] reported that copper was univalent in the salt, but in the present work, it was concluded that the Cu-salt involves a hydroxyl group, as indicated by the chemical formula $Cu(OH)[Cr(NCS)_4(NH_3)_2]$.

In order to ascertain the composition of the Cu-salt, the following experiments were carried out.

Solutions of different concentrations of Reinecke's salt were added to solutions containing a constant number of moles of copper(II) sulfate pentahydrate. The precipitation formed was filtered off and the absorbancy of the filtrates measured at peaks of both the first and second absorption bands in Reinecke's salt. The results are shown in Fig. 1. It suggests that the Cu-salt obtained above has a simple mole ratio 1 : 1 as confirmed by the elementary analysis.

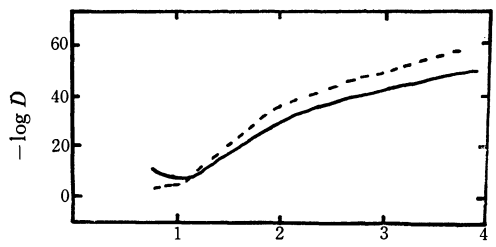

Fig. 1. The absorbancy of the filtrates after the Cu-salt formation.
----- at 520 m (the first band of Reinecke's salt)
—— at 392 m (the second band of Reinecke's salt)

The pH values of Reinecke's salt and copper(II) sulfate hydrate were found to be 4.84 and 4.50, respectively, in their aqueous solutions, whereas that of the filtrate was found to be in the range 2.70 to 2.50. In addition, it was found that the tendency to form the Cu-salt was extremely decreased in strongly acidic solutions. These results also indicate the existence of a hydroxo group in the Cu-salt.

Visible and UV Spectra. The visible and ultraviolet absorption spectra of the Co-salt measured are shown in Fig. 2, together with those of Reinecke's salt; numerical values are 57.69 ($\log\varepsilon=2.03$), 76.53 ($\log\varepsilon=2.00$) and 99.67×10^{13} sec^{-1} ($\log\varepsilon=4.12$) for the Co-salt, and 57.69 ($\log\varepsilon=2.01$), 76.53 ($\log\varepsilon=1.96$) and 99.67×10^{13} sec^{-1} ($\log\varepsilon=4.14$) for Reinecke's salt, respectively.

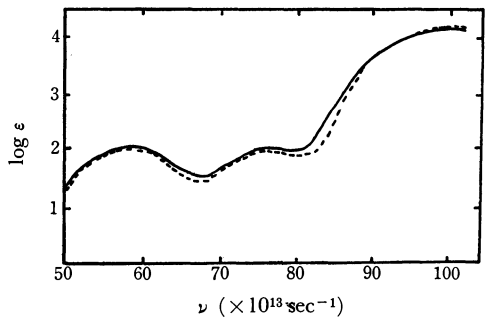

Fig. 2. The absorption spectra of the Co-salt (——) and Reinecke's salt (-----).

It is obvious in Fig. 2 that the absorption spectrum of the Co-salt is in approximate agreement with that of Reinecke's salt within the range of wavelength measured. This may support the assumption concerning the dissociation of the Co-salt as a 1 : 2 valency type, since the contribution of the spectrum of cobalt(II) cation in aqueous solution to that of the Co-salt is very small in the corresponding wavelength region.

Reflection Spectra. Reflection spectra of the Co- and Cu-salts were measured for powdered crystals, the latter being especially meaningful due to its lesser solubility in water. The results are shown in Figs. 3 and 4 for the Co- and Cu-salts, respectively, in which the logarithm of $f(R_d)$ coordinate is equal to $(1-R_d)^2/2R_d$ in the Kubelka-Munk equation, where R_d is the relative diffuse-reflection index.

The reflection spectrum of the grayish-green Co-salt showed two bands: the one appearing at 42.55×10^{13} sec^{-1} ($\log f(R_d)=0.67$) may probably be assigned to charge transfer from sulfur to cobalt, which could not be found in Reinecke's salt, and the other, at 60.00×10^{13} sec^{-1} ($\log f(R_d)=0.068$), may correspond to the first absorption band of Reinecke's salt. On the other hand, the band corresponding to the second band of Reinecke's salt could not be observed in the Co-salt.

In the Cu-salt, the first absorption band corresponding to that of Reinecke's salt is only observed as a shoulder, but the second band could not be observed due to the great shift of the charge transfer

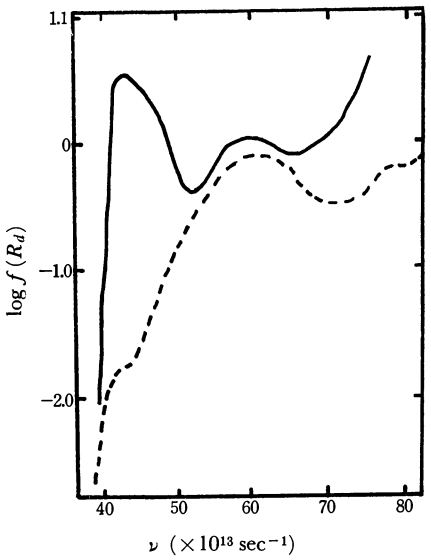

Fig. 3. The reflection spectra of the Co-salt (——) and Reineck's salt (-----).

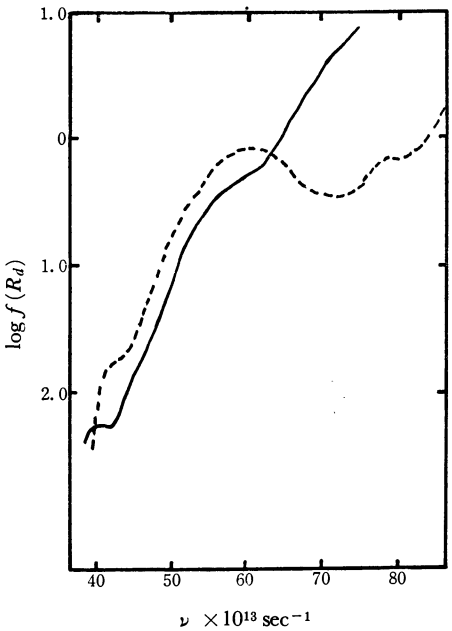

Fig. 4. The reflection spectra of the Cu-salt (——) and Reineck's salt (-----).

band to the visible region. Such a great shift suggests a strong interaction between the copper ion and Reinecke's anion.

IR Spectra. The bond between metal ions and isothiocyanate groups has been known and is classified according to the following three types:

1) a bond through the nitrogen atom in NCS, like M–NCS

2) a bond through the sulfur atom in NCS, like M–SCN

3) a bond through an NCS group bridge with an another metal, like M–NCS–M',
where M and M' are two different metals.

Jones[2] has reported on the three normal vibrational modes of thiocyanate ion in KNCS. Mitchell and Williams[3] proposed that the stretching frequencies of C–N bonding in isothiocyanato type complexes increase in the order $NCS^- < M-NCS \leqslant M-SCN < M-NCS-M'$, and that, especially, the frequencies in the bridged M–NCS–M' become higher as the electronegativity of M' becomes smaller.

Lewis, Nyholm and Smith,[4] on the other hand, noted that the C–S stretching frequency peak of 2) appears in a region lower than that of 1). It may be expected from such information that the peak due to C–S stretching in 3) will appear between the peaks in the above two cases.

The IR spectra of the Co- and Cu-salts with respect to C–N and C–S stretching vibrations are shown in Figs. 5 and 6, respectively, together with that of Reinecke's salt. Numerical data are summarized in Table 1, where data on a few Reinecke type salts by Fujita *et al.*[5] are cited for comparison with values obtained in the present work.

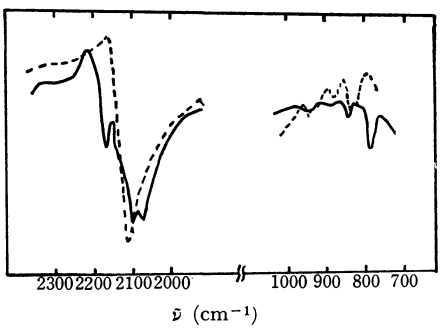

Fig. 5. IR spectra of the Co-salt (——) and Reineck's salt (-----).

The presence of peaks at 2158 cm^{-1} and 795 cm^{-1}, assigned to the C–N and C–S stretching vibrations, respectively, in the Co-salt, as shown in Table 1, suggest a relatively strong bond between cobalt(II) ion and the sulfur atom in the NCS^- group, forming a bridged structure such as Cr–NCS–Co, analogous to a Reinecke type Hg-salt, owing to the complete similarity of the IR spectra of these two salts.

On the other hand, in the Cu-salt, the peak assigned to the C–N stretching vibration did not

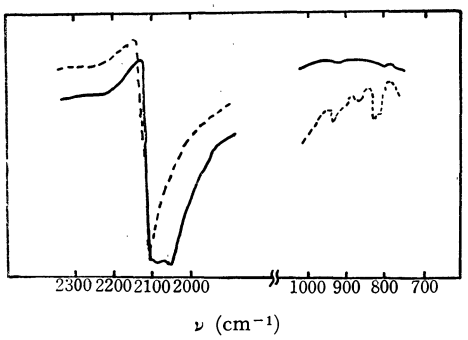

Fig. 6. IR spectra of the Cu-salt (——) and Reinecke's salt (----).

shift from the corresponding one in Reinecke's salt. Therefore, the bridged structure concluded for the Co-salt, M–NCS–M′, must be excluded for the Cu-salt.

However, since the band in the C–N stretching region is found to split into three peaks and the C–S band shifts to a lower wave number region than that of Reinecke's salt, but not so low as that of the Co-salt, another kind of the interaction should be considered between the copper(II) ion and Reinecke's anion.

Thus, a structure in which the copper is weakly coordinated to Reinecke's anion through two sulfur atoms in both adjacent NCS^- groups square planar around the copper atom can be assumed. But such a structure may also be unacceptable, since X-ray analysis data[6] give about 7 Å for the S–S distance between the two sulfur atoms in the adjacent NCS^- groups.

Taking into account also the reflection spectra of the Cu-salt, a structure may be conclusively proposed in which the copper(II) ion is not bound to sulfur atoms, but to the NCS^- groups as a whole, concluding considerable π-bonding character due to the transfer of the π-electron spread over the NCS^- group to the copper ion. Although such a structure, allowing π-bonding with respect to the NCS^- groups, is unknown to date, it may be most reasonable, and is also supported by the far-infrared absorption spectra described below.

Far-IR Absorption Spectra. The far-infrared absorption spectrum of the Co-salt is shown in Fig. 7, togehter with that of Reinecke's salt. The absorption band at 500 cm^{-1} in Reinecke's salt may be assigned to the Cr–N stretching vibrations on the ammonia, since it did not shift even when ammonium ion was replaced by cobalt ion, and it is coincident with the corresponding band in the ammine complexes.

The band at 467 cm^{-1} in Reinecke's salt may be assigned to the NCS bending vibration since it is in good agreement with the corresponding band which has been reported by Sabatini *et al.*[7] concerning metal cyanato, thiocyanato and selenocyanato complexes. In the Co-salt, the corresponding band splits into three peaks, which may be due to the NCS bending vibration free from the counter cation and due to some interactions with the counter cation through the bridged Cr–NCS–Co bond.

The band at 347 cm^{-1} is probably due to the Cr–N stretching vibration in thiocyanate as suggested in the literature.[4,7] The bands observed in the wave number region, 270—245 cm^{-1}, may be assigned to Co–S stretching, but there is no further verification for it.

The far-infrared absorption spectra of the Cu-salt and of Reinecke's salt are shown in Fig. 8. The band near 490 cm^{-1} is assigned to Cr–N stretching involving NH_3. It has a weak shoulder at 505 cm^{-1}, which was not detected in any other

TABLE 2. THE ANALYSES OF THE X-RAY DIFFRACTION AND DENSITY OF THE REINECKE'S TYPE SALTS

	c/a	a (Å)	c (Å)	Density, ρ		Z	Ref.
				Calcd	Found		
Reinecke's salt	1	13.25		1.50		6	6
Co-salt	1.1	10.30	11.34	1.96	1.87	8	
Cu-salt	0.89	9.03	8.07	2.01	1.96	2	

salts treated in the present work. However, it is not clear whether the shoulder is due to the distorted structure of Reinecke's anion in the crystal or not.

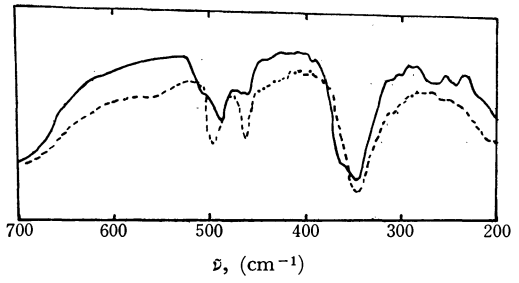

Fig. 8. The far infrared spectra of the Cu-salt (——) and Reinecke's salt (----).

The band assigned to the NCS bending vibration splits into two bands, but does not show the presence of a direct bond between the copper ion and a sulfur atom.

If the copper was bound to an NCS group through a sulfur atom, the absorption band assigned to the Cr–N stretching vibrations involving the NCS group should shift to a lower wave number range as is the case with the Co-salt. However, the corresponding bands were all shifted to a higher wave number region. From the various information described above, it may be reasonable to introduce the concept that the π-electron bond between an isothiocyanate group and copper ion plays an important role in the interaction between copper and Reinecke's anion in the Cu-salt.

Magnetic Susceptibility. From the magnetic susceptibility measurements, a value of 4.50 B. M. was obtained for the Co-salt as the effective magnetic moment. If the divalent cobalt ion is in a high spin state, the number of unpaired electrons contained may be amount to 4.5 (therein 3 for Cr and 1.5 for Co) per molecule of the salt; and then, the spin-only value should be 5.41 B. M. The value obtained in the present work seems to be remarkably small compared with that in the high spin state of cobalt. This supports in addition to the results from absorption and IR spectra, some kind of "superexchange interaction" between Co and Cr ions through an NCS^- group.

The magnetic moment of the Cu-salt is expected to be 4.9 B. M. by evaluating the total number of spins contained. But the value obtained is 3.84 B. M. at 16°C, which is smaller. It may also alow that the copper is bound to Reinecke's anion through the π-electron in the NCS^- groups as explained above on the basis of the IR spectra.

X-Ray Diffraction Measurement. The results of analysis of the X-ray diffraction patterns for the Co- and Cu-salts are summarized in Table 2, together with those for Reinecke's salt already published by Y. Saito *et al.*[6] The structures of these salts are indicated to be tetragonal, except for Reinecke's salt which has a cubic structure. The density of the Co-salt was measured in Nujol, whereas that of the Cu-salt, in water. The result that the Cu-salt has the largest density of these three salts suggest that there is the strongest contraction of the unit cell in the Cu-salt.

The authors wish to express their gratitude for a grant from the Ministry of Education for this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2362—2366 (1968)

Certain Interactions between Transition Metal Ions and the NCS Group in Chromium(III) Isothiocyanato Complexes. II. Reinecke's Salt Type Complexes Involving Nickel(II), Manganese(II) and Iron(III) Ions*[1]

Hisaya Oki, Eishin Kyuno and Ryokichi Tsuchiya

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 18, 1967)

Nickel(II), manganese(II) and black iron(III)-tetraisothiocyanatochromate(III) were prepared by the reaction of nickel(II) nitrate, manganese(II) sulfate and iron(III) chloride with Reinecke's salt, respectively. Each salt exhibits a gradual color change from reddish-purple to brownish-orange, red and black, respectively, when exposed to dry air after preparation, except for the orange iron(III) salt prepared in hydrochloric acid solution, which shows no color change from the original orange. Their absorption spectra give evidence that each salt will dissociate into a metal cation and Reinecke's anion in aqueous solution. Splittings due to the C–N stretching vibration were not observed in the IR spectra. The effective magnetic moments were evaluated as 3.96, 5.13, 5.0 and 4.81 B. M. for the nickel(II)-, the manganese(II)-, the black iron(III)- and the orange iron(III)-salts, respectively. They show that the salts are nearly low spin types, or a type somewhere between low and high spin. From X-ray diffraction analyses, the unit cell of all the salts were found to be tetragonal.

In a preceding paper,[1] cobalt(II) and copper(II) isothiocyanatochromate(III) were prepared and it was concluded that the gradual color change from reddish-purple to grayish-green for the cobalt(II) salt was due to the appearance of an interaction between cobalt ion and the sulfur atom of an NCS group in Reinecke's anion, and that the formation of the insoluble, yellow copper(II) salt showed the presence of the assumed π-bonding between copper ion and an NCS group.

In the present work, the preparation of the nickel(II), manganese(II) and iron(III) salts of Reinecke's salt type has been carried out, and the structures of these compounds discussed with respect to the interaction between the transition metal cations and NCS groups in Reinecke's anion on the basis of electronic and IR spectra, magnetic susceptibility measurements and other chemical techniques.

Experimental

Nickel(II) Salt of Reinecke's Salt Type (called "Ni-salt"). To a solution of Reinecke's salt (1.5 g/100 m*l* of H_2O) at 60°C, crystals of nickel(II) nitrate (4 g) were added. After being kept in a refrigerator over night, reddish-purple scale-like crystal precipitated from the solution. After recrystallizing the precipitate obtained, it was washed with water. When the crystals were dried *in vacuo* over sulfuric acid at room temperature, their color changed to brownish-orange. If they were then heated at 68°C, the color changed further to greensih-brown, but the brownish-orange color was immediately reproduced when exposed to air.

Found: Cr, 14.07; Ni, 7.55; N, 22.96; H_2O, 2.4%. Calcd for $Ni[Cr(NCS)_4(NH_3)_2]_2 \cdot H_2O$: Cr, 14.32; Ni, 8.06; N, 23.56; H_2O: 2.52%.

Manganese(II) Salt of Reinecke's Salt Type (called "Mn-salt"). To a solution of Reinecke's salt (1.5 g/100 m*l* of H_2O) at 60°C, crystals of manganese(II) sulfate tetrahydrate (6 g) were added. When the solution was kept in a refrigerator over night, reddish-purple, scale-like crystals precipitated out. Separated by filtration, the crystals were washed with water. With drying *in vacuo* over sulfuric acid, their color changed to red, and the original color was reproduced when exposed to moist air.

Found: Cr, 13.84; Mn, 8.09; N, 22.91; H_2O, 5.0%. Calcd for $Mn[Cr(NCS)_4(NH_3)_2]_2 \cdot 2H_2O$: Cr, 14.29; Mn, 7.55; N, 23.10; H_2O, 4.95%.

Iron(III) Salts of Reinecke's Salt Type. *a) Black Iron(III) Salts of Reinecke's Salt Type* (called "black Fe-salt"). To a solution of Reinecke's salt (1.5 g/100 m*l* of H_2O) at 60°C, a solution of iron(III) chloride hexahydrate (8 g/10 m*l* of H_2O) was added. When the solution was kept in a refrigerator over night, reddish-purple, scale-like crystals pricipitated out, which were then separated by filtration. After being washed with a small amount of water, and dried *in vacuo* over sulfuric acid, the color of the crystals changed from reddish-purple to black. As recrystallization was repeated in water, the color of the crystal was gradually changed from black to purple or somewhat reddish-purple. This

*1 Read in part at the 16th Symposium on Coordination Compounds of the Chemical Society of Japan, Tokyo, Dec., 1966.

1) H. Oki, E. Kyuno and R. Tsuchiya, This Bulletin, **41**, 2357 (1968).

is probably due to the sublimation of iron(II) trithiocyanate, produced as the result of the partial decomposition of the black Fe-salt, leaving a small amount of ferric oxide. Thus, recrystallization was unsuccessful even in an acidic solution.

Found: Cr, 11.87; Fe, 9.60; N, 23.53%. Calcd for $Fe[Cr(NCS)_4(NH_3)_2]_3 \cdot Fe(NCS)_3$: Cr, 12.57; Fe, 9.00; N, 23.70%.

b) Orange Iron(III) Salt of Reinecke's Salt Type (called "orange Fe-salt"). To a solution of iron(III) chloride hydrate (8 g/10 m*l* of 8 N HCl), a solution of Reinecke's salt (10 g in 6 N hydrochloric acid) at 60°C was added. When the solution was kept in a refrigerator over night, a reddish-orange or orange powder separated out, which was filtered and washed with a small amount of ether. The orange crystals did not show any color change, even when upon drying, differing from the black Fe-salt described above.

Found: Cr, 13.06; Fe, 6.69; N, 22.17; Cl, 9.24%. Calcd for $FeHCl_2[Cr(NCS)_4(NH_3)_2]_2$: Cr, 13.60; Fe, 7.30; N, 21.98; Cl, 9.28%.

Apparatus for Measurement. Conductivity, visible and UV absorption spectra, IR and far-IR absorption spectra, reflection spectra, magnetic susceptibility and X-ray diffractions were measured with the same apparatus described in the preceding paper.[1]

Results and Discussion

Conductivities and Behavior toward Ion Exchangers. Values of the molar conductivity of the salts per equivalent Reinecke's anion in aqueous solution at 25°C are listed in Table 1. They suggest, first, that the Ni- and Mn-salts are 1:2 valency types which can dissociate into a metal cation and two Reinecke anions in aqueous solution.

Table 1. The molar conductivity (at 25°C)

Sample	Concentration mol/*l*	Molar conductivity cm^2ohm^{-1}	Type
Reinecke's salt	2×10^{-2}	103.1	1 : 1
Ni-salt	5×10^{-2}	115.3	1 : 2
Mn-salt	2×10^{-2}	106.3	1 : 2
Black Fe-salt	4×10^{-2}	194.8	1 : 3
Orange Fe-salt	4×10^{-2}	374.8	

On the other hand, the condutivity of the black Fe-salt per equivalent Reinecke anion was found to be much greater than expected for 1 : 3 type salts in general. This can be explained reasonably by their behavior toward ion exchangers.

When an aqueous solution of the black Fe-salt was poured onto a column of anion exchange resin (Dowex 1×8), pink solution passed through, leaving some red material adsorbed on the exchanger. It is thought that the pink solution, in part, contains $Fe(NCS)_3$ and the appearance of the red color on the exchanger is due to the adsorption of Reinecke's anion. The presence of $Fe(NCS)_3$ in the pink solution was verified by detecting the chromium ion formed by the reaction of Reinecke's anion with ferric ion.

Moreover, the orange Fe-salt has the largest molar conductivity of all the complexes, as given in Table 1. This is due to the presence of hydrogen ion which is capable of dissociation in aqueous solution, as indicated by the formula proposed in the Experimental section.

When an aqueous solution of the orange Fe-salt was poured onto the column of the same exchanger as was used above, yellow solution passed through, leaving red material on the exchanger. It is thought that the yellow color of the solution indicates the presence of iron(III) ion, and the red material on the exchanger indicates the adsorption of Reinecke's anion.

Electronic Absorption Spectra. The electronic absorption spectra of the Ni(II)- and Mn(II)-salts of Reinecke's salt type were in approximate agreement with that of Reinecke's salt itself, which supports their complete dissociation to Ni(II) or Mn(II) cations and Reinecke's anion in aqueous solution. The numerals of the electronic spectra of these complexes are listed in Table 2, including those of both Fe-salts described below.

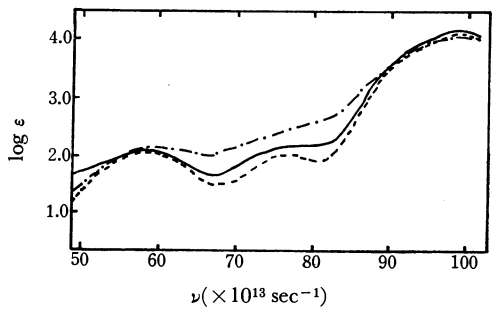

Fig. 1. The absorption spectra of the black Fe- (——), and the orange Fe-salts (— - —) and Reinecke's salt (- - -).

The electronic spectra of the black and orange Fe-salts are shown in Fig. 1, together with that of Reinecke's salt. As seen in this figure, the spectra of these compounds are also similar to that of Reinecke's salt except for the second band being changed to a shoulder. It shows that both Fe-salts dissociate into iron(III) cations and Reinecke's anions in an aqueous solution, the same as the Ni- and Mn-salts, but some amount of hydroxo-iron(III) is formed.

Reflection Spectra. Absorption spectra of the Ni-, Mn- and orange Fe-salts in the solid state were measured by the diffusion-reflection method and are shown in Fig. 2 together with that of Reinecke's salt. In the Ni- and Mn-salts, only the first band corresponding to that of Reinecke's salt is observed, the second band being undetectable probably because of the shift of the intense charge transfer band to the visible region, which can not

Table 2. The absorption spectra of the Reinecke's type salts

	The first band		The second band		The specific band	
	$\nu(10^{13}\,\mathrm{sec}^{-1})$	$(\log \varepsilon)$	$\nu(10^{13}\,\mathrm{sec}^{-1})$	$(\log \varepsilon)$	$\nu(10^{13}\,\mathrm{sec}^{-1})$	$(\log \varepsilon)$
Reinecke's salt	57.69	(2.01)	76.53	(1.96)	99.67	(4.14)
Ni-salt	57.69	(2.01)	76.53	(1.96)	99.67	(4.14)
Mn-salt	57.69	(2.03)	76.53	(1.96)	99.67	(4.14)
Black Fe-salt	57.69	(2.05)			99.01	(4.18)
Orange Fe-salt	60.00	(2.11)			99.01	(4.11)

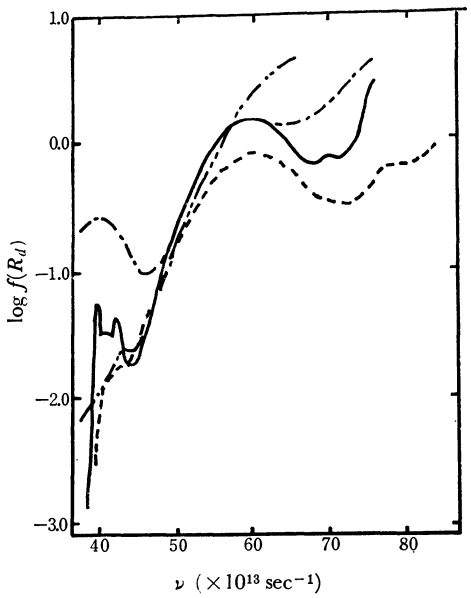

Fig. 2. The reflection spectra of the Mn-salt (——), the Ni-salt (— - —), the orange Fe-salt (— - - —) and Reinecke's salt (- - -).

be observed in the visible absorption spectra of these compounds in aqueous solution.

In the Mn-salt, an absorption peak which seems assignable to the second absorption band of manganese sulfate in aqueous solution is also faintly observed at $69.77\times10^{13}\,\mathrm{sec}^{-1}$. Besides, three absorption bands are observed in the frequency range from $38.71\times10^{13}\,\mathrm{sec}^{-1}$ to $44.44\times10^{13}\,\mathrm{sec}^{-1}$, which are thought probably due to the overlapping of the electron spin forbidden band with the first bands of manganese(II) cation and Reinecke's anion.

In the orange Fe(III)-salt, both the first and second bands corresponding to those of Reinecke's salt could not be observed, and only an electron spin forbidden band was found.

In the reflection spectrum of the black Fe(III) salt, no positive peak was detected because of the black color due to an intense absorbance over all wavelengths measured.

IR Spectra. The infrared absorption spectra of the Ni- and Mn-salts, which are very similar, are shown in Fig. 3, together with those of the Co-salt[1] and Reinecke's salt. Since the absorption peaks assigned to the C-N stretching vibration of the Ni- and the Mn-salts does not shift so greatly, and the peaks due to C-S stretching are also observed in a higher wave number region than that of the Co-salt,[1] but lower than that of Reinecke's salt, the bond between the sulfur atom in an NCS group and nickel(II) or manganese(II) ion is not so strong as the corresponding bond in the Co-salt.

The IR spectra of the black and orange iron(III)-salts are shown in Fig. 4. In the black Fe(III)-salt, two peaks, assigned to C-N stretching at 2117 and 2075 cm^{-1}, are observed; the former peak may be due to an appreciable interaction between the sulfur in coordinated NCS and iron,

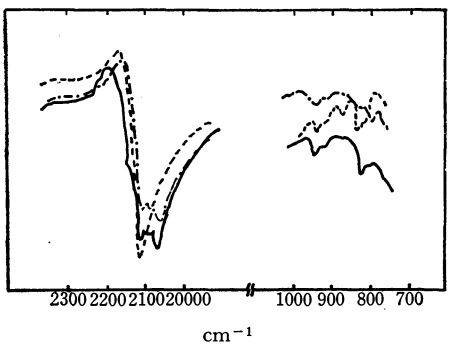

Fig. 3. The infrared spectra of the Mn-salt (——), the Ni-salt (— - —) and Reinecke's salt (- - -).

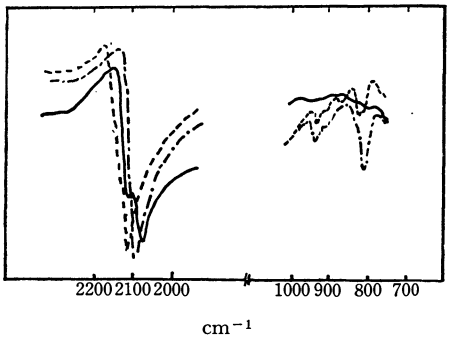

Fig. 4. The infrared spectra of the black Fe-salt (——), the orange Fe-salt (— - —) and Reinecke's salt (- - -).

TABLE 3. THE ANALYSES OF THE X-RAY DIFFRACTION AND DENSITY OF THE REINECKE'S TYPE SALTS

	c/a	a(Å)	c(Å)	ρ Calcd	ρ Found	Z
Reinecke's salt	1	13.42	13.42	1.50		6
Ni-salt	1.3	13.08	17.35	1.59	1.53	8
Mn-salt	0.96	11.41	10.95	1.69	1.12	4
Black Fe-salt	0.9	15.81	14.23	1.55	1.60	8
Orange Fe-salt	1.2	12.24	14.70	1.73	1.45	8

but assumably it will be weaker than that in the corresponding Co-salt; the latter should be independent of such an interaction.

There was found, on the other hand, only one peak at 2098 cm^{-1} due to the C–N stretching vibration in the orange iron(III)-salt as shown in Fig. 4. This may be attributed to the iron being surrounded by large coordinated chloride atoms, as pointed out by Fujita *et al.*[2] In the cholin-salt, the effective charge is small, since the positive charge on the nitrogen atom is screened by bulky aliphatic groups and so the interaction between the thiocyanate group and cholin ion may be negligibly small.

Far-IR Absorption Spectra. The far infrared absorption spectra of the Ni(II)-, Mn(II)-, black Fe(III)- and orange Fe(III)- salts are shown in Fig. 5. In the Ni(II)- and Mn(II)-salts, the band near 500 cm^{-1} assigned to the Cr–N stretching vibration involving NH_3 does not shift or split, whereas the band appearing in the region immediately to lower wave number than that of the former band assigned to NCS bending slightly splits into two peaks, but the splitting is not so large as that in the Co-salt. Thus it is thought that the nickel and manganese ions bind weakly with isothiocyanate groups through the sulfur atom.

The spectrum of the black Fe(III) salt resembles that of the Ni-salt, except for the appearance of a small band at 393 cm^{-1} which is probably due to slight contamination with $FeCl_3$. Hence, the interaction between iron and thiocyanate may have a strength similar to the Ni-salt.

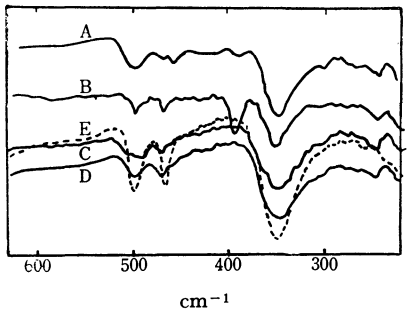

Fig. 5. The far infrared spectra of the Mn-salt (A), the orange Fe-salt (B), the black Fe-salt (C), the Ni-salt (D) and Reinecke's salt (E) (- - -).

The orange Fe(III)-salt has, on the other hand, a new band at 390 cm^{-1}, which has never been observed in the other Reinecke type salts. It consists of two absorption peaks. They are assigned to Fe-Cl stretching vibrations which are attached to hydrogen ion and which are not. Besides, the band assigned to the Cr–N stretching vibration involving an NCS group is commonly observed at 347 cm^{-1} in all Reinecke type salts, and Reinecke's salt itself treated in these papers.[1]

Magnetic Susceptibility. The calculated value of the effective magnetic moment from the magnetic susceptibility in the brownish-orange Ni-salt was 3.96 B. M. and the corresponding calculated value when the nickel is in a low spin state should be 3.87 B. M., which is in good agreement with the observed value described above. It may suggest that the nickel ion is probably surrounded by four sulfur atoms in a square planar arrangement. It is known that when the coordination of four sulfur atoms around nickel ion is square planar, the complex exhibits a brown or orange color; when it is tetrahedral, the complex becomes gray in color. Therfore, it can be predicted that when the former square planar complex is changed to the latter tetrahedral one, the value of the magnetic moment should increase. Nevertheless, the value of the magnetic moment in the Ni-salt heated at 68°C is found to be 4.01 B. M., being not so large as that calculated assuming a tetrahedral configuration around the nickel ion. This is probably due to the incompleteness of the structure change from square planar to tetrahedral.

The observed value of the magnetic moment in the Mn(II)-salt was 5.13 B. M. It is much smaller than the calculated value for a high spin state for manganese, 6.41 B. M. However, it is still larger than that for low spin type manganese, 4.39 B. M. The value of 5.41 B. M. is also expected for the square planar structure for the Mn-salt. These results, therefore, indicate that manganese ion is surrounded by four sulfur atoms in a square planar arrangement in the salt. However, such an interpretation is still inconsistent with that obtained from the reflection spectrum measurement. In addition, the bond between manganese ion and

2) J. Fujita, K. Nakamoto and M. Kobayashi, *J. Am. Chem. Soc.*, **78**, 3256 (1956).

sulfur atoms in a thiocyanate group is weak enough since no shift of the band due to the C–N stretching vibration can be detected in the infrared spectrum. At present, no successful explanation for these phenomena has been given without any discrepancies.

The effective magnetic moment of the black Fe(III)-salt was obtained as 5.0 B. M. The interpretation for the configuration of coordinated atoms around the iron(III) ion can not be appropriately given due to a mixing of iron(III) trirhodanate into the Fe(III)-salt.

The value obtained for the magnetic moment of the orange Fe(III) salt was 4.85 B. M. If iron atom is surrounded by two chloride ions and two Reinecke's anions forming a square planar structure, the calculated value obtained is 4.38 B. M. Therefore it is adequate to consider that this salt has a square planar structure and an ionic character.

X-Ray Diffraction Measurement. The results of an analysis of the X-ray diffraction patterns are summarized in Table 3.

The density of the Ni- and the black Fe-salt are nearly equal to that of Reinceke's salt. This indicates that these salts have not so strong a bond between the metal ions and Reinecke's anion as is the case in the Co- and Cu-salts. The values for the densities of the Mn- and orange Fe-salts obtained do not equal those of the salts mentioned above.

The authors wish to express their gratitude for a grant from the Ministry of Education for these studies.

Synthetic Inorganic Ion-exchange Materials. XII. Some Observation on Surface Structure and Cation-exchange Behaviour of Three Different Antimonic Acids

Mitsuo ABE and Takuji ITO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 20, 1967)

The cation-exchange behaviour and surface functionality of three different antimonic acids, amorphous, glassy and crystalline, were studied by thermogravimetric measurement, infrared absorption spectrometry and change in uptake of potassium ions upon heating. The ion-exchange capacities of the amorphous and glassy antimonic acids decrease with the loss of chemically bonded water. In contrast, the capacities of the crystalline acid heated within 200°C rarely change because of the loss of the interstitial (free) water and no drastic change occurs in the surface structure of the crystal. The crystalline acid with free water removed adsorbs moisture upon exposure to the atomsphere at room temperature. Upon heating above 300°C, the tenaciously bonded water was removed and the cation-exchange capacity decreased simultaneously. The infrared absorption spectra indicated that the surface functionality of the crystalline acid, similar to that of crystalline sodium antimonate $Na[Sb(OH)_6]$, is different from those of the amorphous and glassy acids. It seems that chemically bonded water in the crystalline acid is tenaciously combined as Sb-OH.

In recent years, increased interest in inorganic ion-exchangers has appeared.[1-3] Disadvantages in present types of organic ion-exchangers, such as instability at high temperature and at high levels of ionizing radiation and the limitation in selectivity, sparked the development of inorganic ion-exchangers.

In previous papers we showed that antimonic acid[4] and polyvalent antimonates[5,6] have useful cation exchange properties for akali metal ions,

including a suitable rate for adsorption and desorption in column operation. The antimonic acid showed that differences in selectivity for alkali metal ions are very large and that mutual separation can be achieved with a small column ($0.8\phi \times 6.0$ cm).[7] The antimonic acid obtained through the hydrolysis of antimony pentachloride was gradually peptized by immersing it in pure water for a long period of time. Preparation of the antimonic acid under various conditions has been studied to obtain a chemically stable material[8]; at first, the hydrolyzed precipitate was in an amorphous state, but was gradually transformed into a crystalline powder when it was kept for long time in the mother liquid. Freshly prepared amorphous precipitate in a wet state was dissolved in hot water, and glassy material obtained by cooling the solution rapidly and then evaporating the moisture.

In the investigation of the Sb-O-H_2O system, the thermal decomposition of the three different antimonic acids has already been studied by thermogravimetry and differential thermal analysis, and X-ray powder diffraction analysis and chemical analysis of the oxygen content were made of the thermally decomposed products[9];

$$S_A: Sb_2O_5 \cdot nH_2O \rightarrow Sb_2O_5(\text{amorphous}) \downarrow$$

$$S_G: Sb_2O_5 \cdot nH_2O(G) \rightarrow Sb_2O_5(G) \rightarrow Sb_6O_{13}(C) \rightarrow Sb_2O_4$$

$$S_C: Sb_2O_5 \cdot 4H_2O(A) \rightarrow Sb_2O_5 \cdot 2H_2O(A) \rightarrow Sb_2O_5(B) \rightarrow Sb_6O_{13}(C)$$

(A), (B) and (C), which are cubic space groups $Fd3m(O_h^7)$, have lattice constants of 10.38_2, 10.28 and 10.305 Å, respectively. In order to clarify problems involving the mechanism of the ion exchange ability, the present paper describes the ion-exchange properties and infrared spectra of the three different antimonic acids dried at increasing temperature.

Experimental

Preparations of the Three Different Antimonic Acids. All samples were prepared as described previously[8]: concentrated antimony pentachloride solution (1 : 1), prepared by dropping liquid antimony pentachloride into the same volume of cold water, was hydrolized in a large amount of water at 25°C; $\mathbf{S_A}$, the hydrolyzed precipitate was kept in mother liquor at 25°C for 4 hr, and washed until free of Cl^- with a centrifuger (about 10000 rpm); $\mathbf{S_C}$ the crystalline antimonic acid was obtained by aging the precipitate in mother liquor at 30°C for 20 days; $\mathbf{S_G}$ the antimony pentachloride solution (30 m*l*) was hydrolyzed in 1 *l* of water at 20°C, and let stand for 4 hr. The precipitate, washed with water, was then dissolved in 300 m*l* of hot water. The glassy gel, (G) having five weak inflexions (d; 3.28, 2.63, 1.72, 1.64 and 1.38 Å), was obtained by cooling the solution rapidly and then evaporating the moisture.

When these products were dried with a fan at room temperature over a period of 6 months, they were transformed into granular material suitable for column operation. The dried samples were ground and separated into 100—200 mesh size, and in the sieves the granules of the antimonic acids were washed with water in roder to remove small quantities of adherent antimonic acid dust.

Uptake of Potassium Ions. When the antimonic acid is added to a solution of potassium chloride, hydrogen ions in the material are equivalently liberated by cation exchange in the external solution. The uptake of potassium ions was determined as follows; 50 m*l* of 0.1 N KCl solution was added to 0.4 g of the antimonic acid sample in a 100 m*l* bottle with a glass stooper, and after 48 hr, each solution, containing liberated hydrogen ions, was titrated with standard 0.1 N NaOH solution.

Measurement of Infrared Absorption Spectra. Infrared spectra was measured with a standard KBr disk and hexachloro-1,3-butadiene (H. C. B.) mulls technique, using an Hitachi EPI-S recording spectrometer. Measurements were carried out in comparison with the KBr blank disk, and the H. C. B. was previously dehydrated with anhydrous calcium sulfate.

Results and Discussion

Uptakes of Potassium Ions on Three Different Antimonic Acid at Various Drying Temperatures. The uptake of potassium ions by the antimonic acids, heated for 4 hr at 60°C to 1000°C and then kept in the atmosphere at room temperature, is shown in Fig. 1. The uptakes of

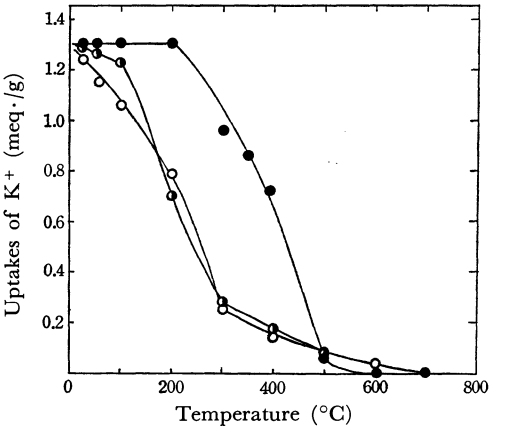

Fig. 1. K^+-uptakes on three different antimonic acids after heating to 900°C.

the heated amorphous and glassy samples decreased continuously with increasing temperature, and showed no exchange properties above 600°C. In contrast, the uptake of the crystalline samples heated at 60 to 200°C scarcely decreased with increasing temperature, but decreased rapidly above 300°C, and then the samples heated to 700°C showed no ion-exchange properties, similar to the amorphous and glassy samples.

Thermal Decomposition and Re-hydration Processes. The particular investigation of the thermal decomposition of three different antimonic acids has been reported previously.[9] The changes in weight loss of the samples heated under the same condition are illustrated in Fig. 2. The

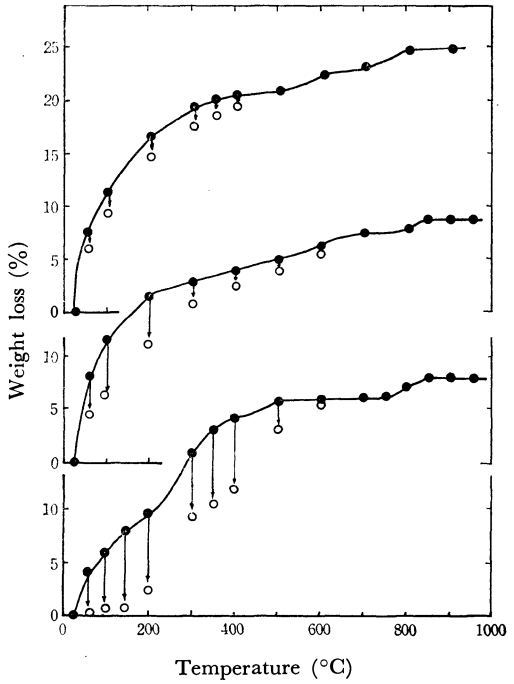

Fig. 2. Water adsorption on the heated antimonic acid samples.

amorphous acid was continuously dehydrated without loss of oxygen by heating below 600°C, and then transformed into Sb_2O_5 (G) showing weak X-ray diffraction intensities. The loss of oxygen began from 650°C and Sb_2O_5(G) transformed into Sb_6O_{13}(C). As the decrease in potassium ion uptake is comparable to the amount of dehydration, it is evident that the ion-exchange capacity decreases with the loss of hydrated water. These results suggest that the concentration of exchangeable hydrogen ions in the material phase is decreased by this treatment.

On the crystalline antimonic acid, the decrease in the uptake is different from that obtained for the amorphous or glassy acids. The weights of all the samples, heated at below 200°C and then kept in air at room temperature for a relatively short time, return to the initial values by adsorbing moisture from the atomosphere. X-ray diffraction analysis indicated that no drastic change in the structure of the crystal occurs when the free water molecule are lost.

The loss of water, found to be reversible, is attributed to the removal of the free water which can be desorbed by heating and adsorbed by cooling without change in the crystal structure. With increasing the temperature above 300°C, the crystalline antimonic acid begins to lose bonded water which constitutes part of the crystal structure. The reversibility of the free water decreased simultaneously with increasing temperature, and samples heated above 700°C showed no adsorptive properties toward moisture. It is evident that the decrease in uptake of the crystalline acid does not occur with the removal of free water, but with a decrease in the bonded water by heating above 300°C.

Infrared Absorption Spectra of the Three Different Antimonic Acids. Any difference between the amorphous or glassy acids and the

IV: Sodium antimonate

crystalline acid in adsorptive properties toward lithium ions is expected to depend on surface functionality. Hence, surface functionality refers collectively to the chemical functional groups which terminate the bulk structure of the solid and their immediate environment, as reported by McDonald.[10]

The absorption band between 2800 and 3800 cm^{-1} with a maximum at 3350 cm^{-1} is characteristic of interstitial water and OH groups, and the band between 1500 and 1760 cm^{-1}, with a maximum at 1630 cm^{-1}, is due to the deformation vibration of the interstitial water. The absorption bands for the amorphous and glassy acids are similar to those obtained for a number of metallic hydrous oxides (such as Zr, Sn and Th[11]), with the exception of the stretching vibration of Sb-O with a maximum at 750 cm^{-1}.

The crystalline antimonic acid showed band having maxima at 2430 and 1280 cm^{-1} in addition to the bands found for the amorphous and glassy acids. Its spectrum is almost the same as that of sodium antimonate $Na(Sb(OH)_6]$ (tetragonal crystal system $P4/n$), as illustrated in Fig. 3. It has been known that the OH groups in the antimonate coordinate with one atom of antimony. Siebert[12] deduced that the intense absorption band between 1000 and 1200 cm^{-1} on the antimonate must be assigned to the Sb-OH deformation vibration of the antimonyl group in octahedra, and the maximum intensity at 2145 cm^{-1} is probably due to an overtone of the Sb-OH deformation vibration. The band between 1100 and 1350 cm^{-1} of the crystalline acid can be assigned to the Sb-OH deformation vibration, though it is shifted to higher frequency in comparison with that of the antimonate. It is concluded that the crystalline antimonic acid is different from the amorphous and glassy acids, not only in fundamental crystal structure, but also in surface functionality. The broad adsorption band between about 2700 and 3800 cm^{-1} implies that hydrogen bonding exists between OH groups and the water molecules surrounding them.

Infrared Spectra of Three Different Antimonic Acids at Various Drying temperatures. Infrared absorption spectra of the amorphous acid heated for 4 hr at 100 to 700°C are shown in Fig. 4. Absorption bands due to OH groups continuously decreased with increasing temperature, and a drastic change in the band at 750 cm^{-1} was caused by heating to 700°C, indicating the formation of Sb_6O_{13}.[9] Measurements with an H. C. B. mull showed that absorption bands involving OH groups and water disappear at 600°C. The disappearance

* absorption band of H.C.B.

of both the OH and H_2O bands supports our conclusion[9] that the product heated at 700°C is not Sb_3O_6OH as reported by Dihlström *et al.*[13] and Schrevelius,[14] but Sb_6O_{13}. Similar changes were observed upon heat treatment of the glassy antimonic acid. The decrease in intensity of the OH-band below 600°C is ascribed to the condensation of acid groups in the amorphous or glassy antimonic acids to Sb-O-Sb. Sb_2O_5 was formed on heating at 600°C for 4 hr. By the condensation of acid groups, as assumed in metallic hydrous oxide,[11,15] it is possible to explain the irreversible loss of water in these acids. The condensation decreases the concentration of exchangeable hydrogen ions in the materials, and therefore causes a lower uptake of potassium ions. However, information obtained from this measurement is not enough to arrive at a proper conclusion on the surface functionality of amorphous antimonic acid. Further confirmation of the surface functionality

must be obtained by checking other physical and chemical properties.

In the crystalline antimonic acid, little change was observed when samples were heated at 60—200°C, but at 300°C, the absorption bands of Sb-OH decreased with increasing temperature, corresponding to the removal of strongly bonded water, which comprises part of the crystal structure, as deduced from the results of X-ray examinations.[9] These results indicate the existence of strongly bonded water combined with Sb-OH. It is possible to interpret that the uptake of the alkali metal ions on the crystalline acid scarcely changes due to the removal of interstitial water, but decreases rapidly upon decomposition of the Sb-OH groups. The infrared spectra of the crystalline acid heated at 700°C showed a change in the intensity of the Sb-O stretching vibration, indicating a drastic change to Sb_6O_{13}, as in the amorphous acid.

Infrared Spectra of Three Different Antimonic Acid adsorbed Alkali Metal Ions. The ion-exchange properties of the surface sites of the hydrous oxides of metals is very important problem, but little is known concerning their immediate environment except in the case of amorphous silica.[10]

When the hydrogen forms of the amorphous samples were converted to sodium or potassium forms by treatment with a solution of 0.1 N NaCl or 0.1 N KCl, using a column technique, the infrared spectra scarcely changed from those of the hydrogen forms, as illustrated in Fig. 6.

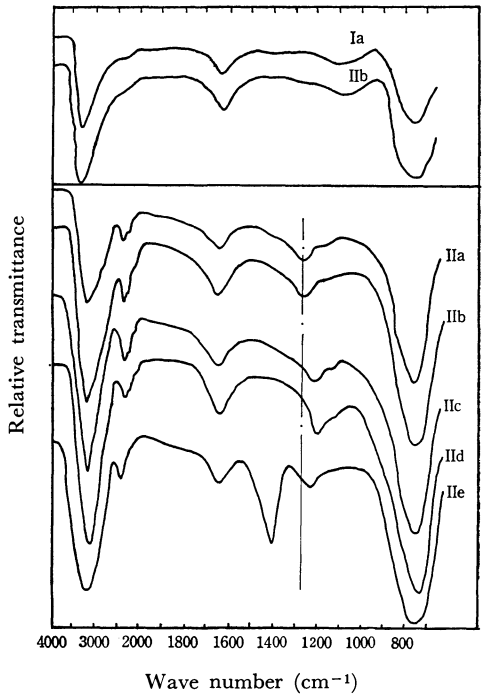

Fig. 6. The infrared absorption patterns of antimonic acids before and after exchange with alkali metals (KBr disk).
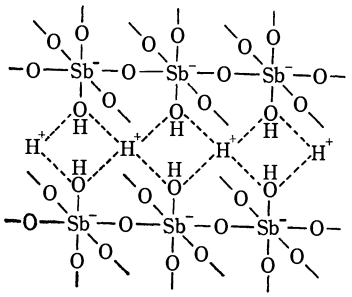
(Top) amorphous antimonic acid, Ia: H-form, Ib: K-form, (Bottom) crystalline antimonic acid, IIa: H-form, IIb: 1.1 mep.K^+/g, IIb: 2.2 meq.K^+/g, IId: 2.8 meq.Na^+/g, IIe 2.0 meq.NH_4^+/g

The spectra of the crystalline acid was similar to that of the hydrogen form, except that the deformation band of Sb-OH was shifted to a lower vibration frequency with the adsorption of alkali metal ions. It has been known that an atom or molecule adsorbed near a surface perturbs the motions of atoms of the group, causing a shift in some group vibration frequency.[10] Such a shift is evidence that the deformation frequency at 1280 cm^{-1} on the hydrogen form is affected by the chemically adsorbed ions. It is possible to explain a shift to lower frequency, assuming that an increase in reduced mass occurs near the surface groups by conversion to alkali metal forms. If hydrogen ions in Sb-OH exchange to the alkali metal ions in the external solution, the absorption intensity of Sb-OH should apparently decrease. However, little change in the intensities were observed in conversions by any alkali metal ions.

From these results, it is possible to propose the

following structure for the crystalline antimonic acid $H_2Sb_2O_5(OH)_2$:

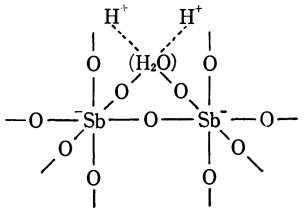


$H_2Sb_2O_5(OH)_2$

The hydrogen ions in the structure may be combined as H_3O^+. If 5 molecules of water are removed from two $H[Sb(OH)_6]$ molecules, modified from $Na[Sb(OH)_6]$, such a structure is easily deduced. It seems that, however, the hydrogen bonding surface groups are constrained by rigid three-dimensional bonding, in the same manner as the Sb_4O_6 molecule in senarmontite (cubic Sb_2O_3),[9] and that the ion-exchangeable hydrogen ions are surrounded by six oxygen atoms, as Na^+ in $Na[Sb(OH)_6]$.

In the amorphous and glassy acids, though information obtained from infrared spectra measurements is too little to allow an evaluation of the surface functionality, the results on the irreversible loss of the water by the heated samples indicates that a large part of water included in these materials are chemically bonded, and decreases continuously with increasing temperature, involving condensation of the acid groups. From a previous experiment, it was thought that the difference between the amorphous and glassy acids is only the difference in particle size.[9] The matrix of the glassy acid is Sb_2O_5 (structure G), and scarcely changes with increasing temperature (below 600°C). The ion-exchange capacity correspondingly decreased with the loss of water molecules in the material. Therefore, it seems that the water included in the amorphous or glassy acids is not simply interstitial water but bonded water. The existence of isolated OH groups was not observed through hydrogen bonding in the materials.

The following surface structure is probable for the amorphous and glassy acids, although the structure of the hydrogen bonded water molecules is uncertain.



$Sb_2O_5 \cdot nH_2O$

We have already pointed out that disparity of lithium adsorptions on the antimonic acid obtained by various preparations is not due to a difference in particle size of the materials, but the existence of different typs having a difference in selectivity toward lithium ion adsorption.[8] In present experiment, it may be concluded that the difference in selectivity is closely connected to the difference in surface functionality in the antimonic acids.

Tensammetric Study of the Adsorption of Brucine

Mutsuo KODAMA, Mitsuko MURATA, Tomohiko NODA and Akiko KIMURA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received October 25, 1967)

This paper will present two results of experiments concerning the adsorption of brucine. We will first discuss the adsorption of brucine on D. M. E. studied tensammetrically. Brucine was found to give a tensammetric wave with two peaks, at +0.10 V and −1.15 V *vs.* SCE. The positive tensammetric peak can be ascribed to the usual adsorption process. The second peak, however, behaved differently from the first, probably due to the reformation of adsorbed brucine film involving the protonation and the reorientation of brucine. Secondly, we will present experimental facts concerning the depressive effects of brucine on the reduction waves of copper(II).

Brucine has been reported to produce a catalytic wave in the pH range from 5.0 to 12.0.[1] In previous papers,[2,3] we studied chronopotentiometrically the perturbation effect of adsorbed

brucine on the electroreduction of copper(II) in a tartrate medium and the discriminative effects of the brucine film toward the electroactive-metal-complex enantiomers. In the absence of brucine, the chronopotentiometry of copper(II) tartrate shows a diffusion-controlled character and the behavior of copper tartrate *d*- and *l*-enantiomers is identical. In the presence of brucine, however, the electrolysis is no longer diffusion-controlled and the product, $i \cdot \tau^{1/2}$, of the chronopotentiometric wave of copper(II) decreases linearly with an increase in the applied current. A measurable difference in $i \cdot \tau^{1/2}$ value between the copper(II) complex of *d*-tartrate and that of *l*-tartrate was also observed. These facts were ascribed to the interaction between the copper tartrate complex and the adsorbed brucine film, but no precise description of the nature of the surface interaction of brucine film with the electroactive species was given.

In view of all this, it is worthwhile to study the nature of the adsorbed brucine film. In the present paper, we will discuss our study of the adsorption of brucine on DME using the tensammetric method.

Experimental

Reagents. The tartaric acid and brucine sulfate used were of an analytical reagent grade (Tokyo Kasei). All the other chemicals were of an analytical reagent grade and were used without further purification.

Apparatus. The tensammetric waves of brucine were measured with a Yanagimoto PA-102 Pen-recording Polarograph either manualy or automatically. The d.c. potentials appllied were determined by using a Shimadzu K-2 potentiometer.

The flow rate of mercury, m, and the drop time, t_d, of the dropping mercury electrode (DME) were measured and found to be 1.24_8 mg/sec and 6.30 sec respectively in an air-free 0.10 M acetate buffer solution of pH 4.80, with an open circuit at 60 cm of a mercury column at 25°C. A saturated calomel electrode (SCE) of a large area was used as a reference electrode and connected to the cell solution through a Hume and Harris type salt bridge. In a. c. polarographic measurements, a 200-μF condenser was used to minimize the effect of cell resistance.[4] The pH of the solution was measured with a glass electrode pH meter (Hitachi-Horiba Model M-4).

All the polarographic studies were carried out at 25°C in solutions of 1.50 ionic strength, which was adjusted by adding appropriate amounts of sodium sulfate. The oxygen dissolved in the sample solution was removed by bubbling pure nitrogen gas through the solution.

Results and Discussion

Tensammetric Behaviors of Brucine. As is obvious from the curves in Fig. 1, brucine lowers the surface tension at the interface of a mercury-electrolyte solution and changes the electrocapillary

curve considerably. The top part of the electrocapillary curve becomes very flat. The surface-tension lowering by brucine was found to be independent of the pH value of the solution and of the nature of the supporting electrolyte (Fig. 1). The lowering of the a.c. base current and the appearance of an a.c. polarographic wave due to the presence of brucine are also shown in Fig. 2. The a.c. polarographic wave, with summit potentials at +0.10 V and −1.15 V *vs.* SCE, can be considered to be tensammetric in nature, because it is not accompanied by a corresponding d.c. step (Fig. 2). The maximum depression of the a.c. base-current was shown to occur at the potential around the e.c.m. (electrocapillary maximum). The surface-tension lowering and the a.c. base-current lowering become greater with an increase in the concentration of brucine in the bulk solution. The dependence of the peak height of the positive tensammetric wave on the brucine concentration is shown in Fig. 3. The peak height increases with the concentration up to 0.1 mM and reaches a limiting height above concentration of 0.2 mM following a typical Langmuir-type relation.

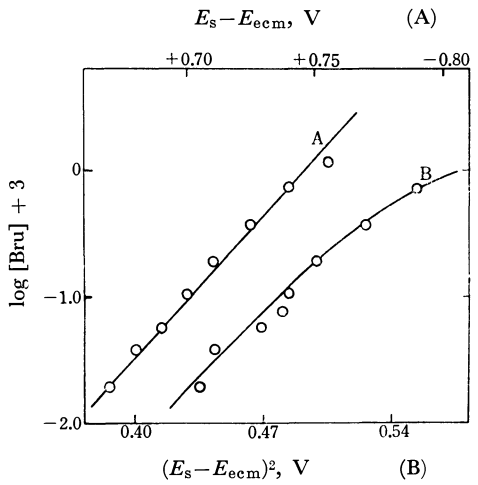

Fig. 4. Relation between log [Brucine] and $E_{ecm}-E_s$ or $(E_{ecm}-E_s)^2$ for the first peak-height.
pH=2.00, 0.50 M sodium sulfate
A: $E_{ecm}-E_s$, B: $(E_{ecm}-E_s)^2$

The positive tensammetric peak was found to shift slightly to the more positive potential with an increase in the pH value and to disappear at pH values higher than 7.0, merging with the mercury dissolution wave. As Fig. 4 shows, it was also found to shift to the more positive potential with an increase in the brucine concentration in all the supporting electrolytes tested (sulfate and tartrate) according to the following relation, given by Breyer and Bauer.[5]

$$E_s - E_{ecm} = K_1 - K_2 \log C_{Bru}$$ [5]

where E_s represents the summit potential; E_{ecm}, the electrocapillary zero potential (−0.50 V *vs.* SCE), and C_{Bru}, the bulk concentration of brucine, and where K_1 and K_2 are constants.

The above experimental results clearly indicate that the positive tensammetric peak arises from the usual adsorption process involving the neutral form of brucine. This conclusion could also be confirmed by examining the effect of adsorbed brucine on the d.c. polarograms of copper(II). As Fig. 5 illustrates, the minimum occurs in the region of the e.c.m., showing the maximum adsorbability and the maximum depression action of brucine at this potential range.[6] At potentials more negative than the e.c.m., the depression of the limiting current becomes less pronounced with an increase in the negative potential; the wave height reaches its full height again at potentials more negative than −0.90 V *vs.* SCE.

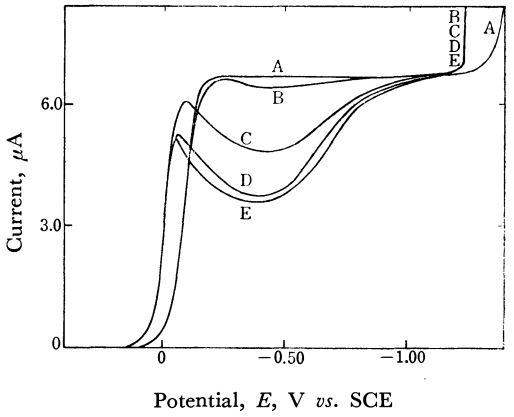

Fig. 5. Depressive effect of brucine on the reduction wave of copper(II), at ionic strength=1.50.
A 0.50 M tartrate, no brucine, pH=3.0
B 0.50 M tartrate, 1.0 mM brucine, pH=3.0
C 0.10 M tartrate, 1.0 mM brucine, pH=3.0
D 0.01 M tartrate, 1.0 mM brucine, pH=3.0
E 0.50 M Na_2SO_4, 1.0 mM brucine, pH=2.10

Conversely, the negative tensammetric peak differs considerably from the usual tensammetric wave involving the adsorption-desorption processes, in which, even at the potential where the negative peak appears, a lowering of the surface tension can still be observed (Fig. 1) and in which neither the plot of E_s-E_{ecm} nor that of $(E_s-E_{ecm})^2$ [5] against log C_{Bru} gives a linear relation, as is shown in Fig. 6.

The kink appearing in the electrocapillary curve shown in Fig. 1 corresponds exactly to the second summit potential, and a rise in the a.c. base-current can be observed on the negative side of the second wave. It is also interesting that the second tensammetric wave was always found to be accompanied by

5) B. Breyer and H. H. Bauer, "Alternating Current Polarography and Tensammetry," Interscience Publishers, New York (1963), p. 89.
6) *Ibid.*, p. 86.

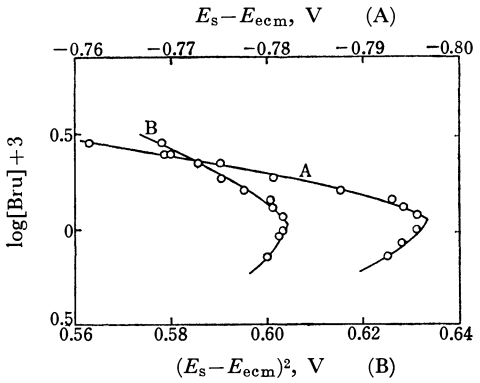

Fig. 6. Relation between log[Brucine] and $E_{ecm}-E_s$ or $(E_{ecm}-E_s)^2$ for the second peak-height.
pH=3.0, 0.50 M sodium sulfate
A: $E_{ecm}-E_s$, B: $(E_{ecm}-E_s)^2$

a catalytic wave (presumably due to the catalytic hydrogen discharge) in the pH range from 3.0 to 8.5 (contrary to the findings by Kirkpatrick[1]). At low concentrations of brucine, the catalytic wave occurs at a potential very close to the second summit potential. However, as the concentration of brucine increases, the separation between the second summit potential and the potential at which a catalytic wave occurs becomes greater.

Since the catalytic effect is generally influenced by the orientation of the catalytically-active species, and since the adsorption of positively-charged species must be advantageous compared with that neutral one at potential sufficiently negative with respective to the e.c.m., we can assume that the second tensammetric peak corresponds to a process such as the reformation of adsorbed brucine film involving the protonation and the reorientation of brucine. Here, the resulting brucine film with a relatively loose structure may be catalytically more active than that with a compact structure which is expected at high brucine concentrations.

The dependence of the peak height on the temperature was also examined in the temperature range from 15°C to 35°C. In this temperature range, both peak heights were found to decrease slightly with an increase in the temperature. On the other hand, it was also found that the peak height is little affected by the addition of 5×10^{-4} M LEO (Polyoxyethylene-Lauryl-Ether). From these results, we can deduce that brucine is firmly adsorbed on DME under the experimental conditions employed.

Strychnine was also found to be adsorbed on DME and to show exactly the same tensammetric behavior as brucine.

The Blocking Effect of Brucine on D. C. Polarographic Waves of Copper(II). Brucine was found to exert a depressive effect on the reduction waves of copper(II) in both sulfate and tartrate solutions. As has been described previously, the maximal depression of the limiting current occurs around the e. c. m.

In contrast to the sulfate system, the depressive effect of brucine on the reduction wave of copper(II) was demonstrated to become less pronounced in a tartrate solution upon an increase in the concentration of tartrate over the pH range from 2.0 to 5.0 (Fig. 5). Copper(II) has been reported to form a variety of complexes, depending on the pH value in solution and the concentration ratio between tartrate and copper(II). At a pH higher than 6 under a low ratio, mixed hydroxy-tartrate complexes have been reported.[7] A low pH value may be responsible for the formation of such a protonated

complex as $CuHT^+$.[8] At a low pH, in addition, a series of complexes expressed by CuT_x^{2-2x} may be expected, where $x=1$ to 4. From the step-by step formation constants for this series, reported to be 3.20, 1.91, −0.34, and 1.71 in logarithm value respectively,[9] the equilibrium compositions can be calculated. Table 1 shows the expected compositions in solution with various pH values. In a 0.50 M tartrate solution, the predominant species in the pH range from 3.0 to 7.0 are CuT_2^{2-} and CuT_4^{6-}. At pH 2.0, the major component is Cu^{2+}, while CuT is present in a small equilibrium concentration of 21%. Considering that the reported values may differ by several tenths from the logarithm values of true formation constants which can be safely used in the calculation, it can be concluded that there is no close relation between the composition of the tartrato-copper(II) complex and the minimizing action of the tartrate ion, but that the complex formation between copper(II) and the tartrate ion is essential. This conclusion is confirmed by the fact that, in a 0.10 M tartrate solution of pH 2.0, where almost all copper(II) ions were present in the form of Cu^{2+}, a pronounced depressive effect of brucine is observed. The importance of the complex formation in minimizing the depressive effect of brucine can also be seen by examining the effect of brucine on the limiting current of copper(II)-nitrilotriacetate complexes (a graph is not shown here). The depressive effect of brucine is eliminated completely by the addition of 10 mM nitrilotriacetate to 2.0 mM copper(II) at pH 4.0. Although the solution components in a 0.50 M tartrate solution of pH 6.0 are quite similar to those in the pH 5.0 solution, the effect of brucine was observed to be greater in the former solution. This clearly indicates that hydrogen ions also play an important role in the minimizing action performed the tartrate ion.

Though the detailed roles that tartrate and hydrogen ions play in the minimization of the depressive effect of brucine on the reduction of copper(II) in a tartrate solution could not completely explained in this study, and since, hence, further systematic investigations must be conducted to describe the characteristic nature of adsorbed brucine film precisely, we hope the results discussed here will provide suggestive clues for the explanation of the interaction between the adsorbed film and the electroactive substance at the electrode surface.

The authors wish to thank the Ministry of Education for the financial support given to this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2375—2378 (1968)

The Kinetics of Substitution Reactions Involving Metal Complexes. XII. The Reactions between Copper(II) Ions and Zinc(II)-nitrilotriacetate Complexes

Nobuyuki TANAKA and Masaru KIMURA*1

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 13, 1967)

The kinetic study of the substitution reaction of copper(II) ions and zinc(II)-nitrilotriacetate complexes in acetate buffer solutions has been carried out with the same procedure as reported previously. The reaction was treated as to proceed through both hydrated metal ions and monoacetato complexes. The rate constants for eight elementary reaction paths, of which four involve the hydrated copper(II) ions and the others the monoacetatocopper(II) complexes, were determined at ionic strength 0.23 at 0°C. The values obtained indicate that all the reactions proceeding through hydrated copper(II) ions are faster than the corresponding reactions proceeding through monoacetatocopper(II) complexes.

Our previous study[1] showed that monoacetatonickel(II) ions react with nitrilotriacetate (NTA) anions faster than hydrated nickel(II) ions do. Since this was considered to be due to the characteristics of nickel(II) but not NTA ions, the confirmation was undertaken in the present study.

*1 Former name: Yu Saito.
Present address: Department of Applied Chemistry, Yamagata University, Yamagata Technical College, Zyonan, Yonezawa.

1) N. Tanaka and M. Kimura, This Bulletin, **40**, 2100 (1967).

The substitution reactions between copper(II) ions and zinc(II)-nitrilotriacetate complexes have been investigated, and the rate constants for eight reactions including the reactions between copper(II) ions and nitrilotriacetate anions have been determined.

Experimental

A solution of zinc(II) nitrate was prepared by dissolving a known amount of pure zinc metal in reagent-grade nitric acid. The preparation and standardization of all other chemicals used were the same as described in the previous paper.[1]

The rate of the reaction between copper(II) ions and zinc(II)-NTA complexes was determined by the measurement of the polarographic limiting diffusion current of copper(II) ions in acetate buffer solutions at 0°C and ionic strength 0.23. The ionic strength was adjusted with potassium nitrate. Gelatin was added as a maximum suppressor by 0.01% in concentration. The pH of the solution was measured after the polarographic measurement with a Hitachi-Horiba Model M-4 pH meter.

Result

In the acetate buffer solution containing acetate ions up to 0.2 M in concentration, the overall substitution reaction of copper(II) ions and zinc(II)-NTA complexes is written as

$$\left\{\begin{matrix}Cu^{2+}\\ \downarrow\uparrow\\ CuOAc^{+}\\ \downarrow\uparrow\\ Cu(OAc)_2\end{matrix}\right\} + ZnX^{-} \overset{k^{+}_{app}}{\rightleftharpoons} CuX^{-} + \left\{\begin{matrix}Zn^{2+}\\ \downarrow\uparrow\\ ZnOAc^{+}\end{matrix}\right\} \quad (1)$$

where X^{3-} means a tervalent NTA anion. Under the condition that both Zn(II) ions and Zn(II)-NTA complexes are present in a large excess over copper(II) ions, the substitution reaction (1) can be treated as a pseudo-first order reaction. The apparent rate constants of the forward reaction (1), k^{+}_{app}, were obtained by similar treatments as given in the previous papers.[2-4] The values of k^{+}_{app} were obtained as a function of the hydrogen ion concentration at two different concentrations of zinc(II) ions and at three different concentrations of acetate ions. Their plots against the hydrogen ion concentration are given in Fig. 1. Figure 1 clearly indicates that a linear relation exists between k^{+}_{app} and $[H^+]$, and that the values of k^{+}_{app} at $[H^+]=0$, which were obtained by extrapolation, are dependent on the concentrations of zinc(II) ions and acetate ions.

On the basis of the dependencies of the observed apparent rate constants on the concentrations of

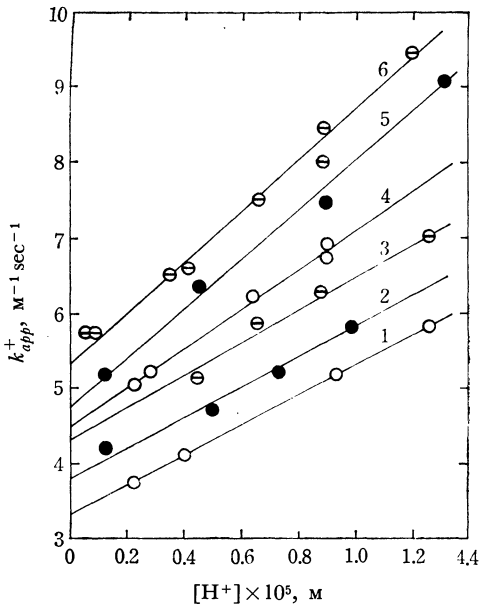

Fig. 1. k^{+}_{app} as a function of the hydrogen ion concentration in acetate buffer - potassium nitrate solutions of ionic strength 0.23 at 0°C. Initial concentrations are $[Cu^{2+}]_{0,app}=2.00\times10^{-4}$ M; $[ZnX^-]_0=4.35\times10^{-3}$ M; $[Zn^{2+}]_{0,app}=11.68\times10^{-3}$ M (plots 1, 2 and 3) and $[Zn^{2+}]_{0,app}=6.34\times10^{-3}$ M (plots 4, 5 and 6). Concentrations of free acetate are 0.048 M for ⊖, 0.097 M for ●, and 0.196 M for ○.

zinc(II) ions, Zn(II)-NTA complexes, hydrogen ions and acetate ions, which are identical to those of the substitution reaction of copper(II) ions and zinc(II)-EDTA complexes,[4] the following mechanisms were set down for reaction (1).

$$\text{(i)}\quad Cu^{2+} + ZnX^{-} \overset{k^{+}_{Ih}}{\rightleftharpoons} CuX^{-} + Zn^{2+} \quad (2)$$

$$CuOAc^{+} + ZnX^{-} \overset{k^{+}_{Ic}}{\rightleftharpoons} CuX^{-} + ZnOAc^{+} \quad (2')$$

$$\text{(ii)}\quad ZnX^{-} + H^{+} \rightleftharpoons ZnHX \quad (3)$$

$$Cu^{2+} + ZnHX \overset{k^{+}_{IIh}}{\rightleftharpoons} CuHX + Zn^{2+} \quad (4)$$

$$CuOAc^{+} + ZnHX \overset{k^{+}_{IIc}}{\rightleftharpoons} CuHX + ZnOAc^{+} \quad (4')$$

$$CuHX \rightleftharpoons CuX^{-} + H^{+} \quad (5)$$

$$\text{(iii)}\quad ZnX^{-} \rightleftharpoons \left\{\begin{matrix}Zn^{2+}\\ \downarrow\uparrow\\ ZnOAc^{+}\end{matrix}\right\} + X^{3-} \quad (6)$$

$$Cu^{2+} + X^{3-} \overset{k^{+}_{IIIh}}{\rightleftharpoons} CuX^{-} \quad (7)$$

2) N. Tanaka, K. Kato and R. Tamamushi, This Bulletin, **31**, 283 (1958).
3) N. Tanaka and K. Kato, *ibid.*, **32**, 1376 (1959).
4) K. Kato, *ibid.*, **33**, 200 (1960).

$$CuOAc^+ + X^{3-} \overset{k^+_{IIIc}}{\rightleftharpoons} CuX^- + OAc^- \quad (7')$$

(iv) $$ZnX^- + H^+ \rightleftharpoons \left\{\begin{matrix} Zn^{2+} \\ \downarrow\uparrow \\ ZnOAc^+ \end{matrix}\right\} + HX^{2-} \quad (8)$$

$$Cu^{2+} + HX^{2-} \overset{k^+_{IVh}}{\rightleftharpoons} CuHX \quad (9)$$

$$CuOAc^+ + HX^{2-} \overset{k^+_{IVc}}{\rightleftharpoons} CuHX + OAc^- \quad (9')$$

From the same treatment in principle as in the previous papers,[2-5] Eq. (10) is obtained for the rate equation for reaction (1).

$$k^+_{app} = \frac{1}{\sum_{n=0}^{2} \beta_{Cu(OAc)_n}[OAc^-]^n}\Big[k^+_{1h} + k^+_{1c}[OAc^-] + (k^+_{2h} + k^+_{2c}[OAc^-])[H^+] + \{k^+_{3h} + k^+_{3c}[OAc^-] + (k^+_{4h} + k^+_{4c}[OAc^-])[H^+]\} \times \frac{1 + \beta_{ZnOAc}[OAc^-]}{[Zn^{2+}]_{0,app}}\Big] \quad (10)$$

where,

$$\left.\begin{aligned} &k^+_{1c} = k^+_{1c}\beta_{CuOAc},\ k^+_{2h} = k^+_{IIh}K^H_{ZnHX}, \\ &k^+_{2c} = k^+_{IIc}\beta_{CuOAc}K^H_{ZnHX},\ k^+_{3h} = k^+_{IIIh}/K_{ZnX}, \\ &k^+_{3c} = k^+_{IIIc}\beta_{CuOAc}/K_{ZnX},\ k^+_{4h} = k^+_{IVh}/(K_{ZnX}K_{HX}), \\ &k^+_{4c} = k^+_{IVc}\beta_{CuOAc}/(K_{ZnX}K_{HX}) \end{aligned}\right\} \quad (10')$$

In Eq. (10), the initial concentration $[Zn^{2+}]_{0,app}$ is substituted for $[Zn^{2+}]_{app}$.

Table 1. Rate constants in Eq. (10) obtained at ionic strength 0.23 at 0°C

	Rate constant	
k^+_{1h}	5.4	$l\ mol^{-1}\ sec^{-1}$

Table 2. Rate constants for reactions (2), (2'), (4), (4'), (7), (7'), (9) and (9') at ionic strength 0.23 at 0°C

	Rate constant, $l\ mol^{-1}\ sec^{-1}$
k^+_{Ih}	5.4
k^+_{Ic}	2.3
k^+_{IIh}	~30
k^+_{IIc}	~10
k^+_{IIIh}	2.0×10^8
k^+_{IIIc}	1.1×10^8
k^+_{IVh}	5×10^3
k^+_{IVc}	1×10^3

The rate constants in Eq. (10) were obtained from the analysis of those plots in Fig. 1, and are given in Table 1.

The rate constants for reactions (2), (2'), (4), (4'), (7), (7'), (9) and (9') were calculated from the relations given in Eqs. (10') and are given in Table 2. The values of K_{ZnX} and K^H_{ZnHX} which were used in the calculation are $10^{10.06}$ and $10^{3.5}$, respectively. They are the values which were determined by the polarographic method at ionic strength 0.2 at 0°C.[6] The values of K_{HX}, β_{CuOAc} and $\beta_{Cu(OAc)_2}$ are the same as those used in the previous paper.[1]

Discussion

The values in Table 2 indicate that all the reactions proceeding through hydrated copper(II) ions are faster than the corresponding reactions through monoacetatocopper(II) ions. This contrasts with the results obtained in the case of the substitution reactions involving nickel(II) ions and confirms our previous consideration.

With the rate constants obtained in this study, the ratios of the rate constants for the reactions,

$$M^{2+} + X^{3-} \underset{k^-_{IIIh}}{\overset{k^+_{IIIh}}{\rightleftharpoons}} MX^- \quad (11)$$

$$M^{2+} + HX^{2-} \underset{k^-_{IVh}}{\overset{k^+_{IVh}}{\rightleftharpoons}} MX^- + H^+ \quad (12)$$

may be discussed. For reactions (11) and (12), the following relation holds.

$$k^+_{IIIh}/k^+_{IVh} = (k^-_{IIIh}/k^-_{IVh})/K_{HX} \quad (13)$$

If it is assumed that the treatment given by Bydalek

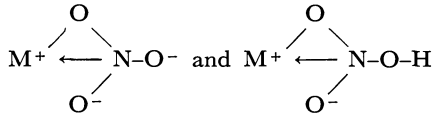
Cu^{2+}	0	0.23	4×10^{4}		This stuydy

and Margerum[7] and Bydalek and Blomster[8] can be applied to these reactions, and that the same reaction intermediates given by the latter authors for the Ni(II)-NTA reactions,



are formed in reactions (11) and (12), respectively, the ratio k^{-}_{IIIh}/k^{-}_{IVh} is considered to be equal to the value of the acid dissociation constant for acetic acid, $10^{-4.7}$. Then, the ratio k^{+}_{IIIh}/k^{+}_{IVh} was calculated to be

$$k^{+}_{IIIh}/k^{+}_{IVh} = (k^{-}_{IIIh}/k^{-}_{IVh})/K_{HX} = 10^{5.3}$$

Since this relation holds for any metal ion, the ratio must be the same irrespective of the kind of metal ions involved. The ratios obtained in the present study are given in Table 3 together with the values reported in the literatures. From Table 3, it can be seen that the observed values are in an essential agreement with the calculated ones.

In the present and the previous[1] studies, the rate constants for the complex-forming reactions of Cu-NTA and Ni-NTA complexes were determined. If the rate constants for Cu-NTA complexes are denoted with $k^{+}_{IIIh}(Cu)$ and $k^{+}_{IVh}(Cu)$ and those for Ni-NTA complexes with $k^{+}_{IIIh}(Ni)$ and $k^{+}_{IVh}(Ni)$, the values of $k^{+}_{IIIh}(Cu)/k^{+}_{IIIh}(Ni)$ and $k^{+}_{IVh}(Cu)/k^{+}_{IVh}(Ni)$ were calculated to be 2×10^{3} and 1×10^{3}, respectively. The values seem to be in an essential agreement with the ratio of the rate constants for the exchange of a water molecule from a hydrated copper(II) ion and a hydrated nickel(II) ion, which was reported by Eigen and Tamm,[10,11] and Connick and Stover.[12]

The authors wish to thank the Ministry of Education for the financial support granted for this research. Thanks are also due to the Teijin-Kumura Shogaku-kai for the scholarship granted to one of the authors (M. K.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2379—2381 (1968)

Studies on Some Telluro-Tungstomolybdates

Keshawa Chandra PATHAK

Department of Chemistry, Banaras Hindu University, Varanasi-5, India

(Received December 1, 1967)

Ammonium telluro-tungstomolybdate $6(NH_4)_2O \cdot 2TeO_3 \cdot WO_3 \cdot 10MoO_3 \cdot 30H_2O$ and the corresponding salts with silver, strontium, barium, cerium, lead, iron and guanidine have been isolated, their properties studied and the composition determined by the analytical methods. IR spectra of ammonium and guanidine salts have been recorded and the characteristic peaks assigned. Thermal decomposition studies (TGA and DTA) of ammonium salt were made. Differential thermal analysis of ammonium salt was done in nitrogen atmosphere too.

Formation of heteropoly salts by tungsten and molybdenum is well known.[1] Tellurium has also been reported to form heteropoly salts with various elements such as molybdenum,[2] tungsten,[3] phosphorus, arsenic.[4]

The condensation reaction of telluric acid with tungstic acid was studied by Rosenheim and Traube.[5] Recently telluric-12 tungstic heteropoly acid[6] and its silver salt[7] was studied by Ganelina.

Formation of heteropoly salts of telluric acid with molybdic acid has been extensively studied.[8] A series of heterotrisalts containing tellurium, vanadium, molybdenum, tungsten, phosphorus has been studied in these laboratories[9-11] and the work is now extended to study the heterotrisalt formation of tellurium, tungsten and molybdenum.

The preparation, analysis and some properties of ammonium telluro-tungstomolybdate and its salts with silver, strontium, barium, cerium, lead, iron and guanidine are reported in this communication.

Experimental

All the chemicals used were of E. Merck or B. D. H. pure quality. Ammonium telluro-tungstomolybdate-telluric acid (4.6 g) and molybdic acid (21.6 g) were refluxed in ammoniacal medium for 6 hr. Five grams of tungstic acid dissolved in sufficient quantity of ammonium hydroxide was added to the above solution and refluxed for another 10 hr. The solution was then evaporated to a small bulk and kept in a refrigerator for crystallization. White crystalline ammonium telluro-tungstomolybdate was obtained which was recrystallized and analysed. The compound is stable at room temperature but decomposes on heating or treatment with acids. The analytical data are shown in Table 1.

Its silver, strontium, barium, cerium, lead, iron and guanidine salts were prepared by adding silver nitrate, strontium acetate, barium chloride, cerous nitrate, lead nitrate, ferric chloride and guanidine hydrochloride solutions to the ammonium salt solution in water.

Tellurium was estimated as metallic tellurium and ammonia as described earlier.[8] Tungstic and molybdic acids were separated by standard method. The other cations silver, strontium, barium, cerium, lead, iron were estimated by usual gravimetric methods and guanidine by microanalytical method. The results are recorded in Table 1.

IR spectra (KBr phase) of ammonium and guanidine salts were recorded on Perkin Elmer infracord in 2—15 μ region.

Thermogravimetric analysis of ammonium salt was carried out on a Stanton Thermobalance of 1 mg sensitivity. The sample of the size 150—170 mesh was heated at a uniform rate of 3°C/min. The loss in weight was obtained as the furnace temperature is increased and the temperature recorded automatically. The TGA curve of ammonium telluro-tungstomolybdate has been given in Fig. 1.

The DTA of the ammonium salt was carried out as reported in an earlier communication.[9] The heating was carried out in nitrogen atmosphere also.

Results and Discussion

Assignment of definite structure to the heteropoly acids and their salts encounters a great difficulty on account of the large size of the molecules involved. However, the composition of ammonium telluro-tungstomolybdate has been arrived at on the basis of analytical results. The stability of the

Guanidine	$6(CN_3H_6)_2O \cdot 2TeO_3 \cdot WO_3 \cdot 10MoO_3 \cdot 20H_2O$	White $(CN_3H_6)_2O$:

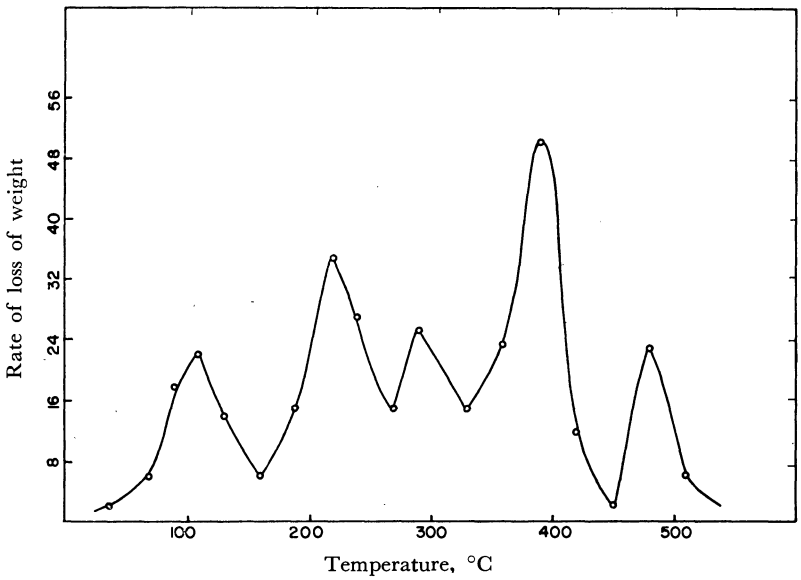

Fig. 1. TGA curve of ammonium telluro-tungstomolybdate.

anion has also been cenfirmed by passing freshly prepared solution of the ammonium salt through a cation exchange resin (Amberlite IR 120 in H^+ form). The composition of the solution after passing through the resin remained the same although free acid could not be crystallized from the solution due to its highly soluble nature. The precipitated silver, strontium, barium, cerium, lead, iron and guanidine salts conform to the same formula except that the cationic part is replaced by the respective metals.

The TGA curve of ammonium telluro-tungsto-molybdate (Fig. 1) shows the weight losses at 110, 222, 290, 390 and 480°C. The peaks upto 300°C are due to the dehydration of the compound which is in good agreement with the DTA curve (Fig. 2A) in which two endothermic peaks at 105 and 280°C are observed. After this temperature the decomposition of the compound occurs resulting in two peaks at 390 and 480°C.

The two endothermic peaks at 105 and 280°C in the DTA curve correspond to the dehydration of the compound. This clearly indicates that the water molecules are removed at two different temperatures, one at 105°C and the other at 280°C. The water molecules of crystallization are removed at 105°C and the water of constitution at a considerably higher temperature (280°C).

The characteristic exothermic peak at 380°C in DTA curve is either due to the oxidation or decomposition of ammonia at the surface of MoO_3 which acts as a ctalyst. The presence of exothermic peak due to the catalytic oxidation of ammonia has been observed by other workers while studying the thermal decomposition of ammonium molybdate[12] and ammonium vanadate[13]. The oxidation of ammonia in the last stage of decomposition has been suggested as a possible source of the exothermic heat. The nitrogen atmosphere

A. Ammonium telluro-tungstomolybdate
B. Ammonium telluro-tungstomolybdate in nitrogen

gives normal endothermic peaks (Fig. 2B) showing thereby that there is no oxidation of ammonia.

In IR spectra of ammonium and guanidine salts, the strong peaks at 3100 cm^{-1} and 3300 cm^{-1}, 1610 cm^{-1} and 1650 cm^{-1} respectively are due to the O–H stretch and O–H bending of water molecules present. In case of ammonium salt a strong peak at 1400 cm^{-1} is attributed to the characteristic deformation vibration of NH_4^+ ion [$\delta(NH_4)$], whereas a strong peak at 1550 cm^{-1} in case of guanidine salt is due to C=N stretch and N–H deformation of the guanidine molecule. The strong peak at 3300 cm^{-1} in case of guanidine salt may not be pure O–H stretch as it is being overlapped by N–H stretch vibrations of guanidine.

The vibrational bands appearing at 910 cm^{-1} in ammonium salt, 940 cm^{-1} and 880 cm^{-1} in guanidine salt may be due to mixed Mo–O and W–O vibrations. The regions of the absorption of the above vibrations are so close that in the compounds they overlap to a considerable extent to form broad bands. The argument may not be exactly valid since no discrete Mo–O or W–O modes of vibrations are present.

The sincere thanks of the author are due to (Late) Dr. Sarju Prasad for his keen interest and helpful suggestions, to Professor G. B. Singh and the authorities of the Banaras Hindu University for the facilities and to C. S. I. R., New Delhi for a research fellowship.

The Inert Gas Extraction-Gas Chromatographic Determination of Hydrogen in Ferrous Metals

Jiro KASHIMA and Takuo YAMAZAKI

The Castings Research Laboratory, Waseda University, Totsuka, Shinjuku-ku, Tokyo

(Received January 16, 1968)

The inert gas extraction-gas chromatographic technique has been applied for the determination of hydrogen in ferrous metals. As this method was dependent on gas chromatography, the simplification was performed on the apparatus and the analytical operation. A procedure was evolved, according to which the extracged hydrogen was measured by means of gas chromatography using the precolumn technique, *viz.*, (1) the hydrogen was rapidly transferred from the metal into an argon stream by means of H-F induction furnace, (2) this was concentrated into the cold precolumn for 4 min to collect the total amount of hydrogen from the extraction tube, (3) this was measured by gas chromatography. Analytical results obtained on 3 iron base metals suggest that the method can be widely used for the determination of hydrogen in ferrous metals.

Several methods for the determination of hydrogen in metals have recently been reviewed.[1] These include vacuum or inert gas extraction by heating or by melting and chemical methods. Among them, *viz.*, gas chromatography,[2,3] emission spectrometry[4] and isotope methods,[5,6] have recently been proposed for the determination of hydrogen in metals. Although hydrogen is generally determined by the hot-extraction method with fair accuracy, the vacuum fusion method[7] is usually employed to extract hydrogen completely in ferrous metals. Marincek and Feichtinger,[8] using a procedure based on the vacuum fusion method, found that some of hydrogen still remained in the metals over a range of temperature from 1300 to 2100°C. Bennek and Klotzbach[9] have proposed a reliable method based on tin-bath technique at 1100—1150°C using quartz crucible instead of graphite one being difficult to degass sufficiently. Bennek's method is widely used to de termine hydrogen in metals. The present paper deals with a procedure for the determination of hydrogen in ferrous metals by means of gas chromatography. The apparatus now in use consists of a compact and convenient unit. One hundred determinations of hydrogen have been carried out, and a reliable results for the extraction of hydrogen in steel and cast iron were obtained.

Experimental

Preparation of Samples. Steel and chill cast iron plate samples approximately 2 mm in thickness and lump ferro silicon samples were used for the test. Steel samples were prepared by cutting or breaking to an appropriate weight. Samples (1 to 1.5 g) were used after treatment of the surface. The treatment was as follows: (1) abrase with grinding paper (with exception of ferro silicon samples which break in pieces); (2) wash with carbon tetrachloride; (3) dry in hot stream of argon. It is advisable to dry the sample in the extraction tube every time just before the experiment, because the gas adsorbed on the surface of the treated sample is considerably increased during storage in a desiccator and then the removal of the gas dependent on sweeping gas is very troublesome.

Apparatus. The apparatus used for the determination of hydrogen in metals which is simplified by attaching a precolumn and is, therefore, different from usual gas collection methods, as shown in Fig. 1.

Purified argon (99.9%) was used as the carrier gas. The moisture contained in the carrier gas was removed by passing it through the desiccant tube.

Procedure. Prior to the analytical experiment, the carrier gas was passed continuously through an extraction system consisting of transparent quartz and glass tubes at 200°C for a few hours until the blank value of hydrogen could be maintained below 10^{-4} ml/min. A sample was introduced into a quartz crucible from upper part of the quartz tube under an argon flow (the flow rate is 60 ml/min) and was dried at 150°C for several minutes. After the flow rate was

controlled to 10 m*l*/min, the system was connected with the precolumn being held below −70°C. The sample was heated to 1400°C for 4 min, and the hydrogen, collected in this precolumn, was determined by gas chromatography.

GC Measurements. Hydrogen collected in the precolumn was measured by using a copper tube (4 mm in dia. ×2.5 m long) packed with Molecular Sieve 5A. The analytical conditions were as follows; column temperature, 45°C; carrier gas (argon) speed, 60 m*l*/min. The precolumn was made of a copper tube (4 mm in dia. ×70 cm long) packed with silica-gel. The operating conditions on the precolumn were as follows: column temperature, −70°C; carrier flow rate for collecting hydrogen, 10 m*l*/min. This precolumn was capable of concentrating hydrogen for 4 min at the operating conditions, as shown in Fig. 2. The hydrogen concentrated in precolumn was introduced without any warming the precolumn.

The method of the streaming of a gas was almost the same as had been reported in a previous paper.[10] A long main column was suitable for moderating the pressure change brought about by the streaming of a gas.

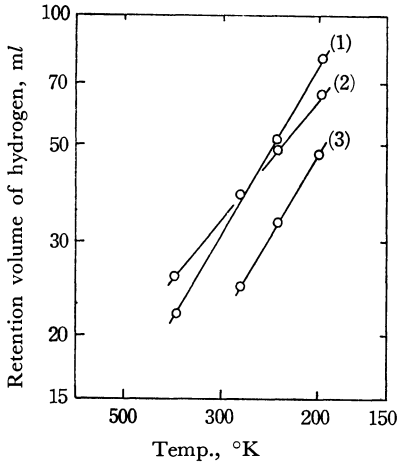

Fig. 2. Relationship between retention volume and concentration column temperature.

Results and Discussion

Reliability of the GC Measurements. The reliability of the GC measurements was tested by using each 0.5 m*l* of the mixed permanent gases kept in a gas container. The results are given in Table 1. This method was found to be convenient for the determination of hydrogen in metals because the gas sample could be concentrated into the precolumn in a short time. The precision was exceedingly good.

Table 1. The precision of GC measurements obtained by using the gas sample*

Concentration time, min	Peak areas, mm²		
	$H_2\times100$	$N_2\times100$	$CO\times10$
3	566	428	1469
3	531	432	1482
3	568	442	(1530)
4	529	441	1491
4	570	438	1459
Average	553	436	1486
Without precolumn	550	430	1461

* The contents of gases in the container were 42% hydrogen, 3.4% nitrogen and 6.6% carbon monoxide.

Inert Gas Extraction. Some typical examples of the extraction of hydrogen are shown in Fig. 3. These data were obtained by heating the samples at 1400°C (black circle) and by extracting hydrogen introduced into the tube without sample (white circle). The fact that, in actual practice, the extraction rate on stell sample 4 mm in thickness is almost the same as that of hydrogen evolution from the sample, reveals the possibility of the rapid extraction of hydrogen from the sample.

The degree of degassing of the sample, which

TABLE 2. REMOVAL OF HYDROGEN FROM STEEL PLATES HEATED AT 1400°C

Plate sample	$T=D_t/R^2$	Q_t/Q_0
2 mm Cast iron	$t=20$ sec → 0.8	0.85
	$t=40$ sec → 1.65	0.96
4 mm Steel	$t=30$ sec → 0.3	0.63
	$t=2.7$ min → 1.65	0.96
5 mm Steel	$t=30$ sec → 0.19	0.53
	$t=4.5$ min → 1.7	0.97
6 mm Steel	$t=30$ sec → 0.13	0.42
	$t=6.5$ sec → 1.7	0.97

Q_t/Q_0 was graphically obtained from the following equation:

$$\frac{Q_t}{Q_0} = \sum_{i=1}^{i=\infty} - \frac{2\sin^2\lambda_i}{\lambda_i^2 + \lambda_i\sin\lambda_i\cos\lambda_i}\left(1-e^{-\lambda_i^2 D_t/R^2}\right)$$

where Q_t is the amount of hydrogen extracted from the metal in time t, Q_0 is the initial hydrogen content of the metal and T is dimentionless time dependent on diffusion coefficient D, thickness ($2R$) and time.

was dependent on sample size, time and temperature, was calaulated according to Fick equation[11] which was obtained by Fistul' for a finite thickness, using dimensionless value. The results are summarized in Table 2. It is preferable to use a steel plate 2 mm in thickness, on the basis of the fact that, when the metal was heated to about 1400°C, the total amount of hydrogen was evolved in 50—60 sec. However, it takes about 4 min to transfer hydrogen into the precolumn. It is unsuitable to use plate samples more than 5 mm in thickness because it takes still 4 min more to extract hydrogen.

Reproducibility. The analyses of steel, cast iron and ferro silicon were carried out by this proposed method. A typical chromatogram of gases concentrated in the precolumn is shown in Fig. 4. The precision of the determinations is markedly dependent on the hydrogen content, hydrogen-pick-up by the walls of the quartz tube and the amount of the surface gas, correction of which under experimental conditions varies from 4 to 9×10^{-4} ml/cm^2. This amount was determined by rewashing an extracted sample and carring out a second extraction, as had been reported in a previous paper.[12] The reproducibility of this proposed method is represented by the following examples.

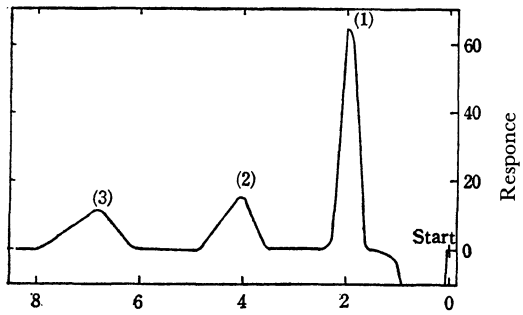

Fig. 4. Typical chromatogram of gases extracted from cast iron sample.
Hydrogen (1), nitrogen (2) and carbon monoxide (3)

(1) On a cast iron, data obtained from 8 determinations varied in the range 1.4—1.6 ppm, with a mean deviation of ±0.09 ppm.

(2) Duplicate determinations on each of 17 samples of mild steel gave results with a mean deviation of ±0.010 ppm. The hydrogen contents varied in the range 0.10—0.57 ppm.

(3) Duplicate determinations on each of 10 samples of ferro silicon gave results with a mean deviation of ±0.5 ppm. The hydrogen contents varied in the range 5.0—6.1 ppm.

Summary

A new inert gas extraction-gas chromatographic method for the determination of minute quantities of hydrogen in ferrous metals has been developed. This method was also available for trace analysis of hydrogen in the sample, because the blank value is extremely lower than that of the conventional method.

The Chromium(III) Complexes with Ammoniapropionicdiacetic Acid*[1]

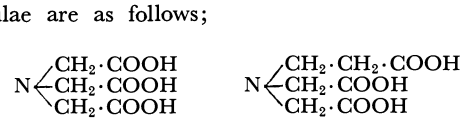
Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received February 5, 1968)

Ammoniapropionicdiacetic acid (APDA), which belongs to a group of chelating agents similar to that of ammoniatriacetic acid, was prepared. The newly-prepared complexes containing this chelating agent were as follows: $[Cr(OH)(apdaH)(H_2O)_2]$ (red purple) (I), NH_4-$[Cr(OH)(apda)(H_2O)]\cdot 2H_2O$ (purple) (II), $(NH_4)_3[Cr(apda)_2]\cdot 2H_2O$ (pink) (III), $(Cr(apda)$-$(bipy)]\cdot 3H_2O$ (brown) (IV), $[Cr(apda)(o\text{-phen})]\cdot 3H_2O$ (brown) (V), and $[Cr(apda)(py)_2]$(pink) (VI), where apda, bipy, *o*-phen, and py are the abbreviations of the ammoniapropionatediacetate ion, *o*-phenanthroline, 2,2'-bipyridyl, and pyridine respectively. On the basis of the chemical and thermal analyses, and on the basis of the measurements of the visible, UV, reflection and IR spectra and molar conductivities, it was concluded that the ammoniapropionatediacetate acts either as a terdentate or a quadridentate ligand in these complexes. Unlike the ATA complex, no complexes in which the nitrogen dose not coordinate with chromium could be prepared in the case of APDA. The values of the effective magnetic moments for these APDA complexes were nearly equal to the spin-only values of tervalent chromium. Further comparisons of the properties of the APDA complexes with those of the ATA complexes were also made.

The preparations of the Cr(III) complexes with ammoniatriacetic acid (ATA) have already been reported;[1,2] here ATA behaves toward a chromium(III) ion not only as a terdentate, but also as a quadridentate ligand. It was also found that some complexes have different coordinating structures in a crystal state and in an aqueous solution. When an additional methylene group ($-CH_2-$) is introduced into ATA, ammoniapropionicdiacetic acid (APDA) is obtained. It was expected that this will indicate how the behavior of APDA is chemically- and sterically-different from that of ATA in complex formation. Their rational formulae are as follows;



ATA APDA

The purposes of the present study were: (1) to investigate as what ligand an APDA can behave toward a chromium(III) ion; (2) to find out whether or not different structures are observed between the APDA complexes in a crystal state and in an aqueous solution, and, at the same time, (3) to compare the properties of the APDA complexes with those of ATA.

Experimental

Preparation of Ammoniapropionicdiacetic Acid, $C_7H_{11}O_6N$. The method of preparation described here is a modification of that one which has already been reported by Schwarzenbach *et al.*[3]

Ninety grams of β-alanine were neutralized with 300 m*l* of water containing 40 g of sodium hydroxide. Besides, 190 g of monochloroacetic acid were dissolved into about 300 m*l* of water and then gradually neutralized with 170 g of sodium bicarbonate. These two neutralized reagents were then mixed and heated on a water bath. When the temperature of the mixed solution reached *ca.* 70°C, 200 m*l* of water containing 80 g of sodium hydroxide were added. The temperature immediately increased because of the exothermic condensation reaction. After the reaction was over, the resultant solution was cooled to room temperature. The gradual addition of concentrated hydrochloric acid and stirring with glass rod produced white, powdered crystals. The recrystallization was achieved by dissolving the crude products into water containing an appropriate amount of sodium bicarbonate, and then by gradually adding hydrochloric acid to the solution.

Yield, about 160 g.

Found: N, 6.42; C, 40.72; H, 5.39%. Calcd for $C_7H_{11}O_6N$: N, 6.84; C, 40.98; H, 5.40%.

Preparation of the Complexes. *1) Hydroxohydrogenammoniapropionicdiacetatodiaquochromium(III),* $[Cr(OH)(apdaH)(H_2O)_2]$ (I). Thirteen grams of chromium(III) chloride hexahydrate were dissolved into 200 m*l* of water, and then 10 g of APDA were added to them. The mixed solution was heated on a water bath until no residue of the unreacted APDA could be seen. Then

2) A. Uehara, E. Kyuno and R. Tsuchiya, *ibid.*, **40**, 2322 (1967).

3) G. Schwarzenbach, H. Ackermann and P. Ruckstuhl, *Helv. Chim. Acta*, **32**, 1175 (1949).

the reddish purple crystals could easily be obtained from its cooled (room temperature) solution. The products were recrystallized from its concentrated purple solution of water. Yield, about 6 g.

Found: Cr, 16.76; N, 4.64; C, 27.61; H, 4.36%. Calcd for $[Cr(OH)(apdaH)(H_2O)_2]$: Cr, 16.84; N, 4.53; C, 27.24; H, 4.57%.

2) Ammonium Hydroxoammoniapropionicdiacetatoaquochromate(III) Dihydrate, $NH_4[Cr(OH)(apda)(H_2O)]\cdot 2H_2O$ (II). Ten grams of Complex I, obtained above, were dissolved into 200 m*l* of water containing 1.8 g of ammonium carbonate, and then the mixture was cooled to 0°C. Purple crystals were thus obtained. Recrystallization was achieved from its concentrated aqueous solution. Yield, about 2 g.

Found: Cr, 14.83; N, 7.96; C, 24.06; H, 5.87; H_2O,*2 9.8%. Calcd for $NH_4[Cr(OH)(apda)(H_2O)]\cdot 2H_2O$: Cr, 15.13; N, 8.15; C, 24.46; H, 5.57; H_2O, 10.48%.

3) Ammonium Bis-(ammoniapropionicdiacetato)chromate-(III) Dihydrate, $(NH_4)_3[Cr(apda)_2]\cdot 2H_2O$ (III). Seven grams of APDA were neutralized with 200 m*l* of water containing 4 g of ammonium carbonate, and then 10 g of Complex I were added. The mixed solution was evaporated to dryness on a water bath. Crude, pale-red crystals were thus obtained. The product was recrystallized from one percent of an aqueous ammonium carbonate solution. Yield, about 2.5 g.

Found: Cr, 9.82; N, 12.90; C, 29.94; H, 6.19; H_2O, 6.8%. Calcd for $(NH_4)_3[Cr(apda)_2]\cdot 2H_2O$: Cr, 9.52; N, 12.81; C, 30.75; H, 5.89; H_2O, 6.85%.

An attempt to obtain crystals such as $NH_4[Cr(apdaH)_2]$, in which one of the carboxyl groups of an APDA does not participate in the coordination, was unsuccessful because of the deposition of the I crystals. On the other hand, in the case of ATA, we were successful in obtaining the corresponding pink crystals of $NH_4[Cr(ataH)_2]\cdot 2H_2O$.[1]

4) Ammoniapropionicdiacetato-2,2'-bipyridylchromium(III) Trihydrate, $[Cr(apda)(bipy)]\cdot 3H_2O$ (IV). Ten grams of I were dissolved into 300 m*l* of water containing 3 g of ammonium carbonate, and then 5 g of 2,2'-bipyridyl neutralized with 6 m*l* of concentrated hydrochloric acid were added. After the mixed solution had been heated on a water bath until it changed from purple to reddish purple, it was cooled to 0°C. Then, brown crystals were separated out. The product was recrystallized from a concentrated aqueous solution or from alcohol. Yield, about 6 g.

Found: Cr, 10.76; N, 9.13; C, 44.49; H, 4.82; H_2O, 12.1%. Calcd for $[Cr(apda)(bipy)]\cdot 3H_2O$: Cr, 11.18; N, 9.04; C, 43.93; H, 4.63; H_2O, 11.72%.

5) Ammoniapropionicdiacetato-o-phenanthrolinechromium-(III) Trihydrate, $[Cr(apda)(o\text{-phen})]\cdot 3H_2O$ (V). Ten grams of I were dissolved into 300 m*l* of water containing 3 g of ammonium carbonate, and then 6 g of *o*-phenanthroline neutralized with 6 m*l* of concentrated hydrochloric acid were added. After the mixed solution had been heated on a water bath until it changed from purple to brown, it was cooled to 0°C; then, brown crystals were separated out. Recrystallization was achieved from water or from an alcohol solution. Yield, about 8 g.

Found: Cr, 10.16; N, 8.82; C, 46.70; H, 4.82; H_2O, 11.7%. Calcd for $[Cr(apda)(o\text{-phen})]\cdot 3H_2O$: Cr, 10.63; N, 8.59; C, 46.68; H, 4.53; H_2O, 11.14%.

6) Ammoniapropionicdiacetatodipyridinechromium(III), $[Cr(apda)(py)_2]$ (VI). Eleven grams of Complex II were dissolved into 30 m*l* of water containing 3 m*l* of concentrated hydrochloric acid, and then 150 m*l* (excess) of pyridine were added. This solution was heated on a water bath by using a reflux-condenser. After the solution had gradually changed in color from purple to pale red, it was immediately cooled to 0°C. Pink crystals were thus obtained. The product was recrystallized from absolute alcohol or from absolute pyridine. Yield, about 3 g.

As will be mentioned below, it was found that these crystals lost the coordinated pyridine, even at room temperature.

Found: Cr, 13.15; N, 9.38%. Calcd for $[Cr(apda)(py)_2]$: Cr, 12.61; N, 10.19%.

Apparatus. The UV and IR absorption spectra were measured with a Hitachi EPS Spectrometer and a Nippon Bunko IR-E Spectrometer respectively, while the reflection spectra were measured in a finely-powder solid state using a Hitachi EPU-2A Spectrometer equipped with the standard Hitachi reflection attachment. The thermal analyses and the conductivity and the magnetic-susceptibility measurement were carried out with a Metrimpex Derivatograph, a Yokogawa Universal Bridge BV-Z-13A, and a Gouy-Balance respectively.

Results and Discussion

Thermal Analyses. By using the derivatograph, three measurements, a thermogravimetric analysis (TGA), a differential thermogravimetric analysis (DTG), and a differential thermal analysis (DTA), can be carried out simultaneously. In this study, above all DTA and TGA were effectively used in order to ascertain the compositions of the complexes obtained. Their DTA, TGA, and temperature curves (T) are shown in Figs. 1-(A)—(F). All the measurements were carried out at a heating rate of 1°C/min in a constant nitrogen stream. The reddish-purple crystals of I gradually lose one mole of water from 130 to 160°C, and then 2 mol of water up to 230°C, as is shown in Fig. 1(A). It was found that the color changed from reddish purple to purple and then to green during the heating. These dehydration temperatures seem to be a little higher than that of crystalline water. More detailed discussions will be undertaken elsewhere.

The waters of crystallization in Complexes II, III, and V are all evolved by the decomposition up to 130°C (Figs. 1-(B), 1-(C) and 1-(E)). For Complex IV, the initial two moles of the crystalline waters and the last one were step-by-step liberated at 90°C and 150°C respectively (Fig. 1-(D)). The coordinated pyridine molecules in VI were liberated at rather a lower temperature (from room temperature to 80°C), as is shown in Fig. 1-(F).

*2 The H_2O appearing in all the analytical data in this paper shows the crystalline water estimated from the derivatogram.

Behavior of the Complexes in Reaction to the Ion Exchanger and Their Molar Conductivity. The behavior of the complexes in reaction to the ion exchanger and the values of their molar conductivities in a 1×10^{-3} mol/*l* solution are listed in Table 1. The + sign shows the possibility of the adsorption of the complexes by the exchanger, while — shows non-adsorption. It is shown in the table that Complexes I, IV, V, and VI were not adsorbed by either exchanger, and that their molar conductivities are extremely small (1—2 mho cm^{-1}), indicating that these complexes are non-electrolytes. On the other hand, the purple crystal, II, and the pink crystal, III, are shown to be adsorbed by the anion exchanger; additionally, their molar conductivities are 121.2 and 346.2 mho cm^{-1} respectively, showing that they are 1 : 1-type and 1 : 3-type electrolytes respectively.

Electronic Absorption Spectra. The absorption spectra for the six complexes from I through VI were all measured in aqueous solutions; those

for III and VI were measured in a buffer solution of pH 6 and in an alcohol-water solution, respectively in order to prevent gradual decomposition. Their spectra concerned are shown in Figs. 2—5, while the numerical values of their absorption maxima are summarized in Table 2.

Figure 2 shows the absorption spectra for the purple solutions of Complex I, of I heated at 160°C, and of the ATA complex (known to have the same structure as, $[Cr(ata)(H_2O)_2]$); in this figure the scale of the ordinate for the $[Cr(ata)(H_2O)_2]$ is arbitrary. Since the spectra of these three complexes show very similar forms, they are considered to have an identical structure in solutions.

The absorption spectra of I, II, and VI for the solid state, as measured by the diffuse-reflection method, are shown in Figs. 6—8. In Fig. 6, a full line shows the absorption spectrum for the solid state of I, while a dotted line gives that of a product which has lost one mole of water upon being heated at 160°C, as has been shown in thermal analyses described above. As Figs. 2 and 6 show, the spectra for the solution of I heated at 160°C and for the solution of I itself have analogous aspects, and differ from that for the solid state of I. Therefore, it may be considered that in solution Complex I has a structure identical with that of $[Cr(ata)(H_2O)_2]$, but not in a crystal state, and that certain changes in the structure occur upon heating.

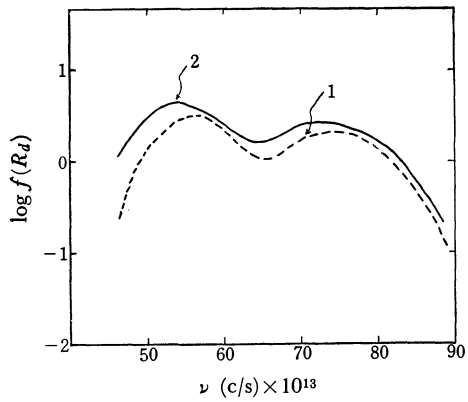

Fig. 6. Electronic absorption spectra for the solid states of
1: $[Cr(OH)(apdaH)(H_2O)_2]$,

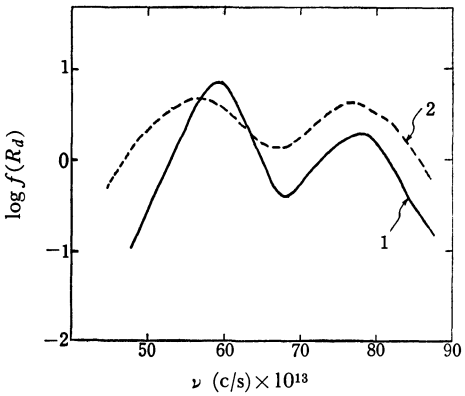

Fig. 8. Electronic absorption spectra for the solid states of
1: $[Cr(apda)(py)_2]$,
2: $[Cr(apda)(py)_2]$ exposed in air.

In Fig. 3, the absorption spectra of the purple crystals of II and the corresponding ATA complex are shown. These curves seem to be somewhat different from each other. On the other hand, Fig. 7 shows the absorption spectra of these complexes in the solid state; these spectra are quite similar to each other. One possible interpretation in these results is given below. In the preceding paper,[1] as ATA complexes corresponding to II, $NH_4[Cr(OH)(ata)(H_2O)]\cdot 2H_2O$ and $NH_4[Cr(OH)(ata)(H_2O)_2]\cdot 3H_2O$ were obtained. The former complex turned from purple to green when dissolved in water; from this it was concluded that this purple crystal is a $[Cr\cdot N\cdot O_5]$-type complex, while the product in the green solution was a $[Cr\cdot O_6]$-type one, in which the nitrogen atom is not directly coordinated to chromium. In the latter ATA complex, also, the nitrogen atom in ATA was not directly coordinated to chromium in either a solution and in a solid state. Nevertheless, in the crystal of APDA complex II, the nitrogen atom in APDA participates in coordination together with the three carboxyl groups, and we have not succeeded in preparing the $[Cr\cdot O_6]$-type complex corresponding to the green ATA complex described above.

The absorption spectra for the solutions of the pink crystal of III and of the one which was left

* The absorptions arising from 2,2'-bipyridyl.
** Those from *o*-phenanthroline.
*** Those from pyridine.

to stand overnight are shown in Fig. 4. The former spectrum indicates a splitting on the first band (a d–d electron transition). This may mean that this crystal has a *trans* structure with respect to the nitrogen atoms in APDAs. Upon standing overnight this solution gradually turned from pink to purple and its spectrum became quite similar to that of II (Figs. 3 and 4). This suggests that there is a gradual decomposition of $[Cr(apda)_2]^{3-}$ to $[Cr(OH)(apda)(H_2O)]^-$. On the other hand, $[Cr(ata)_2]^{3-}$ decomposed to $[Cr(OH)(ata)(H_2O)_2]^-$.[1]

Figure 5 shows the spectra for the solutions of the IV, V, and VI complexes, and that of III exposed to air for three days. The former two give complicated curves similar to those of the corresponding ATA complexes; this was a result of the coordination of 2,2'-bipyridyl and *o*-phenanthroline.[2] In solution, the pink crystals of VI have two absorption peaks, at 57.0 and 77.5, and a shoulder at 107.1×10^{13} c/s (in Curve 3), but the shoulder disappeared and the two peaks shifted to a longer wavelength region in VI which had been exposed to air (in Curve 4), as is shown in Fig. 5. Such a change was also found in the solid state (Fig. 8). These facts indicate that the coordinated pyridines are liberated from the crystals even at room temperature.

Infrared Spectra. The infrared spectra were measured in order to determine whether or not the carboxyl groups in the complexes were coordinated. The numerical values of the absorption bands arising from the carboxyl groups and the other ligands are listed in Table 3, while the spectra of Complex I concerning carboxyl-group stretching are shown in Fig. 9. The crystal of I gives two strong bands due to the carboxyl groups; one is a 1693 cm^{-1}, and the other is a 1670—1598 cm^{-1}. The former may be assigned to the stretching of free carboxylic acid, which disappears upon heating at 160°C, whereas the latter may be assigned to that of the coordinated carboxyl group. The shoulder at 1605 cm^{-1}, appearing only in III, suggests that it has free carboxylate ions. The other complexes show strong absorption bands in

Fig. 9. Infrared spectra for
1: $[Cr(OH)(apdaH)(H_2O)_2]$,
2: $[Cr(OH)(apdaH)(H_2O)_2]$ heated at 160°C.

the region of 1590—1680 cm^{-1}, suggesting that all the carboxyl groups are coordinated. Further, IV, V and VI show bands reflecting the vibrations of C=C, C=N, and C–H in coordinated 2,2'-bipyridyl, *o*-phenanthroline and pyridine.

Magnetic Moment. The effective magnetic moments of these complexes were evaluated from the magnetic susceptibilities as measured by the Gouy method. The numerical data, corrected by introducing each Pascal constant, are summarized

Table 4. Magnetic moments (B. M.)

Complex	B. M. (temp.)
I	3.88 (293°K)
II	3.70 (293°K)
III	3.75 (293°K)
IV	3.88 (293°K)
V	3.84 (293°K)
VI	3.82 (293°K)

in Table 4. These values, 3.7—3.9 B. M., are nearly equal to the spin-only values for tervalent chromium.

Discussion of the Structures and Some Comparisons with the ATA Complexes. The possible structues of these complexes will now be discussed and comparisons will be made with the ATA complexes on the basis of the above results. Fig. 10 shows the patterns of the possible structures, (A), (B), (C), and (D), proposed by the present authors. The classification of the success or

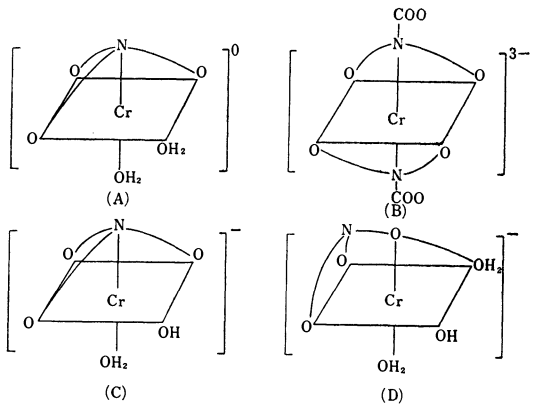

Fig. 10. Possible structures.

failure in the preparation of the ATA and APDA complexes of these four types are summarrized below:

Type	Ligand	
	ATA	APDA
A	×	○
B	○	○
C	○	○
D	○	×

where ○ indicates success in preparation and × shows failure. The crystal of the A-type complex was obtained with APDA, but not with ATA. This may be mainly due to the much lower solubility in the former complex than that in the latter. The B-type complex was prepared with both chelating agents. In the ATA complex, there was a successive decomposition from B to D, but one from B to C was found in the APDA complex. Although the C-type complex was obtained with both ligands, an instantaneous change (in an aqueous solution) into D occurred in the ATA complex, but not in the APDA complex. As has already been reported, the introduction of the methylene group ($-CH_2-$) into ATA probably results in a little more stable complex formation. The inspection by using the molecular model suggests that there is a larger strain on the nitrogen atom in coordination in the ATA complex than in that with the APDA complex. As a result of this steric factor, the nitrogen atom in APDA has the larger coordinating ability than that in ATA. This fact is consistent with the expectation as to the stability shown by Martell *et al.*[4] The failure to prepare the D-type complex, in which the nitrogen atom in APDA does not participate in the coordination, may also support such a steric reason as that described above. With all the mixed ligand complexes, the APDA always acts as a quadridentate ligand.

Finally, as is drawn below, in Complex I there are some interactions between the hydrogen atom in the free carboxylic acid and the oxygen atom in the coordinated OH group; when heated at 160°C the oxygen atom within the free carboxylic acid may participate in the coordination by losing one mole of water. A fact similar to this has previously been reported by one of the present authors.[5]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2393—2400 (1968)

The Chromium(III) Complexes with Ammoniaisopropionicdiacetic Acid*[1]

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received February 19, 1968)

A new chelating agent—ammoniaisopropionicdiacetic acid (abbreviated as AIPDA), one of the derivatives of ammoniatriacetic acid, was prepared. Also, the following chromium(III) complexes containing AIPDA as a ligand were newly prepared: $NH_4[Cr(OH)(aipda)(H_2O)]\cdot 4H_2O$ (purple) (I), $NH_4[Cr(OH)(aipda)(H_2O)_2]\cdot 2H_2O$ (green) (II), $[Cr(aipda)(o\text{-phen})]\cdot 2H_2O$ (brown) (III), $[Cr(aipda)(bipy)]\cdot 3H_2O$ (brown) (IV), [Cr(aipda)(*l*-pn)] (pink) (V), $[Cr(aipda)(py)_2]$ (pink) (VI) and $NH_4[Cr(OH)(aipda)(py)]\cdot 2H_2O$ (reddish purple) (VII), where apipda, *o*-phen, bipy, *l*-pn and py are the abbreviations of the ammoniaisopropionatediacetate ion, *o*-phenanthroline, 2,2'-bipyridyl, *l*-propylenediamine and pyridine respectively. On the basis of the chemical and thermal analyses and the measurements of the electronic absorption spectra, the reflection spectra, and the IR spectra, it was found that, in these complexes, AIPDA can behave as a terdentate or a quadridentate ligand to chromium(III), but the 1 : 2 Cr(III) AIPDA complex like the corresponding ATA one could not be obtained because of the steric hindrance resulting from the introduction of a methyl group into ATA. Further information on the conductivities in an aqueous solution and the reflection spectra suggests that V and VI are gradually aquated. The properties of the AIPDA complexes obtained in the present study were compared with those of ammoniatriacetic acid and those of ammoniapropionicdiacetic acid complexes.

The preparations of the chromium(III) complexes containing ammoniatriacetic acid (ATA) and ammoniapropionicdiacetic acid (APDA) as the chelating agents have already been reported[1-3]; these two complexes behave quite differently. For example, ATA formed a more stable complex as a terdentate (O_3 type) than as a quadridentate ($N\text{-}O_3$ type) ligand in an aqueous solution, while in the solid state it formed a more stable one as a quadridentate ligand. On the other hand, AIPDA did not behave thus as a terdentate ligand (O_3 type).

When one of the hydrogen atoms in a $-CH_2-$ group in ATA is replaced with a methyl group, ammoniaisopropionicdiacetic acid (AIPDA) is obtained. This reagent is expected to indicate any chemically and sterically unique behavior in the complex formation, differing from ATA or APDA. The formula of AIPDA is drawn in Fig. 1, together with those of ATA and APDA. AIPDA has one nitrogen and three oxygen atoms capable of coordinating; therefore, it can be expected to behave either as a quadridentate ligand ($N\text{-}O_3$ type) or as a terdentate ligand ($N\text{-}O_2$ type or O_3 type). On the basis of these observations, this study aimed to find how AIPDA behaves toward a chromium(III) ion and to compare the properties of the AIPDA complexes with those of the ATA and APDA complexes.

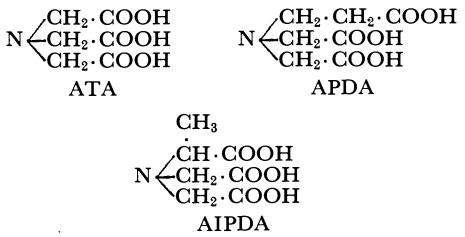

Fig. 1. Structures of the chelating agents.

Experimental

Preparation of Ammoniaisopropionicdiacetic Acid, $C_7H_{11}O_6N$. Ninety grams of *d,l*-α-alanine were neutralized with 200 m*l* of water containing 57 g of potassium hydroxide. Besides, 190 g of monochloroacetic acid was dissolved in about 300 m*l* of water and then gradually neutralized with 200 g of potassium hydrogencarbonate. The two neutralized reagents were then mixed and heated on a water bath. When the temperature of the solution was raised to *ca.* 70°C, 200 m*l* of water containing 112 g of potassium hydroxide was added. Because of the exothermic reaction, the temperature was immediately raised. After the reaction was over, an appropriate amount of concentrated hydrochloric acid was added to the solution until the

*1 Presented in part at the 17th Symposium on Coordination Compounds, Hiroshima, December, 1967.

2) A. Uehara, E. Kyuno and R. Tsuchiya, *ibid.*, **40**, 2322 (1967).
3) A. Uehara, E. Kyuno and R. Tsuchiya, *ibid.*, **41**, 238 (1968).

value of pH dropped from 9 to 1—2. The potassium chloride depositing out first was filtered off. The filtrate was again concentrated to as small an amount as possible. To the resultant solution, an appropriate amount of acetone was gradually added, and then the solution was scrubbed with a glass rod until white, powdered crystals were obtained, after which the solution was kept at 0°C. Recrystallization was achieved from cold water. It is considerably soluble in water, but, is insoluble in alcohol and ether. Yield, about 100 g.

Found: N, 6.43; C, 41.21; H, 5.30%. Calcd for $C_7H_{11}O_6N$: N, 6.84; C, 40.98; H, 5.40%.

Preparations of the Complexes. The methods of preparing the complexes containing AIPDA are very simmilar to those used to prepare those with ATA.[1]

1) Ammonium Hydroxoammoniaisopropionicdiacetatoaquochromate(III) Tetrahydrate, $NH_4[Cr(OH)(aipda)(H_2O)]\cdot 4H_2O$ (purple) (I). Approximately 4.2 g of AIPDA and an appropriate amount of chromium(III) hydroxide freshly prepared from 10 g of chromium alum and aqueous ammonia were mixed in 100 m*l* of hot water; then the mixture was evaporated almost to dryness. The residue was once dissolved in 30 m*l* of not water, and the resultant purple solution was filtered from the residue undissolved. By using this purple solution as a starting material, complexes I and II were prepared as below.

To this purple solution, about 1.5 g of ammonium carbonate were added and the pH was adjusted to 5—6. After it had been cooled to 0°C, purple, scale-like crystals were obtained. The products were recrystallized from their concentrated, greenish solution. Yield, about 1 g.

Found: Cr, 13.42; N, 7.26; C, 21.96; H, 6.81; H_2O,*2 19.7%. Calcd for $NH_4[Cr(OH)(aipda)(H_2O)]\cdot 4H_2O$: Cr, 13.68; N, 7.36; C, 22.12; H, 6.12; H_2O, 19.11%.

2) Ammonium Hydroxoammoniaisopropionicdiacetatodiaquochromate(III) Dihydrate, $NH_4[Cr(OH)(aipda)(H_2O)_2]\cdot 2H_2O$ (green) (II). To the purple solution obtained above, about 2.5 g of ammonium carbonate were added and the pH was adjusted to 7—8. When it was cooled to 0°C, green, scale-like crystals were obtained. Since it was, sometimes, contaminated with purple crystals of I, the pH had to be well adjusted to the above value. The recrystallization was achieved from its concentrated, greenish solution, the pH having been adjusted to 7—8 by adding an appropriate amount of ammonium carbonate. Yield, about 1 g.

Found: Cr, 14.25; N, 7.53; C, 22.96; H, 5.71; H_2O, 9.7%. Calcd for $NH_4[Cr(OH)(aipda)(H_2O)_2]\cdot 2H_2O$: Cr, 14.73; N, 7.74; C, 23.23; H, 5.85; H_2O, 10.03%.

3) Ammoniaisopropionicdiacetato - o - phenanthrolinechromium(III) Dihydrate, $[Cr(aipda)(o\text{-phen})]\cdot 2H_2O$ (brown) (III). About 6 g of *o*-phenanthroline and 2.6 m*l* of concentrated hydrochloric acid were added to about 50 m*l* of water containing 10 g of Complex I. When the solution was then heated for several minutes on a water bath, brown crystals were separated out. The recrystallization was achieved from water. Yield, about 3 g.

Found: Cr, 11.07; N, 8.90; C, 48.09; H, 4.10; H_2O, 7.5%. Calcd for $[Cr(aipda)(o\text{-phen})]\cdot 2H_2O$: Cr, 11.04; N, 8.92; C, 48.48; H, 4.28; H_2O, 7.71%.

4) Ammoniaisopropionicdiacetato - 2,2' - bipyridylchlomium(III) Trihydrate, $[Cr(aipda)(bipy)]\cdot 3H_2O$ (brown) (IV). Five grams of 2,2'-bipyridyl and 2.6 m*l* of concentrated hydrochloric acid were added to about 50 m*l* of water containing 10 g of I. When the solution was then heated on a waterbath for several minutes, brown crystals were obtained. The products were recrystallized from water. Yield, about 4 g.

Found: Cr, 11.02; N, 9.27; C, 44.00; H, 4.11; H_2O, 12.0%. Calcd for $[Cr(aipda)(bipy)]\cdot 3H_2O$: Cr, 11.18; N, 9.04; C, 43.93; H, 4.63; H_2O, 11.72%.

5) Ammoniaisopropionicdiacetato - l - propylenediaminechromium(III), $[Cr(aipda)(l\text{-pn})]$ (pink) (V). About 2 g of *l*-propylenediamine were diluted with 20 m*l* of water and then 2.4 m*l* of concentrated hydrochloric acid were added. To this solution, a 50 m*l* portion of water containing 10 g of I was added, and resultant solution was evaporated to dryness; pink powdered crystals were thus obtained. The crude products were recrystallized from an alcohol-water (1 : 1) mixture. Yield, about 2 g. In an aqueous solution, these crystals were gradually aquated.

Found: Cr, 15.61; N, 12.21; C, 36.94; H, 5.54%. Calcd for $[Cr(aipda)(l\text{-pn})]$: Cr, 15.84; N, 12.80; C, 36.58; H, 5.52%.

The use of *d*- or racemic-propylenediamine instead of *l*-propylenediamine gave a corresponding *d*- or *d,l*-pn complex.

6) Ammoniaisopropionicdiacetato - bis (pyridine) chromium(III), $[Cr(aipda)(py)_2]$ (pink) (VI). Then grams of I were dissolved into 10 m*l* of water containing 2.4 m*l* of concentrated hydrochloric acid, and then 150 m*l* of pyridine were added to it. This mixture was heated on a water bath, using a reflux condenser in order to prevent the pyridine from vaporizing. After the solution had gradually turned from purple to pale red, it was cooled to 0°C. After it had then stood for a few days, pink crystals were obtained. The recrystallization was achieved from absolute alcohol or absolute pyridine. Yield, about 1 g.

Found: Cr, 12.91; N, 9.54%. Calcd for $[Cr(aipda)(py)_2]$: Cr, 12.61; N, 10.19%.

The elementary analyses were repeated several times, but fully satisfactory results could not be obtained since the crystals easily lose the pyridine, even at room temperature. On the basis of the derivatography, the change in the TGA curve, corresponding to two moles of pyridine, reasonably supports such a composition as $[Cr(aipda)(py)_2]$.

7) Ammonium Hydroxoammoniaisopropionicdiacetatopyridinechromate(III) Dihydrate, $NH_4[Cr(OH)(aipda)(py)]\cdot 2H_2O$ (reddish purple) (VII). Ten grams of I were dissolved into 50 m*l* of water, and then 25 m*l* of pyridine was added to the mixture. Being gradually heated on a water bath at *ca.* 40—60°C, the solution turned from green to pink. As soon as reddish purple crystals appeared, the crystals had to be quickly filtered off from the solution since the purple crystals, I, were inclined to deposit as a by-product. The recrystallization from water was always unsuccessful due to the deposition of the purple crystals, I. Moreover, since no optimum solvent for VII was found, no recrystallization could be done. Yield, about 1.5 g. For the above reasons, the results of the elementary analyses were not in

*2 The H_2O which appears in all the analytical data in this paper shows the only distinct crystalline water estimated from the derivatogram.

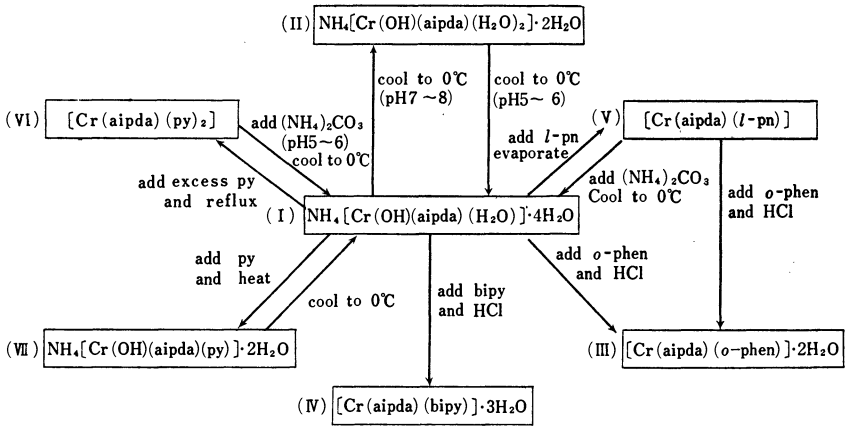

Fig. 2

excellent agreement with the calculated values shown below.

Found: Cr, 12.24; N, 9.80; C, 35.28; H, 4.97; H_2O, 8.2%. Calcd for $NH_4[Cr(OH)(aipda)(py)]\cdot 2H_2O$: Cr, 12.83; N, 10.38; C, 35.59; H, 5.45; H_2O, 8.92%.

The crystalline-water content in these complexes was estimated from the weight loss in the respective thermogravimetric curves (TGA), which were measured with a derivatograph.

Preparative Interconversion among These Complexes. Some interconversions among the complexes prepared in the present work were successful, as in the case of ATA. In Fig. 2, several interconversion procedures are shown schematically.

A) The Interconversion from I to II and Vice Versa. The pH of the greenish solution of I was adjusted to 7—8 by adding small amounts of amonium carbonate; when it had cooled to 0°C, green crystals, II, were obtained. On the other hand, when hydrochloric acid was used instead of ammonium carbonate, the pH of the greenish solution of II was descreased to 5—6 at 0°C, and purple crystals of I were obtained.

B) The Interconversion from V or VI to I. To 10 m*l* of an aqueous solution containing 1 g of V or VI, 0.2 or 0.3 g of ammonium carbonate was added respectively. These solutions turned from pink to green. When they were cooled to 0°C, purple crystals, I, were obtained.

C) The interconversion from V to III. One gram of *o*-phenanthroline was dissolved into 20 m*l* of water containing about 0.5 m*l* of concentrated hydrochloric acid. To this solution, 1.7 g of V were then dissolved by heating it on a water bath. The solution gradually changed from pink to brown. After the resultant solution had stood for several days, brown crystals, III, were obtained.

Apparatus. The apparatus used in this study was the same as has been described in a previous paper.[3)]

Results and Discussion

Thermal Measurements. The DTA, TGA, and temperature curves obtained for the complexes are shown in Figs. 3-A to 3-G, where the scale of DTA is arbitrary; the upper-side deviation of DTA indicacates the appearance of an exothermic reaction, and the under-side one, that of the endothermic reaction. All the measurements were carried out with a heating rate of 1°C/min in a nitrogen stream. As can be seen in Figs. 3-A to 3-D, the I, II, III, and IV complexes are all dehydrated between about 60 and 120°C and decomposed at about 290—300°C. Especially the step-by-step dehydration was observed for Complexes I and III. Figure 3-E shows that Complex V has no crystalline water. The complexes of VI and VII are shown in Figs. 3-F and 3-G to lose their coordinated pyridines, even at relatively low temperatures (from room temperature to 80°C). Moreover, in Complex VII, as may be seen in Fig. 3-G, the liberation of crystalline water was well detected after it had lost coordinated pyridine.

The values of the enthalpy changes in these decomposition processes, which can be evaluated from the DTA curves, will be reported elsewhere.

Behavior in Reaction to the Ion Exchanger and Molar Conductivity. The behavior in reaction to the ion exchangers and molar conductivities of a 1/1000 molar solution of the samples are shown in Table 1, in which the + symbol indicates the adsorption of the complexes by an exchanger, and −, the non-adsorption. The solutions of the purple crystals, I, and the green crystals, II, were both greenish and were adsorbed by the Cl-form anion exchanger. Their molar conductivities are 115.0 and 116.2 mho cm^{-1} respectively, suggesting that they are 1 : 1-type complexes. The value of the conductivity, 98.6 mho cm^{-1}, for VII and its ability to be adsorbed by the Cl-form exchanger indicate that it is also of this type. The complexes of III to VI were adsorbed neither by the Na-form nor the Cl-form exchanger, showing that they are all non-electrolyte molecules. A gradual decomposition in an aqueous solution was found for both V and VI, when their colors turned purple, and the decomposed solutions could not be adsorbed by the exchangers, suggesting that the aquations probably, in part at

those for the corresponding ATA complexes and for the purple solutions of AIPDA and ATA complexes, where the scale of log ε for the purple solutions is arbitrary. A very close resemblance was seen among the spectra for the solutions of I, II, and the corresponding ATA complex.

The absorption spectra for the solid state were measured by the diffuse-reflection method. The spectra for the solid state of I and II are shown in Fig. 5. An appreciable difference between them can be seen. From these data, as with the corresponding ATA complex,[1] both the purple complex, I, and the green complex, II, may be considered to have the same structure, of the [Cr·O$_6$] type in an aqueous solution, whereas in the crystal state they have different structures (*i. e.*, the purple complex is of the [Cr·N·O$_5$] type, and the green complex, of [Cr·O$_6$] type). In addition, the purple solution used as a starting material gave a spectrum very similar to that of the corresponding purple solution of the ATA complex, showing that they have the same structure.

The spectra for the solutions of the brown crystals of III and IV gave complicated curves similar to those of the corresponding ATA and APDA complexes due to the coordination of 2,2'-bipyridyl and *o*-phenanthroline, as can be seen in Fig. 6.

The absorption spectra for the solutions of the pink crystal V, the pink crystal VI, and the reddish-purple crystal VII are drawn in Fig. 7. The complexes of VI and VII show a third absorption maximum, due to the coordinated pyridine. The complexes of V and VI in an aqueous solution have a tendency to lose *l*-propylenediamine and pyridine respectively, and their spectra are found to approach that of the purple solution used as a starting material, as is shown in Fig. 8. This indicates that these complexes may undergo aquation by losing *l*-propylenediamine and the pyridine molecule respectively. Figure 9 shows the absorption spectra for the solid states of Complex VI itself and Complex VI after it has been exposed to air for a few days. A considerable difference between them can be seen; namely, the latter has its maximum at a lower frequency region than the former. This shows that VI easily loses the coordinated pyridine molecules, even at room temperature. Such a phenomenon has also been found in the corresponding APDA complex.[3]

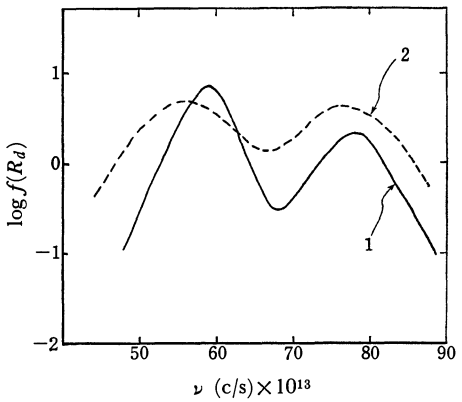

Fig. 9. Electronic absorption spectra for the solid states of
1: [Cr(aipda)(py)$_2$], 2: [Cr(aipda)(py)$_2$] exposed.

IR Spectra. The infrared spectra were measured in order to determine whether or not the carboxyl groups in the complexes are coordinating. The

numerical values of the band arising from the carboxyl groups and the other ligands concerned are listed in Table 3. Strong absorption bands in the 1589—1670 cm^{-1} region can be detected in all these complexes, indicating that all the carboxyl groups in AIPDA participate in the coordination. Furthermore, III, IV, VI, and VII gave bands connected with the vibrations of C–C, C–N, and C–H in coordinated 2,2'-bipyridyl, *o*-phenanthroline, and pyridine.

Magnetic Moments. The magnetic susceptibilities of the complexes were measured by the Gouy method. The numerical data of the effective magnetic moments, as evaluated from the above values, are listed in Table 4. The values for these complexes are 3,75—3.95 B. M., nearly equal to their spin-only values for chromium(III).

TABLE 4. MAGNETIC MOMENTS (B. M.)

Complex	μ_{eff} B. M. (temp. °K)
I	3.82 (293°K)
II	3.91 (293°K)
III	3.87 (293°K)
IV	3.85 (293°K)
V	3.87 (293°K)
VI	3.75 (293°K)
VII	3.81 (293°K)

Discussion of the Structures. *1) Possible Structures of the Complexes Obtained.* The possible structures of these complexes proposed by the present authors on the basis of the above results are given in Fig. 10. The complex species in the solution used as a starting material may have an A structure. The structure for purple crystals, I, may be identified as a C. In green crystals, II, a D structure, may hold in the same way as in the corresponding ATA complex, although the positions of the OH^- and H_2O ligands are still arbitrary. No complex with a B structure was found. In all the mixed-ligand complexes, only AIPDA acted as a quadridentate ligand.

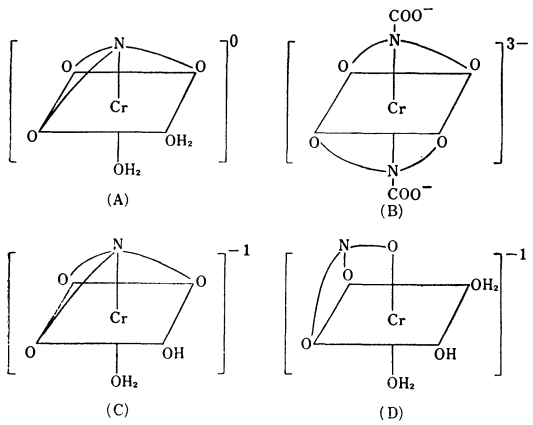

Fig. 10. Possible structures.

2) Some Comparisons among ATA, AIPDA, and APDA Complexes. Of these three ligands, ATA and AIPDA behave toward the chromium(III) ion quite similar manners, but that of APDA is somewhat different. The classification of success or failure in preparing the complexes as a crystal state are summarized in Table 5, where ○ symbolizies a successful preparation and × shows failure. It is immediately noticeable that an A-type complex can be prepared only with APDA; this may be mainly due to the lesser solubility of the complex in water. Their solubilities decrease in the order: AIPDA>ATA>APDA complexes.

TABLE 5. THE COMPLEXES OBTAINED AS A CRYSTAL STATE

	ATA	AIPDA	APDA
A type	×	×	○
B type	○	×	○
C type	○	○	○
D type	○	○	×

○, symbolizes the successful preparation.
×, the reverse.

All these ligands can form C-type complexes. Furthermore, the C-type complexes with ATA and AIPDA were changed instantly to the D-type when dissolved into water, whereas the corresponding C-type complex with APDA did not act thus. These facts may be briefly explained as follows. ATA and AIPDA form three five-membered chelate rings in the complex formation, while APDA forms two five-membered rings and one six-membered one. The inspection by using a molecular model suggests that there are larger strains on the nitrogen atom in coordinated ATA and AIPDA than that in APDA. As a result of these steric factors, the nitrogen atom in APDA has a larger coordinating ability than those in ATA and AIPDA. This fact is consistent with the expectation regarding the stability of Martell *et al.*[4] The attempt to prepare the B-type complex was not successful with AIPDA. This may be because steric hindrance due to the methyl group may arise on the formation of the 1 : 2-type complex; this possibility is supported by an inspection of the molecular model.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2401—2405 (1968)

Use of a Hanging Mercury Drop Electrode in the Alternating Current Polarographic Analysis of Thallium(I)

Mutsuo KODAMA and Tomohiko NODA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received February 28, 1968)

The use of a hanging mercury drop electrode (HMDE) in the a.c. polarographic determination of thallium was studied systematically. Analysis was carried out by scanning anodically the potential of HMDE from the limiting-current potential region at a constant scanning rate and by measuring the a.c. peak-height for the anodic stripping process of thallium. Thallium could be concentrated effectively on the HMDE at the initial stage of this procedure and then stripped anodically. By employing this technique, a marked increase in sensitivity could be obtained and 1.0×10^{-6} M thallium(I) in an EDTA solution was determined accurately. The interference effects of lead, cadmium, zinc, and indium on the determination of thallium were also investigated. When the electrolysis was initiated in the limiting-current potential region of lead(II), the peak-height of thallium was found to be enhanced markedly.

Previously,[1] we have investigated the characteristics of a hanging mercury drop electrode (HMDE) in alternating current (a. c.) polarography and the possibility of using this electrode in the a.c. polarographic analysis of metal ions. Sensitivity was effectively improved by the pre-electrolysis; the metal ion was reduced to an amalgam in the limiting-current region, and then the metal was anodically stripped.

As was proposed by Underkofler and Shain[2] in the a. c. stripping analysis of cadmium(II) using a phase selective detector, the pre-electrolysis and the subsequent electro-dissolution (anodic stripping) processes can be conducted by simply scanning the potential of the working electrode in the anodic direction from the potential, where the limiting current for the metal ion to the amalgam can be observed. In the present paper, the application of this technique to the a. c. polarographic analysis of a micromolar solution of thallium(I) will be discussed.

The interference effects of other metal ions on the determination of thallium(I) in an EDTA solution will also be studied systematically.

Experimental

Reagents. The standard solution of thallium(I) was prepared by a method described previously.[3] The solutions of cadmium(II) perchlorate, zinc(II) perchlorate, lead(II) nitrate, and ethylenediaminetetraacetic acid (EDTA) were also prepared as has been described in previous papers.[4-6] The standard solution of indium(III) chloride was prepared by dissolving pure indium(III) chloride into dilute nitric acid. Its concentration was determined by titration with a standard EDTA solution.[7] The a.c. polarographic analysis showed that indium(III) was not contaminated with lead(II) and thallium(I). All the other chemicals were of an analytical reagent grade and were used without further purification.

Apparatus and Procedure. A. c. polarograms were recorded manually or automatically with a Yanagimoto PA-102 pen-recording polarograph. In a. c. polarographic measurements, a 200-μF condenser was used to minimize the effect of the cell resistance.[8] For the accurate measurement of the d. c. potential, a Shimadzu K-2-type potentiometer was used. The Kalousek circuit used in this study was also given in a previous paper.[9] A dropping mercury electrode with an m value of 1.24_0 mg/sec and a drop time, t_d, of 4.80 sec at a mercury height of 60 cm in an air-free 0.1 M acetate buffer solution of pH 4.8 at -0.60 V *vs.* SCE was used. HMDE was prepared by the method proposed by Ross, Demars and Shain.[10] In the preparation of the HMDE, one drop of mercury from the dropping mercury electrode was used.

Results and Discussion

A. C. Polarographic Behavior of Thallium-(I) in an EDTA Solution at a Hanging Mercury Drop Electrode. Previously,[1] we have applied the a. c. polarographic method to the stripping analysis of metals by using a HMDE as an indicator electrode. In that method, the sensitivity was improved considerably by employing the technique which consists of the pre-electrolysis step and the subsequent anodic-dissolution step. The sample was concentrated effectively on the HMDE by conducting the pre-electrolysis in the limiting current region for the reduction of the metal ion to the amalgam. However, an increase in sensitivity by pre-electrolysis could be obtained only in the analysis of metal ions which behave reversibly in a polarographic sense, such as lead(II) and cadmium(II). This may be one of the characteristic disadvantages of an analysis based on a. c. polarographic measurements. As is well known, thallium-(I) ion behaves reversibly in almost all supporing electrolyte solutions. Therefore, the a. c. polarographic analysis of thallium(I) can be effected successfully by the method involving the anodic-stripping step. For this reason, the reversibility of the electrode process of thallium(I) in an EDTA solution at HMDE was checked first by the a.c. polarographic method. As is shown in Fig. 1, the reversibility of the electrode reaction was almost perfect in an a. c. polarographic sense; the plot of $\log [(I_p/I)^{1/2}-((I_p-I)/I)^{1/2}]$ against the applied d. c. potential, E, gave a straight line with a ± 120 mV slope, which is in good agreement with the theoretically-predicted value of ± 118 mV.[3,11] Here, I_p and I indicate the a. c. peak-height and the height of the a. c. polarogram at E respectively. Under the present pH conditions, the thallium(I) ion can not form the chelate with EDTA and may exist in a hydrate-ion state.

The Concentration of Thallium(I) on the HMDE by the Electrodeposition. Bruckenstein and Nagai[12] have shown that, in the chronopotentiometric analysis of thallium(I), a significant increase in sensitivity can be obtained by emplying the chemical stripping technique, which consists of a pre-electrolysis step and of a subsequent stripping of thallium by chemical oxidation with mercuric ions. In the a. c. polarographic determination of thallium(I), a remarkable increase in sensitivity can also be obtained by emplying the anodic stripping technique. As is illustrated by the a. c. polarograms in Fig. 2, the a. c. peak-height of thallium was greatly increased by the pre-electrolysis and by the subsequent anodic

stripping. In a previous paper,[1] the potential of the working electrode was scanned in the cathodic direction from the potential far anodic with respect to the reduction potential of metal ions after a timed pre-electrolysis interval. Alternatively, the pre-electrolysis and the subsequent anodic stripping can be successfully conducted by scanning anodically from the potential where the limiting current for the reduction of metal ions can be obtained. In this study, unless otherwise stated, this technique was employed. An alternating potential was superimposed on the d. c. potential throughout the experiment. However, this had not effect on the pre-electrolysis step.

At a given initial potential, from which the potential of the working electrode was scanned in the anodic direction, the a. c. peak-height of thallium(I) was linear function of the concentration of thallium(I) in the concentration range from 1×10^{-5} to 5×10^{-4} M with non-stirred solutions (Fig. 3). Although a part of the thallium deposited on the mercury electrode is lost by diffusion into the bulk of the mercury electrode, the peak-height of thallium has been found to be a linear function of the effective pre-electrolysis time (Fig. 4). Here, the pre-electrolysis time, t, can be calculated approximately by the aid of the following relation:

$$t = (E_p - E_i)/r_s + t_p \qquad (1)$$

where E_p and E_i indicate the peak potential and the initial potential respectively: r_s(2.78 mV/sec), the rate of potential scan, and t_p, the time interval during which the solution is electrolyzed at E_i. This relation can be confirmed by comparing the a.c. peak-height obtained by scanning the potential from −1.10 V *vs.* SCE without the timed interval with that obtained by scanning the potential from −0.70 V *vs.* SCE after a timed pre-electrolysis interval of 144 sec. The former agreed well with the latter within the limit of experimental error.

The a. c. stripping analysis of thallium at the HMDE was also studied in a solution stirred by a magnetic stirring bar driven by a synchronous motor. The stirring was stopped at −0.60 V *vs.* SCE to allow the solution to stand. Without stopping the agitation no improvement in sensitivity could be obtained. As is shown by the polarograms in Fig. 2 and the calibration curves in Fig. 3, the stirring of the solution made it possible to obtain a significant increase in sensitivity: the lower limit of the useful sensitivity range with this technique becomes about 1×10^{-6} M.

Interference Effects of Other Metal Ions on the Determination of Thallium(I) by the A. C. Stripping Analysis. To examine the applicability of the above technique to the practical determination of thallium in the presence of a large excess of other metal ions, the effects of the presence of lead(II), cadmium(II), zinc(II), and indium(III) ions on the peak-height of thallium(I) in EDTA solutions were studied. In solutions containing no complex-forming substance, lead(II), cadmium(II), and indium(III) ions are deposited and stripped at potentials very close to the a. c. peak potential of thallium. Therefore, those metal ions may have a considerable effect on the determination of the peak-height of thallium. In solutions containing a large excess of EDTA, however, those metal ions can be deposited on the mercury electrode only at potentials sufficiently negative with respect to the a. c. peak-height of thallium. Therefore, by choosing EDTA as the supporting electrolyte, the interference effects of those metal ions on the determination of thallium may be effectively eliminated. As predicted, when a sample is electrolyzed at the potential of −0.80 V *vs.* SCE, where only thallium(I) is reduced at the mercury electrode, those metal ions have no effect on the a. c. peak-height of thallium. In a 0.05 M EDTA solution of pH 4.0, 0.01 M indium(III) and 0.01 M zinc(II) do not affect the peak-height of 1×10^{-5} M thallium(I), even when the

* Concentration of EDTA=0.10 M

solution is electrolyzed at −1.50 V *vs.* SCE. However, in the presence of a large excess of lead(II) over thallium(I), when the solution is electrolyzed at −1.20 V *vs.* SCE, where lead(II) shows the limiting current, the a. c. peak-height of thallium(I) is markedly enhanced. This can be ascribed to the fact that thallium and lead, deposited together on mercury, are also stripped simultaneously. This explanation can be confirmed by Kalousek's polarogram, shown in Fig. 5. The electrode reaction of lead(II) ions in EDTA solution proceeds irreversibly, and the anodic oxidation of lead metal occurs at a potential far from that for the reduction of lead(II) ions, but very close to the peak potential of thallium.

The peak-height observed in the presence of lead(II), however, was considerably lower than the sum of the peak-heights of lead(II) and thallium(I) measured individually. Quite a similar phenomenon was found in the the Bi(III)-Tl(I) system also. When an excess of bismuth(III) is added to a thallium(I) solution (acidic Na_2SO_4 solution), the peak-height of the thallium obtained by employing the pre-electrolysis step become considerably lower than that obtained with a solution containing only thallium(I). Bismuth and lead are known to form stable intermetallic compounds with thallium.[13] Therefore, the above phenomenon observed in the thallium-lead system may be attributed to the formation of an intermetallic compound between thallium and lead.

In the case of cadmium, despite the fact that the electrode process also proceeds irreversibly under the present experimental conditions (EDTA solution), cadmium has no effect on the peak-height of thallium, even when the sample is pre-electrolyzed in the limiting current region in order to reduce the Cd(II)-EDTA chelate (−1.25 V *vs.* SCE). This may be ascribed to the fact that, in an EDTA solution, cadmium is stripped anodically from the amalgam at −0.60 V *vs.* SCE. Typical data obtained are given in Table 1.

Although an HMDE has the disadvantage that interference effects due to adsorption, contamination, and other surface phenomena are more frequently encountered than with a DME, where the electrode surface is renewed regularly, this electrode may be used successfully in determining traces of thallium(I) in the presence of lead, cadmium, zinc, and indium by employing the a. c. polarographic method involving pre-electrolysis and stripping.

The present authors wish to express their thanks to the Ministry of Education for the financial support granted for this research.

A.C. Polarographic Determination of Lanthanum(III), Nickel(II), Calcium(II), and Magnesium(II) by Using Diethylenetriaminepentaacetic Acid as a Titrant

Mutsuo KODAMA and Mitsuko MURATA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received February 28, 1968)

The a.c. polarographic determination of lanthanum(III), nickel(II), calcium(II), and magnesium(II) with diethylenetriaminepentaacetic acid was studied by using a dropping mercury electrode and a hanging mercury drop electrode as indicator electrodes. Lanthanum(III) and nickel(II) in an acetate buffer solution and calcium(II) and magnesium(II) in an ammonia buffer solution could be titrated with diethylenetriaminepentaacetic acid in the concentration range from 5×10^{-5} to 1×10^{-3} M by measuring the height of the a.c. polarographic wave of diethylenetriaminepentaacetic acid after the end point. The effect of the presence of calcium-(II) ions on the a.c. polarographic determination of lanthanum(III) in an acetate buffer solution of pH 4.0 was also examined and discussed thermodynamically.

As has been reported previously,[1] diethylenetriaminepentaacetic acid (DTPA) gives a single well-defined anodic wave at a dropping mercury electrode (DME) and can be used as a titrant in the amperometric determination of electro-inactive

1) M. Kodama and A. Kimura, This Bulletin, **40**, 1639 (1967).

metal ions.*1 DTPA also shows a well-defined a. c. polarographic wave, the peak-height of which is exactly proportional to the concentration of DTPA. Therefore, electro-inactive metal ions can also be determined successfully by measuring the a. c. peak-height of uncomplexed DTPA.

In this paper, the use of DTPA as a titrant in the a. c. polarographic determination of lanthanum(III), nickel(II), calcium(II), and magnesium(II) was studied by using a DME and a hanging mercury drop electrode (HMDE) as indicator electrodes. In the a. c. polarographic analysis, especially when a stationary electrode is employed, unfavorable interference caused by the contamination by surface-active substances is frequently observed. However, as the a. c. polarographic wave of DTPA occurs at potentials sufficiently positive with respect to the electrocapillary maximum (ECM), the present method, based on the measurement of the a. c. peak-height of DTPA, is free from the effect of contamination with uncharged or positively charged surface-active substances. In this connection, the effect of camphor on the a. c. polarographic determination of lanthanum(III) was also examined.

Experimental

Reagent. The standard solution of nickel(II) perchlorate was prepared by a procedure described previously.[2] Calcium(II) and magnesium(II) perchlorate solutions were prepared by dissolving pure calcium and magnesium carbonates into a dilute perchloric acid solution. Their concentrations were then standardized against the standard EDTA solution.[3] The standard solution of lanthanum(III) nitrate was prepared by dissolving a known amount of 99.9% lanthanum oxide in a reagent-grade nitric acid. The preparation and the standardization of diethylenetriaminepentaacetic acid (DTPA) solution have also been described in the previous paper.[1] All the other chemicals were of an analytical reagent grade and were used without further purification.

Apparatus and Procedure. The a. c. polarograms were recorded manually or automatically with a Yanagimoto PA-102 pen-recording polarograph. In the a. c. polarographic measurements, a 200-μF condenser was used to minimize the effect of the cell resistance.[4] For the accurate measurement of d. c. potential, a Shimadzu K-2-type potentiometer was used.

A dropping mercury electrode (DME) with an m value of 1.24_0 mg/sec and a drop time, t_d, of 4.80 sec at a mercury height of 60 cm in an air-free 0.1 M acetate buffer solution of pH 4.80 at -0.60 V *vs.* SCE was used.

The hanging mercury drop electrode (HMDE) was prepared by the method proposed by Ross, Demars, and Shain.[5] In the preparation of the HMDE, two drops of mercury from the DME were used.

The oxygen dissolved in the solution was removed by bubbling pure nitrogen gas through the solution; measurements were conducted on solutions with a constant ionic strength of 0.50 (Na_2SO_4).

Results and Discussion

A. C. Polarographic Behavior of DTPA in the Absence of Metal Ions. As is shown by the curves in Fig. 1, DTPA in an acetate buffer solution gave a single, well-defined a. c. polarographic wave at both the DME and the HMDE corresponding to the following anodic reaction:[1]

$$\begin{array}{l} Hg + H_nZ^{n-5} \rightleftharpoons HgZ^{3-} + nH^+ + 2e^- \\ \qquad\qquad\quad \downarrow\uparrow H^+ \\ \qquad\qquad\quad HgHZ^{2-} \end{array} \qquad (1)$$

where HgZ^{3-} and $HgHZ^{2-}$ refer to normal and mono-protonated mercury(II)-DTPA chelates respectively, and where H_nZ^{n-5} indicates the incompletely-dissociated DTPA anion.

D: pH=10.0 (Ammonia buffer, 0.10 M), HMDE

are shown in Fig. 2. This clearly indicates that the electrode reaction of DTPA at the mercury electrode is not perfectly reversible in the a. c. polarographic sense, but that it can be said to be reversible to an appreciable extent. The peak-height of DTPA can be compared with that for the reduction of the copper(II)-NTA chelate.[7]

As is illustrated by the calibration curves in Fig. 3, the a. c. peak-heights were found to be exactly proportional to the bulk concentration of DTPA in the concentration range between 5×10^{-5} and 1×10^{-3} M.

In an ammonia buffer solution of pH 10.0, quite similar results were also obtained with regard to the log-plot examination and the relation between peak-hight and DTPA concentration. These results are not shown here, however.

A. C. Polarographic Titration of Metal Ions with DTPA. A good linear relation between the a. c. peak-height and the concentration of uncomplexed DTPA strongly suggests the possibility that electroinactive metal ions, such as lanthanum(III), nickel(II), calcium(II), and magnesium(II) ions, can also be titrated with DTPA by measuring the a. c. peak-height of uncomplexed DTPA after the end point.

As had been attempted previously,[1] lanthanum-(III) was titrated in an acetate buffer solution of pH 4.0. The titration curves in Fig. 4 are demonstrative examples. The end point obtained agrees well with the equivalence point, indicated by an arrow.

A: DME B: HMDE

1.0 mM DTPA proceeds quantitatively at pH=4.0. This value is considerably larger than that of the lanthanum(III)-DTPA chelate ($10^{8.96}$). K_{NiZ}, K^H_{NiZ} and $(\alpha_H)_Z$ in Eq. (2) have their usual meanings. The values in Table 1 were calculated from the related constants in the solution with an ionic strength of 0.10 at 25°C,[8,9] while the activity coefficients of the ions were calculated by means of the well-known Davies equation.[10] Therefore, as in the case of lanthanum(III), the nickel(II) ion in an acetate buffer solution of pH 4.0 is also expected to be titrated successfully with DTPA by measuring the a. c. peak-height of DTPA after the end point. Figure 5 shows typical titration curves. The experimental end point agreed well with the stoichiometric equivalence point, indicated by an arrow.

From the thermodynamic point of view, it is expected that calcium(II) and magnesium(II) ions will form stable chelates with DTPA at pH's higher than 10.0, and that the a. c. peak-potential of DTPA in the absence of any metal ion corresponding to that in Reaction (1) must be located at a potential very negative with respect to that in the presence of calcium(II) or magnesium(II) ions, corresponding to Reaction (3):

$$\begin{array}{ccc} M_2Z^- & & \\ \Big\downarrow\Big\uparrow M^{2+} & & \\ Hg + MZ^{3-} & = HgZ^{3-} + M^{2+} + 2e^- & (3) \\ \Big\downarrow\Big\uparrow H^+ & \Big\downarrow\Big\uparrow H^+ & \\ MHZ^{2-} & HgHZ^{2-} & \end{array}$$

where M^{2+} refers calcium(II) or magnesium(II) ions.

Therefore, at pH 10.0, it is considered that calcium(II) and magnesium(II) can be determined accurately by measuring the a. c. peak-height of

ions can not, the end point in the titration of lanthanum(III) with DTPA may be little affected by the presence of calcium(II) ions. However, even in an acid medium, when a large excess of calcium(II) ions is present in the solution, DTPA reacts partially with calcium(II) ions. Therefore, under such conditions, some positive error may be expected in the lanthanum(III)-DTPA titration. When 1.0 mM lanthanum(III) in a solution of pH 4.0 containing 0.10 M calcium(II) is 100% over-titrated with DTPA, the concentration of the calcium(II)-DTPA chelate is calculated to be 0.85 mM with the aid of the following relation, using the numerical values in Table 1.

$$[CaZ]_t = \frac{1}{1+\dfrac{1}{\dfrac{K_{CaZ}}{(\alpha_H)_z}(1+K^H_{CaZ}[H^+]+K^{Ca}_{Ca_2Z}[Ca^{2+}])}} \quad \text{mM} \qquad (4)$$

where $[CaZ]_t = [CaZ^{3-}]+[CaHZ^{2-}]+[Ca_2Z^-]$, where K_{CaZ} is the stability constant of CaZ^{3-}, where $K^H_{CaZ}=[CaHZ^{2-}]/[CaZ^{3-}]\cdot[H^+]$, where $K^{Ca}_{CaZ}=[Ca_2Z^-]/[Ca^{2+}]\cdot[CaZ^{3-}]$, and where $(\alpha_H)_z$ corresponds to the $(\alpha_H)_Z$ value defined as $1+[H^+]/k_5+\cdots+[H^+]^5/k_1\cdot k_2\cdot k_3\cdot k_4\cdot k_5$.

In the presence of calcium(II) ions, the a. c. polarographic titration of lanthanum(III) with DTPA was also carried out at pH 4.0. The results are given in Table 5.

Even when a large excess of calcium(II) ions is present in the solution, the error in the titration is very small and the agreement between the experimental end point and the stoichiometric equivalence point can be considered to be satisfactory. This is clearly in contrast to the above theoretical prediction. An alternative explanation is possible that, under the present experimental conditions, true equilibrium constants are much smaller than the numerical values in Table 4 used in the calculation of $[CaZ]_t$, and that the actual $[CaZ]_t$ is very small. However, it is also possible to ascribe the above fact to the facts that the peak-potential corresponding to the electrode reaction (1) and that corresponding to Reaction (3) occur at the same potential, and that the a. c. peak-heights per unit of concentration for these two reactions are the same. If the d. c. half-wave potential can be equated with the a. c. peak-potential, peak-potential difference between that in the absence of and that in the presence of a large excess of calcium(II) ions can be calculated with the aid of Relation (6) in Ref. 1. The peak-potential difference calculated for 0.10 M calcium(II) was 20 mV, and the a. c. peak-height ratio obtained experimentally was 0.95 (in an ammonia buffer solution of pH 10.0). These results may support the latter explanation.

The effect of camphor on the a. c. polarographic titration of lanthanum(III) with DTPA was also examined. The presence of 1.0 mM of camphor has little effect on the titration. This can be ascribed to the fact that camphor desorps completely from the mercury electrode[11] at the potential where the a. c. polarographic wave of DTPA is observed.

Finally, it can be mentioned here that the a. c. polarographic method established in this paper may be applied successfully to the determination of rare earths in the alloy of rare earth and alkaline earth oxide.[12]

Kinetics of Electron-Transfer Reactions Involving Ethylenediaminetetraacetatochromate(II) Ions as Reductants. II. Reactions with Some Acidopentaamminechromium(III) Complexes*1

Hiroshi OGINO and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 1, 1968)

The rate of the electron-transfer reactions between ethylenediaminetetraacetatochromate(II) and some acidopentaamminechromium(III), $CrX(NH_3)_5^{2+}$, has been measured at ionic strength 1.0 ($NaClO_4$). The rate constants ($l\,mol^{-1}sec^{-1}$) for $X=F^-$, Cl^-, Br^- and OH^- are 2.07 at 25°C, 2×10^3 at 25°C, $>2\times10^3$ at 15°C and 2.4×10^2 at 25°C, respectively. These reactions produce ethylenediaminetetraacetatochromate(III) ions which do not contain an anion X. The mechanisms of these reactions are discussed.

It is known that the electron-transfer reactions of chromium(II) ions with halogenopentaamminechromium(III) complexes proceed through inner-sphere mechanisms,[1] in which halide ions originally coordinated to chromium(III) complexes act as bridging ligands. It is also known that the order of the efficiency of the bridging groups in the reactions between chromium(II) ions and acidopentaaquo- and hexaaquochromium(III) complexes is $Br^->Cl^->OH^->F^->NCS^->H_2O$.[2,3]

In order to know the effect of the complex formation of chromium(II) ions with ethylenediaminetetraacetate (EDTA) on the electron-transfer reactions and to elucidate the mechanism of the reactions, the kinetics of the electron-transfer reactions between chromium(II)-EDTA and acidopentaamminechromium(III) complexes are dealt with in this paper. The results are compared with those reported in the previous papers.[1-5]

Experimental

A starting material for the preparation of all acidopentaamminechromium(III) complexes used was $[CrH_2O(NH_3)_5](NO_3)_3$, which was prepared by the method of Mori,[6] and from which $[CrH_2O(NH_3)_5](ClO_4)_3$ was obtained by the procedures reported by King.[7] $[CrF(NH_3)_5](ClO_4)_2$ was prepared by the method of Linhard and Weigel[8] from $[CrH_2O(NH_3)_5](ClO_4)_3$. $[CrCl(NH_3)_5]Cl_2$ was obtained by the method reported previously.[9] Its conversion to the perchlorate was carried out by the method of Ogard and Taube[1] with the aid of Dowex 50W-X8 cation exchange resin. $[CrBr(NH_3)_5]Br_2$ was prepared by the procedures reported in literature.[1] This compound was converted to the perchlorate by the recrystallization from aqueous perchloric acid solution. The results of the analysis of the chromium(III) compounds are given in Table 1.

Chromium(II) perchlorate solutions were prepared by the reduction of hexaaquochromium(III) perchlorate with zinc amalgam. Ionic strength of the solution was adjusted to 1.0 with sodium perchlorate. The pH of the solutions was adjusted by using acetate buffer solutions. In most cases, the temperature of kinetic measurement was 25°C and, in some cases, was varied between 5°C and 35°C to determine the kinetic parameters.

Other analytical and kinetic procedures were similar to those reported previously.[4]

Results and Discussion

Kinetics of the Reactions of Chromium(II)-EDTA with $CrF(NH_3)_5^{2+}$, $CrCl(NH_3)_5^{2+}$ and $CrBr(NH_3)_5^{2+}$. Figure 1 shows a typical example of the spectral change of the $CrF(NH_3)_5^{2+}$ in the presence of excess EDTA upon the addition of chromium(II) perchlorate solution (spectra A to D).*2 The reaction seemed to be complete

*2 0.16 mM $[Cr^{III}(H_2O)deta]_{t=0}$ given in Fig. 1 comes from chromium(III) ions which are present as impurity in the chromium(II) perchlorate solution and may be $Cr(H_2O)_6^{3+}$ and/or $[CrOH(H_2O)_4]_2^{4+}$. It was found that, when chromium(II) solution contaminated by chromium(III) ions was injected into excess EDTA solution, the same amount of $Cr^{III}(H_2O)edta^-$ as that of chromium(III) ions in the original solution was formed within the time of mixing.[4]

Table 1. Analyses of the chromium(III) complexes

Complex	Cr, %		N, %	
	Found	Calcd	Found	Calcd

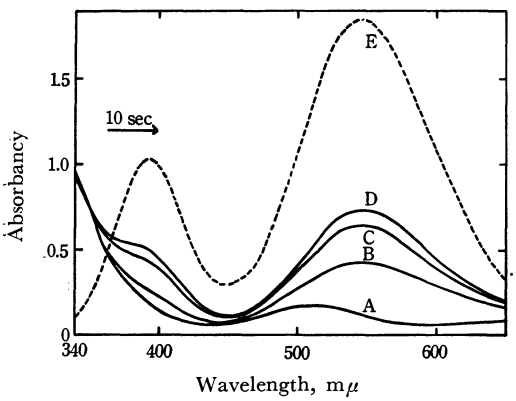

Fig. 1. Spectral change of the $CrF(NH_3)_5^{2+}$ solution in the presence of EDTA upon the addition of chromium(II) ions in sodium acetate-sodium perchlorate media: $[CrF(NH_3)_5^{2+}]_{t=0}=3.18$ mM, $[Cr(II)]_{t=0}=5.73$ mM, $[Cr^{III}(H_2O)edta^-]_{t=0}=0.16$ mM (see footnote), $[EDTA]_{t=0}=20$ mM, $\mu=1.0$, pH 4.99, 25°C, scanning speed = 3.40 mμ/sec and cell length = 1 cm. (A) Spectrum at $t=0$ over the whole range of wave length. (B) 10 sec (C) 130 sec and (D) 660 sec after the addition of chromium(II). Times given are for start of scan at 340 mμ. (E) Spectrum of the solution exposed to air after the measurement of spectrum D.

whithin 660 sec, since no change was observed in the spectrum after the measurement of spectrum D. The spectral change shown in Fig. 1 can be interpreted reasonably by the overall reaction,

$$CrX(NH_3)_5^{2+} + H_jedta^{(4-j)-} + H_2O \rightarrow Cr^{III}(H_2O)edta^- + X^- + 5NH_3 + jH^+ \quad (1)$$

where X should read F in this case. Equation (1) is generalized by writing $CrX(NH_3)_5^{2+}$ instead of $CrF(NH_3)_5^{2+}$. This equation is essentially identical with the overall reaction between chromium(II) ions and $Cr(NCS)_n(NH_3)_{6-n}^{(3-n)+}$ ions in the presence of EDTA.[4] Spectrum E was obtained when the solution was exposed to air after the completion of the reaction. The spectral change from D to E corresponds to the oxidation of $Cr^{II}(H_2O)edta^{2-}$ present in the solution to $Cr^{III}(H_2O)edta^-$ and reveals that the concentration of $Cr^{II}(H_2O)edta^{2-}$ remains constant during the reaction.

By considering the results mentioned above and those reported previously,[4] the mechanism of reaction (1) can be expressed by the following equations:

$$Cr^{2+} + H_jedta^{(4-j)-} + H_2O \rightleftharpoons Cr^{II}(H_2O)edta^{2-} + jH^+ \quad (2)$$

$$Cr^{II}(H_2O)edta^{2-} + CrX(NH_3)_5^{2+} \xrightarrow{k} Cr^{III}(H_2O)edta^- + Cr^{2+} + X^- + 5NH_3 \quad (3)$$

where reaction (3) is a rate-determining step because of the rapidity of the complex-forming reaction (2).[10,11] The rate law of the reaction (1) is given by the equation,

$$-\frac{d[CrX(NH_3)_5^{2+}]}{dt} = \frac{d[Cr^{III}(H_2O)edta^-]}{dt} = k[Cr^{II}(H_2O)edta^{2-}][CrX(NH_3)_5^{2+}] \quad (4)$$

Table 2 gives the results which were obtained on

10) K. Ogino(née Ebata) and N. Tanaka, This Bulletin, **39**, 2672 (1966).
11) N. Tanaka and A. Yamada, *Rev. Polarog. (Kyoto)*, **14**, 234 (1967).

the rate of the reaction between $Cr^{II}(H_2O)edta^{2-}$ and $CrF(NH_3)_5^{2+}$ at 25°C. These data show that the reaction is strictly of second-order. The pH dependence of the rate was analyzed by the method reported previously,[4] in which the formation of $Cr^{II}(H_2O)Hedta^-$ was considered. The rate constant of the reaction,

$$Cr^{II}(H_2O)edta^{2-} + CrF(NH_3)_5^{2+} \rightarrow Cr^{III}(H_2O)edta^- + Cr^{2+} + F^- + 5NH_3 \quad (5)$$

was obtained to be 2.07 $l\,mol^{-1}sec^{-1}$ and the rate constant of the reaction,

$$Cr^{II}(H_2O)Hedta^- + CrF(NH_3)_5^{2+} \rightarrow Cr^{III}(H_2O)Hedta + Cr^{2+} + F^- + 5NH_3 \quad (6)$$

was found to be less than 1 $l\,mole^{-1}sec^{-1}$.

Similar experiments were made on the systems containing $CrCl(NH_3)_5^{2+}$ and $CrBr(NH_3)_5^{2+}$ ions. It was found spectrophotometrically that a product of the reaction of $Cr^{II}(H_2O)edta^{2-}$ with $CrCl(NH_3)_5^{2+}$ or $CrBr(NH_3)_5^{2+}$ was not $Cr^{III}Xedta^{2-}$ but $Cr^{III}(H_2O)edta^-$. The reaction between $Cr^{II}(H_2O)edta^{2-}$ and $CrBr(NH_3)_5^{2+}$ was so rapid that the rate constant could not be determined.

Kinetics of the Reaction of Chromium(II)-EDTA with $CrH_2O(NH_3)_5^{3+}$. In the reaction between chromium(II)-EDTA and $CrH_2O(NH_3)_5^{3+}$, the observed second-order rate constants were considerably dependent on pH as shown in Fig. 2. In the pH range investigated, $CrH_2O(NH_3)_5^{3+}$ ions are appreciably hydrolyzed, because the hydrolysis constant expressed by

$$K_h = \frac{[CrOH(NH_3)_5^{2+}][H^+]}{[CrH_2O(NH_3)_5^{3+}]} \quad (7)$$

is 6.7×10^{-6} moll^{-1} at ionic strength 1.0 ($NaClO_4$) and 25°C.[12] Hence, it is reasonable to assume that the reaction in question proceeds through the following two simultaneous reaction paths:

$$Cr^{II}(H_2O)edta^{2-} + CrH_2O(NH_3)_5^{3+} \xrightarrow{k_1} Cr^{III}(H_2O)edta^- + Cr^{2+} + H_2O + 5NH_3 \quad (8)$$

$$Cr^{II}(H_2O)edta^{2-} + CrOH(NH_3)_5^{2+} \xrightarrow{k_2} Cr^{III}(H_2O)edta^- + Cr^{2+} + OH^- + 5NH_3 \quad (9)$$

By considering these reactions, the following equation can be obtained for the observed rate constant, k.

$$k = \frac{k_1 + k_2K_h/[H^+]}{1 + K_h/[H^+]} \times \frac{1}{1 + K^H[H^+]} \quad (10)$$

where

$$K^H = \frac{[Cr^{II}(H_2O)Hedta^-]}{[Cr^{II}(H_2O)edta^{2-}][H^+]} \quad (11)$$

and the value of K^H has been determined to be $10^{3.00}$.[13]

This equation is rewritten as,

$$k\alpha' = k_1 + k_2K_h/[H^+] \quad (12)$$

where

$$\alpha' = (1 + K_h/[H^+])(1 + K^H[H^+]) \quad (13)$$

If the values of left-hand side of Eq. (12) are plotted against reciprocal hydrogen ion concentrations, linear plots will be obtained. Figure 3 shows the plots of $k\alpha'$ *vs.* reciprocal hydrogen ion concentrations. The best values of intercept and slope were calculated by least square method, with the aid of the data in Fig. 3. The relation,

$$k\alpha' = (0\pm1) + (1.62\pm0.03)\times10^{-3}/[H^+] \quad (14)$$

was obtained. Uncertainties in Eq. (14) represent standard deviations. The value of intercept is practically zero. This means that the reaction proceeds through the sole path represented by Eq. (9). The rate constant of the reaction is 2.4×10^2 $l\,mol^{-1}sec^{-1}$ and the value of k_1 is less than 1 $l\,mol^{-1}sec^{-1}$.

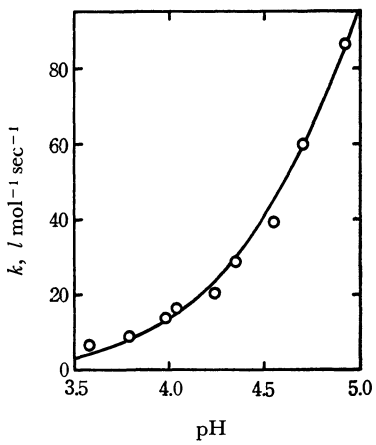

Fig. 2. The pH dependence of the observed second-order rate constant, k, for the reaction between chromium(II)-EDTA and $CrH_2O(NH_3)_5^{3+}$ at 25°C and μ=1($NaClO_4$).

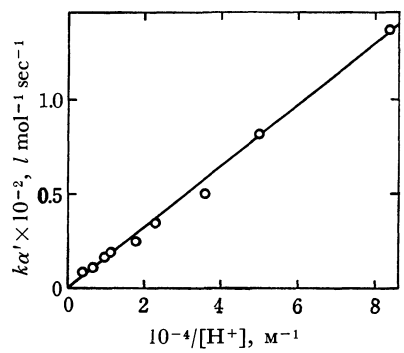

Fig. 3. The values of left-hand side of Eq. (12) as a function of reciprocal hydrogen ion concentration in the reaction between chromium(II)-EDTA and $CrH_2O(NH_3)_5^{3+}$.

12) H. Ogino, unpublished result.

13) R. L. Pecsok, L. D. Shields and W. P. Schefer, *Inorg. Chem.*, **3**, 114 (1964).

It should be noted that reactions other than Eqs. (8) and (9), such as

$$Cr^{II}(H_2O)Hedta^- + CrH_2O(NH_3)_5^{3+} \xrightarrow{k_3} Cr^{III}(H_2O)Hedta + Cr^{2+} + H_2O + 5NH_3 \quad (15)$$

and

$$Cr^{II}(H_2O)Hedta^- + CrOH(NH_3)_5^{2+} \xrightarrow{k_4} Cr^{III}(H_2O)edta^- + Cr^{2+} + H_2O + 5NH_3 \quad (16)$$

could have been considered. From the analysis of the data given in Fig. 2, it was found that there is no significant contribution of reaction (15) to the overall reaction under consideration. Reaction (16) cannot be distinguished from Eq. (8), since the interconversion of the acid and the base form of the reactants is rapid enough to maintain the equilibrium between them during the reaction. By considering both reactions (9) and (16), the following equation can be obtained instead of Eq. (12).

$$k\alpha' = k_4 K^H K_h + k_2 K_h/[H^+] \quad (17)$$

The value of intercept of the linear plots of $k\alpha'$ *vs.* reciprocal hydrogen ion concentrations corresponds to the value of $k_4 K^H K_h$. The value which was estimated with the aid of the values of K^H [13] and K_h [12] was smaller than 2×10^2 l mol^{-1}sec^{-1}.

Discussion on the Rate Constants of the Reactions between $Cr^{II}(H_2O)edta^{2-}$ and $CrX(NH_3)_5^{2+}$ Complexes. The second-order rate constants of the reaction between $Cr^{II}(H_2O)edta^{2-}$ and acido- and aquopentaamminechromium(III) complexes are given in Table 3. The kinetic parameters obtained in this study are given in Table 4 together with those of other related systems. A striking feature presented in Table 3 is a great variety of rate with the nature of the complexes.

TABLE 3. RATE CONSTANTS OF THE ELECTRON-TRANSFER REACTION BETWEEN $Cr^{II}(H_2O)edta^{2-}$ AND ACIDO- AND AQUOPENTAAMMINECHROMIUM(III) COMPLEXES AT μ=1.0 ($NaClO_4$) AND 25°C

Complex	k l mol^{-1} sec^{-1}
$Cr(NH_3)_6^{3+}$	$<10^{-2}$ a)
$CrH_2O(NH_3)_5^{3+}$	< 1
$CrOH(NH_3)_5^{2+}$	2.4×10^2
$CrF(NH_3)_5^{2+}$	2.07
$CrCl(NH_3)_5^{2+}$	2×10^3
$CrBr(NH_3)_5^{2+}$	$>2\times10^3$ b)
$CrNCS(NH_3)_5^{2+}$	0.2a)

a) μ=1.0 (NaCl), from Ref. 4.
b) At 15°C.

14) It should be noted that there is no direct evidence that the reaction between Cr^{2+} and $Cr(H_2O)_6^{3+}$ or $CrOH(H_2O)_5^{2+}$ proceeds through inner-sphere mechanism.

Table 5 shows the rate constants of the following electron-transfer reaction,

$$*Cr^{2+} + CrX(H_2O)_5^{2+} \xrightarrow{k_{Cr(II)}} *CrX(H_2O)_5^{2+} + Cr^{2+} \quad (18)$$

where *Cr denotes labeled chromium atom. It is known that the values of $k_{Cr(II)}$ given in Table 5 correspond to the rate constants of inner-sphere electron-transfer reactions, in which ligand X acts as an electron-transfer bridge and the product criteria apply.[2,3,14] The comparison of $k_{Cr(II)}$ in Table 5 reveals that the order of the efficiency of the bridging groups in reaction (18) is

$$Br^- > Cl^- > OH^- > F^- > NCS^- > H_2O$$ [2,3]

This order is in agreement with that of the rate constants of reaction (3) in Table 3. The plots of log $k_{Cr(II)Y}$ *vs.* log $k_{Cr(II)}$ give at raight line with a slope of approximately unity as shown in Fig. 4,[15] where $k_{Cr(II)Y}$ denotes the rate constant of reaction (3).

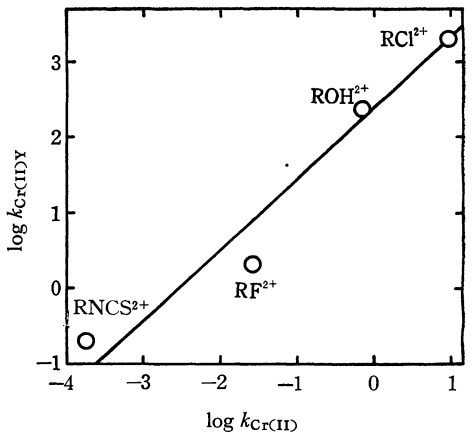

Fig. 4. Relation between the rate constant of reaction 3 ($k_{Cr(II)Y}$) and that of reaction (18) ($k_{Cr(II)}$). R denotes $Cr(NH_3)_5$ for the reaction involving $Cr^{II}(H_2O)edta^{2-}$ and $Cr(H_2O)_5$ for the reaction involving Cr^{2+}.

The facts mentioned above may suggest that the mechanism of the reactions between $Cr^{II}(H_2O)edta^{2-}$ and $CrX(NH_3)_5^{2+}$, except $Cr(NH_3)_6^{3+}$,[4] is of inner-sphere type. This leads naturally to the mechanism expressed as follows for the reaction between $Cr^{II}(H_2O)edta^{2-}$ and $CrX(NH_3)_5^{2+}$:

15) In Fig. 4, 9.1 l mol^{-1} sec^{-1} (at 0°C)[2] is used as the rate constant of the reaction between Cr^{2+} and $CrCl(H_2O)_5^{2+}$, that is, temperature dependence of the rate constant is neglected. On the other hand, the value of one sixth times of the rate constant of the Cr^{2+}-$CrOH(H_2O)_5^{2+}$ reaction should be compared with the rate constants of the other Cr^{2+}-$CrX(H_2O)_5^{2+}$ reactions, the statistical effect being considered. This correction is not made in Fig. 4. The conclusion that the slope of the plots is unity is not affected even by the consideration of these corrections, though the deviation of plots is relatively large.

Table 4. Kinetic parameters of the electron-transfer reactions of acidopentaammine-chromium(III) complexes with $Cr^{II}(H_2O)edta^{2-}$ (Cr(II)-EDTA system) and with Cr^{2+} (Cr^{2+} system)

Complex	Cr(II)-EDTA system[a]		Cr^{2+} system[b]

Complex	$k'_{Cr(II)}$[a] $l\,mol^{-1}sec^{-1}$	$k_{Cr(II)Y}/k'_{Cr(II)}$	Temp. °C
$CrF(NH_3)_5^{2+}$	2.7×10^{-4}	7.7×10^{3}	25
$CrCl(NH_3)_5^{2+}$	5.1×10^{-2}	4×10^{4}	25
$CrBr(NH_3)_5^{2+}$	0.191	$>1\times10^{4}$	15

a) From Ref. 1.

$$Cr^{II}(H_2O)edta^{2-} + Cr^{III}X(NH_3)_5^{2+} \xrightarrow{slow} Cr^{III}Xedta^{2-} + H_2O + Cr^{2+} + 5NH_3 \quad (19)[16]$$

$$Cr^{III}Xedta^{2-} + H_2O \xrightarrow{fast} Cr^{III}(H_2O)edta^{-} + X^{-} \quad (20)$$

Product criteria did not apply to the present cases under the experimental condition. This seems to be due to the lability of $Cr^{III}Xedta^{2-}$, which dissociates rapidly to $Cr^{III}(H_2O)edta^{-}$ and anion X.

Table 6 shows the comparison of $k_{Cr(II)Y}$ with the rate constant of the following electron-transfer reaction[1]:

$$Cr^{2+} + CrX(NH_3)_5^{2+} \xrightarrow{k'_{Cr(II)}} CrX(H_2O)_5^{2+} + Cr^{2+} + 5NH_3 \quad (21)$$

Unfortunately, the comparison is restricted to only a few cases, but it is shown in Table 6 that $Cr^{II}(H_2O)edta^{2-}$ reacts with $CrX(NH_3)_5^{2+}$ faster than chromium(II) ions approximately by ten thousand times. Chromium(II) - EDTA ions are more powerful as reducing agent than chromium(II) ions. Marcus' theory predicts that the rate of electron-transfer reactions increases with free energy of the reactions,[18,19] though the thoery was derived only for outer-sphere electron-transfer reactions. It was shown recently that free energy contributes also to the rate of the inner-sphere electron-transfer reactions.[20] Considering the difference in the standard reduction potentials of $Cr(aq.)^{2+}$ - $Cr(aq.)^{3+}$ couple (−0.412 V *vs.* NHE)[21] and $Cr^{II}(H_2O)edta^{2-}$ - $Cr^{III}(H_2O)edta^{-}$ couple (−0.98$_3$ V *vs.* NHE),[13] it seems reasonable that $Cr^{II}(H_2O)edta^{2-}$ ions react more rapidly than chromium(II) ions. In addition, the electrostatic interaction between reactants is more favorable in reaction (3) than in reaction (21). If kinetic parameters of these reactions in Table 4 are compared, it will be found that the enthalpy of activation of reaction (3) is essentially identical with that of reaction (21) and that the increase in rate is mainly due to the change of the entropy of activation. For reactions between oppositely charged ions, the charge of the activated complex is reduced and hence the solvent molecules in the solvation shell will be released during the activation process. For reactions between like-charged ions, these

16) It is known that the rate for the substitution of an water molecule coordinated to chromium(II) ion is extremely rapid.[17] In Eq. (19), it is assumed that an activated complex, $[edtaCr^{II} - X - Cr^{III}(NH_3)_5]^*$, is formed after release of the coordinated water molecule in $Cr^{II}(H_2O)edta^{2-}$.

situation is opposite. If this electrostriction effect[22,23] is considered, the smaller negative entropy of activation for reaction (3) can be understood at least qualitatively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 3416—3418 (1968)

Formation Constants of Chromium(III) Complexes with (N, N)-, (O, O)- and (N, O)-Type Ligands, and Their Relationship to Structure*1

Shichiro TAKATA,*2 Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 15, 1968)

Formation constants of chromium(III) complexes with β-alanine, anthranilic acid, picolinic acid and 8-hydroxyquinoline, being all (N, O)-type bidentate chelate ligands, were determined by the pH method at an ionic strength $\mu=0.1$, and at 25°C. The formation constants are $\log k_1=9.69$ for β-alanine, $\log k_1=4.35$ and $\log k_2=3.67$ for anthranilic acid, $\log k_1=4.76$, $\log k_2=4.38$ and $\log k_3=4.55$ for picolinic acid and $\log k_2=9.76$ and $\log k_2=8.48$ for 8-hydroxyquinoline, respectively. The relationships between the formation constants of the complexes and the acid dissociation constants of the chelate ligands were discussed, including those for glycine and α-alanine complexes, and those, in addition, for the complexes with several (N, N)- and (O, O)-type ligands reported in a preceding paper.

Several papers have been previously published by the present authors on the formation constants of chromium(III) complexes, for example, with dicarboxylic acids such as oxalic,[1] malonic,[2] succinic,[2] phthalic[3] and maleic[4] acids as (O, O)-type ligands, with ethylenediamine[5] as an (N, N)-type ligand and glycine and α-alanine[6] as (N, O)-type ligands.

In continuation of the studies on (N, O)-type ligands, the formation constants of chromium(III) complexes with β-alanine, anthranilic acid, picolinic acid and 8-hydroxyquinoline were determined at 25°C and $\mu=0.1$, and the relationships among the formation constants of the (N, O)-type complexes presented here and those of (N, N)- and (O, O)-type complexes already published are discussed.

Experimental

Materials. Picolinic acid and β-alanine were of analytical reagent grade from Nakarai Chemicals Co., Ltd., and anthranilic acid and 8-hydroxyquinoline were of guaranteed special grade from Katayama Chemicals Co., Ltd.

Determination of Formation Constants. The formation constants of the complexes were determined by the pH method used in previous papers.[1-6] Solutions containing various concentrations of hexaaquochromium(III) perchlorate and each ligand described above were kept in a thermostat at 25°C; the ionic strength μ was adjusted to 0.1 by adding an appropriate amount of sodium perchlorate. When equilibrium was attained after one month or more, the pH of the solution was measured with a Toa Denpa pH meter, model HM-8, and the formation constants calculated.

Results

Acid Dissociation Constants of the Chelate Ligands. The acid dissociation constants of β-alanine, anthranilic acid and 8-hydroxyquinoline

* the present work

were determined by titrating aqueous solutions containing the ligand alone with hydrochloric acid or sodium hydroxide solution under $\mu=0.1$ and at 25°C, and they were calculated by applying the following equations,[7]

$$pK_1 = pH - \log\left(\frac{C}{A-[H^+]} - 1\right)$$

or

$$pK_2 = pH - \log\left(\frac{C}{B-[OH^-]} - 1\right)$$

where C is the total concentration of the chelate ligand, A and B are the concentrations of the hydrochloric acid and sodium hydroxide solutions calculated from their titres, respectively, and pK_1 and pK_2 are the acid dissociation constants of the ligand. The values of $[H^+]$ and $[OH^-]$ were calculated by applying the activity coefficient of hydrogen ion at $\mu=0.1$, $\gamma=0.83$,[8] to its activity obtained by pH measurement.

The acid dissociation constants of β-alanine, anthranilic acid and 8-hydroxyquinoline were determined in the manner described above, whereas those of picolinic acid were taken from the literature.[9] These values are all listed in Table 1, as well as those of glycine and α-alanine for comparison, together with the values of the formation constants of the complexes concerned.

Formation Constants of Chromium(III) Complexes with (N, O)-Type Chelate Ligands. The method used in determining the formation constants of the chromium(III) complexes with β-alanine, anthranilic acid, picolinic acid and 8-hydroxyquinoline as (N, O)-type chelate ligands was the same as used for the glycine and α-alanine complexes.[6]

By combining the values of the acid dissociation constants of the respective chelate ligands and the measured pH values with the total concentrations of the chromium ion used, of the chelate ligand concerned and of the ionizable hydrogen, the average numbers of ligands coordinated to each chromium ion, $\bar{n}$, and the reciprocal logarithmic values of the free ligand, $p[A^-]$, were calculated. The formation curves, $\bar{n}-p[A^-]$, for the (N, O)-type complexes with picolinic acid, 8-hydroxyquinoline, β-alanine and anthranilic acid, together with those of glycine and α-alanine, are shown in Fig. 1.

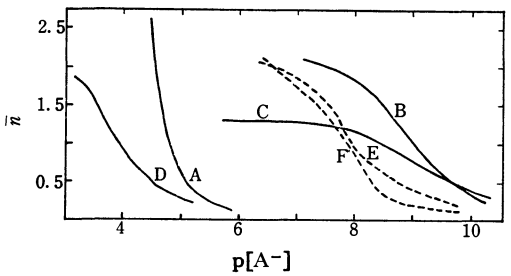

Fig. 1. Formation curves for (N, O)-type chromium(III) complexes.
A, Picolinic acid B, 8-hydroxyquinoline
C, β-Alanine D, Anthranilic acid
E, Glycine F, α-Alanine

Discussion

As given in Table 1, the first and second stepwise formation constants of the complexes, $\log k_1$ and $\log k_2$, decrease in the following order; 8-hydroxyquinoline > β-alanine > glycine > α-alanine > picolinic acid > anthranilic acid. This order runs parallel to the decreasing order of the second acid dissociation constants of these ligands, pK_2, except for 8-hydroxyquinoline.

Although a general linear relationship between the logarithms of the formation constants, $\log k_1$, and the reciprocal logarithms of the acid dissociation constants, pK_2, as expressed by

$$\log k_1 = \alpha pK_2 + C,$$

where α and C are constants, has been proposed by

7) F. Basolo and Y. T. Chen, *J. Am. Chem. Soc.*, **76**, 953 (1954).
8) J. Kielland, *ibid.*, **59**, 1675 (1937).
9) H. H. G. Jellinek and J. R. Urwin, *J. Phys. Chem.*, **58**, 548 (1954); K. Suzuki, M. Yasuda and K. Yamasaki, *ibid.*, **61**, 229 (1957).

Irving and Rossotti,[10,11] such a relationship has not always been strictly applied to many complexes, as pointed out by Jones *et al.*[12] Nevertheless, so far as both copper(II)[13] and iron(III)[14] complexes forming five-membered chelate ring with glycine and its several derivatives as (N, O)-type bidentate ligands are concerned, approximately linear relationships between $\log k_1$ and pK_2 can be obtained, respectively.

The values of the first stepwise formation constants of the complexes listed in Table 1 are plotted against pK_2 in Fig. 2, including those concerning chromium(III) asparagine and glycylglycine complexes.*3 Of these complexes, so far as glycine, α-alanine, asparagine, glycylglycine and picolinic acid, which can form five-membered chelate rings with chromium(III), are concerned, the values of $\log k_1$ against pK_2 fall approximately on a straight line, as shown in Fig. 2.

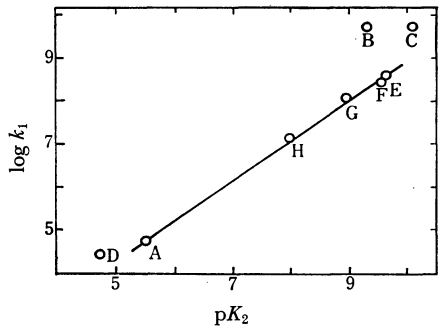

Fig. 2. Relationships between $\log k_1$ and pK_2 in (N, O)-type complexes.
A, Picolinic acid B, 8-hydroxyquinoline
C, β-Alanine D, Anthranilic acid
E, Glycine F, α-Alanine G, Asparagine
H, Glycylglycine

This fact may mean that, in these cases, the chelating tendency is not dependent upon the presence of a side-chain or end-chain in these ligands, but mainly upon the magnitude of their pK_2 values.

On the other hand, the first stepwise formation constants of the chromium(III) complexes with β-alanine and anthranilic acid, as shown in Fig. 2, deviate slightly from the straight line obtained above. This may be due to the six-membered chelate ring formation of these two ligands, which differs from glycine and its derivatives in forming five-membered chelate rings with the metal.

It has been reported by Bjerrum[11] that the values of $\log k_1/\log k_H$ are almost constant for each complex of silver(I), mercury(II), copper(II) and zinc(II) ions with various amines, where k_H is the acid formation constant.

Now, putting the values of the differences, $\Delta = \log k_1 - pK_2$, on the straight line, the relationships shown in Fig. 3 are obtained.

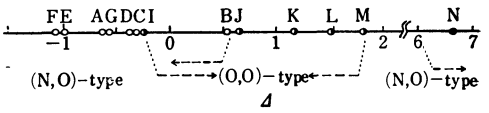

Fig. 3. The values, $\Delta = \log k_1 - pK_2$, for (N, N)-type (●), (N, O)-type (○) and (O, O)-type (◑) complexes.
A, Picolinic acid B, 8-hydroxyquinoline
C, β-Alanine D, Anthranilic acid
E, Glycine F, α-Alanine G, Asparagine
I, Maleic acid J, Phthalic acid
K, Succinic acid L, Oxalic acid
M, Malonic acid N, Ethylenediamine

The values, Δ, for the chelate ligands which can form a stronger coordinate bond with chromium than hydrogen, are placed on the right-hand side of this line, while those forming a weaker coordinate bond with chromium are placed on the left-hand side, and those which have comparable coordination tendencies toward both chromium and hydrogen are placed in the middle region of this line between the above two. Thus, their positions on the line are arranged in the order of (N, N)-, (O, O)- and (N, O)-type complexes from the right to the left. Even though values of $\log k_1$ of the (N, O)-type complexes are in the intermediate region between those of the (N, N)- and (O, O)-type complexes, the values, Δ, referred to the (N, O)-type complexes fall within a small range on the extreme left side of this line.

This may be explained by the fact that the values of pK_2 in (N, O)-type ligands, 8 to 10, except for picolinic and anthranilic acids, are not only strikingly higher than those in (O, O)-type ligands, 4 to 5, but also rather close to those in (N, N)-type ligands, about 10. Such a similarity in values of pK_2 in both (N, N)- and (N, O)-type ligands is reasonably expected, since the second acid dissociation will be, in common, concerned with the liberation of a proton from an amido group in (N, N)- and (N, O)-type ligands, whereas it will be concerned with the liberation of a hydrogen ion from a carboxyl group in (O, O)-type ligands.

That the values of Δ are found as slightly negative in (N, O)-type ligands suggests that the α-amino monobasic acids do not coordinate so strongly to chromium as to hydrogen.

Stability of Some Bivalent Metal Complexes of Benzoyl-thiobenzoylmethane in Aqueous Dioxane

Atsushi MANOME and Kazuo SAITO

Chemistry Department, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 19, 1968)

Concentration equilibrium constants of benzoyl-thiobenzoylmethane (SdbmH) complexes of bivalent magnesium, cobalt, nickel, copper and zinc have been measured in 75% (v/v) aqueous dioxane containing 0.05 M sodium perchlorate. The values for the transition metal ions are greater than those of dibenzoylmethane (dbmH) complexes measured under the same conditions, although the pK value of SdbmH is smaller than that of dbmH. Contribution of d_π–d_π interaction seems to be responsible for such an unusual relationship.

Although the first example of thio homologues of β-diketones was presented by Mitra in 1933,[1] nothing had been known of their metal complexes until Chaston *et al.* prepared several monothio-β-diketones and their metal chelates.[2] Since then further varieties of mono- and di-thio-β-diketones and their transition metal chelates have been prepared and their properties described.[3-5] However, no information is available concerning the stability of their metal complexes in solution. Such studies seem very useful in discussing the characteristics of sulfur as donor atom and the a and b character of metal ions.[6]

We have attempted to measure the stabilities of metal chelates of some monothio-β-diketones in aqueous solution and found that they are soluble only in solutions containing a large amount of organic solvent such as dioxane. Monothio-β-diketones are liable to undergo hydrolysis in such media. Especially thiothenoyl-trifluoroacetone, sulfur derivative of thenoyltrifluoroacetone, is converted into thenoyltrifluoroacetone and hydrogen sulfide in 75% (v/v) aqueous dioxane (molar fraction, 0.380) within a few hours. Its absorption spectrum approaches to that of thenoyltrifluoroacetone, and an isosbestic point is observed at 307 mμ. Such a rapid change seems to be associated with its low pK value. Other monothio-β-diketones decompose more or less similarly, and the weakest acid benzoyl-monothiobenzoylmethane is expected to stand against such a hydrolysis best.

We have found that this compound is stable in the given conditions, and measured its dissociation constant and the stability constants of some of its metal chelates by an alkalimetric titration. The results have been compared with those of dibenzoylmethane (dbmH) under the identical condition.

Experimental

Materials. Thioacetylacetone, thiothenoyltrifluoroacetone, benzoylthioacetone, and benzoylthiobenzoylmethane (SdbmH) were prepared by Chaston *et al.*'s method from their oxo homologues, and identified by melting point, UV and IR spectra and the chemical analysis of carbon and hydrogen of their appropriate metal chelates.

Perchlorates of sodium, copper(II), cobalt(II), zinc, nickel and magnesium were recrystallized from aqueous solutions and dissolved in redistilled and decarbonized water. Their concentrations were determined by EDTA titration with appropriate indicators. Guaranteed grade dioxane was refluxed with concentrated hydrochloric acid and water in a current of nitrogen, shaked with solid potassium hydroxide, the aqueous layer discarded, refluxed with sodium, distilled and preserved in nitrogen atmosphere. Concentrated sodium hydroxide solution free from carbonate was diluted with water and dioxane and mixed with sodium perchlorate to produce 0.02 M sodium hydroxide solution in 0.03 M sodium perchlorate in 75% aqueous dioxane.

Measurement. Hitachi-Horiba Model P pH meter was used for the pH measurement. Horiba's Glass Electrode Type 1026-05T with a double junction mantle was used with 3.33 M potassium chloride in water and 0.05 M sodium perchlorate in 75% aqueous dioxane as bridging solution.

Metal perchlorate (1.5 to 2.0×10^{-3} M), SdbmH (5.0×10^{-3} M), perchloric acid (0.003 M) and sodium perchlorate (0.05 M) were dissolved in 75% aqueous

dioxane in a current of nitrogen. A 20 ml portion was placed in a beaker shielded with copper plates in a thermostat (25.0±0.1°C) and titrated with the alkali solution. The solution was agitated by a current of pure nitrogen saturated with the vapor of 75% aqueous dioxane. The titration was initiated *ca.* 2 hr after the electrodes were inserted into the solution. The time taken to obtain a constant reading of the meter during the course of titration was ordinarily less than 20 min, but sometimes 30 to 60 min, when the pH change between two reading points was large.

Results

In order to know the concentration of hydrogen ions in 75% aqueous dioxane, a potentiometric titration method modified by Ohtaki[7] was used. The pH_C values are interrelated with the reading of the pH meter by Eq. (1).

$$pH_C = pH_R + \Delta pH \quad (1)$$

where pH_R is the reading of the pH meter, and ΔpH is dependent on the concentration of dioxane, the ionic strength, *etc.* The ΔpH value obtained from Gran's plot[8] was +0.355±0.003 on addition of up to 2.5 ml of the sodium hydroxide solution. Hence the apparatus is useful for obtaining concentration equilibrium constants. The results were calculated by the curve fitting method.[9]

The $\log(h-H-K_wh^{-1})$ *vs.* $\log h$ diagrams for dbmH and SdbmH are shown in Fig. 1, where h and H denote the hydrogen ion concentration in equilibrium obtained from Eq. (1), and analysed excessive hydrogen ion concentration, respectively. The H values are known from the following formula,

$$H = [ClO_4^-] - [Na^+] - 2B \quad (2)$$

where B is the total concentration of the metal ion. K_w is the ion product of water under the given experimental conditions. (3.45×10^{-19}) A normalization function $y=-\log(1+x)$ is drawn and the coordinates are chosen to get the best fit with Fig. 1. The pK values are known from $\log x - \log h$. The results are given in Table 1.

Figure 2 illustrates Z *vs.* $\log a$ diagrams of bivalent metal chelates of SdbmH, where Z is the average number of the ligand bound per metal ion and a the concentration of deprotonated free ligand. The molar ratio of the formed complex is 1 to 2 and the Z is related to the overall formation constants β_1 and β_2 as follows:

$$Z = \frac{\beta_1 a + 2\beta_2 a^2}{1 + \beta_1 a + \beta_2 a^2} \quad (3)$$

This formula is simplified to

$$y = \frac{p_2 v + 2v^2}{1 + p_2 v + v^2} \quad (4)$$

where the notations are as follow: $y=Z$, $x=\log a$, $p_1=\frac{1}{2}\log\beta_2$, $x+p_1=\log v$ ($v=a\beta_2^{1/2}$) and $p_2=\beta_1\cdot\beta_2^{-1/2}$. A variety of y *vs.* $\log v$ diagrams are drawn for differing p_2 values, and one of them is chosen to get the best fit with those in Fig. 2. The $\log\beta_2$ values are then known from the reading of $\log a$ at $\log v=0$.

From similar diagrams for dibenzoylmethane complexes their β_2 values are also known. All these results are summerized in Table 1. These are all concentration equilibrium constants.

Discussion

van Uitert and his colaborators measured the pK values and the stability constants of several β-diketones and their bivalent metal chelates in 75% aqueous dioxane and discussed the conversion of concentration stability constants into thermodynamic data.[10] On evaluating the activity coefficients of the chemical species concerned, they gave several assumptions. In case of thio derivatives, however, fundamental information is missing. Dibenzoylmethane is claimed to have the biggest interaction with sodium ions among common β-diketones, and its monothio homologue is expected to have a similar trend. Neither is known its keto-enol tautometric equilibrium under the given conditions. Hence we had to give up to convert our data into thermodynamic parameters. The data in Table 1, however, were obtained under an identical condition, and we can compare them with one another. Although our experimental condition was not equal to van Uitert *et al.*'s, our data of pK and log β_2 values of dbmH and its chelates are parallel with and smaller than their thermodynamic equilibrium constants by more than 4. Such a difference is quite reasonable as they stated.[10]

The results in Table 1 are in accord with Irving-Williams series.[11] On the other hand, the log β_2 values of the thio homologue for the transition elements are greater than those of dbmH, regardless of the fact that the pK value of dbmH is greater than that of SdbmH. Hence the parallel relationship between pK and log β[12] is not seen for the transition metal ions. Only magnesium obeys this empirical law qualitatively. Such a discrepancy could be accounted for by considering the contribution of π-bonding between the transition metal ions and sulfur. Sulfur has vacant 3d orbitals, and can accept d_π electrons of transition metal ions to reinforce ordinary σ-bonding. Magnesium has no delectrons which can be donated to sulfur and gives a lower log β_2 value with SdbmH. A similar trend could have been observed with other thio homologues of β-diketones, if the experimental difficulty had been overcome. Details of the structure of monothio-β-diketone complexes are still unknown. The nickel complexes are diamagnetic and expected to have square planar structures,[2] but their geometrical isomerism is not known. Similar ambiguity remains for the copper complexes. Hence the skeletal structues of dbmH and SdbmH complexes of the semetals ions are different. Nevertheless, the difference between log β_2 values of dbmH and SdbmH complexes of various metal ions could provide an approximate measure indicating the difference in affinity of the metals towards sulfur and oxygen.

We wish to express sincere thanks to Professor M. Tanaka and Dr. H. Ohtaki of Nagoya University for their useful suggestion for the potentiometric titration technique.

Absorption Spectra and Circular Dichroisms of Metal Complexes. II. Preparation and Structure of Isomers of L-Aminoalcohol Cobalt(III) Complexes

Kousaburo OHASHI, Junnosuke FUJITA, Bun-e SHIMOYAMA*1 and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 13, 1968)

Seven new optically active complexes of *fac*-*Δ*- and *fac*-*Λ*-$[Co_2(L\text{-amoH})_3(L\text{-amo})_3]^{3+}$ type have been prepared, where L-amoH and L-amo denote L-aminoalcohol and L-aminoalcoholate ion, respectively. The geometrical and the absolute configuration around the metal ion of these complexes have been determined on the basis of their absorption and circular dichroism (CD) spectra. The complexes are monomeric tervalent complex ions in acid solution. In organic solvents and in crystalline states, they seem to have a dimeric structure with face-to-face O···H···O hydrogen bonds between three OH groups of the triprotonated $[Co(L\text{-amoH})_3]^{3+}$ and three oxygen atoms of the deprotonated $[Co(L\text{-amo})_3]^0$.

Although many examples of the stereospecific coordination of optically active diamines or amino acids to metal ions have been reported,[1] no work has been done concerning the complex containing optically active aminoalcohols. Yoneda and Kida[2] prepared the ethanolamine cobalt(III) complex, in which the ethanolamine coordinates to the cobalt ion as a bidentate ligand to form a five membered ring. Since the conformation of chelated ethanolamine will be a gauche form, the coordination of optically active aminoalcohols, such as L-alaninol, to the metal ion is expected to be stereospecific, as in the case of complex formation from *l*-propylenediamine and cobalt(III) ion.[3] In this paper we report the stereospecific preparation of some optically active cobalt(III) complexes of L-alaninol, -leucinol, -isoleucinol and -prolinol, and assign the geometrical and the absolute configuration of these complexes on the bases of an analysis of their absorption spectra and circular dichroism curves.

Experimental

Ligands. The optically active aminoalcohols, L-alaninol, -leucinol, -isoleucinol and -prolinol were prepared by reducing the corresponding L-amino-acid ethyl esters[4] with lithium aluminum hydride according to the method described by Karrer *et al.*[5] The aminoalcohols were distilled freshly before the use for preparation.

Preparation of the Complexes.[*2] 1) *fac*-*Δ*-$[Co_2(L\text{-alanoH})_3(L\text{-alano})_3](ClO_4)_3\cdot 2H_2O$. A mixture containing 4.0 g of $[Co(OH_2)(NH_3)_5](ClO_4)_3$ and 2.0 g of L-alaninol in 100 m*l* of water was heated on a water bath at 90°C with frequent stirring for an hour. After cooling down to the room temperature, the dark reddish violet solution was filtered to remove $[Co(NH_3)_6](ClO_4)_3$ produced during the reaction. The filtrate was evaporated gradually on a water bath at 60°C to about 20 m*l* and kept at room temperature for two or three days. The reddish violet crystals deposited gradually were filtered off and washed with ethanol and ether. The crude complex was recrystallized from 0.1 N perchloric acid solution by adding a mixture of ethanol and ether (1 : 1) and then cooling it in a refrigerator. This complex is soluble in water, methanol and perchloric acid but insoluble in ethanol and ether. The aqueous solution decomposed gradually and gave a dark brown solution.

Found: C, 24.00; H, 6.21; N, 9.46%. Calcd for $C_{18}H_{55}N_6O_{20}Cl_3Co_2 = [Co_2(L\text{-alanoH})_3(L\text{-alano})_3](ClO_4)_3 2H_2O$: C, 24.02; H, 6.16; N, 9.33%.

An attempt to prepare the corresponding bromide or sulfate was unsuccessful because of their large solubilities in accessible solvents.

2) *fac*-*Δ*-$[Co_2(L\text{-leunoH})_3(L\text{-leuno})_3]_2(SO_4)_3\cdot 3H_2O$. The crude complex was obtained by warming a mixture containing 3.4 g of L-leucinol and 2.9 g of $[Co(OH_2)_2(NH_3)_4](SO_4)_3\cdot 3H_2O$ in 25 m*l* of water at 70°C for three hours. Recrystallization was made as follows; to the 2 N sulfuric acid solution of crude complex was

added dropwise with stirring 1 N sodium hydroxide solution until the pH value of the solution reached 6. After a while, the precipitates, which might be a *Λ*-type leucinol complex contained in the crude complex, were removed by filtration. The desired *Δ*-type complex was obtained by adding more 1 N sodium hydroxide solution to the filtrate to pH 8. This procedure was repeated to give a constant CD curve. The pure complex is insoluble in water, ethanol and ether, but fairly soluble in dilute sulfuric acid, and more in a mixture of concentrated sulfuric acid and methanol (1 : 1).

Found: C, 43.84; H, 10.38; N, 8.52%. Calcd for $C_{36}H_{89}N_6O_{13}S_{3/2}Co_2$=[$Co_2$(L-leunoH)$_3$(L-leuno)$_3$]-$(SO_4)_{3/2}H_2O$: C, 44.12; H, 9.15; N, 8.57%.

3) *fac-Λ*-[Co_2(L-leunoH)$_3$(L-leuno)$_3$]Br_3. The crude complex was obtained by a procedure similar to that used for the *Δ*-leucinol complex, with 2.0 g of L-leucinol and 2.2 g of [$Co(OH_2)(NH_3)_5$]Br_3. The product was dissolved in a mixture of 47% hydrobromic acid and methanol (1 : 1), and 1 N sodium hydroxide solution was added dropwise to the solution to pH 1. The precipitate was recrystallized repeatedly by the above method to obtain a constant CD curve. The pure complex is insoluble in water and methanol, but slightly soluble in concentrated hydrobromic acid and fairly so in a mixture of concentrated hydrobromic acid and methanol (1 : 1).

Found: C, 40.63; H, 8.31; N, 7.78%. Calcd for $C_{36}H_{87}N_6O_6Br_3Co_2$=[$Co_2$(L-leunoH)$_3$(L-leuno)$_3$]$Br_3$: C, 40.88; H, 8.29; N, 7.94%.

4) *fac-Δ*-[Co_2(L-isoleunoH)$_3$(L-isoleuno)$_3$]$_2(SO_4)_3\cdot 7H_2O$ and *fac-Λ*-[Co_2(L-isoleunoH)$_3$(L-isoleuno)$_3$]$Br_3\cdot 3H_2O$. These complexes were prepared by recrystallizing the crude products which were obtained by the procedures similar to those for the corresponding L-leucinol complexes.

Found: C, 39.65; H, 9.17; N, 7.45%. Calcd for $C_{36}H_{101}N_6O_{19}S_{3/2}Co_2$ = [Co_2(L-isoleunoH)$_3$(L-isoleuno)$_3$]-$(SO_4)_{3/2}\cdot 7H_2O$: C, 39.73; H, 9.36; N, 7.72%.

Found: C, 38.88; H, 8.00; N, 7.47%. Calcd for $C_{36}H_{93}N_6O_9Br_3Co_2$ = [Co_2(L-isoleunoH)$_3$(L-isoleuno)$_3$]-$Br_3\cdot 3H_2O$: C, 38.89; H, 8.43; N, 7.56%.

5) A mixture of *fac-Δ*- and *fac-Λ*-[Co_2(L-prolinoH)$_3$-(L-prolino)$_3$]$(ClO_4)_3$. A mixture containing 2.0 g of L-prolinol and 2.3 g of [$Co(OH_2)_2(NH_3)_4$]$(ClO_4)_3$ in 40 m*l* of water was evaporated gradually with frequent stirring on a water bath at 60°C to about 20 m*l*, and kept at room temperature for a day. The reddish purple crystals were a mixture of *fac-Δ*- and *fac-Λ*-L-prolinol complex.

Separation of *Δ*- and *Λ*-Isomer. The product was dissolved in a mixture of 60% perchloric acid and methanol (1 : 1), and filtered once. The crude *Λ*-complex was precipitated by adjusting the pH of the filtrate to 1 with 2 N sodium hydroxide solution. Pure *Λ*-complex was obtained by recrystallizing these precipitates repeatedly by the same method until the CD exhibited identical curves.

To the filtrate which was made free from the *Λ*-complex was added more 2 N sodium hydroxide solution slowly and the pH of the solution was adjusted to about 4. The precipitate was filtered off and recrystallized by the same method repeatedly to have a constant CD curve. Both the *fac-Δ*- and the *fac-Λ*-complex were insoluble in water and methanol, but fairly soluble in acetone and dilute perchloric acid and more in a mixture of 60% perchloric acid and methanol (1 : 1).

Found: *fac-Δ* isomer, C, 31.26; H, 6.38; N, 7.23%. Calcd for $C_{30}H_{77}N_6O_{25}Cl_3Co_2$ = [Co_2(L-prolinoH)$_3$(L-prolino)$_3$]$(ClO_4)_3\cdot 7H_2O$, C, 31.40; H, 6.76; N, 7.32%.

Found: *fac-Λ* isomer, C, 34.17; H, 6.21; N, 7.79%. Calcd for $C_{30}H_{67}N_6O_{20}Cl_3Co_2$ = [Co_2(L-prolinoH)$_3$(L-prolino)$_3$]$(ClO_4)_3\cdot 2H_2O$, C, 34.07; H, 6.39; N, 7.95%.

Measurements. Visible and ultraviolet absorption spectra were obtained by Hitachi recording spectrophotometer Model 124. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. All the measurements were made at room temperature, 15—20°C.

Results and Discussion

Numerical data for the absorption and the CD bands of the complexes are given in Table 1. Figures 1—5 show the absorption and the CD spectra of the complexes prepared here.

Yoneda and Kida[2] reported that the ratio of cobalt to anion in the crystalline ethanolamine cobalt(III) complex salts was always 2 : 3, and assumed that the complex should be regarded as a double salt involving two different cations, [Co eta$_2$ eta′]$^{2+}$ and [Co eta eta′$_2$]$^+$ (eta=$NH_2CH_2CH_2OH$, eta′=$NH_2CH_2CH_2O^-$) bonded with each other through O–H–O hydrogen bonds. All the aminoalcohol complexes prepared here have the same molar ratio as that of the ethanolamine complex.

Configuration of the Isomers. Since the donor atoms of an aminoalcohol are nitrogen and

and no indication of splitting in the solvents used here. These facts indicate that all the complexes have the *fac* configuration around the cobalt(III) ion. The shift of the first and the second absorption bands of the alaninol and the prolinol complex in the different solvents may be related to the deprotonation of the hydroxo group in coordinated aminoalcohols (Figs. 1 and 5). This can be compared to the relation between aquo and hydroxo cobalt(III) complexes in acid and alkaline solutions.

The absolute configuration of the complexes can be assigned safely from their CD spectra. The CD curve of the L-alaninol complex in acid exhibits one strong positive and one weak negative peak in the first band region (Fig. 1). Such a pattern is characteristic of the Δ-type complex with trigonal symmetry and is very similar to those of such complexes of known absolute configuration as *fac*-Δ-[Co(L-alanine)$_3$][7] or Δ-[Co(L-pn)$_3$]$^{3+}$ (pn=propylenediamine)[8]. Since the complex ion in acid will exist as a monomeric protonated tris-alaninol complex, we conclude that the complex ion is of *fac*-Δ type around the cobalt(III) ion. The sulfates of L-leucinol and L-isoleucinol complex show CD curves similar to that of *fac*-Δ L-alaninol complex and can be assigned to the *fac*-Δ type, too (Figs. 2 and 3). The CD curves of the bromides of L-leucinol and L-isoleucinol complex, on the other hand, exhibit only a strong negative peak at *ca.* 19000 cm^{-1}, and are very similar to that of Λ-[Co(D-pn)$_3$]$^{3+}$.[8] Therefore, we have assigned these bromides to the *fac*-Λ-configuration.

Figure 4 shows that both isomers of the L-prolinol complex give very different CD spectra from those of the above complexes in the first band region. Both appear to be typical of the Δ-type complex, although the CD intensity of one isomer is exceptionally large. Since both the isomers have been assigned to the *fac* form from their absorption spectra, they should be diastereomeric with each other. In order to determine the absolute configuration of these isomers, the CD in

the ultraviolet region seems to give a useful information. From the CD spectra of the alaninol, leucinol and isoleucinol complexes in the ultraviolet region, it will be recognized that the Δ-type complex in acid exhibits a strong negative CD band at *ca.* 39000 cm^{-1}, while the Λ-type complex a positive CD band at *ca.* 40000 cm^{-1} with a smaller intensity than that for the Δ-type complex. Such a relation was also observed in the CD spectra of Δ- and Λ-$[Co(L\text{-}pn)_3]^{3+}$.[9] On this empirical observation, the isomer which was separated below pH 1 could be assigned to the Λ-type, and the other isomer which precipitated at a higher pH to the Δ-type, as may be seen in Fig. 4. These CD bands may correspond to the charge transfer transition between the coordinated aminoalcohol and the cobalt(III) ion.

The higher CD intensity of Δ-prolinol complex or anomalous CD appearance of Λ-prolinol complex in the first band region as compared with those of the other aminoalcohol complexes could be explained by considering the vicinal effect of asymmetric nitrogen atoms of L-prolinols. The donor nitrogen atom of L-prolinol coordinated as a bidentate ligand becomes an asymmetric atom, and is forced to take a configuration antipodal to that of the similarly coordinated D-prolinol. The same CD behavior was observed in some L-proline complexes.[10] In the Λ-complex of L-prolinol, a negative CD band due to the Λ-configurational effect would be partly compensated by the strong vicinal effect of such an asymmetric nitrogen atom with positive CD sign. The high CD intensity of the Δ-complex of L-prolinol can be explained by the same consideration.

The Δ- and the Λ-isomer of each L-aminoalcohol complex are not enantiomeric with each other, but diastereomeric. If we assume that the stable conformation of the L-aminoalcohol, which has a similar skeletal structure to that of L-$(+)_D$-pn, is δ-gauche form, the Δ- and the Λ-tris-L-aminoalcohol complex should have the "lel" and the "ob" structure, respectively.[11] The *lel* complex is said to be more stable than the *ob* complex.[11] However, except for the case of L-alaninol complex, the reaction of L-aminoalcohols and cobalt(III) ammine complexes gave always both the *lel* and the *ob* complex of *fac*-type. The formation ratio of these isomers seemed to depend on the kind of outer-anion of starting cobalt(III) complexes, and might be related to the solubility of aminoalcohol complexes produced. More detailed study would be needed to elucidate the stereoselective coordination of such complicated ligands as L-leucinol or L-prolinol. In the case of L-alaninol complex, only a stable *lel* isomer was separated from the reaction mixture.

Attempts to prepare the other geometrical isomers, the meridional complexes, were unsuccessful. This might be related to the difficulty in forming a dimeric structure bonded with the O–H–O or N–H–O hydrogen bonding discussed later.

The higher CD intensity of charge transfer bands of the Δ-complexes than those of the Λ-complexes would be caused by a superposition of two CD bands with the same negative sign resulting from the Δ-configurational effect and the vicinal effect of L-aminoalcohols in δ-conformation. A weak negative CD band at 35600 cm^{-1} of the Λ-prolinol complex might be an imaginary minimum which appeared depending on the relation between the positive CD curve of the Λ-configuration and the negative CD curve of the δ-vicinal effect. The vicinal effect of coordinated L-pn in δ-conformation gave also a negative CD band for the charge transfer band in cobalt(III) complexes.[9]

Corresponding to the second absorption bands, both diastereomers give weak positive CD peaks. However, detailed discussion can not be made at the present stage because their origin is uncertain.

CD Spectra in Organic Solvents and in Alkaline Solutions. As is seen in Fig. 1, the CD curves of L-alaninol complex in methanol and in alkaline solution are very different from that in acid solution. The absorption spectra indicate that no substantial change of the complex itself such as decomposition or isomerization occur, but the complexes containing deprotonated L-alaninols will be present in these solvents as stated before. Therefore, such a big change in CD curves might be caused by a special interaction between the two kinds of complex in methanol or alkaline solution. Mason and Norman[12] reported that the CD curve of Δ-$[Co\,en_3]^{3+}$ (en=ethylenediamine) changes remarkably by forming an ion-pair between the complex ion and the phosphate ion, and that the complex ion and the phosphate ion might have a preferred mutual orientation in the ion-pair. The change of CD in the L-alaninol complex is much more remarkable than that in the ethylenediamine complex. A most probable structure of such an aggregate between the L-alaninol complex ions and molecules in methanol will be a dimeric form with face-to-face O···H···O hydrogen bonding between three OH groups of the triprotonated $[Co(L\text{-}alanoH)_3]^{3+}$ and three oxygen atoms of the deprotonated $[Co(L\text{-}alano)_3]^0$. The dimeric structure would also hold in the solid state as indicated by the chemical analysis. The same discussion could be made for the change on CD curves of L-prolinol complexes in acetone (Fig. 5).

In alkaline solutions, all alcoholic protons would be removed and the dimeric form would have O···H···N hydrogen bonding between three

oxygen atoms of a complex molecule and the three amino groups of another molecule.

As in the case of the Δ-$[Co\,en_3]^{3+}$-phosphate system,[12] the change in CD of the first band in methanol and in alkaline solution might be related to the appearance of a new CD band at *ca.* 36000 cm^{-1}, which originates probably in a charge transfer transition relating to the bridging hydrogen bonding in the aggregate. The absorption spectra in these solvents indicate also the appearance of new absorption bands due to such a transition in the range between 20000 to 40000 cm^{-1}. At present, however, it is almost impossible to interpret the behavior of CD curves of the aggregates in these solvents.

12) R. Larsson, S. F. Mason and B. J. Norman, *J. Chem. Soc., (A)*, **1966**, 301.

Molecular models of the aggregates show that the O···H···O hydrogen bonding seems to be formed more easily between the Λ(*ob*)-complexes than that between Δ-(*lel*)-complexes, when we assume a tetrahedral angle for $\angle$Co–O–H and a linear O···H···O hydrogen bonding. Together with the different stabilities between the *lel* and the *ob* form,[11] two different dimeric forms, Δ-Δ and Λ-Λ, might have different stabilities, and consequently different solubilities. Therefore, the two isomers, *fac*-Δ- and *fac*-Λ- complex of each L-leucinol, L-isoleucinol and L-prolinol could be isolated by the solubility differences in solutions with different pH values.

We wish to thank the Ministry of Education for the financial support granted to this research.

Activation Analysis of Antimony in Tin Based on an Internal-Monitor Method using Thermal Neutrons

Yoshinaga OKA, Toyoaki KATO and Hui-Tuh TSAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 25, 1968)

An internal-monitor method proposed previously has been applied to the determination of trace amounts of antimony in tin by activation with thermal neutrons. After the antimony activity is chemically separated from the irradiated sample, the γ-ray spectrum corresponding to a mixture of ^{124}Sb and ^{125}Sb formed by the β^- decay of ^{125m,125}Sn is measured. Synthetic mixtures of antimony and tin with known weight ratios have been prepared to check the accuracy of the method. Good proportionality has been obtained between the ratios of the ^{124}Sb to ^{125}Sb activities and the ratios of the concentrations. By using this relationship, antimony analysis can easily be carried out. The content of antimony in a sample of tin down to 0.2 ppm can be determined with a relative error of $\pm 2\%$.

In cases of thermal neutron activation, where the atomic number of the element to be analyzed is higher by one unit than that of the matrix element and where the nuclear characteristics of the (n, γ) reaction product of the former and secondary β^- decay product from the latter are favorable for subsequent γ-ray spectrometric measurements, it is possible to determine the content of the element in question on the basis of the activity ratios of both radioactive species.

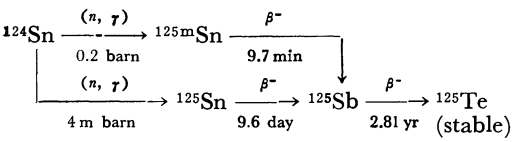
In a previous report,[1] the principles and applicability of this internal-monitor method to the determination of a trace amount of silver in palladium was described. By this method, errors which arise from neutron flux irregularities and self shielding effects can be avoided, and no corrections for chemical yield are neccessary. In the present work, this method was further applied to the determination of trace amounts of antimony in tin by means of thermal neutron activation.

Method of Determination

Antimony can be determined by γ-ray spectrometry through the induced ^{122}Sb or ^{124}Sb activity in an irradiated sample. Tin, on the other hand, gives nine radionuclides as (n, γ) reaction products: ^{113m}Sn, ^{113}Sn, ^{117m}Sn, ^{121m}Sn, ^{121}Sn, ^{123m}Sn, ^{125m}Sn and ^{125}Sn. However, radionuclides of present

1) Y. Oka, T. Kato, H.-T. Tsai and K. Nomura, This Bulletin, **41**, 329 (1968).

importance are formed through the following reaction scheme:



When the antimony activity is separated from the irradiated sample, therefore, a composite γ-ray spectrum which corresponds to a mixture of the 2.8 day-^{122}Sb, the 60.9 day-^{124}Sb and the 2.81 yr-^{125}Sb as β^--decay products of ^{125m,125}Sn is measured. The marked difference in energy of γ-rays emitted from ^{124}Sb (1.69 MeV) and ^{125}Sb (0.427 MeV) permits a γ-ray spectrometric determination of antimony in tin. By applying the principles illustrated in the previous report,[1] the following linear relationship is obtained between the ratio of the photopeak activities determined at identical times after each irradiation (R_{A_t}) and the ratio of the concentrations (R_W):

$$R_W = K R_{A_t}$$

The constant, K, can be determined by irradiating synthetic mixtures of antimony and tin with known compositions.

Experimental

Materials and Irradiation. A series of synthetic antimony - tin mixtures was prepared in the following manner. Tin powder 100 mg was weighed into a quartz tube with an internal diameter of 6 mm, and then known amounts of an aqua regia solution of antimony added. After evaporation to dryness, the tube was sealed.

The tin powder used was processed from tin(II) chloride of a guaranteed grade. After repeated recrystallization, the reagent was dissolved in hydrochloric acid. Tin was precipitated from this solution in the form of metallic powder by the addition of a concentrated sodium hydroxide solution with heating, repeatedly washed with water and dried in a vacuum.

The aqua regia solution of antimony was prepared through the dissolution of 99.9999% antimony metal. Proper dilution with water was made just before use. The hydrochloric acid, nitric acid and water were all redistilled. All other chemicals were of a guaranteed grade.

Commercial tin metal of a granular form and an electrolytic tin rod were tested for their antimony contents. From these samples, small pieces of approximately 60 mg were cut out and analyzed. The samples, a series of synthetic mixtures and 100 mg of the original tin powder were put together in an aluminum capsule for pile irradiation. Irradiation was performed for 180 hr in the JRR-2 reactor of the Japan Atomic Energy Research Institute. The reactor was operated at 10 MW, providing a thermal neutron flux of 2.0×10^{13} n/cm^2/sec at the irradiation site. After irradiation, the samples were cooled for 13 days and then subjected to the radiochemical procedure for the isolation of their antimony activities.

Radiochemical Procedure. Radioantimony was extracted from a hydrochloric acid solution of an irradiated tin target with isoamyl acetate. The irradiated sample was dissolved in a small amount of aqua regia, and made 8 N in hydrochloric acid to a volume of 25 m*l*. To this, 5 m*l* of isoamyl acetate was added and radioantimony extracted with 10 minutes' agitation. The organic extract was washed twice with 10 m*l* portions of 8 N hydrochloric acid, and drained into a polyethylene tube for γ-ray spectrometric measurements.

γ-Ray Measurement. For the γ-ray spectrometric measurement, a $1\frac{1}{2}'' \phi \times 1\frac{1}{2}''$NaI(Tl) crystal connected to an 800-channel pulse-height analyzer made by the Tokyo Shibaura Electric Co., Ltd., Japan was used. The graphical subtraction method[2] was employed to determine accurate photopeak areas from the γ-ray spectra obtained. Decay curve analyses have been performed for photopeak activities to confirm the radiochemical purity.

Results and Discussion

Isolation of Radioantimony. Penta-valent antimony is extractable from a hydrochloric acid solution with ethyl acetate, isoamyl acetate and other extractants,[3-5] and these properties have been utilized for the separation of a trace amount of antimony from tin.[6] To obtain the best procedure for the isolation of radioantimony from a large amount of tin, the extraction properties of both elements with isoamyl acetate have been examined further using ^{124}Sb and ^{113}Sn as tracers. Hydrochloric acid solution of varying concentrations containing definite amounts of either pentavalent antimony[7] or quadrivalent tin[8] was agitated with an equal volume of isoamyl acetate for 10 min. After agitation, both the organic and aqueous layers were γ-counted, and the percentage extraction was computed from the activity data. The extraction curves thus obtained are shown in Fig. 1. The extraction of antimony was best effected from a 7 to 8 N hydrochloric acid solution. Although up to about 20% of tin was accompanied by antimony, this could be completely removed by repeated backwashings with 8 N hydrochloric acid.

7) The neutron irradiated antimony sample was dissolved in aqua regia, and used for the extraction experiment.

8) To prepare this solution, a known amount of irradiated tin was dissolved in aqua regia with heating. From this, tin(IV) hydroxide was precipitated by the addition of a dilute aqueous sodium hydroxide solution. The precipitate was dissolved in 8 N hydrochloric acid, and the antimony activity removed by isoamyl acetate extraction. An aliquot of the aqueous layer was used for the extraction experiment.

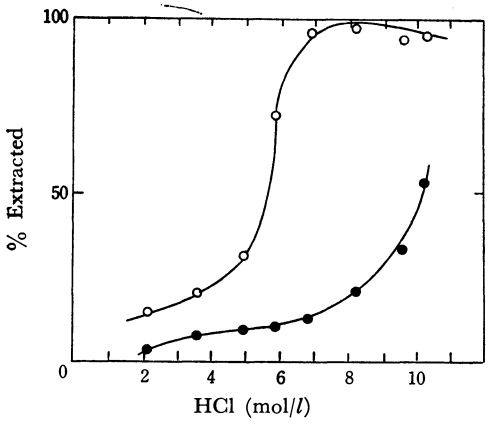

Fig. 1. Extraction curves of antimony(V) and tin(IV) from hydrochloric acid solution with isoamyl acetate.
○: Sb(V) 1.8 μg
●: Sn(IV) 2.6 mg
Org.: Aq. = 1:1 (5 ml)

When the irradiated antimony - tin mixture was subjected to the radiochemical procedure, a composite γ-ray spectrum was obtained in the final radioantimony fraction, which corresponds to a mixture of ^{122}Sb, ^{124}Sb and ^{125}Sb, as shown in Fig. 2-(1). Decontamination from other nuclides was successful.

R_W vs. R_{A_t} From the composite spectra obtained from the antimony - tin mixtures, photopeak areas were measured for 0.427 MeV γ-rays from ^{125}Sb, and for 1.69 MeV γ-ray from ^{124}Sb.

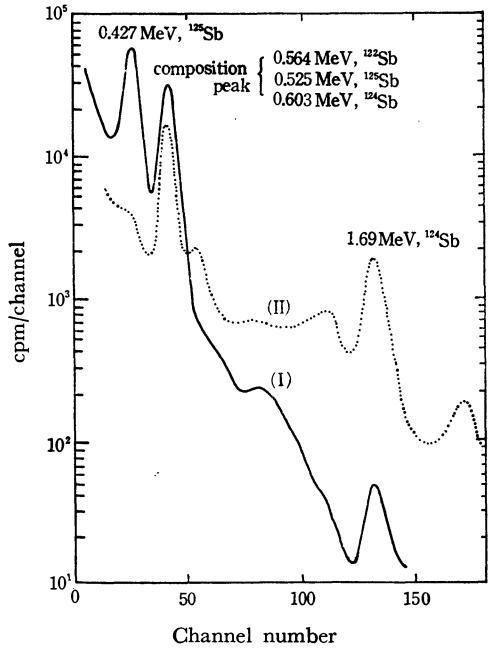

Fig. 2. γ-Ray spectra of radioantimony; (I) separated from irradiated tin - antimony mixture (Sn 101 mg+Sb 0.19 μg), 13 days after irradiation, (II) standard antimony sample.

The R_{A_t}'s were computed from the data thus obtained. At that time, the correction coefficient for ^{124}Sb arising from the original tin, α, was introduced in Eq. (1), obtaining

$$R_W = K\left(\frac{A_{^{124}\mathrm{Sb}}}{A_{^{125}\mathrm{Sb}}} - \alpha\right)_{t=13\ \mathrm{day}} \quad (2)$$

where

$$\alpha = \left(\frac{A_{^{124}\mathrm{Sb}}}{A_{^{125}\mathrm{Sb}}}\right)_{\mathrm{original}} \quad (3)$$

A's represent the photopeak activities. The α value obtained under the present conditions was 1.64×10^{-4}.[9] The reasons for this correction may arise from the antimony content in the original tin as an impurity and from the systematic second-order nuclear reactions as described later. Table 1

Table 1. R_W *vs.* R_{A_t} for tin-antimony mixtures

R_W	R_{At}[a]	R_W/R_{At}
8.67×10^{-6}	5.68×10^{-3}	1.52×10^{-3}
3.88×10^{-6}	2.59×10^{-3}	1.50×10^{-3}
1.85×10^{-6}	1.23×10^{-3}	1.50×10^{-3}
1.00×10^{-6}	6.80×10^{-4}	1.47×10^{-3}
3.13×10^{-7}	2.06×10^{-4}	1.52×10^{-3}
	Mean:	1.50×10^{-3}
	Std. dev.:	$0.01_8\times10^{-3}$ ($\pm1.2\%$)

a) 13 days after the end of irradiation

shows the relation between the weight ratios and the corrected photopeak activity ratios. Good proportionality was obtained between R_W and R_{A_t}. A relative standard deviation of ±1.2% was obtained under the present conditions. The present results show that an accurate determination can be expected using this relationship.

When a minimum photopeak area of 50 cpm is selected as the limit of detection, an antimony content in tin down to about 0.2 ppm (0.02 μg in a 100 mg sample) can be determined with a relative error of ±2%.

Interference. Interference which arises from the tin matrix has been examined. In the present case, the effects of the (n, p) and the (n, α) reactions by fast neutrons give no trouble, but interference through second-order nuclear reactions must be considered which would produce additional amounts of radioactive antimony and thus cause a positive error. ^{124}Sb is formed from tin according to the reaction scheme:

9) This corresponds to an antimony content of 0.25 ppm in the original tin. This can be attributed to the sum of antimony as an impurity and the apparent content produced by second-order reaction. The latter was computed to be 0.05 ppm as described later.

$$^{122}\mathrm{Sn}\begin{cases}(\mathrm{I}) \xrightarrow[0.16\ \text{barn}]{(n,\gamma)} {}^{123m}\mathrm{Sn} \xrightarrow[41\ \text{min}]{\beta^-} \\ (\mathrm{II}) \xrightarrow[1\ \text{m barn}]{(n,\gamma)} {}^{123}\mathrm{Sn} \xrightarrow[129\ \text{day}]{\beta^-} {}^{123}\mathrm{Sb} \xrightarrow[2.5\ \text{barn}]{(n,\gamma)} {}^{124}\mathrm{Sb}\end{cases}$$

The production rate of ^{124}Sb was computed using the Bateman equation.[10] Because of the small activation cross section for the ^{122}Sn(n, γ)^{123}Sn reaction and of the long half-life of the product, the production rate of ^{124}Sb through reaction path (II) can be excluded from the present calculation. Thus the scheme is simplified to successive reactions of the type:

$$N_1 \xrightarrow[\sigma_1]{\phi} N_2 \xrightarrow[A_1]{\lambda_2} N_3 \xrightarrow[\sigma_3]{\phi} N_4 \xrightarrow[A_4]{\lambda_4} N_5 \qquad (4)$$

where A's=activity; N's=number of atoms; λ's=disintegration constant; σ's=effective activation cross-section; and ϕ=effective neutron flux.

In order to compute the growth of the ^{124}Sb activity (A_4), a practical formula derived by De Neve *et al.*[11] was used in the present work. An apparent antimony concentration in ppb is defined by:

$$C_{\mathrm{ppb}} = \frac{A_4(\text{for 1 g Sn})}{A_4'(\text{for } 10^{-9}\text{ g Sb})} \qquad (5)$$

For an irradiation time of t, this becomes:

$$C_{\mathrm{ppb}} = \frac{N_1\sigma_1\phi}{N_4'(1-e^{-\lambda_4 t})}\left[t - \frac{\lambda_2+\lambda_4}{\lambda_2\lambda_4} + \frac{\lambda_2}{\lambda_4(\lambda_2-\lambda_4)}e^{-\lambda_4 t} - \frac{\lambda_4}{\lambda_2(\lambda_2-\lambda_4)}e^{-\lambda_2 t}\right] \qquad (6)$$

This apparent antimony content induced in the tin sample during 180 hr irradiation at a flux of 2.0×10^{13} n/cm^2/sec was computed to be 52 ppb.[12] This value must be subtracted from the gross antimony concentration to obtain the true antimony content in a sample of tin.

Antimony Analysis. This method of antimony analysis was tested on both granular tin and an electrolytic tin rod. The results obtained are shown in Table 2. These data were corrected for the effect of second-order reactions. Good agreement for antimony content in granular tin was obtained. The results for electrolytic tin, however, show an irregularity over the range of 2—3 ppm. The reason for this behavior may be inhomogeneities involving antimony as an impurity in this sample.

TABLE 2. RESULTS OF ANTIMONY ANALYSES

Sample	R_{A_t}	Antimony content (ppm)	Average
Granular tin	1.38×10^{-2}	20.7	20.4±0.3
	1.38×10^{-2}	20.7	
	1.34×10^{-2}	20.1	
	1.34×10^{-2}	20.1	
	1.37×10^{-2}	20.5

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 41 2431—2434 (1968)

1-Acylindoles. VI. On the Deacylation of the N¹-Position in the Formation of a 1,2,3,4-Tetrahydrocarbazole

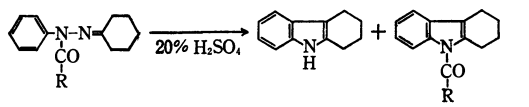
Hisao YAMAMOTO and Toshio ATSUMI

Pharmaceuticals Division, Sumitomo Chemical Co., Kasugade-cho, Konohana-ku, Osaka

(Received November 18, 1967)

The cyclization reaction of cyclohexanone acetylphenylhydrazone to produce a tetrahydrocarbazole derivative has been reinvestigated. Although other workers obtained only a deacylated derivative in the reaction products, we found also an acylated product. It can be concluded from the experimental results that an acyl group of the N¹-position of a phenylhydrazine derivative participates only a little in the indole cyclization and that the deacetylation occurs mainly after formation of a new C–C bond.

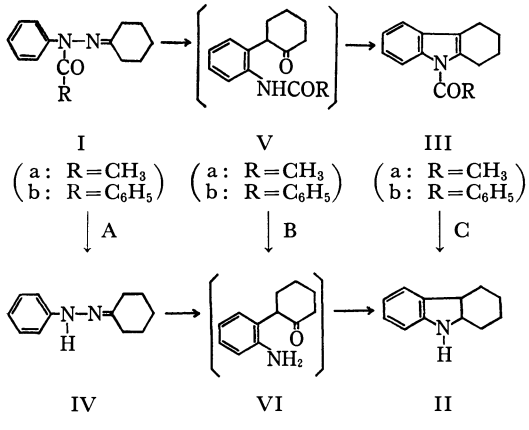
It has been found that 1,2,3,4-tetrahydrocarbazole (II) and 9-acetyl-1,2,3,4-tetrahydrocarbazole (IIIa) could be prepared by boiling cyclohexanone acetylphenylhydrazone in dilute sulfuric acid[1,2] (Scheme I).



I (a: R=CH₃, b: R=C₆H₅) II III (a: R=CH₃, b: R=C₆H₅)

Scheme I

However, Suvorov *et al.* have reported that the heating of cyclohexanone acetylphenylhydrazone in 20% aqueous sulfuric acid under reflux produced 1,2,3,4-tetrahydrocarbazole, but did not give 9-acetyl-1,2,3,4-tetrahydrocarbazole, suggesting that an acyl group of the N¹ atom of the hydrazone derivative stabilizes the p-electron pair of that nitrogen atom, thus inhibiting the formation of a new C–C bond.[3] We attempted to ascertain whether the hydrolysis of the acetyl group should preceded Fischer's indole cyclization or not.



I (a: R=CH₃, b: R=C₆H₅) V (a: R=CH₃, b: R=C₆H₅) III (a: R=CH₃, b: R=C₆H₅)

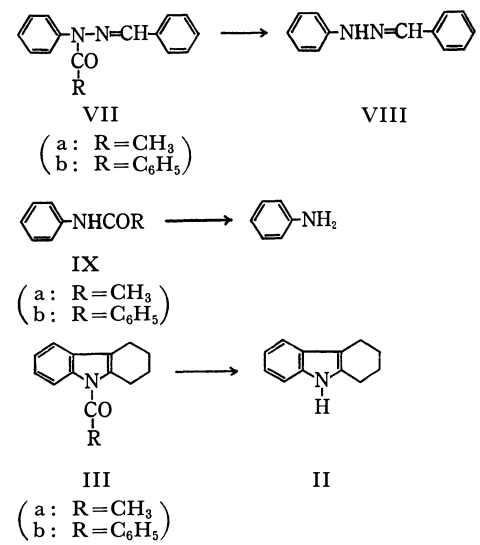
A B C

IV VI II

Scheme II

The processes for preparing IIIa and II from Ia are thought to be as follows (Scheme II).

II is considered to be obtained from I through Route A, B or C. Moreover, if the indole formation of an N¹-acylated compound is retarded remarkably by the substitution of the acyl group, the deacylation should precede the formation of a new C–C bond. The assumption suggests that the reaction proceeds through Route A. Therefore, II is thought to be formed from Ia *via* Route A.



VII (a: R=CH₃, b: R=C₆H₅) VIII

IX (a: R=CH₃, b: R=C₆H₅)

III (a: R=CH₃, b: R=C₆H₅) II

Scheme III

1) H. Yamamoto, *J. Org. Chem.*, **32**, 3639 (1967).
2) W. H. Perkin and S. G. P. Plant, *J. Chem. Soc.*, **119**, 1825 (1921).
3) N. N. Suvorov and N. P. Sorokina, *Doklady Acad. Nauk S.S.S.R.*, **136**, 840 (1961).

In order to make this point clear, we studied the deacylation rates of the intermediates of each step during the reaction. The following model experiments were carried out (Scheme III). From the model experiments of VII to VIII and IX to aniline, the possibilities of Route A and B may be estimated. The rates of deacylation in all the steps of the carbazole formation can be estimated to some degree from the results of these model experiments and the process of transforming III to II. In these experiments designed to transform VII to VIII, IX to aniline, and III to II, a starting material was heated under reflux in 20% aqueous sulfuric acid for a few minutes, and the reaction products were analyzed quantitatively.

Experimental

Ultraviolet Spectrometry. The ultraviolet spectra were measured with a Shimadzu RS-27 spectrophotometer, using a 1 cm quartz cell. Quantitative analyses were carried out by means of spectra taken in ethanol. The results are shown in Table 1.

TABLE 1.

Starting material (I)	Refluxing time (min)	Reaction products (mol%) III (IIIa or IIIb	II	III+II
Ia	3	9.5	14.1	23.6
	5	10.9	21.1	32.0
	8	15.6	30.2	45.8
	12	16.0	35.6	51.6
	16	17.0	40.9	57.9
Ib	5	54.5	—	54.5
	8	65.3	3.6	68.9
	12	73.3	5.4	78.7

Thin-layer Chromatography and Photometric Analyses. The quantitative analyses of several products were carried out by thin-layer chromatography and by means of the ultraviolet absorption spectra. The products were isolated by thin-layer chromatography. The conditions for this procedure were as follows: silica gel G (Merck & Co.); thickness, 0.25 mm; solvent, carbon tetrachloride - methanol (100 : 2). The portion of the product in the thin layer was extracted with ethanol, and then the ethanol solution was analyzed by a Shimadzu RS-27 spectrophotometer. The results are shown in Table 1.

Gas Chromatography. The gas chromatographs were taken on a Yanagimoto GCG-550 F gas chromatograph. The conditions for the chromatographs of the reaction products in the process of transforming Ia to IIIa and II were as follows: column, 5% PEG-20 M 3m×1.5 mm; column temperature, 220°C; carrier gas, hydrogen; gas speed, 15 ml/min; internal standard substance, tribenzylamine.

For the gas chromatography of products in processes of transforming VIIa to VIII and VIIb to VIII, the conditions are changed in the following points: column temperature, 230°C and 210°C; internal standard substance, dicyclohexyl phthalate and diphenyl phthalate respectively.

TABLE 2.

Starting material (VII)	Refluxing time (min)	Reaction products (mol%) VIII	Recovery of starting material VII
VIIa	3	7.2	55.7
	5	9.9	61.7
	8	11.5	47.2
	12	18.2	39.2
	16	24.5	31.8
VIIb	3	3.4	87.1
	5	5.0	85.0
	12	4.7	78.8
	16	4.6	80.6

For the gas chromatography of products in the hydrolysis of transforming III to II, the conditions were as follows: column, 5% PEG-20M 0.75 m×3 mm; column temperature, 200°C; carrier gas, hydrogen; gas speed, 20 ml/min; internal standard substance, tribenzylamine.

From the areas of the individual peaks, the mol% figures were calculated for each product after a relative response date had been determined by the internal standard method using an appropriate internal standard substance. The individual peaks were identified by means of the retention times of authentic samples. The results are shown in Table 2.

Potentiometric Titration. Aniline was estimated by the potentiometric titration of a 0.1 N perchloric acid solution in glacial acetic acid, using a Hitachi-Horiba Mode M-5 glass electrode pH-meter. The results are shown in Table 3.

TABLE 3.

Starting material	Refluxing time	Reaction products (mol%) Aniline	Recovery of starting material
IXa	3	20.2	
	5	24.3	
	8	41.8	
	12	49.3	
	16	60.2	
IXb	16	0	98—99

Materials. The starting substances and authentic samples for analyses were prepared as follows:

Cyclohexanone Acetylphenylhydrazone (Ia). To a mixture of 28.8 g of cyclohexanone phenylhydrazone[4] (IV), 14 g of pyridine, and 130 ml of dry ether, 13.5 g of acetyl chloride were added drop by drop on cooling. Stirring was continued for additional 3 hr at room temperature. After the completion of the reaction, the filtrate was concentrated to an oily, yellow substance, which was then distilled in a bath of 165°C to give oily,

4) A. Baeyer, *Ann.*, **278**, 105 (1894).

yellow Ia, bp 136—141°C/0.2 mmHg (lit[2] bp 210—220°C/14 mmHg).

Cyclohexanone Benzoylphenylhydrazone (Ib). According to the above procedure, 39.2 g of cyclohexanone phenylhydrazone afforded 23.2 g of colorless prisms of Ib, mp 121—123°C (recryst. from ether). Found: C, 78.69; H, 6.76; N, 9.53%. Calcd for $C_{19}H_{20}N_2O$: C, 78.05; H, 6.90; N, 9.58%.

1,2,3,4-Tetrahydrocarbazole (II). According to the method of Perkin and Plant,[2] the heating of IV under reflux in glacial acetic acid gave white needles of II, mp 113—116°C (recryst. from aqueous alcohol).

9-Acetyl-1,2,3,4-tetrahydrocarbazole (IIIa). To a solution of 1.9 g of N¹-acetylphenylhydrazine hydrochloride in 10 m*l* of glacial acetic acid, 1.0 g of cyclohexanone was added at room temperature. The mixture was then heated at 70—75°C for 2.5 hr with stirring. After the reaction, the reaction mixture was evaporated under reduced pressure to an oily residue, to which water was added to yield an oily, brown substance. This was extracted with chloroform and dried over anhydrous sodium sulfate. The chloroform solution was concentrated to a residue, which was then recrystallized from alcohol to give white needles of IIIa, mp 77—78.3°C (lit[2] mp 77°C).

9-Benzoyl-1,2,3,4-tetrahydrocarbazole (IIIb). According to the above method, 6.4 g of white needles of IIIb, mp 83.5—84.5°C (lit.[5] mp 85°C), were prepared from 7.5 g of N¹-benzoylphenylhydrazine hydrochloride.

Benzaldehyde Acetylphenylhydrazone (VIIa). According to the method of v. Auweres and Wolter,[6] the treatment of benzaldehyde phenylhydrazone with acetyl chloride gave white needles of VIIa, mp 120—122°C (lit.[6] mp 122°C).

Benzaldehyde Benzoylphenylhydrazone (VIIb). According to the above procedure, 10 g of white needles of VIIb, mp 114—115°C (recryst. from ethanol) (lit.[6] mp 115—116°C) were prepared from 11.3 g of benzaldehyde phenylhydrazone.

Benzaldehyde Phenylhydrazone (VIII). After 5.4 g of phenylhydrazine had been added to 5.3 g of benzaldehyde, the reaction mixture was allowed to cool in an ice-water bath. The resultant precipitate was filtered and recrystallized from alcohol to give 8.3 g of white needles of VIII, mp 154—156°C (lit.[7] mp 152°C).

Acetanilide (IXa). IXa, mp 114.5—116°C, was prepared from aniline and acetic acid.[8]

Benzanilide (IXb). IXb, mp 164—165°C, was prepared from aniline and benzoic acid.[9]

General Procedure of Hydrolysis or Ring Formation. After a compound has been heated under reflux in 20% aqueous sulfuric acid for 3 min, 5 min, 8 min, 12 min, or 16 min, the reaction mixture was poured into cold water, extracted with an appropriate solvent, and analyzed quantitatively.

Results and Discussion

I was refluxed in equimolar 20% aqueous sulfuric acid to yield the deacylated compound (II) as well as the corresponding III, the yield of which was calculated with thin-layer chromatography and photometric analysis. The results are shown in Table 1.

As a model experiment, IX was heated under reflux in 20% aqueous sulfuric acid. Aniline as a hydrolyzed product of IX was quantitatively measured by the potentiometric titration. These results are shown in Table 3.

VII was hydrolyzed under reflux in 20% aqueous sulfuric acid to yield VIII, which was then quantitatively analyzed by gas chromatography (Table 2).

IIIa or IIIb was refluxed in 20% aqueous sulfuric acid. The results of analysis by gas chromatography are shown in Table 4.

Table 4.

Starting material	Refluxing time	Reaction products (mol%)	
		Deacylated compound (II)	Recovery of starting material III
IIIa	5	4.3	79.3
	8	4.3	78.4
	12	3.9	80.8
IIIb	8	0.0	89.2
	12	0.0	84.0

From the results shown in Table 4, the deacylation of IIIa or IIIb is so difficult under reflux in 20% aqueous sulfuric acid that it can be said that IIIa is hardly deacylated, and that IIIb is, in fact, practically not deacylated at all. Moreover, the formation of II from Ia proceeds much more rapidly than the formation of VIII from VIIa. As the deacylation rate of I to IV (Route A) is considered to be similar to that of VII to VIII, the formation of II from Ia has to proceed more rapidly than the deacylation of I to IV (Route A).

However, the results shown in Table 3 show that IXa is easily deacylated to aniline, therefore, it seems that a considerable part of the reaction intermediate, Va, is easily deacylated to VI, which is then cyclized to II.

These results suggest that Route B participates considerably in the formation of the deacylated compound, II. Therefore, the greater part of II is proved to be a product deacylated after the formation of a new C–C bond.

Under refluxing in dilute sulfuric acid, the acid-amide bonding of IXb is not easily cleaved. IIIb was prepared from Ib quantitatively, and the rate of the carbazole formation of Ib is little different from that of Ia.

6) K. v. Auwers and E. Wolter, *Ann.*, **487**, 79 (1931).
7) E. Fischer, *Ber.*, **9**, 887 (1876).
8) L. F. Fieser, "Experiments in Organic Chemistry," D. C. Heath & Co., Boston (1957), p. 151.
9) C. N. Webb, "Org. Synth.," Coll. Vol. I, p. 82 (1956).

These results show that a considerable yield of 9-acetyl-1,2,3,4-tetrahydrocarbazole (IIIa) is given by treating cyclohexanone acetylphenylhydrazone (Ia) in 20% aqueous sulfuric acid under reflux, and that a 9-benzoyl derivative (IIIb) can be prepared in a much better yield from a corresponding hydrazone derivative (Ib) under the same conditions. In view of these facts, it can be concluded that a greater part of the deacylated compound is formed through the process of Route B.

Conclusion

In the case of $R=CH_3$, the refluxing of Ia in 20% aqueous sulfuric acid causes II as well as IIIa to be formed. II is considered to be formed mainly by the deacylation of Va to VI (Route B) on the basis of the following facts:

1. It can be concluded from the results of the model experiment (VIIa to VIII) that the deacylation of Ia is quite difficult under the same conditions.

2. The results of the deacylation of another model experiment (IXa to aniline) demonstrate that Va must be deacylated easily to VI.

3. It is very difficult for IIIa to be cleaved to II.

On the other hand, the same treatment of a compound, Ib, having $R = C_6H_5$ gave IIIb as the only product; it was nearly impossible to find II in the reaction products. This fact coincides with the results of the model experiments transforming VIIb to VIII, IXb to aniline, and IIIb to II.

It may be concluded that Fischer's indole cyclization is not notably affected by an acyl group of the N^1-position of a phenylhydrazine derivative and that deacylation mainly occurs in the step of V to VI (Route B) after the formation of a new C–C bond.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2434—2439 (1968)

The Dechloro-addition of β-Chloropropionitrile to Acrylonitrile with a Sodium Amalgam

Akira MISONO, Tetsuo OSA, Takamasa ASANO and Takeo SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 22, 1967)

The reaction of a mixture of β-chloropropionitrile, acrylonitrile, and water with a sodium amalgam was investigated. The main product was adiponitrile, which was formed mainly *via* a route consisting of three steps: I. The replacement of the chloride of β-chloropropionitrile with sodium. II. The addition of the organometallic intermediate formed to acrylonitrile. III. The replacement of the sodium in the final intermediate with hydrogen. The amount formed through the Wurtz reaction was small. The by-products were propionitrile, acrylonitrile, polymers of acrylonitrile, and organometallic compounds. The details of this reaction are given in this paper.

Adiponitrile has attracted much attention from industry in connection with the production of hexamethylenediamine, the raw material of Nylon-6,6, which has been usually synthesized from adipic acid or butadiene. Recently the dimerization of acrylonitrile has aroused interest because of its simplicity.

The methods of dimerization may mainly be classified into two from the industrial point of view: The method using the various kinds of alkali metal amalgams, and the electrolytic method using an aqueous or nonaqueous solvent containing McKee's salt as a supporting salt. By the former method, adiponitrile was, in 1949, obtained by the use of a sodium amalgam, but in a yield of only 5%.[1] The yield was increased to 62% (based on the acrylonitrile) by the use of a potassium amalgam and 20 wt% hydrochloric acid, but the efficiency of the amalgam consumed was only 12%.[2] In a similar reaction, adiponitrile was formed in a 75% yield with an alkali metal amalgam in an acidic medium in the presence of a catalyzer, such as phenol, hydroquinone, or aromatic amines, and a promotor, such as ferrous, ferric, nickel, or cobalt ions, and with the addition of acetone.[3] However,

many polymers of acrylonitrile were produced in this case.

The latter method has been reported on by Baizer since 1964;[4] much acrylonitrile was dissolved into an aqueous solution containing a high concentration of McKee's salt (for instance, tetraethylammonium *p*-toluenesulfonate), and then the solution was electrolytically dimerized. The yield reached almost 100%, and no by-products were formed. This method appears industrially promising.

The hydrodimerization of acrylonitrile has been investigated in our laboratory for the last several years, using an alkali metal amalgam in an acidic medium, in order to clarify the mechanism and the various factors of the reaction.[5]

We have found that the efficiency of the amalgam consumed was only 32% at most; the rest of the amalgam consumed was wasted in the formation of hydrogen gas. These reactions were, however, carried out in an aqueous medium. Therefore, the reaction in a non-aqueous medium was examined, but here a greater quantity of polymers of acrylonitrile was produced. The lack of a proton donor, such as water or alcohol, in the reaction system gave many organomercuric compounds.

In 1963, Knapsack proposed a method of producing adiponitrile[6] in which a mixture of β-chloropropionitrile, acrylonitrile and a small quantity of water was treated with alkali metal amalgam. The mechanism suggested was as follows:

1. $XCH_2CH_2CN + M\text{-}Hg \rightarrow \dot{C}H_2CH_2CN + MX + Hg$
2. $\dot{C}H_2CH_2CN + CH_2{=}CHCN \rightarrow NCCH_2CH_2CH_2\dot{C}HCN$
3. $\dot{C}H_2CH_2CN \rightarrow CH_2{=}CHCN + \dot{H}$
4. $NCCH_2CH_2CH_2\dot{C}HCN + \dot{H} \rightarrow NC(CH_2)_4CN$
5. $\dot{C}H_2CH_2CN + \dot{H} \rightarrow CH_3CH_2CN$
6. $2\ \dot{C}H_2CH_2CN \rightarrow NC(CH_2)_4CN$
7. $2\ \dot{C}H_2CH_2CN \rightarrow CH_3CH_2CN + CH_2{=}CHCN$

We have now developed a method similar to that of the Knapsack method in the course of our investigation of how to raise the efficiency of the alkali metal in the amalgam method. The factors affecting the reaction were not known, and the mechanism proposed by Knapsack was very doubtful; we undertook our investigation in order to clarify these problems.

Experimental

Acrylonitrile, Ethyl Acrylate and Methyl Acrylate. Commercial reagents were used after drying over "Drierite" and after distillation. The acrylates were distilled under a nitrogen atmosphere, and the distillates were kept under refrigeration in a brown bottle. Bp 78—79°C, 80—84°C, and 100—101°C respectively.

β-Chloropropionitrile, Ethyl β-Chloropropionate, and Methyl β-Chloropropionate. β-Chloropropionitrile was prepared as in the literature.[7] Bp 73—74°C/30 mmHg.

Ethyl β-chloropropionate and methyl β-chloropropionate were prepared by methods similar to the one described in the literature.[7] Ethyl β-chloropropionate: yield 80%, bp 161°C/760 mmHg; methyl β-chloropropionate: yield 72.5%, bp 147—148°C/760 mmHg.

Hydroquinone. Commercial hydroquinone was used without further purification.

Sodium Amalgam. The sodium amalgam was prepared by the electrolysis of a sodium hydroxide solution, using nickel as a cathode. The concentration of the amalgam was measured by titration.

Apparatus and an Example of the Reaction Procedure. β-Chloropropionitrile (0.3 mol), acrylonitrile (0.2 mol), and water (0.5 wt% of reaction mixture) were poured in a 100 m*l*, four-necked, round-bottomed flask equipped with a condenser, a thermometer, a dropping funnel, and a stirrer. The sodium amalgam (sodium 0.5 wt%, 0.1 g atom) was dropped from the funnel into the mixture with vigorous stirring. The temperature was kept between 40 and 42°C with water cooling. After 80 min, the reaction mixture was poured into a separatory funnel, and the amalgam separated was introduced into 4 N hydrochloric acid. The amount of residual sodium was determined quantitatively by the back titration of the acid. The pure water was charged into the separatory funnel to dissolve the neutral salt formed. Then the organic layer was separated from the aqueous layer and the aqueous layer was extracted with chloroform several times. All the organic parts were collected together and then analyzed by vapor-phase chromatography. The acrylonitrile and propionitrile were measured on a four-meter column packed with 10% dioctyl sebacate on diasolid M at 120°C. The β-chloropropionitrile was analyzed on a two-meter column packed with 10% silicone oil D. C. 550 on diasolid M at 120°C. The adiponitrile was analyzed on a three-meter column containing 10% diethyleneglycol sebacate on diasolid M at 200°C. The polymers of the yellow solid formed were not examined.

The deuterated compounds were analyzed with a mass spectrometer (Hitachi RMU-6E), using the ionization temperature of 110°C. The deuteration was determined by measuring the heights of the parent peak (P) and the (P−1) peak; the adiponitrile and the deuter ated adiponitrile were decomposed independently, and

the ratio of P and P+1 does not change very much whether a compound contains a deuterium or not.[8]

The calculation may be exemplified as follows (Table 1).

Table. 1.

Mass number	107	108	109	110	111
AN*		100 (P)	7.38 (P+1)*	0.24 (P+2)*	
DAN*			100 (P)*	7.39 (P+1)*	0.24 (P+2)*
AN		100 (P)	6.71 (P+1)		0.23
Reaction product (AN+DAN)		38.1	100	6.53	0.23

* These values are quoted from Ref. 8.

The mass number, 109, of the reaction product contains not only the parent peak of the deuterated adiponitrile, but also the P+1 peak of the pure adiponitrile.

Therefore, the strength based on only the deuterated adiponitrile can be calculated by a conventional proportion using the values cited above:

$$100 - 38.1 \times \frac{6.71}{100} = 97.4$$

The deuteration is determined from the next equation:

$$\frac{97.4}{38.1 + 97.4} \times 100 = 71.9\ (\%)$$

This method of calculation gives the percentage of a monodeuterated adiponitrile. Furthermore, it is sure that the method is suitable for this investigation, because the formation of the adiponitrile containing two deuterium atoms may be neglected; the simple calculation shows that the existence of this compound results in the measurement of a larger value than the 0.23 of the 111 peak.

The symbols used in this report have the following meanings:

$$\eta_{ADN} = \frac{\text{formed adiponitrile (mol)} \times 2}{\text{consumed sodium (g atom)}} \times 100\ (\%)$$

$$\eta_{PN} = \frac{\text{formed propionitrile (mol)} \times 2}{\text{consumed sodium (g atom)}} \times 100$$

Results and Discussion

When a mixture of β-chloropropionitrile and acrylonitrile was treated with a sodium amalgam in the presence of water, the same products as those reported by Knapsack, namely, adiponitrile as the main product, and propionitrile, acrylonitrile, polymers of acrylonitrile, and organomercuric compounds as by-products, were obtained. These products were explained by him as being produced through the radical mechanism described above. However, the possibility of the mechanism could be eliminated because of the fact that hydroquinone added to the reaction solution did not disturb the reaction (Fig. 1). Therefore, the addition of β-chloropropionitrile to acrylonitrile with a sodium amalgam was dealt with in detail in order to clarify the reaction mechanism.

In the above-mentioned reaction, the water, added over a range of 0 to 1.0% by weight based

A little amount of water (0—0.1 wt%) produces so much organomercuric compounds that the exact efficiencies are difficult to be obtained.

on the reaction solution, changed the η_{ADN} and η_{PN} values considerably (Fig. 2). To clarify the effect of water further, the deuterated water was added to the reaction solution in place of the water. The resulting adiponitrile and propionitrile were deuterated, whereas the reagents, such as β-chloropropionitrile and acrylonitrile, were not deuterated.

Figure 3 shows the correlation of the deuteration with the time. The deuteration of adiponitrile was 100% for the first ten minutes, after which it gradually decreased, while that of propionitrile decreased from the beginning of the reaction. The fact that deuterated compounds are obtained may mean that the water plays an important role as a proton donor and that some water is gradually formed during the reaction and then takes part in it, resulting in the decrease in the amount of deuterated products with the time. On the basis of the above findings, the reaction process producing adiponitrile may be expressed by the following equations. β-Chloropropionitrile reacts with a sodium amalgam to produce a cyanoethyl radical(I):

$$ClCH_2CH_2CN + NaHg \rightarrow \underset{\text{I}}{\dot{C}H_2CH_2CN} + NaCl + Hg \quad (1)$$

As a free radical is detected by a ESR spectrometer in a similar reaction, using methyl acrylate and methyl β-chloropropionate in place of acrylonitrile and β-chloropropionitrile[9] respectively, Eq. (1) is also adequate for this reaction. As estimated in the report that an acrylonitrile radical in a solution easily initiated the polymerization of acrylonitrile,[10] only a little of the cyanoethyl radical (I) may exist in the solution. Polyacrylonitrile was produced in this dimerization. However, relatively little of the polymer was formed, and the formation was suppressed by the addition of hydroquinone. However, hydroquinone did not disturb the desirable reaction, namely, the formation of adiponitrile. Therefore, as is generally understood, almost all the hydroquinone added may be surmised to dissolve in the reaction solution, little remaining on the surface of the amalgam. Thus the desirable reaction is disturbed little. In other words, the cyanoethyl radical (I) seems to attach to the surface of an amalgam and diffuses little into the solution, thus making it suitable for the dimerization. The compound I, then, reacts with another sodium atom to produce a cyanoethyl sodium compound (II).

$$I + NaHg \rightarrow \underset{\text{(II)}}{NaCH_2CH_2CN} + Hg \quad (2)$$

$$II + CH_2{=}CHCN \rightarrow \underset{\text{(III)}}{NCCH_2CH_2CH_2\underset{\displaystyle Na}{\underset{|}{C}}HCN} \quad (3)$$

Equation (3) is an example of the Schorigin reaction, which involves the addition of the organometallic compound to the unsaturated bonds, such as C=C, C=O, and C≡N.

The compound III may produce adiponitrile by a protonation reaction, as is generally accepted in the reaction of an organometal σ-complex with a proton, the added water acting as a proton donor.

$$III + H_2O(\text{or } D_2O) \rightarrow NC(CH_2)_4CN(\text{or } NC(CH_2)_3CHDCN) + NaOH(\text{or } NaOD) \quad (4)$$

$$NaOH + ClCH_2CH_2CN \rightarrow CH_2{=}CHCN + H_2O + NaCl \quad (5)$$

This theory is supported by the formation of deuterated adiponitrile ($NCCH_2CH_2CH_2CHDCN$). The deuterated position was determined by a mass spectrometer. The peak of the mass number 41 was considerably higher in the case of the deuterated adiponitrile than in that of adiponitrile, showing the existence of a CHDCN fragment. In addition, a little α-cyanoethyladiponitrile was formed during the dimerization reaction. These facts indicate that the α-carbon carried deuterium, that is, that contained sodium.

When a little water (usually 0.5 wt%) is present in the organic layer, the above steps proceed smoothly, because Eq. (5) holds and reproduces water as a proton donor, which then takes part in Eq. (4).

This is confirmed by independent experimental results and by the decrease in the deuteration with time (Fig. 2). Furthermore, two other mechanisms producing adiponitrile can be considered: (a) the

Table 2. Codimerizations with some vinyl compounds and their hydrochlorinated compounds*

Raw material		Reaction products		
Hydrochlorinated compound	Polar vinyl compound	Wurtz dimer (%)	Schorign dimer (%)	Hydrodimer (%)
β-Chloropropionitrile	Ethylacrylate	Adiponitrile 0	Ethyl δ-cyanovalerate 39.8	Diethyll adipate 23.9
β-Chloropropionitrile	Methylacrylate	Adiponitrile 0	Methyl δ-cyanovalerate 29.1	Dimethyl adipate 30.4
Ethyl β-chloropropionate	Acrylonitrile	Diethyl adipate 1	Ethyl δ-cyanovalerate 11	Adipo-nitrile nitrile 5
Methyl β-chloropropionate	Acrylonitrile	Dimethyl adipate 3	Methyl δ-cyanovalerate 33.1	Adiponitrile 16.1

Reaction conditions:
hydrocholrinated compound, 0.3 mol; vinyl compound, 0.2 mol; temperature 40°C; water 0.5 wt%/reaction mixture

* The yield was calculated from the assumption that 100% of amalgam was consumed within 80 min of the reaction time, even if all the amalgam was not used at 80 min.

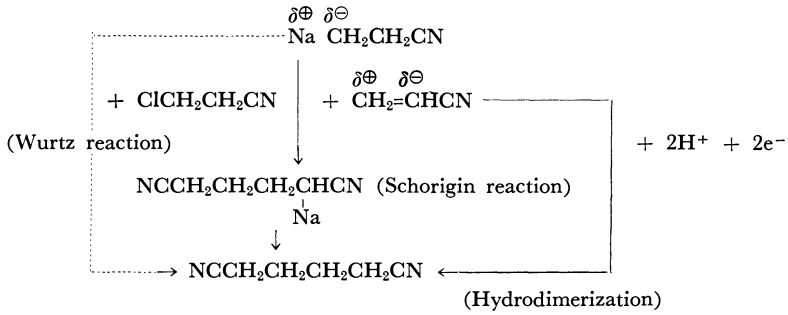

Fig. 4.

Wurtz reaction and (b) hydrodimerization. In the former reaction, the compound II reacts only with β-halogenopropionitrile, as is shown in Eq. (6):

$$II + ClCH_2CH_2CN \rightarrow NC(CH_2)_4CN + NaCl \quad (6)$$

In the latter one, on the other hand, acrylonitrile reacts with two protons and two electrons:

$$2CH_2{=}CHCN + 2H^+ + 2e^- \rightarrow NC(CH_2)_4CN \quad (7)$$

The ratio of these three types of dimerizations was determined using several hydrohalogenated compounds and polar vinyl compounds. The results of these experiments are shown in Table 2. The above-mentioned dimerization was found to occur obviously in three types of reactions: 1) the Schorigin reaction (Eq. (3)), 2) the Wurtz reaction (Eq. (6)), and 3) hydrodimerization (Eq. (7)). The yield of products by the Wurtz reaction was lowest. In general, the Schorigin reaction may be considered to occur more preferably than the hydrodimerization.

In these reaction conditions, the compound II seems to attack acrylonitrile nucleophilically, because the β-carbon of acrylonitrile has a larger $\delta\oplus$ charge than that of β-chloropropionitrile (Fig. 4).

Figure 2 showed that the formations of adiponitrile and propionitrile were competitive. Therefore, in order to obtain adiponitrile in a high yield, the water added must be suitably controlled. When water is added in an excessive amount, the propionitrile formation becomes the main process.

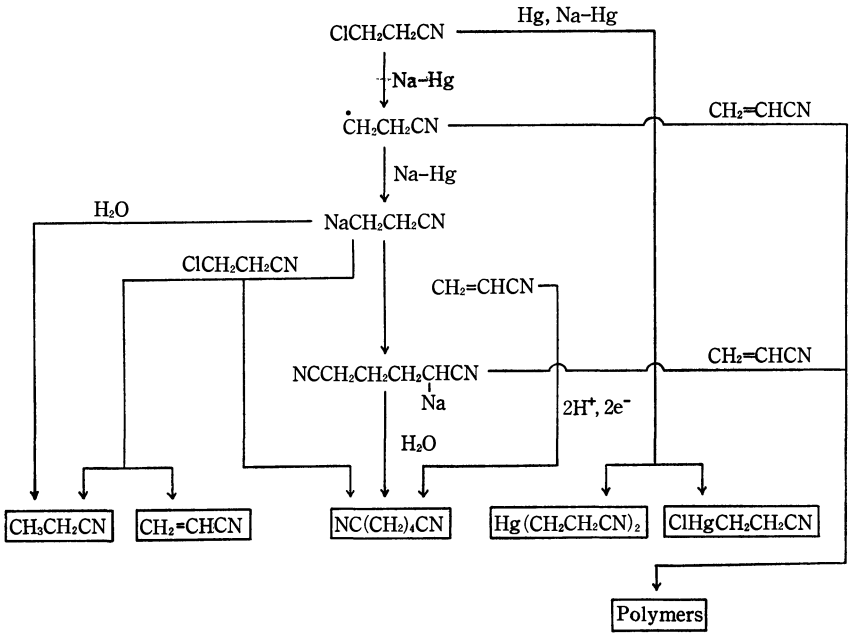
The increase in η_{ADN} with the addition of water in the range from 0 to 0.5 wt% suggests that the excess water participates in the reaction through Eq. (8):

$$II + H_2O \rightarrow CH_3CH_2CN + NaOH \quad (8)$$

The decrease in η_{PN} in the range between 0 to 0.5 wt% suggests that another reaction, such as Eq. (9), is predominant:

$$II + ClCH_2CH_2CN \rightarrow CH_3CH_2CN + CH_2{=}CHCN + NaCl \quad (9)$$

Accordingly, the total reaction is as follows:



$$NaOH + ClCH_2CH_2CN \rightarrow H_2O + NaCl + CH_2{=}CHCN$$

Fig. 5. Reaction scheme.

$$2ClCH_2CH_2CN + 2NaHg \rightarrow NC(CH_2)_4CN + 2NaCl + 2Hg \quad (10)$$

and

$$2CH_2{=}CHCN + 2H^+ + 2e^- \rightarrow NC(CH_2)_4CN \quad (7)$$

Eq. (10) appears to be simply an example of the Wurtz reaction and does not show the role of acrylonitrile, because the acrylonitrile consumed by Eq. (3) is regenerated by Eqs. (5) and (9).

The polymers of acrylonitrile may be produced by the insertion reaction of III and the cyanoethyl radical diffused into the solution containing acrylonitrile:

$$III + nCH_2{=}CHCN \rightarrow \text{Polymers of acrylonitrile} \quad (11)$$

$$\dot{C}H_2CH_2CN + nCH_2{=}CHCN \rightarrow \text{Polymers of acrylonitrile} \quad (12)$$

The formation of organomercuric compounds may be explained by Eqs. (13) and (14):

$$ClCH_2CH_2CN + Hg \rightarrow ClHgCH_2CH_2CN \quad (13)$$

$$2ClCH_2CH_2CN + 2NaHg \rightarrow Hg(CH_2CH_2CN)_2 + 2NaCl + Hg \quad (14)$$

These reactions (11—14) waste the β-chloropropionitrile, sodium, and acrylonitrile.

From all these considerations, the following scheme (Fig. 5) may be proposed for this reaction. It is important that the formation of by-products shown in this scheme can be controlled by the preferable selection of additives. For example, when an adequate quantity of water is added, the formation of the organomercuric compounds can be completely suppressed, while the addition of hydroquinone can suppress the polymerization of acrylonitrile.

Consequently, adiponitrile was obtained in a yield of 50.1% (η_{ADN}) under these conditions; β-chloropropionitrile, 0.3 mol; acrylonitrile, 0.2 mol; water, 0.5 wt%; sodium amalgam, 0.5 wt% (0.1 g atom) of sodium; temperature, 40°C.

The authors wish to express their appreciation to Mr. Teruyuki Kodama for his discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2440—2442 (1968)

Catalytic Activity of Polymeric Vitamin B_{12} Model Compounds

Tadashi SASAKI and Fujinao MATSUNAGA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received December 11, 1967)

[$CoX(DH)_2$·P-4VP] (X: CN, Cl)-type polymeric complexes were prepared from dimethylglyoxime (DH_2) and poly-4-vinylpyridine (P-4VP) by a procedure similar to that reported for the preparation of [$CoX(DH)_2$·Pyr] (Pyr: pyridine) (T. Sasaki and F. Matsunaga, submitted to *Bull. Chem. Soc. Japan*). Moreover, their catalytic activities in the decomposition reaction of hydrogen peroxide were compared with those of the corresponding monomeric complexes [$CoX(DH)_2$·Pyr]; it was found that their activities decreases in the following order:

[$CoCl(DH)_2$·P-4VP] > [$CoCl(DH)_2$·Pyr] ≫ [$CoCN(DH)_2$·P-4VP] > [$CoCN(DH)_2$·Pyr]

About the relationship between structure and activity, it was concluded that the activity is much influenced by the nature of the X ligand of cobaloximes. It increases with a decrease in the interaction between the cobalt and nitrogen of a pyridine ring and with a weakening in the basicity of the coordinated bases. The structures of the polymeric complexes are discussed on the basis of their spectral data.

Much attention has been paid to the syntheses and catalytic behavior of polymeric chelates and studies have been made on the basis of their reactivity being similar to that of some enzymes with the object of obtaining enzymatic models from polymeric chelates. They were expected to show a "polymer effect" in their chemical character on the one hand, and to show some specific properties as polyelectrolytes on the other.[1] Akabori *et al.*[2] have found the catalytic activity of synthesized resins involving pyridoxal and salicylaldehyde in the racemization of amino acid, and Keyer[3] has reported on the catalytic activity of polymeric chelates in the decomposition reactions of hydrazine hydrate and hydrogen peroxide, though the corresponding monomeric chelates show no activity. Hatano *et al.*[4] have also described similar catalytic activity in polymeric chelates derived from some β-diketones and copper, while Roginski[5] has discussed the relationship between the electroconductivity and the catalytic activity of Cu-phthalocyanines in the oxidation of cumene, cyclohexene, and stilbene, including the decomposition reaction of hydrazine hydrate.

In a continuation of our previous examination,[6] we carried out the syntheses of polymeric vitamin B_{12} model compounds from dimethylglyoxime and poly-4-vinylpyridine according to the previous methods[6] and measured their catalytic activities in the decomposition reaction of hydrogen peroxide in comparison with the corresponding monomeric complexes, both in heterogeneous systems. The structures of the polymeric chelates will be discussed on the basis of their infrared and far-infrared spectra in the correlation with their catalytic activities.

Experimental

Materials. All the materials used in this experiment are commercially available except for poly-4-vinylpyridine, which was prepared by the procedure described by Katchalsky.[7] This polymer was soluble in hydrochloric acid and alcohol, but not in chloroform, dimethylformamide, *n*-pentane, or boiling benzene. η_{sp}=0.23 (EtOH, 0.33 g/100 m*l* at 20°C).

Preparation of Polymeric Chelates. The polymeric chelate, [$CoCN(DH)_2$·P-4VP], was prepared by the following scheme:

DH_2 (0.687 g, 0.0058 mol) and 0.35 g (0.0033 mol) of p-4VP were dissolved in 40 m*l* of hot 95% ethanol, and into this solution there was stirred a solution of 0.65 g (0.0028 mol) of $CoAc_2·4H_2O$ and 0.65 g (0.0025 mol) of KCN in 10 m*l* of water. The reaction mixture was then aerated vigorously for 4 hr while it was being heated at 70—80°C. Cobalt acetate was added last to avoid any cross-linkage of P-4VP with a cobalt atom. The precipitated brown powder was then collected and washed several times with large amounts of water,

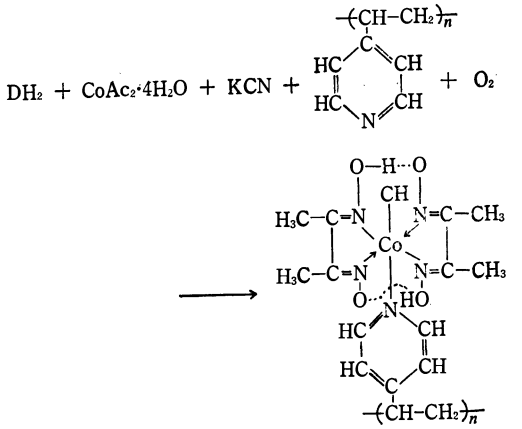
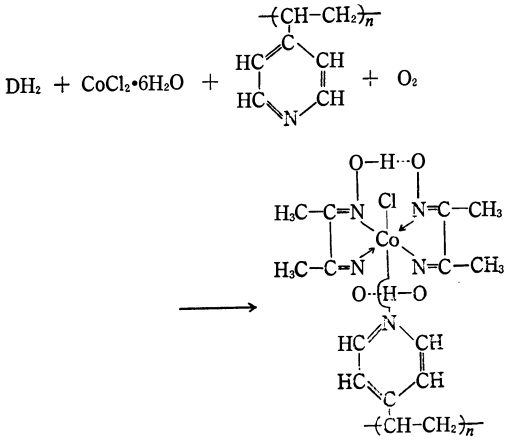
Table 1. Microanalyses and degree of chelation

Composition	Found (Calcd) C%	H%	N%		Degree of coordination
$[CoCN(DH)_2 \cdot Pyr] \cdot \frac{1}{2}H_2O$	41.69 (41.56)	5.02 (5.00)	20.38 (20.84)		
$[CoCN(DH)_2 \cdot P\text{-}4VP]$	48.53 (47.74)	5.25 (5.63)	17.65 (17.65)		65%
$[CoCl(DH)_2 \cdot P\text{-}4VP]$	48.26 (48.01—49.25)	5.44 (5.21—5.18)	16.45 (15.82—15.89)	Cl: 7.82 (6.93—7.10)	84—86%
$[CoCl(DH)_2 \cdot Pyr]$	N: 17.19 (17.34)	Cl: 9.14 (8.78)			



ethanol, and ether successively and dried under a vacuum. The yield was 0.9 g, mp >300°C. The microanalysis and the degree of coordination*1 are given in Table 1.

Similarly, a polymeric chelate, $[CoCl(DH)_2 \cdot P\text{-}4VP]$, was prepared by:



The yield was 1.4 g from 1.357 g (0.00116 mol) of DH_2. The microanalysis and the degree of coordination are given in Table 1.

Catalytic Activity of $[CoX(DH)_2 \cdot P\text{-}4VP]$ (X: CN, Cl). The decomposition rate of hydrogen peroxide in the presence of $[CoX(DH)_2 \cdot Pyr]$ and $[CoX(DH)_2 \cdot P\text{-}4VP]$ was measured at 40°C as follows: 10 m*l* of 30% aqueous hydrogen peroxide (8.8×10^{-3} mol), 10 m*l* of a phosphate buffer at pH 7.0 and a small amount of a non-ionic surface-active reagent, polyoxyethylene nonylphenol ether $\bar{P}=10$, were added to 60 m*l* of distilled water so as to bring the total volume to exactly 80 m*l*. After adding to this solution enough cobalt chelate to correspond to the 2.48×10^{-4} atom/*l* cobalt content, 5 m*l* aliquots were taken at regular time intervals, the decomposition was stopped by adding 10 m*l* of 9 N sulfuric acid, and the residual hydrogen peroxide was titrated with a 1/100 N $KMnO_4$ solution.

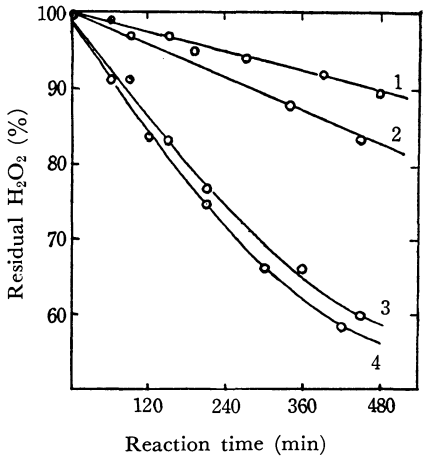


Fig. 1. Decomposition reaction of hydrogen peroxide.

Reaction temp: 40°C
Cobalt content in catalyst: 2.48×10^{-4} g atom/*l*
$[H_2O_2]_0 = 8.8 \times 10^{-3}$ mol/*l*
1 $[CoCN(DH)_2 \cdot Pyr]$
2 $[CoCN(DH)_2 \cdot P\text{-}4VP]$
3 $[CoCl(DH)_2 \cdot Pyr]$
4 $[CoCl(DH)_2 \cdot P\text{-}4VP]$

*1 The degree of coordination means the mole percentage of the chelate per monomer unit of P-4VP; it is readily calculated from the elemental analysis—that is, 100% means C, 45.71; H, 5.00; N, 20.00% calcd. for $(C_{16}H_{21}O_4N_6Co)_n$, and 0% means C, 79.96; H, 6.71; N, 13.32% calcd. for $(C_7H_7N)_n$. The observed values are located between these two values, for example, between 45.71 and 79.96 for C, and the deviations are expressed in the degree of coordination.

Table 2. Characteristic bands of monomeric and polymeric chelates (cm^{-1})

Compound	$\nu_{C=N}$	$\nu_{O-H\cdots O}$	$\nu_{C=N}$	ν_{NO}	δ_{NO}	ν_{Co-N}
[CoCN(DH)$_2$·Pyr]	2155	1745	1561	1239	1091	529, 518
[CoCN(DH)$_2$·P-4VP]	2155	1740	1563	1240	1095	529, 518
[CoCl(DH)$_2$·Pyr]		1740	1561	1239	1090	518
[CoCl(DH)$_2$·P-4VP]		1740	1562	1240	1095	518

The results are summarized in Fig. 1. When, in the above experiment, a mixture of P-4VP and DH_2 was used instead of [CoX(DH)$_2$·P-4VP], no activity was observed.

p*K* Values of the Coordinated Pyridine. The p*K*' values of pyridine and P-4VP were obtained from their titration curves. Because P-4VP was insoluble in water, P-4VP was previously dissolved in dilute hydrochloric acid of a known concentration, and this solution was titrated with 0.01 N NaOH. As NaOH was added to the solution, P-4VP was precipitated.

Infrared and Far-infrared Spectra. The infrared spectra of the chelates were measured in KBr pellets with a JASCO recording infrared spectrophotometer, Model IR-S, while the far-infrared spectra were measured with a Perkin-Elmer grating infrared spectrophotometer, Model 337.

Results and Discussion

Structural Elucidation of Polymeric Chelates. For this purpose, the infrared and far-infrared spectra of polymeric chelates were investigated and compared with the corresponding monomeric chelates. As is shown in Tables 2 and 3, the general patterns of the polymeric chelates were similar to those of the monomeric chelates except for the absorption due to the $\nu_{C=C,\ C=N}$ of a pyridine ring, which was observed to be shifted to a somewhat higher wave number by the coordination with a cobalt atom, presumably because of a lowering of the pyridine-ring conjugation.

The p*K*' values of pyridine and P-4 VP were given as 5.03 and 3.44 respectively at 20°C from their titration curves. Brown[8] has reported an increase in the basicity of pyridine derivatives upon the introduction of an alkyl group at the 4-position of the pyridine ring, but the fact that the basicity of P-4VP was less than that of pyridine can be explained by the prohibition of a proton attack on a pyridine ring caused by electrostatic repulsion by the positive-charged pyridinium ion structure in the polymer chain, an idea of which is supported by the above infrared spectral results.

Table 3. Change of frequency due to pyridine ring double bond (cm^{-1})

Compound	$\nu_{C=C,C=N}$	$\Delta\nu_{C=C,C=N}$*
[CoCN(DH)$_2$·Pyr]	1609	29
[CoCN(DH)$_2$·P-4VP]	1617	17
[CoCl(DH)$_2$·Pyr]	1609	29
[CoCl(DH)$_2$·P-4VP]	1616	16
Pyr	1580	
P-4VP	1600	

* Shifts by the coordination with a cobalt atom, for example: 1609−1580=29 and 1617−1600 =17

Relationship between Catalytic Activity and Structure. As may be clearly seen from Fig. 1, the fact that chlorocarboximatocobalt(III) showed a stronger activity than cyanocarboximatocobalt(III) in both monomeric and polymeric chelates indicates that the catalytic activity is much influenced by the X ligand and that there may be some relationship between the activity and the electronic state of the chelates. Since the characteristic absorption due to ν_{Co-N} in the far-infrared region is the same in monomeric and polymeric chelates, as Table 2 shows, their bond distances are thought to remain constant. The 29 cm^{-1} higher-frequency shift between [CoX(DH)$_2$·Pyr] and pyridine is bigger than the 16—17 cm^{-1} shift between [CoX(DH)$_2$·P-4VP] and P-4VP, indicating that the catalytic activity increased with a decrease in the interaction between a cobalt and a nitrogen atom of the pyridine ring. This result can be explained also on the basis of electronic theory: the electron-withdrawing cyano group enriches the positive charge on the cobalt atom, resulting in a stronger Co–N interaction and making the catalytic activity weaker than that of the corresponding chlorocomplexes; the reverse reasoning can be applied to an electron-donating chlorine group. About the relation between the p*K* values and the catalytic activities, it can be tentatively concluded that the weaker the coordinate base, the stronger the catalytic activity becomes, as is shown by a comparison of activity between polymeric and monomeric chelates, though further studies using several monomeric catalysts with known p*K* values are necessary to confirm this relation.

Stereospecific Synthesis of 1,4-Dienes. III. The Cobalt Chloride - Phosphorus Compound - Triethylaluminum Catalyst System

Go HATA and Akihisa MIYAKE

Basic Research Laboratories, Toyo Rayon Co., Ltd., Kamakura

(Received December 31, 1967)

The admixture of cobalt chloride, $(RO)_nPCl_{3-n}$(n=0—3), and triethylaluminum catalyzes the codimerization of 1,3-dienes with ethylene to give exclusively *cis* isomers of 1,4-dienes, which result from the 1,4-addition of a C-H bond of ethylene to the 1,3-dienes. The addition of ethylene to methyl-substituted 1,3-dienes occurs predominantly on the substituted sides of the 1,3-dienes. The activity of the catalyst is strongly affected by the nature of the trivalent phosphorus components.

The admixture of first-row transition metal compounds of Group VIII of the periodic table and organoaluminum compounds catalyzes reactions between butadiene and ethylene. Wilke has reported the formation of *trans, cis*-1,5-cyclodecadiene by the reaction of butadiene with ethylene using the nickel acetylacetonate - ethoxydiethylaluminum catalyst system (zerovalent nickel).[1] On the other hand, the cobalt acetylacetonate - triethylaluminum system[2] and the iron acetylacetonate - triethylaluminum system[3] have afforded linear codimers, 1,3-hexadiene and 1,*cis*-4-hexadiene respectively. It has recently been found that admixtures of ditertiary phosphine complexes of cobalt or tertiary phosphine complexes of nickel and organoaluminum compounds also catalyze the formation of 1, 4-hexadiene.[4,5] We have investigated an effective catalyst system for this reaction. This paper will report the results of the 1,4-diene synthesis by means of a ternary catalyst system, cobalt chloride - $(RO)_nPCl_{3-n}$ triethylaluminum (n=0—3), and the effect of the nature of the phosphorus compounds upon the catalytic activity.

Results

The catalyst was prepared by mixing cobalt chloride, $(RO)_nPCl_{3-n}$ (n=0—3, R=ethyl, *n*-butyl, phenyl, chlorophenyl and tolyl) and triethylaluminum in the presence of butadiene. The addition of ethylene (40 kg/cm^2) to the resultant mixture at 60—80°C led to the formation of 1,*cis*-4-hexadiene. The preparation of the catalyst in the absence of butadiene showed a poor activity. When the molar ratio of a phosphorus component to cobalt chloride was higher than one, the catalyst showed an excellent activity and a high selectivity (95%). After the complete consumption of the butadiene, the isomerization of 1,*cis*-4-hexadiene to 2,4-hexadiene took place, as may be seen in Fig. 1. The stereospecific formation of 1,*cis*-4-hexadiene has also been observed in $Fe(acac)_3$ - Et_3Al catalyst system[3] and the $CoCl_2(Ph_2PCH_2CH_2PPh_2)_2$-$Et_3Al$ catalyst system.[4] However, the $NiCl_2(PR_3)_2$-R_2AlCl catalyst system[5] and the

$RhCl_3$ catalyst[6] have been reported to afford a mixture of the geometrical isomers of 1,4-hexadiene.

The product corresponds to the 1,4-addition of a C-H bond of ethylene to butadiene. In unsymmetrical 1,3-dienes, there are two possible modes of the addition of ethylene. Isoprene reacted with ethylene to afford 4-methyl-1, *cis*-4-hexadiene and 5-methyl-1,4-hexadiene (in a ratio of 84 : 16) in about a 90% yield (Table 2). This reaction proceeded more slowly than that of butadiene with ethylene (Fig. 2). 1,3-Pentadiene reacted with ethylene to give 3-methyl-1,*cis*-4-hexadiene and 1,*cis*-4-heptadiene in a ratio of 91 : 9. The *trans* isomer of 1,3-pentadiene was found to be consumed faster than the *cis* isomer. These ratios of the products show that a vinyl moiety of ethylene attaches to the terminal carbon atom of the substituted double bond of a 1,3-diene system rather than to that of the non-substituted one.

○ butadiene, ● isoprene

The activity of the catalyst has been found to be strongly influenced by the nature of the trivalent phosphorus components. The results obtained by using different kinds of phosphorus components are listed in Tables 1, 3, and 4. Although the activity of the catalyst containing trialkyl phosphite was low, the catalyst containing triphenyl phosphite showed quite a high activity. The replacement of the butoxyl groups of tri-*n*-butyl phosphite or the phenoxyl groups of triphenyl phosphite by chlorine atoms increased the catalytic activity remarkably. The effect of the number of chlorine atoms in $(C_6H_5O)_nPCl_{3-n}$ upon the catalytic activity is summarized in Table 3. The results show that the phosphorus compound with more chlorine atoms directly bonded to the phosphorus atom is the more effective component of the catalyst. The effectiveness of the phosphorus components increases in the following order: $(C_6H_5O)_3P < (C_6H_5O)_2PCl < (C_6H_5O)PCl_2 < PCl_3$. In the catalyst system containing triphenyl phosphite, the higher molar ratio of triethylaluminum to cobalt chloride shows a higher activity. However, the catalyst systems of which phosphorus components have at least one P-Cl bond show a maximum activity at an appropriate molar ratio, as is shown in Table 3.

The results of the reaction using methyl or chlorine-substituted triphenyl phosphite as a catalyst component are summarized in Table 4. Tris(chlorophenyl)phosphites were more effective components than tritolyl phosphites. The effect of the *ortho*-substituents on the catalytic activity was quite large compared with that of the *para*-substituents. The *ortho*-substituted phenyl phosphites are arranged in the order of increasing effectiveness: $(o\text{-}CH_3C_6H_4O)_3P < (C_6H_5O)_3P < (o\text{-}ClC_6H_4O)_3P$.

TABLE 4. EFFECT OF A SUBSTITUENT OF TRIARYL PHOSPHITE UPON THE CATALYTIC ACTIVITY

Triaryl phosphite	Yield of 1,4-HD (g)
$(o\text{-}ClC_6H_4O)_3P$	25.9

Reaction conditions: $CoCl_2$ 0.5 mmol, triaryl phosphite 2 mmol, Et_3Al 12 mmol, toluene 20 cc, butadiene 0.6 mol, ethylene 40 kg/cm², 80°C, 1.5 hr

Discussion

An organoaluminum compound has been found to reduce a cobalt compound to yield a cobalt hydride complex.[7] It is known that a cobalt hydride complex adds to 1,3-dienes to give substituted π-allylcobalt complexes.[8] Recently, a substituted π-allylcobalt complex has been recognized as an important intermediate in the linear dimerization of butadiene by the $CoCl_2$-$Al(C_2H_5)_3$ catalyst system.[9] These facts suggest that the most probable intermediates in this reaction are substituted π-allylcobalt complexes coordinated with the phosphorus compounds. The reaction is believed to proceed through the following steps: the addition of ethylene to the 1-methyl-π-allylcobalt complex, **1**, and the subsequent reaction of the 4-hexenylcobalt intermediate, **2**, with butadiene. A 1-methyl-π-allylcobalt complex may exist in two isomeric forms, *syn* and *anti*. Since the 1,4-hexadiene obtained consists only of the *cis* isomer, the 1-methyl-π-allyl group must be bonded to the cobalt atom in the *anti* form, **1**.

The investigation of the effect of the phosphorus component upon the catalytic activity indicates that a less basic phosphorus component accelerates the reaction. Triphenyl phosphite has been reported to be less basic than triethyl phosphite,[10] as is to be expected from the electron-attracting property of a phenyl group. The former compound is a more effective catalyst component than the latter. The electron-attracting ability of a chlorine atom is expected to be greater than those of alkoxyl and phenoxyl groups. Therefore, the basicities of the phosphorus compounds would decrease in the following order: $(n\text{-}C_4H_9O)_3P > n\text{-}C_4H_9OPCl_2$; $(C_6H_5O)_3P > (C_6H_5O)_2PCl > (C_6H_5O)\text{-}PCl_2 > PCl_3$. This order accords with the increasing order of the activities of the phosphorus components.

The introduction of a substituent on each phenyl group of triphenyl phosphite affected the catalytic activity. An electron-attracting substituent accelerated the reaction, while an electron-donating substituent retarded the reaction, as expected. The increasing order of the inductive effect of the substituents is: *para* < *meta* < *ortho*. A remarkable effect of the *ortho* substituents was observed.

The catalyst systems the phosphorus components of which has P-Cl bonds were deactivated by excess triethylaluminum (Table 3). It has been reported that a P-Cl bond has been alkylated by trialkylaluminum.[11,12] This deactivation of the catalyst would be due to the alkylation of the P-Cl bond of the phosphorus components by triethylaluminum. The alkylation is accompanied by an increase in the basicity of the phosphorus components, which results in a decrease in the catalytic activity.

Trivalent phosphorus compounds can participate in both σ- and π-bonding in transition metal complexes. A decrease in the electron density on the phosphorus atom is believed to increase the π-bonding ability of the phosphorus ligand. The above results indicate that the π-bonding character of the Co–P bond of the catalyst species greatly affects the activity of the catalyst.

Experimental

Butadiene was purified by vaporization from a mixture of the liquefied diene and triethylaluminum. Isoprene and 1,3-pentadiene were distilled over calcium hydride. The solvents were refluxed over a K-Na alloy prior to distillation.

Triethyl phosphite, tri-*n*-butyl phosphite, triphenyl phosphite, and phosphorus trichloride were purified by distillation. Tris(*o*-chlorophenyl) phosphite, tris(*p*-chlorophenyl) phosphite, tri-*o*-tolyl phosphite, tri-*m*-tolyl phosphite, and tri-*p*-tolyl phosphite were each prepared by the addition of phosphorus trichloride to a *n*-hexane solution of the corresponding phenol and pyridine. *n*-Butyl phosphorodichloridite[13] and diphenyl phosphorochloridite[14] were prepared by the previously-reported methods. Phenyl phosphorodichloridite was synthesized by the following method. In a 1 *l* flask, 411 g (3 mol) of phosphorus trichloride were gently refluxed, and then 188 g (2 mol) of phenol were added. A vigorous evolution of hydrogen chloride occurred. After the addition, the unreacted phosphorus trichloride was removed under reduced pressure. Phenyl phosphorodichloridite distilled at 71°C/3 mmHg; 195 g (50% yield based on phenol). All of the above phosphorus compounds were distilled under a vacuum. Anhydrous cobalt chloride was prepared by the reaction of cobalt acetate with acetyl chloride.[15]

Addition of Ethylene to Butadiene. A 100 m*l* autoclave was charged with 20 m*l* of toluene, 5.0 m*l* of *n*-heptane (as an internal standard for gas chromatographic analysis), 0.065 g (0.5 mmol) of cobalt chloride, and 0.620 g (2 mmol) of triphenyl phosphite. After the gas within the autoclave has been replaced by ethylene, 52 m*l* (0.6 mol) of liquefied butadiene and a toluene solution of triethylaluminum (12 mmol) were added. The resultant mixture was stirred under ethylene pressure (40 kg/cm^2) at 80°C. The results are shown in Fig. 1.

Addition of Ethylene to Isoprene. A 100 m*l* autoclave was charged with 20 m*l* of xylene, 0.130 g (1 mmol) of cobalt chloride, 1.240 g (4 mmol) of triphenyl phosphite, 21.0 g (0.3 mol) of isoprene, and a xylene solution of triethylaluminum (20 mmol). The resultant mixture was stirred under ethylene pressure (40 kg/cm^2) at 80°C for 2 hr. The reaction product was decomposed with methanol and dilute hydrochloric acid. The oily layer was analyzed by gas chromatography using a squalane column. It contained 25.3 g (88% yield) of a mixture of 4-methyl-1,*cis*-4-hexadiene and 5-methyl-1,4-hexadiene and 2.6 g of C_7-conjugated dienes. The ratio of 4-methyl-1,4-hexadiene to 5-methyl-1,4-hexadiene was determined to be 84 : 16 by gas chromatography using a silver nitrate-benzyl cyanide column.

Addition of Ethylene to 1,3-Pentadiene. A 100-m*l* autoclave was charged with 10 m*l* of toluene, 0.065 g (0.5 mmol) of cobalt chloride, 0.620 g (2 mmol) of triphenyl phosphite, 20.4 g of 1,3-pentadiene (*trans*-*cis* ratio 66 : 34, purity 89%), and a toluene solution of triethylaluminum (12 mmol). The resultant mixture was stirred under ethylene pressure (40 kg/cm^2) at 80°C for 2 hr, yielding 13.8 g of 3-methyl-1,*cis*-4-hexadiene and 1.4 g of 1,*cis*-4-heptadiene in a 91% yield based on the 1,3-pentadiene consumed. The recovered 1,3-pentadiene consisted of 38% *trans* isomer and 62% *cis* isomer.

The addition products were identified by a comparison of their infrared spectra and gas chromatographic retention times with those of authentic samples.[3]

The Hydrogenation of Pyran Derivatives. IV. The Skeletal Rearrangement in the Gas-phase Dehydration of Tetrahydropyran-2-methanol

Akira MISONO, Tetsuo OSA and Yoshitomo SANAMI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received January 24, 1968)

The gas-phase dehydration of tetrahydropyran-2-methanol (TPM), prepared by the hydrogenation of the acrolein thermal dimer (3,4-dihyro-2H-pyran-2-carboxaldehyde (AD)), was investigated over various catalysts under atmospheric pressure. In this reaction, some of the pyran ring was found to be rearranged rapidly to a seven- or five-membered ring. For example, the highly-purified and crystalline η-alumina without any carrier produced cyclopentanecarboxaldehyde (CPA) as the main product in the yield of 71% at 330°C. Over the commercial alumina catalyst, considerable amounts of 2,3,4,5-tetrahydrooxepine (THO) and oxepane (OXP) were produced as by-products, though CPA was the main product; in some cases, as much THO and OXP were produced as CPA. On the other hand, the use of a dehydrogenation catalyst resulted in THO as the main product and CPA as a by-product; in the case of the use of copper-chromium oxide supported on Kieselguhr, with hydrogen as a carrier gas at 430°C, the yields of THO and CPA were 44.8% and 4.7% respectively. In these skeletal rearrangements, the seven-membered carbonium ion compound produced by the Wagner-Meerwein-type rearrangement must be a reaction intermediate. From this intermediate, mainly CPA was produced over alumina, influencing the lone-electron pair of the ethereal oxygen. THO, on the contrary, was produced mainly over a dehydrogenation catalyst. Moreover, twice as high a yield of 1,6-hexanediol was obtained from the hydrogenation of the hydrated THO than from the hydrogenolysis of TPM or AD, as has been noted in a previous paper.

It is well known that dihydropyran is produced by the skeletal rearrangement during the dehydration of tetrahydrofurfuryl alcohol over an alumina catalyst. The reaction mechanism has been accurately established by many reports,[1,2] during the skeletal rearrangement, the carbonium ion, which is produced by the dehydroxylation of the side-chain alcohol at an acidic point on the surface of the alumina catalyst, may be rearranged to enlarge its ring *via* a step analogous to the Wagner-Meerwein rearrangement, followed by deprotonation. Accordingly, if such a reaction can be applied to the side-chain alcohol of a six-membered ring compound, the dehydration of tetrahydropyran-2-methanol (TPM) is likely to produce oxepine derivatives.

In only one patent[3] dealing with the dehydration of TPM, however, CPA has been reported as the main product; in this one case it was derived as an intermediate from the skeletal rearrangement of 2,3,4,5-tetrahydrooxepine (THO). If CPA was produced by the isomerization of THO, THO would be very unstable under the reaction conditions. However, it has been reported that the THO produced by the ring-closing dehydration of 1,6-hexanediol (1,6-D) is not changed at 250°C.[4] Therefore, the mechanism proposed by the patent is very doubtful.

In this paper, the skeletal rearrangement during the dehydration of TPM over various catalysts is accurately discussed on the basis of results concerning obtaining the unsaturated ring ether compound, THO, which is converted into 1,6-D in a good yield by hydration and by consecutive hydrogenation.

Experimental

Materials. *Acrolein Thermal Dimer (AD), 3,4-Dihydro-2H-pyran-2-methanol (DPM), and Tetrahydropyran-2-methanol (TPM).* These substances were shynthesized according to the methods described in previous papers,[5,6] except that the Diels-Alder reaction of acrolein was carried out under a 1—20 kg/cm² pressure of hydrogen instead of nitrogen, because then the yield of AD was increased a little compared with that under nitrogen.

Cyclohexylcarbinol (CHC). This was also prepared according to the method described in a previous paper.[7] All the other chemicals used in the present experiment were commercial compounds of the first grade.

Catalysts. The γ-alumina catalyst without any carrier was prepared as follows. Fifty milliliters of an aqueous ammoniac solution was added to a saturated solution of 50 g of aluminum nitrate in water; the gel of aluminum hydroxide thus precipitated was rinsed with water five times and filtrated. The filtrated gel was dried in air for 10 hr at about 80°C and then sintered in air for 12 hr at about 600°C. The fine, white, sintered powder was tableted under a pressure of 150 kg/cm^2 and then crushed into particles 8—12 in mesh size. Commercial alumina catalysts, Neobead C (NC) (Al_2O_3: 100), Neobead D (ND) (Al_2O_3: 90, SiO_2: 10) and Neobead P (NP) (Al_2O_3: 88, SiO_2: 9, Na_2O: 3), were kindly supplied by the Mizusawa Chemical Co. Moreover, N631 (Al_2O_3: 15, SiO_2: 85), copper - chromium oxide (N208), copper - zinc oxide (N211), and nickel (N111), all except N631 supported on Kieselguhr were supplied by the Nikki Chemical Co.

Catalyst Activation. A catalyst was placed into the atmosphere of the feed and carrier gas for 3 hr at about 300°C, and then only a carrier gas, mostly hydrogen, was let flow through continuously until no water was formed. This pretreatment was carried out in all runs. The reaction over N111 was carried out as follows. The catalyst was renewed before each reaction, activated for 3 hr at about 450°C under the hydrogen carrier gas and at a constant flow rate of 10 ml/sec, and then placed in the atmosphere of the feed and nitrogen for 30 min.

The catalyst with tetrahydrofurfuryl alcohol (TFA) pretreated was prepared as follows; over an alumina catalyst TFA was passed by means of a nitrogen carrier for 20 min at about 300°C, and then nitrogen gas was allowed to flow through for 3 hr. The alumina catalyst obtained in this way was brown and was submitted to the reaction like other untreated aluminas.

Equipment and Methods. The dehydration reaction was carried out in the apparatus shown in Fig. 1.

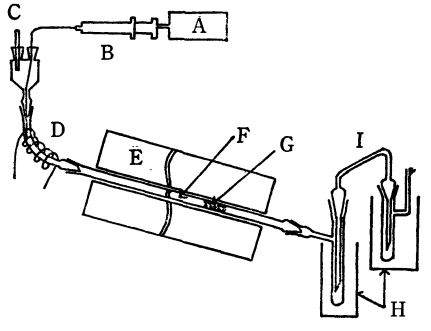

Fig. 1. Apparatus.

C	Gas inlet	H	Vessel with cooling material
D	Vaporizer		
E	Electric furnace	I	Trap

7) A. Misono, T. Osa and Y. Sanami, *ibid.*, **71** 680 (1968).

The reactor was equipped with a thermostat and was wrapped around with Nichrome heating wire. The reactor tube was packed with 15 ml of catalyst pellets, while the temperature was maintained at from 150°C to 500°C within ±3°C. The contact time was controlled by changing the rate of the material fed in. The majority of the product was condensed in a first trap cooled with methanol and dry ice at about −50°C, while the more volatile products were caught in a second trap cooled with methanol and dry ice below −60°C or, in some runs, with liquid nitrogen. The carrier gas was passed through the vaporizer to the reactor at a rate of from 5 to 35 ml/sec. As a carrier gas, hydrogen was generally used, because the selectivity of THO, as shown in Table 1, was slightly higher under the hydrogen carrier gas than under the nitrogen one. All the products except 1,6-hexanediol (1,6-D) were gas chromatographically analyzed using a 2 m×6 mm o.d. column containing silicon oil DC 550 on Diasolid M at 160°C. For the determination of 1,6-D and other compounds having higher boiling points, a column of 2 m×6 mm o.d. containing 10% polyphenyl ether and 2% Carbowax 20 M on Fruolopack 80 (60—80 mesh) was used at 170°C. 1,6-D recrystallyzed from a commercial product with carbon tetrachloride was used.

Identification of the Reaction Products. Pure samples of the reaction products were gas chromatographically isolated, or fractionally distilled, and identified by means of an IR spectrometer (Hitachi EPS-2) and an NMR spectrometer (Japan Electric Co. C-60). Both the preparative and analytical gas chromatographic work were carried out with a Kotaki-Superfractioner.

2,3,4,5-Tetrahydrooxepine (THO) ($C_6H_{10}O$): bp 112—114°C/760 mmHg, n_D^{25} 1.4509. IR (cm^{-1}); 2920, 2860, 1656(sh), 1650, 1302(sh), 1295, 1280(sh), 1125, 1080, and 740 (Fig. 2). NMR (ppm); multiplets at 8.3 (4 protons) and 7.95 (2 protons), a triplet at 6.15 (2 protons), a quadruplet at 5.35 (1 proton), and a doublet at 3.8 (1 proton).

Results and Discussion

In the gas-phase dehydration of tetrahydropyran-2-methanol (TPM), seven-membered compounds were detected using a catalyst other than the η-alumina catalyst, though a five-membered cyclopentanecarboxaldehyde (CPA) was mainly produced in the patent described above. Furthermore, there were many cases where an unsaturated ring ether compound, THO, was obtained in good yields. As the catalyst in this patent, there were employed one or more of the materials customarily referred to as dehydration catalysts, such oxides of the divalent or the polyvalent metals as alpha alumina, thorium oxide and titanium oxide. Catalysts with two functions, dehydration and hydrogenation, were also employed.

The results of the present investigation are illustrated in Table 2. Over the three commercial alumina catalysts, NC, ND and NP, the total amounts of the selectivities of THO and OXP were increased with a decrease in the acidity of a catalyst by analogy with its composition,[8] but that of CPA was decreased. The commercial alumina catalyst used is considered to participate with the reaction as in the dehydration of tetrahydrofurfuryl alcohol (TFA), and to produce seven-membered compounds. However, in the skeletal rearrangement during the dehydration of TPM, it might be a dominant characteristic that the selectivity of THO was higher over a catalyst used after the dehydration of TFA than over the same catalyst used directly.

The effect of pretreatment with an alumina catalyst with TFA upon the dehydration of alcohols has been little reported on; for example, the alumina catalyst pretreated with TFA decreased the rate of the dehydration of ethanol.[9] However, this effect, decreasing the selectivity of CPA and increasing that of THO, may result not only in a decrease in the dehydrating activity due to the occupation of the active points by TFA, but also in an essential change in a crystallinity of the catalyst. To elucidate these results, there is a need for further investigation of the effect of TFA on a catalyst. Therefore, the authors will report on this problem in a subsequent paper.

Over N631 as a silica-alumina catalyst, the selectivities of CPA, THO, and OXP decreased in all runs, but those of MCPE and CHE increased. MCPE and CHE are estimated to be derived from the decomposition of THO under the reaction conditions, because THO produced them selectively over N631 (Table 3).

*1 Feed rate of TPM and flow rate of carrier gas were constant at 10 ml/hr and 10 ml/sec, respectively. Carrier gas was H_2 except in runs of N111 with N_2.

*2 NDF and NPF were the catalysts pretreated with tetrahydrofurfuryl alcohol. Length of catalyst bed was 5 cm. In N111 runs, it was difficult to maintain the activity of the catalyst at constant, and therefore these data were the averages of the three kinds of reactions.

*3 *t*=trace.

It has been reported[10] that a dehydrogenation catalyst, for example, copper-chromium oxide, is applicable to the dehydration of some alcohols. Though such a catalyst, as was effected, decreased the conversion to some extent, it was used in the dehydration of TPM in order to study the reaction mechanism in more detail, for the activity of a dehydrogenation catalyst for isomerization during the dehydration of alcohols is markedly less than that of such a dehydration catalyst as an alumina. The results obtained are shown in Table 2. In all runs, only a trace of OXP was formed the main product being THO. Moreover, the amounts of MDHP increased with an increase in the reaction temperature, and also that of CPA decreased considerably, especially in N111 runs.

The behavior of THO and OXP under the present reaction conditions was also investigated. The results are shown in Table 3. As is shown in Table 3, in the use of the η-alumina catalyst, CPA

and MTHP were mainly obtained from the corresponding seven-membered compounds. However, over the other catalysts some skeletal rearrangement from seven to six or five occurred, though with difficulty.

In order to clarify the action of the catalyst in the dehydration of TPM, cyclohexyl carbinol (CHC), which is similar to TPM, was dehydrated over various catalysts. These results are shown in Table 4. It was seen that the dehydration occurred much faster over the η-alumina catalyst than over ND and N208 catalysts; that over the alumina catalyst the selectivity of CHYM was almost equal to that of MCHE; that the differences in between the selectivities of CHYM and MCHE lessened with an increase in the reaction temperature, and that, nevertheless, the differences were roughly constant until the reaction temperature over ND and N-208 catalysts. Higher reaction temperatures were, moreover, required in runs with ND and N208 catalysts than in runs with the η-alumina catalyst.

The results obtained can be explained satisfactorily by the following general estimation.[8,11] The relative rate of carbonium-ion rearrangement in the dehydration mechanisms of several alcohols over alumina catalysts can be estimated from the relative stabilities of the carbonium ions involved; the stabilities are in the order: tertiary > secondary > primary. Therefore, rearrangements to olefines

proceeding through primary carbonium ions are believed to occur at reasonably fast rates only on relatively strong acid sites, whereas those involving secondary and tertiary carbonium ions take place on both strong and weak acid centers.

Therefore, the reaction pathway of the dehydration of CHC may be concluded to be as shown in Fig. 3. Over a dehydration catalyst, such an alumina catalyst, the first step producing a carbonium ion (I) was very fast by virtue of its acidic sites,[8] so a large amount of I may exist in the reaction system. By the way, the deprotonation may change I into CHYM, or into MCHE *via* the methylcyclohexyl carbonium ion (II), which is produced by isomerizations and which rearranges its form to a more stable one under a high temperature. The faster the dehydration rate and the higher the reaction temperature, the smaller the difference in the selectivities between CHYM and MCHE may be. Over the dehydrogenation catalyst, on the contrary, the first dehydroxylation step producing an ionic structure (I) may be reasonably slow, and, moreover, the deprotonation may proceed extraordinarily fast as a result of the strong dehydrogenation activity of the catalyst.

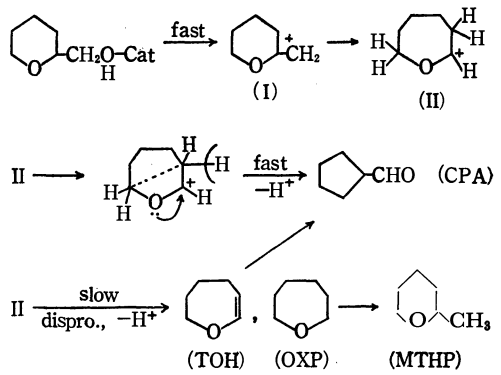
Therefore, the reaction producing CHYM may be predominant, and a small quantity of MCHE may be produced by the deprotonation of the carbonium ion (II) rearranged from I.

Conclusion

The behavior of each catalyst has been clarified by elucidating the dehydration pathway of CHC. Over the dehydration catalyst, to put it simply, the rate of the dehydroxylation step is very fast, and that of the deprotonation step is very slow; therefore, the carbonium ion produced by the dehydroxylation migrates into the more stable form of the tertiary carbonium ion.[12] Over the dehydrogenation catalyst, it has been established that the deprotonation of the carbonium ion produced at the first step, contrary to the case of the dehydration catalyst, occurs faster than the migration of the primary carbonium ion to the tertiary one.

Considering the results of the dehydration of CHC and the established reaction mechanism with respect to the dehydration of TFA, the skeletal rearrangement during the dehydration of TPM over various catalysts may be estimated to be as shown in Fig. 4. Over the dehydration catalyst, the carbonium ion (I) produced II by ring enlargement through a process analogous to the Wagner-Meerwein rearrangement, after which CPA was formed by ring-shrinking isomerization. In this step, the migration of the lone-electron pair of ring ethereal oxygen to the carbonium ion resulted in simultaneous deprotonation. As a result of the

Over dehydration catalyst:



Over dehydrogenation catalyst:

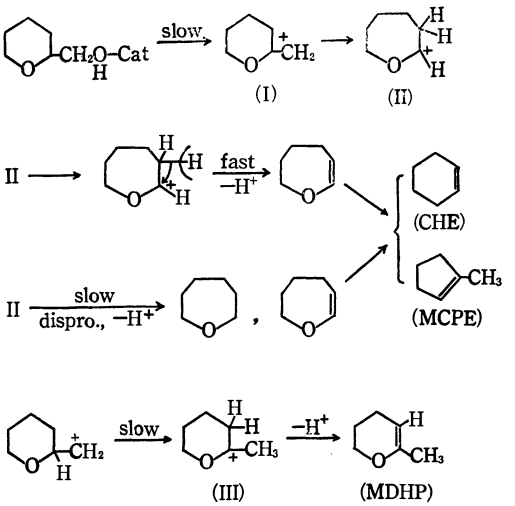


Fig. 4. Reaction pathway of dehydration of TPM.

strong influence of the acidic sites of the catalysts on the lone-electron pair of ethereal oxygen, the electron transfer from the loosened electron pair to the carbonium ion may occur with ease; on the other hand, the weaker the acidity of the catalyst, the less may the lone pair of ethereal oxygen be affected. Therefore, over each Neobead catalyst having a weaker acidity on its surface than that of η-alumina, THO and OXP may be obtained from II by deprotonation and disproportionation; then THO may go through the step from II to CPA by means of protonation. On the other hand, though OXP can be isomerized to MTHP, its very slow reaction rate scarcely produced as much MTHP as was detected. Therefore, over the dehydration catalyst, the reaction pathway of I→II→CPA may be the main route.

On the contrary, over the dehydrogenation catalyst, the reaction step producing I was very slow and THO was the main product. Since the lone-electron pair of ethereal oxygen is not affected by the catalyst at all and may be very stable in itself,

12) H. Pines and W. O. Haag, *ibid.*, **83**, 2847 (1961).

it may be difficult for the electron transfer from ethereal oxygen to the carbonium ion to occur, resulting in the predominance of the deprotonation. Moreover, a small part of the THO and OXP was produced from II by disproportionation. Taking the affinity and the basisity of the catalyst for ethereal oxygen into account, the reaction pathway from I to III can be estimated over the dehydrogenation catalyst, wherein MDHP may be produced from III by deprotonation.

The affinity of each catalyst for the lone-electron pair may depend on its acidity, so alumina may be more active in responce to it than a nickel or copper-chromium oxide catalyst.

THO was obtained in the highest yield with a copper-chromium oxide catalyst 70 mm long under a 5 ml/sec flow of a hydrogen carrier and a TPM rate of 10 ml/hr at 430°C; therefore, the selectivity of THO was about 58%, and the conversion of TPM was about 87%. However, the patent literature regarding the dehydration of TPM, as has previously been mentioned, has touched upon THO only very briefly, treating it as a mere reaction intermediate, and has not isolated it from the reaction system at all. Consequently, the dehydration of TPM with the dehydrogenation catalyst may be considered to be a new and a more useful method by which THO was obtained in better yields than by the other reactions.

Therefore, a useful application of THO may be considered to be as follows; 5 ml of THO were added to 10 ml of a 0.01 N H_2SO_4 solution and the mixture was refluxed for 30 min at 90°C. Then the mixture was hydrogenated with 0.5 g (wet) of Raney Ni (W-2) at 100°C under an initial hydrogen pressure of 20 kg/cm^2 until no more hydrogen was absorbed. After the reaction product had then been filtrated, a vacuum distillation gave about 4.7 g of 1,6-D (84% yield. Moreover, 1,6-D was synthesized directly from TPM in a 42% yield by dehydration and subsequent hydrogenation *via* THO. This skeletal rearrangement during the dehydration of TPM may become a very useful reaction for synthesizing 1,6-D.

The authors wish to thank their co-worker, Mr. Tadaomi Yamada. The authors also wish to express their gratitude to the Mizusawa Chemical Co. and the Nikki Chemical Co. for kindly suppling the various catalysts.

Further Studies on Acetoxylation of Isodihydro-*O*-acetylisophotosantonic Lactone

Tadashi SASAKI and Shoji EGUCHI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya

(Received January 25, 1968)

Acetoxylation of *O*-acetylisophotosantonic lactone (I) and its isodihydro derivative (III) with lead tetraacetate was reinvestigated. The reaction of III in refluxing benzene afforded the known 2-acetoxy derivative (V) as the main product and α-diketone as the minor product which was isolated in its 2-keto-3-ol form (VII). The use of boron trifluoride - etherate as a catalyst in this acetoxylation, however, did not give good results. The ORD curves of dihydro-*O*-acetylisophotosantonic lactone (II), III, 2-bromo-isodihydro-*O*-acetylisophotosantonic lactone (IV), V and one of the hydrogenolysis product of I (X) were measured and some stereochemical problems of these compounds were discussed.

Acetoxylation of *O*-acetylisophotosantonic lactone (I) and its isodihydro derivative (III) by the oxidation with lead tetraacetate has been reported by White and his coworkers;[1] they isolated the corresponding 2-acetoxyl derivative XI and V, respectively in low yields but did not describe the stereochemistry of the 2-acetoxyl group, although the stereochemistry of several derivatives of *O*-acetylisophotosantonic lactone have been established, in particular, that of its 2-bromo derivative IV by X-ray analysis.[3]

In the present paper, acetoxylation of I and III has been studied and compound VII, one of the by-products, has been isolated from III in addition to the normal acetoxylation product V.

The optical rotatory dispersion (ORD) curves of dihydro derivatives of I (II and III), 2-bromo derivative of III (IV), V and one of the hydrogenolysis products of I (X) have been measured and their stereochemical correlations are discussed.

Results and Discussions

Acetoxylations. *O*-Acetylisophotosantonic lactone (I)[3] was hydrogenated by the known method to give the unstable dihydro derivative II which was easily converted to its C-4 epimer by treatment with alumina.[1] Hydrogenation of I afforded X, one of the hydrogenolysis products which has also been reported.[1a]

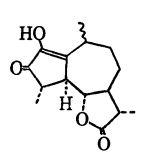
VII



VIII

Oxidation of III with lead tetraacetate in refluxing benzene afforded the reported acetoxyl compound V[1] with a melting point of 166—168°C in a 38% yield. This yield was more or less similar to those reported.[1a] However, a new compound with a melting point of 207—210°C was isolated in a 10% yield upon alkaline hydrolysis of the residue. This compound was shown to be VII by the following evidence; the elemental analysis and the high resolution mass spectrum (M^+ at *m/e* 262.121) indicated a molecular formula $C_{15}H_{18}O_4$. The infrared spectrum which exhibited absorption bands at 3320 (OH), 1770 (γ-lactone), 1675 (cross conjugated cyclopentadienone), 1654 and 1610 (double bonds) cm^{-1}, was very similar to those of achillin[4] and desacetoxy matricarin[5] except for the presence of hydroxyl bands. The ultraviolet spectrum had maxima at 265 mμ (ε 9570) and 294 (7279) in ethanol, and at 270.5 mμ (ε 6836) and 352 (5912) in 1 N ethanolic potassium hydroxide. The NMR ($CDCl_3$) had signals at τ 3.63 (1 H, s, disappeared on deuteration, OH), 6.42 (1 H, unsym. t, J=9.5 Hz, C-6-H), 6.73 (1 H, d, J=10.0 Hz, C-5-H),[5d] 7.51 and 7.81 (each 3 H, s, two allylic methyls at C-3 and C-10) and 8.73 (3 H, d, J=6.0 Hz, methyl at C-11). The presence of an enolic hydroxyl group was indicated by a positive ferric chloride test (violet). Since White and Marx[1b] have synthesized from III desacetoxy matricarin, a C-11 epimer of achillin, VII seems to be a 3-hydroxy analogue of desacetoxy matricarin, although the isolation of this compound from natural sources has not been reported.

VII may be produced from the α-diketone VI after elimination of acetic acid, followed by enolization. This conversion to 2-keto-3-ol system is of interest, since the acetoxy compound V is known to be converted to a 3-keto-2-ol system VIII by alkaline hydrolysis.[1a] On the other hand, in steroid series, Fieser and Stevenson[6] have reported the isomerization of Δ^5-cholesten-4α-ol-3-one acetates (XII) to Δ^5-cholesten-3β-ol-4-one acetate (XIII).

Possibilities of the formation of VII from V by air oxidation upon alkaline hydrolysis were excluded

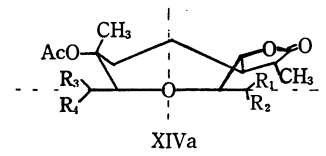
by the fact that V afforded exclusively compound VIII by alkaline treatment,[1] although it is known that 2-acetoxy tetrahydrosantonin gives its α-diketone derivative in a good yield upon alkaline hydrolysis.[7] The facile deacetoxylation and enolization of VI to VII was also shown by the isolation of VII from selenium dioxide oxidation of III, followed by chromatography on alumina.

Acetoxylation with lead tetraacetate is known to be catalyzed by a Lewis acid such as boron trifluoride-etherate[8] and in fact, Barton *et al.*[9] have reported the 2-acetoxylation of deoxygeigerin in an excellent yield using boron trifluoride - etherate as a catalyst. However, acetoxylation of III with lead tetraacetate by Barton's procedure using boron trifluoride-etherate as a catalyst did not proceed smoothly, and resulted in recovery of starting material, which was accompanied by a trace of a compound melting at 187—189°C. This compound had infrared absorption bands at 1770 (γ-lactone), 1750 (cyclopentanone), 1735 (acetate) and 1647 (double bond) cm^{-1}, and a weak ultraviolet absorption at 275 mμ (ε 205) and was tentatively assigned structure IX.

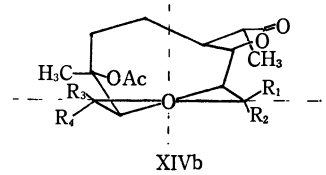
In the acetoxylation of I, the use of boron trifluoride-etherate was also ineffective and only the starting material was recovered, although its acetoxylation in refluxing benzene afforded 2-acetoxy derivative (XI)[1a] in a low yield.

Optical Rotatory Dispersion Studies. Successful applications of the Octant rule to the cyclopentanone series have been achieved by Klyne.[10] It is well known that ORD depends strongly on the conformation of a cyclopentanone ring itself.[11] Therefore, considerations on the conformation of the ring systems in question are required for ORD studies. The Dreiding stereomodel studies for our ring systems suggest three possible basic conformation, XIVa, b, and c.

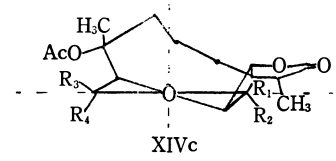
XIVa has a very flat half-chair or an almost planar cyclopentanone ring which could enter slightly in a positive or a negative octant, and a chair cycloheptane ring.[12] In this conformation, the effect of the cyclopentanone ring on the Cotton effect will be small since C-1 and -5 more or less



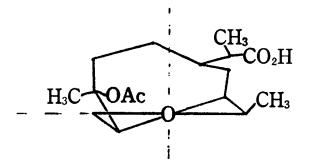
XIVa



XIVb



XIVc



Xa

lie in the plane, and substituents at C-2 and/or C-3 are expected to contribute strongly to the Cotton effect.[13] Thus in this conformation, we can anticipate a weak positive or a weak neagtive Cotton effect, depending on substituents. XIVb has a half-chair cyclopentanone ring and a twisted-chair cycloheptane ring.[12] In this conformation, C-1 and -5 are severely skewed in negative octants and we can, therefore, expect a strong negative Cotton effect. XIVc has a half-chair cyclopentanone ring, in which C-1 and -5 are strongly skewed in the positive octants, and a boat or a twisted boat cycloheptane ring.[12] In this conformation, a strong positive Cotton effect will be anticipated.

The ORD curves of II and III are shown in Fig. 1 and those of IV, V, and X, in Fig. 2. As seen in Fig. 1, II showed a strong negative Cotton effect ($a=-112$) while III exhibited a weak positive Cotton effect ($a=+25$), but both exhibiting a fine structure of similar shape. The fact that II and III give such different values in amplitude indicates clearly that the whole molecular shape of II and III must be different, since the C-4-methyl

13) The effect of a cycloheptane ring on the Cotton effect will be small, since the replacement of a cyclohexane ring by a cycloheptane ring in the hexahydrindan-2-one system did not change the sign of the Cotton effect but only slightly decreased the amplitude; C. Djerrasi and J. E. Gurst, *J. Am. Chem. Soc.*, **86**, 1755 (1964).

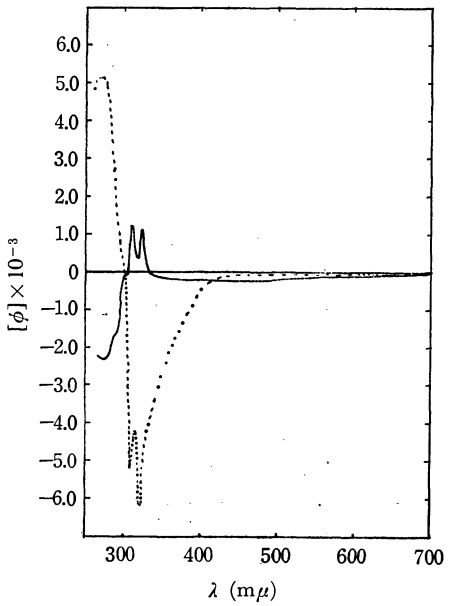

Fig. 1. ORD curves of II (·····) and III (——).

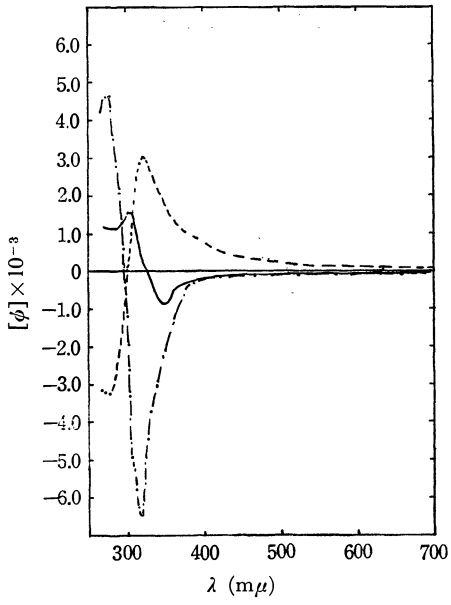

Fig. 2. ORD curves of IV (——), V (----) and X (·—·—).

alone should not cause such a large change. Only the conformation XIVb ($R_1=CH_3$; R_2, R_3, and $R_4=H$ for II) can explain the strong negative Cotton effect of II. The weak positive Cotton effect of III can not be explained by this conformation ($R_2=CH_3$; R_1, R_3, and $R_4=H$), since the negative contribution of the severely skewed cyclopentanone ring should be predominant, even if the C-4-methyl enters a positive octant. Thus, the weak positive Cotton effect of III can be explained most reasonably by conformation XIVb ($R_2=CH_3$; R_1, R_3, and $R_4=H$). The reason why II and III, respectively, adopt conformations of type XIVb and type XIVa are uncertain. The type XIVa conformation seems to be common to C-4α-methyl derivatives of this series, since IV is shown to have a very flat half-chair cyclopentanone ring and a chair cycloheptane ring by X-ray analysis.[2] Therefore, assuming that IV has the conformation of type XIVa (R_1 and $R_3=H$; $R_2=CH_3$; $R_4=Br$), a weak negative Cotton effect might be predicted, since the contribution of 2α-bromine in a negative octant may surmount that of 4α-methyl in a positive octant.[14] In fact, the observed value of IV was a weak negative Cotton effect ($a=-24$) as illustrated in Fig. 2.

The acetoxyl compound V showed a relatively weak positive Cotton effect, $a=+62$, indicating clearly that the 2-acetoxyl group is contributing more or less to the positive Cotton effect, since the amplitude is larger than that of III. Based on the conformation of type XIVa,[15] the 2-acetoxyl group seems to enter in a front positive octant (for 2α-OAc, R_1 and $R_3=H$; $R_2=CH_3$; $R_4=$OAc) or in a front negative (for 2β-OAc, R_1 and $R_4=H$; $R_2=CH_3$; $R_3=$OAc).[16] Thus, the 2α-acetoxyl structure (Va) is assigned to compound V.[17] Ketol acetates often give abnormal ORD curves,[18] even in the steroid series, and therefore, our assignment based on the ORD data might need further support, for which studies are in progress.[19]

The stereochemistry at C-4 in compound X is unknown and its ORD showed a strong negative Cotton effect ($a=-112$) which is reminiscent of the ORD of II. Such a large negative amplitude can not be expected on the basis of conformations of type XIVa and XIVc. Therefore, the conformation Xa which belongs to the conformation of type

14) For example, see C. Beard, C. Djerassi, J. Sicher, F. Sipos and M. Tichy, *Tetrahedron*, **19**, 919 (1963).

15) XIVb predicts a negative Cotton effect and XIVc, a strong positive, since the substituent effect will be small in these conformations. Such large effects of the substituents as seen in III, IV and V might also suggest the validity of the XIVa conformation.

16) The degree of the contribution of 2-OAc to the positive or the negative front octant depends on the conformation of the actoxyl group but molecular model studies indicate clearly the contribution to the front octant assuming some stable conformations of the 2-OAc.

17) It may be noted that 2α-OAc will be more stable than the 2β-isomer, since in the latter, oxygen atoms of the two acetoxyl groups at C-2 and C-10 are very close to each other and therefore, an electrostatic or a dipole-dipole repulsion might be expected.

18) For example, see; a) C. Djerassi, J. Fishman and T. Nambara, *Experientia*, **17**, 565 (1961); b) C. Djerassi, D. Halpern, V, Halpern and C. Tamm, *Helv. Chim. Acta*, **41**, 250 (1958).

19) The NMR data might be useful in some cases but in the cyclopentanone series, their application to the stereochemistry require model compounds, since for example, *cis* and *trans* lactones in our systems have almost the same coupling constants for C-6 and C-7 protons; see Refs. 1b and 5d.

XIVb, was suggested and thus, the C-4β-methyl structure was assigned to X.

Experimental[20]

***O*-Acetylisophotosantonic Lactone (I).** This was prepared by irradiation of α-santonin by the known method[3] and it melted at 182—134°C (recrystallized from methanol).

Dihydro-*O*-acetylisophotosantonic Lactone (II). Catalytic hydrogenation of I (10% Pd-C in ethyl acetate) afforded II, mp 171—173°C (from ethyl acetate).[1]

Hydrogenolysis Product of I (X). After more than 1 mol of hydrogen was uptaken in the above reduction, acidic portion was purified by crystallization from an acetone - *n*-hexane mixture to give an acid X with a melting point of 154—156°C (lit.[1a] 156—157°C).

Isodihydro-*O*-acetylisophotosantonic Lactone (III). This was obtained from II as needles with a melting point of 165.5—167°C (benzene - *n*-hexane) by epimerization on alumina.[1]

Oxidation of III with Lead Tetraacetate in Benzene. The same procedure as that of White *et al.*[1] was applied except the use of a small amount of acetic anhydride. A mixture of 1.54 g of III, 0.5 m*l* of acetic anhydride and 3.10 g of lead tetraacetate (a commerical sample was dried *in vacuo* on KOH pellets just before use) in 50 m*l* of benzene (dry benzene was distilled from $Pb(OAc)_4$) was refluxed for 12 hr until KI-strach paper became negative and the cooled reaction mixture was washed with water several times and dried over anhydrous sodium sulfate. The removal of the solvent afforded a sticky residue, from which needles with a melting point of 166—168°C was isolated in a 38% yield after crystallization from methanol. The spectral data (infrared, ultraviolet and NMR) of this compound were the same with those of the reported[1a] and thus this was identified as V.

The mother liquor was dried up to a sticky residue which was dissolved in 10 m*l* of methanol and stirred for 2 hr at room temperature in nitrogen stream after addition of 5 m*l* of 1 N aqueous potassium hydroxide. Neutralization with acetic acid and concentration afforded precipitates which were recrystallized from methanol to give needles of VII (130 mg, 9.9%), mp 207—210°C. TLC examination of the residue showed the presence of III and some unidentified materials. Mass spectrum of VII had peaks at 262.121 (M^+), 247.097 ($M-CH_3$) and 244.108 ($M-H_2O$).

Found: C, 68.21; H, 6.96%. Calcd for $C_{15}H_{18}O_4$: C, 68.16; H, 7.63%.

Oxidation of III with Selenium Dioxide. A mixture of 0.308 g of III and 0.133 g of selenium dioxide (sublimed before use) in 5 m*l* of dioxane was heated at 60°C for 5 hr. Dioxane was removed *in vacuo* and the residue was purified on alumina (neutral, activity grade III) to give crude VII from ether eluent after elution with benzene. Recrystallization from methanol gave VII with a melting point of 206—209°C in a 14% yield.

Oxidation of III with Lead Tetraacetate in the Presence of Boron Trifluoride - etherate. A mixture of 0.308 g of III, 1.0 of lead tetraacetate, 1.0 m*l* of acetic anhydride and 2.0 m*l* of BF_3 - etherate in 20 m*l* of glacial acetic acid was stirred for 24 hr at room temperature. After the TLC examination indicated that no more starting material was remained, the reaction mixture was diluted with water and extracted with chloroform (20 m*l*×5). The combined extracts were washed with water, dried over sodium sulfate and dried up to a brownish residue which was chromatographed on a silica gel column. The first fraction eluted with chloroform gave crystals of IX with a melting point of 187—189°C (from methanol) in a 3.5% yield.

Found: C, 66.53; H, 7.31%. Calcd for $C_{17}H_{22}O_5$: C, 66.65; H, 7.31%.

The second fraction gave 100 mg of the starting material (32% recovery).

Oxidation of I with Lead Tetraacetate. Oxidation was carried out in benzene by the method of White *et al.*[1a] and the acetoxyl compound XI with a melting point of 174—176°C (lit.[1a] 175—176°C) was obtained in an 11% yield. The oxidation in the presence of BF_3 - etherate was carried out as follows: A mixture of I (0.306 g), lead tetraacetate (1.0 g), acetic anhydride (0.5 m*l*) and BF_3 - etherate (1.0 m*l*) in 15 m*l* of glacial acetic acid was stirred for 20 hr at room temperature and the worked-up product was needles with a melting point of 176—181°C, infrared spectrum of which was identical with that of the starting materials (77% recovery).

2-Bromo-isodihydro - *O* - acetylisophotosantonic Lactone (IV). This was prepared by the Barton's procedure and had a melting point of 115—117°C dec. (lit.[21] 117—118°C dec.).

Optical Rotatory Dispersion Measurements. All ORD measurements were carried out in dioxane solution at room temperature (at *ca.* 20°C).

The authors are much indebted to Professor E. H. White (Johns Hopkins Univ., U. S. A.) for his deep interests and kind suggestions for this studies and to the Nippon Shinyaku Co., Ltd., for his kind supply of Santonin. Thanks are also due to Mr. Akiho Ishihara for elemental analyses and ORD measurements.

20) All melting points were determined on a Yanagimoto micromelting point apparatus and are uncorrected. Microanalyses were carried out on a Yanagimoto C. H. N. Coder, Model MT-1. Infrared spectra were recorded on a JASCO Model IR-S infrared spectrophotometer and NMR spectra were obtained with a Varian A-60 spectrometer, using TMS as an internal standard. Ultraviolet spectra and ORD curves were measured on a JASCO Model ORD/UV-5 spectrophotometer. Mass spectrum of VII was obtained by a Mattauch-Herzog type high resolution mass spectrometer, JMS-O1S, using PFK as an internal standard.

(Received February 1, 1968)

The configurations of three stereoisomers, α, β and γ, of perhydroacridine and those, α, β and γ, of perhydrophenanthridine have been assigned as *trans,syn,trans, trans,anti,cis, trans,syn,cis, trans,anti,trans, trans,syn,cis* and *cis,syn,cis*, respectively, on the basis of both the process of their syntheses and the rate of formation of methiodides of the *N*-methyl derivatives. These configurations are consistent with the infrared-spectral behavior of their *N*-methyl derivatives in carbon tetrachloride solutions containing *n*-butanol as well as with the result of their exhaustive methylations. The relative steric requirement of the lone pair and the hydrogen on the N atom is also discussed.

One decade ago we reported[2] on the preparation of three stereoisomers, α, β and γ (I, II and III), of perhydroacridine, whose configurations were assigned tentatively as *trans,trans*, *trans,cis*, and *cis,cis*, respectively. In a continuing study, these compounds were converted into the corresponding *N*-methyl derivatives (Ia, IIa and IIIa), mp 38—40°C, 36—38°C and 46—48°C, and it was attempted to prepare these derivatives from *N*-methyl-*trans*- and *cis*-1,2,3,4,4a,9,9a,10-octahydroacridines[3,4] (IVa and Va). Contrary to the expectation, hydrogenation of IVa over platinum at room temperature produced Ia and IIIa in moderate yields, but no IIa, and that of Va gave IIIa as a major product along with a small amount of a new isomer (VIa), named *N*-methyl-δ-perhydroacridine. Since (1) both I and II have been obtained from *trans*-octahydroacridine (IV) by hydrogenation under the same conditions, and both II and III from the *cis* isomer (V),[2] and (2) the *trans* isomer IV has been recovered unchanged on treatment under the conditions differing from the afore-mentioned only in replacement of hydrogen by nitrogen, the configuration of III must be revised to be *trans,cis* (Chart 1).

Thus, both β- and γ-perhydroacridines II and III have one *trans* and one *cis* linkages, one of them being a *trans,anti,cis* modification, and the other a *trans,syn,cis*. On the other hand, α-perhydroacridine I involves at least one *trans* linkage[2] and, therefore, should have a *trans,trans* structure.

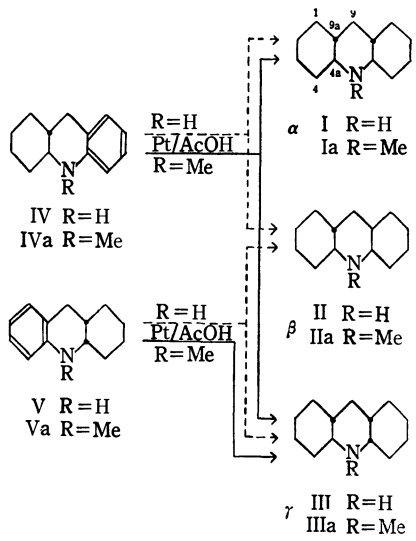

Chart 1

Only one perhydrophenanthridine (VII) has been reported: hydrogenation of 7,8,9,10-tetrahydrophenanthridine over Raney nickel at high temperature has afforded VII in a good yield, while that over platinum at room temperature a compound (VIII) assigned as a dodecahydro derivative.[5] Since VII has also been obtained from *trans*-5,6,6a,7,8,9,10,10a-octahydrophenanthridine[3] (IX) by hydrogenation over platinum at room

temperature,[5] reduction of the corresponding *cis* isomer[3] (X) was undertaken under the same conditions to obtain a new stereoisomer. However, the reaction led to formation of a good yield of compound VIII, which was also produced in a good yield by hydrogenation of *trans*-1,2,3,4,4a,5,6,10b-octahydrophenanthridine[6] (XI) in the presence of platinum in ethanol containing hydrochloric acid.[7] This fact, coupled with repeated analyses, led to the assignment of VIII as a perhydro compound, which was confirmed by the mass spectrum. The same treatment of a *cis* isomer[6] (XII) of XI gave a new perhydrophenanthridine (XIII), mp 37—38°C, and VIII, suggesting that the *cis* isomer XII would rearrange partially to the *trans* isomer XI under the acidic conditions used. These results (Chart 2) indicate that the stereoisomers VII, VIII and XIII, named α-, β- and γ-perhydrophenanthridines, have *trans,trans*, *trans,cis* and *cis,cis* configurations, respectively, in view of the well-known stereochemistry in hydrogenation of 1,2,3,4-tetrahydroisoquinoline.[8] The relative configurations of hydrogens at C-9a and C-8a in the perhydroacridines and those at C-10a and C-10b in the perhydrophenanthridines will be determined in the following.

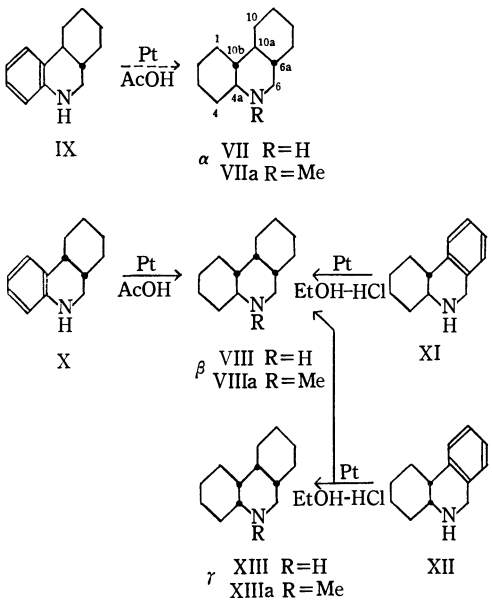

Chart 2

Formation of Methiodides of *N*-Methyl Derivatives. The rates of reaction with methyl iodide were determined for *N*-methyl derivatives of three perhydroacridines I, II and III, three perhydrophenanthridines VII, VIII and XIII, two octahydrophenanthridines XI and XII, *trans*- and *cis*-perhydroquinolines[9] (XIV and XV), piperidine (XVI), *cis*-perhydroindole[10] (XVII) and perhydrocarbazole[11] (XVIII), and the result is summarized in Table 1. In view of the fact that, in the absence of important steric hindrance, a stronger base reacts faster with a given alkyl halide,[12] the basicities of these *N*-methyl compounds were also measured. The transition state in the formation of these methiodides is supposed to have a steric arrangement similar to an ammonium cation formed by addition of a proton to each tertiary amine. Because of the small size of proton, a serious steric hindrance against the addition would hardly exist. To the contrary, it is expected that the presence of an axial methylene (β-axial methylene) group at the β-position to the N atom of a piperidine ring in these compounds would remarkably retard the rate of the quarternization, because either one of two methyl groups (N-$\underline{CH_3}$ and $\underline{CH_3}$I) on the N atom exists in an axial conformation.[13] In order to clarify these steric effects,

Table 1. The reaction rate with methyl iodide and basicity of *N*-methylperhydroacridines and related compounds

Compound (*N*-methyl derivative)	Rate constant[a] $k\times10^2$ (l/min·mol)	Basicity[b] pK_a
I	0.41	9.63
II	0.42×10^{-2}	9.67
III	0.44	9.65
VII	2.05	9.47
VIII	1.98	9.54
XIII	1.95	9.49
XI	0.52	8.54
XII	0.48	8.48
XIV	1.60	9.37
XV	1.67	9.41
XVI	1.30	9.11
XVII	3.09	9.73
XVIII	$<10^{-3}$	9.90

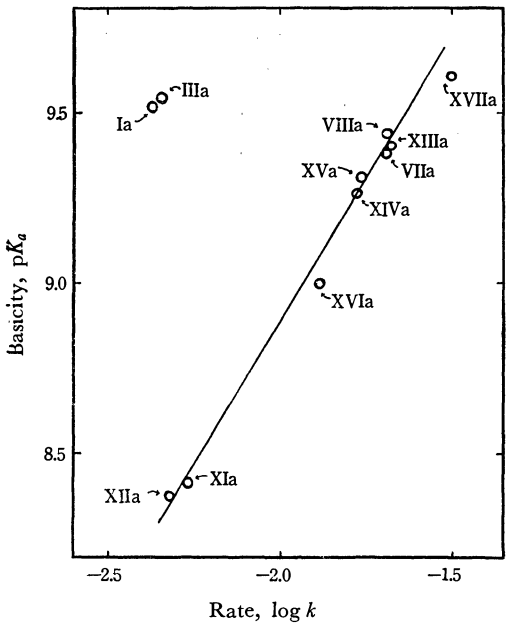

Fig. 1. The relation between the rate of *N*-methyl methiodides formation and the basicity of *N*-methylperhydroacridines and related compounds.

the logarithms of the rate constants were plotted against their pK_a values (Fig. 1).

trans-Perhydroquinoline (XIV), *trans*-octahydrophenanthridine (XI) and probably α-perhydrophenanthridine (VII) have only β-equatorial methylene substituents in the respective piperidine ring. Accordingly, the transition states in the reaction of their *N*-methyl derivatives would have approximately equal steric interactions, suggesting the presence of a linear relationship. In fact, it was true as shown in Fig. 1. Besides these bases, the corresponding *cis* isomers XVa, XIIa, VIIIa and also *N*-methyl-γ-perhydrophenanthridine (XIIIa) fell on this line, reflecting that these compounds involve the same steric requirement for the reaction as their stereoisomers. This linear relation indicates that these compounds contain no β-axial methylene substituents, as far as all the rings adopt chair conformations; namely, compounds VII, VIII and XIII have *trans,anti,trans*, *trans,syn,cis* and *cis,syn,cis* configurations, respectively.*4 *N*-Methyl derivatives, XVIa and XVIIa, of piperidine and *cis*-perhydroindole deviated slightly from the line. In the former, the deviation would be attributed to the absence of an α-substituent, and in the latter it would be due to the fact that a methylene group in a five-membered ring offers less steric hindrance than that in a six-membered ring.[14] With *N*-methyl-α- and γ-perhydroacridines Ia and IIIa, considerable deviations were observed, which apparently resulted from the substitution of two α-methylene groups in the piperidine ring. On the other hand, *N*-methyl-β-perhydroacridine IIa and *N*-methylperhydrocarbazole XVIIIa revealed conspicuous decrease in the rate (the outside of Fig. 1). Whilst the rate of the latter is not interpretable well owing to its whole ambiguous steric arrangement, it is evident that the presence of a β-axial methylene group in the piperidine ring of IIa has brought about the remarkable retardation. This result, coupled with the synthetic process, establishes that the configurations of α-, β- and γ-perhydroacridines are *trans,syn,trans*, *trans,anti,cis* and *trans,syn,cis*, respectively.

Formation of Hydrogen Bonds with *n*-Butanol.[15] The method for determination of the configurations described in the preceding section is based on measurement of the reaction rates and rather troublesome. Furthermore, no consideration is given to the conformation in tertiary amine of compounds in which ring inversion is possible. As an attempt to approach to these problems by more practical experiments under mild conditions, we examined the infrared spectra near 3400 cm^{-1} of carbon tetrachloride solutions containing the afore-mentioned tertiary amines (0.1 to 0.2 M) and *n*-butanol. To avoid the confusion due to association of the butanol itself,[16] the concentration was fixed to be 0.05 M, where only absorptions at 3640 cm^{-1} (free OH) and near 3520 cm^{-1} (dimeric OH) were observed.

The ternary solution containing *N*-methyl-α-perhydroacridine Ia exhibited a definitely different spectrum from the corresponding containing the β-isomer IIa (Fig. 2); in the former a broad band centered at *ca.* 3240 cm^{-1} appeared in addition to a sharp band at 3640 cm^{-1} due to unassociated hydroxyl groups, while in the latter a new absorption with relatively weak intensity was instead centered at *ca.* 3420 cm^{-1} along with the sharp band. These broad absorptions near 3240 and 3420 cm^{-1} are undoubtedly attributed to the hydroxyl group (OH-N) bonded with the lone pairs of N atom. Kuhn,[17] Nakamoto[18] and others[19] showed, from measurement of the infrared spectra of a number of hydrogen-bonded compounds in the crystalline state, that an approximately

*4 If compound XIII had a *cis,anti,cis* configuration, the rate of quarternization would be reduced, no matter what conformation of the piperidine ring is taken, a chair or a twist-boat form.

linear relation exists between the length of hydrogen bond and the shift of frequency of the associated hydroxyl group from that of the unassociated. This correlation comes into existence if the hydrogen bond is of linear type and, especially, becomes important if the relevant tertiary amines have equal basicities such as the present compounds Ia and IIa. The observed difference in the frequency shifts between Ia and IIa (400 and 240 cm^{-1}, respectively) apparently arises from that in the hydrogen bond length between both the isomers, provided that the correlation holds for the compounds in the liquid (solution) state. Thus, this result indicates that there exists a steric hindrance in IIa, which obstructs proximity of the butanol molecule to the lone pair of N atom and which must result from the presence of a β-axial methylene group. This inference is consistent with the well-established fact that the *N*-methyl group is almost exclusively oriented equatorial in *N*-methylpiperidines.[20] The ternary solutions containing *N*-methyl derivatives of γ-perhydroacridine (III), α- and β-perhydrophenanthridines (VII and VIII), *trans*-perhydroquinoline (XIV) displayed practically the same spectra in the relevant region as the corresponding containing Ia, whereas *N*-methylperhydrocarbazole (XVIIIa) showed essentially the same absorption pattern concerning the spectrum of the solution in question as IIa. These spectral behaviors are in good accord with the result obtained in the preceding section.

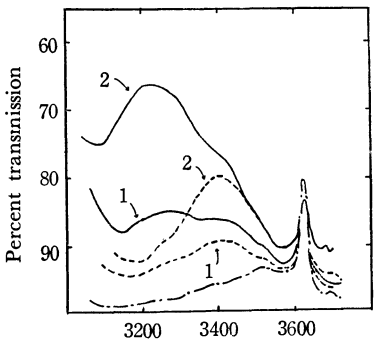

Fig. 2. Infrared spectra of *N*-methyl-α- and β-perhydroacridines (Ia and IIa) in carbon tetrachloride solutions containing *n*-butanol: —— 1, Ia (0.1 M); ——2, Ia (0.2 M); ----1, IIa (0.1 M); ----2, IIa (0.2 M); —·—, *n*-BuOH (0.05 M).

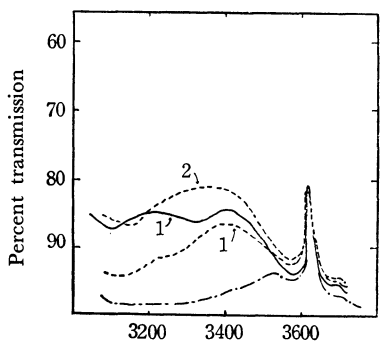

Fig. 3. Infrared spectra of *N*-methyl-γ-perhydrophenanthridine (XIIIa) and *cis*-perhydroindole (XVIIa) in carbon tetrachloride solutions containing *n*-butanol: —— 1, XIIIa (0.1 M); ---- 2, XVIIa (0.2 M); ---- 1, XVIIa (0.1 M); ——, *n*-BuOH (0.05 M).

N-Methyl derivatives of γ-perhydrophenanthridine (XIII), *cis*-perhydroquinoline (XV) and also *cis*-perhydroindole (XVII) exhibited interesting absorption bands in the spectra of their ternary solutions (Fig. 3). In the former two compounds XIIIa and XVa, both the relevant bands centered near 3240 and 3420 cm^{-1} were observed. The intensities of the latter band increased and, conversely, those of the former decreased, when compared with the corresponding bands of the respective *trans* isomers (XIIIa and VIIIa, and XVa and XIVa). With compound XVIIa such a tendency was further intensified, and the spectrum became rather similar to that of compound IIa. These facts may be explicable well on the basis of the following: compounds XIIIa and XVa involve no *trans* linkage and, therefore, would exist as an equilibrium mixture of conformers formed through ring inversion, one having β-equatorial methylene group(s) and the other β-axial. For compound XVIIa, the similar discussion would be applied, if we consider that the pyrrolidine ring adopts a half-chair conformation or we regard XVIIa as a cyclohexane derivative substituted vicinally with methylene and amino groups. This inference is not contradictory to the previous conclusion but rather supports the configuration of compound XIII.

We next measured the spectrum of the solution containing *n*-butanol (0.05 M) and the secondary amine I or II (0.15 M), in each of which both the relevant, broad and sharp bands appeared near 3240 and 3640 cm^{-1} (Fig. 4). The broad bands are ascribed to the hydroxyl groups bonded to the N atoms, because compound I or II showed only weak absorptions ($\varepsilon < 5$) near 3300 cm^{-1} at the concentration of 0.02 to 1.25 M in carbon tetrachloride and, therefore, the intensities due to the free and *N*- or *O*-bonded imino groups would be negligibly small. In the spectrum of the solution containing I, the broad band appeared with stronger intensity than the sharp. The situation became the opposite in the case of II, where the intensity of the broad band was weaker than that in the case of I. This behavior is interpretable well

20) For example, a) N. L. Allinger, J. G. D. Carpenter and F. M. Karkowski, *J. Am. Chem. Soc.*, **87**, 1232 (1965), and b) J. B. Lambert, R. G. Keske, R. E. Carhart and A. P. Jovanovich, *ibid.*, **89**, 3761 (1967).

on the basis of that the lone pair takes largely an axial conformation in both the compounds and, when the alcohol is added, only compound II is partly inverted to a less stable conformer with the lone pair equatorial and forms the hydrogen bond of almost the same length as I. This provides additional qualitative evidence supporting arguments[21] that the lone pair is smaller than the hydrogen atom.

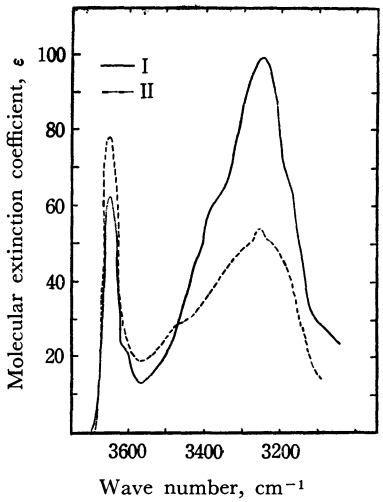

Fig. 4. Infrared spectra of α- and β- perhydroacridines (I and II) in carbon tetrachloride solutions containing *n*-butanol: I and II (0.15 M), *n*-BuOH (0.05 M), cell 0.5 mm.
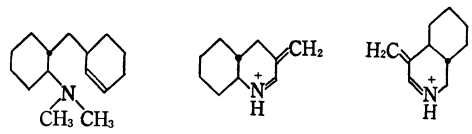
The intensity ε denotes the difference of the molecular extinction coefficient between each ternary solution and the corresponding containing no *n*-butanol.

The Hofmann Degradation. The exhaustive methylation of the stereoisomers of perhydroacridine and perhydrophenanthridine was next investigated. The addition of methyl iodide into ether or acetone solutions of the *N*-methyl derivatives of the compounds readily yielded the corresponding *N*-methyl methiodides (Ib), mp 273—275°C, (IIb), mp 210—212°C, (IIIb), mp 262—264°C, (VIIb), mp 265—267°C, (VIIIb), mp 272—274°C, and (XIIIb), mp 315—316°C. Pyrolysis of the methohydroxides obtained by treatment of all the methiodides except IIb with silver oxide produced the respective original *N*-methyl compounds in 65—80% yields. On the other hand, the same treatment of IIb gave an oily product, from which a base (XVIII) $C_{15}H_{27}N$, bp 154—156°C/17 mmHg, was isolated in 65% yield in pure state through the picrate, mp 147—149°C. The compound XVIII showed absorption maxima at 1660 and 720 cm^{-1} in the infrared spectrum and gave the dihydro derivative by catalytic hydrogenation. It also afforded the glycol by oxidation with osmium tetroxide, which was readily converted into the diacetate. These facts showed the presence of a disubstituted and probably *cis* double bond. Treatment of XVIII with boiling acetic acid followed by addition of potassium iodide yielded a mixture consisting mainly of Ib, showing that no ring contraction was encountered during the pyrolysis. Hence, compound XVIII can be assigned as 3-(2'-dimethylaminocyclohexylmethyl)-cyclohexene.



XVIII XIX XX

The methohydroxide obtained from IIb underwent the normal Hofmann degradation to give XVIII, as expected from its steric arrangement. Furthermore, with the methohydroxides which are derived from Ib, IIIb, VIIb and VIIIb and have rigid conformations, a suitable geometrical disposition[22] is not available for the normal E2 process leading to olefin, and it would not be unreasonable that only elimination of methanol took place in the degradation. On the other hand, the remaining methohydroxide derived from XIIIb may adopt at least two conformations, one having two axial β-methylene substituents in respect to the piperidine ring and the other two equatorial. The former is an unfavorable conformation owing to the severe 1,3-diaxial interaction between the axial *N*-methyl and the two methylene groups in question, although it satisfies the stereochemical arrangement required for E2 elimination. This is inferred from the observed rate in the formation of the methiodide and, in fact, the degradation has led mainly to the elimination of methanol, proving the preference of the latter conformation.

Experimental[23]

***α*-, *β*- and *γ*-Perhydroacridines (I, II and III).** These compounds were prepared according to the procedures described previously,[2] and complementary data are described here.

Compound I; mass spectrum, *m/e* 193 (M^+), 192, 151, 150, 136, and *ca.* 117 (a metastable ion). The strongest peak at *m/e* 150 would be due to an ion formulated as XIX.[24] The picrate had mp 192—194°C (lit.,[2] 173—176°C) after preparation in ether or benzene and recrystallization from ether - ethanol. The hydroiodide melted over 360°C after addition of aqueous

23) All the melting points are uncorrected.

24) *Cf.* The mass spectra of IV and V; *m/e* 187 (M^+), 186, 144, 130, and *ca.* 110 (a metastable ion).

hydrogen iodide into I in acetone and recrystallization from ethanol.

Found: N, 13.01%. Calcd for $C_{19}H_{26}O_7N_4$: N, 13.26%.

Found: N, 4.55%. Calcd for $C_{13}H_{24}NI$: N, 4.36%.

Compound II had mp 51—53°C (lit.,[2] 48—51°C) after purification described in the following; the crude base before recrystallization was converted into the hydroiodide, mp >300°C, by addition of aqueous hydrogen iodide in acetone, which on regeneration followed by recrystallization from petroleum ether afforded II having mp 51—53°C. Compound II showed practically the same mass spectrum as I, and its benzoyl derivative had mp 87—89°C on recrystallization from petroleum ether.

Found: N, 4.88%. Calcd for $C_{20}H_{27}ON$: N, 4.71%.

Compound III showed essentially the same mass spectrum as I, and its picrate had mp 211—213°C on recrystallization from ethanol.

Found: N, 13.15%. Calcd for $C_{19}H_{26}O_7N_4$: N, 13.26%.

N-Methyl-α-, β-, γ- and δ-Perhydroacridines (Ia, IIa, IIIa and VIa) and Their Methiodides (Ib, IIb and IIIb). *a) Methylation wtih Formic Acid and Formalin.* A mixture of I (2.8 g), formic acid (1.5 m*l*) and 33% formalin (2.8 m*l*) was gently refluxed for 6 hr, and into the cooled mixture was added water (50 m*l*) and ether (30 m*l*). After separation of the aqueous layer, the ether solution was shaken with 1 N aqueous acetic acid. The aqueous and acetic acid solutions were combined and made alkaline to yield oily substance, which was extracted with ether, dried and subjected to distillation under reduced pressure. A fraction (2.3 g) boiling at 155—161°C/15 mmHg was collected and refluxed in acetic anhydride (7 g) for 30 min. The whole solution was warmed with water (50 m*l*) on a water bath for 1 hr and then treated with ether. The aqueous solution gave oil on alkalization, which was purified by distillation. The *N*-methyl derivative (Ia, 2.0 g) thus obtained had bp 158—160°C/17 mmHg and mp 38—40°C on recrystallization from petroleum ether.

Found: C, 81.20; H, 12.25; N, 6.67%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15; N, 6.76%.

The picrate and the hydroiodide had mp 169—170°C (from ethanol) and mp 220—222°C (from ethanol), respectively.

Found: C, 55.28; H, 6.74; N, 13.08%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47; N, 12.84%.

Found: C, 49.93; H, 7.80; N, 3.88%. Calcd for $C_{14}H_{26}NI$: C, 50.15; H, 7.82; N, 4.18%.

N-Methyl derivatives (IIa and IIIa) of II and III were prepared in the same way as Ia. These bases and their derivatives had the following melting points. IIa, mp 36—38°C (from petroleum ether): the picrate, mp 211—213°C (from ethanol); the hydroidodie was not obtained in crystalline state.

Found: C, 81.00; H, 12.18; N, 6.65%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15; N, 6.76%.

Found: C, 54.98; H, 6.53%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47%.

IIIa, mp 46—48°C (from petroleum ether); the picrate, mp 164—166°C (from ethanol); the hydroiodide was not obtained in crystalline state.

Found; C, 80.78; H, 12.20; N, 6.88%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15; N, 6.76%.

Found: C, 54.89; H, 6.81%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47%.

b) Hydrogenation of N-Methyl-trans-1,2,3,4,4a,9,9a,10-Octahydroacridine (IVa) over Platinum. Compound IVa[3] (2.1 g) in acetic acid (20 m*l*) was hydrogenated over Adams' platinum (0.4 g as pltainum oxide) at room temperature for 1.5 hr, when 790 m*l* of hydrogen had been consumed (the calculated for complete hydrogenation, 770 m*l*). After removal of the catalyst and the solvent, the residue was shaken with ether and water, and the ether solution gave an oily mixture of bases on being dried and evaporated, which was dissolved in acetone. To the acetone solution was added aqueous hydrogen iodide (bp 125°C), when the hydroiodide precipitated and was collected by filtration. This compound (1.8 g) had mp 218—220°C on recrystallization from ethanol and was then reconverted to a free base (0.85 g), mp 36—38°C, which was identified as Ia. The filtrate free from this hydroiodide was concentrated under reduced pressure and then treated with 2 N sodium hydroxide solution and ether. The ether extract, after evaporation, was converted into the picrate in methanol, which had mp 153—155°C on recrystallization from ethanol and amounted to 1.5 g. This picrate was reconverted into IIIa (0.65 g), mp 46—48°C.

c) Hydrogenation of N-Methyl-cis-1,2,3,4,4a,9,9a,10-Octahydroacridine (Va) over Platinum. Compound Va (5.0 g) was hydrogenated over Adams' platinum (0.5 g) in the same manner as mentioned above, and 1850 m*l* of hydrogen was consumed (the calculated, 1770 m*l*) after 4 hr. An oily mixture of bases obtained by usual methods was dissolved in acetone and treated with aqueous hydrogen iodide, when a hydroiodide (0.4 g) separated out and was collected by filtration. It had mp 224—226°C on recrystallization from ethanol, which was depressed to 185—200°C on admixture with the hydroiodide of Ia, mp 220—222°C. Regeneration gave a free base, bp 157—160°C/20 mmHg. As the hydroiodide of IIa or IIIa was not obtained in crystalline state, this base would be a new isomer (VIa) named δ, but the compound was not further characterized because of the small amount.

Found: C, 80.80; H, 12.03%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15%.

Found: C, 49.88; H, 8.03%. Calcd for $C_{14}H_{26}NI$: C, 50.15; H, 7.82%.

The aqueous acetone solution obtained on filtration of the hydroiodide of VIa was evaporated, made alkaline and extracted with ether. The ether extract, after removal of the solvent, was converted into the picrate in methanol, from which the picrate (6.0 g), mp 154—156°C, of IIIa, was isolated. Regeneration followed by distillation afforded IIIa (2.6 g), mp 45—47°C.

d) Methiodides. To an acetone or ether solution of Ia (1.7 g) was added methyl iodide (8.0 g) dropwise under cooling, when the methiodide separated out and was collected by filtration. Recrystallization from ethanol gave Ib (1.9 g), mp 273—275°C. On concentration of the mother liquor, an additional amount (0.3 g) of the crude methiodide, mp 263—266°C, was obtained.

Found: C, 51.63; H, 7.99%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

Compound IIa (1.2 g) in acetone was refluxed with an excess of methyl iodide for 1 hr. Recrystallization

of the resulting methiodide from 95% ethanol afforded IIb (1.2 g), mp 210—212°C.

Found: C, 51.33; H, 8.28%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

Compound IIIa (2.0 g) was converted into the corresponding methiodide (IIIb, 2.7 g) in the same manner as Ia, which had mp 262—264°C on recrystallization from ethanol.

Found: C, 51.64; H, 8.24%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

α-Perhydrophenanthridine (VII). Compound VII was prepared according to the method reported previously[5] and had mp 103—104°C; mass spectrum, *m/e* 193 (M^+), 192, 151, 150, 136, and *ca.* 117 (a metastable ion). The strongest peak would be due to an ion formulated as XX.[25] The picrate had mp 231—233°C (lit.,[5] 210—212°C) on recrystallization from ethanol.

Found: N, 13.21%. Calcd for $C_{19}H_{26}O_7N_4$: N, 13.26%.

β-Perhydrophenanthridine (VIII). a) Compound VIII was obtained in 25% yield by hydrogenation of 7,8,9,10-tetrahydrophenanthridine over Adams' platinum.[5]

b) *trans*-1,2,3,4,4a,5,6,10b-Octahydrophenanthridine[6] (XI, 1.0 g) in ethanol (30 m*l*) containing 2.4 N hydrochloric acid[12] (2.5 m*l*) was hydrogenated over Adams' platinum (0.2 g) at room temperature for 5 hr, when 460 m*l* of hydrogen had been adsorbed (the calculated, 450 m*l*). The reaction mixture, after being worked up as usual, gave a solid base (0.85 g) melting at 105—118°C. Recrystallization from petroleum ether afforded a pure sample (0.7 g) of VIII, mp 122—123°C (lit.,[5] 119—121°C).

Found: C, 80.80, 80.95, 81.00; H, 12.02, 12.27, 11.74; N, 7.25%. Calcd for $C_{13}H_{23}N$: C, 80.76; H, 11.99; N, 7.25%.

Compound VIII showed essentially the same mass spectrum as VII, and the picrate had mp 223—225°C on recrystallization from ethanol.

Found: C, 54.33; H, 6.54%. Calcd for $C_{19}H_{26}O_7N_4$: C, 54.02; H, 6.20%.

c)[26] *cis*-5,6,6a,7,8,9,10,10a-Octahydrophenanthridine[5] (X, 500 mg) was hydrogenated over Adams' platinum (50 mg) at room temperature in acetic acid for 4 hr, when 200 m*l* of hydrogen had been consumed (the calculated, 180 m*l*). The reaction product, after being worked up as usual, crystallized, amounted to 522 mg, and melted at 115—120°C. Recrystallization from petroleum ether gave VIII (338 mg), mp 118—120°C.

γ-Perhydrophenanthridine (XIII). *cis*-1,2,3,4,4a,5,6,10b-Octahydrophenanthridine[6] (XII, 1.35 g) was hydrogenated over Adams' platinum (0.50 g) at room temperature in ethanol (70 m*l*) containing 2.4 N hydrochloric acid (3.5 m*l*). The reaction ceased after 24 hr, when 500 m*l* of hydrogen had been consumed (the calculated, 530 m*l*). The product (1.30 g) obtained after usual treatment was semi-solid and recrystallized from petroleum ether to yield XIII (0.32 g), mp 122—123°C. The mother liquor on the recrystallization was evaporated to dryness, and the residue (0.75 g) was converted into the picrate in ether. Upon repeated recrystallizations of the picrate from methanol, three kinds of picrates having mp 194—196°C (0.96 g), mp 178—180°C (60 mg) and mp 180—181°C (20 mg) were isolated, but the last two were not further examined. Regeneration of the picrate of mp 196°C gave a free base (348 mg), mp 35—37°C. Recrystallization from petroleum ether afforded an analytical sample (100 mg) of XIII, mp 37—38°C, which showed practically the same mass spectrum as VII.

Found: C, 80.60; H, 12.17; N, 7.48%. Calcd for $C_{13}H_{23}N$: C, 80.76; H, 11.99; N, 7.25%.

Found: N, 12.98%. Calcd for $C_{19}H_{26}O_7N_4$: N, 13.26%.

N-Methyl-α-, β- and γ-perhydrophenanthridines (VIIa, VIIIa and XIIIa) and Their Methiodides (VIIb, VIIIb and XIIIb). a) These *N*-methyl derivatives were prepared from the respective secondary amines (VII, VIII and XIII) by the same treatment (formic acid and formalin) as Ia, and had the following melting and/or boiling points. Compound VIIa had mp 26—28°C on recrystallization from petroleum ether and bp 155—157°C/20 mmHg, and the picrate mp 199—201°C after preparation in ether and recrystallization from 95% ethanol.

Found: C, 81.26; H, 11.99; N, 6.56%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15; N, 6.76%.

Found: C, 54.88; H, 6.61%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47%.

Compound VIIIa and its picrate had mp 62—64°C (from petroleum ether) and mp 190—192°C (95% ethanol).

Found: C, 81.22, 80.00; H, 12.20, 11.91; N, 6.42%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 11.99; N, 6.56%.

Found: C, 55.19; H, 6.71%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47%.

Compound XIIIa, oil, boiled at 155—159°C/20 mmHg, and its picrate had mp 198—199°C after preparation in ether and recrystallization from methanol.

Found: C, 81.35; H, 11.89; N, 6.88%. Calcd for $C_{14}H_{25}N$: C, 81.09; H, 12.15; N, 6.76%.

Found: C, 55.23; H, 6.56%. Calcd for $C_{20}H_{28}O_7N_4$: C, 55.03; H, 6.47%.

b) Methiodides. Methylation of these *N*-methyl derivatives (VIIa, VIIIa and XIIIa) with methyl iodide proceeded as smoothly as Ia to give the corresponding methiodides (VIIb, VIIIb and XIIIb) in good yields, which on recrystallization from ethanol had mp 265—267°C, 272—274°C and 315—316°C, respectively.

Found (VIIb): C, 51.33; H, 8.12%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

Found (VIIIb): C, 51.56; H, 8.05%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

Found (XIIIb): C, 51.36; H, 7.89%. Calcd for $C_{15}H_{28}NI$: C, 51.57; H, 8.08%.

Formation of Methiodides. The rate of the methiodide formation was measured in 20 m*l* of a 99.5% ethanol solution. In practice, 10 m*l* of the ethanol solution of a tertiary amine (0.03—0.05 M) and equal volume of the ethanol solution containing 1 m*l* of methyl iodide (*ca.* 1.5 M) was separately brought to constant temperature and then mixed in a brown flask closed with a tightly fitting stopper. After suitable intervals, 2 m*l* of the solution was drawn and 5 m*l* of 0.02 N hydrochloric acid was added. The excess of the acid was back-titrated with an aqueous barium hydroxide

solution, using methyl-red as an indicator. It was found that 5.0 m*l* of the hydrochloric acid was equivalent to 2.96 m*l* of the barium hydroxide solution. The rate constant was then calculated using the usual expression for a second-order reaction in which methyl iodide was present substantially in a constant concentration. The result is summarized in Table 1.

Measurement of Basicity. This was carried out at 20°C in 60% aqueous ethanol according to the method of Thomson.[27] The basicity is expressed by the pK_a value of a conjugate acid of each base and the result is summarized in Table 1.

Formation of Hydrogen Bonds with *n*-Butanol. Infrared absorption spectra were determined at 20°C using a Nihon Bunko double-beam spectrophotometer, Model DS 301, equipped with sodium chloride optics. The measurement was run at 0.1—0.2 M of tertiary or secondary amines in carbon tetrachloride containing 0.05 M of *n*-butanol. The sodium chloride cell of 0.5 mm of thickness was used and the absorption of the solvent was compensated by placing a cell of the same thickness filled with the solvent in the reference beam.

Carbon tetrachloride used as the solvent was first washed with conc. sulfuric acid, dil. sodium carbonate solution and water, successively, dried with anhydrous sodium sulfate, and distilled over phosphorus pentoxide. *n*-Butanol was used after being refluxed with calcium oxide for 20 hr and distilled under reduced pressure.

The Hofmann Degradation of Methiodides of *N*-Methyl-α- and γ-perhydroacridines (Ia and IIIa) and of *N*-Methyl-α-, β- and γ-perhydrophenanthridines (VIIa, VIIIa and XIIIa). A solution of Ia (1.2 g) in 50% aqueous ethanol (20 m*l*) was shaken with silver oxide prepared from silver nitrate (0.8 g) at room temperature for 3 hr. After filtration followed by evaporation of the filtrate, the syrupy residue was heated to 180°C (bath temperature) under reduced pressure. The pyrolysis of the methohydroxide took place violently at 140—150°C. The distillate was extracted with ether, and the ether solution gave a solid base (0.45 g) on removal of the solvent, which had mp 38—40°C on recrystallization from petroleum ether and was identified as Ia. The picrate melted at 170—172°C on recrystallization from ethanol.

The pyrolysis of IIIb, VIIb, VIIIb and XIIIb was carried out in the same manner as Ia. Compound IIIb (2.8 g) produced IIIa (1.1 g), mp 46—48°C; the picrate, mp 162—164°C. Compound VIIb (1.8 g) gave VIIa (0.7 g), bp 152—153°C/18 mmHg and mp *ca.* 25°C; the picrate, mp 198—200°C. Compound VIIIb (1.1 g) afforded VIIIa (0.4 g), mp 62—64°C; the picrate, mp 190—192°C. Compound XIIIb (100 mg) gave XIIIa (52 mg), oil, which was converted into the picrate, mp 198—199°C.

The Hofmann Degradation of *N*-Methyl-β-perhydroacridine Methiodide (IIb).[28] Compound IIb (1.2 g) was converted into the syrupy methohydroxide by treatment with silver oxide prepared from silver nitrate (0.6 g), which decomposed at 120—130°C (bath temperature). The product was purified by distillation under reduced pressure followed by conversion into the picrate in ether-methanol, which had mp 147—149°C on recrystallization from ethanol. Regeneration of the picrate gave a free base, which was again distilled to yield an oily base (XVIII, 0.4 g) in pure state, bp 154—156°C/17 mmHg; IR, ν_{max}^{film} 1660 (w) and 720 (m) cm^{-1}.

Found: C, 81.25; H, 12.09; N, 6.25%. Calcd for $C_{15}H_{27}N$: C, 81.38; H, 12.29; N, 6.33%.

Found: C, 56.09; H, 6.68%. Calcd for $C_{21}H_{30}O_7N_4$: C, 55.99; H, 6.71%.

Compound XVIII (0.20 g) in acetic acid (10 m*l*) was hydrogenated over Adams' platinum (0.05 g) at room temperature for 3 hr. The reaction mixture was worked up as usual and gave the dihydro derivative (0.10 g), oil, which showed no absorption near 1660 and 720 cm^{-1} and gave the picrate, mp 147—149°C (from ethanol).

Found: C, 80.47; H, 13.23; N, 6.26%. Calcd for $C_{15}H_{29}N$: C, 80.64; H, 13.09; N, 6.27%.

Found: C, 55.51; H, 7.09; N, 12.19%. Calcd for $C_{21}H_{32}O_7N_4$: C, 55.74; H, 7.13; N, 12.38%.

Compound XVIII (100 mg) was oxidized with osmium tetroxide (173 mg) in dry benzene (5 m*l*) at room temperature. After 24 hr black osmate precipitated out, was centrifugalized and collected by filtration. The osmate (280 mg) was treated with sodium sulfite (1550 mg as $Na_2SO_3 \cdot 7H_2O$) for 5 hr in a refluxing mixture of water (10 m*l*) and ethanol (7 m*l*). After filtration of the resulting precipitate, the aqueous ethanol solution was evaporated under reduced pressure and shaken with ether repeatedly. The ether solution afforded an oily glycol (70 mg), which without further purification was acetylated with acetic anhydride (0.7 m*l*) and pyridine (0.15 m*l*) on a water bath for 2 hr. The mixture gave an oily acetate (60 mg) after being worked up as usual and distilled under reduced pressure, which showed no absorption near 3400 cm^{-1}.

Found: C, 67.28; H, 9.94; N, 3.88%. Calcd for $C_{19}H_{33}O_4N$: C, 67.22; H, 9.80; N, 4.13%.

Compound XVIII (0.30 g) was refluxed in acetic acid (10 m*l*) for 3 hr. The solution was then evaporated under reduced pressure, made alkaline with aqueous potassium hydroxide solution, and treated with ether to remove ether-soluble substance. To the aqueous solution was added potassium iodide, and the resulting solution was again evaporated to dryness and extracted with hot ethanol. Concentration of the ethanol solution gave a mixture of methiodides, from which *N*-methyl-α-perhydroacridine methiodide (Ib, 0.18 g), mp 272—275°C, was isolated on recrystallization from ethanol.

Infrared-spectral Studies on the Orientation of the Lone Pairs in Piperidine Derivatives[1]

Tadashi MASAMUNE, Mitsuo TAKASUGI and Minoru MATSUKI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received February 1, 1968)

The infrared spectra of stereoisomers of several piperidines and their *N*-methyl derivatives in carbon tetrachloride have been measured in the region of 3020 to 2500 cm^{-1}. The estimated intensities (A) of their Bohlmann bands have been analyzed, provided that Formula (1) concerning the intensity defined in the text holds for the compounds examined. The result indicates that piperidine exists mainly, but not exclusively, in the conformation with the lone pair axial.

For some years attention has been drawn to the steric requirement of a nitrogen lone pair.[2] In 1958 Aroney and LeFèvre[3] examined the Kerr constants of piperidine and *N*-methyl piperidine and concluded that the nitrogen lone pair is more bulky[4] than the hydrogen and approximately equivalent to the methyl group. Their conclusion has since been criticized by several groups,[5-11] especially by Allinger,[7] Katritzky,[5b] Lambert,[8a] and their co-workers,[12] and there remains now little doubt that the lone pair is axially oriented in *N*-substituted piperidines. However, no consistent conclusion is drawn regarding the relative orientation of the hydrogen and the lone pair in *N*-unsubstituted piperidines, although evidence has recently accumulated that the latter is smaller than the former.[13] In a preliminary communciation[11] we reported an attempt to determine a preference of the hydrogen for the equatorial position in *N*-unsubstituted piperidines on the basis of their Bohlmann bands, and the present paper describes the full details.

Bohlmann[14] reported an empirical relation between the configurations of quinolizidine derivatives and their infrared bands in the region of 2800 to 2700 cm^{-1} (general region, no exact limits) called the Bohlmann bands; namely, these bands have been correlated with the presence of at least two α-hydrogens oriented *anti*-coplanar to the lone pair. The property of this correlation has since been confirmed in the determination of configurations of related compounds[15]. Recently Hamlow and his co-workers[16] attempted to rationalize such "absorption bands" in the spectra and also "the large chemical shift difference[16,17] (0.80—0.93 ppm)" between the axial and equatorial α-protons, and proposed that these facts would be caused by the overlap of the lone pair and the anti-bonding σ^* C–H_{axial} orbital on the adjacent carbon. Apart from this rationalization, although it seems to be most valid at least concerning the infrared

bands, the Bohlmann bands are expected to appear in *N*-unsubstituted piperidines as well as in quinolizidines, as far as the above-mentioned spatial requirement is satisfied for the lone pair and the α-hydrogen. However, only little attention[6,18,19] has been paid to the bands of the piperidines and no quantitative estimation appears to have been reported. In the preceding paper[20] of this series, we described the preparation and configuration of stereoisomers of perhydroacridine and perhydrophenanthridine. Having utilized these and related piperidines, it was attempted to determine the orientation of the lone pair by measurement of their Bohlmann bands and subsequent analysis of the intensities on appropriate assumptions.

Experimental

The infrared absorption bands of the following piperidine derivatives have been measured in the region of 3020 to 2500 cm^{-1}: piperidine (I), *trans*- and *cis*-perhydroquinolines[21] (II and III), *trans, syn, trans*-, *trans, anti, cis*- and *trans, syn, cis*-perhydroacridines[20,22] (IV, V and VI), *trans, anti, trans*-, *trans, syn, cis*- and *cis, syn, cis*-perhydrophenanthridines[20,23] (VII, VIII and IX), *trans*- and *cis*-2,6-dimethylpiperidines[24] (X and XI), *N*-methyl derivatives (Ia to XIa) of I to XI, and quinolizidine[25] (XII). The configurations of these compounds have all been established. The spectra of the *N*-benzoyl derivatives (Ib to XIb) of I, II, V,[26] VII, and XI have also been measured.

Materials. Most of the compounds examined were prepared by procedures described in the literatures. Solid compounds were recrystallized to constant melting point and liquids were freshly distilled before use. Only *N*-benzoyl-α-perhydrophenanthridine (VIIb) and *N*-methyl-*trans*- and *cis*-2,6-dimethylpiperidines (Xa and XIa) were new.

Treatment of VII (200 mg) in ether (10 m*l*) with benzoyl chloride (0.6 m*l*) and 3 N aqueous potassium hydroxide solution (10 m*l*) at room temperature for 20 hr gave the crude *N*-benzoyl derivative, which on recrystallization from *n*-hexane afforded a pure sample (107 mg) of VIIb, mp 98—100°C.

Found: C, 80.55; H, 9.32; N, 4.44%. Calcd for $C_{20}H_{27}ON$: C, 80.76; H, 9.15; N, 4.71%.

A mixture of XI (350 mg), formic acid (1.0 m*l*) and 33% formalin (0.9 m*l*) was heated on a steam bath for 3 hr and then cooled. The mixture was diluted with conc potassium hydroxide solution, saturated with sodium chloride and extracted with ether. The ether extract, after being dried with anhydrous sodium sulfate, was distilled over solid potassium hydroxide. The distillate was redistilled over calcium oxide and a fraction (XIa, 78 mg) of bp 139—142°C was collected. In a similar way, the corresponding *trans* isomer (Xa) was obtained and had bp 140—143°C.

Found (XIa): C, 75.35; H, 13.61%. Calcd for $C_8H_{17}N$: C, 75.52; H, 13.47%.

Found (Xa): C, 75.23; H, 13.75%. Calcd for $C_8H_{17}N$: C, 75.52; H, 13.47%.

Measurements of the Infrared Spectra. The spectra were recorded at 23°C on a Nippon Bunko 402-G spectrophotometer with 0.2 and/or 0.5 mm cells, using carbon tetrachloride solutions containing about 0.03 M of the samples. The wave numbers quoted were believed to be accurate to ± 3 cm^{-1}. The integrated intensities were expressed in this paper by $\int \varepsilon_\nu \delta\nu$, where ε_ν is the molecular extinction coefficient at the wave number ν.[27] The estimated uncertainty of the intensity was about 10%.

Results and Discussions

The spectra of several compounds are given in Figs. 1 to 4. As shown in the figures, each spectrum of *N*-unsubstituted- and *N*-methyl-piperidines and quinolizidine exhibited a sharp absorption minimum at 2820 ± 3 cm^{-1}, but, to the contrary, that of *N*-benzoyl derivatives only a plain absorption curve near the region. This strongly suggests that the Bohlmann bands must be included in the bands below 2820 cm^{-1},[28] and also indicates that, in the amides, the overlap[16] in question of the lone pair is largely forbidden due to the overlap with the benzoyl group. Thus the bands below 2820 cm^{-1} of *N*-benzoyl derivatives would be reasonably regarded as the background in the region of the corresponding piperidines. Then we have defined the difference between the integrated intensity (I_A) of the band in the 2820 to 2500 cm^{-1} range and that (I_B) of its background at that (A) of the Bohlmann band.

Before considering the intensities, it is desirable to mention the conformations of piperidine rings. *trans*-Perhydroquinoline II, three perhydroacridines IV to IV, two perhydrophenanthridines VII and VIII, and their *N*-methyl derivatives all include at least one *trans*-fused linkage and exist in rigid

conformations consisting of only chair-formed rings.[20] The other compounds except XII can take two conformations formed by ring inversion. In *trans*-2,6-dimethylpiperidine (X) and its *N*-methyl derivative Xa, the inversion leads to formation of the same conformer as the original, apart from the *N*-substituents, which has a conformation with one α-methyl group axial and with the other equatorial. To the contrary, the *cis* isomers XI and XIa, when flipped, are converted from a conformation with two equatorial α-methyl groups into a definitely unstable one with the two axial groups and are, therefore, essentially confined to the former. The same is the case in quinolizidine XII;[29] XII is practically fixed at one conformation with *trans*-fused rings, and only a negligible amount of the other conformer exists in the equilibrium mixture, which is formed by inversion of configuration at the nitrogen. Each of the remaining four compounds, *cis*-perhydroquinoline III, *cis, syn, cis*-perhydrophenanthridine IX, and their *N*-methyl compounds IIIa and IXa, would exist as an equilibrium mixture of conformers flipped with each other, one having two axial α-hydrogens and the other only one.*1 At the present stage it might be impossible to discuss the ratio of the conformers, as it would very largely depending on the relative steric requirement of the lone pair and the *C*-hydrogen. In summary, all the compounds other than III, IIIa, IX and IXa have rigid or essentially fixed conformations. In most of those compounds two hydrogens are oriented axial on the α-carbons in the respective piperidine rings, while in VI, VIa, X and Xa only one hydrogen and in XII three hydrogens exist at the axial conformation.

Francis[30] measured the integrated intensities of

the bands near 2900 cm^{-1}, produced by the in-plane and out of plane C–H vibrations, of a series of aliphatic hydrocarbons, and indicated the intensities to be interpretable well on the basis that the hydrocarbon molecule behaves like a non-interacting mixture of methyl, methylene and methine structural groups. Hence we first estimated the integrated intensities (I_t) of the bands

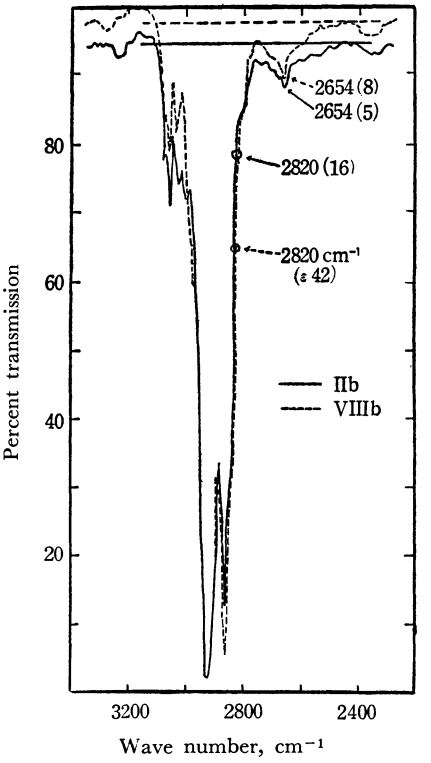

Fig. 4. Infrared spectra of *N*-benzoyl-*trans*-perhydroquinoline (IIb) and α-perhydrophenanthridine (VIIb).
IIb, 13.7 mg in 0.20 m*l* CCl_4, cell 0.2 mm
VIIb, 14.3 mg in 0.25 m*l* CCl_4, cell 0.2 mm

in the 2820 to 3000 cm^{-1} range of the present compounds. Although the intensities varied largely depending on the number of the vibrations concerned (Table 1), the average (I_m) per one C–H vibration fell within $(1.6\pm0.1)\times10^3$ $l/cm^2\cdot mol$, which was roughly equal to the corresponding, 1.3×10^3 $l/cm^2\cdot mol$,[30] for a methylene group of aliphatic hydrocarbons.

The integrated intensities (A) of the Bohlmann bands are summarized in Table 2. As shown in the table, the bands exhibited considerable intensity not only in *N*-unsubstituted piperidines having two axial α-hydrogens but also in those with only one. This observation, however, does not imply that the lone pair assumes exclusively the axial position in the piperidines.

Qualitative Consideration. The compounds examined are classified into two groups by the conformation of *N*-substituents. Compounds involved in the first class are *N*-methylpiperidines (Ia to XIa) and quinolizidine (XII). These compounds would be locked almost exclusively into a conformation with the lone pair axial. In compounds Ia, IIa, IVa Va, VIIa, VIIIa, XIa, and XII, which have two α-axial hydrogens and, accordingly, three hydrogens *anti*-coplanar to the axial lone

a) The unit; $(l/cm^2 \cdot mol) \times 10^{-3}$.
b) The "I_A, I_B and A" refer to the integrated intensities of the band in the region below 2820 cm^{-1}, its background and the Bohlmann band, respectively.
c—g) These figures denote the intensities (I_B) in the 2820 to 2500 cm^{-1} range of Ib, IIb, Vb, VIIb and XIb, respectively.
h—l) These figures were obtained by multiplication of I_B of Ib, IIb, Vb, VIIb and XIb and the following fractions, 8/10, 14/16, 20/22, 20/22 and 12/14, respectively.[31]

pair and participating in the Bohlmann band, the intensities fell within (8.6 to 10.9) $\times 10^3$ $l/cm^2 \cdot$ mol (the unit will be omitted). On the other hand, compounds VIa and Xa, having only the two relevant hydrogens, showed the weak intensity of 4.7. Compounds of the second class are *N*-unsubstituted piperidines, in which the lone pair is located in an undetermined position. Of these piperidines, compounds except VI and X have two axial α-hydrogens and showed intensities of 3.2 to 5.8, which amounted to only 46% (55—36%) of those of the respective *N*-methyl derivatives. The two compounds have only one axial α-hydrogen and exhibited the weak intensity of 2.0, which accounted for only 43% of that of VIa and Xa.

31) Both the numerator and denominator of the fraction refer to the number of hydrogens associated with the usual C-H vibrations in each compound. For example, both IIb and IIa would contain 16 relevant hydrogens, while II 14 hydrogens of such a kind. It should be mentioned that, without such a treatment which appears arbitrary, we arrive at almost the same value of N_H*.

If these decreases (46 and 43%) in intensity resulted from only a shift from axial to equatorial lone pair, it would be concluded that the lone pair assumes an equatorial conformation with a slight preference. However, the decreases are undoubtedly attributed to various factors, and one of those must be the number of the relevant hydrogens. As described above, the intensities of the compounds, when compared in the respective class, decreased to about half (55—43 and 62—35%) in passing from the three to two relevant hydrogens and from the two to one, respectively. These facts suggest that the number of α-axial hydrogens as well as the orientation of the lone pair would play a considerably great role for the decrease (46 and 43%) in question. Although it might be impossible to estimate these factors at the present stage, it would be inferred certainly that the lone pair adopts an equatorial conformation preferentially.

Quantitative Consideration. Bearing in mind the afore-mentioned qualitative consideration, we next attempted to analyze the observed intensities on the basis of the following assumptions: *the intensity (A) of the Bohlmann band in each compound is the sum of those due to individual C–H vibrations in question.* Apparently, this assumption might not strictly be correct, as bands due to overtone and/or combination would be included in the region in question. However, the perplexity due to these bands would be mostly eliminated, because the background would also include such bands. Moreover, the intensities of the bands, even if not completely eliminated, would not be great. In the previous section it has been shown that the intensity of absorption near 2900 cm^{-1} of usual C–H vibrations equals the sum of those due to individual vibrations concerned in both aliphatic hydrocarbons and the present compounds. The assumption described above was proposed on the analogy of this fact. In the present paper, we will proceed further with the analysis, leaving the detailed examination for the validity of this analogy till later on.

The intensity A of the Bohlmann band is concerned not only with the orientation of the lone pair and the number and kind of the relevant hydrogens (oriented on the α-carbon and *anti*-coplanar to the lone pair) as discussed already, but also with the extent of the overlap in question[16] and the ring distortion.[18] Hence, the above-mentioned assumption is expressed by the following formula:[32]

$$A = \sum N \times n \times I \times S \times R \qquad (1)$$

where N is N_H or N_{Me}, n is n_p, n_s or n_t, I is I_p, I_s or I_t, S is $S_{2\beta}$ or $S_{1\beta}$, and R is R_1 R_2 or R_3.

32) The intensity A might be affected by factors other than those described. If so, Formula (1) is not a mathematical expression of the first assumption but rather a new assumption. However, as far as we know, the intensity appears to depend only or mostly on these factors.

The "N_H and N_{Me}" refer to the mole fractions of conformers with an axially oriented lone pair on the nitrogen. The "n_p, n_s and n_t" are the number of relevant hydrogens in methyl, methylene and methine groups, respectively, and are given directly from the structure of the compound. The "I_p, I_s and I_t" represent the intensities for the C–H vibrations in question (whose hydrogen is present *solely* in a compound involving no distortions and located in methyl, methylene and methine groups, respectively) and are called the unit intensity. The "$S_{2\beta}$ and $S_{1\beta}$" are the ratios of the intensity produced by each vibration in question to the corresponding unit intensity, when an axial methylene or methyl substituent is present at the β-position to two α-carbons and one α-carbon bearing the relevant hydrogen(s), respectively.[18] The "$R_1(=1)$, R_2 and R_3" are the ratios of the intensity of each vibration to the corresponding unit intensity, when there are one, two and three relevant hydrogens in a compound, respectively.[16]

The second assumption follows as. *The mole fractions N_H and N_{Me} are approximately constant for all the N-unsubstituted- and N-methyl-piperidines having no methylene or methyl group syn-axial to the lone pair or the hydrogen on nitrogen, respectively;* namely, $N_H = N_H^*$ (N_H of piperidine) and $N_{Me} = 0.95$.[33] On the other hand, for compound V having the afore-mentioned axial group, the mole fraction N_H is expressed by $N_H^* \times \beta_s$, where β_s is a parameter showing the effect of the group. *In compound Va, the N-methyl group is essentially fixed at the equatorial position;* namely, $N_{Me} = 1$. On the basis of these assumptions, the following equations are obtained for all the piperidines, having rigid or essentially fixed conformations, other than III, IIIa, IX and IXa.

For compounds with R_1;

VI and X $N_H^* \times I_t \times S_{1\beta} = 2.0,\ 2.0 = 2.0$[34] (2)

For compounds with R_2;

I $N_H^* \times 2I_s \times R_2 = 5.0$ (3)

II and VII $N_H^* \times (I_s + I_s) \times R_2 = 4.6,\ 4.6 = 4.6$ (4)

IV and XI $N_H^* \times 2I_t \times R_2 = 4.4,\ 4.6 = 4.6$ (5)

V $N_H^* \times 2I_t \times R_2 \times \beta_s = 5.4$ (6)

VIII $N_H^* \times (I_s + I_t) \times R_2 \times S_{2\beta} = 3.2$ (7)

VIa and Xa $(I_p + I_t) \times R_2 \times S_{2\beta} = 4.95,\ 4.95 = 4.95$ (8)

For compounds with R_3;

Ia $(I_p + 2I_s) \times R_3 = 11.1$ (9)

33) This value is cited from the report by Allinger *et al.*[7] The mole fraction N_{Me} of Ia has recently criticized by Katritzky *et al.*[5c]

34) The unit in Eqs. of (2) to (13); $10^{-3} \times l/cm^2 \cdot mol$.

IIa and VIIa $(I_p+I_s+I_t)\times R_3$
$=10.5,\ 10.5=10.5$ (10)

IVa, Va and XIa $(I_p+2I_t)\times R_3$
$=10.5,\ 10.7,\ 10.0=10.4$ (11)

VIIIa $(I_s+I_t)\times R_3\times S_{2\beta}+I_p\times R_3=9.05$ (12)

XII $(2I_s+I_t)\times R_3=10.5$ (13)

From Eqs. (9), (10), (11) and (13), we obtain

$$I_s=0.94\times I_p \quad (14)$$

and

$$I_t=0.84\times I_p \quad (15)$$

From Eqs. (3) (4) and (5), we obtain $I_s=1.11\times I_t$, which is consistent with Eqs. (14) and (15). Inserting Eqs. (14) and (15) into Eqs. (9), (10), (11), (13) and Eqs. (3), (4) and (5) yields

$$I_p\times R_3=3.88\times 10^3\ l/\mathrm{cm}^2\cdot\mathrm{mol} \quad (16)$$

and

$$N_H{}^*\times I_p\times R_2=2.64\times 10^3\ l/\mathrm{cm}^2\cdot\mathrm{mol} \quad (17)$$

Inserting Eqs. (17) and (16) into Eqs. (7) and (12) respectively gives

$$S_{2\beta}=0.68,\ 0.74=0.71$$

From the value of $S_{2\beta}$, Eqs. (8) and (6), we obtain

$$N_H{}^*=0.70 \quad \text{and} \quad \beta_s=1.22^{35)}$$

For compounds III and IIIa of the four piperidines, in which two conformations are possible, the intensities were calculated, using the estimated values for the parameters and the above assumptions. For conformations of III and IIIa, having a methylene group *syn*-axial to the lone pair or the *N*-hydrogen and, accordingly, two axial α-hydrogens, the intensities of 5.7 and $10.8\times 10^3\ l/\mathrm{cm}^2\cdot$mol were calculated, respectively. On the other hand, for the other conformations which include only one axial α-hydrogen, the calculated intensities were 2.2 and $5.2\times 10^3\ l/\mathrm{cm}^2\cdot$mol. These values, when compared with the corresponding observed intensities (Table 2), strongly suggest that these compounds assume the former conformation mainly.

The present result $N_H{}^*=0.70$ indicates that piperidine exists preferentially in the conformer with the lone pair axial, and is consistent with that obtained by Allinger ($N_H{}^*=0.68$),[7] Katritzky,[5a,5b] Booth,[10] and their co-workers, but not with those of other authors.[3,8a] We would emphasize that, while the value for $N_H{}^*$ is derived provided that the assumptions described hold for the compounds examined, this conclusion is considerably certain qualitatively. The above disagreement might be attributed to the difference in the experimental conditions or methods, or to the assumptions involved tacitly in the analysis of the results.

The authors wish to express their thanks to Dr. Takao Iijima for helfpul discussion and Mr. Shigehiro Ohuchi for preparation of some samples.

35) The following values are obtained for the other parameters on the assumption that $S_{2\beta}$ is equal to $S_{1\beta}$, although it appears improbable:
I_p, I_s and $I_s=4.79$, 4.50 and $4.02\times 10^3\ l/\mathrm{cm}^2\cdot$mol
R_2 and $R_3=0.79$ and 0.81.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2473—2479 (1968)

A Cationic Polymerization of *N*-Phenylethylenimine by Various Carboxylic Acid Catalysts

Tsutomu KAGIYA, Tomizo KONDO and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 22, 1968)

The polymerization of *N*-phenylethylenimine was carried out using various carboxylic acid catalysts (pK_a=0.23—4.87) in acetonitrile at 0°C. The number-average molecular weight was determined by measuring the allyl-group content in the infrared spectrum of the polymer initiated with allylformate. The relationship between the number-average molecular weight and the reduced viscosity was determined. Both the conversion and the number-average molecular weight increased with the reaction time when weak acid (pK_a=2.85—4.87) was used. On the other hand, when strong acid (pK_a=0.23—2.85) was used, conversion reached a limited value which increased in proportion to the amount of the catalyst. With the strong acid, the efficiency factor of the catalyst was almost unity, and was independent of the reaction time. On the other hand, with the weak acid, it was smaller than unity and increased proportionally with the amounts of the polymer formed. The rate constants of the elementary reactions were evaluated on the basis of the kinetic study. The rates of the initiation, propagation, and termination reaction increased with a decrease in the pK_a of the acid. With a weak acid, the termination reaction is slow at a low temperature (below 50°C), and increases with the reaction temperature, whereas with a strong acid the termination reaction occurs markedly even at a low temperature (above 0°C), and increases slightly with the temperature. The mechanism of the termination reaction was discussed on the basis of a structural study of the end group of the polymer.

It has already been reported by the present authors that *N*-phenylethylenimine and β-propiolactone copolymerized with various Brönsted acid catalysts, and that the monomer reactivity ratio varies with the pK_a of the acid used as the catalyst.[1]

In order to determine the role of the catalyst in the elementary reactions in the polymerization, the polymerization of *N*-phenylethylenimine was studied with various carboxylic acids, and the rate constants of the elementary reactions were determined on the basis of the kinetics. Furthermore, the mechanism of the termination reaction was discussed on the basis of the structural study of the end group of the polymer.

Experimental

Polymerization Procedure. *N*-Phenylethylenimine was prepared according to the method described in the literature[2] from β-bromoethylaniline hydrobromide. It was dried over sodium sulfate and fractionated twice before use, bp 70—70.5°C/13 mmHg. Acetonitrile was purified by the usual method.[3] Acids of guaranteed reagents were used without further purification.

Definite amounts of a catalyst and a solvent were placed into a glass ampule under a nitrogen atmosphere, and then *N*-phenylethylenimine was added to this system at −78°C. The ampule was sealed and maintained at 0—1°C for the definite period of the reaction time. The product was then washed with diethyl ether, separated by a centrifuge, and dried *in vacuo*.

Physical Analysis of the Polymer. The melting point of the polymer was measured visually in a nitrogen atmosphere in a capillary on an electric heater. The reduced viscosity of a 0.25% solution of 99—100% formic acid was measured at 35°C with an Ostwald viscometer. The infrared spectrum was obtained with the use of the potassium bromide pellet technique on a Shimadzu infrared spectrophotometer, Model IR-27. The X-ray diffraction diagram was recorded with a powder camera on a Shimadzu X-ray diffractometer, Model GX-3B. The differential thermogram was obtained with the use of a Rigaku Denki differential thermal apparatus, Model VIP-32.

Determination of Molecular Weight. It was found that *N*-phenylethylenimine polymerized with cationic reagents, such as triphenylmethyl chloride, allyl formate or allyl acetate, as well as with Brönsted acid. The absorption peak of the infrared spectrum of the polymer initiated with allyl formate at 910 cm^{-1} assigned to the vinyl group, and that at 1600 cm^{-1} assigned to the phenyl group, were used in order to determine the number-average molecular weight of the

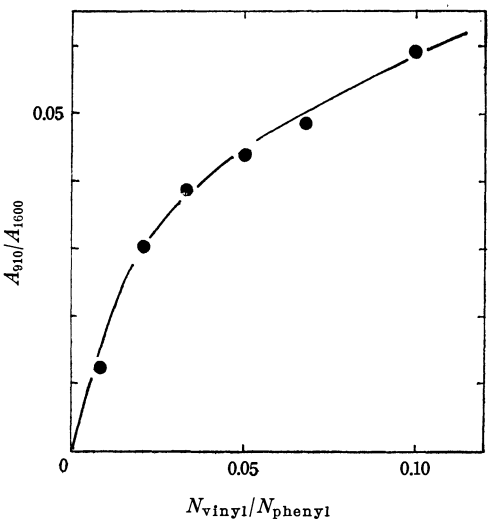

Fig. 1. Plots of A_{910}/A_{1600} *vs.* the ratio of the number of vinyl group (N_{vinyl}) in allyl urea to the number of phenyl group (N_{phenyl}) in the polymer.

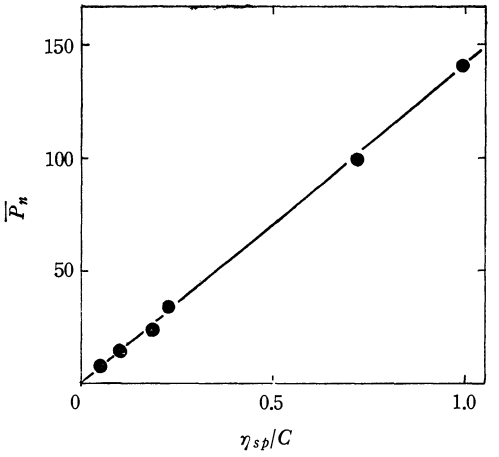

Fig. 2. The plots of the degree of the polymerization *vs.* the reduced viscosity of the polymer.

polymer. The calibration curve was obtained by plotting the optical density ratio, D_{910}/D_{1600}, in the infrared spectrum against the ratio of the number of vinyl and phenyl groups in the mixture of allyl urea and polymer obtained with formic acid (Fig. 1). The relation between the number-average molecular weight, $\overline{M}_n$, and the reduced viscosity, η_{sp}/C, is shown in Fig. 2. From Fig. 2, the following empirical equation may be obtained:

$$\eta_{sp}/C = 0.6\times10^{-4}\,\overline{M}_n$$

Results and Discussion

Physical Properties of the Polymer. The polymer is a white powdery solid soluble in formic acid, but insoluble in the other organic solvents.

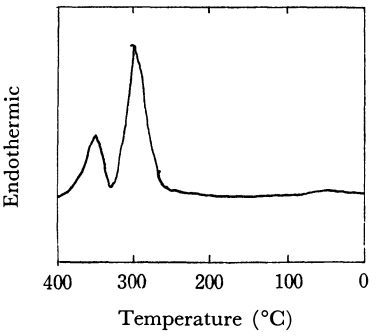

Fig. 3. Differential thermogram of the polymer.

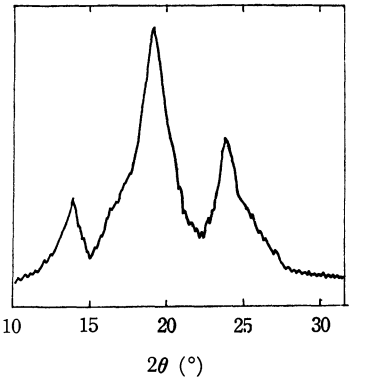

Fig. 4. X-Ray diffraction of the polymer.

The melting point of the polymer is from 287 to 292°C, and the differential thermogram of the polymer showed a sharp endothermic peak corresponding to the melting point of the polymer at 300°C (Fig. 3). In an X-ray diffraction diagram of the polymer (Fig. 4), sharp peaks were observed at 13.6, 19.4, and 23.3 θ. The figure showed that the polymer had a fairly good crystallinity.

Polymerization of *N*-Phenylethylenimine with Various Carboxylic Acids. The polymerization was carried out with various carboxylic acids (pK_a=0.23—4.87) at 0°C in acetonitrile. Figure 5 shows the variation in the polymer yield with the reaction time. With weak acid catalysts (pK_a=2.85—4.87), such as formic acid, acetic acid, and propionic acid, the polymer yield increased with the reaction time. On the other hand, with strong acids (pK_a=0.23—2.85), such as trifluoroacetic acid, dichloroacetic acid, and monochloroacetic acid, the conversion reached a saturated value ($<$ 50%) in a few minutes after the start of the polymerization. The number-average molecular weight of the polymer obtained with weak acid varied with the reaction time, whereas that obtained with strong acid remained constant (Fig. 6). With weak acid, the rate of the monomer consumption is expressed by a first-order rate equation with respect to the monomer

concentration in the early stages of the polymerization, but not in the later stages. These facts suggest that the termination reaction occurs in this polymerization. In order to confirm that the termination reaction takes place, the following experiment was carried out. In the polymerization with monochloroacetic acid, the catalyst was added after the conversion reached the saturated value. The increase in the polymer yield in this experiment leads to the conclusion that the saturation is caused by the deactivation of the propagating species.

Kinetics of the Polymerization. The rate equations of the initiation, propagation, and transfer reactions may be assumed to be as follows:

$$R_i = k_i[\mathrm{C}][\mathrm{M}] \quad (1)$$

$$R_p = k_p[\mathrm{P}^*][\mathrm{M}] \quad (2)$$

$$R_{tr} = k_{tr}[\mathrm{P}^*][\mathrm{Y}] \quad (3)$$

where:
[C], [M], [P*], and, [Y]: the concentrations of the catalyst, monomer, the propagating species, and the substance to which the acitivity of P* is transferred.
R_i, R_p, and R_{tr}: the rates of the initiation, the propagation, and the transfer reaction.
k_i, k_p, and k_{tr}: the rate constants of the initiation, the propagation, and the transfer reaction.

The number-average degree of polymerization at a given reaction time may be written for the polymerization with no termination by recombination as follows:

$$\overline{P}_n = \int R_p dt / \left(\int R_i dt + \int R_{tr} dt \right) \quad (4)$$

By combining Eqs. (2), (3) and (4), and considering $\int R_p dt$ to be approximately equal to the polymer yield, [M_p], the reciprocal of the degree of polymerization may be expressed by the following equation:

$$1/\overline{P}_n = \int R_i dt/[\mathrm{M_p}] + (k_{tr}[\mathrm{Y}])/k_p \quad (5)$$

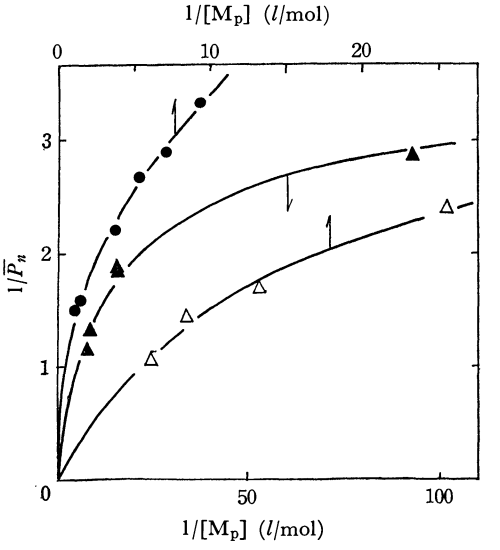

Fig. 7. Reciprocal of degree of polymerization *vs.* reciprocal of the polymer yield.
(Reaction conditions and notes are the same as Fig. 5.)

The plots of the reciprocal of $\overline{P}_n$ against the reciprocal of the polymer yield give a upward-concave curve through the point of origin, as is shown in Fig. 7. Figure 7 shows that $\int R_i dt$ increases with the reaction time. Moreover, the fact that the curve goes through the point of origin indicates that no chain transfer occurs in the polymerization with the weak acid. Equation (4) thus becomes:

$$\overline{P}_n = [M_p]/\int R_i dt \qquad (6)$$

For the polymerization without chain transfer and bimolecular termination, the value of $[M_p]/([C]_0/\overline{M}_n)$ may be called the efficiency factor of the catalyst, α. The plots of α against the reaction time are shown in Fig. 8. In the polymerization with strong acid catalysts, α is independent of the reaction time and is found to be almost unity (Fig. 8). This fact indicates that this system with strong acid involves polymerization with a rapid initiation and no chain transfer reaction. On the other hand, on the basis of the findings that, with a weak acid, α is smaller than unity and increases with the reaction time, this system may be considered to involve polymerization with a slow initiation.

The relationship between α and the amount of the polymer formed, $[M_p]$, when a weak acid is used is shown in Fig. 9. Figure 9 shows that α is proportional to the amount of the polymer formed, and is independent of the pK_a of the acid. This result may be interpreted by assuming that the stationary state is applicable, and that the termination reaction occurs with the monomer

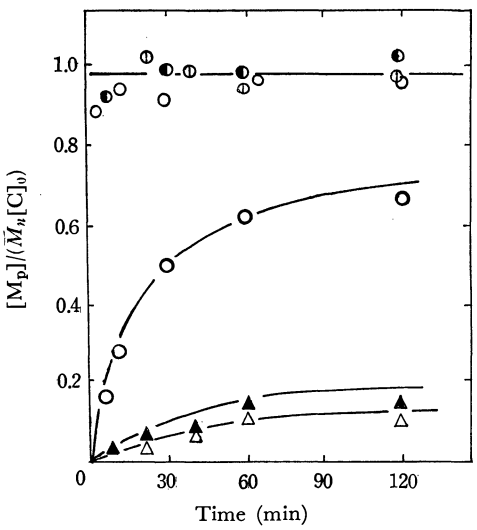

Fig. 8. The plots of efficiency factor of catalyst, *vs.* reaction time.
(Reaction condition and notes are the same as Fig. 5.)

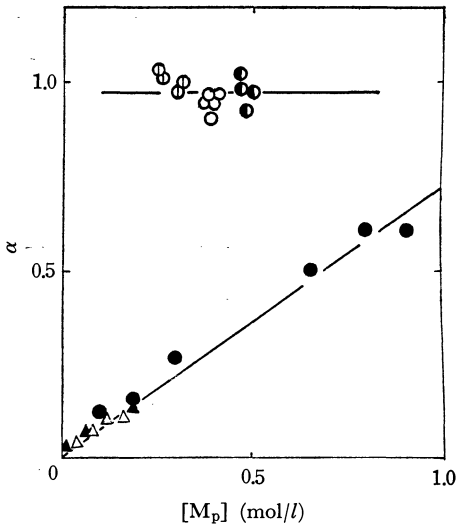

Fig. 9. The relationship between α and $[M_p]$. (Reaction conditions and notes are the same as Fig. 5.)

as is expressed by Eqs. (7) and (9):

$$R_i = R_t \qquad (7)$$

or

$$\int R_i dt = \int R_t dt = \alpha[C]_0 \qquad (8)$$

$$R_t = -d[P^*]/dt = k_t[P^*][M] \qquad (9)$$

where R_t and k_t are the rate and the rate constant of the termination respectively. By integrating Eqs. (2) and (9), and by then dividing the latter by the former,

$$\int R_t dt / \int R_p dt = k_t/k_p = \int R_t dt/[M_p] \qquad (10)$$

From Eqs. (8) and (10), Eq. (11) is derived:

$$\alpha[C]_0 = (k_t/k_p)[M_p] \qquad (11)$$

The relationship of Eq. (11) is in accord with Fig. 9; that is, α is proportional to $[M_p]$. From Eq. (11), the value of k_t/k_p was estimated to be 1.26×10^{-2}.

With a weak acid catalyst, the rate constant of the initiation reaction was obtained by using the following method. From a combination of Eqs. (1), (7), and (9), Eq. (12) is derived:

$$k_t[P^*][M] = k_t[C][M] \qquad (12)$$

By substituting the $[P^*]$ from Eq. (12) into Eq. (2), the rate of the monomer consumption becomes:

$$-d[M]/dt = (k_p k_t/k_t)[C][M] \qquad (13)$$

On the other hand, Eq. (11) may be expressed as Eq. (14):

$$[C]_0 - [C] = (k_t/k_p)([M]_0 - [M]) \qquad (14)$$

where $[M]_0$ is the initial monomer concentration. From Eqs. (13) and (14), Eq. (15) is derived:

$$-d[M]/dt = (k_p k_i/k_t)[M]\{[C]_0 - (k_t/k_p)([M]_0 - [M])\} \quad (15)$$

or:

$$\frac{-d[M]}{(k_t/k_p)[M]^2 - \{(k_t/k_p)[M]_0 - [C]_0\}[M]} = (k_p k_i/k_t)dt \quad (16)$$

On integrating, Eq. (17) is obtained:

$$\ln\left\{\frac{k_p[C]_0}{k_t[M]_0}\,\frac{[M]}{([M]-[M]_0)+(k_p/k_t)[C]_0}\right\} = k_i\{[M]_0 - (k_p/k_t)[C]_0\}t \quad (17)$$

By substituting the value, $(k_p/k_t)[C]_0 = 1.43$ mol/l, obtained from Eq. (11), $[M]_0 = 1$ mol/l and $([M]_0-[M])/[M]_0 = x$, into Eq. (17), one obtains

$$\log\{(1-0.7x)/(1-x)\} = 0.187k_i t \quad (18)$$

A plot of the left hand of Eq. (18) against t defined a straight line through the point of origin (Fig. 10). From the slope of the line, the k_i values were evaluated. The values of k_i in the polymerization with weak acid are summarized in Table 1. The fact that k_i increases with a decrease in the pK_a of the acid may be ascribed to the larger dissociation constant of the stronger acid than that of the weaker acid.

The values of k_p and k_t with a weak acid catalyst were estimated graphically as follows. The concentrations of the propagating species are expressed by Eq. (19):

$$[P^*] = \int R_i dt - \int R_t dt \quad (19)$$

By substituting Eqs. (2), (6), and (9) into Eq. (19), Eq. (20) is derived:

$$R_p/([M][M_p]) = k_p/\bar{P}_n - k_t \quad (20)$$

As is shown in Fig. 11, the plots of $R_p/([M][M_p])$ against $1/\bar{P}_n$ gave straight lines with the weak acid catalyst. Therefore, the assumption of the rate equation is considered to be suitable.

From the slope and intercept on the ordinate axis, k_p and $-k_t$ can be obtained graphically. The rate constants obtained by this method are summarized in Table 1. It is found that, with the weak acid catalyst, the rate constant of the termination reaction is about a hundredth that of the propagation, and that both k_p and k_t increase with a decrease in the pK_a of the catalyst. In the polymerization with strong acid catalysts such as trifluoroacetic acid, the rate constants can not be evaluated by the above method because the conversion is saturated immediately after the start

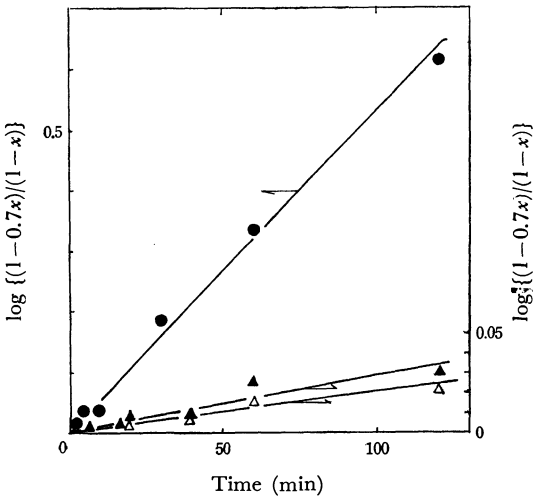

Fig. 10. The plots of $\log\{(1-0.7x)/(1-x)\}$ according to the Eq. (18).
(Reaction conditions and notes are the same as Fig. 5.)

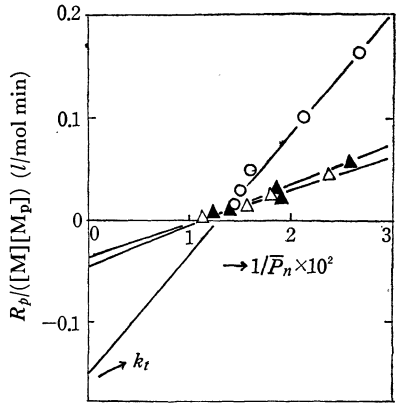

Fig. 11. The plots of $R_p/([M][M_p])$ *vs.* the reciprocal of the degree of the polymerization according to Eq. (9).
(Reaction condition and notes are the same as Fig. 5.)

Table 1. The rate constants of elementary reactions in the polymerization with weak acid catalyst

Catalyst	pK_a	$k_i \times 10^2$ l/mol min	k_p l/mol min	$k_t \times 10^2$ l/mol min	$(k_t/k_p) \times 10^2$
Formic acid	3.75	2.86	12	15	1.25
Acetic acid	4.76	0.167	3.8	4.8	1.26
Propionic acid	4.87	0.131	3.5	4.2	1.20
					mean 1.24

of the polymerization. Therefore, k_t/k_p was obtained by using the limited conversion $[M_p]_\infty$ according to the following method: From Eq. (10), Eq. (21) is derived:

$$\int R_t dt / \int R_p dt = k_t/k_p = \int R_t dt/[M_p]_\infty \quad (21)$$

On the basis of the facts that, with a strong acid catalyst, no chain-transfer reaction occurred in this polymerization, that α was almost equal to unity, and that the propagating species deactivated quantitatively, Eq. (22) can be assumed:

$$\int R_t dt = \int R_i dt = [C]_0 \quad (22)$$

By substituting Eq. (22) into Eq. (21), Eq. (23) was derived:

$$[M_p]_\infty = (k_p/k_t)[C]_0 \quad (23)$$

In the polymerization with monochloroacetic acid, the conversion reached a limited value which was dependent on the catalyst concentration. A plot of a limited conversion $[M_p]_\infty$ *versus* the initial concentration of the catalyst gave a straight line through the point of origin, as is shown in Fig. 12. This fact is in accordance with the relationship shown in Eq. (23). From the relation of $[M_p]_\infty$ and $[C]_0$ in Eq. (23), k_t/k_p can be determined.

The values of k_t/k_p are plotted against the pK_a of the catalyst in Fig. 13. This figure shows that the value of k_t/k_p decreases with an increase in the pK_a of the acid, and reaches a limited value of 1.24×10^{-2} with a weak acid. This value is almost in accord with the value, 1.26×10^{-2}, obtained from the slope of the line in Fig. 9.

Mechanism of the Termination Reaction. In order to investigate the temperature dependency of the termination reaction, the polymerization was studied with formic acid (a weak acid) or monochloroacetic acid (a strong acid) at various temperatures. A two-stage polymerization method was used. The polymerization was carried out for five minutes at a definite temperature (first stage), and then continued for 25 min at 0°C (second stage). The polymer yield obtained in the first stage, or the total of that obtained in the whole period, is plotted against the reaction temperature in Fig. 14. With the monochloroacetic

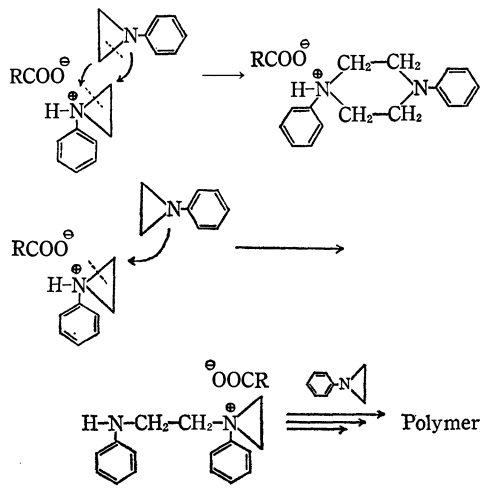
◑ second stage, Continued for 25 min at 0°C.

acid catalyst, the conversion increased only a little in the second stage at temperatures of about 0°C. On the other hand, with formic acid the increase in conversion was observed in the second stage at temperatures below 50°C, and the termination reaction increased markedly above 50°C. This indicates that, with a weak acid, the termination reaction is slow at low temperatures and increases with the reaction temperature, while with a strong acid the termination reaction occurs remarkably at even low temperatures.

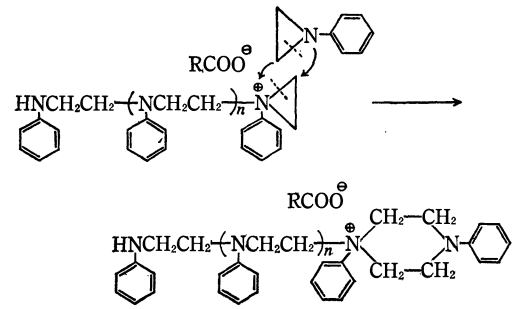
Chemical and spectral analyses of the products of the reaction of *N*-phenylethylenimine with excess amounts of monochloroacetic acid were carried out in order to elucidate the mechanism of the termination reaction. The reaction was carried out in an acetonitrile solution at room temperature for five hours. A white crystal precipitate (A) was filtered out. When this filtrate was neutralized by an 1/10 N sodium aqueous solution, a white resinous crystal (B) was precipitated. The product (A) was soluble in formic acid and insoluble in the other organic solvents. The infrared spectrum of (A) was identical to that of poly-*N*-phenylethylenimine. On the other hand, the product (B) was soluble in formic acid and ethanol, and its infrared spectrum indicated the characteristic peak at 930 cm^{-1} assigned to a piperazine ring.

It has been reported by Dick that *N*-substituted ethylenimine reacts with allyl bromide in acetone at 40°C to produce the piperazine derivatives and the polymer, and that the infrared spectrum of the polymer showed the characteristic peak of the piperazine ring at 930 cm^{-1}.[4]

In view of these facts, the *N*,*N*-diphenylpiperazine derivative and the polymer were considered to be produced in the reaction of *N*-phenylethylenimine and monochloroacetic acid by the following mechanism:



The infrared spectrum of the polymer initiated by a strong acid catalyst shows the characteristic peak of the piperazine ring at 930 cm^{-1}. Therefore, the mechanism of the termination reaction may also be considered to be piperazine ring formation at the end of the polymer.



The increase in the termination reaction with a decrease in the pK_a of the acid may be ascribed to the separation of the counter anion from the growing immonium ion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2480—2483 (1968)

Ribonuclease T_1 Peptides. III. Synthesis of a Protected Heptapeptide Corresponding to Sequence 24—30

Tetsuo KATO, Nobuo MITSUYASU, Michinori WAKI, Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received March 26, 1968)

A protected heptapeptide corresponding to sequence 24—30 of ribonuclease T_1, namely benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucyl-L-histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine ethyl ester (XI), was synthesized by coupling of benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucine azide with a tetrapeptide ester, L-histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine ethyl ester, which is derived from N^{α},N^{im}-dibenzyloxycarbonyl tetrapeptide ester by the catalytic hydrogenolysis. These tri- and tetrapeptide components were prepared with stepwise syntheses free from racemization.

The syntheses of the protected *N*-terminal undecapeptide (1—11) of ribonuclease T_1 containing asparagine residue in the 3rd position and the protected pentapeptide (12—16) were previously reported.[1,2] In the present paper, we will describe the synthesis of the protected heptapeptide corresponding to sequence 24—30, that is benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucyl-L-histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine ethyl ester (XI).

It has been known that one or more histidine residue in ribonuclease T_1 molecule play an important role to the enzymatic activity.[3] Hence the organic synthesis of peptide fragment of the enzyme containing histidine was supposed to be valuable to study the relationship of the structure and function of the enzyme molecule. Moreover this heptapeptide sequence contains acidic, basic and phenolic functional groups in a rather short peptide, so the preparation of this compound seemed to be interesting as an object of organic synthesis of a peptide.

The scheme of reactions used for the synthesis of XI was shown in Fig. 1. Benzyloxycarbonyl-β-*t*-butyl-L-aspartyl-glycine ethyl ester (I) was prepared by coupling of benzyloxycarbonyl-β-*t*-butyl-L-aspartic acid dicyclohexylammonium salt[4] with glycine ethyl ester hydrochloride using dicyclohexylcarbodiimide[5] as a coupling reagent. Furnished semisolid of I was catalytically hydrogenated to yield the dipeptide ester hydrochloride (II), which was then coupled with benzyloxycarbonyl-γ-*t*-butyl-L-glutamic acid[6] in the same manner as used for I. The protected tripeptide derivative (III) obtained was subjected to hydrogenolysis and then coupled with N^{α},N^{im}-dibenzyloxycarbonyl-L-histidine.[7] Crystals of the tetrapeptide derivative (V) thus obtained were again hydrogenated and then used to obtain the required heptapeptide derivative. The preparation of the *N*-terminal tripeptide (IX) was carried out as follows: L-leucine ethyl ester was coupled with benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester[8] to furnish the protected dipeptide ester (VII), and after the hydrogenolysis of VII, the dipeptide ester (VIII) was coupled with benzyloxycarbonyl-*O*-benzyl-L-tyrosine *p*-nitrophenyl ester.[8] The tripeptide ester derivative (IX) obtained was converted to the corresponding hydrazide (X) by the treatment with hydrazine.

The tripeptide hydrazide (X) was converted to the corresponding azide, and the azide was coupled with the tetrapeptide ester (VI). The protected heptapeptide ester derivative (XI) obtained was catalytically hydrogenated to remove the benzyloxycarbonyl and *O*-benzyl protecting groups,

and the heptapeptide ester acetate (XII) obtained was then treated with trifluoroacetic acid to secure the heptapeptide ethyl ester trifluoroacetate (XIII). The peptide XIII was homogeneous as judged by the paper and thin-layer chromatography and its acid hydrolysate gave the theoretically expected amino acid ratios. Furthermore, the stereospecific purity of the peptide (XIII) was ascertained by the digestion with leucine aminopeptidase.

The syntheses of several peptides related to the ribonuclease T_1 enzyme are being continued in this laboratory.

Experimental

The melting points were not corrected. The paper chromatography and thin-layer chromatography were carried out on Toyo Roshi No. 52 paper and Merck silica gel G, respectively. Spots of materials possessing a free amino group on a thin-layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin. The developing solvent system most commonly used was n-butanol : acetic acid : pyridine : water (4 : 1 : 1 : 2). The optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type. Prior to analysis, the samples were dried over anhydrous phosphorus pentoxide at 70°C and 2 mmHg to a constant weight.

Benzyloxycarbonyl-β-t-butyl-L-aspartyl-glycine Ethyl Ester (I). A suspension of benzyloxycarbonyl-β-t-butyl-L-aspartic acid dicyclohexylammonium salt[4] (5.047 g, 10 mmol) and glycine ethyl ester hydrochloride (1.396 g, 10 mmol) in chloroform (30 ml) was stirred for 30 min and the mixture was chilled to −5°C. Dicyclohexylcarbodiimide[5] (2.06 g, 10 mmol) was added to the mixture, the mixture was stirred for 2 hr at 0°C, and then it was allowed to stand overnight at 0°C. The mixture was then evaporated *in vacuo*, ethyl acetate (30 ml) was added to the residue, and the mixture was stored for several hours in a refrigerator. The dicyclohexylurea and dicyclohexylammonium hydrochloride deposited were filtered off (4.346 g, 99%), and the filtrate was washed successively with water, 10% citric acid and 4% sodium bicarbonate, and dried over sodium sulfate. The filtrate from the salt was evaporated and the residual semisolid was collected with the aid of a mixture of ether and petroleum ether (3.71 g, 91%). A portion of this was reprecipitated from ethyl acetate - ether - petroleum ether, and the semisolid obtained was analyzed; R_f 0.90 on thin-layer.

Found: C, 58.43; H, 6.99; N, 7.26%. Calcd for $C_{20}H_{28}N_2O_7$: C, 58.81; H, 6.91; N, 6.86%.

β-t-Butyl-L-aspartyl-glycine Ethyl Ester Hydrochloride (II·HCl). A solution of I (3.26 g, 8 mmol) in ethanol (30 ml) was hydrogenated in the presence of palladium black at 0°C. After 15 min, 0.52 N hydrogen chloride in ethanol (13.1 ml) was added into the solution, and hydrogenolysis was continued for 4 hr at 0°C. The filtrate from the catalyst was evaporated *in vacuo* at low temperature; yield of the hygroscopic crystals, 2.49 g (100%); R_f 0.95 on paper, 0.71 on thin-layer.

Benzyloxycarbonyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine Ethyl Ester (III). A mixture of benzyloxycarbonyl-γ-*t*-butyl-L-glutamic acid dicyclohexylammonium salt[6] (3.371 g, 6.5 mmol), II·HCl (2.03 g, 6.5 mmol), dicyclohexylcarbodiimide (1.339 g, 6.5 mmol) and chloroform (30 ml) was stirred for 2 hr at −5°C and then left to stand overnight at 0°C. The mixture was evaporated *in vacuo*, and ethyl acetate was added. After filtration, the ethyl acetate solution (*ca.* 100 ml) was washed with water, dilute acid and alkali as described for I, and dried. The filtrate from the salt was evaporated and the resulting crystals were collected by filtration with the aid of petroleum ether; yield, 3.438 g (90%); R_f 0.92 on thin-layer. A portion (134 mg) of the crystals was recrystallized from ether-petroleum ether for analysis; 119 mg; mp 58—60°C; $[\alpha]_D^{30}$ −20.0° (*c* 1, dimethylformamide).

Found: C, 58.44; H, 7.39; N, 6.92%. Calcd for $C_{29}H_{43}N_3O_{10}$: C, 58.67; H, 7.30; N, 7.08%.

γ-*t*-Butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine Ethy Ester Hydrochloride (IV·HCl). A solution of III (3.002 g, 5.06 mmol) in ethanol (25 ml) was hydrogenated in the presence of palladium black and 0.52 N hydrogen chloride in ethanol (10.2 ml) as described for the preparation of II. The filtrate from the catalyst was evaporated *in vacuo*; yield of the oily product (IV·HCl), 2.717 g (109%); R_f 0.97 on paper, 0.80 on thin-layer.

N^{α},N^{im}-Dibenzyloxycarbonyl-L-histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine Ethyl Ester (V). A mixture of N^{α},N^{im}-dibenzyloxycarbonyl-L-histidine[7] (2.27 g, 5 mmol), IV·HCl (the oily product from 5 mmol of III), triethylamine (0.73 ml), dicyclohexylcarbodiimide (1.03 g, 5 mmol) and chloroform (20 ml) was stirred for 2 hr at −5°C, allowed to stand overnight at 0°C, and evaporated *in vacuo*. Ethyl acetate (50 ml) was added to the residue, and the dicyclohexylurea deposited was filtered off (993 mg). The filtrate was washed with water, dilute citric acid and sodium bicarbonate solution as described previously. The solution dried was evaporated *in vacuo* and the residual oil was crystallized after the addition of ether and petroleum ether. Recrystallization from ethyl acetate - ether - petroleum ether gave 3.14 g (73%) of pure substance; R_f 0.93 on thin-layer; mp 85—87°C; $[\alpha]_D^{17}$ −8.0° (*c* 1, dimethylformamide).

Found: C, 59.40; H, 6.65; N, 9.41%. Calcd for $C_{43}H_{56}N_6O_{13}$: C, 59.71; H, 6.53; N, 9.72%.

L-Histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine Ethyl Ester Dihydrochloride (VI·2HCl). A solution of V (2.112 g, 2.5 mmol) in ethanol (30 ml) was hydrogenated at 0°C in the presence of palladium black and 0.52 N hydrogen chloride in ethanol (8 ml) as described for the preparation of II·HCl. The filtrate from the catalyst was evaporated *in vacuo*; yield of the oily product (VI·HCl), 1.696 g (101%); R_f 0.98 on paper, 0.70 on thin-layer.

Benzyloxycarbonyl-L-glutaminyl-L-leucine Ethyl Ester (VII). To a solution of L-leucine ethyl ester hydrochloride[9] (1.469 g, 7.5 mmol) dissolved in a mixture of triethylamine (1.16 ml, 8.5 mmol) and dimethylformamide (15 ml), a solution of benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester[8] (3.011 g, 7.5 mmol) in dimethylformamide (8 ml) was added. The solution was then allowed to stand overnight at room temperature and then poured into 225 ml of water. The crystalline product deposited was collected by filtration and washed successively with 3% sodium bicarbonate, M citric acid and water, and dried; 2.39 g. Recrystallization from ethanol - ether - petroleum ether gave 2.13 g (67%) of pure substance; R_f 0.97 on thin-layer; mp 128—130°C; $[\alpha]_D^{20}$ −9.4° (*c* 1.0, dimethylformamide).

Found: C, 59.74; H, 7.33; N, 9.90%. Calcd for $C_{21}H_{31}N_3O_6$: C, 59.84; H, 7.41; N, 9.97%.

L-Glutaminyl-L-leucine Ethyl Ester Hydrochloride (VIII·HCl). To a solution of VII (2.11 g, 5 mmol) dissolved in methanol (30 ml) was added 0.72 N methanolic hydrogen chloride (7.63 ml, 5.5 mmol). The solution was hydrogenated in the presence of palladium black. After 6 hr the filtrate from the catalyst was evaporated to dryness *in vacuo*; yield of the oily product (VIII·HCl), 1.667 g (103%). The homogeneity of the oil was ascertained by paper and thin-layer chromatography; R_f 0.80 on paper and 0.75 on thin-layer.

Benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucine Ethyl Ester (IX). To a solution of VIII·HCl (1.667 g, 5 mmol) dissolved in a mixture of triethylamine (0.78 ml, 5.5 mmol) and dimethylformamide (25 ml), a solution of benzyloxycarbonyl-*O*-benzyl-L-tyrosine *p*-nitrophenyl ester[8] (2.663 g, 5 mmol) in dimethylformamide (12 ml) was added. The solution was then allowed to stand overnight at room temperature and then poured into 200 ml of water. The crystalline product deposited was collected by filtration, washed and dried as described for VII. Recrystallization from methanol - ether - petroluem ether gave 2.725 g (86%) of IX; R_f 0.98 on thin-layer; mp 210—211°C; $[\alpha]_D^{15}$ −16.2° (*c* 1, dimethylformamide).

Found: C, 65.83; H, 6.90; N, 8.25%. Calcd for $C_{37}H_{46}N_4O_8$: C, 65.86; H, 6.87; N, 8.30%.

Benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucine Hydrazide (X). A solution of IX (2.022 g, 3 mmol) and hydrazine hydrate (3 ml, 60 mmol) in dimethylformamide (12 ml) was allowed to stand for 2 days at room temperature. The solution was then evaporated *in vacuo* in order to remove excess hydrazine, and then 120 ml of water was added to the residual solution. The resulting crystals (1.932 g) were collected by filtration and recrystallized from dimethylformamide-ethanol to give 1.74 g of X (90%); R_f 0.84 on thin-layer; mp 237°C; $[\alpha]_D^{15}$ −13.6° (*c* 1, dimethylformamide).

Found: C, 62.03; H, 6.76; N, 12.39%. Calcd for $C_{35}H_{44}N_6O_7 \cdot H_2O$: C, 61.93; H, 6.83; N, 12.38%.

Benzyloxycarbonyl-*O*-benzyl-L-tyrosyl-L-glutaminyl-L-leucyl-L-histidyl-γ-*t*-butyl-L-glutamyl-β-*t*-butyl-L-aspartyl-glycine Ethyl Ester (XI). Into a solution of X (1.652 g, 2.5 mmol) in a mixture of acetic acid (70 ml) and dimethylformamide (14 ml), there were added successively N hydrochloric acid (2.75 ml), sodium nitrite (190 mg) and N hydrochloric acid (2.75 ml) under stirring below −5°C. The faintly turbid solution changed to transparent in a few minutes. Then cold water (160 ml) was added to the solution, and the stirring was continued at 0°C for 30 min. The precipitate was then collected, washed successively with water, 4% sodium bicarbonate and water, and dried *in vacuo* at 0°C. The azide was then

9) F. Rohman, *Ber.*, **30**, 1978 (1897).

added to a chilled solution of VI·HCl (1.696 g, 2.5 mmol) in a mixture of dimethylformamide (40 m*l*) and triethylamine (0.73 m*l*). The solution was stirred for 3 days at 0°C, and diluted with 800 m*l* of cold water. The precipitate was collected, washed with 4% sodium bicarbonate, 10% citric acid and water, and dried; yield, 2.342 g. Recrystallization from methanol-dioxane-ether gave 2.11 g (69%) of XI; R_f 0.85 on thin-layer; mp 213—214°C; $[\alpha]_D^{30}$ −21.1° (*c* 1, dimethylformamide).

Found: C, 59.71; H, 6.78; N, 10.94%. Calcd for $C_{62}H_{84}N_{10}O_{16}\cdot H_2O$: C, 59.88; H, 6.97; H, 11.26%.

L-Tyrosyl-L-glutaminyl-L-leucyl-L-histidyl-L-glutamyl-L-aspartyl-glycine Ethyl Ester Ditrifluoroacetate (XIII·2CF$_3$COOH). A solution of XI (50 mg, 40 μmol) in 80% acetic acid (1 m*l*) was subjected to hydrogenolysis in the presence of palladium black. After 1 hr, the filtrate from the catalyst was evaporated to dryness; yield of hygroscopic crystals (XII·2AcOH), 51 mg; R_f 0.75 on thin-layer. XII·2AcOH (48 mg) was dissolved in trifluoroacetic acid (0.4 m*l*), and the solution was left to stand for 30 min and evaporated to dryness. The resulting crystals were collected by filtration with the aid of ether (46 mg); mp 180—185°C; $[\alpha]_D^{25}$ −10.0° (*c* 0.3, acetic acid); R_f 0.80 on paper, 0.71 on thin-layer; amino acid ratios in acid hydrolysate, $Tyr_{1.0}$, $Leu_{1.2}$, $His_{0.9}$, $Glu_{2.2}$, $Asp_{0.9}$, $Gly_{0.9}$.

Found: C, 44.91; H, 5.67; N, 12.30%. Calcd for $C_{39}H_{56}N_{10}O_{14}\cdot 2C_2HO_2F_3\cdot 2H_2O$: C, 44.79; H, 5.42; N, 12.15%.

The digestion of XIII·HCl by leucine aminopeptidase was carried out by the procedure of Hofmann and Yajima.[10] The paper chromatography of the digest with a solvent system of *n*-butanol : acetic acid : water (4 : 1 : 2) revealed the presence of seven ninhydrin-positive components with R_f values identical with those of authentic samples of aspartic acid (R_f, 0.25), histidine (0.28), glutamine (0.31), glycine (0.33), glutamic acid (0.36), tyrosine (0.54) and leucine (0.76).

Photo-induced Reactions. XIX. Photopinacolization of Unsymmetric Aromatic Ketones[1]

Teruo MATSUURA and Yoshihiko KITAURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received March 28, 1968)

Stereochemistry of the photopinacolization of unsymmetrical aromatic ketones was investigated. In the photopinacolization of aromatic ketones of type PhCOR in isopropyl alcohol, the *dl* : *meso* ratio of diastereoisomeric pinacols formed tends to increase as the size of the substituent R becomes bulkier. The *dl* : *meso* ratio of pinacols obtained from *p*-substituted acetophenone, *p*-X-C_6H_4-$COCH_3$, is about 1 in the cases that X is H, Cl, and CH_3, whereas the ratio is 1.25 in the case of X=OCH_3. The photopinacolization of acetophenone in three solvent systems cyclohexane, isopropyl alcohol, and benzene-isopropyl alcohol, was also investigated, and no solvent effect was observed on the *dl* : *meso* ratio of acetophenone pinacols.

The photoreduction of ketones, especially aromatic ketones, is one of the most extensively investigated field in organic photochemistry.[2] Unsymmetrical ketones, which can undergo photopinacolization, should give two diastereoisomeric pinacols, *dl* and *meso* forms. However, there have been only a few reports in which the ratio of such diastereoisomeric pinacols is described. It was reported that *o*-phenylbenzophenone[3] and desoxybenzoin[4] yield a higher melting pinacol predominantly over a lower melting isomer. Bencze and his coworkers found that 3-acetylpyridine yields a higher melting pinacol accompanying with a small amount of a lower melting one, while 2-acetylpyridine gives approximately an equal amount of two isomeric pinacols.[5] Brown reported that the photolysis of benzyl alcohol in acetone affords an equal amount of *dl*- and *meso*-hydrobenzoin.[6] Furthermore, acetophenone was shown to give corresponding pinacols with the *dl* : *meso* ratio of 11 : 10[7] Since there has been no systematic investigation on the

stereochemistry of the photopinacolization of unsymmetric aromatic ketones, we initiated to examine effects of substituents and solvents in this reaction. Particular attention was drawn to following three factors; namely, (i) effects of the bulkiness of the substituents R in ketones of type PhCOR, (ii) electronic effects of the para substituent in *p*-substituted acetophenone, and (iii) solvent effects with acetophenone.

A mixture of diastereoisomeric pinacols could be easily separated by a column chromatography on silica gel from the reaction mixture which was obtained by the photolysis of PhCOR (I) and *p*-X-C_6H_4-$COCH_3$ (II) in isopropyl alcohol. The *dl* : *meso* ratio of these diastereoisomeric pinacols was determined from their peak areas in the NMR spectrum of the pinacol mixture. The results are shown in Tables 1 and 2. In the case of pinacols III obtained from I, the chemical shifts of protons of the substituent R are different between *dl* and *meso* forms, and the signals of the *dl* form appear in a higher field than those of the *meso* form. The assignment of the signals was accomplished by a comparison with authentic samples.*1 The authentic sample of *dl*-hydrobenzoin (III, R=H) was prepared by a known method, and other authentic samples of the pinacols III (R=CH_3, C_2H_5, and i-C_3H_7) were obtained by fractional recrystallization of the pinacol mixture and they were characterized by a comparison of their melting points with those reported in the literature. In the case of pinacols III (R=i-C_3H_7), the *dl* and *meso* forms were characterized, from their infrared spectra, according to the method of Mosher and Heindel.[10] A mixture of the *dl* and *meso* pinacols of type IV was also separated from the reaction mixture, but each isomer was not isolated. For these pinacols, an isomer showing a methyl signal in a higher magnetic field was assigned as the *dl* form and in a lower field as the *meso* form.[8]

Table 2. Photopinacols IV from *p*-substituted acetophenone II

p-X-$C_6H_4COCH_3 \longrightarrow$ (*p*-X-$C_6H_4C(OH)CH_3)_2$
(II) (IV)

Cl	88	8.60	8.52	1.0
CH_3O	90	8.60	8.50	1.2_5

*1 The NMR data of acetophenone pinacols[9] and propiophenone pinacols[9] have been reported.

As shown in Table 1, the *dl* : *meso* ratio of the pinacols III obtained from I appears to have a tendency to increase slightly as the size of the substituent R becomes bulkier. Contrary to the recent results by Stocker and Kern,[7] our results indicate that the *dl* : *meso* ratio is practically 1 : 1 for R=CH_3 and C_2H_5. Although we also examined the photopinacolization of *n*-butyrophenone (I, R=*n*-C_3H_7) and *t*-butyl phenyl ketone (I, R=*t*-C_4H_9) in isopropyl alcohol, photopinacolization was found to be a minor pathway and the yield of the pinacols were so low that the *dl* : *meso* ratio could not be determined. It was found that the former undergoes the Norrish Type I process whereas the latter does the Type II process as the major pathway. The somewhat lower yield of the pinacols III (R=i-C_3H_7) is probably due to the co-occurrence of the Type I process in some extent.

Table 2 summarizes the effect of the *p*-substituent of acetophenone on the *dl* : *meso* ratio of pinacols

IV. The *dl* and *meso* isomers are formed practically in an equal amount in the cases of X=H, CH_3, and Cl. On the other hand, the *dl* isomer is formed predominantly over the *meso* isomer when X is a methoxyl group, a strong electron-donating group. Similarly, *p*-anisaldehyde gives a mixture of the *dl* and *meso* pinacols with 2 : 1 ratio.[11] Analogous observation has been reported by Pitts and his coworkers[12] who show that, in the Norrish Type II reaction of *n*-butyrophenone, the quantum yield is remarkably affected by introducing a *p*-methoxyl group while a *p*-methyl group has little effect.

It was reported that, in the photopinacolization of acetophenone, there is no solvent effect on the *dl* : *meso* ratio of its pinacols formed in isoproyl alcohol or cyclohexane.[12] We also carried out the photopinacolization of acetophenone in three solvent systems and similar results were obtained. A mixture of two diastereoisomeric pinacols was obtained in 80% yield in isopropyl alcohol, 87.5% in 50 : 1 benzene-isopropyl alcohol, and 68% in cyclohexane. In all cases, the *dl* : *meso* ratio was found to be 1 : 1 within experimental errors.

From the above results, it appears that there are at least two factors, which influence the *dl* : *meso* ratio of photopinacols, namely steric and electronic effects of the substituent. Further examples and mechanistic consideration will be reported in a future paper. After completion of this work, Stocker and his coworkers have reported that *p*-substitution of acetophenone with an electron-donating group results in the predominant formation of the *dl* pinacol over *meso* pinacol,[13] and that, in the photopinacolization of acetophenone, neutral organic solvents do not change appreciately the *dl* : *meso* ratio.[14] These results are essentially same as our results.

Experimental

Materials. The starting materials were commercially available. Their purities were checked by gas chromatography. The solvents, isopropyl alcohol, cyclohexane, and benzene, were dried and distilled before use. *dl*-Hydrobenzoin was prepared from *trans*-stilbene by a known method,[15] mp 123—125°C.

General Procedure for Photopinacolization. The following procedure was used for experiments of Table 1. A solution of 2.00 g of the starting aromatic ketones in 200 m*l* of isopropyl alcohol was irradiated under nitrogen at room temperature using a 100 W high-pressure mercury lamp (Ushio, UM 100) with a water-cooled Pyrex jacket. After the starting material had been consumed (6—9 hr), the mixture was evaporated under reduced pressure, and the residue was chromatographed on a silica gel column. Elution with chloroform yielded a mixture of *dl*- and *meso*-pinacols. The *dl* : *meso* ratio of the mixture was determined by NMR analysis. The results are summarized in Table 1. In the case of isobutyrophenone, 2.00 g of the ketone was dissolved in 350 m*l* of isopropyl alcohol and the solution was irradiated using a 450 W high-pressure mercury lamp (Ushio, UM 450).

For experiments of Table 2, 1.10 g of *p*-methylacetophenone, 1.00 g of *p*-methoxyacetophenone, and 0.55 g of *p*-chloroacetophenone were dissolved in 300 m*l* of isopropyl alcohol, respectively. Each solution was irradiated by a 450 W lamp for 7—8 hr as described above.

For experiments in different solvent systems, the following solution was irradiated by a 450 W lamp: 0.50 g of acetophenone in 350 m*l* of cyclohexane (12 hr) and 2.00 g of acetophenone in 500 m*l* of benzene containing 10 m*l* of isopropyl alcohol (19.5 hr).

Isolation and Characterization of Diastereoisomeric Pinacols. Some of the diastereoisomeric pinacols were separated by fractional recrystallization (*n*-hexane or petroleum ether) from the pinacol mixtures obtained as above. The melting points of pinacols isolated are listed below: *dl*-acetophonone-phinacol, 124—125°C (lit.[10] 122—123°C); *meso*-acetophenonepinacol, 119—120°C (lit.[10] 117—118°C); *dl*-hydrobenzoin, 123—125°C (lit.[16] 120°C); *meso*-hydrobenzoin, 137°C (lit.[17] 137°C); *dl*-propiophenonepinacol, 113—114°C (lit.[10] 113°C); *meso*-propiophenonepinacol, 140—141°C (lit.[10] 138—139°C); *dl*-isobutyrophenonepinacol, 159°C; *meso*-isobutyrophenone-pinacol, 130—133°C. Stereochemistry of the latter two pinacols was assigned by infrared spectroscopy[10]: $\nu_{max}^{CCl_4}$ 3568 (strong), 3612 (medium), 1150, and 1177 cm^{-1} for the *dl*-isomer and 3574 (weak) 3614 (strong), and 1121 cm^{-1} for the *meso*-isomer. Other diastereoisomeric pinacols were not separated.

Azetidines. V. Preparation and Deamination of Azetidinylpropylamines[1]

Teng-Yueh CHEN[2]

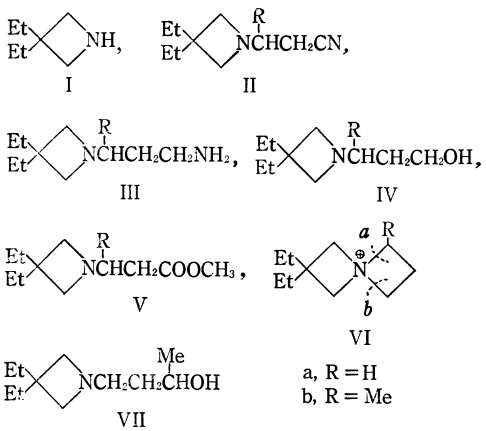
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 16, 1968)

The addition of 3,3-diethylazetidine to acrylonitrile and crotononitrile, followed by reduction, gave the corresponding azetidinylpropylamines. The deamination products of the amines were identical with the alcohols prepared by the addition of diethylazetidine to methyl acrylate and crotonate, followed by reduction with lithium aluminum hydride.

In Part I[3] of this series, it has been reported that azetidine gave addition products readily with active unsaturated compounds. The addition product with acrylonitrile is of particular interest since it may be converted to the corresponding amine, which then gives a cationic intermediate on deamination. It seemed to be of interest to see if the cation so generated can be attacked by the nitrogen atom in the molecule to give the spiro-azetidinium cation. The formation of such a spiro-azetidinium cations as intermediates has been suggested from time to time, and they have actually been isolated in some cases.[4]

A relatively readily accessible 3,3-diethylazetidine[5] (I) was used as the starting meterial, because the NMR spectra of its derivatives can be easily analyzed. The reaction of I with acrylonitrile proceeded readily to give β-(3,3-diethylazetidinyl-1)propionitrile (IIa), which was then reduced with lithium aluminum hydride to the corresponding amine IIIa in a good yield. The alcohol isolated after the deamination of the amine IIIa with nitrous acid was homogeneous, as judged by v.p.c., and its NMR spectrum was completely consistent with the structure IVa. It shows two triplets, at τ 6.47 and 7.43, corrresponding to the two protons on the methylene groups adjacent to the hydroxyl group and to those two adjacent to the nitrogen atom respectively (See Experimental Section). Conclusive evidence in support of the structure IVa could be obtained by the preparation of IVa by the addition of I to methyl acrylate to give Va, followed by its reduction with lithium aluminum hydride to IVa. This product was identical with the deamination product of IIIa.



These results may be explained by considering the direct attack of an hydroxyl anion on the cation, but it does not rigorously exclude an alternative path *via* the spiro-azetidinium intermediate VIa, since it has been known that the less-heavily-substituted azetidine rings are in general more unstable than those which are more heavily substituted.[4] Hence, even if the spiro-azetidinium intermediate VIa may be formed as the intermediate, it will invariably give the alcohol IVa by the cleavage of the unsubstituted ring (at *a* or *b*).

In order to check this possibility, 3-(3,3-diethylazetidinyl-1)butylamine (IIIb) was prepared from I and crotononitrile by the method described above; it was then subjected to the deamination reaction. It was expected that if the spiro intermediate VIb was formed, it would give the product VII, resulting mainly from the cleavage of the ring at *a*.

The structure and purity of the nitrile IIb and the reduction product, amine IIIb, were determined by correct analyses, infrared spectra, and v.p.c.,

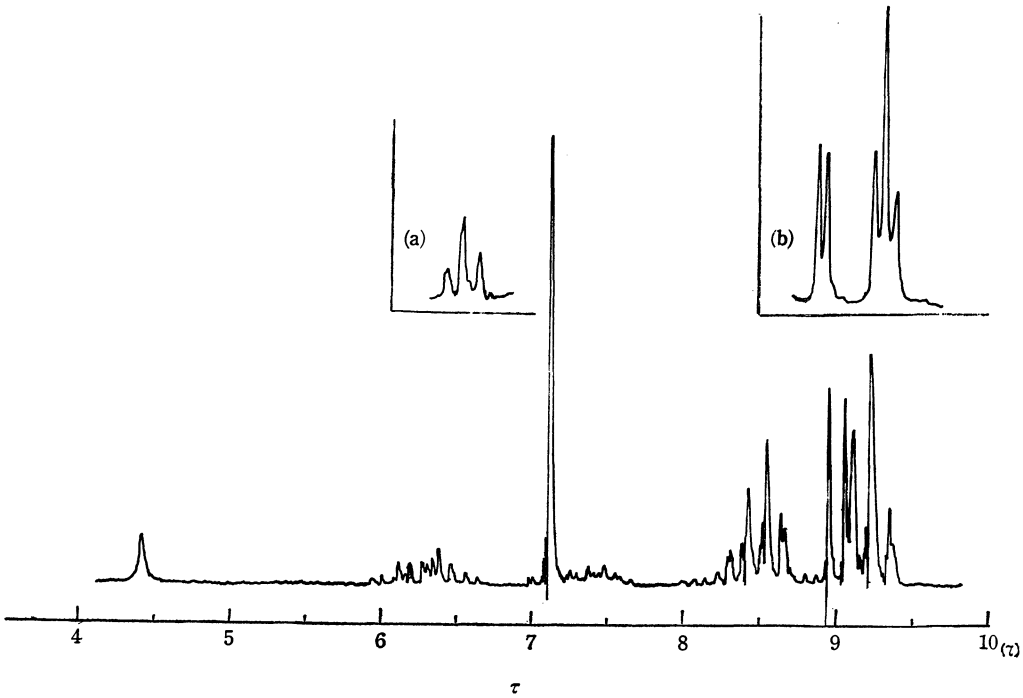

Fig. 1. The NMR spectrum of the deamination product of 3-(3,3-diethylazetidinyl)butylamine in $CDCl_3$. (a) Partial NMR spectrum of the same compound in DMSO; (b) Partial NMR spectrum of the HCl salt of the same compound in D_2O.

and were confirmed by means of a study of the NMR spectra.

The alcohol isolated after the deamination of the amine IIIb was homogeneous, as judged by v.p.c., and gave a correct analysis. The NMR spectrum shown in the figure contains ABX-pattern multiplets at τ 6.98—7.68 and 7.95—8.9 because of the asymmetric carbon adjacent to the ring nitrogen. The resonance peak of the methylene adjacent to the hydroxyl group appears at τ5.8—6.65 as complex multiplets, and the chemical shift of the hydroxyl proton appears at τ 4.41 as a singlet. The remaining part of the NMR spectrum is essentially similar to that of the amine IIIb (See Experimental Section). The integrated areas of the peaks agree well with the structure IVb. The NMR spectrum is not changed by changing the temperature of measurement. The purest sample isolated by v.p.c. also shows the same NMR spectrum as the distilled sample. However, the possibility of the formation of the alcohol VII through the nitrogen spiro intermediate VIb can not be precluded on the basis of the appearance of the NMR spectrum alone.

For purposes of confirmation, the preparation of IVb by the addition of I to methyl crotonate, followed by reduction with lithium aluminum hydride, was attempted. The product so obtained was found to be identical with the deamination product. The use of a dimethyl sulfoxide solvent for the NMR determination did not cause the expected splitting of the hydroxyl group coupled by the adjacent methylene group[6,7]; instead, a broad peak at τ 5.8 was found. It is noteworthy that the NMR spectrum of the methylene group adjacent to the hydroxyl group appears as a simple triplet at τ 6.64 in this solvent (See Fig. 1(a)).

The complex multiplicity for the methylene adjacent to the hydroxyl group in $CDCl_3$ may be explained by considering that the compound forms an intramolecular hydrogen bonding between the oxygen and the ring nitrogen; thus, the chain fixes as a six-membered ring. As a result, the free rotation of the methylene group is limited and the protons are no longer equivalent. In the dimethyl sulfoxide solvent, such hydrogen bonding is broken by forming a stronger hydrogen bonding between the alcohol and the solvent; therefore, the free rotation permits the terminal methylene to split as a normal triplet.

Moreover, the doublet at τ 9.0 and the triplet at 9.22 were found to be separated further enough to permit an accurate integration when the HCl salt of the alcohol was measured in D_2O because of the deshielding effect of the quaternary nitrogen cation; the ratio of the two peak areas was found

6) O. L. Chapman and R. W. King, *J. Am. Chem. Soc.*, **86**, 1256 (1964).
7) J. G. Traynham and G. A. Knesel, *ibid.*, **87**, 4220 (1965).

to be exactly 1 : 2 (See Fig. 1(b)).

From these results, it may reasonably be concluded that the alcohols obtained both from the deamination of the amine IIIb and from the reduction of the ester Vb are identical compounds, IVb, and that the alcohol arises from direct attack of the hydroxyl anion on the cation produced by the deamination rather than through the spiro-azetidinium intermediate.

Experimental[8]

β-(3,3-Diethylazetidinyl-1)propionitrile (IIa). This was prepared, by the general procedure described in Part I,[3] in an almost quantitative yield from 4 g of 3,3-diethylazetidine (I) and 2 g of acrylonitrile. Bp 65—67°C/1.5 mmHg, n_D^{25} 1.4502. IR: 2250 cm^{-1}.

Found: C, 72.35; H, 10.91; N, 16.77%. Calcd for $C_{10}H_{18}N_2$: C, 72.24; H, 10.91; N, 16.85%.

β-(3,3-Diethylazetidinyl-1)butyronitrile (IIb). This was prepared in a 68% yield from I and crotononitrile. Bp 68—75.5°C/1.5 mmHg, n_D^{25} 1.4511. IR: 2250 cm^{-1}. NMR(τ): 7.3—8.2 (3H, multiplet); 7.18 (4H, singlet); 8.48 (4H, quartet); 9.0 (3H, doublet); 9.22 (6H, triplet). V.p.c.: Carbowax 20 M on Diasolid A, 4 mm×150 cm, 147°C, He flow rate 50 ml/min, retention time 15 min; Apiezon Grease L on Diasolid A, 4 mm×150 cm, 147°C, He flow rate 60 ml/min, retention time 8 min.

Found: C, 73.12; H, 10.95; N, 15.43%. Calcd for $C_{11}H_{20}N_2$: C, 73.28; H, 11.18; N, 15.54%.

Picrate of IIb: mp 157—158°C.

Found: C, 49.94; H, 5.81; N, 17.27%. Calcd for $C_{17}H_{23}N_5O_7$: C, 49.87; H, 5.60; N, 17.11%.

Methyl β-(3,3-Diethylazetidinyl-1)propionate (Va). This was prepared in a 91% yield from 3 g of I and 2.3 g of methyl acrylate. Bp 64.5—67.5°C/1.5 mmHg, n_D^{25} 1.4430. IR: 1745 cm^{-1}.

Found: C, 65.99; H, 10.75; N, 7.20%. Calcd for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03%.

Methyl β-(3,3-Diethylazetidinyl-1)butyrate (Vb). This was prepared in a 84% yield from I and methyl crotonate. Bp 67—68°C/1.5 mmHg, n_D^{25} 1.4445. IR; 1745 cm^{-1}. NMR in $CDCl_3$(τ): 6.38 (3H, singlet); 7.12 (4H, singlet); 7.16—8.21 (3H, multiplet); 8.42 (4H, quartet); 9.03 (3H, doublet); 9.24 (6H, triplet). V.p.c.: Silicone Grease DC550, 4 mm×225 cm, 154°C, He flow rate 60 ml/min, retention time 22 min; Apiezon Grease L on Diasolid A, 4 mm×150 cm, 150°C, He flow rate 60 ml/min, retention time 8 min; Carbowax 20 M on Diasolid 4 mm×150 cm, 150°C, He flow rate 60 ml/min, retention time 6 min.

3-(3,3-Diethylazetidinyl-1)propylamine (IIIa). A solution of 6 g of IIa in 20 ml of ether was stirred into a suspension of 1.6 g of lithium aluminum hydride in 80 ml of ether. After two hours, the reaction mixture was hydrolyzed by the addition of dilute aqueous sodium hydroxide. The ether layer was separated, and the residue was washed several times with a total of 200 ml of ether. The combined ether extract was then dried and distilled *in vacuo* to afford 4.5 g (75% yield) of a product boiling at 55—57°C/1.5 mmHg, n_D^{25} 1.4565. IR: 3360, 3290, 1590 cm^{-1}.

Found: C, 70.35; H, 12.33; N, 15.73%. Calcd for $C_{10}H_{22}N_2$: C, 70.53; H, 13.02; N, 16.45%.[9]

Picrate of IIIa: mp 199.5—201.5°C (decomp).

Found: C, 42.39; H, 4.40; N, 17.93%. Calcd for $C_{22}H_{28}N_8O_{14}$ (dipicrate): C, 42.04; H, 4.49; N, 17.83%.

3-(3,3-Diethylazetidinyl-1)butylamine (IIIb). This was similarly prepared, in a 88% yield, from 3.2 g of IIb and 1 g of lithium aluminum hydride. Bp 62—63°C/1.5 mmHg, n_D^{25} 1.4590, IR: 3362, 3295, 1600 cm^{-1}. NMR in $CDCl_3$ (τ): 7.16 (4H, singlet); 7.34 (2H, triplet with each peak split); 7.52—8.0 (1H, multiplet); 8.1—8.85 (2H, multiplet); 8.45 (4H, quartet) (These two peaks are superimposed); 9.11 (3H, doublet); 9.23 (6H, triplet) (These two peaks separate further when the HCl salt of IIIb is measured in D_2O and the ratio of the peak area was found to be exactly 1 : 2). V.p.c.: Carbowax 20 M on Diasolid A 4 mm ×150 cm, 150°C, He flow rate 40 ml/min, retention time 9 min; Apiezon Grease L on Diasolid 4 mm× 225 cm, 150°C, He flow rate 70 ml/min, retention time 10 min.

Found: C, 71.63; H, 12.97; N, 14.99%. Calcd for $C_{11}H_{24}N_2$: C, 71.68; H, 13.13; N, 15.20%.

Picrate of IIIb: mp 238—241°C (decomp).

Found: C, 42.73; H, 4.71; N, 17.16%. Calcd for $C_{23}H_{30}N_8O_{14}$ (dipicrate): C, 42.99; H, 4.70; N, 17.44%.

γ-(3,3-Diethylazetidinyl-1)propanol (IVa). This was prepared in a 88% yield by the reduction of 4.8 g of Va with 1 g of lithium aluminum hydride. Bp 65—69°C/1.5 mmHg, n_D^{25} 1.4575. IR: a broad peak between 3500 and 3100 cm^{-1}. V.p.c.: Carbowax 20 M on Diasolid A 4 mm×225 cm, 150°C, He flow rate 60 ml/min, retention time 31.5 min.

Found: C, 70.00; H, 12.04; N, 8.09%. Calcd for $C_{10}H_{21}NO$: C, 70.12; H, 12.36; N, 8.18%.

γ-(3,3-Diethylazetidinyl-1)butanol (IVb). The reduction of 2.2 g of Vb with 0.7 g of lithium aluminum hydride afforded an alcohol fraction in a 70% yield; bp 85—90°C/1.5 mmHg, n_D^{25} 1.4615. IR: a broad peak between 3450 and 3180 cm^{-1}. NMR in $CDCl_3$ (τ): 4.41 (1H, singlet); 5.8—6.65 (2H, multiplet); 6.98—7.68 (1H, multiplet); 7.95—8.9 (2H, multiplet); 7.12 (4H, singlet); 8.48 (4H, quartet); 9.0 (3H, doublet); 9.22 (6H, triplet) (The last two peaks separate further when the HCl salt of IVb is measured in D_2O and the ratio of the peak area is exactly 1 : 2. Fig. 1 (b)). The multiplet between τ 5.8 and 6.65 appears as a simple triplet when IVb is measured in DMSO (Fig. 1(a)). V.p.c.: Apiezon Grease L on Diasolid A 4 mm× 225 cm, 160°C, He flow rate 60 ml/min, retention time 13 min; Carbowax 20 M on Diasolid A 4 mm×225 cm, 160°C, He flow rate 60 ml/min, retention time 13.4 min;

8) The general conditions for the measurements of physical constants and spectra were the same as described in Part I.[3] The v.p.c. were run on a Shimadzu Type GC-1B Gas Chromatograph.

9) Although the elemental analysis of this amine agreed only poorly with the theoretical, the picrate gave correct analysis and the v.p.c. analysis showed this compound to be homogeneous.

Silicone DC550 4 mm×225 cm, 154°C, He flow rate 60 ml/min, retention time 13 min.

Found: C, 71.42; H, 12.36; N, 7.87%. Calcd for $C_{11}H_{23}NO$: C, 71.30; H, 12.51; N, 7.56%.

Deamination of 3-(3,3-Diethylazetidinyl-1)propylamine (IIIa). A solution of 1.2 g of sodium nitrite in 7 ml of water was slowly stirred into a solution of 2 g of IIIa in 4.4 g of 50% acetic acid below 0°C. After five hours, the evolution of nitrogen was no longer observed; the mixture was made alkaline with potassium carbonate and extracted with ether. The combined extract was dried over sodium sulfate, and the solvent was removed by distillation. The crude product, which consisted of the alcohol IVa and its acetate, was treated with aqueous sodium hydroxide to hydrolize the acetate, and the mixture was extracted with ether, dried, and distilled *in vacuo* to give 1.3 g (65% yield) of IVa boiling at 70—78°C/1.5 mmHg. The IR spectrum and refractive index were identical with those of the product of the reduction of Va. NMR(τ): 5.64(1H, singlet); 6.47 (2H, triplet); 7.11 (4H, singlet, ring methylene); 7.43 (2H, triplet); 8.25—8.70 (2H, multiplet); 8.46 (4H, quartet); 9.19 (6H, triplet). V.p.c.: The results were similar to those described in the reduction of Va.

Found: C, 70.29; H, 12.24; N, 8.37%.

Deamination of 3-(3,3-Diethylazetidinyl-1)butylamine (IIIb). Two grams of IIIb were treated by the method described above except that the acetate byproduct was treated with lithium aluminum hydride instead of sodium hydroxide. The alcohol was obtained in a 62% yield. Bp 89—96°C/1.5 mmHg, n_D^{25} 1.4615, IR: a broad peak between 3450 and 3180 cm^{-1}. The NMR spectrum (See Fig. 1) was identical with that of the product obtained by the reduction of Vb; no change in the NMR spectra was observed whether it was taken at 24, 50, or 100°C. V.p.c.: this product and the mixture with the reduction product of the Vb ester showed the same retention time under the same conditions, as has been explained in the reduction of Vb.

Found: C, 71.15; H, 12.19; N, 7.95%.

The author is indebted to Professor Masaki Ohta and Dr. Hiroshi Kato for invaluable discussion and encouragement, and to Miss Mizuko Yoshida for the measurement of NMR spectra.

The Grignard Reaction of 3-Halotropolone Methyl Ethers[1]

Haruki TSURUTA and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received April 17, 1968)

The Grignard reaction of the methyl ethers (I and III) of 3-bromotropolone and those (II and IV) of 3-chlorotropolone with methylmagnesium iodide or phenylmagnesium bromide were investigated. When I or II was allowed to react with methylmagnesium iodide, 2-methoxyphenyldimethylcarbinol (V) and 2-methoxy-6-isopropylphenol (VI) were obtained. The reaction of I or II with phenylmagnesium bromide afforded 2-phenyl-7-halotropones (XIII or XVII), accompanied by 2-halobenzophenones (XV or XVIII) and the triphenylcarbinol derivative (XIV). The Grignard reaction of III or IV using phenylmagnesium bromide gave 2-phenyl-3-halotropones (XVI or XIX). The mechanistic pathway for the formation of these products was discussed.

The Grignard reaction of troponoid derivatives has attracted much attention as a useful tool for the synthesis of alkyl[2,3] and aryl derivatives.[4-10] In addition, peculiar interest is also attached to the mechanism of the Grignard reactions because they are one of the most complicated nucleophilic reactions of the troponoid system. For instance, unexpected abnormal substitution reactions[6,11-13] and rearrangement reactions leading to benzenoid derivatives,[7,10-13] as well as the expected normal substitutions, usually take place, depending on the variety of substituents presented on the tropone ring, the kind of Grignard reagents,[10,11] and the

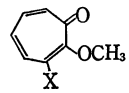
reaction conditions used.[14]

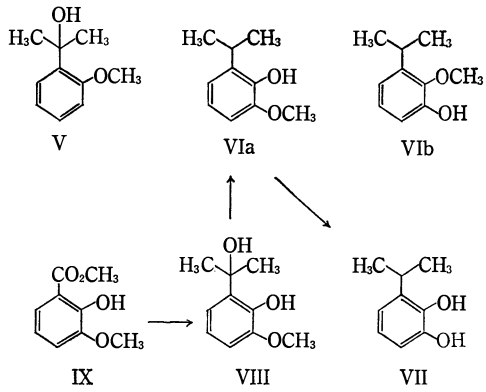
A few papers, however, have been reported on the Grignard reactions of the troponoid with two active functional groups, such as halogen or methoxyl groups.[13,14] To elucidate in more detail the Grignard reaction of such tropone derivatives, the reactions of 3-bromotropolone methyl ethers (I and III) and 3-chlorotropolone methyl ethers (II and IV) with methylmagnesium iodide and phenylmagnesium bromide were reinvestigated. In this series of experiments, an ethereal solution of the Grignard reagent was added to an ethereal solution of I—IV at room temperature in order to avoid the further reaction of tropone derivatives with an excess of the Grignard reagents present.

I X=Br
II X=Cl



III X=Br
IV X=Cl

The reaction of I with 2.5 equivalents of methylmagnesium iodide afforded an oil in a 80% yield; this oil was found by vapor phase chromatographic analysis to be composed of four compounds in a ratio of 1 : 10 : 10 : 1. The oil was, by the use of column chromatography, separated into two main components (V and VI), both of which had the same formula, $C_{10}H_{14}O_2$. Compound (V), with a shorter retention time in the vapor phase chromatography, showed the presence of a hydroxyl group (3571 cm^{-1}) in its IR spectrum, but it was not phenolic. The NMR spectrum of V exhibited signals ascribed to two methyl groups (singlet at τ 8.51, 6H) and a methoxyl group (singlet at τ 6.14, 3H) besides a phenyl group (multiplet at τ 2.97, 4H). These data suggest that V is *o*-methoxyphenyl dimethyl carbinol. The final decision of the structure of V was made by a comparison of its infrared spectrum and vapor phase chromatographic retention time with those of an authentic sample.[15] The ultraviolet spectrum of compound VI exhibited an absorption maximum at 277 mμ, suggesting that VI is a rearranged benzenoid derivative. Compound VI indicated the presence of a hydroxyl group (3524 and 1220 cm^{-1}) and adjacent three hydrogens of substituted benzene (779 and 821 cm^{-1}) in the infrared spectrum. Its NMR spectrum showed signals due to an isopropyl group (doublet at τ 8.79 and multiplet at τ 6.77, J=7 cps, 7H), a methoxyl group (singlet at τ 6.14, 3H), a hydroxyl group (singlet at τ 4.48, 1H), and aromatic protons (ABC-type pattern centered at τ 3.33). The demethylation of VI by treating it with hydrobromic acid in acetic acid afforded an oily product (VII), $C_9H_{12}O_2$, which was soluble in a dilute sodium hydroxide solution and which showed green coloration with ferric chloride, indicating the presence of the phenolic hydroxyl group. The NMR spectrum of VII was almost the same as that of VI, except for the lack of a singlet ascribed to the methoxyl group. On the basis of the above data, two structures VIa and VIb may be proposed for the rearranged product VI, and the structure VII, for the demethylated product. However, compound VI was sparingly soluble in a dilute sodium hydroxide solution and showed no coloration with ferric chloride. These facts suggest that the phenolic hydroxyl group of VI is hindered severely, leading to VIa being preferred to VIb. The structural proof of VI was carried out by the synthesis of VI using proven manner.



V VIa VIb

IX VIII VII

The reaction of methyl 3-methoxysalicilate (IX)[16] with methylmagnesium iodide afforded colorless crystals (VIII), $C_{10}H_{14}O_2$, which showed infrared and NMR spectra consistent with the structure of the expected 2-hydroxyisopropyl-6-methoxyphenol (see Experiment Section). Catalytic hydrogenation of VIII in the presence of a trace of acid resulted in the consumption of one equivalent of hydrogen and produced an oil, which was found to be completely identical with VI by a comparison of their infrared spectra. Thus compound VI was proved to be 6-isopropyl-2-methoxyphenol (VIa).

The Grignard reaction of 2-chloro-7-methoxytropone (II) with methylmagnesium iodide afforded an oil in a good yield; this oil was composed of seven products in a ratio of 20 : 2 : 2 : 2 : 1 : 1 : 1. The major product was found to be VI, and one of the minor products (ratio 2) was found to be V, by a comparison of their retention times in vapor phase chromatography with those of authentic

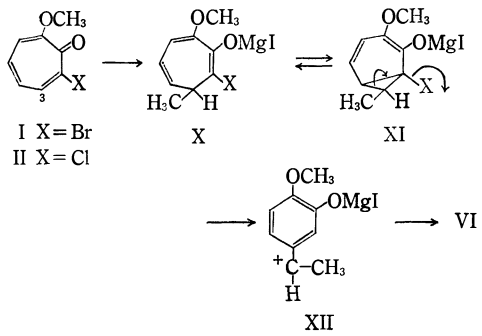
14) For example, when 3,7-dibromotropolone methyl ether was treated with *o*-tolylmagnesium bromide at room temperature, triphenyl carbinol derivatives were obtained, but 2-tolyl-3,7-dibromotropone was obtained as the main product at −30°C.

15) A. Béhal and M. Tiffeneau, *Bull. Soc. Chim. Paris*, [4], **1908**, 315; *Chem. Zentr.*, **1908**, Ib 1625.

16) I. A. Pearl, *J. Org. Chem.*, **12**, 85 (1947).

samples. The remaining products could not be elucidated because they were only minor products.

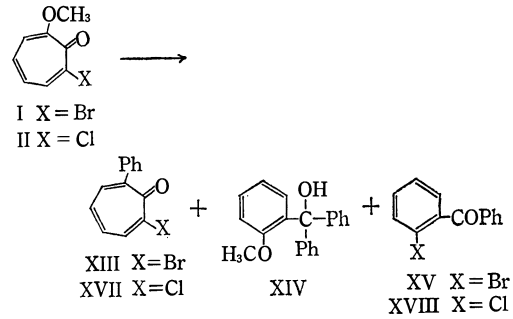
Thus, it may be concluded that the reaction of I and II with methylmagnesium iodide took place in almost the same manner, giving mainly V and VI, although the yields of the products were different. There are precedent examples similar to the formation of the rearranged product V in the Grignard reaction of other troponoids.[7-13] Thus, V apparently results from a nucleophilic attack by methylmagnesium iodide on the carbonyl carbon of the tropone ring, followed by ring contraction with the elimination of the halogen atom and by the further reaction of another molecule of methylmagnesium iodide. On the other hand, the formation of VI is an interesting example of the rearrangement of the troponoid occurring by means of the attack of the nucleophilic reagents,[17] and it can conveniently be interpreted by the following scheme. Methylmagnesium iodide may attack the C_3-position of I or II in the 1,4-addition manner, giving a cycloheptatriene-type intermediate (X) or its valence isomer (XI), which then undergos ring



contraction with the elimination of the halogen atom, as shown by the arrow, to give a benzylium-type intermediate (XII). Another molecule of the reagent then attacks the intermediate (XII), leading to the formation of VI. Otherwise, VI may result from the concerted reaction of the intermediate (X or XI) with methylmagnesium iodide.

The Grignard reaction of another type of methyl ether (III and IV) of 3-halotropolone was investigated using methylmagnesium iodide. In the cases of both III and IV, the products were oils which were unstable and which turned into resineous tars upon standing in air. Although purification was attempted after complete hydrogenation, the reduced product showed the presence of nearly the same amounts of the nine components in the vapor-phase chromatography. This complex result made us abandon any further investigation of the reactions of III and IV.

To find what differences arise when the Grignard reagent is changed, the reactions of compounds I—IV with phenylmagnesium bromide were investigated. A preliminary report[13] has already pointed out that, upon reaction with phenylmagnesium bromide, I afforded mainly triphenylmethyl derivatives, while III gave crystals, mp 115—115.5°C, which were assumed to be bromophenyltropone. The reaction of 2-bromo-7-methoxytropone (I) with 2.2 equivalents of phenylmagnesium bromide afforded three kinds of products: 2-bromo-7-phenyltropone (XIII),[18] mp 80°C, *o*-methoxyphenyldiphenylcarbinol (XIV),[20] mp 126°C, and *o*-bromobenzophenone (XV),[19] an oil, in 20, 10 and 10% yields, respectively. The structures of these products were elucidated by mixed melting point determinations or by comparisons of the infrared spectra with those of authentic samples. The formation of XIV has already been reported,[13] but XIII and XV were isolated first in this experiment. Compound XIII is a product arising from the normal replacement of the methoxyl group at the C_7 position by the phenyl group, while XV is a rearranged product resulting from the attack of the phenyl group on the carbonyl carbon atom of I, followed by ring contraction, with the elimination of the methoxyl group. However, no other tropone derivatives, such as phenyltropolone or its methyl ether,[13] resulting from the substitution by the phenyl group could be isolated.



Similarly, the reaction of 2-methoxy-3-bromotropone (III) with phenylmagnesium bromide afforded 2-phenyl-3-bromotropone (XVI),[21] mp 108°C, and XV in 30 and 5% yields. However, the previously reported product, with a mp of 115—115.5°C, could not be obtained.[13] The product XVI is, of course, a normal substitution product resulting from the replacement of the methoxyl group at the C_2-position by the phenyl group.

III X=Br XVI X=Br XX
IV X=Cl XIX X=Cl

The Grignard reaction of 2-chloro-7-methoxytropone (II) and phenylmagnesium bromide took place in almost the same manner as the reaction of the bromo derivative (I), giving 2-chloro-7-phenyltropone (XVII),[22] mp 74°C, 2,7-diphenyltropone (XX),[23] mp 125°C, and *o*-chlorobenzophenone (XVIII), an oil, in 8, 1.5 and 20% yields, respectively. The formation of XX can be explained by the reaction of XVII with another reagent. The Grignard reaction of 2-methoxy-3-chlorotropone (IV) with phenylmagnesium bromide also afforded 2-phenyl-3-chlorotropone (XIX),[21] mp 132°C, in 60% yield.

From the results obtained in this experiment, the following noticeable facts can be deduced. First, the reaction of methylmagnesium iodide failed to form tropone derivatives, but it did result in the formation of two benzenoid derivatives (V and VI), each with no halogen substituents. This rearrangement indicates that the reagent attacked mainly the carbonyl carbon atom and C_3-position. This may be ascribed to the fact that methylmagnesium iodide reacts as a stronger nucleophile than phenylmagnesium bromide. Second, phenylmagnesium bromide attacked the methoxyl group of the tropone ring, thus leading to the normal substitution products, phenylhalotropones. In addition, this reagent also attacked the carbonyl carbon atom to give rearranged products. It is of interest that the severely-hindered methoxyl group could be replaced by the phenyl group in a considerable yield in the cases of III and IV. Haworth and Tinker[6] have observed abnormal substitution in the reaction of 2-methoxy-6-methyltropone with phenyl magnesium bromide, in which case 2-phenyl-3-methyltropone was formed. It should be noted that no such abnormal substitution took place in the Grignard reactions of III and IV.

Unfortunately, it is impossible to explain reasonably all of the results described above. At any rate, they give some knowledge regarding the nucleophilic reactions of the troponoid systems.

Experimental

Reaction of 2-Bromo-7-Methoxytropone (I) with Methylmagnesium Iodide. Formation of V and VI. A solution of methylmagnesium iodide (7.0 mm) dissolved in ether (16 m*l*) was added, drop by drop over a 15 min period, to a solution of I (600 mg; 2.8 mm) in benzene (5 m*l*) and ether (40 m*l*). After 30 min of stirring, the reaction mixture was decomposed with 2 N sulfuric acid; the organic layer separated here was washed with 1 N potassium hydroxide solution and with water, and was dried over sodium sulfate. The evaporation of the organic layer afforded an yellow oil (455 mg). The vpc analysis (20% silicone grease at 160°C) showed it to contain four components in a relative intensity of 1 : 10 : 10 : 1 in order of retention time. When the oil was subjected to chromatographic separation using a column of neutralized alumina (Brockman II-III, 15 g), one of the main products (V) was eluted by petroleum ether - benzene (from 10 : 1 to 2 : 1). ν_{max}^{neat} 3571, 3460, 1235, 1183, 1029, 755 cm^{-1}. V was proved to be *o*-methoxyphenyldimethylcarbinol by a comparison of its infrared spectrum with that of an authentic sample.[15] Subsequent elution with petroleum ether - benzene (1 : 1) provided VI as a colorless oil; bp 122°C/25 mmHg. λ_{max}^{MeOH} mμ (log ε); 277(3.53). ν_{max}^{neat} 3571, 2967, 1284, 1272, 1220, 1063, 1048, 821, 779, 734 cm^{-1}.

Found: C, 72.22; H, 8.54%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

The aqueous alkaline extract was acidified with 6 N hydrochloric acid and extracted with ether. The evaporation of the ether layer gave a viscous yellow oil (94 mg), which in turn afforded 10 mg of VI when submitted to column chromatography using silicagel as the absorbent and benzene as the eluting solvent. The yield and the ratio of the products were practically unchanged when the amount of methylmagnesium iodide was changed from 2 to 4 equivalents.

Hydrolysis of VI. Preparation of VII. A mixture of VI (250 mg), acetic acid (2 m*l*), and 47% hydrobromic acid (2 m*l*) was refluxed for 1 hr at 140°C under a stream of nitrogen. The reaction mixture was then diluted with a large amount of water and extracted with ether. The ether layer was washed with 2 N sodium carbonate and with water, and dried over sodium sulfate. The subsequent evaporation of the ether furnished a brown oil (200 mg), which was passed through a column of silica gel (using petroleum ether-ether (10 : 2) as the eluent) and distilled to give a colorless, hygroscopic oil (VII), bp 119—121°C/26 mmHg. Compound VII was soluble in a 2 N sodium hydroxide solution, and it gave deep green complex with ferric chloride in ethanol. λ_{max}^{MeOH} mμ(log ε), 278(3.58); ν_{max}^{neat} 3497(broad), 2976, 2882, around 1250, 821, 782, 734 cm^{-1}; NMR in CCl_4 (60 Mc): τ 8.80 (doublet, J=7.0 cps, 6H), 6.88 (septet, J=7.0 cps, 1H), *ca.* 4.5 (very broad peak, 2H. Shift to a lower field in CF_3COOH), 3.38 (9 peaks, 3H).

Found: C, 68.83; H, 7.92%. Calcd for $C_9H_{12}O_2 \cdot 1/4\ H_2O$; C, 68.98; H, 8.04%.

Preparation of VIII. A solution of *o*-vanilline methyl ether (IX) (1.82 g; 10 mm) dissolved in ether (70 m*l*) was added, drop by drop, to a solution of methylmagnesium iodide (50 mm) in ether (70 m*l*) at room temperature. After the reaction mixture had then been refluxed for 30 min, it was decomposed with 20% ammonium chloride and acetic acid (4 m*l*). The organic layer separated here was washed with saturated sodium bicarbonate and with water, and dried over sodium sulfate. The evaporation of the solvent afforded crystals which were recrystallized from methanol or benzene to afford crystals (1.30 g) with a mp of 122—125°C as the first crop and then crystals containing the starting ester (410 mg), mp 54—56°C (*vide infra*).

22) T. Mukai, This Bulletin, **32**, 272 (1959).
23) T. Mukai, *ibid.*, **31**, 852 (1958).

Several recrystallizations of the crystals from methanol gave colorless prisms (VIII), mp 124—125°C. Compound VIII gave greenish-yellow complex with ferric chloride in ethanol. λ_{max}^{MeOH} mμ (log ε), 219 (3.82), 280 (3.40); ν_{max}^{KBr} 3559, 3195(b), 2985, 1290, 1266, 1222, 1056, 952, 892, 788, 746 cm^{-1}; NMR in $CDCl_3$ (60 Mc) τ 8.39 (singlet, 6H), 6.18 (singlet, 3H), 6.13 (singlet, 1H), 3.23 (singlet, 3H), 2.34 (singlet, 1H). Two peaks, those at τ 6.13 and 2.34, disappeared upon the addition of deuterium oxide.

Found: C, 65.96; H, 7.93%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%.

Reduction of VIII. Preparation of VI. A solution of VIII (100 mg; 0.55 mm) dissolved in ethanol (10 m*l*) containing a drop of concentrated hydrochloric acid was hydrogenated in the presence of 5% Pd-C (100 mg). It absorbed 1 equivalent of hydrogen (12.5 m*l*; Calcd 12.3 m*l*) in 2 hr. The filtration of the catalyst, followed by the evaporation of the solvent, afforded a residue. After an ethereal solution of the residue had been washed with water and dried over magnesium sulfate, the ether was removed, thus affording a pale yellow oil (87 mg) whose infrared spectrum was completely identical with that of VI.

Reaction of 2-Chloro-7-Methoxytropone (II) with Methylmagnesium Iodide. To a solution of II (500 mg; 2.9 mm) dissolved in ether (25 m*l*) and benzene (5 m*l*), there was added methylmagnesium iodide (8.7 mm) in ether (25 m*l*) for 15 min. After the reaction mixture had then been stirred for 30 min, it was decomposed with 2 N sulfuric acid and extracted with ether. The combined ether extract was washed with water, dried over sodium sulfate, and evaporated to give a yellowish-brown oil (530 mg), which showed seven peaks in a vapor-phase chromatogram (20% silicone grease at 160°C). The relative ratio of the four main peaks was 1 : 1 : 1 : 10 in order of retention time. The largest peak corresponds to VI, and one of the other three peaks to V.

Reaction of 2-Bromo-7-Methoxytropone (I) with Phenylmagnesium Bromide. *(a)* A solution of phenylmagnesium bromide (7.5 mm) in dry ether (22 m*l*) was added, drop by drop at room temperature, to a solution of I (610 mg; 2.8 mm) dissolved in a mixture of ether (50 m*l*) and benzene (15 m*l*) for 15 min. After 1 hr of stirring, the white precipitate (Grignard complex) formed was filtered off in a nitrogen stream and decomposed by adding ethanol (12 m*l*) and a large amount of ether. The organic layer was washed with 2 N sulfuric acid, 2 N potassium hydroxide, and water and dried over sodium sulfate. The evaporation of the solvent afforded a yellow oil (230 mg), which was then dissolved in benzene and passed through a column of alumina (Brockman O-I, 6 g). The evaporation of an elute with benzene gave a yellow oil (15 mg) whose infrared spectrum was identical with that of authentic *o*-bromobenzophenone.[19] The evaporation of a subsequent elute with benzene afforded yellow crystals (90 mg), which were then recrystallized from ethanol to give 2-bromo-7-phenyltropone (XIII), mp 79—80°C. Identification was made by the mixed-melting-point method and by a comparison of the infrared spectrum with that of an authentic sample.[18] Subsequent elution with ether-ethanol (1 : 25) gave crystals (30 mg), mp 84—89°C, whose infrared spectrum (ν_{max}^{KBr} 3067, 2967, 1582, 1548, 1479, 1350, 1248, 1245, 1199, 1167, 1099, 969 cm^{-1}) did not show the C=C and C=O bands characteristic of tropone derivatives. The structure of the product was not elucidated. On the other hand, the filtrate separated from the Grignard complex was treated in the usual manner to afford a yellow oil (200 mg), which was passed through a column of alumina (Brockman O-I, 5 g). A yellow oil (60 mg) obtained from an elute with benzene was proved to be *o*-bromobenzophenone (XV) contaminated by a small amount of *o*-methoxyphenyldiphenylcarbinol (XIV) by an inspection of its infrared spectrum. Subsequent elution with benzene gave XIII (30 mg), mp 73—75°C. The aqueous potassium hydroxide extract was acidified with 2 N sulfuric acid and extracted with benzene. The evaporation of the benzene extract and the recrystallization of the residue obtained from cyclohexane afforded yellow crystals (100 mg), mp 108°C, which proved to be 3-bromotropolone, a hydrolyzed product of the starting material (I).

(b) A solution of phenylmagnesium bromide (9.0 mm) in ether (30 m*l*) was added, drop by drop over a 30 min period, to a solution of I (660 mg; 3.0 mm) dissolved in a mixture of ether (50 m*l*) and benzene (12 m*l*), and then it was worked up just as in (a). The solid complex was decomposed with 2 N sulfuric acid and extracted with benzene. The benzene layer was washed with 2 N potassium hydroxide and then with water, and dried over sodium sulfate. The evaporation of the benzene afforded a brown oil (280 mg), which was then passed through a column of alumina as in (a). Elution from petroleum ether - benzene (1 : 1) to benzene afforded a mixture of XIV and XV (40 mg). Compound XIII (50 mg), mp 74°C, was obtained from the elute with benzene, and a viscous yellow oil (40 mg), from the elute with ether - methanol (1 : 25). The filtrate separated from the complex also afforded a yellowish-brown oil (470 mg), which was separated by the use of column chromatography using alumina. The evaporation of the elute with petroleum ether-benzene (1 : 1) gave XV (45 mg) and colorless crystals (75 mg), mp 105—110°C. The recrystallization of the latter crystals from ethanol afforded colorless prisms, mp 125—126°C, which were proved to be *o*-methoxyphenyldiphenylcarbinol (XIV) by the mixed melting point method and by a comparison of the infrared spectrum with that of an authentic sample.[20] Compound mp XIII (55 mg), mp 65—70°C, was obtained from the elute with benzene, and a viscous oil (*ca.* 100 mg), from an elute with ether. The aqueous alkaline extract gave no 3-bromotropolone when it was treated as has been described in (a).

Reaction of 2-Methoxy-3-Bromotropone (III) with Phenylmagnesium Bromide. *(a)* A solution of phenylmagnesium bromide (5.0 mm) dissolved in ether (10 m*l*) was added, drop by drop over a 20 min period, to a solution of III (430 mg; 2.0 mm) in ether (30 m*l*). After the mixture had then been stirred for 1.5 hr, the deposited white Grignard complex was filtered out and the solution was decomposed with ethanol (5 m*l*) and extracted with ether. The ether layer was washed with 2 N sulfuric acid, 1 N potassium hydroxide, and water, and dried over sodium sulfate. The evaporation of the ether afforded a viscous reddish-yellow oil, which, upon standing, yielded yellow crystals (85 mg), mp 96—103°C. The residual part was dissolved in petroleum ether-benzene (1 : 1) and passed through a column

of alumina (Brockman III, 13 g). Yellow crystals (75 mg), mp 93—100°C, were obtained by the evaporation of the elute with petroleum ether - benzene (1 : 1) and benzene. The crystals obtained here were combined and recrystallized from ethanol to afford 2-phenyl-3-bromotropone (XVI), mp 108°C. On the other hand, the ethereal filtrate separated from the complex was washed with 2 N sulfuric acid, 2 N potassium hydroxide, and water, and dried over sodium sulfate. The residual oil obtained by the evaporation of the ether was dissolved in petroleum ether - benzene (1 : 1) and passed through a column of alumina to give oily crystals (30 mg); these crystals did not show the bands characteristic of tropone derivatives in the infrared spectrum and could not be elucidated, because of their small amount. An aqueous potassium hydroxide solution was acidified with 2 N sulfuric acid and extracted with benzene; from the extract no clear compound could be obtained except for phenol.

(b) Reaction at −30°C. A solution of phenylmagnesium bromide (6.9 mm) dissolved in ether (20 m*l*) was added, at −30°C (dry ice-acetone) over a 15 min period, to a solution of III (500 mg; 2.3 mm) in ether (40 m*l*). The solution was then stirred at −30°C for an additional 30 min. After the complex formed had been filtered, the complex part and the filtrate were separately treated in the manner described in (a). The complex part gave a brown oil (390 mg), which was then dissolved in petroleum ether - benzene (2 : 1) and passed through a column containing alumina. The evaporation of an elute with benzene-ether (9 : 1) afforded pale yellow crystals (240 mg), mp 57—60°C, while an elute evaporated with ether gave a yellow oil (15 mg). The crystals were found by a mixed melting point determination to be recovered III. An aqueous potassium hydroxide extract was acidified with concentrated hydrochloric acid and extracted with ether. The ether was washed with water and dried over sodium sulfate. The evaporation of the solvent gave an oil with phenolic odor (165 mg); this oil was dissolved in benzene, and hydrogen bromide gas was passed into the solution. The deposited HBr-salt was neutralized with a saturated sodium bicarbonate solution and extracted with benzene. The evaporation of the benzene-extract afforded 3-bromotropolone (60 mg), mp 101—102°C. On the other hand, the filtrate separated from the complex afforded a yellow oil (102 mg); this oil was dissolved in petroleum ether - benzene (1 : 1) and passed through an alumina column. Evaporation of an elute with benzene gave XVI (32 mg), mp 104—106°C, while an elute with ether yielded a yellow oil (15 mg), which was found by an inspection of its infrared spectrum to be identical with the oily product isolated from the complex part.

Reaction of 2-Chloro-7-Methoxytropone (II) with Phenylmagnesium Bromide. A solution of phenylmagnesium bromide (8.7 mm) in ether (27 m*l*) was dropped into a solution of II (500 mg; 2.9 mm) dissolved in a mixture of benzene (5 m*l*) and ether (45 m*l*). After the mixture had been stirred for 1 hr, the precipitated complex was separated and treated in the manner described for the reaction of I with phenylmagnesium bromide. The complex part gave a brown oil (330 mg); this oil was dissolved in petroleum ether-benzene (2 : 1) and passed through a column of alumina (Brockman O-I, 12 g), The evaporation of an elute with petroleum ether - benzene (2 : 1) afforded a colorless oil (25 mg), whose infrared spectrum was very similar to that of *o*-bromobenzophenone and which afforded an oxime (mp 130°C) in a sealed tube.[24] The oil was identified as *o*-chlorobenzophenone (XVIII). Evaporation of a subsequent elute with benzene afforded a yellow oil (160 mg) which was separated using preparative thin-layer chromatography of silica gel developed by benzene; two kinds of crystals (mp 65—69°C, 50 mg; mp 121—121.5°C, 30 mg) were thus obtained. The compound with the lower melting point was recrystallized from cyclohexane to give a sample with a mp of 74—74.5°C; it was proved to be 2-chloro-7-phenyltropone (XVII) by a comparison of its infrared spectrum with that of an authentic sample[22] and by the mixed melting point method. The other crystal was found to be 2,7-diphenyltropone by a comparison of its infrared spectrum with that of an authentic sample.[23] On the other hand, the filtrate part gave a brown oil (430 mg) which was dissolved in petroleum ether - benzene (2 : 1) and separated using a column of alumina (Brockman O-I, 12 g). An elute with petroleum ether - benzene (2 : 1) was evaporated to give *o*-chlorobenzophenone (XVIII) (85 mg). Besides these products, more than ten products (each product in a quantity less than 10 mg) were obtained, but their structures could not be elucidated.

Reaction of 2-Methoxy-3-Chlorotropone (IV) with Phenylmagnesium Bromide. A solution of phenylmagnesium bromide (6.4 mm) in ether (30 m*l*) was added, drop by drop over a 10 min period, to a solution of IV (500 mg; 2.9 mm) dissolved in ether (50 m*l*). After the mixture had been stirred for 1 hr, the complex formed was filtered out and decomposed with 47% borontrifluoride etherate (4 m*l*), and the resulting solution was worked up in the usual manner. The evaporation of the ether gave crystals (400 mg) which were then recrystallized from cyclohexane to afford yellow prisms, mp 127—129°C (142 mg). The filtrate was dissolved in benzene and passed through a column of alumina (Brockman II-III, 12 g). An elute with benzene was evaporated to furnish yellow crystals (161 mg), mp 104—120°C. These crystals were combined and recrystallized from cyclohexane to afford a sample with a mp of 131—132°C; this was proved to be 2-phenyl-3-chlorotropone (XIX) by a comparison of the infrared spectra and by mixed melting point determination with an authentic sample.[21] The filtrate separated from the complex was treated like the above complex; this gave a brown oil (280 mg), which was dissolved in benzene and passed through a column of alumina (Brockman II-III, 12 g). Evaporation of an elute with benzene afforded XIX (82 mg), mp 120—122°C. The total yield of XIX was 385 mg.

The authors are indebted to Professor Tetsuo Nozoe for his encouragement throughout this work. Financial support from the Sankyo Co. is also acknowledged. The infrared spectrometer used in this study was purchased by a grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., to which the authors are grateful.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2495—2503 (1968)

Acetonated Sorbofuranoses and Their Favored Conformations as Determined by Proton Magnetic Resonance Spectroscopy[1)]

Takashi MAEDA, Kazuo TORI, Shiroh SATOH and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received April 23, 1968)

A series of L-sorbofuranose derivatives have been studied by PMR spectroscopy in order to determine their favored conformations from the coupling constants obtained by applying the spin-decoupling techniques and the solvent effects of benzene at 100 MHz. The coupling constants $J_{3,4}$, have disclosed that the furanose ring of methyl 1,3,4,6-tetra-*O*-acetyl-α-L-sorbofuranoside (IIa) in solutions has a conformation close to a C_3-*endo*-C_4-*exo* half-chair, while that of its β-anomer (IVa) has a C_3-*exo*-C_4-*endo* half-chair conformation. Their conformations are unchanged over the temperature range of 32—74°C, but they are affected by the introduction of a 4,6-*O*- or 2,3-*O*-isopropylidene group, either of which locks the furanose ring to a C_3-*exo*-C_4-*endo* half-chair conformation. This effect is thought to play an important role in the exclusive formation of 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (XII) during the acetonation of L-sorbose.

The acetonation of L-sorbose yields 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (XII) exclusively.[2)] Recent investigations of the reaction using acetone dimethyl ketal have shown the isolation of many kinds of acetonated sorbofuranoses as intermediates,[3,4)] whose relative yields are much influenced by the reaction conditions employed; *e. g.*, they were hardly detectable under usual acetonation conditions.[5-7)] The results have suggested that conformational factors play an important role in the reaction; accordingly, we were prompted to study the ring conformations of L-sorbofuranoses by mean of proton magnetic resonance (PMR) spectroscopy, as it has proved to be a powerful tool for this purpose. The present conformational study may provide important information about the differences in the stability of many intermediate L-sorbofuranoses.

Experimental

All the meting points were recorded on a Kofler microstage and have been corrected. The optical rotations were measured in acetone solutions unless otherwise stated, and the concentrations are recorded in percentages. The thin-layer chromatography (TLC) was carried out on a silica-gel plate with acetone-chloroform (1 : 9 v/v) (Solvent A) and with ether-petroleum ether (2 : 1 v/v) (Solvent B). The separated materials were developed with a Seliwanoff reagent[8)] and then heated in an oven. The preparative thin-layer chromatography (PTC) was performed on silica gel with the same solvent systems for detection, and the spots developed with iodine vapor were extracted with acetone. The evaporation of the acetone under reduced pressure yielded the materials.

Isolation of Methyl 4,6-*O*-Isopropylidene-α-L-sorbofuranoside (I). This substance was prepared essentially according to a previously-reported procedure.[4)] L-Sorbose (40 g) was refluxed in acetone dimethyl ketal (100 m*l*)[9)] containing *p*-toluenesulfonic acid (500 mg) for 2 hr. The solution was then neutralized with a slight excess of methanolic sodium methoxide. After the removal of the solvent, the residual syrup was extracted with benzene (200 m*l*); thin-layer chromatograms showed the presence of methyl 1,3 : 4,6-di-*O*-isopropylidene-β-L-sorbofuranoside (III)[4)] and 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (XII)[2)] as the major products, and of 1,2-*O*-isopropylidene-α-L-sorbopyranose,[10)] 2,3-*O*-isopropylidene-α- (XI),[11)] 1,2 : 4,6-di-*O*-isopropylidene-α-(VIII),[3,4)] and -β- (X),[4)] 1,3 : 4,6-di-*O*-isopropylidene-β- (VI),[4)] 1-*O*-α-methoxyisopropyl-2,3 : 4,6-di-*O*- isopropylidene -α-L- sorbofuranose,[4)] and I as the minor products. The benzene solution was then extracted with water (50 m$l \times 3$). The aqueous layer was saturated with sodium chloride

and extracted with chloroform (200 ml×3), and the solvent removed. From the residue (10.6 g), I (2.1 g) was separated by PTC (R_f, 0.1—0.15, Solvent A) as a crystalline syrup. Two successive recrystallizations from ether gave I as colorless needles, mp 108—109°C $[\alpha]_D^{25}$ −65.0 (*c* 1.024). Found: C, 51.47; H, 7.82; OCH_3, 13.19%. Calcd for $C_{10}H_{18}O_6$: C, 51.27; H, 7.75; OCH_3, 13.25%.

Hydrolysis of I. I (1.0 g) was treated with 60% acetic acid (10 ml) at 50°C. After 1.5 hr, the solvent was evaporated to dryness, giving L-sorbose (0.5 g).

Methyl 1,3-Di-*O*-acetyl-4,6-*O*-isopropylidene-α-L-sorbofuranoside (Ia). A mixture of I (100 mg), acetic anhydride (1 ml), and pyridine (1 ml) was kept overnight in a refrigerator, and then evaporated to dryness. The recrystallization of the residue from ether gave Ia as colorless needles (51 mg), mp 104—105°C, $[\alpha]_D^{25}$ −63.9 (*c* 0.549). Found: C, 52.53; H, 6.93%. Calcd for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%.

Methyl 1,3,4,5-Tetra-*O*-acetyl-α-L-sorbofuranoside (IIa). A solution of Ia (310 mg) in 60% acetic acid (2 ml) was allowed to stand at room temperature for 2 hr. The solvent was then removed twice by the addition of an excess of ethanol, and by concentration. Without further purification, the residual syrup was acetylated with acetic anhydride (2 ml) and pyridine (2 ml) in a refrigerator for 4 hr. The evaporation of the solvent gave a syrup (315 mg); this syrup was subsequently purified by PTC with Solvent B. IIa was obtained as a syrup, $[\alpha]_D^{22}$ −66.1 (*c* 0.672). Found: C, 50.03; H, 6.24%; mol wt, 363. Calcd for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12%; mol wt, 362.

Hydrolysis of Methyl 1,3:4,6-di-*O*-isopropylidene-β-L-sorbofuranoside (III). A solution of III[3] (1.42 g) in 60% acetic acid (20 ml) was allowed to stand at room temperature. After 1 hr, the solution was worked-up by a procedure similar to the above. The thin-layer chromatograms of the obtained syrup (1.56 g) showed the presence of methyl 1,3,4,6-tetra-*O*-acetyl-β-L-sorbofuranoside (IVa) and methyl 1,3-*O*-isopropylidene-4,6-di-*O*-acetyl-β-L-sorbofuranoside (Va); IVa (285 mg, R_f 0.38—0.46) and Va (0.60 g, R_f 0.50—0.65) were isolated by PTC with Solvent B. IVa: colorless needles (95 mg), mp 49—50°C (recrystallized from *n*-hexane), $[\alpha]_D^{24}$ +34.7 (*c* 0.773, chloroform). Found: C, 49.53; H, 6.18%. Calcd for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12%. Va: syrup, $[\alpha]_D^{25}$ +34.9 (*c* 0.815). Found: C, 53.02; H, 7.20%. Calcd for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%.

1,2-*O*-Isopropylidene-3,4,6-tri-*O*-acetyl-α-L-sorbofuranose (VIIa). 1,2 : 4,6-Di-*O*-isopropylidene-α-L-sorbofuranose (VIII)[3,4] (60 mg) was treated with 60% acetic acid (1.2 ml) at 40°C for 80 min. The solution was then evaporated to dryness and extracted with chloroform. The removal of the solvent gave a hygroscopic syrup (36.5 mg), which was immediately acetylated with a mixture of acetic anhydride (1 ml) and pyridine (1 ml) at room temperature. After 4 hr, the evaporation of the solution gave VIIa as a syrup, $[\alpha]_D^{23}$ −67.3 (*c* 0.989). Found: C, 52.06; H, 6.68%. Calcd for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40%.

1,2-*O*-Isopropylidene-3,4,6-tri-*O*-acetyl-β-L-sorbofuranose (IXa). IXa (230 mg) was prepared from 1,2 : 4,6-di-isopropylidene-β-L-sorbofuanose (X)[4] (500 mg) in a manner similar to the above. IXa: syrup, $[\alpha]_D^{23}$ +45.6 (*c* 1.128). Found: C, 51.85; H, 6.41%. Calcd for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40%.

PMR Spectra Measurements. The PMR spectra were recorded on a Varian HA-100 spectrometer by using about 5% (w/v) solutions of the samples in chloroform-d ($CDCl_3$) and/or benzene-d_6 (C_6D_6). The spectrometer was operated at 100 MHz in the frequency-swept and internal TMS-locked mode. Spin-decoupling experiments were carried out by using two Hewlett-Packard HP-200ABR audiooscillators. The spectral charts were calibrated by direct readings of the resonance frequencies by means of a Hewlett-Packard HP-5212A electronic counter. The accuracies of the chemical shifts and coupling constants described are within ±0.02 and ±0.2 Hz, respectively.

Results and Discussion

Sorbofuranosides. *a) Preparation.* Methyl 1,3,4,6-tetra-*O*-acetyl-α- (IIa) and -β-L-sorbofuranoside (IVa) could be obtained from methyl 4,6-*O*-isopropylidene-α- (I) and 1,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranoside (III)[4] respectively. The former starting material, I, was newly isolated as a minor product from the acetonation of L-sorbose with acetone dimethyl ketal. The combined data on the elemental analysis and the mild hydrolysis yielding L-sorbose showed that I is a methyl monoacetonated sorboside. I gave a diacetate (Ia) with acetic anhydride and pyridine at an ordinary temperature. The deacetonation of Ia with 60% acetic acid, followed by acetylation, afforded a new glycoside tetraacetate, one which was not identical with the known methyl 1,3,4,5-tetra-*O*-acetyl-α-[12] or -β-L-sorbopyranoside.[12] On the basis of the negative sign of its optical rotation, the tetraacetate was identified as the desired α-furanoside IIa. Consequently, the structure of I should be either methyl 1,3- or 4,6-*O*-isopropylidene-α-L-sorbofuranoside. β-Furanoside IVa was successfully obtained by the deacetonation of III, followed by acetylation. In this case, a partially-deacetonated sorboside (Va) was also isolated as a diacetate; this should be either the diacetate of methyl 1,3- or 4,6-*O*-isopropylidene-β-L-sorbofuranoside. The determination of the I and Va structures, which are 4,6- and 1,3-*O*-isopropylidene derivatives, respectively, leaned heavily on their PMR spectral interpretations, as will be described below.

b) Conformations. The conformations of the sorbofuranosides IIa and IVa were establsihed by means of PMR spectroscopy. In their PMR spectra, singlets due to *O*-acetyl, *O*-methyl, and *O*-isopropylidene protons are easily assigned. Methylene protons at C_1 (H_1, $H_{1'}$) usually appear as an AB-type quartet, and those at C_6 (H_6, $H_{6'}$), as the AB part of an ABX system, being coupled to H_5. The remaining ring protons, H_3, H_4, and H_5, can be expected to appear as a doublet, a quartet,

and a multiplet respectively, according to the first-order approximation. However, H_6, $H_{6'}$, H_5, H_4, and H_3 constitute an ABXYZ spin system, the signals of which can appear as a second-order pattern, depending on the $\Delta\nu_{ij}/J_{ij}$ values, where $\Delta\nu_{ij}$ is the difference in chemicals shifts (in Hz) between two interacting protons. Spin-decoupling experiments and the solvent effects of benzene[13] were mainly used to obtain the chemical shifts and coupling constants by means of the first-order approximation. However, in the present study, second-order patterns were sometimes analyzed by the usual procedure.[14]

The spectrum of IIa in $CDCl_3$ (Fig. 1a) shows a doublet at τ 4.58 due to H_3 and a doublet of doublets at τ 4.50 due to H_4 ($J_{3,4}$=5.8 and $J_{4,5}$=6.0 Hz). Double irradiation at the resonance frequency of a multiplet due to the H_5 centered at τ 5.50 changes the signal due to H_4 into a doublet, from the spacing of which the $J_{3,4}$ value (5.8 Hz) was confirmed (Fig. 1b). Reverse double-irradiation at the center of the resonance frequencies of H_3 and H_4 causes a collapse of the H_5-multiplet into a triplet, but it does not change the AB-type quartet due to H_1

and $H_{1'}$ at τ 5.71 and 5.78 ($J_{1,1'}$=(−)12.2 Hz); the AB-type quartet is further split into doublets by the coupling to H_5 at τ 5.75 (H_6) and 5.88 ($H_{6'}$) ($J_{5,6}$=5.0, $J_{5,6'}$=5.1, and $J_{6,6'}$=(−)11.8 Hz). Similar decoupling experiments on the spectrum in C_6D_6 also support the above assignments. The J values are unchanged by the alteration in the solvent.

The spectrum of IVa in C_6D_6 (Fig. 2a) shows a doublet at τ 4.28 due to H_3 ($J_{3,4}$=2.5 Hz) and a doublet of doublets at τ 4.58 arising from H_4 ($J_{4,5}$=5.8 Hz). Singnals appearing as the AB part of an ABX system at τ 5.68 (H_6) and 5.76 ($H_{6'}$) are due to C_6-methylene protons ($J_{5,6}$=5.3, $J_{5,6'}$=7.2, and $J_{6,6'}$=(−)11.8 Hz). On the double irradiation of H_4, a change in the shape of the H_5-multiplet centered at τ 5.45 was observed (Fig. 2b). The decoupling of H_5 changes the H_4-signal into a doublet. The observation of the spectrum in $CDCl_3$, including spin-decoupling experiments, also supports these assignments.

a) Values in parentheses are those observed in C_6D_6.

Since the only available J values for the conformational studies of ketofuranoses are $J_{3,4}$ and $J_{4,5}$, it seems rather difficult to distinguish rigorously their furanose-ring conformations from possible C_s (envelope) and C_2 (half-chair) conformations. However, it has been suggested that cyclopentane derivatives containing one hetero-atom (*e. g.*, tetrahydrofuran, tetrahydrothiophene, and pyrrolidine) exist in the half-chair conformation (C_2) with the hetero-atom located on the axis of symmetry.[15] In the case of L-sorbofuranoses, there are only two possible C_2-conformations, *i. e.*, a C_3-*endo*-C_4-*exo* (A) and a C_3-*exo*-C_4-*endo* half-chair (B).[16] By using Dreiding models, the

a) Not determinable.

dihedral angles between H_3 and H_4 in the A and B conformers are found to be about 150—160° and 90—110°, respectively, whereas the angles between H_4 and H_5 are measured to be about 10—30° in both the conformers. Therefore, only the $J_{3,4}$ values in the compounds examined can be used for determining their conformations, for the dihedral angles between H_3 and H_4 in the two conformers should lead to obviously different $J_{3,4}$ values according to the Karplus equation, even though it is used in a very qualitative sense.[17] The $J_{3,4}$ values can thus be expected to be in the range of 5—6 Hz for the A conformer and in the range of 0—2.5 Hz for the B conformer.

On the basis of the $J_{3,4}$ values determined above, the conformation of IIa was concluded to be one close to C_3-*endo*-C_4-*exo* half-chair ($J_{3,4}$=5.8 Hz), and that of IVa, one close to C_3-*exo*-C_4-*endo* half-chair ($J_{3,4}$=2.5 Hz). Both conformations can satisfy the operation of the anomeric effect of the OCH_3 group and probably, the reverse anomeric effect of the CH_2OAc group[18] at the C_2 atom. The C_3-*exo*-C_4-*endo* half-chair conformation of the β-D-fructofuranose moiety of sucrose, as determined by neutron diffraction,[19] also supported the above conclusion.

The spectra of IIa and IVa in $CDCl_3$ are unchanged in chemical shifts and coupling constants over the temperature range of 32—74°C. The results show that they exist in fixed conformations in this temperature range.

Conformations of Acetonated Derivatives. The assignments of the spectra of acetonated sorbofuranoses were established in a manner similar to those described above. The data obtained are listed in Tables 1 and 2, while some of the spectra are shown in Figs. 3—6.

At the outset we investigated the conformation of the acetate (VIa) of 1,3:4,6-di-*O*-isopropylidene-β-L-sorbofuranose (VI),[4] which has two 1,3-dioxane rings. An examination of Dreiding models suggests that when the furanose-ring conformation is C_3-*exo*-C_4-*endo* half-chair, the 1,3-*O*- and 4,6-*O*-isopropylidene rings can be formed without severe non-bonded interactions, whereas when the ring has a C_3-*endo*-C_4-*exo* half-chair conformation, there are strong interactions between axial methyl groups at 1,3-dioxanes and either H_3 or H_4. As expected, the characteristic value for $J_{3,4}$ (0.5 Hz) in VIa indicates that its most favored conformation is C_3-*exo*-C_4-*endo* half-chair, where the dihedral angles are slightly contracted compared with the corresponding angles in IVa.

The determination of the spectra of the two monoisopropylidene derivatives containing one 1,3-dioxane ring, Ia and Va, provided important information. The fact that the signals due to H_3 and C_1-methylene protons are remarkably shifted downfield in the spectrum of Ia in comparison with those observed in the spectrum of VIa, confirmed the structure of I to be methyl 4,6-*O*-isopropylidene-α-L-sorbofuranoside. Similar lower-field shifts of the signals due to H_4 and C_6-methylene protons confirmed the structure of Va to be methyl 1,3-*O*-isopropylidene-4,6-di-*O*-acetyl-β-L-sorbofuranoside. The small values for $J_{3,4}$ (1.5 Hz in Ia and 0.6 Hz in Va) indicate that both monoisopropylidene furanoses also exist in a C_3-*exo*-C_4-*endo* half-chair conformation. It should be noted that the conformation of Ia is a C_3-*exo*-C_4-*endo* half-chair. This fact suggests that the restrictive influence of the 4,6-*O*-isopropylidene ring is stronger than that of the anomeric effect in the opposite direction; the 4,6-*O*-isopropylidene ring locks the

furanose-ring to a C_3-*exo*-C_4-*endo* conformation.

This effect is also observed in other 4,6-*O*-isopropylidene-sorbofuranoses: 1,2 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (VIII),[3,4] the acetate of VIII (VIIIa),[4] the acetate (Xa) of 1,2 : 4,6-di-*O*-isopropylidene-β-L-sorbofuranose (X),[4] XII, and the acetate of XII (XIIa).[4] The furanose-ring conformations of such furanoses were found from the small values for $J_{3,4}$ (0.3—1.5 Hz) to be C_3-*exo*-C_4-*endo* half-chairs.

The conformation of the acetate (XIa)[4] of 2,3-*O*-isopropylidene-α-L-sorbofuranose (XI),[11] the unlocked derivative of XII, seems interesting because a C_3-*endo*-C_4-*exo* half-chair conformation seems likely

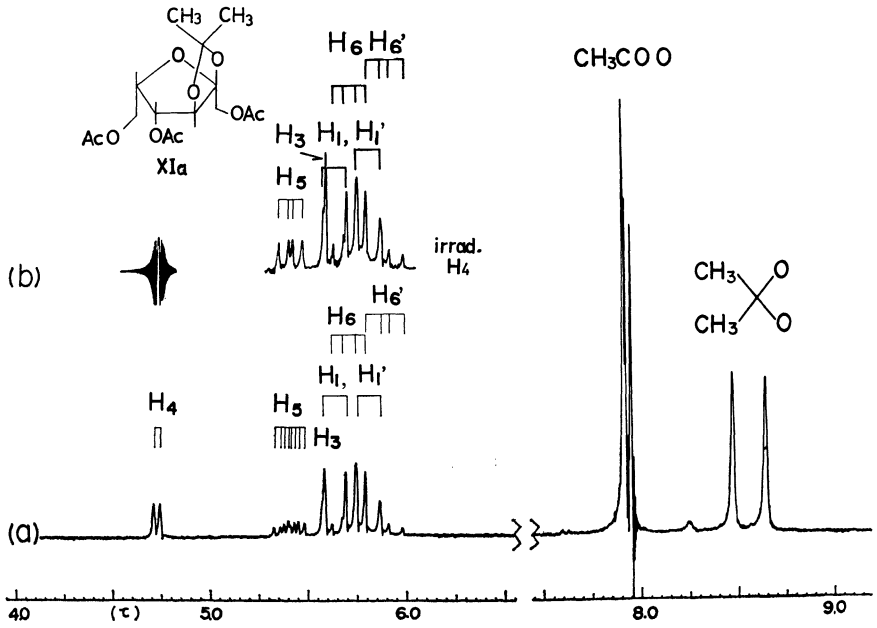

Fig. 5. PMR spectra of XIa in chloroform-d at 100 MHz.
a) Normal spectrum, b) PMDR spectrum

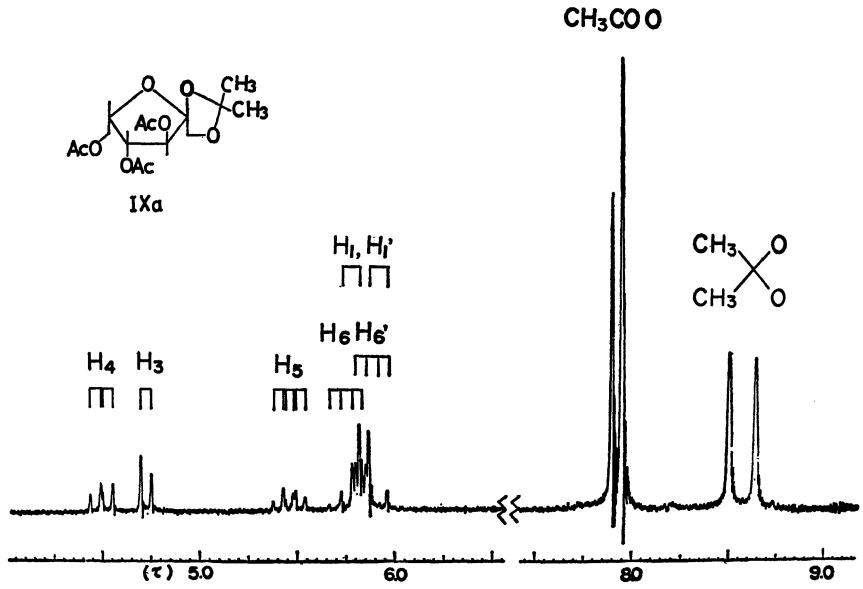

Fig. 6. PMR spectrum of IXa in chloroform-d at 100 MHz.

in view of the non-bonded interaction and the anomeric effect. However, the small $J_{3,4}$ value established that XIa adopts a similar conformation to XII. A similar situation has been found in the conformation of 1,2-*O*-isopropylidene-α-D-glucofuranose derivatives ($J_{2,3}$=0.5 Hz).[20,21] Therefore, the 2,3-*O*-isopropylidene ring was concluded to lock the furanose-ring conformation in the same direction as does the 4,6-*O*-isopropylidene ring.

20) Recently, the value of 0.5 Hz for $J_{2,3}$ in 1,2-*O*-benzylidene-α-D-xylofuranose was reported by R. J. Ferrier and L. R. Hotton, *Carbohyd. Res.*, **5**, 132 (1967).

21) R. J. Abraham, K. A. McLauchlan, L. D. Hall and L. Hough, *Chem. Ind.*, **1962**, 213; R. H. Abraham, L. D. Hall, L. Hough and K. A. McLauchlan, *J. Chem. Soc.*, **1962**, 3699.

In order to compare it with the above results, the effect of a 1,2-*O*-isopropylidene ring was studied in a similar manner by using 1,2-*O*-isopropylidene-3,4,6-tri-*O*-acetyl-α- (VIIa) and β-L-sorbofuranose (IXa), derived from VIII and X, respectively. As can be seen from Table 2, the J values in VIIa are in substantial agreement with those in IIa; the α-anomer VIIa has the same conformation as the α-furanoside IIa. Similarly, the J values provided evidence that the β-anomer IXa has the same conformation as the β-furanoside IVa. Thus, the 1,2-*O*-isopropylidene ring orients the furanose ring in the same direction as does the influence of the anomeric effect of the OCH_3 group.

Under usual reaction conditions, the acetonation of L-sorbose affords XII exclusively.[2] DeJongh and Biemann[6] suggested that the reason why VIII and X were not found might be the steric interference between the 1,3-dioxane and the 1,3-dioxolane. However, such interactions in VIII and X, if they do exist, are believed to be essentially of a degree similar to those in XII, because the VIII and X isolated by us have a similar conformation to XII. Since both the isopropylidene rings of XII lock its furanose ring in the same direction, the furanose ring of XII is thought to be stable. Both the isopropylidene rings of X similarly lock the furanose ring in the same direction. However, the difference in $J_{3,4}$ values between IXa (2.5 Hz) and Xa (0.3 Hz) suggests that there are some other factors governing the small instability in the X molecule. On the other hand, the 1,2-*O*-isopropylidene ring of VIII tends to destabilize to some extent the furanose-ring conformation restricted by the 4,6-*O*-isopropylidene ring. Therefore, a spiro-1,3-dioxolane ring at the 1,2-position of a furanose is considered to be less stable than a fused-1,3-dioxolane ring at the 2,3-position. A similar example has been reported in the acetonation of D-fructose; 2,3 : 4,6-di-*O*-isopropylidene-β-D-fructopyranose is formed as a final product *via* 1,2 : 4,5-di-*O*-isopropylidene-β-D-fructopyranose.[22]

Finally, the fact that VI has a lower stability than XII, can be reasonably explained by the lower stability of the 1,3-*O*-isopropylidene (1,3-dioxane) ring than that of the 2,3-*O*-isopropylidene ring (1,3-dioxolane), according to the Brown-Brewster-Schechter rule.[23]

On the basis of the conformational data presented above, it can be concluded that 2,3-*O*-isopropylidene derivatives are more stable than 1,2- or 1,3-*O*-isopropylidene derivatives in sorbofuranoses locked by the 4,6-*O*-isopropylidene ring. This conclusion accords well with the predominant formation of XII in the acetonation of L-sorbose under strongly acid conditions. The effect of the 4,6-*O*-isopropylidene group must play an important role in the acetonation, a mechanism for which will be proposed in future papers.

The authors wish to express their deep gratitude to Professor Toshihiko Okamoto, University of Tokyo, and Dr. Ken'ichi Takeda, Director of this Laboratory, for their encouragement.
