BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2504—2508 (1968)

Reaction of Alkylbenzene. III.*[1] The Reaction of *sec*-Butylbenzene Induced by Aluminum Chloride*[2]

Kazuyoshi ITOH, Genji YAMADA, Sawako HAMANAKA and Masaya OGAWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka

(Received November 13, 1967)

The products successively obtained from the reaction between *sec*-butylbenzene and aluminum chloride were investigated. Transalkylation was the first observed reaction, followed by the isomerization of the side chain and then by dealkylation. The isomerization of the side chain was observed in the transalkylation products of a high basicity, such as *m*-di- and 1,3,5-tri-substituted compounds, and not in the others. The *n*-butane, resulting from dealkylation, was obtained simultaneously with 2,2di-phenylbutane. On the basis of these results, the reaction mechanism was discussed.

The reaction which alkylbenzenes undergo in the presence of aluminum chloride have been investigated by a number of workers. Transalkylation, dealkylation, and isomerization each having been considered to be a major reaction process in an early step, the reactions have been substantially clarified independently. However, the relations of these three reactions have not yet been reported on except for a few papers.[1] In fact, though, all these reaction are so complicated that the obtained products can not be attributed confidently to any reaction process.

In this investigation, the authors investigated the reaction of *s*-butylbenzene induced by aluminum chloride under comparatively mild conditions, and then detected the successive products obtained in the course of the reaction.

Experimental

Materials. *s*-Butylbenzene, which had been ascertained to be fairly pure by vpc analysis, was synthesized by the Friedel-Crafts alkylation of benzene with *s*-butylalcohol at 40°C. The purity of the products decreased at a higher reaction temperature as a result of the isomerization to isobutylbenzene.

The other hydrocarbons used as the authentic materials in vpc analysis were synthesized by the usual methods, except for *n*-butane and isobutane, which were commercially-available chemicals of the highest grade.

All the *s*-butylated benzenes (*p*-di-, *m*-di-, and 1,3,5-tri-*s*-butylbenzene) were synthesized with *s*-butylbenzene and *s*-butyl chloride in the presence of aluminum chloride at a low temperature. These products were not thoroughly pure, but were used satisfactorily for the identification of the individual alkylbenzene in vpc analysis.

2,2-Diphenylbutane was synthesized by the reaction of 2-phenyl-2-butanol with benzene in the presence of aluminum chloride, using the procedure of Serijan and Wise.[2] 2-Phenyl-2-butanol, bp 83—85°C/8 mmHg, was prepared by Grignard reaction in a 42% yield based on ethyl bromide using ethylmagnesium bromide and acetophenone. The purity was ascertained by vpc analysis to be more than 90%, and also its NMR spectrum was consistent with its formulation. The reaction of 2-phenyl-2-butanol with excess benzene was carried out at 35°C for 3 hr. The products, bp 150—152°C/3 mmHg, was found by vpc analysis to be slightly contaminated with unknown compounds, but the structure was confirmed by NMR and infrared analyses.

2,3-Diphenylbutane was synthesized by the direct reduction of 2,3-diphenylbutane-2,3-diol, which in turn had been prepared by the Grignard reaction of methylmagnesium bromide and benzil. This diol, bp 165—170°C/7 mmHg, was obtained in a 68% yield based on benzil; it was shown by vpc analysis to be more than 95% pure. The reduction of the diol was carried out in a 100 m*l* autoclave, using hydrogen and copper chromium oxide catalyst in methanol, under a pressure of 150 kg/cm² at 150—210°C for 18 hr. The reduction product, bp 112—116°C/2 mmHg, was purified by recrystallization from methanol, and the meso-isomer, mp 125°C, was isolated. (lit.[3] mp 127°C). The NMR spectrum of 2,3-diphenylbutane was consistent with its formulation.

The Reaction of *s*-Butylbenzene. *s*-Butylbenzene (0.3 mol) and aluminum chloride (0.1 mol) were placed in a 100 m*l*, three-necked flask equipped with a stirrer, a thermometer, and a condenser. After stirring, 1 m*l* of the reaction mixture was pippeted out and quenched with cold water. The hydrocarbon layer was then analyzed by vpc. As aluminum chloride was used without any particular treatment, the reaction proceeded

in a heterogeneous system throughout almost all the process.

Analyses of the Products. The products were mainly analyzed by gas chromatography using a Hitachi Model KGL-2 apparatus, fitted with a 90 m, 0.25-mm i. d. capillary column coated with Apiezon grease L or polypropylene glycol (Ucon oil LB-550X) and equipped with a hydrogen-flame ionization detector. Nitrogen was used as the carrier gas, and the operating temperature was varied from 60°C to 190°C according to the boiling points of the samples. Infrared analyses were made with a Shimadzu Model IR-27 apparatus, equipped with a sodium chloride prism. The NMR spectra were taken with a JEOL Model 3H-60 spectrometer at 60 Mc and at room temperature on 10—20% (w/v) solutions of the samples in carbon tetrachloride containing tetramethylsilane as the internal standard.

Results

Identification of Products. A gas chromatogram of all the products obtained from the reaction at 70°C for 3 hr is shown in Fig. 1. In Fig. 1, A, B, and C were identified as *n*-butane, benzene, and *s*-butylbenzene, respectively. The X-group

consisted of dibutylbenzenes, of which X_1 and X_4 were identified as *m*- and *p*-di-*s*-butylbenzene with each authentic compound by the internal standard method. It was also considered that X_2 and X_3 consisted of *m*-*s*-butylisobutylbenzene and *m*-diisobutylbenzene, respectively; this consideration was based on the retention volume in vpc and some other evidence, such as the conversion rate shown in Fig. 2 and the existence of an isobutyl group in the following results. The peaks of the Y-group consisted of tributylbenzenes, of which three butyl groups were either *s*- or isobutyl ones substituted at 1,3,5-positions. Y_1 was identified as 1,3,5-tri-*s*-butylbenzene by vpc with an authentic material. Y_2, Y_3, and Y_4 could not be isolated individually. However, the three components were obtained from the reaction products by fractionation; the purity was 94.5% for the three components. The fraction was ascertained to be a mixture of 1,3,5-tri-substituted benzenes on the basis of its infrared spectrum pattern in the 5—6μ region, and was also ascertained to have both the *s*-butyl- and the isobutyl-group in the side chain on the basis of its NMR spectrum,[4] which was as follows; $\tau=9.3$ (triplet, γ-methyl-H), $\tau=8.7$ (doublet, β-methyl-H), and $\tau=8.3$—8.5 (multiplet, α-methylene-H) for the *s*-butyl group, and $\tau=9.0$ (doublet, γ-methyl-H) and $\tau=7.4$ (doublet, β-methylene-H) for the isobutyl group. On the basis of this evidence, Y_2, Y_3, and Y_4 were considered to be 1,3,5-di-*s*-butyl-isobutylbenzene, 1,3,5-*s*-butyldiisobutylbenzene, and 1,3,5-triisobutylbenzene respectively. The Z-group consisted of the major products, Z_3 and Z_4, identified as 2,2-diphenylbutane and 2,3-diphenylbutane, respectively by vpc with authentic substances. Some other diphenylalkanes, such as 2-methyl-1,2-diphenylpropane and 2-methyl-1,1-diphenylpropane, were not identified in the peaks of the Z-group.

Reaction at 20°C. The yields of the products obtained at 20°C are plotted against the reaction time in Fig. 2.

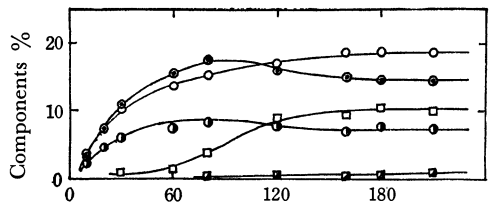

Fig. 2. Reaction product at 20°C.

◉ *m*-di-*s*-Buφ (X_1)
◑ *p*-di-*s*-Buφ (X_4)
□ 1,3,5-tri-*s*-Buφ (Y_1)
◪ 1,3,5-di-*s*-Bu-*i*-Buφ (Y_2) or 1,3,5-di-*i*-Bu-*s*-Buφ (Y_3)

In the gas chromatogram of the reaction products at 20°C, neither the peak of butane nor that of any Z-component was detected during the first 3 hr. After 260 min, however, the peaks of butane and Z_3 were detected slightly. In the early steps of the reaction, X_1 and X_4 were obtained predominantly; Y_1 was detected 30 min later. The molar ratio of X_1 to X_4 was estimated to be about 2; it kept the same value throughout the reaction course. X_2 and Y_2, each with one isobutyl group,

were detected 120 min later, but X_3, Y_3, and Y_4, each having two or three isobutyl groups, were not produced under the present conditions. In the reaction at 20°C, an apparent equilibrium appeared after 180 min.

Reaction at 40°C and 50°C. The X- and Y-groups of reaction products at 40°C and 50°C are shown in Fig. 3 and 4, respectively.

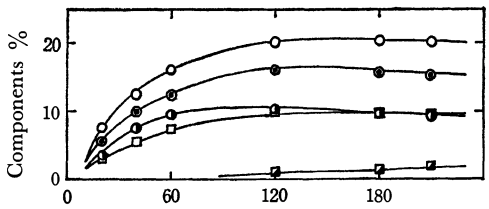

Fig. 3. Reaction products at 40°C.
- ○ Benzene
- ⊙ *m*-di-*s*-Buφ (X_1)
- ◑ *p*-di-*s*-Buφ (X_4)
- □ 1,3,5-tri-*s*-Buφ (Y_1)
- ◪ 1,3,5-di-*s*-Bu-*i*-Buφ (Y_2) or 1,3,5-di-*i*-Bu-*s*-Buφ (Y_3)

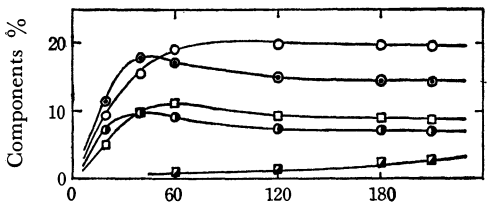

Fig. 4. Reaction products at 50°C.

- □ 1,3,5-tri-*s*-Buφ (Y_1)
- ◪ 1,3,5-di-*s*-Bu-*i*-Buφ or 1,3,5-di-*i*-Bu-*s*-Buφ (Y_2, Y_3)

These profiles are roughly the same as that of the reaction at 20°C. An apparent equilibrium could be observed after 120 min at 40°C and after 60 min at 50°C. In the latter case, the increase in X_2 and Y_2 were accelerated considerably; then X_1, X_4, and Y_1 decreased.

Reaction at 70°C. The reaction products at 70°C are shown in Fig. 5, with the X-group in the upper figure and the Y-group in the lower one; the Z-group can not be shown precisely because of the difficulty of quantitative determination. In the reaction at 70°C, X_1, X_4, Y_1, X_2, and Y_2 were obtained during the first 10 min, while the A and Z-groups were obtained 20 min later. After these initial reactions, X_3, Y_3, and Y_4, which each possessed two or more isobutyl groups, increased slowly and attained an apparent equilibrium after 180 min.

Discussion

In the reaction of *s*-butylbenzene induced by aluminum chloride at 20°C, transalkylation was the reaction observed first, followed by the isomerization of the side chain and dealkylation. The above reaction sequence was also ascertained at higher temperatures.

Transalkylation > Isomerization > Dealkylation

However, the rate of transalkylation under the present conditions is slower than that of the usual Friedel-Crafts alkylation, in which a reaction equilibrium is completed rapidly, sometimes within a second.[5] The present slower reaction rate may be considered to result in part from the heterogeneous reaction and in part from the structure of the attacking species.

The alkylcarbonium ion dissociated from the present reactants may be different from that liberated from alkyl halide in the Friedel-Crafts alkylation. The former ion may be unstable and not so free from the rest; hence, it has a large steric require ment. Consequently, *o*-di-, 1,2,4,-tri-, and 1,2,3-tri-substituted isomers were not obtained among the present reaction products. On the other hand, in alkylation with alkyl halide, the alkylcarbonium ion may be substantially free from paired anions

5) H. C. Brown and H. Jungh, *J. Am. Chem. Soc.*, **78**, 2182 (1956).

and can be substituted at the ortho position of alkylbenzene. For the meta-para isomer ratio of alkylbenzene, it has been generally said that the ratio is around 2 : 1, except for the case of a particular alkylbenzene such as di-*t*-butylbenzene.[6] Our present results support the above isomer ratio.

The isomerization of the side chain in which the *s*-butyl group is isomerized to the isobutyl group, which occurred after transalkylation, proceeded to a certain extent. Interestingly, the isomerized products were detected in *m*-di- and 1,3,5-trisubstituted compounds only and not in mono- and *p*-di-substituted ones. In one previous article,[7] the basicities of methylbenzenes were reported to be in the order of the following sequence:

Mesitylene > *m*-Xylene > *p*-Xylene > Toluene

Thus, the present results may be considered to be connected with the basicities of the alkylbenzene concerned. From the above consideration, the relation between transalkylation and isomerization may be represented as in Fig. 6:

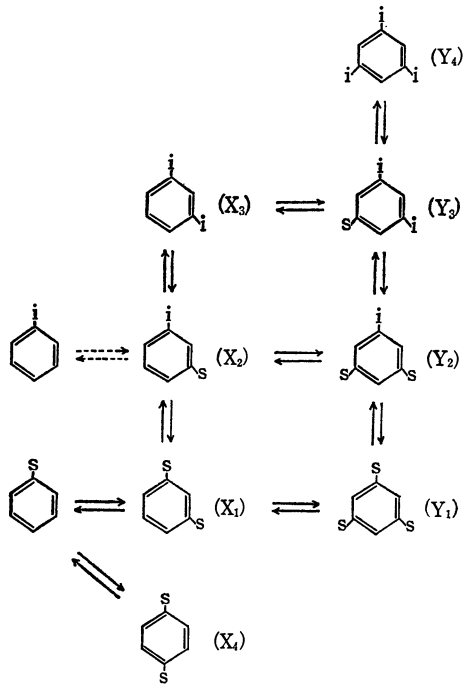

Fig. 6. Route of isomer formation.
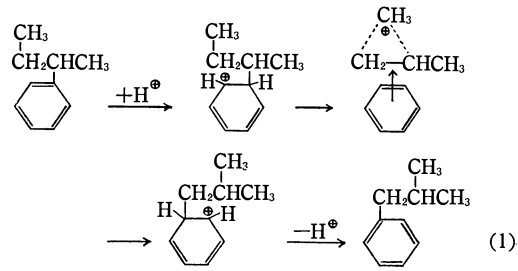
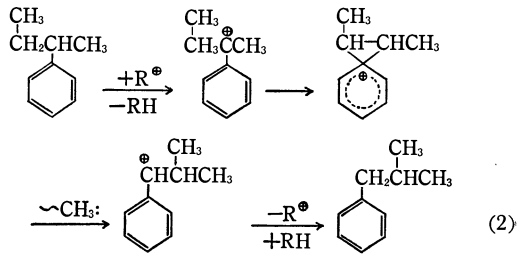
s : *s*-butyl group
i : isobutyl group

For the isomerization of such an alkyl group, two mechanisms have been postulated; in one alkylbenzene is coordinated to the proton, isomerized through the methyl-bridged cation,[8] as is shown in Eq. (1), while in the other one the isomerization is initiated by hydride-ion abstraction from the alkyl group and then proceeds *via* a carbonium-ion mechanism, as is shown in Eq. (2).[9]



(1)

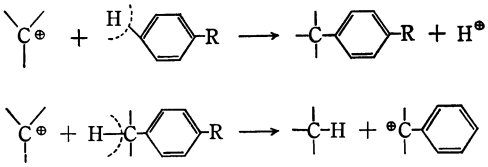


(2)

Our present results support the former mechanism. The latter mechanism can not illustrate how the isomerization in an early step proceeds without the formation of any butane or diphenylbutanes on one side or how *m*-di- and tri-*s*-butylbenzene is isomerized considerably faster than are mono- and *p*-di-*s*-butylbenzene.

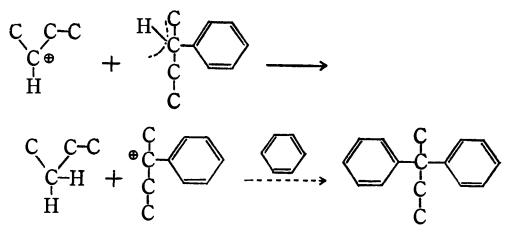
Dealkylation was the last reaction in the reaction process. The dealkylation products were detected after 260 min at 20°C and after 20 min at 70°C. In the reaction at 20°C, *n*-butane was obtained simultaneously with 2,2-diphenylbutane (Z_3), while in the reaction at 70°C an unknown compound (Z_2) was first obtained, and then 2,2-diphenylbutane (Z_3), 2,3-diphenylbutane (Z_4) and other Z compounds were obtained succesively.

In a previous paper,[10] we postulated that, in secondary or tertiary alkylbenzene, the dealkylation competed with transalkylation through alkylcarbonium ions.



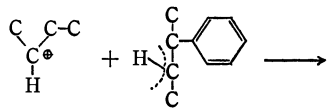
On the basis of the above results and discussion, the following reaction scheme may be suggested for the formation of 2,2-diphenylbutane:

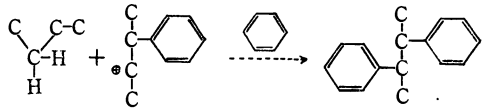
7) S. U. Choi and H. C. Brown, *J. Am. Chem. Soc.*, **88**, 903 (1966).
8) R. M. Roberts, Y. W. Han, C. H. Schimid and D. A. Davis, *ibid.*, **81**, 640 (1959).
9) R. M. Roberts and Y. W. Han, *ibid.*, **85**, 1168 (1963).
10) K. Itoh, R. Kurashige, S. Hamanaka and M. Ogawa, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **70**, 918 (1967).



(Z_3)

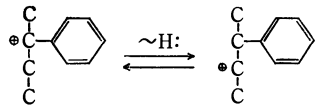
Similarly, the formation of 2,3-diphenylbutane may be described as follows:





(Z_4)

In the latter case, another route could also be adopted:



The same discussion may hold for other diphenylbutanes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2508—2514 (1968)

Syntheses of Citral and Citronellal by the Dehydrogenation of Geraniol Using Cu, Cu-Zn, Cu-Cr, and ZnO Catalysts

Kunio KOGAMI and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Tokyo

(Received January 10, 1968)

The present paper describes the study of the syntheses of citral and citronellal by the catalytic dehydrogenation of geraniol with Cu, Cu-Zn, Cu-Cr, and ZnO catalysts under an atmospheric or a reduced pressure in vapor and liquid-phase systems. The following results were obtained: (1) the vapor-phase dehydrogenation with the Cu-Zn catalyst, conducted at a reduced pressure, was found to be most favorable, (2) when using this catalyst at 230°C, the addition of citronellal as a hydrogen acceptor prior to the dehydrogenation increased the yield of the citral from 50% to 85% (at 185°C, the highest yield of citronellal, 70%, was obtained). The composition of the product was analyzed by means of G. L. C. The reaction scheme under various conditions is also described briefly.

Citral is a raw material for the increasingly-important ionone and Vitamine A, whereas citronellal is a raw material for menthol and hydroxy-citronellal. Geraniol, a basic material for both citral and citronellal, has recently become available by means of an entirely synthetic process, instead of having to be derived from the limited natural-product source. Therefore, the present authors, in the course of their study of the synthesizing of important monoterpene compounds used for perfumery, have attempted to make citral and citronellal by the catalytic dehydrogenation of geraniol.

Concerning the present studies, only a few papers and patents have been published. Bouveault reported the quantitative conversion of geraniol into citral in the catalytic dehydrogenation of geraniol over copper at 200°C;[1] Treibs observed the formation of citronellal in the distillation of geraniol at an atmospheric pressure in the presence of copper[2]; a Russian patent described the vapor-phase dehydrogenation of geraniol at 220—230°C at a pressure of 100 mmHg, using the Cu-Cr catalyst (9% citral and 65% citronellal were thus produced)[3]; a Japanese patent[4] claimed the use of methyl ethyl ketone or butyraldehyde as a hydrogen acceptor in the liquid-phase catalyzed dehydrogenation, using a Raney-Cu, Cu-Zn or Cu-Cr catalysts, thus showing the possibility of

4) T. Hashimoto and T. Shibuya, Japanese Pat. 15007 (1965).

producing citral in an improved yield of 42—43%.

The present paper will describe the syntheses of citral and citronellal by the catalyzed dehydrogenation of geraniol with a Cu, Cu-Zn, Cu-Cr, or ZnO catalyst under varying experimental conditions.

Experimental

Materials. The geraniol was purchased from the ABRAC Company, Ltd.; bp 99°C/5 mmHg, n_D^{30} 1.4740, d_{30}^{30} 0.8863. Its purity was confirmed by G.L.C. to be 98.0%. The citronellal was obtained from citronellal oil (from Formosa) by a previously described[5] method; bp 72—73°C/6 mmHg, d_{30}^{30} 0.8594, n_D^{30} 1.4492, $[\alpha]_D^{25}$ +10.8°C.

Catalysts Used. Cu-Cr-, Cu-Zn-, and ZnO-type catalysts were supplied by the Nikki Chem. Company, Ltd. Various forms of the catalyst suitable for each dehydrogenation system were used; (a), (b) and (c) were tableted catalysts 6 mm in dia. and 6 mm high, 6 mm in dia. and 3 mm high, and 3 mm in dia. and 3 mm high respectively, while (d) was a powder. The copper catalyst was used in the form of a copperwire gauze (50 mesh), as has been described by Bouvealt.[1]

Apparatus Used for Dehydrogenation. The general structure of the apparatus used for the dehydrogenation of geraniol is presented in Fig. 1. Geraniol vapor was supplied through an evaporator (2) into a reactor (3), and the reaction product was collected in a receiver (6). The catalysts were packed in the constant-temperature region of the reaction tube, as shown in Fig. 1. The evaporator (2) was heated to approximately 205°C, using Bay oil as the heating medium.

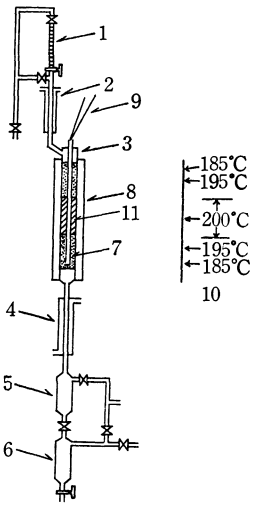

Fig. 1. Catalytic dehydrogenation apparatus.
1 Feed burette, 2 Evaporator, 3 Reactor (dia. 28 mm, length 400 mm), 4 Condenser, 5 Product receiver, 6 Product receiver, 7 Glass Rassig ring, 8 Electric-furnace, 9 Thermocouple, 10 Temperature gradient in reactor, 11 Catalyst

A portion of the glass tube leading from the evaporator to the reaction tube was also heated to 205°C by using a ribbon heater, thus keeping the temperature gradient along the reaction tube constant.

Vapor-phase Dehydrogenation Procedure at Atmospheric Pressure. After the packed catalyst had been activated with hydrogen, the reaction tube was allowed to cool to room temperature in a hydrogen stream; then the hydrogen was turned off, and nitrogen was introduced for 30 min at a rate of 500 m*l*/min. Then geraniol vapor was passed through the reacting zone of the reaction tube (kept at 200°C) under various conditions. After the reaction, the product collected in the receiver was taken with 100 m*l* of ether. The ether solution was neutralized with an aqueous solution of sodium carbonate, washed with water, dehydrated with sodium sulfate, and submitted to the evaporation of ether on a water bath to give an oily product (97—98% by weight for geraniol supplied). The composition of the product was determined by G.L.C. In the case of using a hydrogen acceptor, ethylene[6] (obtained commercially; purity 99.2%), rather than nitrogen, was passed through at a rate of 300 m*l*/min after the activation of the catalyst with hydrogen; acetone[7] or quinoline[8], mixed in geraniol, was passed through the reacting zone under a nitrogen flow.

Vapor-phase Dehydrogenation Procedure at Reduced Pressure. After the treatment of the catalyst with hydrogen and subsequent displacement with nitrogen much as has been described above, the gas inlet-cock was closed. Then the reaction system was evacuated to a certain reduced pressure, and the geraniol vapor was supplied to the reaction tube at a given L.S.V. The product was treated much as in the dehydrogenation at an atmospheric pressure. When the copper catalyst was used, the dehydrogenation was carried out under the same conditions as have been described by Bouveault.[1]

Liquid-phase Dehydrogenation Procedure at Atmospheric Pressure. A given amount of a catalyst was placed in a 300-m*l* four-necked flask equipped with an air-tight stirrer, a hydrogen inlet-tube, a Stark-Dean trap (fitted with a hydrogen outlet-tube to remove any water formed during the activation of the catalyst with hydrogen), and a thermocouple in contact with the catalyst placed at the bottom of the flask. The catalyst was heated at 200°C in an oil bath, and hydrogen was passed through the catalyst at a rate of 200 m*l*/min for 30 min; then the flask was displaced with nitrogen for 30 min at the rate of 200 m*l*/min. Thereupon, geraniol (50 g, 0.32 m) was put in the flask, and it was kept at 200°C with stirring under a nitrogen flow. The progress of the reaction was followed by G.L.C., by which the end point of the reaction was determined.

Identification and Analysis of the Product by G.L.C. In the selective dehydrogenation of geraniol to form citral or citronellal, the isolation of each product was attempted by means of a precise fractional distillation technique. The gas chromatograph Kotaki

GU-21, with a thermal conductivity detector, was used, and the quantitative analysis of the composition of the product was based on the normalization method. The experimental conditions were as follows; a stainless column (dia., 3 mm; length, 2 m) packed with Dia Base A, 60—80 mesh, which was coated with 10% of Silicone DC 550, 15% of PEG 1500 and 5% of PEG 4000; helium inlet pressure, 0.78 kg/cm^2, flow rate of 30 m*l*/min; column temperature, 180°C; split temperature, 250°C; sensivity, 8 mv; chart speed, 0.5 cm/min. The standard materials used in this analysis were prepared according to the methods described in the literature or were obtained by rectifying commercially-available chemicals. Each of these materials was found to give a single peak in its respective gas chromatogram; myrcene (from the ABRAC Company, Ltd.) bp 39°C/4 mmHg, n_D^{30} 1.4690, d_{30}^{30} 0.7883; limonene (from orange oil purchased from the Polak Frutal Company, Ltd.), bp 40°C/4 mmHg, n_D^{30} 1.4717, d_{30}^{30} 0.8407; ocimene was prepared from linalool according to the Naves method,[9] bp 42°C/4 mmHg, n_D^{30} 1.4861, d_{30}^{30} 0.8655; citronellol (from the ABRAC Company, Ltd.), bp 100°C/6 mmHg, n_D^{30} 1.4539; d_{30}^{30} 0.8572; citronellal was the same as that described in the preceding section; citral was prepared by the known method[5] from lemon-grass oil; bp 102—104°C/6 mmHg, n_D^{30} 1.4881, d_{30}^{30} 0.8962; geraniol (from the ABRAC Company, Ltd.), bp 100—102°C/6 mmHg, n_D^{30} 1.4492, d_{30}^{30} 0.8594; isopulegol (from the Tokyo Kasei Ind. Compnay, Ltd.), a mixture of 20% neoisopulegol, 75% isopulegol and 5% iso-isopulegol (by G. L. C.), bp 74—78°C/6 mmHg, n_D^{30} 1.4679; d_{30}^{30} 0.9074.

Activity of the Catalyst Used. As may be seen in Table 1, the Cu-Zn catalyst gave a similar product distribution when 15 m*l* of geraniol was supplied for the 2nd and 3rd runs under the experimental conditions indicated. The results of the first run were considered to be inadequate and unreliable. On the basis of the above results and on the technical information supplied by the Nikki Chem. Company, Ltd., the data collected on the second run of 15 m*l* of geraniol was considered pertinent to this experiment (see Table 1).

Results and Discussion

Product Distribution in the Catalyzed Vapor-phase Dehydrogenation of Geraniol at Atmospheric Pressure. The results obtained are summarized in Tables 2 and 3.

a) Comparison of the Catalysts. In the dehydrogenation of geraniol over copper at 200°C or 250°C (see Table 2), contrary to Bouveault's finding indicating the quantitative transformation of geraniol into citral, a very small conversion of geraniol and, in addition, the formation of various by-products, such as terpene hydrocarbons as well as citral and citronellal, was observed; citral had a yield of only 20%. With the ZnO catalyst system, at a reaction temperature between 190°C and 230°C,

TABLE 1. CHANGES IN PRODUCT DISTRIBUTION *vs.* SUPPLYING TIME OF GERANIOL (15 m*l*) USING Cu-Zn CATALYST

Composition of products by G. L. C. (wt%)

Time of supplying	Terpene hydrocarbons	Citronellal	Isopulegol	Citronellol	Citral	Geraniol
1	17.0	30.9	12.9	6.5	32.7	
2	14.7	38.0	15.5	4.9	26.9	
3	14.4	39.2	14.4	6.1	25.8	

* The experimental condition was identical to that indicated in the first run of Table 3.

TABLE 2. VAPOR-PHASE DEHYDROGENATION OF GERANIOL USING THE REDUCED COPPER AT A REDUCED PRESSURE

Run	Reaction temperature	Reduced pressure mmHg	Geraniol flow rate	Composition of products by G.L.C. (wt%)			
				Terpene hydrocarbon	Citronellal	Citral	Geraniol
1	200°C	4— 5	65 m*l*/hr	7.3	7.2	20.6	64.9
2	200°C	41—45	65 m*l*/hr	11.7	10.1	17.1	61.1
3	230°C	3— 4	65 m*l*/hr	4.7	5.9	16.3	73.1
4	230°C	4	21 m*l*/hr	4.9	7.1	21.2	66.8
5	250°C	4	65 m*l*/hr	4.5	7.5	18.7	69.3

* Form of the catalyst used was of (d). ** Yield for geraniol reacted.

no dehydrogenation reaction occurred; the terpene hydrocarbon was given in a yield of 25%, while 75% of unreacted geraniol was recovered, indicative of the inefficient catalysis of the ZnO catalyst in the dehydrogenation.

The Cu-Zn and Cu-Cr catalyst systems gave similar product distributions: citral (26%; 23% (theor.)), citronellal (37%; 38%), isopulegol (15%; 12%), terpene hydrocarbons (14%; 20%), including myrcene, limonene and ocimene, and citronellol (4%; 6%). Although the difference in the product distribution was not remarkable between them, the Cu-Zn catalyst was found to be preferable to the Cu-Cr catalyst because of its smaller formation of terpene hydrocarbons and its increased yield of citral (see Table 3).

From the above results, it was concluded that the copper or ZnO system showed less catalytic activity in the dehydrogenation of geraniol, and that, with regard to the Cu-Zn and Cu-Cr catalyst systems, various products were formed, the major product being citronellal, not citral.

b) The Effect of the Hydrogen Acceptor when Added to Reaction System. In the catalyzed dehydrogenation of geraniol, as will be described later, an equilibrium can be assumed between citral, citronellal, and geraniol in the reacting zone; it is reasonable to prevent the hydrogenating of citral into citronellal, and thereby increase the yield of citral, by using a hydrogen acceptor. Therefore, a hydrogen acceptor, such as ethylene, acetone or quinoline, was used. The results obtained are indicated in the columns for runs 4, 5 and 6 in Table 3. When acetone (1 : 1 by volume for geraniol) was used in the Cu-Zn catalyst system, the conversion of geraniol decreased and the formation of terpene hydrocarbons increased. When ethylene was used,[6] however, a decrease of a few percentage points in terpene hydrocarbons and an increase in citronellal from 37.8% (without hydrogen acceptor) to 45.2% were observed. When quinoline was used,[8] decreased yields of citral and citronellal were observed.

c) Contribution to the Hydrogenation of Hydrogen Molecules Adsorbed on the Catalyst. The product distributions already shown for various systems suggest the possibility that citronellal and citronellol may be formed by the hydrogenation of citral and citronellal, respectively. Therefore, the contribution of the adsorbed hydrogen molecules to the hydrogenation was examined in the system of citral and a catalysts pretreated with hydrogen in a stream of nitrogen or of nitrogen mixed with hydrogen (10 : 1 by volume). As may be seen in columns 7 and 8 in Table 3, citronellol was not formed, while a comparable amount of citronellal was formed. The fact that no geraniol was made in this system can be explained; in view of the polarographic redox potentials corresponding to the reduction of citral into citronellal or geraniol,[10] it is reasonable to consider that geraniol, formed first, is then dehydrogenated into citronellal.

Liquid-phase Dehydrogenation. Liquid-phase dehydrogenation as well as vapor-phase dehydrogenation is a conveniently available method for preparing citral from geraniol, not only at the laboratory but also at the plant.

When using a Cu-Zn or Cu-Cr catalyst (2% by weight of the geraniol used the dehydrogenation should be carried out in a flask under gentle boiling between 200°C and 205°C; below this temperature, for example, at 180°C, the reaction is slow and inefficient.

In a comparison of the catalytic activity of Cu-Zn and Cu-Cr catalysts, it is evident that the latter catalyst gives terpene hydrocarbons and decreased yields of both citronellal and isopulegol (see runs 2 and 3 in Table 4).

To increase the yield of citral by preventing the conversion of the once-formed citral into citronellal, either citronellal or cyclohexanone, as a hydrogen acceptor, was added at the beginning of the reaction. From the results shown in Table 4 for the system with a Cu-Zn catalyst, when citronellal or cyclohexanone was used, the reaction resulted in a relatively increased yield of citral for the converted geraniol, the yield being even larger than that obtained in the vapor-phase dehydrogenation at an atmospheric pressure. Moreover, a larger amount of isopulegol was formed in the

addition of citronellal than in that of cyclohexanone, indicating the transformation of citronellal into isopulegol.

Vapor-phase Dehydrogenation of Geraniol at Reduced Pressure. The fact that citral, as is shown in runs 7 and 8 in Table 3, gave various products, such as terpene hydrocarbons, citronellal and isopulegol, suggests the possibility of increasing the yield of citral by quickly removing the citral formed from the reacting zone. Therefore, the vapor phase dehydrogenation of geraniol was attempted with the Cu-Zn catalyst system at a reduced pressure and at a given L. S. V.; the results are summarized in Table 5.

a) The Effect of the Reaction Temperature at a Given L. S. V. The effect of the reaction temperature on the product distribution was examined between 175°C and 230°C and at a L. S. V. of 0.7, using a reaction tube packed with 10 m*l* of the catalyst (b), the results obtained are presented in Table 5. At the lower temperature, 175°C, citral decreased and citronellal increased markedly, reaching a yield of 48.4% after 7 m*l* of geraniol had been passed through in 1 hr, with the raising of the reaction temperature, the amount of citral increased, while that of citronellal, in turn, gradually decreased. In addition, an appreciably decreased conversion of geraniol was found in this system in comparison with that in dehydrogenation under an atmospheric pressure.

b) The Effect of L. S. V. The product distribution when 30 m*l* of the Cu-Zn catalyst (b) was used was examined at the most favorable reaction temperature, 230°C, with various contact times, the results obtained are summarized in Table 6. In this system, it will be noted that in comparison with the systems previously studied, there was an appreciably improved yield of citral (50%), a smaller amount of by-products, and no citronellol. In this case, the geraniol conversion *versus* the contact time shows a linear relation, as is shown in Fig. 2. This indicates, by extrapolation, that the complete conversion of geraniol would be approximately 60% under the present conditions.

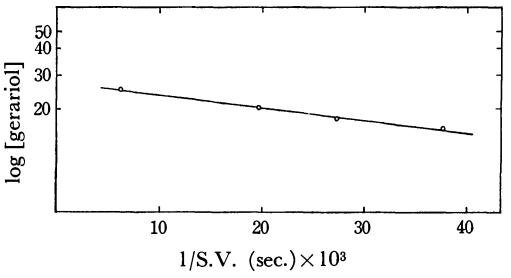

Fig. 2. Linear relationship between logarithm of geraniol molar concentration and contact time at 230°C in catalytic dehydrogenation using Cu-Zn catalyst.

c) The Effect of the Addition of Citronellal. In the results of the detailed observation of the product distribution shown in Table 7, it will be noted that the relation of the amounts of citral and citronellal is inverse, in that one increases as the other decreases, suggesting the possibility of these existing an equilibrium relation between citral, citronellal, and geraniol in this reacting zone, or of their changing the catalytic activity, controlling the equilibrium between them.

On the basis of the above reasoning, for the purpose of increasing the yield of citral, the present authors conducted the dehydrogenation at a reduced pressure by using mixtures of geraniol and citronellal in various ratios as the starting material.

As may be seen in the results shown in Table 8, the expected increased conversion of geraniol into citral was observed, while a maximum yield of citral of 84.0% was obtained.

The Preparation of Citronellal. It has already been demonstrated that the yield of citronellal was greatly affected by both the contact time and the reaction temperature. Therefore, in order to increase the yield of citronellal, the dehydrogenation of geraniol was carried out with a longer reaction tube and at a lower reaction temperature; the reaction temperature was 185°C, the reduced pressure 15 to 16 mmHg, and a reaction tube 28 mm in dia., 400 mm long, and packed with 35 m*l* of the catalyst (c) over a distance of 70 mm, was used. The results obtained are shown in Table 7. There was an excellent yield of citronellal (70%), but no formation of either isopulegol or citronellol.

A Proposal for the Catalyzed Dehydrogenation of Geraniol. On the basis of the dehydrogenation products already revealed, the following reaction process may be considered. Citronellal is formed by the hydrogenation of citral, not with hydrogen adsorbed on the catalyst, but with hydrogen participating in the dehydrogenation of geraniol. Such an example has been shown by Constable[11] in the catalyzed dehydrogenation of allyl alcohol,[12] where propionaldehyde, not acrolein, is formed as a result of hydrogen migration from the alcohol to the carbon-carbon double bond of the possibly-made acrolein.

Regarding citral, judging from its increased yield upon the addition of citronellal, there is the possibility of an equilibrium relation between citral, citronellal, and geraniol in the reacting zone, or a poisoning of the catalyst, thereby resulting in a selectivity in the making of citral.

NOTES

Asymmetric Hydrogenation with Modified Raney Nickel.*1 X. Effect of the β-Substituent of α-Amino Acid as a Modifying Reagent

Yoshiharu IZUMI, Kazuyoshi MATSUNAGA, Susumu TATSUMI and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received August 7, 1967)

The asymmetric activities of Raney nickel catalysts modified with optically active α-amino acids in the hydrogenation of methyl acetoacetate have previously been reported on by the present authors.[1]

From the relation between the asymmetric activities of catalysts and the structures of the modifying reagents upon modification with α-amino acids at 0°C and at their isoelectric points, it was concluded that a catalyst modified with an α-amino acid, such as L-valine or L-isoleucine, which is replaced at the β-position by a methyl group shows a higher asymmetric activity than a catalyst modified with an α-amino acid which does not have a β-alkyl substituent.

The present paper will report on the asymmetric activities of catalysts modified with L-3-ethylnorvaline,*2 its acetyl derivative, and L-alloisoleucine. The specific rotation of the materials used in the present paper are as follows:

TABLE 1. OPTICAL ROTATIONS OF MODIFYING REAGENTS

Modifying reagent	Optical rotation, $[\alpha]_D^{20}$
L-3-Ethylnorvaline	+38° (*c* 1, 6 N HCl)
N-Acetyl-L-3-ethylnorvaline	+17° (*c* 2, EtOH)

The asymmetric activity of the catalyst was studied in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, as has been described in previous papers.[2,3] In Fig. 1 the asymmetric activity of the catalyst modified with L-3-ethylnorvaline at the isoelectric point is shown as a function of the modifying temperature.

In Fig. 2 the asymmetric activities of the catalyst modified with *N*-acetyl-L-3-ethylnorvaline at 0°C and 100°C are shown. In comparison with L-3-ethylnorvaline, a decrease in the asymmetric activity of the catalyst was also found, as was also

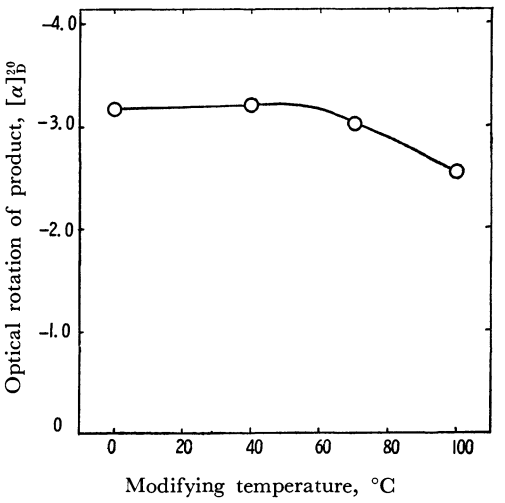

Fig. 1. Effect of modifying temperature modified with L-3-ethylnorvaline at the isoelectric point.

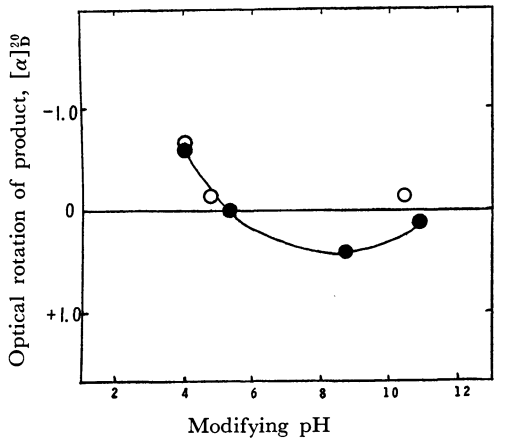

Fig. 2. Effect of modifying pH on the modifications at 0°C and 100°C with *N*-acetyl-L-3-ethylnorvaline.

observed in the catalyst modified with the acetyl derivative of L-glutamic acid. On modification at 0°C, an inversion of the direction of asymmetric activity was observed at pH 5.0.

The asymmetric activities of catalysts modified with L-valine and L-aminobutyric acid at 0°C and at the isoelectric points, which were presented in the previous paper,[2] and those with L-3-ethylnorvaline and L-alloisoleucine in the present work are compared in Fig. 3. It may be seen from the figure that alloisoleucine gave a higher asymmetric a ctivity to the catalyst than did isoleucine, the diastereomer of alloisoleucine. As the threo configuration is more effective for the asymmetric activity of the catalyst than the erythro form, the (R)-configuration of the β-carbon in an L-α-amino acid increases the activity of the catalyst. The asymmetric activity of a catalyst modified with alloisoleucine is less than that of one modified with 3-ethylnorvaline, and the asymmetric activity caused by valine is intermediate between the asymmetric activities caused by *threo* and *erythro*-isoleucine.

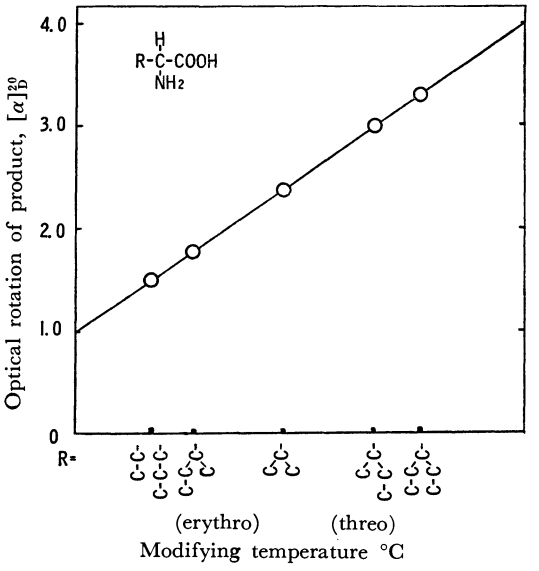

Fig. 3. Comparison of symmetric activities modified at 0°C and the isoelectric point.

As the catalysts modified with aminobutyric acid and with norvaline had the same asymmetric activity, the δ-carbon of *n*-alkyl amino acid (I) is not effective in increasing the asymmetric activity. Unlike as with *n*-alkyl amino acids, a catalyst modified with 3-ethylnorvaline has a higher asymmetric activity than one modified with valine. These facts show that the δ'-carbon of the β-side chain of β-alkyl amino acids (II) is effective in increasing the asymmetric activity.

$$\overset{\delta}{CH_3}-\overset{\gamma}{CH_2}-\overset{\beta}{CH_2}-\overset{\alpha}{CH}-COOH \quad (I)$$
$$\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad NH_2$$

$$\begin{matrix}\overset{\delta}{CH_3}-\overset{\gamma}{CH_2} \\ \overset{\delta'}{CH_3}-\overset{\gamma'}{CH_2}\end{matrix}\!\!>\overset{\beta}{CH}-\overset{\alpha}{CH}-COOH \quad (II)$$
$$\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad NH_2$$

The asymmetric activity caused by *threo*-isoleucine greatly differs from that caused by *erythro*-isoleucine. This shows that the relative conformations of the β-carbon to the α-carbon in the two isoleucines are different when they are adsorbed on the catalyst. Let us name the adsorbed conformations of an β-alkyl amino acid similar to those of the *threo*- and *erythro*-isoleucines threo- and erythro-type conformations, respectively. Valine and 3-ethylnorvaline allow at least these two types of adsorbed conformations on the catalyst, even though valine and 3-ethylnorvaline have the β-carbon, which is replaced symmetrically. Consequently, as a result of the difference between the stabilities of threo- and erythro-type conformations formed by valine or 3-ethylnorvaline, the threo- and erythro-types of the asymmetric centers may be supposed to exist in different proportions. According to the disproportion in the existent ratios of the two asymmetric centers, the observed asymmetric activity of the catalyst caused by valine or 3-ethylnorvaline can hardly be expected to show the arithmetical mean of each asymmetric activity of the two types of centers.

Because of the above reason, it is difficult to discuss the exact role of β-alkyl-substituents in the asymmetric activity of β-alkyl amino acids. A study of the asymmetric activity of a catalyst modified with 3-methylnorvaline, which may give further information on this point, will, however, be reported in this Bulletin in the near future.

The authors would like to express their thanks to M. Sc. Tadashi Tanabe for his help. This research was supported by Kawaken Fine Chemicals Co., Ltd., Tokyo.

The Reaction of Nitrosobenzene with Benzenesulfonylhydrazide in the Presence of a Base

Suketaka Ito

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano

(Received December 29, 1967)

The action of benzenediazonium salt upon *p*-toluenesulfonamide in the presence of an excess of sodium hydroxide,[1] and the reaction of benzenesulfonyl azide with phenylmagnesium bromide, followed by the hydrolysis[2] or pyrolysis[3] of the product, lead to the formation of phenyl azide.

These reactions involve the formation of the salt of 1-*p*-toluenesulfonyl- or 1-benzenesulfonyl-3-phenyltriazene and the elimination of the salt of arenesulfinic acid from the triazene salt.

$$C_6H_5N_2Cl + C_7H_7SO_2NH_2 \xrightarrow[NaOH]{}$$

$$C_6H_5\text{-}N{=}N\text{-}N(Na)\text{-}SO_2C_7H_7 \longrightarrow$$

$$C_6H_5N_3 + C_7H_7SO_2Na$$

$$C_6H_5MgBr + C_6H_5SO_2N_3 \longrightarrow$$

$$C_6H_5\text{-}N{=}N\text{-}N(MgBr)\text{-}SO_2C_6H_5 \longrightarrow$$

$$C_6H_5N_3 + C_6H_6SO_2MgBr$$

Accordingly, one can expect to obtain phenyl azide from the disubstituted triazene or its salt, prepared in a different reaction sequence. Since the triazene may be regarded as the condensation product of nitrosobenzene with arenesulfonylhydrazide, it is conceivable that the triazene can be prepared by the condensation of these compounds. However, the nitroso compounds do not give triazenes by reaction with hydrazines,[4,5] although the condensation reactions of aromatic nitroso compounds with such compounds as aniline,[6] hydroxylamine,[7] *N*-phenylhydroxylamine,[8] and benzyl cyanide[9] are similar to those of carbonyl compounds. In the present study, the reaction of nitrosobenzene with benzenesulfonylhydrazide was attempted for the purpose of obtaining phenyl azide.

Results and Discussion

When a mixture of nitrosobenzene and benzenesulfonylhydrazide was refluxed in absolute ethanol for thirty minutes, and then for one more hour with sodium ethoxide, azoxybenzene was obtained; the additional formation of a trace amount (0.5%) of phenyl azide was confirmed by infrared spectroscopy. The addition of a small amount of sulfuric acid in the first run of the reaction did not promote the yield of phenyl azide.

When powdered nitrosobenzene was added to an aqueous solution of equimolar amounts of benzenesulfonylhydrazide and potassium or sodium hydroxide at 45—50°C with vigorous stirring, there separated a yellowish-brown oil, and nitrogen evolved. The yield of phenyl azide increased as much as 1.4%. Along with unaltered benzenesulfonylhydrazide (24%), azoxybenzene (45%) and benzenesulfinic acid (47%) were also obtained.

The results can be outlined by the following scheme:

$$C_6H_5SO_2NHNH_2$$

$$\downarrow\uparrow OH^-$$

$$C_6H_5SO_2N^-NH_2 \rightleftarrows C_6H_5SO_2NHN^-H$$

$$\downarrow 2C_6H_5NO \qquad \downarrow C_6H_5NO$$

$$C_6H_5SO_2^- + C_6H_5N{=}NC_6H_5 \quad C_6H_5SO_2^- + C_6H_5N_3$$

$$\downarrow O$$

$$+ N_2$$

When benzenesulfonylhydrazide was treated in an aqueous alkaline solution at 60°C for an hour, no remarkable reaction occurred and no benzenesulfinic acid was obtained.[10] Furthermore, the amount of benzenesulfinic acid obtained in the reaction of benzenesulfonylhydrazide with nitrosobenzene was, as has been shown above, almost equimolar to that of azoxybenzene. Phenyl azide did not react with nitrosobenzene at 70°C, even

10) It has been reported that benzenesulfonylhydrazide decomposes by heating with water, alcohol or alkali for a long time.[11]

in the presence of alkali. Therefore, it can be concluded that the following reactions did not occur to any significant extent:

$$C_6H_5SO_2NHNH_2 \xrightarrow[OH^-]{} C_6H_5SO_2^- + H\text{-}N{=}N\text{-}H$$

$$C_6H_5NO + H\text{-}N{=}N\text{-}H \longrightarrow C_6H_5NHOH + N_2$$

$$C_6H_5N_3 + C_6H_5NO \longrightarrow C_6H_5N{=}NC_6H_5 \quad (\downarrow O)$$

The reaction in the presence of sodium ethoxide was also carried out in ethanol or *N*,*N*-dimethylformamide, but phenyl azide was thus obtained in lower yields than in water.

In conclusion, by benzenesulfonylhydrazide, nitrosobenzene is mainly subjected to reduction to *N*-phenylhydroxylamine, which then easily condenses with nitrosobenzene to give azoxybenzene.

Experimental

The reaction in an aqueous alkaline medium was described alone. The melting points are uncorrected.

Materials. Benzenesulfonylhydrazide was prepared by the action of benzenesulfonyl chloride (1 mol) upon an aqueous solution of hydrazine hydrate (1 mol) and sodium hydroxide (1 mol); yield: 76%, and recrystallized from ethanol, mp 104.5—105.5°C (lit.[11] mp 104—106°C).

The Reaction of Nitrosobenzene with Benzenesulfonylhydrazide in aqueous Potassium Hydroxide Solution. Into a vigorously-stirred solution of 17.2 g (0.1 mol) of benzenesulfonylhydrazide and 6.5 g (*ca.* 0.1 mol) of potassium hydroxide in 150 m*l* of water, there were added, over a period of 30 min, 10.7 g (0.1 mol) of powdered nitrosobenzene at 45—50°C. The reaction mixture was kept at this temperature for an additional 30 min with stirring. During the reaction, a yellowish-brown oil separated, the aqueous solution turned light brown, and nitrogen evolved.

The reaction mixture was then cooled, extracted with ether, and separated to an ether layer (A) and an aqueous layer (B). By removing the solvent from the ether solution (A), which was then washed with water and dried over anhydrous sodium sulfate, a brown liquid (A′) (9.4 g) was obtained. This liquid became solid on cooling. The infrared spectrum of the brown residue showed the absorption of azoxybenzene, accompanied with a small amount of phenyl azide. By using the absorption of the azido group at 2170 cm^{-1}, the yield of phenyl azide was determined to be 1.4%, calculated from nitrosobenzene.

The ether extract (A′) (9.3 g) was then chromatographed on 30 g of silica gel and eluted with *n*-hexane and *n*-hexane - ether; phenyl azide was concentrated in the first 20-m*l* fraction of the elution. After the solvent had been removed from the fraction, the yellow residue was fractionally distilled *in vacuo* (5 mmHg). Pure pale yellow phenyl azide was collected in a trap at −70°C (131 mg, n_D^{23}: 1.5587); its infrared spectrum was identical with that of an authentic sample. Found: N, 34.90%. Calcd for $C_6H_5N_3$: N, 35.27%.

By the reaction of dimethyl acetylenedicarboxylate with the phenyl azide, the 1-phenyl-1,2,3-triazole-4,5-dicarboxylic acid dimethyl ester, mp 127.5—128.5°C (lit.[12] mp 127—128°C), was obtained. (Found: C, 55.10; H, 4.63; N, 16.02%.)

The chromatographic treatment of the ether extract (A′) also gave 9.0 g (45%, calculated from nitrosobenzene) of yellow crystals of azoxybenzene, which melted at 35.5—36.5°C (lit.[13] mp 35.5—36.5°C) after recrystallization from methanol. (Found: C, 72.60; H, 5.43; N, 14.42%). Its infrared spectrum was identical with that of an authentic sample.

The water layer (B), when combined with washings of the ether extract of the reaction mixture, was acidified with concentrated hydrochloric acid and fully extracted with ether. From the acidic aqueous layer, by neutralization, 4.1 g (24%) of unaltered benzenesulfonylhydrazide were recovered. The ether layer was extracted with a solution of sodium hydroxide and water; the alkaline solution was then acidified with hydrochloric acid and saturated with sodium chloride. The resulting precipitate was filtered and dried to give 6.7 g (47%, calculated from benzenesulfonylhydrazide) of benzenesulfinic acid, the infrared spectrum of which was identical with that of an authentic sample.

By the treatment of the sodium salt of the sulfinic acid with benzyl chloride in ethanol, phenyl benzyl sulfone was obtained; it melted at 147.0—148.0°C (lit.[14] mp 148°C) after recrystallization from ethanol. (Found: C, 67.09; H, 5.29%.) No depression of the melting point was observed on admixture with an authentic sample.

Preparation of Polyamines by the Michael Reaction

Kentaro YODA and Takao TODA

Katata Research Institute, Toyobo Co., Ltd., Honkatata-cho, Otsu

(Received January 22, 1968)

It is well known concerning the Michael reaction that amines containing an active hydrogen add to activated double bonds.[1-3] A few attempts have been made to prepare polyamines by the Michael reaction.[4,5]

In this paper the Michael reaction was used in the preparation of polyamines from piperazine and several divinyl compounds.

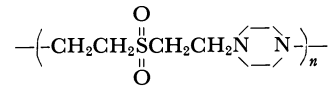
Polyamine from Piperazine and Divinyl Sulfone. A typical run of the preparative method of the polyamine is shown below.

To a solution of 9.370 g (0.108 mol) of anhydrous piperazine in 60 m*l* of absolute methanol was added dropwise a mixture of 12.84 g (0.108 mol) of divinyl sulfone and 20 m*l* of absolute methanol with vigorous stirring at room temperature. The exothermic reaction took place quite rapidly. The reaction mixture was stirred for 30 min. Then the separated white solid was filtered off and washed with methanol. The yield of dried material, melting at 232—234°C, amounted to 21 g (99.0% of the theoretical amount).

Found: C, 46.45; H, 8.10; N, 13.75; S, 15.56%. Calcd for $(C_8H_{16}N_2O_2S)_n$: C, 47.03; H, 7.48; N, 13.72; S, 15.67%.

The product was soluble in sulfuric acid, glacial acetic acid, and formic acid. However, it was insoluble in *n*-hexane, benzene, methanol, ethanol, ether, chloroform, tetrahydrofuran, dioxane, dimethylformamide, dimethyl sulfoxide, dimethyl sulfate, and methyl formate. It should be noted that the product is swollen with water. The product had an intrinsic viscosity of 0.36 in sulfuric acid and one of 0.30 in glacial acetic acid at 30°C.

As the electron density of the double bonds in divinyl sulfone is decreased by the electron-withdrawing character of the oxygen atom, divinyl sulfone acts as a strong electron-acceptor in the Michael reaction. The addition reaction of piperazine to divinyl sulfone proceeded rapidly at a low temperature and formed a polymeric substance in a high yield. The results of elementary analysis and the infrared spectrum (Fig. 1) showed the polymer to have the following polyamine structure:



The influences of the solvents and the feed ratio of piperazine to divinyl sulfone on the yield and the molecular weight of polyamine were examined; the results are listed in Table 1. The polymer with the highest molecular weight was attained when the two reactants used were equimolar in amount. The polymerization method in which divinyl sulfone was slowly added to a solution of piperazine seemed to give a higher molecular weight and higher yield than when the two reactants were added at the same time.

No polymeric addition product was obtained by the reaction of *trans*-2,5-dimethylpiperazine with divinyl sulfone. The failure of this reaction may be due to the steric effect of the methyl group which would prevent, more or less, the attack of the nitrogen atom on the β-carbon of divinyl sulfone.

Polyamine from *p*-Phenylene Diacrylate and Piperazine. To a mixture of 10 m*l* of methanol, 40 m*l* of chloroform and 1.291 g (0.015 mol) of piperazine was added a solution of 3.273 g (0.015 mol) of *p*-phenylene diacrylate in 40 m*l* of chloroform with vigorous stirring over a period of 30 min. The temperature was maintained at 10°C during the addition of *p*-phenylene diacrylate. After the addition, the reaction mixture was refluxed for 60 min under a nitrogen atmosphere. Then the solvents were distilled off under reduced pressure. After the residual liquid has been poured into a large amount of ether, a white solid was filtered. After drying, 1.5 g of white powder was obtained, mp 180—182°C.

Found: C, 61.76; H, 6.91; N, 8.06%. Calcd for $(C_{16}H_{20}N_2O_4)_n$: C, 63.14; H, 6.22; N, 7.88%.

This polymer was readily soluble in chloroform dimethylformamide, dimethyl sulfoxide, and acetic acid. The intrinsic viscosity of this polymer was 0.11 in glacial acetic acid at 30°C. The infrared spectrum of this polymer, as shown in Fig. 2, indicates the following polyester-amine structure:

An attempt to obtain a polymeric substance from *p*-phenylene dimethacrylate and piperazine failed. It is expected that, in this reaction, the inductive effect of the methyl group is not significant, while

the steric hindrance of the methyl group can not be disregarded. That is, in the Michael reaction the rate-determining step[6,7] is the attack of the nitrogen atom on the β-carbon of the vinyl group, and not only the stability of the ambient anion formed, but also the steric effects of reactants play an important role.

Experimental

Materials. Anhydrous piperazine, *trans*-2,5-dimethylpiperazine, and divinyl sulfone may be obtained from commercial sources. Anhydrous piperazine and *trans*-2,5-dimethyl piperazine were purified by the azeotropic distillation of water with benzene. Divinyl sulfone was purified by distillation under reduced pressure. Most of the solvents were dried and subjected to a simple distillation. Chloroform was freed of any alcohol stabilizer by washing it with a 5% sodium bicarbonate solution and water successively. It was

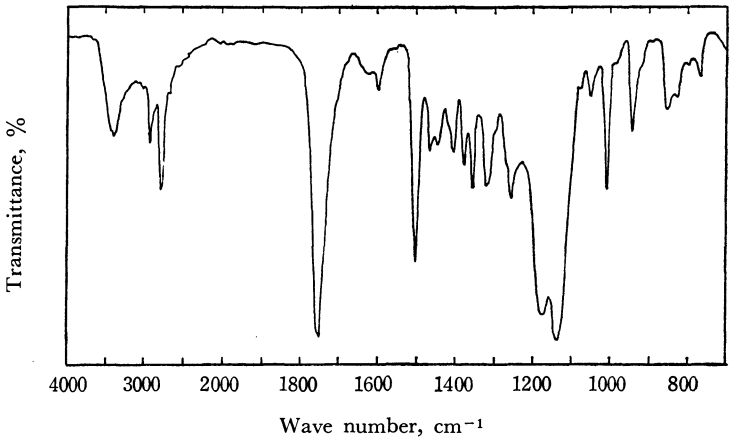

Fig. 2. Infrared spectrum of the polymer from piperazine and *p*-phenylene diacrylate.

dried over calcium chloride and then distilled. *p*-Phenylene dimethacrylate was prepared by the following method. To 23.12 g (0.12 mol) of hydroquinone in a 300 m*l*, four-necked flask, 16.8 g (0.42 mol) of sodium hydroxide in 200 m*l* of water was added with stirring under a nitrogen atmosphere. Then 43.85 g (0.42 mol) of methacrylyl chloride were added, drop by drop, over a 30-min period at 30°C. The reaction mixture was extracted with 400 m*l* of ether, and the extract was washed three times with 150 m*l* of a 5% sodium bicarbonate solution. The ether solution was then dried over 50 g of anhydrous sodium sulfate overnight, and the ether was removed. Eighteen grams of white needles were obtained by two recrystallizations from ether, mp 88°C.

Found: C, 68.17; H, 5.78%. Calcd for $C_{14}H_{14}O_4$: C, 68.28; H, 5.78%.

IR (KBr disk): 3420, 2940, 2910, 2830, 1734, 1635, 1504, 1445, 1395, 1373, 1320, 1295, 1185, 1145, 1123, 1013, 934, 885, 807 cm.$^{-1}$

p-Phenylene diacrylate was prepared from 23.12 g (0.21 mol) of hydroquinone and 37.01 g (0.42 mol) of acrylyl chloride in the presence of 16.8 g (0.42 mol) of sodium hydroxide according to a method similar to that used in the case of *p*-phenylene dimethacrylate. Seven grams of white needles were obtained after two recrystallizations from a mixture of ether and petroleum ether (1 : 1), mp 84—85°C.

Found: C, 65.64; H, 4.80%. Calcd for $C_{12}H_{10}O_4$: C, 66.04; H, 4.62%.

IR (KBr disk): 3419, 3090, 3040, 1740, 1723, 1630, 1500, 1400, 1290, 1250, 1150, 1008, 980, 908, 793, 770 cm.$^{-1}$

Synthesis of α,β-Unsaturated Carboxylic Hydrazides

Rokuro HARADA and Hisao KONDO

Basic Research Laboratories, Toyo Rayon Company, Ltd., Tebiro, Kamakura

(Received January 24, 1968)

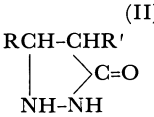
Carboxylic hydrazides are usually prepared by the reaction of carboxylic esters with hydrazine hydrate.[1] However, when this general method is applied to the synthesis of α,β-unsaturated carboxylic hydrazides, the main product is not simple carboxylic hydrazide, but pyrazolidone (III) resulting from the Michael addition.[2]

$$RCH{=}CR'COOR'' + NH_2NH_2 \rightarrow$$

(I)

$$[NH_2NHCHR\cdot CHR'COOR''] \rightarrow$$

(II)



(III)

Therefore, pyrazolidones obtained by this method have often been believed to be carboxylic hydrazides. Godtfredsen[3] has, however, shown

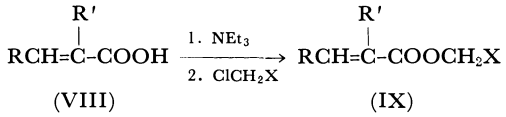
that the cinnamohydrazide synthesized by Muckermann[4] was not the hydrazide, but in fact 5-phenyl-3-pyrazolidone, he synthesized real cinnamohydrazide (VI) by the reaction of cinnamic ethoxyformic anhydride (V) with hydrazine hydrate.

Several papers have appeared reporting the synthesis of acrylo-,[5] methacrylo-[6] and crotonohydrazide[4] by the reaction of the corresponding esters with hydrazine hydrate. The structures of these hydrazides have seemed doubtful, however, so we attempted the synthesis of real hydrazides.

To accelerate the attack of hydrazine on the carbonyl carbon instead of on the α,β-double bond, the activated esters, which are usually used for the synthesis of peptides, seemed to be useful. We wish to report on the synthesis of α,β-unsaturated carboxylic hydrazides (X) by the reaction of activated esters (IX) with hydrazine hydrate.



a: X=CN
b: X=OMe
c: X=COOMe
d: X=$C_6H_5NO_2$-(*p*)

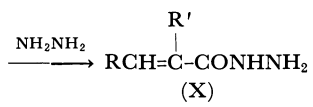


Table 1.* The reaction of hydrazine hydrate with methacrylate

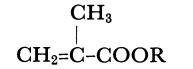

R	Yield of product (%)	
	Methacrylohydrazide	4-Methyl-3-pyrazolidone
$-CH_2CN$	83	0
$-CH_2OCH_3$	33	0
$-CH_2COOC_2H_5$	7	0
$-CH_2C_6H_4NO_2$-(*p*)	0	35

* The solvent was chloroform.

The reaction of hydrazine hydrate with several activated esters (IX) of methacrylic acid have been examined; the results are shown in Table 1.

Of these activated esters, cyanomethyl methacrylate gave the best results. The reaction was influenced by the solvents; when chloroform or methylene chloride was used as the solvent, methacrylohydrazide was obtained in 83% or 69% yield, respectively. In ethanol, however, 17% *N,N'*-dimethacroyl hydrazine, 28% 4-methyl-3-pyrazolidone, and no hydrazide were obtained.

In chloroform, cyanomethyl cinnamate gave 82% hydrazide, but under the same reaction conditions cyanomethyl acrylate and crotonate gave no hydrazides, but only 11% and 27% pyrazolidones, respectively.

For the sake of comparison with the activated ester methods, the mixed acid anhydride methods have been tried; in the case of methacrylic ethoxyformic anhydride, 72% hydrazide and 11% *N,N'*-dimethacroyl hydrazine were formed.

The methacrylohydrazide obtained above has a mp of 86—88°C and ν_{max}^{KBr} 3325, 3200, 1663, 1612, 1550, 890 cm^{-1}, and it is different from Shvaika's methacrylohydrazide (bp 140°C/11 mmHg,[6] ν_{max} 3300, 1670 cm^{-1}).

Several attempts to isolate acrylohydrazide prepared by the mixed acid anhydride method were unsuccessful because of its high polymerizability. The fairly-pure acrylohydrazide (yield 30%) isolated by silica-gel column chromatography was a viscous oil (ν_{max} 3250, 1660, 1610, 1545, 990, 910 cm^{-1}) and gave acrylic benzylidenehydrazide by the reaction with benzaldehyde.

The crotonohydrazide synthesized above has a mp of 87—89°C and ν_{max}^{KBr} 3300, 1664, 1615, 1550, 895 cm^{-1}, it is different from Muckerman's crotonohydrazide (bp 120°C/4 mmHg).[4]

The acrylo-, methacrylo-, and crotonohydrazide obtained above absorbed one mole of hydrogen and gave propiono-, isobutyro-, and *n*-butylohydrazide, respectively.

Experimental

Activated Esters of Methacrylic Acid. *a) Cyanomethyl Ester.* The ester was prepared according to the general procedure of Schwyzer.[7] Triethylammonium methacrylate (14.3 g) was reacted with chloroacetonitrile (6.8 g) in ethyl acetate. Yield, 73.2%; bp 48—49°C/2 mmHg.

b) Ethoxycarbonylmethyl Ester. The ester was prepared from methacrylic acid, triethylamine, and ethyl chloroacetate according to the general method.[7] Yield, 59%; bp 67—68°C/0.8 mmHg.

Found: C, 55.67; H, 6.39%. Calcd for $C_9H_{12}O_4$: C, 55.80; H, 7.03%.

c) Methoxymethyl Ester. The ester was prepared from the acid, triethylamine, and chloromethyl methyl ether.[7] Yield, 62%; bp 70—71°C/40 mmHg.

Found: C, 55.65; H, 7.63%. Calcd for $C_6H_{10}O_3$: C, 55.40; H, 7.69%.

d) p-Nitrobenzyl Ester. The ester was prepared from the acid, triethylamine, and *p*-nitrobenzyl chloride.[8] Yield, 55%; mp. 82—84°C.

Found: C, 59.69; H, 4.97; N, 6.22%. Calcd for $C_{11}H_{11}O_4N$: C, 59.71; H, 5.01; N, 6.33%.

Methacrylohydrazide. *a) A Typical Activated-ester Method.* To a solution cyanomethyl methacrylate (3.75 g) in chloroform (100 cc), 80% hydrazine hydrate (3.0 g) was added. The solution was stirred for 2 hr at room temperature and then refluxed for 1 hr. After drying, the solvent was removed. The crystallization of the residue from ethanol-ether (1 : 1) gave colorless needles. Yield, 83%; mp 86—88°C.

Found: C, 47.85; H, 8.01; N, 27.95%. Calcd for $C_4H_8ON_2$: C, 47.98; H, 8.05; N, 27.98%.

Methacrylic benzylidenehydrazide was prepared according to the general method; mp 155—156°C, ν_{max}^{KBr} 3200, 1660, 1620, 1600, 1555 cm^{-1}.

Found: C, 69.86; H, 6.45; N, 14.82%. Calcd for $C_{11}H_{12}ON_2$: C, 70.18; H, 6.43; N, 14.88%.

Methacrylohydrazide in ethanol absorbed 1 mol of hydrogen at room temperature with a Raney nickel catalyst and afforded crystals (mp 103—104°C), just like the authentic isobutyrohydrazide.

When the reaction was carried out in ethanol, *N,N'*-dimethacroylhydrazine (yield, 17%; mp 136—137°C, ν_{max}^{KBr} 3250, 1665, 1615, 1560, 890 cm^{-1}, Found: C, 57.05; H, 7.61; N, 16.71%. Calcd for $C_6H_8O_2N_2$: C, 57.13; H, 7.19; N, 16.17%.) and 4-methyl-3-pyrazolidone (yield, 28%; 115°C/4 mmHg, ν_{max} 3300, 1670 cm^{-1}) were obtained after the reaction products had been purified by sillica-gel column chromatography.

b) Mixed Acid Anhydride Method. The hydrazide was synthesized according to the general procedure of Godtfredsen.[3] The mixed acid anhydride prepared from potassium methacrylate (13.8 g), pyridine (0.2 g), and ethyl chloroformate (12.0 g) in chloroform (100 cc) was added rapidly to a stirred, ice-cooled suspension of 80% hydrazine hydrate (10.0 g) in chloroform (100 cc). After standing at 0°C overnight, the solution was filtered. The filtrate was washed with a saturated sodium bicarbonate solution, and then dried. The solvent was removed, and the residue recrystallized from benzene. Yield, 72%; mp 86—88°C, which was identical with that of the product of Method a).

8) B. Iselin and R. Schwyzer, *ibid.*, **40**, 373 (1957).

Acrylohydrazide. *a) Mixed Acid Anhydride Method.* The mixed acid anhydride prepared from potassium acrylate (20.0 g), pyridine (0.5 g), and ethyl chloroformate (22.6 g) in methylene chloride (200 cc) was added to a stirred, ice-cooled suspension of 80% hydrazine hydrate (18.0 g) in methylene chloride (150 cc). After stirring for 30 min at 0°C, potassium chloride was filtered off. The filtrate was kept at 0°C overnight, and dried, and then the solvent was removed. The oily residue was purified by silica-gel column chromatography. From the chloroform-methanol (5%) eluted fractions, a colorless, viscous oil was obtained. Yield, 30%; ν_{max}^{KBr} 3250, 1670, 1620, 1550, 980 cm^{-1}.

Acrylic benzylidenehydrazide was prepared by the general method: Yield, 78%; mp 131—132°C.

Found: C, 68.68; H, 5.90; N, 16.27%. Calcd for $C_{10}H_{10}ON_2$: C, 68.95; H, 5.79; N, 16.08%.

Acrylohydrazide in ethanol absorbed 1 mol of hydrogen at room temperature with a Raney nickel catalyst; the product (mp 38—40°C) was identical with the authentic propionohydrazide.

b) Activated-ester Method. Cyanomethyl acrylate was prepared according to the general method. Yield, 71%; bp 66—68°C/6.5 mmHg.

Found: C, 54.22; H, 4.59; N, 12.55%. Calcd for $C_5H_5O_2N$: C, 54.05; H, 4.54; N, 12.61%.

80% Hydrazine hydrate (4.5 g) was added to a solution of the cyanomethyl ester (3.3 g) in chloroform (100 cc), and the solution was stirred for 2 hr at room temperature. After drying, the solvent was removed *in vacuo*.

The residue was purified by silica-gel chromatography. From the chloroform-methanol (5%) eluted fractions, an oily product (0.24 g, yield, 9.3%) was obtained, its IR spectrum (ν_{max}) 3300, 1670 cm^{-1}) was identical with that of the 3-pyrazolidone derivative.

Crotonohydrazide. Crotonohydrazide was prepared according to the general procedure of Godtfredsen.[3] Yield, 48%; mp 86—89°C, ν_{max}^{KBr} 3300, 1665, 1620, 1530, 960 cm^{-1}.

Found: C, 48.07; H, 8.02; N, 27.90%. Calcd for $C_4H_8ON_2$: C, 47.98; H, 8.05; N, 27.98%. The crotonic benzylidenehydrazide was prepared by the general method. Yield, 58%; mp 165—166°C.

Found: C, 69.91; H, 6.41; N, 14.83%. Calcd for $C_{11}H_{12}ON_2$: C, 70.18; H, 6.43; N, 14.88%.

Crotonohydrazide in ethanol absorbed 1 mol of hydrogen at room temperature in the presence of a Raney nickel catalyst. The product (mp 41—43°C) was identical with the authentic butyrohydrazide.

Cinnamohydrazide. Cyanomethyl cinnamate was prepared by the same procedure as cyanomethyl methacrylate. Yield, 79.0%; mp 62—63°C.

Found: C, 70.47; H, 4.86; N, 7.57%. Calcd for $C_{11}H_9O_2N$: C, 70.58; H, 4.85; N, 7.48%.

The reaction of cyanomethyl cinnamate with 80% hydrazine hydrate gave 82% of cinnamohydrazide, mp 116—117°C, which was identical with Godtfredsen's cinnamohydrazide (mp 117—117.5°C).[3]

Azirines. IV. The Photolysis of β-Azidovinyl Ketones*[1]

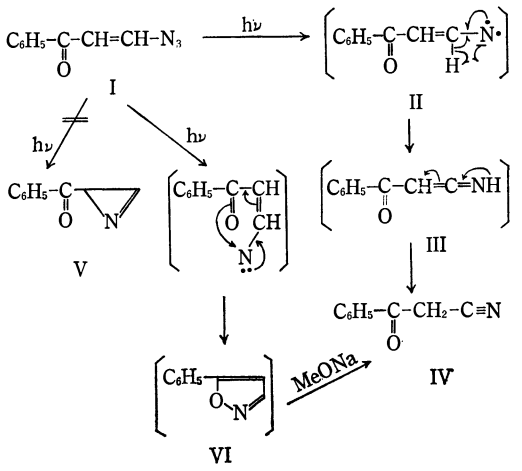
Shimao SATO

Kyorin Chemical Laboratory, Kyorin Pharmaceutical Co., Ltd., Ukima, Kita-ku, Tokyo

(Received February 15, 1968)

Although the pyrolysis[1] and photolysis[2-4] of vinyl azides as a method of preparing azirine have already reported on, there has been no report with regard to the photolysis of azidovinyl ketones. Therefore, we have been trying to obtain the functional derivatives of azirine by means of the photolysis of azidovinyl ketones. During the course of our work, Maiorana[5] reported the photolysis of azidovinyl phenyl ketone. Since, however, we tried the photolysis under slightly different conditions from his, we want here to report our results with this compound and with a cyclic azidovinyl ketone which has not hitherto been reported.

First, β-azidovinyl phenyl ketone[6] (I) was chosen as the azidovinyl ketone. The photolysis of I in benzene gave, with the evolution of nitrogen, benzoylacetonitrile (IV) in a 20% yield instead of 3-benzoylazirine (V). When the residual solution was treated with sodium methoxide, another crop of IV was obtained in a 17% yield. The formation of the second crop of IV may most reasonably be explained in terms of the alkaline hydrolysis of 5-phenylisoxazole (VI). The ready ring cleavage of isoxazoles unsubstituted at the 3-position with sodium methoxide has been known.[7] The results thus show that the nitrene II formed by the photolysis of I does not add to the double bond, but rather attacks the carbonyl group to give the VI or rearranges to the IV by the migration of a hydrogen atom, as is shown in the chart.



It is known[6] that β-azidovinyl ketones are decomposed on contact with acids to give substituted isoxazoles and nitriles, presumably through a vinyl nitrene intermediate.

When the photolysis of I was carried out in aqueous tetrahydrofuran instead of benzene in order to detect the III, Compound IV was obtained in a 27% yield instead of the desired benzoylacetamide. However, the v.p.c. analysis of the residual oil showed the presence of three other components (A, B and C). Component A was identified as methyl benzoate by a comparison of their v.p.c. retention times and infrared absorption spectra. The mechanism of the formation of this compound is not clear. The structure of Component B has not yet been elucidated, but it may be presumed to be a carbonyl compound because its IR spectrum exhibits a band at 1690 cm^{-1}. Component C was solidified on cooling, mp 31—33°C; the infrared spectrum of this compound has no characteric absorption bands except for that of phenyl group. These spectral data and the melting point suggest that it may be presumed to be a 5-phenyloxazole or its isomer.

Next, we attempted the irradiation of 5,5-dimethyl-3-azido-2-cyclohexene-1-one, prepared by the reaction of 5,5-dimethyl-3-chloro-2-cyclohexene-1-one and sodium azide, as a cyclic azidovinyl ketone, in benzene, but no nitrogen evolved. When this photolysis was carried out in aqueous tetrahydrofuran, the evolution of nitrogen was observed and colorless plates with a composition of $C_8H_{13}NO_2$ were obtained. This product was assigned as 6,6-dimethylhexahydroazepine-2,4-dione (XI) on the basis of the spectral data described below. The infrared spectrum of this compound exhibits bands at 3090 and 3200 cm^{-1} for the cyclic lactam NH group, 1710 cm^{-1} for the carbonyl group, and 1670 cm^{-1} for the amido-carbonyl group. The NMR spectrum shows a singlet at

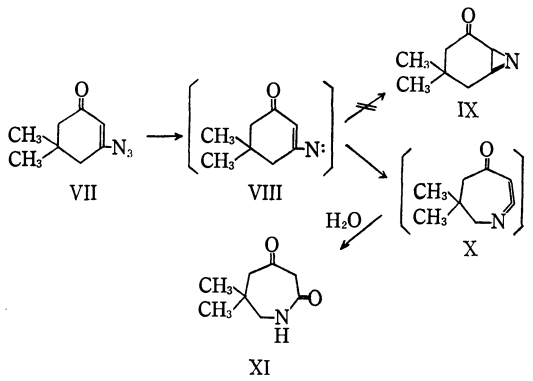
τ 9.1 (6H) for the *gem*-dimethyl group, a singlet at τ 7.6 (2H) for the methylene on the 5-position of the ring, a multiplet at τ 6.8—6.9 (2H) for the methylene on the 7-position of the ring, a singlet at τ 6.6 (2H) for the methylene on the 3-position of the ring, and a multiplet at τ 2.0 (1H for the hydrogen on the nitrogen.



These results show that the migration of the methylene group to the nitrene occurs, giving a cyclic seven-membered keteneimine X, in preference to the intramolecular addition of the nitrene, giving condensed azirine IX.

Experimental

All the melting points were determined on a micro hot stage and are not corrected. The infrared spectra were taken on KBr tablets or neat liquid films.

Photolysis of β-azidovinyl Phenyl Ketone. a) A solution of 3.4 g (0.02 mol) of β-azidovinyl phenyl ketone[6] in 100 m*l* of dry benzene was irradiated through a Pyrex filter with a high-pressure mercury lamp under a nitrogen atmosphere for 20 hr, until nitrogen evolution ceased. The solution was then concentrated, and the residual oil was dissolved in ether and extracted with 10% sodium hydroxide, after which the extract was acidified with 10% hydrochloric acid. The solid which separated out was collected and recrystallized from water to give benzoylacetonitrile as colorless needles, mp 76—78°C (lit. 80.5°C).[8] (Found: C, 73.96; H, 4.88; N, 9.80%.) IR: 2200 (C≡N) and 1690 cm^{-1} (C=O). To the residual ethereal solution, a solution of excess sodium methoxide in 10 m*l* of methanol was added with cooling and stirring. The mixture was then stirred for one hour, after which 20 m*l* of water was added; the resulting mixture was washed with ether, and then the aqueous layer was acidified with 10% hydrochloric acid to give 0.3 g of colorless needles melting at 76—78°C. The melting point of this substance was undepressed on admixture with the benzoylacetonitrile obtained previously.

b) A solution of 2.2 g of I in 100 m*l* of tetrahydrofuran and 15 m*l* of water was irradiated through a Pyrex filter with a high-pressure mercury lamp under a nitrogen atmosphere for 16 hr, until nitrogen evolution ceased. When the solution was then treated by the method described above, 0.8 g of benzoylacetonitrile was obtained. The v.p.c. analysis of the residual oil showed the presence of three components; one of them was identified as methyl benzoate by a comparison of the retention times and the IR spectrum.

5,5-Dimethyl-3-azido-2-cyclohexene-1-one (VII). To a solution of 10 g (0.063 mol) of 5,5-dimethyl-3-chloro-2-cyclohexene-1-one[9] in 40 m*l* of methanol, a solution of 4.5 g (0.069 mol) of sodium azide in 70 m*l* of methanol and 5 m*l* of water was added with cooling and stirring. The mixture was then stirred for two hours at room temperature. To the reaction mixture, 100 m*l* of water was added, and the resulting mixture was extracted with ether; the extract was then washed thoroughly with water and dried over sodium sulfate. The solvent was removed by distillation; the IR spectrum of this residual oil exhibits a band at 2100 cm^{-1} for the azido group, 150 m*l* of tetrahydrofuran was added to the residue and the resulting solution was used for the photolysis without purification.

Photolysis of VII. To a solution of VII in THF, 30 m*l* of water was added. The mixture was irradiated with a high-pressure mercury lamp for 18 hr, until nitrogen evolution ceased. The solution was then concentrated by distillation under reduced pressure. The residual aqueous layer was washed with ether to remove any unreacted material, and then concentrated on a rotary evaporator. The solid which separated out was collected and recrystallized from *n*-pentane-ethanol to give 1 g of colorless plates, mp 148—149°C. Found: C, 61.91; H, 8.39; N, 8.92%. Mol wt, 142.8. Calcd for $C_8H_{13}NO_2$: C, 61.91; H, 8.44; N, 9.30%. Mol wt, 155.1.

The Stereochemistry of Tetralin-1-ols

Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai

and Akira KASAHARA and Kaoru HANAYA

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received February 15, 1968)

Clark-Lewis *et al.*[1] and other authors[2] have studied the NMR spectra of the 4α- and 4β-hydroxyflavans and their relative configurations as deduced from the coupling constants. Inoue *et al.*[3] and Anjaneyulu *et al.*[4] have carried out similar investigations on isoflavanols.

Tetralin-1-ols are considered to have configurations similar to those of the corresponding hydroxyflavans. One of the present authors, Hanaya, obtained 3-phenyl-1-tetralol (Ia, Ib),[5] 3-methyl-1-tetralol (IIa, IIb),[5] 2-phenyl-1-tetralol (IIIa, IIIb)[6] and 2-methyl-1-tetralol (IVa, IVb)[7] by the reduction of the corresponding α-tetralones, as is show in Table 1; he tentatively assigned a *trans* configuration to Ia, IIa, IIIb, and IVb and a *cis* configuration to Ib, IIb, IIIa, and IVa,[5-7] on the basis of the mechanism of the reduction and their IR spectra.

TABLE 1

Compound		mp or bp
	Ia	mp 100—101.5°C
	Ib	mp 96—98°C
	IIa	mp 96.5—98°C
	IIb	mp 113—115°C
	IIIa	mp 66—68°C
	IIIb	mp 80—81°C
	IVa	bp 109—113°C/7 mmHg
	IVb	mp 69—70°C

In order to confirm these assignments and to decide whether or not a relationship similar to those found in the case of the hydroxyflavans exists between the coupling constants and the configurations of the tetralin-1-ols, we investigated the NMR spectra of the tetralin-1-ols.

Already, Argabright *et al.*[8] have reported that IIb exhibits a triplet with $J_{1\cdot2}=3.2$ cps in the NMR spectrum and that the hydroxyl group must be axial, while IVb exhibits a doublet with $J_{1\cdot2}=7$ cps and both the hydroxyl and methyl groups must be of the equatorial conformation.

The experimental results are summarized in Table 2.

The hydroxyl group exists in the α-position to the phenyl or methyl group, and if it is assumed that the phenyl or methyl group is in the equatorial conformation on a half-chair ring, the Karplus relationship[9] predicts that $J_{1\cdot2}$ will be significantly smaller for 1,2-*cis* than for 1,2-*trans* isomers. In the NMR spectra of III, IV, and their acetates the $J_{1\cdot2}$ values of IIIb and IVb are larger than those of IIIa and IVa, respectively. Therefore, these results indicate that in IIIb and IVb the phenyl or methyl group is *trans* to the hydroxyl group, and in IIIa and IVa, *cis*. These findings are consistent with the assignment proposed in preceding papers.[6,7] On the other hand, when the hydroxyl group exists in the β-position to the phenyl or methyl group, the assignment based on the examination of the NMR spectra is contrary to the assignment made before.[5] In the NMR spectra of I, II, and their acetates, the signal of the 1H protons of Ib and IIb appears as a triplet, while the signal of the 1H protons of Ia and IIa appears as a double doublet. Consideration of the Karplus relationship[9] suggests that the 1H protons of Ib and IIb exist in a quasi-equatorial conformation, while the 1H protons of Ia and IIa exist in a quasi-axial conformation on a half-chair

TABLE 2. NMR SPECTRA OF TETRALIN-1-OLS AND THEIR ACETATES

Compound	Position of peaks (ppm)	No. of protons	Assignment	Remark
Ia	5.21	1	H	Double doublet $J_{1\cdot2}$=6.0 ; 11.0 cps
Acetate of Ia	1.90	3	$CH_3\cdot CO\cdot O$	Singlet
	5.98	1	H	Double doublet $J_{1\cdot2}$=6.5 ; 11.0 cps
Ib	5.13	1	H	Triplet, $J_{1\cdot2}$=3.0 cps
Acetate of Ib	1.82	3	$CH_3\cdot CO\cdot O$	Singlet
	5.93	1	H	Triplet, $J_{1\cdot2}$=3.5 cps
IIa	1.05	3	CH_3	Doublet, J=6.0 cps
	4.64	1	H	Double doublet $J_{1\cdot2}$=6.0 ; 11.0 cps
Acetate of IIa	1.04	3	CH_3	Doublet, J=6.0 cps
	2.07	3	$CH_3\cdot CO\cdot O$	Singlet
	6.0	1	H	Double doublet $J_{1\cdot2}$=6.0 ; 10.5 cps
IIb	1.07	3	CH_3	Doublet, J=6.0 cps
	4.63	1	H	Triplet, $J_{1\cdot2}$=3.0 cps
Acetate of IIb	1.06	3	CH_3	Doublet, J=5.6 cps
	1.98	3	$CH_3\cdot CO\cdot O$	Singlet
	6.01	1	H	Triplet, $J_{1\cdot2}$=3.0 cps
Acetate of IIIa	1.65	3	$CH_3\cdot CO\cdot O$	Singlet
	6.08	1	H	Doublet, $J_{1\cdot2}$=3.5 cps
Acetate of IIIb	1.83	3	$CH_3\cdot CO\cdot O$	Singlet
	6.18	1	H	Doublet, $J_{1\cdot2}$=8.0 cps
IVa	1.12	3	CH_3	Doublet, J=6.0 cps
	4.51	1	H	Doublet, $J_{1\cdot2}$=3.0 cps
Acetate of IVa	1.00	3	CH_3	Doublet, J=6.0 cps
	1.95	3	$CH_3\cdot CO\cdot O$	Singlet
	5.92	1	H	Doublet, $J_{1\cdot2}$=3.0 cps
IVb	1.08	3	CH_3	Doublet, J=6.0 cps
	4.25	1	H	Doublet, $J_{1\cdot2}$=6.0 cps
Acetate of IVb	1.02	3	CH_3	Doublet, J=6.2 cps
	2.08	3	$CH_3\cdot CO\cdot O$	Singlet
	5.75	1	H	Doublet, $J_{1\cdot2}$=6.5 cps

ring. The conformations of the phenyl or methyl group in the 3-position of I and II are assumed to be equatorial, as usual. Therefore, these results indicate that Ib and IIb have a *trans* relation between the phenyl or methyl group and the hydroxyl group, and that Ia and IIa have a *cis* relation.

From the above findings, the relationship between the 1,2-coupling constants and the configurations which was observed with tetralin-1-ols is similar to that seen in the case of the hydroxyflavans. Therefore, it may be concluded that the configuration of the tetralin-1-ols can be assigned on the basis of the coupling constant of the 1- and 2-protons. When the hydroxyl group exists in the β-position to the phenyl or methyl group, as has been mentioned before, the assignment based on the examination of the NMR spectra is contrary to that made on the basis of the mechanism of the reduction. This problem will be discussed in more detail later.

Experimental

Samples. The tetralin-1-ols were prepared according to the method previously reported.[5-7] The acetates of the tetralin-1-ols were prepared by the acetylation of the corresponding tetralin-1-ols with acetic anhydride and pyridine at room temperature overnight. The crystal products were purified by recrystallization, while the oily products were checked by a study of their IR spectra and VPC.

The acetate of Ia, mp 74.5—76.5°C.

Found: C, 80.88; H, 6.91%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

The acetate of IIIa, mp 102—103°C.

Found: C, 81.49; H, 6.56%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.
The acetate of IIIb, mp 112—113°C.

Found: C, 80.87; H, 7.15%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

NMR Measurements. The NMR spectra were measured at 60 MHz on a Varian A-60 spectrometer. The sample was dissolved in $CDCl_3$, containing TMS as the internal reference.

The authors wish to express their gratitude to Dr. Hiizu Iwamura, The University of Tokyo, and Dr. Yasuhisa Senda, Tohoku University, for their useful advice.

A Kinetic Study of the Hydrogenation of Mesityl Oxide over Unpoisoned and Poisoned Raney Nickel Catalysts. Temperature Variation of the Reaction Order

Sanae KISHIDA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received February 17, 1968)

The kinetics of the liquid-phase hydrogenation of acetone in *n*-hexane over a Raney nickel catalyst, and of various ketones in cyclohexane over a nickel boride catalyst, have been successfully interpreted by a simplified Langmuir-type rate equation,[1]

$$v = kaC_R/(1+aC_R)^2, \quad (1)$$

where C_R represents the concentration of the reactant to be hydrogenated and where a has the form:

$$a = a_0 \exp(-\delta\Delta G/\boldsymbol{RT}), \quad (2)$$

where $\delta\Delta G$ is the difference between the free energies of the adsorption of the reactant and hydrogen and where a_0 is a constant which is independent of the temperature.

The rate equation has been derived on the following assumptions:

i) Hydrogen and the reactant adsorb reversibly and compete for the same surface sites, whence the ratio of the fractional surface coverage of the reactant(ϑ_R) to that of hydrogen(ϑ_H) is given by[2]:

$$\vartheta_R/\vartheta_H = aC_R \quad (3)$$

The liquid-phase concentration of hydrogen is considered to be independent of the temperature and is included in the a_0 constant.

ii) The surface of the catalyst is fully covered by the adsorbed species of the reactant and hydrogen during the reaction:

$$\vartheta_R + \vartheta_H = 1 \quad (4)$$

iii) The rate-determining step is the surface reaction:

$$v = k\vartheta_R \cdot \vartheta_H \quad (5)$$

where k is the rate constant of the surface reaction.

In this paper the rates of the liquid-phase hydrogenation of the carbon-carbon double bond of mesityl oxide have been measured over a wide range of temperature, and the kinetics of the reaction have been interpreted by Eq. (1).

The rate over the catalyst poisoned by potassium iodide has also been measured, and the kinetics over unpoisoned and poisoned catalysts have been compared. It has been found that the thermodynamic parameter in the rate equation, a, as well as the rate constant decreases as a result of the poisoning.

Experimental

The preparation of the catalyst, the apparatus, and the procedure for the rate measurements were as previously reported.[1]

To poison the catalyst by KI, the sample prepared was added to 10 cc of a KI solution, the concentration of which was 1.07 mol/*l*, and stirred for 10 min. The sample was then washed with water by decantation until no trace of KI was detected. The amount of KI adsorbed on the catalyst by such a treatment was found to be 0.169 mmol/g-Ni.

The analysis by gas chromatography certified that the product of the initial state of the reaction was only isobutyl methyl ketone, the further hydrogenation of which did not proceed until mesityl oxide had been completely hydrogenated. The reaction in this paper is, therefore, concerned with the hydrogenation of the C=C of mesityl oxide.

Results and Discussion

The rate of the hydrogenation of mesityl oxide was found to decrease with an increase in the concentration. The results of the rate measurement

2) G. C. Bond, "Catalysis by Metals," Academic Press, London and New York (1962), p. 124.

at −10°C, −35°C, −50°C, and −78°C are shown in Fig. 1. The peak of the rate expected from

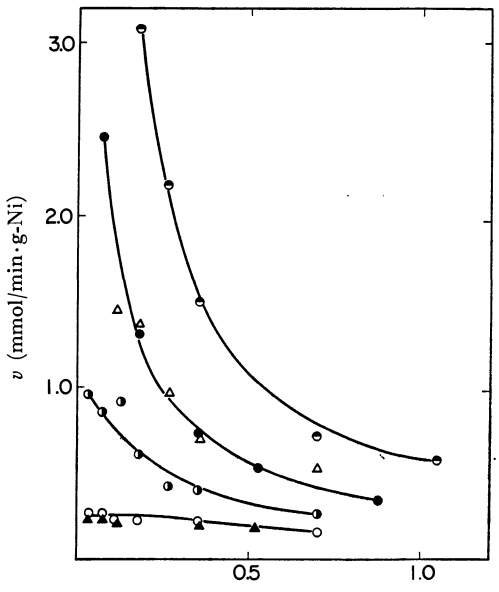

Fig. 1. Hydrogenation of mesityl oxide in *n*-hexane.
i) on unpoisoned Raney nickel catalyst
◓, −10°C; ●, −35°C; ◑, −50°C; ○, −78°C
ii) on poisoned catalyst
△, −10°C; ▲, −35°C

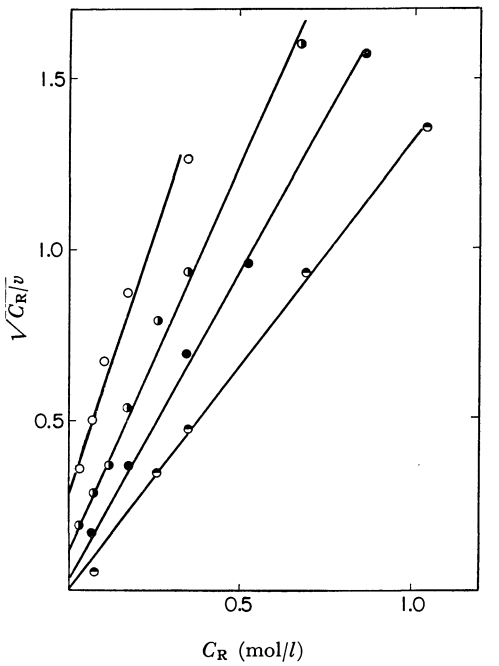

Fig. 2. $\sqrt{C_R/v}$-C_R plots for unpoisoned catalyst.
◓, −10°C; ●, −35°C; ◑, −50°C; ○, −78°C.

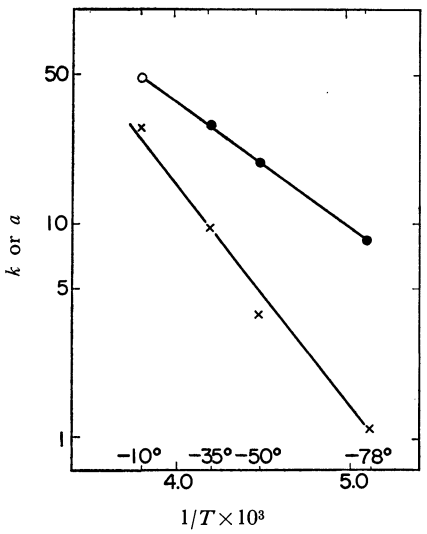

Fig. 3. Arrhenius plot (×) and log a - $1/T$ plot (●) for unpoisoned catalyst.

Eq. (1) could not be observed, indicating that a is so large that the peak exists in a lower concentration range than the experimental one.

Since Eq. (1) can be rearranged as:

$$\sqrt{C_R/v} = \sqrt{1/a\cdot k} + \sqrt{a/k}\cdot C_R \qquad (6)$$

the plot of $\sqrt{C_R/v}$ *vs.* C_R gives a straight line. Figure 2 shows the plots, from which the rate constant and the adsorption parameter, a, can be evaluated at each temperature. However, k and a at −10°C can not be evaluated from the plot, since the plot at −10°C passes through the point of origin. It is obvious from Eq. (6) that the intersect (or the slope) of the plot becomes near zero when a is too large (or too small), and that, in these cases, it is not possible to determine k and a separately. Therefore, a at −10°C was determined by extrapolating the plot of log a *vs.* $1/T$ (see the open circle in Fig. 3), and k at −10°C was then evaluated from the slope of the plot of $\sqrt{C_R/v}$ *vs.* C_R.

The rate constants and the adsorption parameters are listed in Table 1. The a increases as the reaction temperature rises, indicating that $\delta\Delta G$ is positive and that the adsorption of hydrogen is stronger than that of mesityl oxide.

The reaction orders with respect to mesityl oxide at each temperature, as evaluated from the plot of log v *vs.* log C_R, are also listed in Table 1. The order with respect to mesityl oxide becomes lower as the reaction temperature rises.

Since Eq. (1) predicts that the reaction order with respect to the reactant is −1 when $a\cdot C_R \gg 1$ and 1 when $a\cdot C_R \ll 1$, the reaction order determined over the limited concentration range becomes higher as the a value decreases. Therefore, the temperature variation of the reaction order depends

TABLE 1. TEMPERATURE VARIATIONS OF k, a AND REACTION ORDER OF HYDROGENATION OF MESITYL OXIDE

Temperature (°C)	k (mmol/min·g-Ni)	a (l/mol)	Order of reaction
−78	1.11	8.53	−0.15
−50	3.81	19.7	−0.60
−35	9.60	29.0	−0.75
−10	(27.9)	(48.0)	−1.0
Temperature coefficient (kcal/mol)	4.35	2.63	

on that of a. When $\delta\Delta G$ is positive (or negative), the reaction order becomes higher (or lower) with a decrease in the temperature.

It can, therefore, be said that the temperature variation of the reaction order with respect to the A, for example, of a heterogeneous catalytic reaction between A and B, tells us whether the adsorption of A or that of B is stronger.

The rate data measured over the poisoned catalyst at −10°C and −35°C are shown by, respectively, the open and filled triangles in Fig. 1. It was observed that k and a become smaller by the poisoning. This indicates that the adsorption of mesityl oxide is more inhibited by the poisoning than that of hydrogen.

It has been reported by the present authors that, for the liquid-phase hydrogenation of isobutyl methyl ketone and mesityl oxide over a Raney nickel catalyst,[3] the fractional surface coverage of hydrogen in course of the reaction (ϑ_H) is increased by the poisoning. This phenomenon has been interpreted as evidence that the adsorption strength of the reactant is decreased more than that of hydrogen by the poisoning.

Since ϑ_H is given by Eq. (7):

$$\vartheta_H = 1/(1+a\cdot C_R) \tag{7}$$

the ϑ_H measured at the same concentration of the reactant increases with a decrease in the a.

The poisoning effect on kinetics has scarcely been considered in the literature.[4] This phenomenon appears important, however, and has to be taken into account in discussing the mechanism of the poisoning.

Cyclization of Citronellal to Isopulegol by Cu-Cr and Cu-Cr-Mn Catalysts

Kunio KOGAMI and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Tokyo

(Received February 23, 1968)

Isopulegol is usually prepared by heating[1] citronellal with or without silica gel,[2] active carbon,[3] or boric acid.[4]

In their studies of the catalytic dehydrogenation of geraniol, the present authors found that Cu-Cr-Mn also catalyzes the cyclization of citronellal to isopulegol. In this paper, the results of the catalysis of Raney Nickel, Ni-diatomaceous earth, Cu-Cr, and Cu-Cr-Mn, and the effect of the hydrogen treatment of the catalysts on the cyclization, will be presented. Cu-Cr and Cu-Cr-Mn, without any hydrogen treatment, were found to be good catalysts for this reaction.

Experimental

Materials. Citronellal was prepared from citronellal oil (made in Formosa) by the known method.[5] The catalysts used here were supplied by the Nikki Chem. Co., Ltd. Raney Nickel was pretreated with alkali. Cu-Cr N202, Cu-Cr-Mn N203, and Nickel-diatomaceous earth N111, treated or untreated, were used.

The Procedure of the Cyclization of Citronellal. In the case of a catalyst pretreated with hydrogen, a 0.5 g portion of it placed at the bottom of a 300 m*l* flask equipped with an air-tight stirrer, a reflux condenser, a gas outlet tube with a rubber stopper, and a

5) A. Lewinson, *Perfumery and Essential Oil Record*, **14**, 360 (1923).

two-necked glass tube with a thermometer, and then a glass inlet-tube reaching to the bottom of the flask was fitted on. The flask was immersed in an oil bath at 150—170°C. The hydrogen was passed through the catalyst at a rate of 200 ml/min for 1.5 hr, and then it was replaced by nitrogen at the same flow rate for 0.5 hr. Then citronellal (50 g, 0.23 m) was put into the flask, and the flask was kept at 160—200(±1)°C with stirring under a nitrogen flow. In a case without a catalyst or with a catalyst not treated with hydrogen, citronellal was put into a flask which had previously been filled with nitrogen, and the flask was kept at 205°C by means of an oil bath and allowed to react much as has been described above for 5 to 7 hr under a nitrogen atmosphere.

When the reaction was complete, the reacting mixture was cooled to room temperature, and 150 ml of ether was added to it. After the catalyst had been removed by filtration, the ethereal solution was washed with an aqueous solution of sodium carbonate, and then with water, and dehydrated over sodium sulfate. After evaporation, an oily product was obtained.

Determination of the Composition of the Product by Gas Chromatography. Each sample (0.05 ml) was taken by a mycrosyringe from the reactor through the rubber stopper and analyzed by a gas chromatograph, Kotaki GU-21, under the following conditions: column temperature, 150°C; split temperature 250°C; carrier gas, helium; inlet pressure, 0.8 kg/cm^2; flow rate, 26 ml/min; sensitivity, 8 mV; chart speed, 0.5 cm/min. The column was of stainless steel and was 3 mm in diameter and 3 m long, packed with Diabase A, 80—60 mesh, coated by an acetone solution of Hyprose SP 80. The accuracy of the analysis was estimated to be ±1% (the product obtained at 200°C for 5 to 7 hr was analyzed for the fraction; bp 72—110°C/4 mmHg).

The standard materials used for the analysis were: (1) citronellal (the same as the starting material); (2) citronellol (from the ABRAC Co., Ltd.; bp 100°C/6 mmHg, n_D^{30} 1.4639, d_{30}^{30} 0.8572); (3) isopulegol (from Tokyo Kasei, Inc.); a mixture of 20% neo-isopulegol; 75% isopulegol; and 5% iso-isopulegol (by gas chromatographic analysis; bp 74—78°C/6 mmHg, n_D^{30} 1.4679), and (4) pulegone (from Tokyo Kasei, Inc.; bp 98°C 6 mmHg, n_D^{30} 1.4880, d_{30}^{30} 0.9731, $[\alpha]_D^{25}$ +20°).

Separation of Isopulegol. The cyclization product (154 g) which was obtained under the conditions (Run 4) shown in Table 1 was treated with 400 ml of a 35% sodium hydrogen sulfite solution at 40°C for 3 hr. The reaction mixture was then cooled to room temperature and extracted with 300 ml of benzene. The benzene layer was washed with an aqueous sodium carbonate solution and with water, and then dried over sodium sulfate. Upon the removal of the benzene, the oily product was distilled *in vacuo* to give a fraction of bp 72—90°C/4 mmHg (124 g), together with the residue (9.2 g); the former was found to be a mixture of 1.8% pulegone and 98.2% isopulegol isomers (20.2% neo-iso, 70% iso, and 8.0% iso-isopulegol); while the latter exhibited no peak in its gas chromatogram. From the aqueous sodium hydrogen sulfite solution, 12 g of citronellal used recovered.

Results and Discussion

The results obtained at 200°C are given in Table 1. Table 1 shows that, among the catalysts used here, Raney Nickel and Ni-diatomaceous earth were ineffective. The Cu-Cr and Cu-Cr-Mn catalysts, without hydrogen treatment, gave higher cyclization yields. The latter catalyst (Run 4) was most useful; the yield with it was 80% of the theoretical value. Using the Cu-Cr-Mn catalyst, further studies were then undertaken at 160°C, 180°C, and 200(±1)°C. Figure 1 and Table 2 show some of these results. In Table 2, the results obtained without a catalyst are also given. From these results, the rate of reaction was found to be first order with respect to the concentration of citronellal (see Table 2). The activation energies for the catalytic and non-catalytic reactions were

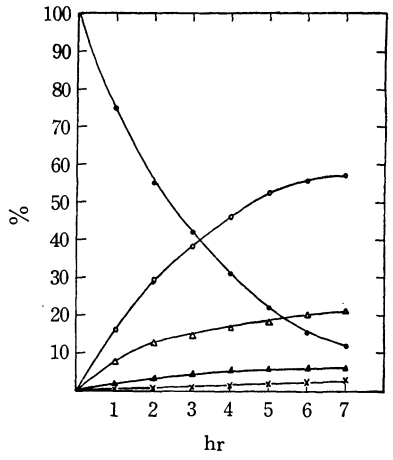

Fig. 1. The composition of reacting mixture *vs.* reaction time, using Cu-Cr-Mn catalyst (1 wt%) without H_2 pretreatment; reaction temperature 200°C; ● citronellal, ○ isopulegol, △ neo-isopulegol, ▲ iso-isopulegol, × pulegone.

estimated to be 17.2 kcal/mol and 20.4 kcal/mol, respectively.

Table 2. Rate constant K and activation energy E

Reaction temperature °C	K*, $sec^{-1} \times 10^5$	
	Cu-Cr-Mn (1% by weight) without H_2 treatment	Thermal reaction without catalyst
200	10.3	8.14
180	4.01	3.41
160	1.37	1.19
Activation energy obtained from Arhenius plots E	17.2 kcal/mol	20.4 kcal/mol

* $K = 1/t \cdot \log(100/(100-X))$
X: Weight percent of remaining citronellal

It has become obvious that the Cu-Cr and Cu-Cr-Mn catalysts without hydrogen treatment have a catalytic activity for the cyclization. The reaction process with the Cu-Cr-Mn catalyst without hydrogen treatment may proceed according to the thermal isomerization mechanism already proposed by Ohloff.[6]

Oxidation of Dihydrothiophenes with Iodosobenzene*[1]

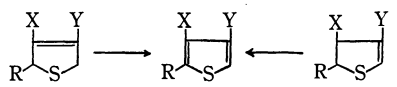
Takao TAKAYA, Satoru HIJIKATA and Eiji IMOTO

Department of Applied Chemistry, School of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received February 26, 1968)

In a previous paper,[1] we have reported that the oxidation of 3,4-disubstituted 2,5- and 4,5-dihydrothiophenes with 30% hydrogen peroxide in acetic acid or with perbenzoic acid in chloroform gives the following results: 1) when both of the two substituents attached to the 3- and 4- positions are electron-withdrawing, oxidation with 30% hydrogen peroxide in acetic acid tends to produce the corresponding thiophene derivatives; 2) when one of two substituents is electron-withdrawing and the other is electron-releasing, the oxidation tends to produce the corresponding sulfone derivatives, and 3) the oxidation of 2,5- and 4,5-dihydrothiophenes with perbenzoic acid in chloroform produces mainly the corresponding sulfone derivatives.

In this paper, we will report that the oxidation of 3,4-disubstituted 2,5- and 4,5-dihydrothiophenes with iodosobenzene in dioxane gives the corresponding thiophene derivatives (III) without any dependence on the nature of the substituent, as is shown in Table 1. This finding is in contrast with that concerning the oxidation with 30% hydrogen peroxide in acetic acid or with perbenzoic acid in chloroform.



I II III

A probable mechanism for the formation of the thiophene, III, is as follows: the 3,4-disubstituted dihydrothiophenes, I or II, are oxidized by iodosobenzene[2] to the corresponding sulfoxide derivatives, which are then dehydrated to the thiophene derivatives, III.

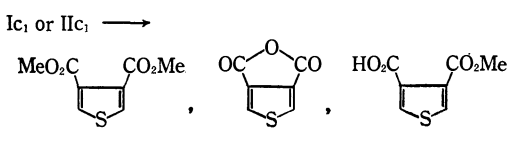
*2 Mp 145—146.[5]

The other interesting fact is that the reaction of 3,4-dimethoxycarbonyl-2,5- and 4,5-dihydrothiophene (Ic_1 and IIc_1) with iodosobenzene afforded thiophene-3,4-dicarboxylic acid anhydride (IV) and 3-carboxy-4-methoxycarbonylthiophene (V) as by-products in addition to the main product, 3,4-dicarbomethoxythiophene ($IIIc_1$). When Ic_1 was treated in dry toluene with iodosobenzene using a 1 : 1 ratio, two products, $IIIc_1$ and V, were isolated, in 81 and 14% yields respectively. The similar treatment of IIc_1 gave $IIIc_1$ (73%) and V (11%). When a 1 : 2 ratio of Ic_1 or IIc_1 to iodosobenzene was used in dry dioxane; a mixture of $IIIc_1$ and IV was obtained, along with a trace of V. The approximate ratio[3] of the mixture of $IIIc_1$ and IV was in a range from 8 : 2 to 9 : 1. Neither IV nor V was obtained in



$IIIc_1$ IV V

3) The approximate molar ratio of the two derivatives in the mixture was estimated by comparing the infrared spectra of the reaction mixture with those of a mixture of the authentic samples, $IIIc_1$ and IV, the relative concentrations of $IIIc_1$ and IV being varied correspondingly.

the reaction of $IIIc_1$ with iodosobenzene.

All the starting materials, 3,4-disubstituted 2,5- or 4,5-dihydrothiophenes, I or II, and the authentic samples, $IIIa_1$, $IIIa_2$, $IIIb_1$, $IIIb_2$ and $IIIc_1$, were prepared according to the methods described in the previous paper.[1]

Experimental

A General Procedure for the Oxidation of I and II by Iodosobenzene. A mixture of the 3,4-disubstituted dihydrothiophene, I or II (10 mmol), and iodosobenzene (11 mmol) in dry dioxane (30 m*l*) was refluxed for 12 hr in a stream of nitrogen gas. After the solvent and iodobenzene had then been removed *in vacuo*, the residue was distilled under reduced pressure or recrystallized from an appropriate solvent to give the corresponding thiophene, III, whose properties were identical in every respect with those of the authentic sample.

Reaction of 3,4-Dimethoxycarbonyl-2,5- and 4,5-dihydrothiophene, Ic_1 and IIc_1. *In Toluene.* A solution of 1.01 g (5 mmol) of IIc_1 and 1.21 g (5.5 mmol) of iodosobenzene in 20 m*l* of dry toluene was gently refluxed for 6 hr in a stream of nitrogen gas. After the solvent and iodobenzene had then been carefully removed *in vacuo*, the residue was distilled to give 0.81 g (81%) of $IIIc_1$, bp 125—127°C/3 mmHg. After the distillation of the $IIIc_1$, the residue was sublimed under a pressure of 0.2 mmHg at the bath temperature of 120°C to give 0.31 g (14%) of V, mp 105—109°C.

In a similar manner, 0.73 g (73%) of $IIIc_1$ and 0.10 g (11%) of V were obtained from 1.01 g of Ic_1 and 1.21 g of iodosobenzene.

In Dioxane. A solution of 3.06 g (15 mmol) of IIc_1 and 6.6 g (30 mmol) of iodosobenzene in dry dioxane (60 m*l*) was refluxed for 12 hr in a nitrogen stream. After the evaporation of the solvent and iodobenzene, the residue was distilled at 80—100°C/0.2 mmHg to give a mixture (2.22 g) of $IIIc_1$ and IV. A trace of V was obtained by the sublimation of the residue remaining after the distillation of the above mixture.

In a similar manner, a mixture (2.0 g) of $IIIc_1$ and IV was obtained, along with a trace of V, from 3.02 g of Ic_1 and 6.6 g of iodosobenzene.

Preparation of the Authentic Samples of the Oxidation Products, $IIId_1$, $IIId_2$, $IIIe_1$, $IIIe_2$ and $IIIf_1$. The following procedure is representative of those used for the preparation of 3-ethoxycarbonyl-4-ureidothiophene ($IIId_1$) and 2-methyl-3-ethoxycarbonyl-4-ureidothiophene ($IIId_2$). A mixture of 3-ethoxycarbonyl-4-ureido-2,5-dihydrothiophene (Id_1, 10 mmol) and chloranil (11 mmol) was refluxed for 12 hr in dry toluene (20 m*l*). The reaction mixture was then cooled, washed with a dilute sodium hydroxide solution and with water, and then evaporated to dryness *in vacuo*. Several recrystallizations from ethyl acetate gave the pure product. The yields of $IIId_1$ and $IIId_2$ were 40 and 35%, respectively.

The following procedure is representative of those used for the preparation of 3-ethoxycarbonyl-4-ethoxycarbonylaminothiophene ($IIIe_1$), 2-methyl-3-ethoxycarbonyl-4-ethoxycarbonylaminothiophene ($IIIe_2$), and 3-ethoxycarbonyl-4-methoxythiophene ($IIIf_1$). A mixture of 3-ethoxycarbonyl-4-ethoxycarbonylamino-2,5-dihydrothiophene (Ie_1, 10 mmol) and chloranil (11 mmol) in dry toluene (20 m*l*) was refluxed for 6 hr. After the evaporation of the solvent *in vacuo*, the residue was diluted with chloroform (5 m*l*). The chloroform solution was chromatographed on alumina (20 g) using a mixture of chloroform and petroleum ether[4] (5 : 1) as an eluent. After the evaporation of the solvent, the residue was distilled *in vacuo* to give the product. The yields of $IIIe_1$, $IIIe_2$, and $IIIf_1$ were 80, 65 and 40% respectively.

Thiophene-3,4-dicarboxylic Acid Anhydride IV. The anhydride IV was prepared in a 67% yield by refluxing thiophene-3,4-dicarboxylic acid ($IIIa_1$)[1] with acetyl chloride for 4 hr according to the method of Sice.[5]

3-Carboxy-4-methoxycarbonylthiophene V. A solution of 1.0 g of IV in 10 m*l* of absolute methanol was refluxed for 1 hr. After the solvent had then been removed *in vacuo*, the residue was recrystallized to give 0.84 g (70%) of V.

The physical properties and analytical data for $IIId_1$, $IIId_2$, $IIIe_1$, $IIIe_2$, $IIIf_1$, IV and V are summarized in Table 2.

Absorption Spectra of Cation Radicals Derived from *p*-Phenylenediamine and Its *N*-Methyl Derivatives

Yôichi IIDA and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 9, 1968)

The cation radical salts made by the one-electron oxidation of aromatic diamines have been the subject of interest for many years. Naturally, considerable attention has been paid to their magnetic properties. In connection with our spectroscopic study of the solid salts, we examined the absorption spectra of the cation radicals derived from *p*-phenylenediamine and all the *N*-methyl derivatives in a dilute ethanol solution. The spectra of the same cations were examined by Michaelis *et al.* nearly thirty years ago.[1] Unlike us, however, they oxidized the diamines in a methanol+dilute aqueous solution of acetic acid with bromine and examined the spectra without isolating the salts. Their measurements were very qualitative and covered only the α band. Therefore, we wish to present here a brief summary of our measurements.

The following solid salts were prepared by the methods given in the references[2-4]: *p*-phenylenediamine bromide (I), *N*-methyl-*p*-phenylenediamine bromide (II), *N,N*-dimethyl-*p*-phenylenediamine bromide (III), *N,N'*-dimethyl-*p*-phenylenediamine perchlorate (IV), *N,N,N'*-trimethyl-*p*-phenylenediamine iodide (V), and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine perchlorate (VI).

The measurements were performed at room temperature, using a Beckman DK-2A spectrophotometer, on ethanolic solutions at concentrations of the order of 10^{-5} mol/*l*.

All the spectra bear a close resemblance to each other and show the general features shown schematically in Fig. 1. The positions and molar extinction coefficients (ε) of the three electronic absorption bands, designated as α, β and γ, are summarized in Table 1.

The structures of the α bands are regarded as vibrational.[5] The α band shows a remarkable red-shift upon the introduction of the methyl group (about 1 kK per group), while the other two bands are nearly independent of the number of the substituent.

The agreement between our positions and those reported by Michaelis *et al.*[1] is fair. Accurate measurements of the molar extinction coefficients are much hampered by the instability of the salts. Moreover, in the case of the *p*-phenylenediamine cation the presence of a small amount of the dimeric

Wave number (kK)

Fig. 1. General feature of the spectra of the cation radicals derived from *p*-phenylenediamine and its *N*-methyl derivatives.

form, indicated by a peak around 16.4 kK, hinders the estimation.[6] The values in parentheses must, therefore, be considered no more than rough estimates.

A simple molecular orbital consideration of the *p*-phenylenediamine cation shows that the odd electron is in the orbital of the b_{3g} symmetry. The transitions associated with the α, β, and γ bands are $^2B_{3g}\rightarrow{}^2B_{1u}$, $^2B_{3g}\rightarrow{}^2A_u$ and $^2B_{3g}\rightarrow{}^2B_{1u}$, respectively. Thus, from symmetry considerations the transition moments in the α and γ bands appear to be along the long axis of the molecular ion, and that in the β band, along the short axis. It is gratifying to see that this prediction agrees well with the results obtained by Albrecht and Simpson, by means of polarized photo-oxidation in a rigid medium, for the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine cation.[5]

Excess Volumes of Binary Solutions Containing Some Diketones

Koichiro NAKANISHI,*1 Hidekazu TOUHARA,*1 Kohei SATO and Makoto NAGAO

Department of Industrial Chemistry, Shinshu University, Wakasato, Nagano

(Received March 22, 1968)

As part of thermodynamic studies on binary solutions containing diketones, the excess volumes of the following four systems have been measured at 25.00°C. They are acetylacetone(2,4-pentanedione)-acetone, acetylacetone-isopropanol, acetonylacetone(2,5-hexanedione)-acetone, and acetonylacetone-isopropanol. Acetylacetone is one of those molecules which exhibit keto-enol tautomerism. It is frequently used as a substrate of metal complex in coordination chemistry. The purpose of this study is to examine a combined effect of size difference in polar molecules and keto-enol equilibrium on the thermodynamic excess functions, in this particular case, on the excess volume.

Experimental

All the sample liquids were purified by distillation under nitrogen atmosphere and/or at reduced pressure. The final purified liquids obtained from the middle fraction gave no peaks due to impurities on gas chromatogram. The density measurements were done by the pycnometry described in our previous report.[1]

Results and Discussion

The densities of the four systems studied are shown in Table 1. The excess volumes which were calculated from the density data are also given in the same table and are plotted as a function of mole fraction in Fig. 1. The excess volumes of acetone-isopropanol system, calculated from the density data given by Parks and Chaffee,[2] are also included. The solid lines in Fig. 1 are based on the values calculated by the following equation,

$$\Delta V^E = x_1(1-x_1)\sum_{n=0}^{2} A_n(1-2x_1)^n \qquad (1)$$

where the constants A_n's were estimated by the method of least-squares. The data for acetonylacetone-acetone system show fairly large scatter owing to a high relative volatility and viscous nature of one component. The results for other systems are satisfactory.

The results shown in Fig. 1 may be summarized as follows:

*1 Present address: Department of Industrial Chemistry, Kyoto University, Kyoto.

1) K. Nakanishi, N. Kato and M. Maruyama, *J. Phys. Chem.*, **71**, 817 (1967).

2) G. S. Parks and C. S. Chaffee, *ibid.*, **31**, 439 (1927).

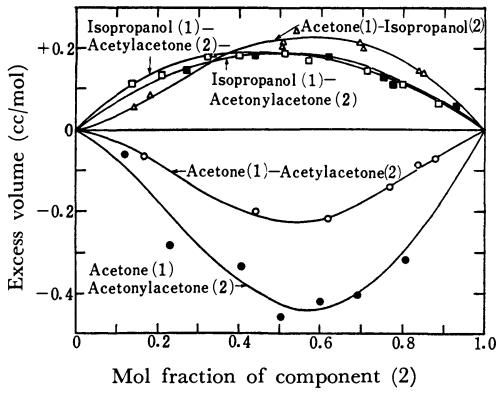

Fig. 1. Excess volumes at 25.00°C.

1) In binary systems containing isopropanol, the excess volumes are positive and their values coincide almost completely with each other.

2) Since the molar volume ratio of acetone, acetylacetone and acetonylacetone is 1.00 : 1.40 : 1.60, the first two can be regarded approximately as dimers of acetone molecule. The excess volumes of the systems containing acetone and diketones are negative and their absolute value increases with the molar volume difference.

Owing to the lack of adequate theory for such polar and associated solutions, quantitative evaluation of the present data is difficult. However, it is interesting to compare them with the results for mixtures of nonpolar molecules. For mixtures of nonpolar molecules, it is found by Brønsted and Koefoed[3] that the absolute value of the excess volume changes regularly with the size difference (principle of congruence). According to the available experimental evidences,[4-6] the magnitude of the excess volume is proportional to the size difference. On the other hand, the sign of the excess volume is dependent of the shape of molecules. For example, negative excess volume is observed for mixtures of molecules of similar shape such as *n*-alkane-*n*-alkane,[4] and an opposite result is obtained for mixtures of molecules of different shape (*e. g.*, cyclohexane-*n*-alkanes[5] or *trans*-decalin-*n*-alkane[6]).

Synthetic Studies Starting from β-Cyanopropionaldehyde. VI.*1 The Synthesis of α-Cyanomethylacrolein

Sadayoshi SATSUMABAYASHI and Shinichi MOTOKI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received March 22, 1968)

As a part of synthetic studies starting from β-cyanopropionaldehyde (β-CPA) (I), the synthesis of a new vinyl compound, α-cyanomethylacrolein (VI) containing an aldehyde group and a nitrile group, will be presented in this paper. Two synthetic methods illustrated in Fig. 1 have been used.

The reaction of the diethyl acetal of β-CPA (II) with acetyl chloride caused an exchange of ethoxy group for chlorine leading to obtain α-ethoxy-γ-cyanopropyl chloride (III). This reaction was carried out at room temperature, but the reaction was difficult to control and a large amount of tar was formed above 60°C. Treatment of this chloride (III) in dry diethyl ether with an excess of anhydrous pyridine gave ethyl γ-cyanopropenyl ether (IV), which was also obtained by heating II with phthalic anhydride with loss of ethyl alcohol from II. As the boiling point of this product was not so different from that of II, several times of fractional distillation were required. When dibutyl acetal was used in place of II, the corresponding butyl derivative was obtained. A reaction of IV with diethyl formal in the presence of boron trifluoride etherate as a catalyst was carried out, and the reaction mixture obtained was directly hydrolyzed with hydrochloric acid to give α-cyanomethylacrolein (VI). In these successive reactions, V was regarded as an intermediate,[1] but it was not really isolated.

Some examples of the reaction of acetals with vinyl ethers were reported by Hoaglin,[1] but formaldehyde acetal was not used for this reaction. As stated above, however, it was found that formaldehyde diethyl acetal undergoes the same reaction with vinyl ether as diethyl acetal of other aldehydes containing more than two carbon atoms does.

The IR spectrum of the product (VI) showed the characteristic absorptions of unconjugated nitrile at 2250 cm^{-1}, of α,β-unsaturated aldehyde at 1693 cm^{-1} and of the carbon-carbon double bond at 1640 cm^{-1}. Moreover, the structure of VI was confirmed by the NMR spectrum, as illustrated in Fig. 2.

On the other hand, the labile hydrogen at the α-position of the aldehyde group of β-CPA was readily removed by condensation with both formaldehyde and an amine as in the Mannich reaction. When morpholine or piperidine was used as the amine component, a Mannich base was obtained and subsequent thermal decomposition of the base gave VI. When dimethylamine was used, however, no Mannich base was obtained.

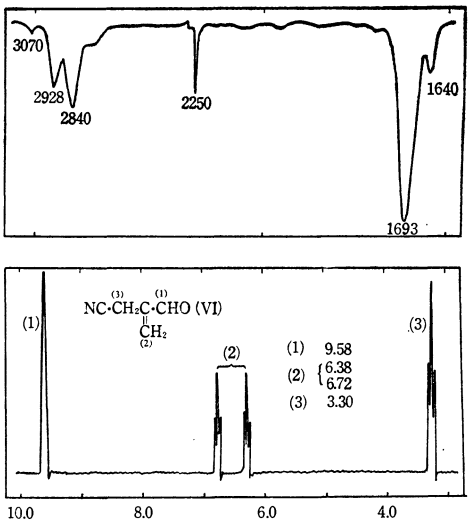

Fig. 2. The IR and NMR spectra of VI.
A Varian A-60 NMR spectrometer was employed using tetramethylsilane as an internal standard.

Experimental

α-Ethoxy-γ-cyanopropyl Chloride (III). To 31.4 g (0.2 mol) of β-CPA diethyl acetal, 23.6 g (0.3 mol) of acetyl chloride was added slowly at about 20°C, and the mixture was stirred for 5 hr at room temperature. By fractional distillation, 23.0 g of III was obtained, bp 68—70°C/3 mmHg, yield 78.0%. Found: C, 48.65; H, 7.07; N, 9.73%. Calcd for $C_6H_{10}ONCl$: C, 48.82; H, 6.83; N, 9.49%.

Ethyl γ-Cyanopropenyl Ether (IV). Under an anhydrous condition, 29.5 g (0.2 mol) of III was added slowly to 39.5 g (0.5 mol) of pyridine at room temperature. After the solution was stirred for 6 hr, the reaction mixture was extracted with ether, washed with water and dried. Distillation of the extract gave 9.4 g of IV, bp 60—61°C/4 mmHg, yield 42.3%. Found: C, 64.92; H, 8.33; N, 12.74%. Calcd for C_6H_9ON: C, 64.84; H, 8.16; N, 12.60%.

A mixture of 157 g (1 mol) of II and 177.6 g (1.2 mol) of phthalic anhydride was heated at 150°C for 8 hr, and filtered. The filtrate was then distilled and the fraction boiling at 55—75°C/4 mmHg was collected. When this fraction was redistilled two more times, 31.4 g of IV was obtained, bp 60—62°C/4 mmHg, yield 28.5%. Found: C, 64.55; H, 8.11; N, 12.89%. Calcd for C_6H_9ON: C, 64.84; H, 8.16; N, 12.60%.

Similarly, 26.8 g of *n*-butyl γ-cyanopropenyl ether was obtained from 106.5 g (0.5 mol) of β-CPA dibutyl acetal, bp 83—85°C/4 mmHg, yield 38.5%. Found: C, 68.81; H, 9.60; N, 10.14%. Calcd for $C_8H_{13}ON$: C, 69.03; H, 9.41; N, 10.06%.

α-Cyanomethylacrolein (VI) from IV. A mixture of 22.2 g (0.2 mol) of IV and 31.2 g (0.3 mol) of diethyl formal was stirred. To this mixture was added 1.0 g of boron trifluoride etherate in 10 m*l* of diethyl ether, with the internal temperature kept at about 20°C. After 10 hours' stirring, the catalyst was neutralized with good agitation by 4 g of anhydrous sodium carbonate during a period of 4 hr. The reaction mixture thus obtained was refluxed with 100 m*l* of 5% hydrochloric acid for 8 hr. The product was extracted with ether, washed with water and dried. Distillation gave 3.5 g of VI, bp 96—98°C/20 mmHg, yield 18.4%. Found: C, 63.02; H, 5.25; N, 14.61%. Calcd for C_5H_5ON: C, 63.15; H, 5.30; N, 14.73%.

α-Cyanomethylacrolein (VI) from I. Into a solution of 41.5 g (0.5 mol) of β-CPA (I) dissolved in 50 m*l* of water, a solution of 61.8 g (0.5 mol) of morpholine hydrochloride and 50 g of 37% formaline was added over a two-hours' period, the temperature being maintained at about 65°C. After another 8 hours' stirring, the solution was neutralized with potassium carbonate, extracted with chloroform and the extract was dried. Dry hydrogen chloride was run into the extract, then the yellowish white Mannich base was precipitated as its hydrochloride. This crude Mannich base was placed in a Claisen flask and heated gently for half an hour using an oil bath, the temperature of which was maintained at about 150°C. At the end of this period, the system was placed under a reduced pressure of about 20 mmHg. The fraction which boiled at 70—110°C/20 mmHg was collected, washed with water, extracted with ether and the extract was dried. After redistillation, 7.5 g of VI was obtained, bp 96—97°C/21 mmHg, yield 15.8% based on I. Found: C, 62.96; H, 5.47; N, 14.75%. Calcd for C_5H_5ON: C, 63.15; H, 5.30; N, 14.73%.

Mannich reaction was also carried out with piperidine instead of morpholine. Yield 18.0%.

The authors wish to thank Professor Yojiro Tsuzuki for his helfpul advice and encouragement.

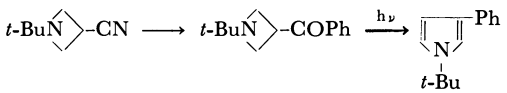
Preparation and Photolysis of 1-*t*-Butyl-3-benzoylazetidine

Teng-Yueh CHEN[1]

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 16, 1968)

A photo-induced ring expansion of 1-*t*-butyl-2-phenyl-3-benzoylazetidine to 1-*t*-butyl-2,4-diphenylpyrrole has recently been reported by Padwa *et al.*[3] Since this is the first example of the conversion of an azetidinyl ketone into the corresponding substituted pyrrole, further study was carried out with 1-*t*-butyl-3-benzoylazetidine (II), which had been synthesized by the reaction of 1-*t*-butyl-3-cyanoazetidine (I)[3] with phenylmagnesium bromide.



I II III

The infrared spectrum of the azetidinyl ketone II shows a carbonyl band at 1680 cm^{-1} and is quite consistent with the proposed structure. The formations of 2,4-dinitrophenylhydrazone and the picrate of the azetidinyl ketone II and their analytical data all support the assigned structure.

A dilute solution of II in ethanol was irradiated through a Pyrex filter with a high-pressure mercury lamp to give the corresponding 1-*t*-butyl-3-phenylpyrrole (III). The structure of III was determined by comparing the IR and NMR spectra with those data obtained by Padwa *et al.*[2] The infrared spectrum of the distilled product exhibits some small peaks between 3080—3030 cm^{-1} and sharp peaks at 1605, 1555, 1500, 750, and 693 cm^{-1} for the characteristic absorptions of phenyl and the pyrrole ring. The strong absorptions of the tertiary butyl group appear at 1245 and 1225 cm^{-1}. The NMR spectrum of the product exhibits a sharp singlet at τ 8.54 (9H) for the *t*-butyl group, and three signals of doublet of doublet at 3.77 (1H), 3.40 (1H), and 3.12 (1H) for the three protons at the 4, 5, and 2-positions of the pyrrole ring. The phenyl group on the pyrrole ring appears between 2.6 and 3.06 (5H) as a multiplet.

Isomerization was not observed when an alcoholic solution of II was warmed in the presence of boron trifluoride etherate or when the ketone II was heated at 254°C or at 340°C.

Experimental[4]

1-*t*-Butyl-3-benzoylazetidine (II). A solution of 5.4 g (0.039 mol) of I in 7 m*l* of absolute ether was stirred into a cooled solution of phenylmagnesium bromide prepared from 2.5 g (0.12 mol) of magnesium and 21 g (0.13 mol) of bromobenzene in 80 m*l* of absolute ether. After the completion of the addition, the reaction mixture was stirred for another four hours and then set aside overnight at room temperature. The reaction mixture was decomposed with about 100 m*l* of ice water and extracted four times with a total of 200 m*l* of ether. After drying over magnesium sulfate, the ether was removed and the residue was distilled to give 3.5 g (40% yield) of a colorless liquid; bp 140—144°C/ 3 mmHg, n_D^{25} 1.5062. IR: 3060, 1600, 1580, 700 cm^{-1} (C_6H_5), 1680 cm^{-1} (CO), 1240 and 1225 cm^{-1} (*t*-Bu).

Found: C, 77.72; H, 8.75; N, 6.11%. Calcd for $C_{14}H_{19}NO$: C, 77.38; H, 8.81; N, 6.45%.

2,4-Dinitrophenylhydrazone of II: mp 88—89.5°C.

Found: C, 60.89; H, 5.90; N, 17.36%. Calcd for $C_{20}H_{23}N_5O_4$: C, 60.44; H, 5.83; N, 17.62%.

Picrate of II: mp 157.5—159.5°C.

Found: C, 54.11; H, 4.96; N, 12.64%. Calcd for $C_{20}H_{22}N_4O_8$: C, 53.81; H, 4.97; N, 12.55%.

Photolysis of II. A solution of 0.5 g of II in 100 m*l* of 99% ethanol was irradiated through a Pyrex filter with a 100 W high-pressure type mercury lamp under a nitrogen atmosphere for seventeen hours. After the removal of the ethanol under reduced pressure, the residue was distilled *in vacuo* to give 0.1 g of a colorless liquid; bp 120—124°C/1 mmHg. The product was positive to a pine-splinter test (red color).

Found: C, 83.93; H, 8.76; N, 6.83%. Calcd for $C_{14}H_{17}N$: C, 84.37; H, 8.60; N, 7.03%.

The author is indebted to Professor Masaki Ohta and Dr. Hiroshi Kato for their discussions and to Miss Mizuko Yoshida for the measurement of the NMR spectra.

SHORT COMMUNICATIONS

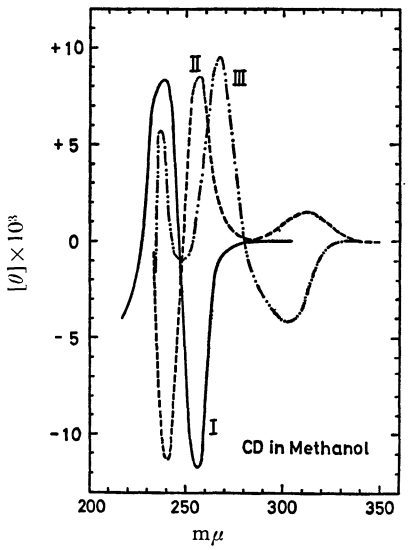
Die Absolutkonfiguration des Melleins

Hisao ARAKAWA

Science Education Institute of Osaka Prefecture, Karitacho, Sumiyoshiku, Osaka

(Eingegangen am 10. Juli, 1968)

Aus der Kulturlösung von *Aspergillus melleus*[1] wurde ein Dihydroisocumarin-Derivat, Mellein (I) isoliert, das optisch aktiv ist und mit Ochracin aus der Kulturlösung von *Aspergillus ochraceus* identisch ist.[2] Die Struktur wurde synthetisch sichergestellt.[3] Die Absolutkonfiguration wurde nun mit Hilfe des Circulardichroismus bestimmt.



Neuerdings hat der Verfasser die Absolutkonfiguration von anderen Dihydroisocumarin-Derivaten, Phyllodulcin (II)[4] und Agrimonolid (III),[5] bestimmt und diese Verbindungen zeigten in beiden Fällen einen positiven CD um 257—268 mμ (in Methanol), der mit der K-Bande des konjugierten Enlactons zusammenhängt.[5]

Mellein (I) und Phyllodulcin(II) enthalten einen Salizylsäure-Rest als Chromophor, aber einerseits zeigte II einen positiven CD bei 257 mμ, anderseits zeigte I einen negativen CD bei 257 mμ (in Methanol).

Danach, unter der Annahme, daß große Substituent am Dihydroisocumarin äquatoriale Konformation einnimt, muss Mellein (I) das (3R)-konfigurierte Dihydroisocumarin-Derivat sein. Diese ist ähnlich der Beziehung zwischen dem CD um 260 mμ und der Absolutkonfiguration der Parasorbinsäure (IV).[6]

Separation of Cr(III)-Hexacyanoferrate(II)-Complexes by Sephadex Column Chromatography*1

Yoshio MATSUMOTO, Michiko SHIRAI and Hiroko SAITO

Department of Chemistry, Faculty of Hygienic Science, Kitasato University, Minato-ku, Tokyo

(Received May 18, 1968)

The color reaction between chromium(III) ions and potassium hexacyanoferrate(II) has attracted the attention of the several investigators.[1-6] However, reaction products have not been isolated because of their great solubility in water. The chemical compositions of the products remain undetermined after a variety of electroanalytical and spectrophotometric investigations were carried out applying a continuous variation method.[4-6]

In the present work, employing a chromatographic method using Sephadex columns, at least three complex compounds differing with each other in color, chemical composition and molecular size were separated from the reaction mixture. The mixture obtained by reacting potassium hexacyanoferrate(II) with Cr(III) ions (chrome alum) in a molar ratio of 5 : 1 for one hour in an aqueous solution at 47°C, when applied to a Sephadex G-25 column, gave a bluish-green fraction eluting first and a reddish-brown one eluting second, the unreacted hexacyanoferrate(II) and sulfate ions remaining behind in the column. After repeating chromatography a further three times, the second fraction appeared to be pure, not only in paper electrophoresis but in further subjection to chromatography with Sephadex of a smaller pore size. The first fraction, giving two components in paper electrophoresis, was definitely separated when further applied to Sephadex G-75 or G-100 columns, into two fractions, blue and green. Each proved to be a definite constituent in paper electrophoresis and in any further application to a Sephadex column of larger pore size. The three substances separated all consisted of K, Cr, Fe and CN. The reddish-brown and green substances permeated a cellophane film, while the blue substance did not, being confirmed of high molecular size.

The reddish-brown substance was the main product in which more than 90% of the reacted Cr(III) ions were contained, and was the smallest of the three substances in molecular size. It proved on electrophoretic and polarographic examination[3] to include a negatively charged complex ion containing Cr, Fe and CN. The reddish-brown solution described above was evaporated to dryness *in vacuo* in a rotary evaporator at 30°C, and the composition of the resulting solid film was determined by elementary analysis to have the empirical formula $K_5CrFe_2(CN)_{12}\cdot 7H_2O$.

Found: K, 24.2; Cr, 6.5; Fe, 13.8; C, 17.6; N, 20.7; H_2O, 15.1%. Calcd for $K_5CrFe_2(CN)_{12}\cdot 7H_2O$: K. 24.5; Cr, 6.5; Fe, 14.0; C, 18.1; N, 21.1; H_2O, 15.7%.

The same three components separated from reaction mixtures as long as the molar ratio of the reactants, potassium hexacyanoferrate(II) to Cr(III) ions, remaining not below 2.5. The elution diagram in Fig. 1 illustrates the chromatographic separation of the reddish-brown complex on a Sephadex G-25 column from the reaction mixture resulting at a reactant ratio of 2.5.

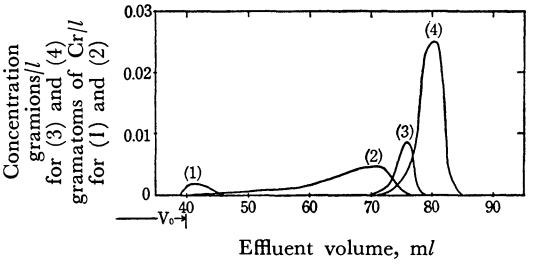

Fig. 1. Separation of the reaction mixture resulting from the mixture containing the reactants in the molar concentrations of 0.076 for $KCr(SO_4)_2$ and 0.19 for $K_4Fe(CN)_6$.
Sephadex G-25, fine (particle size 20—80 microns)
Column dimensions: dia. 2 cm, length 27 cm
Sample volume: 0.8 ml Eluant: Water
Elution velocity: 98 ml/hr Temp: 26°C
(1) Bluish green (In this curve the concentration was exaggerated for distinctness.)
(2) Reddish brown
(3) Hexacyanoferrate(II) ion
(4) Sulfate ion

Details on the products at varying reactant ratios, as well as the results of a structural study, will be presented later.

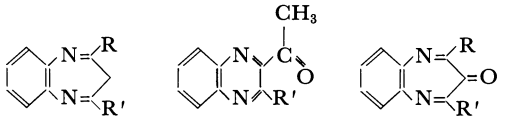
Photooxidation of Some 1,5-Benzodiazepines

Teijiro YONEZAWA, Masakatsu MATSUMOTO and Hiroshi KATO

Department of Hydrocarbon Chemistry, Kyoto University, Kyoto

(Received June 10, 1968)

It has been reported that 1,5-benzodiazepines (I) are oxidized to 3-acylquinoxalines (II) with monopersulfuric acid or with peracetic acid, but do not give 3,6-diaza-4,5-benzotropones (III). Syntheses of the ketones (III) have been attempted by several workers, but no attempts have been successful.[1,2]



(I) (II) (III)

a: R, R'=CH_3 a: R'=CH_3 a: R, R'=CH_3
b: R=CH_3, R'=C_6H_5 b: R'=C_6H_5 b: R=CH_3, R'=C_6H_5
c: R, R'=C_6H_5 c: R, R'=C_6H_5

This communication will report that 3,6-diaza-4,5-benzotropones (III) can be prepared by the photooxidation of 1,5-benzodiazepines (I) in a non-aqueous medium.

The compound (I-c) in a 4% benzene solution was irradiated with a low-pressure mercury arc under an oxygen atmosphere for 20 hr. After this irradiation, the reaction mixture was chromatographed on silica gel in benzene. Thus a ketone (IV) and an amide (V) were obtained in yields of 1.4% and 2.0%, respectively.

The ketone (IV) consisted of pale yellow needles melting at 120—121°C. The infrared spectrum in KBr showed the absorption of the carbonyl group at 1680 cm^{-1}. The NMR spectrum in $CDCl_3$ simply showed two multiplets centered at τ= 2.0 and 2.6. The ultraviolet spectrum in ethanol showed λ_{max} at 264 mμ (ε=19200), 297 (11300), and 333 (8910). The mass spectrum[3] showed a parent peak at *m/e* 310 and a fragment peak at *m/e* 282 which was probably produced through the elimination of the carbonyl group of the parent ion. On the basis of these results, the ketone (IV) was identified as 2,7-diphenyl-3,6-diaza-4,5-benzotropone (III-c). This compound was very unstable and easily formed 2,3-diphenylquinoxaline by decarbonylation in warm concentrated sulfuric acid or in warm acetic acid.[4]

The amide (V) consisted of colorless needles which melted at 301°C; it was identified as dibenzoyl-*o*-phenylenediamine. The infrared spectrum in KBr showed $\nu_{C=O}$ at 1649 cm^{-1}.

In the case of the photooxidation of 2,4-dimethyl-1,5-benzodiazepine(I-a) in benzene, the corresponding benzotropone (III-a) was not obtained; the ring contraction products, 2-acetyl-3-methylquinoxaline (II-a) and 2-hydroxy-3-methylquinoxaline (VI), were obtained in yields of 29% and 4%, respectively.

2-acetyl-3-methylquinoxaline (II-a) consisted of colorless needles which melted at 87°C after crystallization from aqueous ethanol. The infrared spectrum showed $\nu_{C=O}$ 1668 cm^{-1} in KBr.

As in the oxidation of (I-a) with peracids, in the photooxidation of (I-a) the quinoxaline (II-a) might be produced through the 6-oxo intermediate (III-a). We presumed that the quinoxaline (II-a) might be produced *via* either Scheme I or II;

In Scheme I, as has been described in the work of Barltrop *et al.*,[1] the 6-oxo intermediate (III-a) is hydrolyzed in the first step.

In Scheme II, the benzotropone (III-a) formed under the action of ultraviolet light is subjected to the second photochemical reaction.

Hydrogen-Deuterium Exchange in the Methyl Group of Diammine-bis-(acetylacetone)ethylenediimine-cobalt(III) Chloride in Deuterium Oxide Solution

Hayami YONEDA* and Yukiyoshi MORIMOTO**

* *Department of Chemistry, Wakayama University, Masagocho, Wakayama*

** *Research Laboratories, Fujisawa, Pharmaceutical Company, Kashimacho, Higashiyodogawa-ku, Osaka*

(Received June 18, 1968)

We have reported several papers on the study of the proton magnetic resonance spectra of a series of cobalt(III) complexes.[1] In this communication we should like to report hydrogen-deuterium exchange found in the study of the proton magnetic resonance spectra of diammine-bis(acetylacetone)-ethylenediimine-cobalt(III) chloride $[Co(NH_3)_2$-acac-en$]Cl$[2] dissolved in deuterium oxide, where

acac-en=

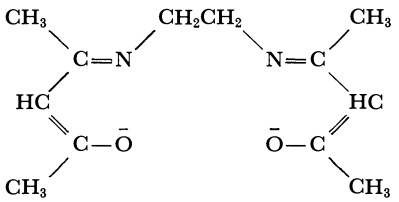

Figure 1 shows the spectra of the complex. Curve (a) represents the spectrum of the complex dissolved in neutral deuterium oxide. Putting aside a large peak due to HOD (the second peak from the left-hand side), the spectrum consists of four peaks, whose assignments can be made by considering their relative intensities. The small peak on the extreme left (I) is assigned to the CH proton, the peak in the middle (II) to the CH_2CH_2 protons, and the two peaks of equal intensities on the right (III, III') to the two kinds of CH_3 protons. Addition of a few drops of concentrated NaOD solution caused a slight downfield shift of all four peaks and, at the same time, a time-dependency of intensity of peaks I and III as shown in curves (b), (c), and (d). The CH peak on the extreme left decreased its intensity markedly after standing one hour and disappeared completely after 72 hr. This fact indicates that the hydrogen atom of the CH had been replaced by deuterium. This exchange can be expected, since several electrophilic substitution reactions of the CH of the acetylacetonato complexes have been reported.[3] In addition to this, the inspection of curve (d) reveals another exchange. Here one of the two CH_3 peaks (III) is markedly smaller than the other (III'). Since the two CH_3 signals should have an equal intensity, this inequality can be interpreted as a result of the deuterium exchange in one of the two CH_3 groups. To ascertain this interpretation, the solution was kept at 100°C for 10 min to accelerate the exchange. As shown in curve (e), one of the two CH_3 peaks disappeared almost completely. Thus the above interpretation proved to be valid. The latter exchange is very interesting, because it provides an example where the CH_3 protons also can be activated by chelation.

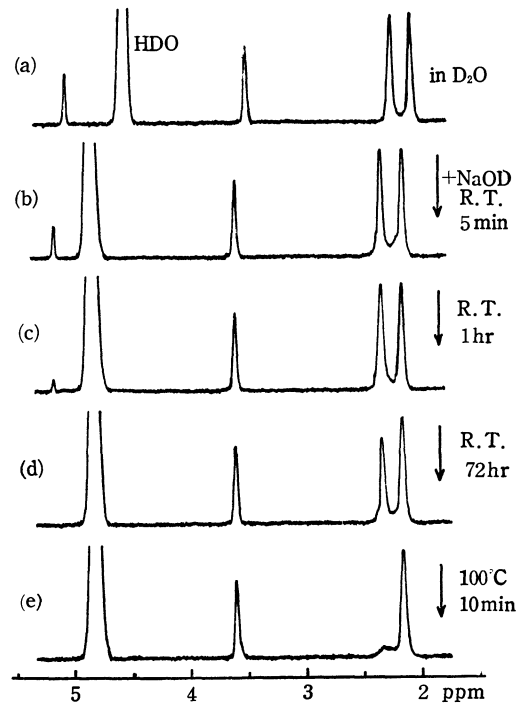

Fig. 1. The PMR spectra of $[Co\ acacen(NH_3)_2]Cl$ in D_2O, recorded by Varian A-60 spectrometer. Tetramethylsilane was used as an external standard.

We are now working on complexes of other metal ions to see the effect of the central metal ion on the exchange. The details of the investigation will be reported elswhere.

Raman Effect in Ferroelectric Sodium Nitrite Crystal

Masamichi TSUBOI,* Minoru TERADA** and Teruo KAJIURA***

* *Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

** *Mitsubishi Atomic Power Industries, Inc., Omiya, Saitama*

*** *Japan Electron Optics Laboratory, Company, Nakagami, Akishima, Tokyo*

(Received June 24, 1968)

The Raman effect in sodium nitrite ($NaNO_2$) crystal has been observed by the use of the continuous helium-neon and ionized argon lasers as sources.[1] Several single crystals in the ferroelectric phase C_{2v}^{20}-*Im*2*m* of $NaNO_2$ were obtained through the kindness of Dr. S. Hirotsu and Mr. K. Suzuki, Tokyo Institute of Technology. The instruments used were a Perkin-Elmer Model LR-1 Laser-Excited Raman Spectrometer and a Spex 1400II Spectrometer.

In the first four columns of Table 1, a part of the result of our experiment is given. Here, the orientations of the crystal, directions of the incident and scattered beams, and the directions of the electric vectors of the incident and scattered beams were fixed so that all of the nine Raman-active fundamental frequencies (*i. e.* $3A_1+1A_2+2B_1+3B_2$) should be observed and that, for A_1, B_1, and B_2-type vibrations, frequencies of the pure transverse vibrations should be observed. In the fifth and sixth columns of Table 1, resonance frequencies are given, which were derived from the result of a recent measurement of the infrared reflectivity as the parameters characterizing the dielectric dispersion of this crystal.[2] On the basis of these data, all of the fundamental frequencies of the expected nine optically-active (in-phase), transverse vibrations have now been fixed. The translatory vibrations along the b and a axes are considered to cause only very small polarizability oscillation in the crystal in comparison with the rotatory vibrations of the NO_2^- ion. Therefore, it is probable that the Raman scatterings corresponding to these vibrations are not detected in our present experimental set up. This was taken into account in the assignments which are given in the last column of Table 1.

Besides what are given in the second column of Table 1, various orientations of the incident and scattered beams have been examined, and in many cases appreciably different frequencies from what are given in the third column of Table 1 have been observed. In the c(bc)a (instead of a(bc)b) orientation, for example, the B_2 frequencies are observed at 158, 172, and 1307 cm^{-1} (instead of 158, 191, and 1230 cm^{-1}). From such frequencies, we can obtain an information of the polarization forces[3] besides the elastic forces in the crystal.

TABLE 1. OPTICALLY-ACTIVE (TRANSVERSE) VIBRATIONS IN THE $NaNO_2$ CRYSTAL WITH THE C_{2v}^{20} SYMMETRY

Enhancement of Hydrogen Adsorption on an Acetone-covered Nickel Catalyst

Yutaka KUBOKAWA, Hisashi MIYATA and Mitsuhiko MINOBE

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka

(Received July 20, 1968)

In order to obtain information on the nature of the adsorption complex during the hydrogenation of acetone on metal catalysts, the interaction of hydrogen with acetone adsorbed on a silica-supported nickel catalyst (15 wt % Ni) was investigated. On the catalyst which had already adsorbed acetone it was found that the amount of hydrogen adsorbed was increased markedly compared to the adsorption on the cleaned catalyst. Such an enhanced adsorption of hydrogen was an activated process, its rate being increased with increasing temperature. The activation energy of adsorption was determined as 10—13 kcal/mol in the temperature range 0—20°C. Adsorption equilibrium was almost attained after several hours at 20°C. The increase in the amount of hydrogen adsorbed at equilibrium q_{H_2} was proportional to the amount of acetone previously adsorbed q_A as seen in Fig. 1. The ratio of q_{H_2} to q_A was 0.83 at 20°C.[1] After the adsorption of hydrogen, the hydrogen remaining in the gas phase was removed by Töpler pump at 0°C. The temperature of the catalyst was raised up in stages, the desorbed gas being collected. It was found that by evacuation at 0°C 25 per cent of the hydrogen adsorbed was removed while after evacuation at 50°C only 20 per cent of the hydrogen adsorbed remained on the surface. On the other hand, the amounts of acetone and isopropyl alcohol appearing in the gas phase during such experiments were very small even at 50°C.[2] Such behavior suggests that hydrogen is held relatively weakly on the acetone-covered nickel surface.

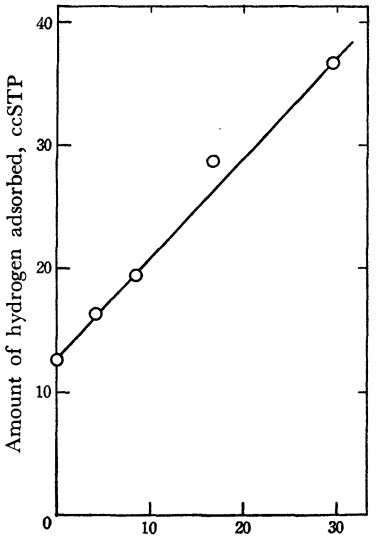

Fig. 1. Adsorption of hydrogen on the acetone-covered surface.
The amount of catalyst and the equilibrium pressure were 6.67 g and 20 mmHg, respectively.

The infrared spectra of the adsorbed layer were investigated by means of an apparatus similar to that used by Peri.[3] When hydrogen was admitted to the acetone-covered surface, no new bands due to hydrogen adsorption were detected, and in addition, little or no change in the band at 1706 cm^{-1} due to the C=O stretching vibration, was observed. The spectra obtained were completely different from those with the surface which had adsorbed isopropyl alcohol.

The results described above suggest the formation of an acetone-hydrogen complex on the nickel catalyst when hydrogen is adsorbed at room temperature in the presence of acetone. In the temperature range above 80°C at which formation of isopropyl alcohol takes place considerably, the situation may be somewhat different. It seems necessary, however, to take into consideration the formation of such an acetone-hydrogen complex when we work out the mechanism of the hydrogenation of acetone.

1) Such an increase in the hydrogen adsorption caused by the preadsorbed acetone was also found for a non-supported nickel catalyst.

2) The desorbed products were analyzed gas chromatographically by using a 2 m polyethylene glycol column at 65°C.

Reduction Process of Silver(I) Oxide By Ethylene in the Presence of Oxygen

Toshiro YAMASHINA and Masahiro SEO

Faculty of Engineering, Hokkaido University, Sapporo

(Received July 26, 1968)

It has been postulated by several workers[1-3] that the some particular species of surface oxygen on silver catalyst may be reactive for the partial oxidation of ethylene. In order to reveal the property of the species, it is of interest to study the reaction process of silver oxide with ethylene. In the present report, the reaction velocity was found to be considerably accerelated by the presence of oxygen in ethylene, an optimum pressure of oxygen being found to give the maximum velocity.

The CP grade Ag_2O powder was used as the sample of silver oxide in the experiment. Gravimetric analysis by hydrogen reduction showed that the sample contains the nonstoichiometric excess oxygen of 7.8%, *i. e.*, $Ag_2O_{1.078}$. The reaction gases were prepared by redistillating the cylinder grade ethylene (99.8%) and oxygen (99.9%) at liquid nitrogen temperature. The reaction velocities were measured in all glass, closed system (1800 m*l*) of a Gulbransen type microbalance with a sensitivity of 6.34×10^{-7} g/div. (1 div.=0.01 mm).

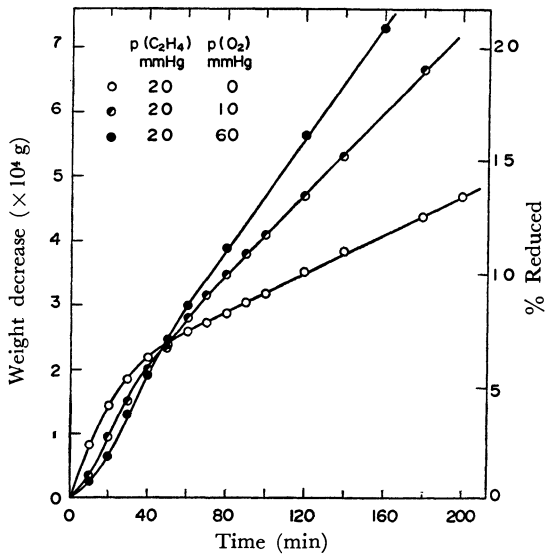

Fig. 1. Typical reaction curves of silver(I) oxide with ethylene and oxygen (170°C).

The reaction experiments were performed in duplicate and were found to be quite reproducible. Figure 1 shows typical results for the reaction of silver oxide (100 mg) with ethylene of 20 mmHg at 170°C in the presence of oxygen. The progress of the reaction with the time was followed by a complicated form in the initial 50 min. It was found that after about 8% reduction of silver oxide sample, the reaction became to proceed linearly with time in any case. The reaction rate constants are shown in Fig. 2 as a function of the oxygen

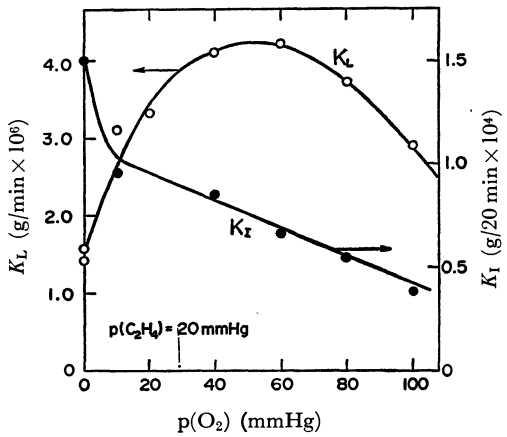

Fig. 2. Reaction velocities as a function of oxygen pressure under a constant pressure of ethylene (170°C).

pressure, where K_I is the reduced amount with the reaction during initial 20 min while K_L is the reaction velocity estimated from the slope of the linear part subsequent to the initial process of 50 min. It is noted that K_I and K_L values changed in much different ways with the oyxgen pressure, K_I being decreased with the pressure while in the curve for K_L the maximum reaction rate being observed in about 50 mmHg of oxygen pressure. No changes in weight of the silver oxide sample were found in pure oxygen (50 mmHg) at 170°C. It is of particular interest that the reaction of silver oxide with ethylene could be accelerated by the coexisting oxygen in the certain partial pressure. It would appear that a coupled reaction of oxidation-reduction on the surface occurred to accelerate the reaction of silver oxide with ethylene.

Major Source of Intensity in the $n\pi^*$ Transition of Aromatic Carbonyls

Martin Vala, Jr.,*[1] and Jiro TANAKA

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received July 26, 1968)

The problem of the major source of intensity in the nominally orbitally forbidden, spin allowed $n\pi^*$ transitions in aromatic carbonyl compounds has been investigated by several authors.[1-3] However, no conclusive evidence has been presented in support of either of the two most probable mechanisms: (1) Herzberg-Teller vibronic coupling and (2) delocalization of the carbonyl n and/or π^* orbitals onto the substituents.

We report here the main conclusions of our investigation on the polarized absorption spectrum of the spin-allowed $n\pi^*$ transition in single crystals of 4,4'-dichlorobenzophenone (DCBP) at room and liquid helium temperatures. Details of this work and further work on the singlet-triplet absorption and emission will be reported later.

Our major findings are discussed below. (1) The $n\pi^*$ transition is exclusively polarized in the carbonyl plane and parallel to the carbonyl axis. From this finding we may immediately reject vibronic coupling *via* non-totally symmetric b-type modes and magnetic dipole allowed transitions as possible source of intensity since a perpendicular-to-CO polarization is expected for these mechanisms. It is not possible to eliminate vibronic coupling *via* totally symmetric (a) vibrational modes, as they will have parallel-to-CO polarization. Indeed, there is evidence that several weaker vibronic bands observed in the structure-rich $n\pi^*$ band are gaining intensity in this manner. (2) The 0-0 transition is observed as a very sharp band ($\simeq 2$ cm^{-1} wide) at 26552 cm^{-1}. A careful study of thick crystals (up to 2.5 mm) at room and liquid helium temperatures failed to reveal any absorption to the red of this band which could be assigned to a singlet-singlet transition. The 0-0 transition is followed by a long ($\simeq 10$ member) progression of broad vibronic bands of 38 cm^{-1} spacing. These observations are strongly indicative of the intrinsic allowed electronic character of the $n\pi^*$ transition. (3) The appearance of a large number of sharp vibronic origins upon which are built 38 cm^{-1} progressions of varying length is a prominent feature of the 4.2°K spectrum. We interpret these progressions as due to the totally symmetric in-phase torsional oscillations of the phenyl rings about their long axes. The fact that such oscillations can be observed in the $n\pi^*$ transition is direct experimental proof of the delocalization of the carbonyl n and/or π^* orbitals onto the phenyl rings.

We may write the wave function for the perturbed carbonyl n and π^* orbitals as:

$$\Psi_n{}^{\dagger} = \phi_n + \lambda_\pi{}'\phi_\pi{}'$$

$$\Psi_\pi{}^{*\dagger} = \phi_\pi{}^* + \lambda_\pi{}^{*\prime}\phi_\pi{}^{*\prime}$$

where ϕ_n and $\phi_\pi{}^*$ are the unperturbed carbonyl orbitals and $\phi_\pi{}'$ and $\phi_\pi{}^{*\prime}$ are the substituent pi orbitals. $\lambda_\pi{}'$ and $\lambda_\pi{}^{*\prime}$ are the first order mixing coefficients, for example:

$$\lambda_\pi{}' = \frac{\langle \phi_n | V | \phi_\pi{}' \rangle}{\varepsilon_n - \varepsilon_\pi{}'}$$

Here ε_n and $\varepsilon_\pi{}'$ are the respective orbital energies. Now writing the transition moment integral to first order, we find:

$$\langle \Psi_n{}^{\dagger} | \vec{R} | \Psi_\pi{}^{*\dagger} \rangle =$$

$$\lambda_\pi{}^{*\prime} \langle \phi_n | \vec{R} | \phi_\pi{}^{*\prime} \rangle + \lambda_\pi{}' \langle \phi_\pi{}' | \vec{R} | \phi_\pi{}^* \rangle$$

Thus the $n\pi^*$ transition gains electronic allowed character from intramolecular CT transitions in so far as the perturbation coefficients are non-zero, *i. e.*, as long as there is finite overlap of the carbonyl orbitals with the phenyl orbitals. The intensity of the $n\pi^*$ transition is directly dependent on the magnitude of this mixing. Since the mixing is a first order effect, it will be inversely proportional to the energy separation between the $n\pi^*$ and intramolecular CT transition.

To further test this explanation we have determined the $n\pi^*$ intensities of three different compounds in this class, whose $n\pi^*$ and intramolecular CT transition energy separations are dissimilar. From these energy differences, we predict the $n\pi^*$ intensity to decrease in the order 4,4'-dimethoxybenzophenone > DCBP > benzophenone.[3] Observation gave $f=0.006$, 0.004 and 0.0024, respectively, as predicted. This result leads to the overall conclusion of our work that the $n\pi^*$ transition in symmetric aromatic carbonyl compounds is formally electronically allowed and gains the major component of its intensity by mixing with the intramolecular CT transition.

Spectroscopic Investigation of Foreign Gas Effect upon CO_2 Laser Frequencies

Isao SUZUKI* and Shigeko SUZUKI**

* *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo*

** *Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo*

(Received August 6, 1968)

Under CW (continuous wave) operating conditions in a CO_2 laser, the laser action normally occurs on a few P-branch transitions of the 10.6 μ band of CO_2. Wood and Schwarz[1] observed that introduction of sulfur hexachloride gas to a cell placed within the cavity causes the laser oscillations to shift to a few R-branch transitions. We have found that similar phenomena occur in a wide variety of organic and inorganic gases as well as in SF_6. Not only were the frequencies of the laser transitions dependent upon the foreign gases employed, but they were found very sensitive to the pressures of given gases. With some foreign gases of appropriate pressures within the cavity we have also observed the CW laser oscillations in a few P-branch lines of the 9.6 μ band: a Fermi resonance partner of the 10.6 μ band.

The experimental setup is similar to that reported by Wood and Schwarz[1] and will be described in detail elsewhere.[2] The gases were introduced to a 10 cm cell with KCl windows which was placed inside the cavity. The spectroscopic studies were made with a Perkin-Elmer 112G grating spectrophotometer with a KBr foreprism.[3] Part of our results is shown in Table 1 and in Fig. 1.

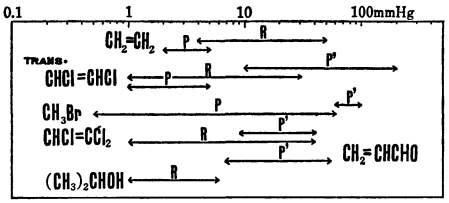

Fig. 1. Dependence of laser frequencies on the vapour pressures of foreign gases. (P' refers to the P-branch of the 9.6 μ band.)

In most cases, our results can be interpreted simply from the absorbances of given gases in this region. A good example is sulfur hexafluoride shown in Table 1. This molecule absorbs strongly in the P-branch region of the 10.6 μ band, much less strongly in the R-branch region, and it has practically no absorption in the P-branch region of the 9.6 μ band. This explains rather remarkable changes in its oscillation frequencies with the gas pressures. This interpretation seems to hold for the most gases observed. Similar results were also obtained when some liquids were introduced in a liquid cell inside the cavity. However, ammonia and methyl bromide seem to be exceptions. In the case of NH_3 gas (85 mmHg), the usually strong P(20) line was completely missing from the emmis on spectrum, whereas no strong absorption seems to be present at the corresponding frequency. Even when the pressure of NH_3 was reduced to 7 mmHg, the P(20) line was the weakest among the transitions in the P-branch region. This result may be related to a near coincidence of the laser line with one of vibration-rotation transitions of NH_3. The 2sQ(4,2) line which Garing *et al.* reported at 944.14 cm^{-1} is most likely to coincide with the P(20) line at 944.18 cm^{-1}. This band is very weak in intensity, however, a close matching in frequency may suppress the laser oscillation of the particular line involved. It may also be the case with methyl bromide.

TABLE 1. THE EFFECT OF FOREIGN GASES ON THE OSCILLATION OF CO_2 LASER
(in approximate order of intensisties)

(a) NH_3 Pressure (mmHg)	10.6 μ band P-branch	10.6 μ band R-branch	(b) SF_6 Pressure (mmHg)	10.6 μ band P-branch	10.6 μ band R-branch	9.6 μ band P-branch

Chromatographic Behavior of Magnesium and Ethylenediaminetetraacetate Ions, and Their Complex on Sephadex G-15 Column

Norimasa YOZA, Takayuki OGATA, Yôichiro UENO and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 8, 1968)

Several investigations concerning the chromatographic behavior of inorganic species on columns of Sephadex[1,2] (cross-linked dextran) and Bio-Gel[3] (cross-linked polyacrylamide) have recently been reported. From the fact that in general the chemical species on the Sephadex column were eluted in the order of decreasing molecular weight (or molecular size) the principle of this method has been explained in terms of molecular sieving effect[4] in the gel phase. The elution volume, V_e, of individual species in column operation is characterized by the equation

$$V_e = V_0 + K_d V_i \qquad (1)$$

where V_0 represents the void volume, V_i the internal volume and K_d a fraction of internal volume available for the solute.

In column operation of the equilibrium system such as Mg+EDTA⇌Mg-EDTA, where magnesium and ethylenediaminetetraacetate (EDTA) ions interact rapidly to form magnesium ethylenediaminetetraacetate complex, it is required to characterize the behavior of metal complex in addition to that of metal and ligand ions. The present paper describes briefly the behavior of magnesium and EDTA ions, and their complex eluted on a Sephadex G-15 column ($1.5\phi \times 56.5$ cm) at room temperature with 0.1 M sodium chloride solution as an eluent. Sample solutions for three chemical species were prepared by dissolving magnesium chloride, disodium ethylenediaminetetraacetate and disodium magnesium ethylenediamintetraacetate in 0.1 M sodium chloride solution, respectively.

The observed elution volumes and K_d values (calculated by Eq. (1)) of four species are shown in Table 1, together with those of Blue Dextran (molecular weight=2000000) and tritiated water which were used as standard materials of K_d=0 and 1, respectively. Both magnesium and EDTA ions gave symmetrical elution curves when 0.01 M sample solutions were individually eluted. However, the peak skewing became more remarkable with increase of the sample concentration, which might be ascribed to the nonlinear isotherm. It resembles type III of Brunauer *et al.*[5] but is in contrast with adsorption behavior of calcium ion on cation exchanger.[6]

TABLE 1. ELUTION VOLUMES AND K_d VALUES ON SEPHADEX G-15 COLUMN
(Flow rate: 20—30 ml/hr, Volume of fraction: 1.02 ml)

Chemical species	V_e, ml	K_d
Blue Dextran	35.7	0.00
EDTA ion	45.9	0.22
Magnesium-EDTA complex	50.0	0.31
Magnesium ion	64.3	0.62
Sodium ion	70.4	0.76
Tritiated water	81.6	1.00

The sample composed of equimolar concentrations (0.05 M) of magnesium and EDTA ions gave a more complicated elution profile because of the partial dissociation of magnesium-EDTA complex into two reactants which migrated on the Sephadex column with different velocities. However, a sharp, well-defined elution peak of magnesium-EDTA complex was obtained by differential analysis (complexiometric titration) of three components. The complex showed an elution position of molecular size slightly smaller than free EDTA ion. Graphic representation of their behavior will be presented in the near future.

Phosphorescence of Crystalline Pyrazine: Emission due to Crystal Defects

Tohru AZUMI, Yasuko NAKANO and Mitsuo ITO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received August 13, 1968)

Phosphorescence of crystalline pyrazine at 4°K is considerably more complex when compared with the solution spectrum. The onset of the phosphorescence spectrum of a vacuum sublimed pyrazine crystal, which is shown in Fig. 1a, consists of several dozen bands. In this communication we present experimental evidences which reveal that all of these bands are due to pyrazine at some crystalline defects; this observation is in contrast to the interpretation given recently by Moomaw and El-Sayed.[1] The present paper also aims to point out the importance of the sample preparation in the measurements of crystal emission.

Of the bands shown in Fig. 1a we focus our attention to the highest energy weak band, labeled A, and to the relatively intense and sharp bands, B,C···, and G. All of these bands constitute progressions of 606, 759, 953, 1012 and 1254 cm^{-1}. In view of the agreement of these values with the observed Raman frequencies[2] it is certain that all of the above-mentioned bands are due to pyrazine, and not to some chemical impurities.

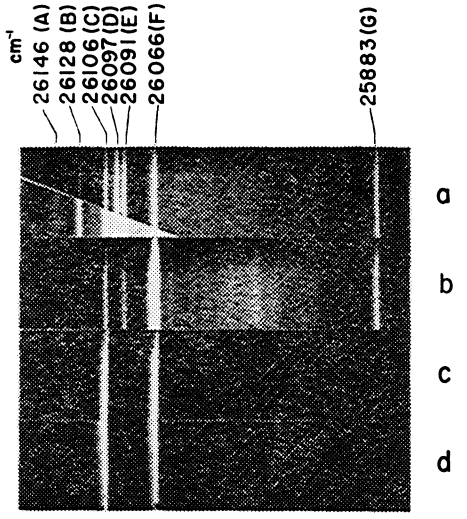

Fig. 1. Phosphorescence spectrum of crystalline pyrazine at 4°K. Spectrum for vacuum sublimed sample, shown in a), changes by successive continuation of zone-melting as shown in b), c) and d).

The vacuum sublimed sample, for which the phosphorescence shown in Fig. 1a is obtained, is subject to zone-melting. Phosphorescence spectra observed at various stages of zone-melting are shown in Fig. 1b, c and d. As is clear from Fig. 1 in the earlier stage of zone-melting bands B and D are weakened. By further continuation of zone-melting bands E and G also are weakened, and finally, only bands C and F remain intense. These observations lead us to conclude that those bands which disappear by the zone-melting process, which is nothing but a repetition of slow crystallization, are due to pyrazine at some crystal defects. The nature of the remaining bands C and F, which are 40 and 80 cm^{-1} apart, respectively, from the highest-energy band A, remains unsolved. However, since no ground state phonons of these frequencies exist, we believe that these bands are also due to crystal defects, which are very difficult to remove.

Moomaw and El-Sayed[1] interpreted the bands shown in Fig. 1a to be due to the coupling with the ground state phonon. They state that bands E and F are[3] due to two strongly coupled phonons of 57 and 86 cm^{-1}. Disagreeing with these authors, we emphasize, in the first place, that the former band is to disappear by zone-melting process, and secondly, that for the latter band the energy separation of 80 cm^{-1} (which is accurate to within 1 cm^{-1}) from band A is greatly different from the observed Raman frequency of 86 cm^{-1} (which is accurate to within 2 cm^{-1}) at 4°K and can, is no way, be correlated with the phonon.[4]

In further support of the above conclusion, phosphorescence lifetimes are obtained for bands E and F, separately, and the results are 19 and 22 msec, respectively. Such different decay behavior alone can unambiguously verify the fact that the emitting states are different for these bands.

2) M. Ito and T. Shigeoka, *ibid.*, **44**, 1001 (1966).

3) Wave numbers given by Moomaw and El-Sayed[1] are different from ours by about 10 cm^{-1}. This difference is probaly caused by the two factors: a) These authors *apparently* did not convert to the wave numbers *in vacuo*. b) The errors of the wave numbers given by these authors[1] amount to 3 cm^{-1}.

4) It is probably the large wave number errors (as much as 3 cm^{-1}) inherent to the work of Moomaw and El-Sayed[1] which have led these authors to the interpretation different from ours.

Synthesis of Pyrrole Nucleosides by Photodehydrogenation of a Δ^3-Pyrroline Derivative

Masajiro KAWANA and Sakae EMOTO

Rikagaku Kenkyusyo (The Institute of Physical and Chemical Reseach), Yamato-machi, Kita-Adachi-gun, Saitama

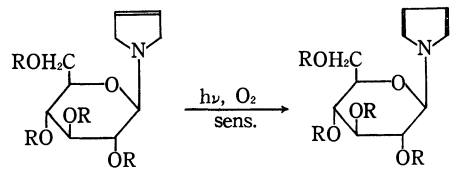
(Received August 6, 1968)

Although extensive studies of the synthesis of the nucleosides of heterocycles have been carried out by many workers, simple pyrrole nucleosides have been neglected. Plisov[1] reported that when a mixture of glucose and pyrrole was heated, a probable product (mp 190°C) formed by the condensation of the two was obtained after crystallization from pyridine. However, its structure was unsubstantiated by experimental details or physical data.

We wish to report the synthesis of pyrrole nucleosides by means of a novel photochemical dehydrogenation of a Δ^3-pyrroline derivative. D-Glucose was heated with Δ^3-pyrroline[2] (2 mol eq.) without solvents at 80—85°C to produce 1-(D-glucosy)-Δ^3-pyrroline (I) in a 74% yield, the structure being tentatively identified; mp 130—135°C (decomp.), $[\alpha]_D^{20}$ −28.8°(4 min) → +13.0° (46 hr, constant, *c* 0.40, H_2O). 60-Mc NMR (in D_2O); τ 4.23 2H), singlet, olefinic protons). Found: C, 51.78; H, 7.14; N, 6.09%. Calcd for $C_{10}H_{17}O_5N$: C, 51.94; H, 7.41; N, 6.06%.

On acetylation with acetic anhydride in pyridine, I gave 1-(2',3',4',6'-tetra-*O*-acetyl-β-D-glucopyranosyl)-Δ^3-pyrroline (II) in a 73% yield; mp 121—122°C, $[\alpha]_D^{25}$ −23.7° (*c* 0.49, degassed $CHCl_3$). Found: C, 54.10; H, 6.05; N, 3.51%. Calcd for $C_{18}H_{25}O_9N$: C, 54.13; H, 6.31; N, 3.51%. The site of the glycosidic linkage of the pyrroline ring and the pyranose structure were confirmed by, respectively, the IR spectrum of II and the degradation of II with aqueous formic acid to the known 2,3,4,6-tetra-*O*-acetyl-D-glucose. The NMR spectrum (in $CDCl_3$) was consistent with the structure of II. The methylene and olefinic protons of the pyrroline ring appeared as a singlet at τ 6.22 and 4.32 respectively. The anomeric proton was observed as a doublet centered at τ *ca.* 5.7 (J=*ca.* 8 cps), thus indicating the β configuration.

After a solution of II in benzene containing benzophenone as a sensitizer[3] had been irradiated[4] externally in a Pyrex vessel under bubbling O_2 at 20°C for 1 hr, the TLC analysis of the reaction mixture showed the presence of one main product as well as of several minor by-products. The evaporation of the benzene gave, after recrystallization from ethanol, 1-(2',3',4',6'-tetra-*O*-acetyl-β-D-glucopyranosyl)pyrrole (III) in a 85% yield; mp 178—178.5°C, $[\alpha]_D^{22}$ −10.9° (*c* 0.67, $CHCl_3$). UV; λ_{max}^{EtOH} 211 mμ (ε 8150). Found: C, 54.53; H, 5.73; N, 3.52%. Calcd for $C_{18}H_{23}O_9N$: C, 54.40; H, 5.83; N, 3.53%. A reagent useful for dehydrogenation, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone, was also effective in obtaining III from II in the dark.



I: R=H
II; R=$COCH_3$
III: R=$COCH_3$
IV: R=H

The NMR spectrum (in $CDCl_3$) of III showed two characteristic triplets, centered at τ 3.83 and 3.21, indicative of the presence of the pyrrole ring. The position of the 2'-acetyl signal (τ 8.15) was at a higher field than the other acetyl signals (τ 7.99—7.93), as has been observed in the case of acetylated nucleosides.[5]

The deacetylation of III with sodium methoxide in methanol afforded 1-(β-D-glucopyranosyl)pyrrole (IV) (76% yield) as a hygroscopic glassy mass after chromatography on a silica-gel column (ethyl acetate-ethanol, 4 : 1); mp *ca.* 80°C, $[\alpha]_D^{25}$ +10.3° (*c* 0.74, H_2O). UV; $\lambda_{max}^{H_2O}$ 210 mμ (ε 6950). Found: C, 52.15; H, 6.38; N, 6.09%. Calcd for $C_{10}H_{15}O_5N$: C, 52.39; H, 6.60; N, 6.11%. Its purity was ascertained by GLC and TLC analyses. The NMR spectrum (in D_2O) exhibited two characteristic triplets centered at τ 3.74 and 3.01 for the protons of the pyrrole ring, and a doublet centered at τ 4.86 (J=8.4 cps) for the anomeric proton. Therefore, the β configurations of III and IV were assigned. Further investigations are in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2553—2557 (1968)

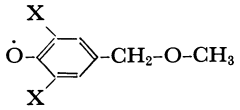
Solvent and Temperature Effects on the Proton hfs in the ESR Spectra of the Organic Radical

Shigeyuki AONO and Masahiko SUHARA

Department of Chemistry, Faculty of Science Kanazawa University, Maru-no-uchi, Kanazawa

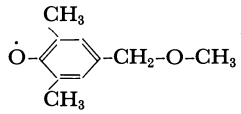
(Received January 25, 1968)

A theoretical investigation is made into the solvent and temperature effects on the proton hfs in the ESR spectra of such organic radicals as:



where X stands for the CH_3 group, in several solvents. Both effects are explained on the assumption that a molecular complex is formed between radical and solvent, so that the charge-transfer occurs from radical to solvent: The solvent effect is caused by the fact that, in various solvent molecules, slight changes take place in their lowest vacant levels, which are occupied by the electron transferred from the radical; on the other hand, the temperature effect is explained by the thermal motion of the molecules, which changes the probabilities of the radical being in the solvated state and in the free state.

Recently, experimental observations were made by Deguchi[1] of the proton hfs in the ESR spectra of such phenoxyl radicals as:



under various conditions. The results are shown in Table 1.

TABLE 1. THE METHYLENE PROTON HFS CONSTANTS

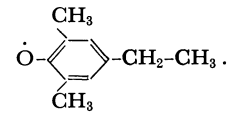
a) at room temperature and in various solvents

Solvent	Coupling const. (gauss)
n-Hexane	11.68
Benzene	12.00
Toluene	12.25
o-, *m*-, *p*-Xylene	12.50
Mesitylene	12.70

b) in tetrahydrofuran at two different temperatures

Temperature (°C)	Coupling const. (gauss)
−54	12.88
9	12.29

These results indicate, in short, that the proton hfs constants increase with an increase in the number of methyl substituents in solvent molecules, and with a decrease in the temperature. However, no such behavior of the coupling constants was not observed in another type of radical:



Therefore, we can presume that these phenomena are responsible for the existence of the lone-pair electrons in the oxygen of the methoxy group. Further it should be pointed out that the solvents used here are known to be non-polar.

Mechanism

First of all, we assume that a sort of molecular complex between radical and solvent is formed. It then seems reasonable to assume that the charge-transfer from the oxygen lone-pair of the methoxy group in the radical to the lowest vacant level of the solvent molecule is a characteristic property responsible for the change in the proton hfs constants in the radical, since radicals which have no lone pair never behave thus. On the above assumptions, our theoretical procedures are as follows: The charge-transfer brings about a change in the coulomb term of oxygen by the amount of α'_O, which in turn alters the odd-electron density at the methylene proton by q'_M. Using the standard perturbation procedure, we then obtain:

$$q'_M = 2\alpha'_O c_{iO} c_{iM} \sum_{j \neq i} c_{jO} c_{jM}/(\varepsilon_i - \varepsilon_j), \qquad (1)$$

where ε_j is the orbital energy of the jth level, and where the ith level represents, especially, the level

1) Y. Deguchi, private communication.

for the odd electron, to the zeroth approximation. c_{jO} and c_{jM} are the LCAO coefficients of the jth orbital at the positions of the oxygen atom and the methylene H_2 group respectively. Here it must be noted that the H_2 or H_3 in the methylene or methyl group respectively gives a pseudo-π orbital constructed of 1s atomic orbitals. The radical in question is a π-radical, so that the odd electron occupies, to a good approximation, the highest occupied level of the mother molecule. In the perturbation calculation shown by Eq. (1), the main contributions should be those from the levels closest to the previous one. It follows from a simple investigation that the ith level is nearly the zero level, having a little of the bonding character due to the deeper coulomb terms of the oxygen in both the methoxy and phenoxy groups; the closest two levels, which are refered to the jth and j'th levels, corresponding to those occupied and vacant respectively, may be expected to show, roughly, the pairing property. Taking into account the facts that the contribution from the jth level exceeds than that from the j'th, and also that the oxygen atom of the methoxy group and the methylene H_2 belong to the same class (in the sense of classification to put star or unstar in the alternant hydrocarbon), the coefficient of α'_O in Eq. (1) must be positive. Therefore, we rewrite Eq. (1) as:

$$q'_M = C_1\alpha'_O, \quad C_1 > 0. \tag{2}$$

It can be seen that the sign of C_1 depends upon the position of the proton under consideration.

Since the value of the proton hfs is proportional to the odd-electron density at that position, a change in the latter produces one in the former with the same proportionality constants:

$$a'_M = C_2q'_M, \quad C_2 > 0. \tag{3}$$

Next, let us discuss α'_O in relation to solvent molecules. It is assumed that the radical in question combines to some extent with the solvent molecule. There being several ways in which the molecular complex may originate, the charge transfer from radical to solvent will be picked up as a property responsible for the above-mentioned phenomena.

The ground-state wave function of this complex, to the zeroth approximation, is written as non-bonding, $\Psi_0(R, S)$, where R and S represent radical and solvent respectively. In the higher approximation, the dative structure denoted by $\Psi_1(R^+, S^-)$ will mix with $\Psi_0(R, S)$ to make a more accurate ground state[2]:

$$\Psi = \Psi_0(R, S) + \lambda\Psi_1(R^+, S^-). \tag{4}$$

Here the mixing parameter, λ, is determined by the perturbation method to be:

$$\lambda = H_{01}/\Delta E_{01}, \tag{5}$$

where, using the electronic Hamiltonian H,

$$\left.\begin{aligned} E_{01} &= H_{00} - H_{11} - e^2/r\sigma, \\ H_{ij} &= (\Psi_i|H|\Psi_j). \end{aligned}\right\} \tag{6}$$

In the above, r is the distance between the radical and the solvent, and σ the dielectric constant of the solvent.

As a result, the charge density at the oxygen atom of the methoxy group is reduced by the factor of the normalization factor of Eq. (4), namely $(1+\lambda^2)^{-1}$. Then we have:

$$q'_O \propto (1 + \lambda^2)^{-1} - 1 = -\lambda^2. \tag{7}$$

On the other hand, the charge density is related with the coulomb term by such a formula as:

$$\alpha = \alpha_1 - \alpha_2q'_O, \tag{8}$$

where α_1 and α_2 are constants. Hence:

$$\alpha'_O \propto -q_O'. \tag{9}$$

By combining Eqs. (2), (3), (7) and (9), we obtain:

$$a'_M \propto \lambda^2. \tag{10}$$

That is to say, the formation of the charge-transfer complex results in an increase in the proton hfs coupling constant of the methylene group in the radical.

As to the ring proton at the meta position, since the carbon atom next to the proton belongs to a different class, the sign of C_1 in Eq. (2) must be reversed. However, in the relation:

$$a_H = Qq \tag{11}$$

which relates the ring proton hfs constant, a_H, with the odd electron density on the neighboring carbon atom, the sign of the proportionality constant, Q, is negative, so that we also have the solvent effect, which increases the meta proton hfs constants in the radical. This is consistent with Deguchi's observation.[1]

Solvent Effect Depending on the Number of Substituent Groups

Since, in Eq. (5), the resonance integral in the charge-transfer process refers essentially to the interaction between the carbon and oxygen 2p atomic orbitals, in, respectively, the solvent and the radical, its value is nearly independent on the solvent species, but the denominator, ΔE_{01} is dependent on it. ΔE_{01} can be approximately rewritten, by using the oxygen lone-pair level, ε_0, and the lowest vacant level of the solvent molecule, $\varepsilon_1(n)$, as:

$$\Delta E_{01} = \varepsilon_0 - \varepsilon_1(n) - e^2/r\sigma, \tag{12}$$

where n represents the number of methyl substituents in the solvent molecule. We denote $\varepsilon_1(n)$ as a function of n:

2) R. S. Mulliken, *J. Am. Chem. Soc.*, **74**, 811 (1952).

$$\varepsilon_1(n) = \varepsilon_1(0) - \nu_n\delta, \quad \delta > 0, \tag{13}$$

in which δ is a small positive quantity: ν_n, the function of n, depending on the relative positions of the substituents, and $\varepsilon_1(0)$, the value for benzene. The last term in Eq. (13) arises from the very small perturbation due to the methyl substitution. Then:

$$\begin{aligned} \Delta E_{01} &= \varepsilon_0 - \varepsilon_1(0) - e^2/r\sigma + \nu_n\delta\,, \\ &= \Delta E_{01}(0)(1 - \nu_n\delta'), \end{aligned} \tag{14}$$

with:

$$\left.\begin{aligned} \Delta E_{01}(0) &= \varepsilon_0 - \varepsilon_1(0) - e^2/r\sigma\,, \\ \delta' &= -\delta/\Delta E_{01}(0) > 0\,. \end{aligned}\right\} \tag{15}$$

Considering that $|\nu_n\delta'| \ll 1$, we obtain:

$$\lambda^2 \propto \Delta E_{01}{}^{-2} \cong (1+2\nu_n\delta')/(\Delta E_{01}(0))^2\,. \tag{16}$$

Now we can define:

$$\Delta a(n) = (a'_{\mathrm{M}}(n) - a'_{\mathrm{M}}(0))/a'_{\mathrm{M}}(0)\,, \tag{17}$$

where $a'_{\mathrm{M}}(n)$ or $a'_{\mathrm{M}}(0)$ is the deviation of the proton hfs constant at the methylene group, when benzene or the n methyl-substituted benzene, respectively, is used as the solvent, from that with no solvent effect. Using Eqs. (9), (16) and (17), we get finally:

$$\Delta a(n) = 2\nu_n\delta'. \tag{18}$$

Thus, we conclude that, since ν_n should be positive, the proton hfs constants under consideration increase with an increase in the n value. In order to get a rough estimation, neglecting the position factors of the substituents, and by putting:

$$\nu_n \cong n, \qquad \delta' \cong 0.1 \tag{19}$$

say, $\Delta E_{01}(0)=1$, $\delta=-0.1$ in units of β, the resonance integral of benzene, we have $\Delta a(3)$ to be nearly 0.6. It should be noted that r is nearly 4 Å in usual molecular complexes, while σ is larger than 2 in the solvents under consideration. As to the empirical value, $a'(0)$, we might estimate it from Table 1a as:

$$a'(0) = a(\text{benzene}) - a(n\text{-hexane}) = 0.3 \text{ gauss}.$$

However, taking into account the fact that $a(n$-hexane) has some solvent effect, we have to use a little smaller value for the coupling constant in the bare state. If we take $a(\text{bare})=11.0$ gauss instead of $a(n\text{-hexane})=11.7$ gauss, we can obtain:

$$\Delta a(3) = (12.7 - 12.0)/(12.0 - 11.0) = 0.7$$

in accordance with the calculated value.

Temperature Effect

In discussing the temperature effect or the hfs constants of the solvated radical, it seems that two points are important; first, the equilibrium between the radical-solvent pair and the radical in the free (or loosely-combined) state,[3,4] second, the structural factor in the radical-solvent pair.[5] For the system under consideration, the first seems more important.

Let Ψ_{A} denote the solvated radical which corresponds to the ground state in the higher approximation, as has been discussed in the preceding section, of the radical-solvent pair formed by some sort of intermolecular forces, including the charge-transfer force, and let Ψ_{B} denote the radical in the free state, which was previously written as $\Psi_0(\mathrm{R}, \mathrm{A})$. Assuming the rapid exchange between two states, the value of the hfs coupling constant is observed as:

$$\bar{a} = a_{\mathrm{A}}P_{\mathrm{A}} + a_{\mathrm{B}}P_{\mathrm{B}}\,, \tag{20}$$

where, for example, a_{A} and P_{A} are values of the coupling constant and the existing probability respectively of A state.

As has been shown in the preceding treatment,

$$a_{\mathrm{A}} = a_{\mathrm{B}} + a' \tag{22}$$

with a small positive quantity, a'. Then, considering that P_{A} and P_{B} are temperature-dependent, if we define such a quantity that:

$$\Delta a(T) = (a(T) - a(T_0))/a(T_0),$$

we can easily derive:

$$\Delta a(T) = (a'/a_{\mathrm{B}})(P_{\mathrm{B}}(T_0) - P_{\mathrm{B}}(T)), \tag{23}$$

where we have used the $a_{\mathrm{B}} \gg a'$ relation. Then, further, using $\Delta T = T - T_0$, we can rewrite Eq. (23) as:

$$\begin{aligned} \Delta a(T) &= (a'/a_{\mathrm{B}})\Delta T(P_{\mathrm{B}}(T_0) - P_{\mathrm{B}}(T))/\Delta T \\ &= -(a'/a_{\mathrm{B}})\Delta T\left(\frac{\partial P_{\mathrm{B}}}{\partial T}\right)_{T=T_0}. \end{aligned} \tag{24}$$

Therefore, if we can show that $(\partial P_{\mathrm{B}}/\partial T)_{T=T_0}$ has a positive value, it may be concluded that the hfs coupling constant tends to decrease with an increase in the temperature.

Now let us consider the perturbation causing the transition from the A state to the B state. It originates in the colliding motions of solvents against the radical; the perturbing Hamiltonian is written as:

$$V(t) = Vf(t), \tag{25}$$

where $f(t)$ is the time-dependent factor, which may reasonably be assumed to have a random property with an average value of zero, fluctuating many times in the time interval, t_0(actually the reciprocal of the hfs frequency).

Describing the wave function of the system under consideration as:

3) A. H. Reddoch, *J. Chem. Phys.*, **43**, 225 (1965).
4) A. Crowly, N. Hirota and R. Kreilick, *ibid.*, **46**, 4815 (1967).
5) S. Aono and K. Oohashi, *Prog. Theoret. Phys.*, **30**, 162 (1963); **32**, 1 (1964).

$$\Psi = C_A(t)\Psi_A e^{-i\omega_A t} + C_B(t)\Psi_B e^{-i\omega_B t} \quad (26)$$

with standard notations, we can obtain:

$$C_B(t) = -\frac{i}{\hbar} V_{BA} \int_0^t f(t') e^{-i\omega_{AB} t} \, dt', \quad (27)$$

$$\omega_{AB} = \omega_A - \omega_B, \quad (27a)$$

$$V_{BA} = (\Psi_B | V | \Psi_A). \quad (27b)$$

Here it should be noted that, since we have derived Eq. (27) under the initial conditions, $C_A(0)=1$ and $C_B(0)=0$, the existing probability of the B state is replaced by the transition probability from A to B. Therefore, we have:

$$P_B(t_0) = \frac{1}{\hbar^2} |V_{BA}|^2 \int_0^{t_0} dt \int_{-t_0}^{t_0-t} d\tau \times f(t+\tau) f(t) e^{-i\omega_{AB}\tau}. \quad (28)$$

As in the case in the treatment of the NMR relaxation problem, the integral (28) is a random function, but the statistical average value of the expression:

$$G(\tau) = \overline{f(t+\tau) f(t)}$$

for a fixed τ generally has a definite value, independent of the time t. $G(\tau)$ is generally a rapidly decreasing function of τ, and when t_0 is large, the second integral in Eq. (28) (taking the statistical average) becomes almost independent of t_0, while integration with respect to t_0 gives a factor of t_0 in the answer:

$$P_B(t_0) = t_0 P_B, \quad (30)$$

in which P_B, the transition probability from A to B per unit of time, is:

$$P_B = \frac{1}{\hbar^2} |\overline{V}_{BA}|^2 \int_{-\infty}^{\infty} G(\tau) e^{i\omega_{BA}\tau} \, d\tau. \quad (31)$$

Now, we assume that $G(\tau)$ decays exponentially with a characteristic correlation time τ_c:

$$G(\tau) = e^{-|\tau|/\tau_c}. \quad (32)$$

The transition probability per unit time then becomes:

$$P_B = \frac{1}{\hbar^2} |\overline{V}_{BA}|^2 \frac{2\tau_c}{1+\omega_{BA}^2 \tau_c^2}. \quad (33)$$

At this stage, we need to consider τ_c and ω_{BA} a little more deeply. Colliding motions of solvents against the radical will cause the translational and rotational motions of the radical, and their characteristic correlation times are known to be orders of 10^{-11} sec and 10^{-8} sec respectively, while the value of ω_{BA} may be estimated as the order of the activation energies for the corresponding motions, having values of a few kcal. Therefore, as we have the relation:

$$\omega_{AB}^2 \tau_c^2 \gg 1$$

in our case, P_B in Eq. (33) is approximately:

$$P_B = \frac{1}{\hbar^2} \frac{|\overline{V}_{BA}|^2}{\omega_{AB}^2} \frac{2}{\tau_c}. \quad (34)$$

Since τ_c(rotational) $\ll \tau_c$(translational), it is obvious that the effect of the rotational motion predominates in our case.

According to Debye,[6] the rotational correlation time is:

$$\tau_c = \frac{4\pi\eta a^3}{3kT}, \quad (35)$$

where k is the Boltzman constant, and where the assumption is made that the molecules are spheres with the a radius. η, the viscosity of the liquid, is also temperature-dependent; it is given, by the use of the Eyring transition state theory,[7] as:

$$\eta = nh \, e^{\Delta G^{\neq}/RT}, \quad (36)$$

where n is the number of molecules per unit of volume and $\Delta G^{\neq}$, the Gibbs free energy of the transition state.

Using the relation:

$$\Delta G^{\neq} = -\Delta S^{\neq} T + \Delta H^{\neq} \quad (37)$$

and substituting Eqs. (35) and (36) into Eq. (34), we obtain:

$$P_B = \frac{|\overline{V}_{BA}|^2}{(E_A - E_B)^2} \frac{3kT}{2\pi nha^3} e^{\Delta S^{\neq}/R} e^{-\Delta H^{\neq}/RT}. \quad (38)$$

Inserting this into Eq. (24), we can obtain the temperature dependence of the hfs coupling constant in terms of macroscopic quantities. We may expect that these values, $\Delta S^{\neq}$ and $\Delta H^{\neq}$, negative in sign, will be several tens of eu and a few kcal respectively. As to the temperature-dependent factors, the exponential term should exceed the linear one, so that the value of the coupling constant will decrease with an increase in the temperature. However, it seems almost impossible to estimate it numerically because of the difficulty of determining the parameters, $\Delta S^{\neq}$, $\Delta H^{\neq}$, and so on.

Conclusion

We have presented some considerations concerning the solvent and temperature effects on the proton hfs coupling constants in the ESR spectra of the phenoxy radicals, on the assumption that the charge-transfer takes place from the oxygen lone pair of the radical to the vacant levels of the solvent. The increase in the values of the hfs constants with an increase in the number of the methyl substituents in the solvents is interpreted in terms of the lowering of the lowest vacant level of the solvent

7) J. O. Hirschfelder and C. F. Curtis, "Molecular Theory of Gases and Liquids," Wiley, New York (1945), p. 627.

due to the methyl substitution. In this case, we have used the rough proportionality which holds between the extent of the lowering in level and the number of methyl substituents.

On the other hand, the temperature effect has been explained by the use of an idea similar to those of Reddoch and Crowly *et al.* in some details. Using the time-dependent perturbation theory, we have obtained the hfs constant in terms of the rotational correlation time, or the liquid viscosity constant, from which the temperature-dependent factor arises. However, it was almost impossible for us to make a quantitative estimate because some parameters were difficult to determine.

Decomposition of Formic Acid over Metal Phthalocyanines

Sadao TANAKA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 21, 1968)

The decomposition of formic acid was studied over two sorts of metal phthalocyanines: Mg- and Fe-phthalocyanines. The rates of the decomposition reactions over Mg-Phc and Fe-Phc were proportional to the pressure of formic acid, and the decomposition proceeded to dehydrogenation as well as to dehydration over these phthalocyanines. The isotope distribution in the hydrogen (H_2, HD, and D_2) produced by the decomposition of HCOOD leads to the conclusion that the hydrogen molecule is mainly formed between the hydrogen atom bonded to the carbon atom and that bonded to the oxygen atom in the formic acid molecule. Formic acid was adsorbed to a considerable extent over Mg-Phc in the temperature range between 70°C and 220°C. The amount of formic acid adsorbed obeyed the Langmuir adsorption isotherm, and the infrared spectra demonstrated the presence of the formate ion $HCOO^-$ on the Mg-Phc. It was also confirmed that Mg-Phc was hydrogenated during the course of the decomposition. The adsorption during the catalytic reaction was also measured. These measurements revealed that the overall rate of the reaction is proportional to the amount of formic acid adsorbed. The mechanism of formic acid decomposition was discussed on the basis of these results.

Catalysis by organometallic compounds in the liquid phase is a topic of great interest in the field of chemistry, and the reactivity of such compounds is in many cases correlated with their electronic properties. In heterogeneous catalysis over metals or metal oxides, the complexity of surface properties, such as the heterogeneity of the surface, frequently brings ambiguity into the elucidation of the reaction mechanism. However, the catalysis by molecular crystals of organometallic compounds proceeds over each of the surface molecules independent of the others, and may be treated as catalysis over each of the surface molecules, as with homogeneous catalysis.

The metal phthalocyanine is a biologically-notable substance as it is similar to heme and chlorophyll in its structure. Over this compound the decomposition of formic acid was studied.[1-3] The reaction is known for its selectivity, as it proceeds to different reaction products, dehydrogenation and dehydration. The selective catalysis over the phthalocyanine molecular crystal is, accordingly, a subject of considerable interest.

The importance of adsorption measurements during the course of the reaction has already been emphasized by one of the present authors.[4] The adsorption on the catalyst surface and the behaviour of the chemisorbed species in its working state is directly associated with the elucidation of the mechanism of the surface catalysis.

In this report, by means of adsorption measurements during the course of the decomposition over the phthalocyanines of magnesium and iron, as well as by means of infrared technique and hydrogen isotope distribution, the mechanism of the catalytic decomposition of formic acid will be studied.

Experimental

Mg-Phc and Fe-Phc were synthesized according to the Linstead procedures.[5] A magnesium metal film, or iron powder (either 99.9% pure), was boiled with phthalonitrile for 30 hr; the phthalocyanines thus prepared were then carefully purified by washing them with benzene, alcohol, acetone, and water, and by recrystallization in quinoline and by repeated sublimation. The visible and infrared spectra of these phthalocyanines were in reasonable agreement with those reported previously by Linstead[6] and Sidorov[7]. The formic acid was purified by distillation at room temperature, after the removal of the water with anhydrous boric acid. The phthalocyanines of magnesium and iron were evacuated at 250°C and 290°C respectively for 10 hr prior to their use.

The apparatus employed was a closed circulating system with an electromagentic circulating pump. The amount of gases adsorbed on the catalyst surface was calculated from the amount of the reactant introduced into the reaction system and that of the circulating gases. The reactant and products were analyzed by means of gas chromatography: the formic acid, water, and carbon dioxide were analyzed by a dioctyl sebacate (D.O.S.) separatory column, while the carbon monoxide and hydrogen were measured by a silica column at 90°C, employing helium as the carrier gas. The isotopic abundance in hydrogen, H_2, HD, and D_2, was determined by gas chromatography.[8] The infrared cell used in this study was similar to that described previously.[9]

Results and Discussion

I. Adsorption of Formic Acid over Mg-Phc. The adsorption of formic acid over Mg-Phc was studied by a volumetric method at 70, 100, and 130°C, where the decomposition of formic acid scarcely takes place. Due allowance was made for the adsorption of formic acid by the apparatus. The total surface area of the Mg-Phc evaporated film employed was 13.6 m^2. The adsorption was reversible, and, as shown in Fig. 1, it is approximated by the Langmuir adsorption isotherm; the rate of adsorption was proportional to the formic acid pressure throughout the coverage. The heat of adsorption was estimated from the Clapeyron-Clausius equation to be about 5.5 kcal/mol. The adsorption equilibrium constant was also calculated to be $K=e^{-8.85}e^{5.5\times10^3/RT}$ $mmHg^{-1}$, while the saturated amount of adsorption was 10 m*l* (stp) of monomer formic acid. The number of Mg-Phc molecules in the surface

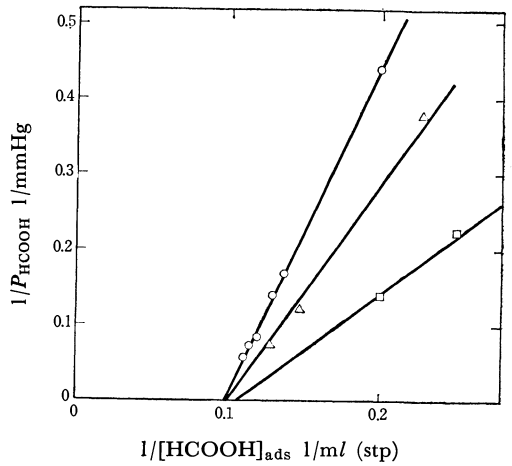

Fig. 1. Dependence of the amount of formic acid adsorbed upon the pressure of formic acid over Mg-Phc.

was estimated to be approximately 3.1×10^{11}, asuming that a (001) plane is exposed on the surface, this value corresponds to nearly one-ninth the number of formic acid molecules having saturated adsorption.

When water was first adsorbed on Mg-Phc at room temperature, and subsequently formic acid was introduced into the adsorption system, all the preadsorbed water was desorbed, being replaced by the formic acid molecules; this demonstrates that formic acid was adsorbed on the sites where water was adsorbed.

II. Decomposition of Formic Acid. Formic acid was decomposed over Mg-Phc at 200°C. Some typical results are given in Fig. 2, where the amounts of formic acid (m*l*, stp as monomer)

and of the reaction products (m*l*, stp) are plotted against the reaction time (hr). Trace amounts of HCHO, CH_3OH, and $HCOOCH_3$ were also detected.*1 It should be noted here that the amount of hydrogen produced was much less than that of carbon dioxide.

The results obtained over Fe-Phc, where the total surface area is 1.6 m^2, are shown in Fig. 3. In this case as much hydrogen as carbon dioxide

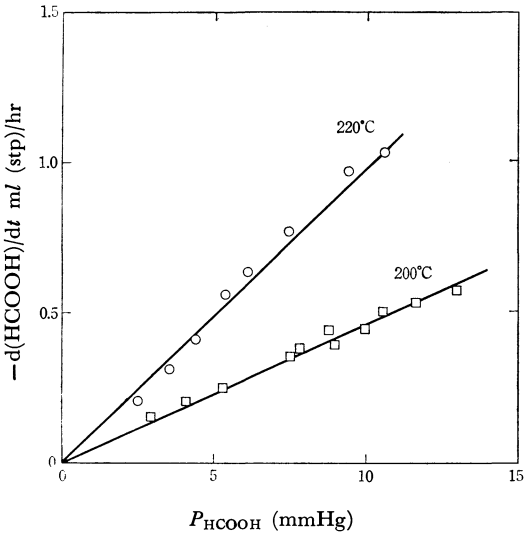

Fig. 4. Dependence of the rate of the decomposition of formic acid upon the partial pressure of formic acid over Mg-Phc.

*1 CH_3OH and $HCOOCH_3$ were clearly found by infrared spectra when formic acid was decomposed at 150°C.

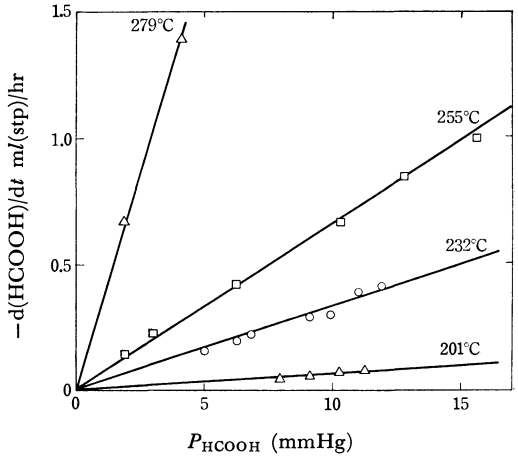

Fig. 5. Dependence of the rate of the decomposition of formic acid upon the partial pressure of formic acid over Fe-Phc.

was evolved unlike the case of Mg-Phc. The ratios of dehydration to dehydrogenation were 1 : 5 at 200°C and 1 : 3 at 279°C.

The rates of formic acid decomposition over Mg-Phc and Fe-Phc were proportional to the pressure of formic acid, as is shown in Figs. 4 and 5. The temperature dependence of the decomposition rate gave the activation energies for the decomposition as 17 kcal/mol for Mg-Phc and 26.1 kcal/mol for Fe-Phc. The frequency factors were calculated to be $5.5\times10^2(m)^{-2}(sec)^{-1}$ for Mg-Phc and $1.1\times10^7(m)^{-2}(sec)^{-1}$ for Fe-Phc.

The adsorption during the decomposition on Mg-Phc was estimated from Fig. 2; it is given in Fig. 6. The composition of the adsorbate was approximately equal to that of formic acid in the first stage of the reaction; later it had a composition richer in hydrogen. The amount of formic acid in the first stage of the reaction was in conformity with the amount estimated by the extrapolation of the adsorption equilibrium up to the

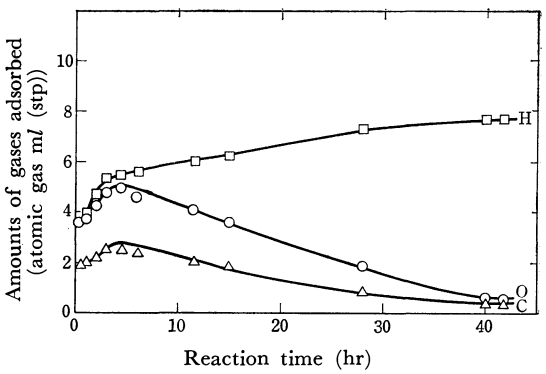

Fig. 6. The adsorption during the course of the decomposition of formic acid over Mg-Phc at 220°C.

reaction temperature. Water, hydrogen, carbon monoxide, and carbon dioxide were separately introduced over the phthalocyanine; it was confirmed that these gases were not adsorbed in the temperature range studied. These results suggest that Mg-Phc is hydrogenated during the course of the formic acid decomposition.

From the results given in Fig. 6, the amount of formic acid adsorbed was plotted against the rate of the decomposition; this plot is given in Fig. 7, where a linear relation was obtained under similar reaction conditions. The adsorption over Fe-Phc, the total surface area of which was 17 m^2, was much less than that over Mg-Phc, and Fe-Phc was not hydrogenated during the course of the decomposition.

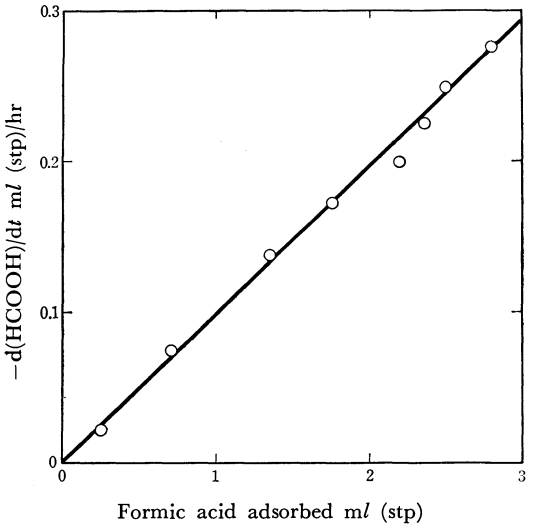

Fig. 7. Dependence of the rate of the decomposition of formic acid upon the amount of formic acid adsorbed over Mg-Phc at 220°C.

When the monodeuterated formic acid, HCOOD, was introduced onto the hydrogenated Mg-Phc, which had previously been evacuated for 10 hr at 250°C, an exchange reaction took place between the deuterium in the HCOOD and the hydrogen in the hydrogenated Mg-Phc, and exchange equilibrium being reached at 100°C. Then the ambient HCOOD was replaced by HCOOH; HCOOD was consequently formed. Accordingly, during the reaction, the isotopic mixing takes place between the hydrogen in water, that in the OH group of formic acid, and that added to the phthalocyanine. The hydrogen in a fresh Mg-Phc, or Fe-Phc, on the other hand, did not participate in the exchange reaction, and no hydrogen exchange with HCOOD could be detected.

When HCOOD was decomposed over a fresh Mg-Phc at 220°C, the ratio of hydrogen to deuterium in the hydrogen gas produced was the same as in the case of HCOOD, though a part of the hydrogen was fixed by the phthalocyanine. The isotopic abundance in the hydrogen produced is given in Table 1.

TABLE 1

Catalyst		Observed %	Equilibrium value %
Mg-Phc*	H_2	13	32
	HD	84	46
	D_2	3	22
Fe-Phc**	H_2	18	29
	HD	79	48
	D_2	3	23

* The D content in HCOOD was 90%.
** The D content in HCOOD was 95%.

Hydrogen was mostly HD, while D_2 corresponded to 13.6% of the equilibrium value of the isotopic exchange.

When HCOOD was similarly decomposed over Fe-Phc at 250°C, a considerable amount of HD was produced and the D_2 corresponded to 12.9% of the exchange equilibrium. It may, accordingly, be concluded that the majority of the hydrogen was produced between the hydrogen bonded to carbon and that bonded to oxygen. The H_2-D_2 exchange reaction did not proceed over Mg-Phc or Fe-Phc under the conditions of formic acid decomposition.

Formic acid was repeatedly introduced over Mg-Phc in order to continue the decomposition for more than 20 days at 220°C. The colour of the Mg-Phc film thereupon changed from violet to blue. When formic acid was decomposed over the catalyst thus treated, the amount of hydrogen produced was the same as that of carbon dioxide; this seemingly suggests the saturation of the hydrogenation. The selectivity or the ratio of CO_2 to CO in the reaction products was not changed.

The infrared spectra, in the region from 4000 to 700 cm^{-1}, of the evaporated Mg-Phc film on a NaCl plate are shown in Fig. 8(a). The spectra were those of the α-form of Mg-Phc. When the Mg-Phc was evacuated for two hours at 200°C, its infrared spectra were changed to the β-form, as is shown in Fig. 8(b). The spectra changed markedly when the β-form of Mg-Phc was treated with 2 cmHg formic acid for a few hours at 100°C, as is shown in Fig. 8(c). The change in the spectra was almost the same as that when CH_3COOH was adsorbed on the α-form of Mg-Phc at room temperature.[10] Most of the change may be interpreted as being due to the α-β transformation. In addition to this change, the spectra of the formate ion, such as 1610 and 1375 cm^{-1}, were observed; this indicates that formic acid was adsorbed on the Mg-Phc, dissociating to a formate ion and a proton. When

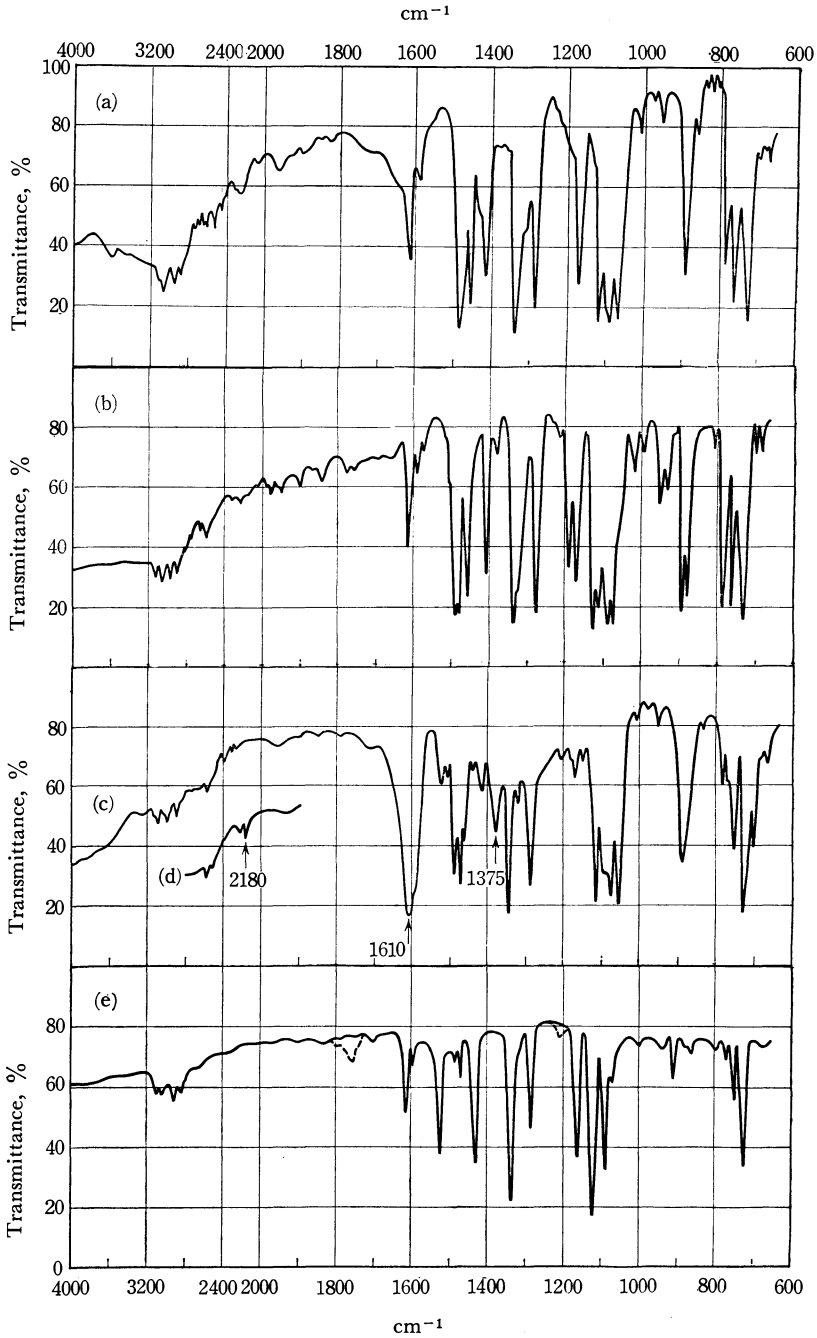

Fig. 8. (a) Infrared spectra of evaporated Mg-Phc film.

(e) Infrared spectra of Fe-Phc (——) and after the exposure to HCOOH vapour at room temperature (- - -).

the Mg-Phc which adsorbed formic acid was evacuated for two hours at 200°C, the spectra of the formate ion disappeared and the structure of the phthalocyanine returned to the β-form.

The infrared spectra were also studied during the decomposition of DCOOD over Mg-Phc for ten hours at 150°C, as is shown in Fig. 8(d); a new weak band at about 2180 cm^{-1} was observed,

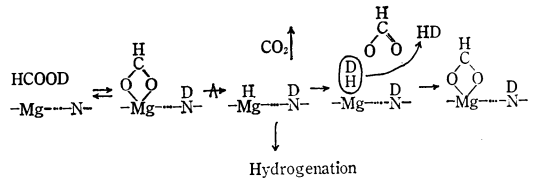
a band which became stronger with the progress of the decomposition. The band at 2180 cm^{-1} is close to that of the ND^+ stretching vibration, which appears when DCl is adsorbed on Mg-Phc, deuterium being added to the peripheral nitrogen of Mg-Phc.[10] This band did not disappear upon evacuation. After evacuation, HCOOH was introduced into the reaction system and the band at 2180 cm^{-1} rapidly disappeared.

When Fe-Phc which had been evacuated for two hours at 220°C was exposed to formic acid for a few hours in the temperature range between room temperature and 100°C, neither any formate ions nor any changes in its crystal structure were detected, except for the weak peaks resulting from physically adsorbed formic acid.

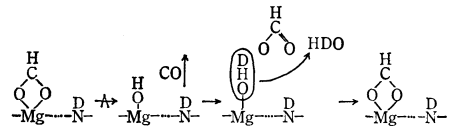
From these results, it was concluded that the hydrogenation takes place at the nitrogen of Mg-Phc and that the hydrogen thus fixed can exchange with the proton in the formic acid molecules. Formic acid is adsorbed over Mg-Phc, dissociating to a formate ion and a proton, as is demonstrated in the infrared spectra. The adsorption quickly reaches an adsorption equilibrium, and the amount of formic acid adsorbed in the first stage of the reaction is in conformity with the amount calculated from the adsorption equilibrium.

The linear relation between the adsorption and the overall rate of the decomposition excludes the possibility of the mechanism of the reaction taking place between the adsorbed species and the acid molecule in the ambient gas. It indicates that the reaction intermediate for the decomposition over Mg-Phc is the adsorbed species, or the surface formate ion, and that the reaction takes place *via* the unimolecular decomposition of the formate ion in a manner similar as that over zinc oxide.[11]

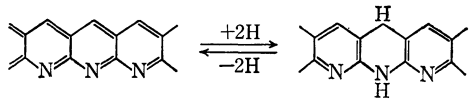
The amount of hydrogen evolved was much less than that of carbon dioxide in the initial stage of the decomposition, and Mg-Phc is hydrogenated during the course of the decomposition. The hydrogen thus added to Mg-Phc takes part in the exchange reaction with the hydrogen of the OH group in the formic acid and water molecules. Accordingly, when HCOOD was decomposed over Mg-Phc the hydrogenation of Mg-Phc proceeds to the extent of the reaction; this results in the quick mixing of hydrogen isotopes in the hydrogen bonded to oxygen in the acid and water. The hydrogen-isotope mixing should not be marked in the initial stage of the reaction, where the extent of hydrogenation, and also the amount of water produced, are little. As the rate of hydrogen evolution was much slower than that of carbon dioxide, it took some time to collect enough hydrogen sample for the isotopic analysis; this delay inevitably results in some isotopic mixing. If we take this mixing into consideration, the results given in Table 1 indicate that dehydrogenation overwhelmingly takes place, forming hydrogen from the hydrogen in OH and from that of the CH in the formic acid molecule, as follows, in a manner similar to that with ZnO:[11]



The selectivity of the decomposition, on the other hand, was independent of the extent of hydrogenation; this suggests that different reaction intermediates can be excluded for the dehydrogenation and dehydration for instance, the hydrogen in the phthalocyanine molecule added from the acid molecule. As the dehydration also proceeds in proportion to the amount of adsorption, the following mechanism may be considered for the dehydration:



It has been reported that some organic polymer catalysts are also hydrogenated.[12] For example, polycyanoacetylene was hydrogenated during the course of the dehydrogenation of alcohol or cyclohexene, as follows:



The uptake of hydrogen by the organic polymers is interesting in connection with the behaviour of Mg-Phc.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2563—2570 (1968)

Sensitization of Photoconductivity. Poly-*N*-vinylcarbazole with the Copolymerized Dye Molecule

Kenichi OKAMOTO, Yo HASEGAWA,*1 Shigekazu KUSABAYASHI and Hiroshi MIKAWA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received March 25, 1968)

The sensitization of the photoconductivity of PVCz by dyes was investigated by the measurement of the characteristics of the decay of the surface charge put on the polymer films. MG was selected as a dye and the following three systems were measured and the degree of the sensitization was compared; *i. e.*, PVCz-MG, copolymer of VCz and VMG and PVCz-PVMG systems. The sensitization was observed in the wavelength region from 300 to 1200 mμ. Sensitization in the visible region was larger than in the ultraviolet. The copolymer system was inferior to the PVCz-MG system, probably because of the large loss of the carriers by the recombination and trapping in the bulk. There was the optimum concentration of the dye content, probably because of the disturbing effect of the dye molecule for the migration of the carriers. To make sure this point, the inhomogeneous films with the dye only on the surface were investigated. The results were explained by the difference in the distiribution of the centers of carrier generation and those of recombination and trapping of the carriers in the bulk.

Poly-*N*-vinylcarbazole (PVCz) film is photoconductive and useful as an organic photoconductive material for electrophotography. However its sensitivity is small and limited only in the ultraviolet region. It is, therefore, necessary to improve the senstivity. There are two kinds of method which have been much studied. One is the formation of charge transfer complexes,[1-4] and the other is the addition of dyes.[2,3]

There are many reports about the sensitization with dyes, but there are none about the sensitization by the copolymerization with dye monomers. It has been reported that the absorption spectrum of polyvinylmalachitegreen (PVMG) shows a new peak at 590 mμ in methanol solution beside the absorption bands of the malacitegreen (MG).[5] This peak seems to be due to the associated MG structures caused by the large interaction between neighboring MG groups.[6] If we introduce MG dye molecules directly into the PVCz molecular chain by chemical bond, we may expect results different from the case where MG dye is simply mixed, because the interaction between carbazole groups and MG groups will be different in both cases.

From this view point *N*-vinylcarbazole(CVz)-4''-vinylmalachitegreen(VMG) copolymer was synthesized, and the characteristics of the surface potential decay of its film were investigated and compared with that of the PVCz film mixed with MG (PVCz-MG system). The characteristics of the surface potential decay of the PVCz film mixed with PVMG (PVCz-PVMG), were investigated also.

PVCz: Purified VCz was polymerized by azobisisobutylonitrile in benzene and the polymer obtained was used after being purified by repeated reprecipitation ($\overline{M}_v=110000$).

MG: Commercial MG was purified by the L. Lewis's method.[7]

PVMG: PVMG was prepared from VMG carbinol.[8]

VCz-VMG Copolymer: The copolymer was obtained from VCz and VMG carbinol.[6] The dye mentioned above was used as HCl salts. In changing the dye carbinols into HCl salts, all attention was payed in order to prevent the formation of their dications by excess HCl, chlorine content being confirmed by potentiometric analyses.

(b) Preparation of the Films for the Measurement. In the case of the PVCz-MG and PVCz-PVMG systems, the methanol solution of MG or PVMG was added to the benzene solution of PVCz with stirring (benzene : methanol=20 : 1 by volume), 0.2 m*l* of 5 wt% solution thus prepared was dropped on a copper plate (22 mm in diameter) and the solvent was evaporated slowly.

In the case of the VCz-VMG system, 5 wt% benzene solution of the copolymer was treated likewise. The films were used for the measurement, after being dried for more than 20 hr under 1 mmHg vacuum. These films were estimated to be 20 μ thick.

(c) Measurement of the Decay of Surface Potential. A 500 W xenon lamp was used for the light source. Its energy distribution is shown in Fig. 1. This is different from the usual energy distribution of the xenon lamp, for the relative light intensity is expressed by the number of photons and the slit width of the monochrometer is fixed at 2 mm in the whole wavelength region. Figure 2 is the schematic representation of the experimental arrangement. The films were charged positive or negative by corona discharge. The initial surface potential of the films as observed by our arrangement was about 100 V.

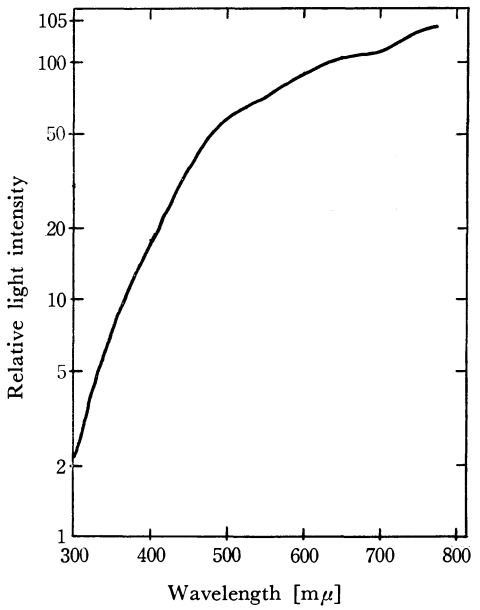

Fig. 1. Energy distribution of the light of xenon lamp measured by a thermopile using a monochrometer (slit width: 2 mm).

Results

(a) Absorption Spectra of the Films. The absorption spectra of PVCz, MG, PVMG, VCz-VMG copolymer and PVCz-MG mixture*2 (99.7 : 0.3 mol%) are shown in Fig. 3. The absorption spectrum of the film of PVCz-MG mixture is similar to that of the MG solution rather than to the MG solid film. In the film of PVCz-MG mixture, the splitting reported in MG solid[9] was not observed and only a slight red-shift of the first absorption peak was observed with somewhat broadening of the peak in comparison with that of the MG solution.

(b) Experimental Equation of the Surface Potential Decay. An example of the decay of surface potential is shown in Fig. 4(a). A linear relation was found between the logarithm of surface potential V and the root of time t as shown

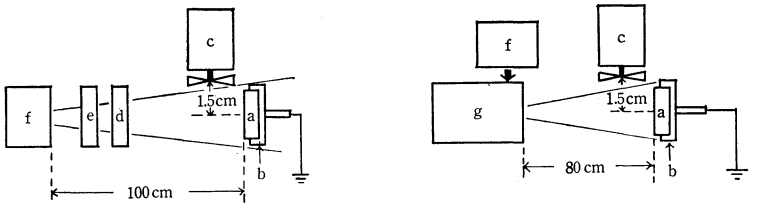

Fig. 2. Schematic arrangement of the measurement of the photo-decay of surface charge.

in Fig. 4(b). The results can be described as $V=V_0\exp(-\alpha t^{1/2})$, which equation had been used for ZnO by Inoue[10] and for several organic materials by us.[1,11] We shall use the value of α as the decay constant in the present paper.

(c) Effect of the Dye Content on Dark Decay Constant α_d. As shown in Fig. 5, α_d increases a little with the dye content (especially in the VCz-VMG copolymer system). The sign

of the charge put on the film causes no difference in the α_d value.

(d) Effect of the Dye Content on the Light Decay Constant $\alpha_{1,v}$ and $\alpha_{1,t}$. $\alpha_{1,v}$ is defined as the decay constant observed under the illumination with visible light covering from 390 to 1200 mμ and $\alpha_{1,t}$ as that under illumination with the total light from the ultraviolet to 1200 mμ. Preliminary experiment with the PVCz-MG system showed that $\alpha_{1,v}$ reached a maximum at the MG concentration of about 0.1 mol% and decreased considerably at higher concentrations. Decay constants were, therefore, measured with the films containing about 0.1 mol% of the dye.

Figure 6 shows the relation between $\alpha_{1,v}$ or $\alpha_{1,t}$ and the dye content. In every system, the light decay constants have maximum values at the dye content of 0.1 mol% and these values are in the following order; *i.e.*, PVCz-MG system>VCz-VMG copolymer system$\gg$ PVCz-PVMG system. The value of $\alpha_{1,t}$ is much larger as a film is charged positive than as it is charged negative. These values denoted respectively as $\alpha^+{}_{1,t}$ and $\alpha^-{}_{1,t}$. There is no large difference in $\alpha_{1,v}$ between a film charged positive ($\alpha^+{}_{1,v}$) and a one charged negative ($\alpha^-{}_{1,v}$). However in PVCz-MG system and PVCz-PVMG copolymer system $\alpha^-{}_{1,v}$ is a little larger than $\alpha^+{}_{1,v}$, and in VCz-VMG copolymer system $\alpha^+{}_{1,v}$ is a little larger than $\alpha^-{}_{1,v}$.

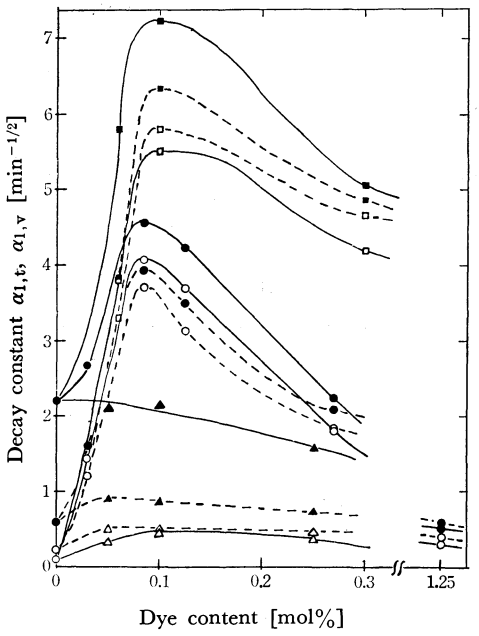

Fig. 6. Decay constant *versus* dye content.

—●—	—○—	VCz-VMG copolymer
—▲—	—△—	PVCz-PVMG

Solid lines show α values when charged positive and dotted lines show α values when charged negative.

The value, $\alpha_{1,UV}$, which is defined as $\alpha_{1,t}-\alpha_{1,v}$, is a measure of the effect of the UV light under the illumination with the total light. Figure 7 shows the effect of the dye content on $\alpha_{1,UV}$. The $\alpha^-{}_{1,UV}$ value ($\alpha_{1,UV}$ for the films charged negative) decreases

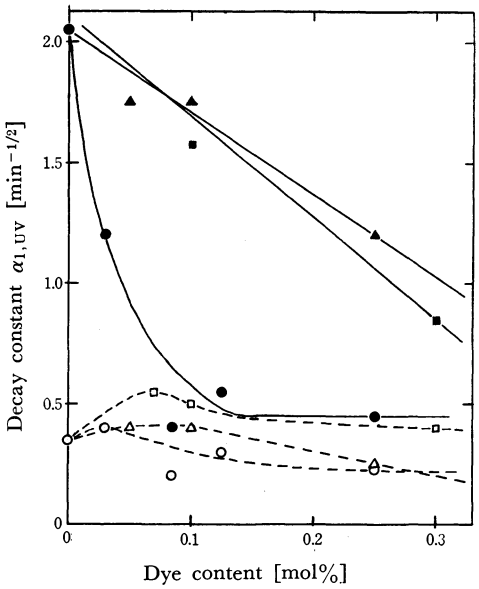

Fig. 7. Decay constant *versus* dye content.

--■-- (+)	435 mμ	PVCz-MG

with the increasing dye content after having reached a maximum, but $\alpha^{+}_{1,UV}$ decreases uniformly with the increasing dye content. It must be noted that in VCz-VMG copolymer system the amount of decrease is much larger than in the other systems.

(e) Spectral Response of the Decay Constant. The linear relation between the decay constant under the illumination with a monochromatic light, $\alpha_{1,m}$ and the relative light intensity is shown in Fig. 8. Figure 9 shows the spectral response of the decay constant normalized for the relative light intensity shown in Fig. 1, photon number of 365 mμ light being defined as a unity. In every system the sensitization by the dyes is positive at every wavelength measured and its degree is in the following order; *i.e.*, PVCz-MG system > VCz-VMG copolymer system ≫ PVCz-PVMG system. This order is the same with one

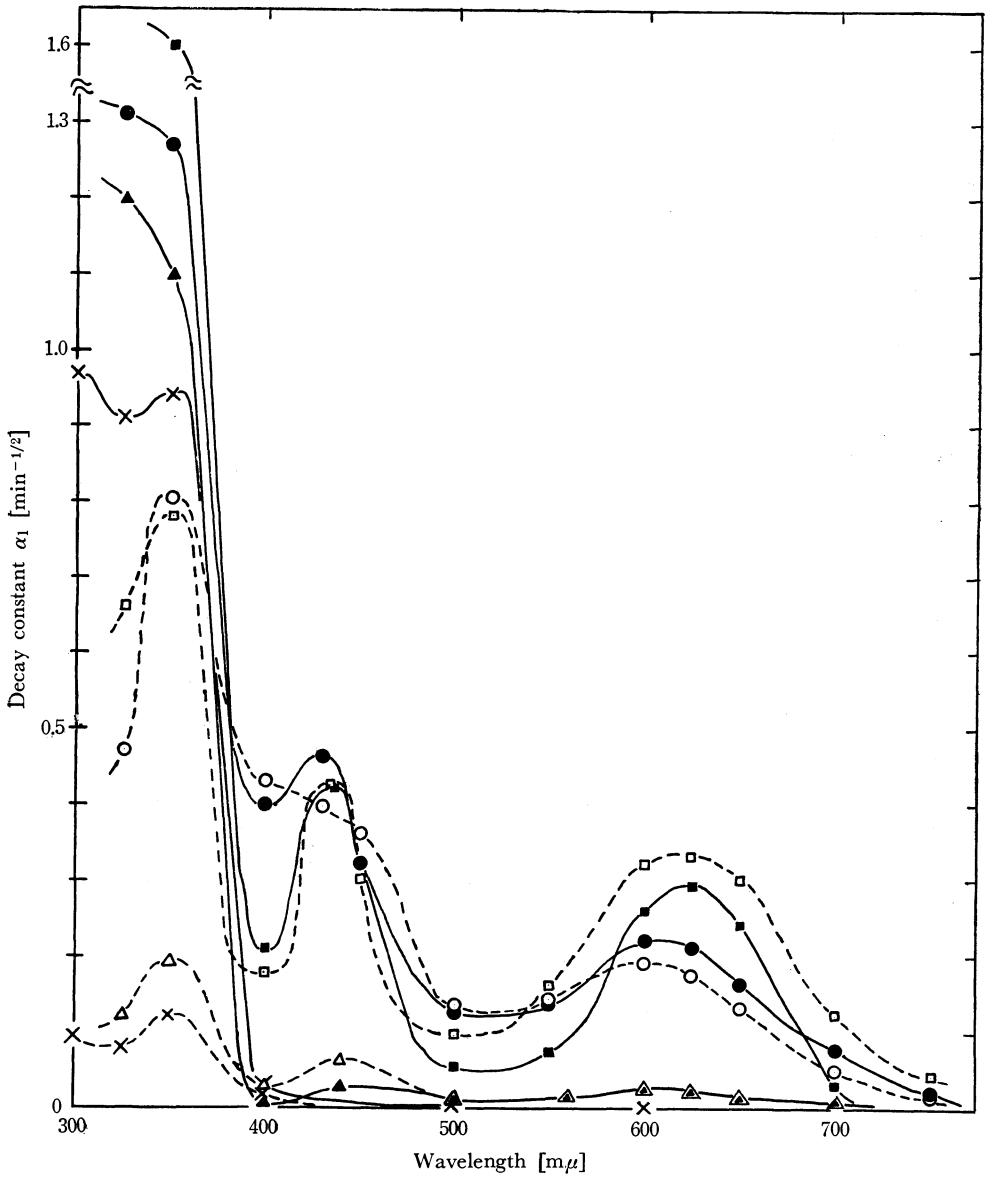

Fig. 9. Spectral response of decay constants normalized for the light intensity at 365 mμ.

Charged: Positive	Charged: Negative	System
—×—	--×--	PVCz
—●—	--○--	VCz-VMG copolymer (0.085 mol%)
—■—	--□--	PVCz-MG (0.1 mol%)
—▲—	--△--	PVCz-PVMG (0.1 mol%)

for $\alpha_{1,v}$ mentioned above.

The spectral response of $\alpha_{1,m}$ is in agreement with the absorption spectra of the films, although in VCz-VMG copolymer system the considerable sensitization is found even in the weakly absorbed region (400 mμ) in comparison with PVCz-MG system. There is no difference in $\alpha_{1,m}$ between the films charged positive and negative in the visible light region. In the ultraviolet region, however, $\alpha_{1,m}$ of the former is considerably larger than the latter. The degree of sensitization in the ultraviolet region is about one and a half-fold when charged positive and about seven-fold when charged negative.

Discussion

(a) The Effect of HCl Addition on the Decay Constant. MG reacts with excess HCl to give its dication and the photoconductivity of this dication has been reported to be smaller than that of MG.[12] In preparing HCl salts of MG, PVMG and VCz-VMG copolymer, therefore, strictly controlled amount of HCl was used in order to avoid any formation of the dication structure.

The effect of HCl on the decay constants when added to PVCz and PVCz-MG (0.1 mol%) systems is shown in Fig. 10. By the addition of HCl the PVCz-MG system was desensitized, probably because of the formation of the dication structure. The PVCz system was, however, sensitized especially in the case of the positively charged film illuminated with total light.

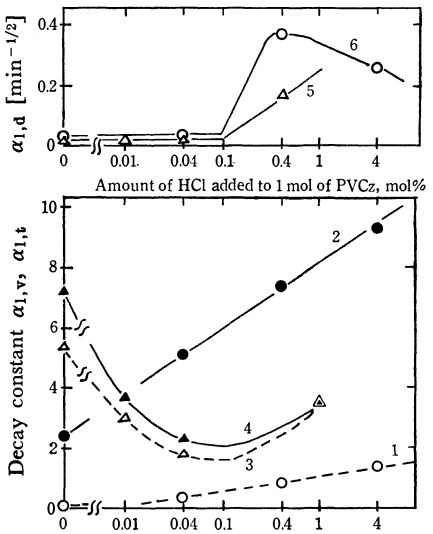

Fig. 10. Effect of HCl on decay constant (when charged positive).
1 $\alpha_{1,v}$ of PVCz, 2 $\alpha_{1,t}$ of PVCz,
3 $\alpha_{1,v}$ of PVCz-MG (0.1 mol%),
4 $\alpha_{1,t}$ of PVCz-MG (0.1 mol%),
5 α_d of PVCz,
6 α_d of PVCz-MG (0.1 mol%)

α_d of both films increased with the increasing amount of HCl. Thus HCl gives a large effect on the decay constants.

As one and a half-fold excess of HCl was used to get the HCl salt of the copolymer, the dication structure might be formed and this dication structure might have made the light decay constant of the copolymer smaller than that of PVCz-MG film. In order to confirm this point the effect of the amount of HCl on α was investigated which was added to obtain the HCl salt of the copolymer. As the amount of HCl (up to two fold excess) had no effect on α, the HCl salt of the copolymer used in this experiment seems not to contain the dication structure and the α_1 value of the copolymer seems to be small in itself.

(b) A Simple Model Explaining the Surface Potential Decay Constant under Light Illumination. The surface potential of the amorphous selenium charged positive by the corona discharge has been investigated as a function of the illumination time and explained by a model based on trapping and recombination of carriers.[13] The experimental results in this paper can also be explained by assuming an appropriate location of generation, trapping and recombination of carriers.

(i) In the case of the illumination with strongly absorbed light, the light creates electrons and holes near the illuminated surface. A part of them disappears by recombination and the rest moves in the electric field causing the surface potential decay. The carriers trapped in the bulk contribute also to the surface potential decay according to their positions.

All investigated systems when illuminated with only UV light and the PVCz system when illuminated with total light belong to the case (i). The values of $\alpha_{1,m}$ in the UV region and of $\alpha_{1,t}$ in the PVCz system are much larger when charged positive. This suggests that the hole carrier is more mobile than the electron carrier in these systems. PVCz film has been reported to be p-type.[1,3]

(ii) In the case of the illumination with weakly absorbed light, the light is absorbed uniformly in the bulk creating electron and hole carriers and the carriers move to the oppositely charged surfaces, a part of them being lost by trapping and recombination. As the situation is nearly equal both for positive and negative polarity, $\alpha^+_{1,v}$ and $\alpha^-_{1,v}$ are almost equal. The PVCz-MG, VCz-VMG copolymer and PVCz-PVMG systems containing less than 0.3 mol% of dye structures belong to the case (ii) when illuminated with visible light. As

12) R. C. Nelson, *J. Chem. Phys.*, **19**, 798 (1951).

13) H. Tung Li and P. J. Regensberger, *J. Appl. Phys.*, **34**, 1730 (1963).

expected, $\alpha^{+}_{1,v} \approx \alpha^{-}_{1,v}$ in these systems.

(iii) In the case of the simultaneous illumination with strongly and weakly absorbed light, the phenomena (i) and (ii) take place simultaneously. The PVCz-MG, VCz-VMG copolymer and PVCz-PVMG systems containing less than 0.3 mol% of dye structural unit belong to the case (iii)when illuminated with total light.

The results of Fig. 7 suggest as follows. The $\alpha_{1,UV}$ value may be thought to be the measure of the surface potential decay by the carriers which are created near the illuminated surface and move through the bulk to the oppositely charged surface. If no dye is contained, the loss of the carriers in the bulk may be small.

If dyes are contained, however, the carriers are generated also in the bulk by the light absorbed by dyes. The dyes may act as the trapping centers for the carriers and a part of the carriers generated near the surface by UV light will be lost by the recombination and by the trapping in the bulk. For this reason $\alpha_{1,UV}$ seems to decrease with the increasing amount of dyes. As the decrease of $\alpha^{+}_{1,UV}$ is larger than that of $\alpha^{-}_{1,UV}$, the hole carriers will be lost much more than the electron carriers while passing through the bulk containing the dye. It should be noted that this loss of carriers in the VCz-VMG copolymer system may apparently be much larger than that in the other systems.

(c) Comparison of the Surface Potential Decay Constants of Homogeneous Films with That of the Inhomogeneous Films. Probably because of the two reasons there will be the most effective concentration of dyes for the sensitization of PVCz. One is a change in the state of the aggregation of the dye structures causing the change in the efficiency of carrier generation[14,15] and another is the disturbance of the carrier migration through the bulk. The following experiment was done to confirm the latter effect.

Inhomogeneous films (about 24 μ thick) were made from PVCz film (about 20 μ thick) by coating the surface with 0.04 m*l* of the 5 wt% benzene solution of PVCz-MG or VCz-VMG copolymer. These inhomogeneous films consist of the surface layer (about 4 μ thick) containing dyes and the base film of PVCz (about 20 μ thick). Decay constants of the inhomogeneous films thus prepared were compared with those of the homogeneous films (about 24 μ thick). In the case of the inhomogeneous films the decay curves deviated considerably from $V=V_0\exp(-\alpha t^{1/2})$. The experimental results were, however, expressed by this equation, and the parameter α thus obtained was compared with the α values of the homogeneous films. The results are shown in Table 1. The following four important differences were evident.

(i) $\alpha^{+}_{1,v} > \alpha^{-}_{1,v}$ In homogeneous films $\alpha^{+}_{1,v}$ is nearly equal to $\alpha^{-}_{1,v}$, on the other hand, in inhomogeneous films $\alpha^{+}_{1,v}$ is much larger than $\alpha^{-}_{1,v}$. As the surface potential decay in inhomogeneous films belongs to the case of (b-i) mentioned above, this result is explainable.

(ii) $\alpha^{h+}_{1,UV} < \alpha^{ih+}_{1,UV}$ There is no difference in $\alpha^{-}_{1,UV}$ between homogeneous and inhomogeneous films, but $\alpha^{+}_{1,UV}$ of the latter ($\alpha^{ih+}_{1,UV}$) is much larger than $\alpha^{+}_{1,UV}$ of the former ($\alpha^{h+}_{1,UV}$). As in inhomogeneous films the base PVCz film does not contain the dye and carriers are not created in the bulk, the carriers created near the illuminated surface will not be lost much by the recombination and trapping in the bulk. $\alpha^{ih+}_{1,UV}$ may be, therefore, larger than $\alpha^{h+}_{1,UV}$.

On the other hand in negative polarity, both for inhomogeneous and homogeneous films the values of $\alpha^{ih-}_{1,UV}$ and $\alpha^{h-}_{1,UV}$ are nearly equal to each other, probably because the loss of electrons by the existence of the dyes in the bulk, as stated above, is much smaller than that of holes, and

Table 1. Comparison of α values of homogeneous films with those of inhomogeneous films

	0.127	3.1	1.4	4.8	1.3	1.7	0
	0.27	3.7	1.3	4.5	1.4	0.8	0.1

14) R. C. Nelson, *J. Opt. Soc. Am.*, **1958**, 948 .

15) R. C. Nelson, *J. Phys. Chem.*, **71**, 2517 (1967).

consequently, for electrons, the influence of the difference of the bulk constituents in homogeneous and inhomogeneous films may effectively be very small.

(iii) In homogeneous films $\alpha^{h+}{}_{l,v}$ decreases much with the increasing dye concentrations both in PVCz-MG films and in VCz-VMG copolymer films. In inhomogeneous films, however, $\alpha^{ih+}{}_{l,v}$ changes little with increasing dye concentrations. $\alpha^{ih+}{}_{l,v}$ is therefore much larger than $\alpha^{h+}{}_{l,v}$.

In carrier generation, the homogeneous films must be superior to the inhomogeneous films, as the increase of the total carrier is expected with the increasing volume where the dye molecules exist. The fact that in positive polarity $\alpha^{ih+}{}_{l,v}$ is larger than $\alpha^{h+}{}_{l,v}$ must, therefore, be understood by assuming the dual effect of the dye molecules, the generation of carriers and the disturbance for carrier migration. The latter effect must be predominant in this case.

In the case of the VCz-VMG copolymer system $\alpha^{-}{}_{l,v}$ of the homogeneous films is larger than that of the inhomogeneous films, probably because the carrier generation effect may be superior to the disturbance effect. In the case of the PVCz-MG system, however, the former is smaller than the latter, probably because the carrier generation effect may be inferior to the disturbance effect.

These results, (ii) and (iii), support that the hole carrier is lost much more than the electron carrier while passing through the bulk by the existing dye molecules and the loss is especially much in the VCz-VMG copolymer films.

(iv) α_d of inhomogeneous films is considerably smaller than that of homogeneous films in both VCz-VMG copolymer and PVCz-MG systems.

(d) The Degree of Sensitization. The degree of sensitization is in the following order; *i. e.*, PVCz-MG system > VCz-VMG copolymer system $\gg$ PVCz-PVMG system.

From this result it will be supposed that the efficiency of the carrier generation of PVMG is inferior to that of MG and the copolymer. The dyes in the aggregated states have been reported to have poor efficiency of sensitization, which fact has been explained on the electron transfer mechanism.[14,15]

If so, the small degree of sensitization of PVMG as observed in the present investigations will be due to easy aggregation of the dye structures in the polymer chain.

In sensitizing PVCz the copolymer is inferior to the PVCz-MG system because of the loss of mobile carriers by the recombination and trapping in the bulk.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2570—2574 (1968)

Unperturbed Dimension of Poly(butylene oxide)

Masahiro MATSUSHIMA, the late Masaaki FUKATSU and Michio KURATA

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received April 5, 1968)

Viscosity and light scattering measurements of poly(butylene oxide) were carried out in various solvents, including a theta solvent, isopropanol. The intrinsic viscosity *vs.* molecular weight relationships obtained in the range of molecular weight from 2.1×10^5 to 2.3×10^6 were:

$$[\eta]=3.39\times10^{-5}M_w^{0.84} \text{ in benzene at } 30°C,$$

$$[\eta]=4.08\times10^{-5}M_w^{0.79} \text{ in methyl ethyl ketone at } 30°C,$$

$$[\eta]=8.65\times10^{-4}M_w^{0.50} \text{ in isopropanol at } 29.8°C.$$

The ratio σ between the end-to-end distance of the polymer chain in the unperturbed state and that in the freely rotating state was estimated to be 1.66.

As the second part of a series of papers on the dilute solution properties of polyoxides,[1] we here report the results of light scattering and viscosity measurements performed on poly(butylene oxide).

Experimental

Polymer Sample. Poly(butylene oxide) was a gift from Dr. Yutaka Matsui of the Takeda Chemical Industries, Ltd., which was polymerized in *n*-hexane at 60°C using a zinc diethyl complex catalyst with butylene glycol.[2] The polymer was dissolved in acetone to make an original solution for the fractionation. The

1) Part I of this series: M. Kurata, H. Utiyama and K. Kamada, *Makromol. Chem.*, **88**, 281 (1965).

2) Y. Matsui, N. Hashimoto, T. Saegusa and J. Furukawa, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **69**, 1375 (1966).

concentration was 0.8 g/dl. To the solution, methanol was added at 34°C until the solution became turbid. Then, the solution was cleared at an elevated temperature, cooled again and stood at 34°C at which phase separation was proceeded. After removal of the solution phase by siphoning, the precipitate was dissolved in benzene, and dried, and dissolved again in benzene with a small amount (about one hundredth of polymer weight) of antioxidant, *p*-benzylamino phenol. This solution was freeze-dried, and stored in a freezer at about −20°C. The removed solution phase was subjected to the next cycle of the fractionation. The procedures described above were repeatedly applied until the original polymer was separated into 20 fractions. Nine of these fractions were put in light scattering and viscosity measurements.

Solvents. Benzene, methyl ethyl ketone and isopropanol were used as solvents. These solvents were put in physical measurements after dried with drying agents and fractionally distilled. The drying agents used were sodium metal for benzene, active anhydrous calcium sulfate for methyl ethyl ketone and anhydrous copper sulfate for isopropanol, respectively.

Theta Temperature. The theta temperature was found to be 29.8°C in isopropanol by light scattering measurements. Figure 1 shows the apparent second virial coefficient for the whole polymer plotted against the temperature. In the figure, an arbitrary scale is used for the ordinate, since the refractive index increment was not determined in this solvent.

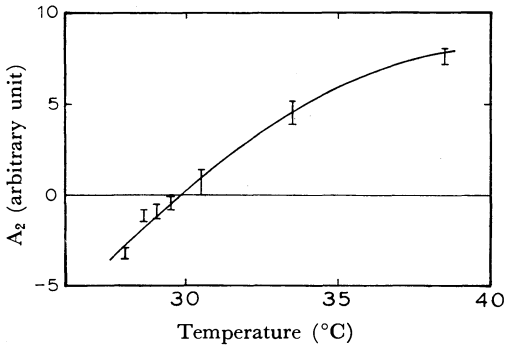

Fig. 1. Determination of the theta temperature.

Intrinsic Viscosity. Viscosity measurements were made in three solvents, *i. e.*, benzene at 30.0°C, methyl ethyl ketone at 30.0°C and isopropanol at 29.8°C, using dilution viscometers of the Ubbelohde type. Corrections for kinetic energy and shear rate were both immaterial. The intrinsic viscosities $[\eta]$ and the Huggins constants k' were determined by extrapolating the plots of η_{sp}/c *vs.* c, and of $(\ln \eta_{rel})/c$ *vs.* c to zero concentration in such a manner that both plots gave the same ordinate intercept. In such a case that the η_{sp}/c *vs.* c plot displayed a marked curvature, the plot of η_{sp}/c *vs.* η_{sp} was used for the extrapolation.

Refractive Index Increments. Measurements were made in a differential refractometer of the Debye type (Shimadzu Seisakusho, Ltd., Kyoto) which was calibrated against aqueous potassium chloride. Five solutions with different concentrations were prepared by dilution from two initial solutions whose concentrations were determined by weighing the dried amount of polymers recovered from a known volume of the solutions. The refractive index increment obtained for the light of 436 mμ wavelength was 0.0863 ml/g in methyl ethyl ketone at 30°C.

Light Scattering. Measurements were made on nine fractions of the polymer in methyl ethyl ketone at 30°C by using a light scattering photometer of the Brice type (Shimadzu Seisakusho, Ltd., Kyoto). The calibration of the photometer was made against pure benzene using the Rayleigh ratio determined by Carr and Zimm. The test solutions were cleaned by spinning for 1.5 hr at 22000 rpm in a preparative centrifuge (type 55P, Hitachi Ltd., Tokyo). Vertically polarized light of 436 mμ wavelength was used as the incident beam, and the vertical component of the scattered light was measured at various scattering angles between 30° and 140°. The weight average molecular weight M_w, the second virial coefficient A_2 and the z-average value of the mean-square statistical radius $\langle S^2 \rangle_z$ were determined by the standard method.

Results and Discussion

Intrinsic Viscosity *vs.* Molecular Weight Relationships. The results of the light scattering and viscosity measurements are summarized in Table 1. These data of the intrinsic viscosities

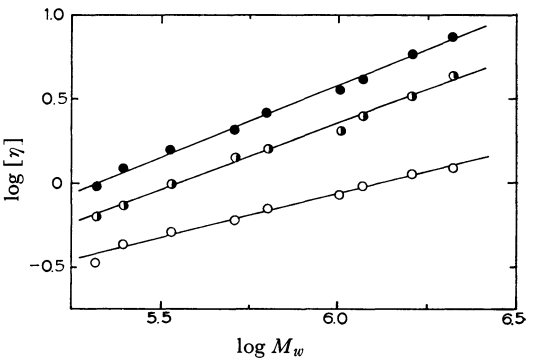

Fig. 2. Intrinsic viscosity *vs.* molecular weight relationships for poly(butylene oxide). White circles, in isopropanol at 29.8°C; half-filled circles, in methyl ethyl ketone at 30.0°C; black circles, in benzene at 30.0°C.

are plotted in Fig. 2 against the molecular weight using the double logarithmic scale. The following relationships are obtained between these two quantities in the range of molecular weight from 2.1×10^5 to 2.3×10^6:

$$[\eta] = 3.39 \times 10^{-5} M_w^{0.84}$$

(in benzene at 30.0°C),

$$[\eta] = 4.08 \times 10^{-5} M_w^{0.79}$$

(in methyl ethyl ketone at 30.0°C),

$$[\eta] = 8.65 \times 10^{-4} M_w^{0.50}$$

(in isopropanol at 29.8°C).

As expected, the intrinsic viscosity in the theta solvent was proportional to the square-root of

the molecular weight. On the other hand, the intrinsic viscosity in benzene was proportional to as high the power of the molecular weight as 0.84, indicating benzene was an extremely good solvent.

Unperturbed Dimension. The viscosity data given in Table 1 are replotted in Fig. 3 according to the Kurata-Stockmayer-Fixman theory:[3,4]

$$[\eta]/M^{1/2} = K + 0.51\,\Phi_0\,BM^{1/2} \quad (4)$$

$$K = \Phi_0(\langle L^2\rangle_0/M)^{3/2} \quad (5)$$

Here $\langle L^2\rangle_0$ is the mean-square end-to-end distance of the unperturbed chain, B is a parameter representing the thermodynamic interaction between polymer segments, and Φ_0 is the Flory universal constant. As shown in Fig. 3, we can determine three straight lines with a common ordinate intercept, showing that the value of K, and hence the unperturbed dimension of the chain, is essentially independent of the solvents. It has recently been pointed out by various investigators that the $[\eta]/M^{1/2}$ *vs.* $M^{1/2}$ plots for the good solvent systems often display downwards curvature in the region of high molecular weights. Such a tendency, however, was not observed in the present systems.

The unperturbed dimension $(\langle L^2\rangle_0/M)^{1/2}$ is determined to be 0.700×10^{-8} (cm·mol$^{1/2}$·g$^{-1/2}$), assuming that $\Phi_0 = 2.5\times 10^{21}$. The conformational parameter σ which is defined as the ratio of the end-to-end distance of the unperturbed chain to that of the freely-rotating chain is then evaluated as 1.66×0.05.

a) expressed in Å unit. b) $\Phi=[\eta]M_w/6^{3/2}\langle S^2\rangle_z^{3/2}$. c) expressed in mol·ml·g^{-2}.

The unperturbed dimensions of various poly(epoxide) chains given in literature are listed in Table 2. The data show that the side group of poly(butylene oxide) gives rise to an enlarging effect on the unperturbed chain dimension to the same degree as that of the methyl group in poly(propylene oxide).[5-7] The effect is clearly smaller than that of the phenyl group in poly(styrene oxide).[8] The similar trend can be found within the group of vinyl polymers, in which polypropylene and polybutene show approximately the same value of σ, 1.6—1.8, while polystyrene a relatively high value, 2.3.[3,7]

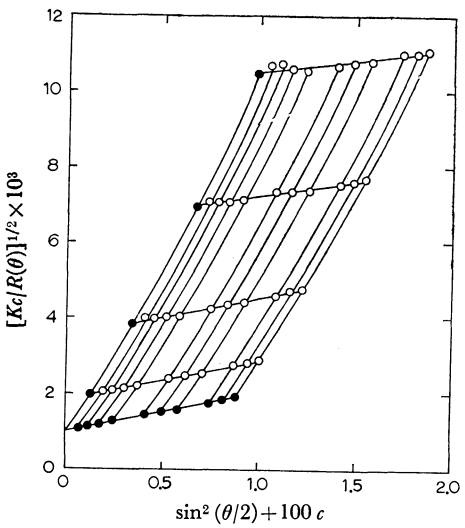

Fig. 4. Plots of $Kc/R(\theta)$ *vs.* $\sin^2(\theta/2)+100\,c$ for the sample, fraction 7. The polymer concentrations c are 0.00991, 0.00671, 0.00345 and 0.00128 g/ml from top to bottom. The scattered angles θ are 30, 40, 50, 60, 80, 90, 100, 120, 130 and 140° from left to right. Black circles represent the values of $Kc/R(\theta)$ extrapolated to $\theta=0$ or $c=0$.

Mean-square Statistical Radius and the Second Virial Coefficient. The z-average value of the mean-square statistical radius $\langle S^2\rangle_z$ can be estimated from the angular dependence of the scattered light intensity using the plots either of $Kc/R(\theta)$ or of $[Kc/R(\theta)]^{1/2}$ *vs.* $\sin^2(\theta/2)$. Here K is an optical constant, $R(\theta)$ is the reduced intensity of scattered light at the scattering angle θ, and c is the polymer concentration. The former ordinate $Kc/R(\theta)$ is known to be appropriate to ordinary polymer samples, especially to the samples with the most probable distribution of the molecular weight, while the latter ordinate $[Kc/R(\theta)]^{1/2}$ to the monodisperse polymers.[9] Since the present

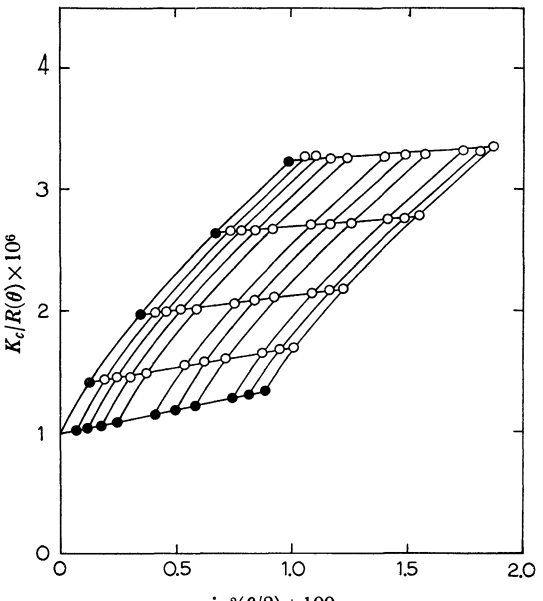

Fig. 5. Plots of $[Kc/R(\theta)]^{1/2}$ *vs.* $\sin^2(\theta/2)+100c$ for the sample, fraction 7. The polymer concentrations and scattering angles are the same as those in Fig. 4.

polymer samples are intermediate in the nature between the two above, we tried the two plots and obtained the results given in Table 3. For illustration, the two plots for fraction 7 are shown in Figs. 4 and 5. These plots lead to the same value of molecular weight, but to rather different values of $\langle S^2 \rangle_z$. As is seen from the table, the $\langle S^2 \rangle_z$ values obtained by the $[Kc/R(\theta)]^{1/2}$ plot lead to values of Φ close to the widely accepted value, $2.1—2.2 \times 10^{21}$, while those by the $Kc/R(\theta)$ plot to lower values of Φ.

As for the concentration dependence of the scattered light intensity, the plot of $Kc/R(\theta)$ *vs.* c gave correlation curves with curvature less than the plot of $[Kc/R(\theta)]^{1/2}$ *vs.* c does. The second virial coefficients A_2 evaluated from the ordinary $Kc/R(\theta)$ plot were found to be larger by a factor about 1.5, on the average, than those evaluated from the $[Kc/R(\theta)]^{1/2}$ plot. Because of the uncertainties involved in the estimates of $\langle S^2 \rangle_z$ and A_2, we here avoid further discussions on these quantities.

This work was supported in part by a grant from the Takeda Chemical Industries, Ltd. Kind help of Dr. Yutaka Matsui of this industries in supply of the original polymer samples is gratefully acknowledged.

Kinetics of Oxidation of Pinacol by Peroxydisulphate Catalysed by Silver Ions

G. D. MENGHANI and G. V. BAKORE[1]*

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received December 20, 1967)

The kinetics of the reaction between peroxydisulphate and piancol catalysed by silver ions (Ag^+) has been studied. The rate of peroxydisulphate disappearance was found to be dependent (i) on $[S_2O_8^{2-}]$ (ii) on (Ag^+). The rate is independent of the concentration of pinacol. Effects of $[H^+]$, temperature on the rate were studied. ΔE, Pz, ΔS, ΔF, *etc.* were evaluated. Mechanism of oxidation of pinacol based on the formation of reactive $[Ag^{2+}]$ is postulated.

Kinetic studies on oxidation of a variety of substrates, both organic and inorganic by peroxydisulphate were reviewed recently by House[1)] and Wilmarth and Haim.[2)] The reactions involving peroxydisulphate ion are generally slow at ordinary temperature and the oxidation does not proceed at a convenient rate at room temperature unless a catalyst is present. The most thoroughly investigated catalyst is silver(I) ion, although cupric ion (Cu^{2+}) has also been studied.

A review of literature on the oxidation by peroxydisulphate shows that oxidation of diols by peroxydisulphate has not received any attention. This investigation, has therefore been undertaken. The present work summarizes the results obtained in the oxidation of pinacol by peroxydisulphate, catalysed by silver(I) ions.

Experimental

Material. Pinacol (B. D. H. A. R.) and potassium peroxydisulphate E. Merck were used. All other chemicals were chemically pure.

Kinetic Method. Reactions were carried out in bottles at constant temperature (±0.03°C). Reaction mixture containing the requisite quantities of diol, Ag^+ was prepared in reaction vessel. The reaction mixture and peroxydisulphate solution were thermostated for about 20 min to attain experimental temperature (48.5°C). A known volume of peroxydisulphate solution was then transferred to the reaction mixture and aliquots were removed and analysed from time to time. The rate at which peroxydisulphate was consumed was estimated by the method of BARTLETT and COTMAN.[3)]

Results

The rate at which the peroxydisulphate was consumed follows first order rate laws. The first order rate constants at different peroxydisulphate concentrations are summarised in Table 1.

Table 1. Variation of rate constant with concentration of peroxydisulphate

$[Pinacol]=4.90\times10^{-2}$ M Temp. 48.5°C
$[Ag^+]=5.30\times10^{-4}$ M

$[S_2O_8^{2-}]\times10^3$ mol/l	$k_1\times10^3$ sec^{-1}
0.98	1.81
1.96	1.70
2.94	1.34
3.92	1.18
4.90	1.08

The first order rate constants are expected to be independent of initial concentration of peroxydisulphate, however, results show a small decrease with increase in concentration of the oxidant. This decrease may be ascribed to specific inhibitory effect of potassium ions, as reported in the oxidation of oxalate[4] also.

Table 2. Variation of rate constant with concentration of pinacol

$[S_2O_8^{2-}]=1.96\times10^{-3}$ M Temp. 48.5°C
$[Ag^+]=5.30\times10^{-4}$ M

0.981	15.3
1.96	15.1
2.94	15.2
3.92	16.0
4.90	15.1

The results show that the rate is independent of the concentration of pinacol.

The results show that rate of oxidation is proportional to the first power of the concentration of silver(I) ions. The effect of H^+ ion concentration on the rate of oxidation was studied by adding sulphuric acid, at the same time adjusting the concentration of sulphate to a constant value by adding potassium sulphate. It is found that when the sulphate ion concentration is kept constant, addition of small quantities of acid decreases the rate constant appreciably, but further addition of acid does not produce any change in the rate of oxidation. The effect of ionic strength on the rate of reaction has been summarised in Table 5. The effect of ionic strength was studied by adding potassium sulphate and potassium nitrate. It is observed that change in ionic strength produced by either K_2SO_4 or KNO_3 has more or less the same effect on rate.

TABLE 7

Specific rate constant at 48.5°C	2.96
Frequency factor, l mol^{-1} sec^{-1}	8.28×10^7
ΔE, kcal/mol	10.87
ΔS, e. u.	−23.1
ΔF, kcals	18.3

slope equal to 0.97 and 0.82 respectively. The reaction was studied at 28.5, 40.0, 48.5 and 54.0°C. The specific rate constant (K) was obtained by dividing the first order rate constant by the concentration of silver ions. A plot of $\log k_1$ against inverse of absolute temperature gives a straight line. This show that Arrhenius equation is valid. The energy of activation was estimated from the slope of the straight line obtained by plotting $\log k_1$ against the inverse of T. The energy of activation comes out to be 10.87 kcal mol^{-1}. The frequency factor and entropy of activation, free energy of activation were estimated from data in Table 6 and have been summarised in Table 7.

Discussion

The reaction between pinacol and peroxydisulphate in absence of silver(I) ions is extremely slow. The rate of (Ag^+) ions catalysed reaction is proportional to the concentration of (Ag^+) ions and of peroxydisulphate but independent of the concentration of pinacol. Since the uncatalysed reaction between peroxydisulphate and pinacol is extremely slow, it therefore suggests that peroxydisulphate or sulphate radical ions do not react with pinacol. However, to explain the increased rate of disapprearance of peroxydisulphate on addition of substrate, it is necessary to postulate that reactive silver species and pinacol react to produce a radical. The radical so produced from the substrate further induces peroxydisulphate decomposition.

Gupta and Ghosh[4] have proposed a mechanism involving an equilibrium which is followed by a termolecular rate determining step:

$$S_2O_8^{2-} \rightleftharpoons 2SO_4^- \text{ (rapid)} \quad (1)$$

$$2SO_4^- + Ag^+ \rightarrow 2SO_4^{2-} + Ag^{3+} \text{ (slow)} \quad (2)$$

The break down of peroxydisulphate into sulphate free radicals appears to be irreversible, as it seems likely that sulphate free radicals would exchange electrons with sulphate ions at a rate comparable with their recombination to perxoydisulphate. However no exchange has been observed under the conditions of the kinetic experiments.[5-8] Thus postulation of termolecular rate determining step introduces difficulties and consequently any proposed mechanism of decomposition involving equilibrium between peroxydisulphate and sulphate ion radicals—step (i) is probably incorrect.

Alternatively catalytic effects of silver ions may be explained by considering the following initial steps:

$$Ag^+ + S_2O_8^{2-} \rightarrow Ag^{2+} + SO_4^- + SO_4^{2-} \quad (3)$$

$$Ag^+ + SO_4^- \rightarrow Ag^{2+} + SO_4^{2-} \quad (4)$$

The nature of the silver intermediate in the oxidations by peroxydisulphate is uncertain. Both Ag^{2+} and Ag^{3+} ions have been postulated as intermediates.[4,9-13] The postulation of Ag^{2+} and SO_4^- as the reactive species accords with the observations of Subbaraman and Santappa,[14] Higgenison and Marshall[15] that one electron transfer is more likely in oxidation-reduction system between a transition

metal ion and an ion derived from a non transition element. In view of the above consideration we are led to suggest the following mechanism:

$$Ag^+ + S_2O_8^{2-} \xrightarrow{k_3} Ag^{2+} + SO_4^- + SO_4^{2-} \quad (3)$$

$$Ag^+ + SO_4^- \xrightarrow{k_4} Ag^{2+} + SO_4^{2-} \quad (4)$$

$$Ag^{2+} + \begin{matrix}(CH_3)_2COH\\ |\\ (CH_3)_2COH\end{matrix} \xrightarrow{k_5} CH_3COCH_3 + Ag^+ + H^+ + (CH_3)_2\dot{C}OH \quad (5)$$

$$(CH_3)_2\dot{C}OH + S_2O_8^{2-} \xrightarrow{k_6} (CH_3)_2CO + H^+ + SO_4^{2-} + SO_4^- \quad (6)$$

$$(CH_3)_2\dot{C}OH + SO_4^- \xrightarrow{k_7} (CH_3)_2CO + H^+ + SO_4^{2-} \quad (7)$$

Application of steady state condition gives:

$$\frac{d[Ag^{2+}]}{dt} = k_3[Ag^+][S_2O_8^{2-}] + k_4[Ag^+][SO_4^-] - k_5[Ag^{2+}][(CH_3)_2COHCOH(CH_3)_2] = 0 \quad (I)$$

$$\frac{d[(CH_3)_2\dot{C}OH]}{dt} = k_5[Ag^{2+}]\left[\begin{matrix}(CH_3)_2COH\\ |\\ (CH_3)_2COH\end{matrix}\right] - k_6[(CH_3)_2\dot{C}OH][S_2O_8^{2-}] - k_7[(CH_3)_2\dot{C}OH][SO_4^-] = 0 \quad (II)$$

$$\frac{d[SO_4^-]}{dt} = k_3[Ag^+][S_2O_8^{2-}] + k_6[(CH_3)_2\dot{C}OH][S_2O_8^{2-}] - k_4[Ag^+][SO_4^-] - k_7[(CH_3)_2\dot{C}OH][SO_4^-] = 0 \quad (III)$$

From I, II and III following relationship follows:

$$[k_3[Ag^+] - k_6[(CH_3)_2\dot{C}OH]][S_2O_8^{2-}] = [k_7[(CH_3)_2\dot{C}OH] - k_4[Ag^+]][SO_4^-]$$

$$[k_3[Ag^+] + k_6[(CH_3)_2\dot{C}OH]][S_2O_8^{2-}] = [k_7[(CH_3)_2\dot{C}OH] + k_4[Ag^+]][SO_4^-]$$

and

$$[(CH_3)_2\dot{C}OH] = \left\{\frac{k_3k_4}{k_6k_7}\right\}^{1/2}[Ag^+]$$

The rate at which peroxydisulphate disproportionates is given by:

$$\frac{-d[S_2O_8^{2-}]}{dt} = k_3[Ag^+][S_2O_8^{2-}] + k_6[(CH_3)_2\dot{C}OH][S_2O_8^{2-}] = \left[k_3 + k_6\left\{\frac{k_3k_4}{k_6k_7}\right\}^{1/2}\right][Ag^+][S_2O_8^{2-}] = K[Ag^+][S_2O_8^{2-}]$$

Where $K = \left[k_3 + k_6\left\{\frac{k_3k_4}{k_6k_7}\right\}^{1/2}\right]$

This mechanism leads to correct rate laws and explains the dependence of rate constant on the first power of silver(I) ion concentration. The product of the oxidation of pinacol as confirmed by its usual tests has been found to be Acetone.

Formation and Decay of the Transient Species in Radiation Chemistry. Radiolysis of Alkyl Halide Systems

Hisashi UEDA

Department of Chemistry, The Ohio State University, Columbus, Ohio 43210, U.S.A., and Tokyo Kogyo Shikenjo, Mita, Meguro-ku, Tokyo

(Received April 15, 1968)

Biphenyl and *trans*-stilbene were irradiated by a pulse of 300 mA × 0.5 μsec in two types of solvents, alkyl halides and methyltetrahydrofuran. The spectra obtained by *n*-butylchloride, 1,1-dichloroethane, 1,2-dichloroethane, 1,1,2-trichloroethane, and 1,1,2,2-tetrachloroethane were concluded to be those of the cations, while the spectra obtained by CCl_4, 1,1,1-trichloroethane, and pentachloroethane were concluded to be due to something other than the cations. The spectra of *o*-terphenyl in 1,1,2-trichloroethane and in 2-methyltetrahydrofuran were different, the reason for this was discussed. The decay curves of the optical densities due to both the cations and the anions all exhibited first-order rates. The decay of the cation of the aromatic solute was concluded to consist of two processes, the transportation of the charged species and the neutralization of the ion pair thus formed. The rate-determining step is the neutralization process, the activation energies of which are 2.17 and 3.62 kcal/mol for *trans*-stilbene and biphenyl respectively. The transportation of the charged species was concluded to be not by the movements of the anion and the cation across the solution, but by the electron-trap- and hole-conductions, such as have been observed in semiconductors.

Shida and Hamill[1] established the existence of the cations of aromatic compounds in the frozen-glass or polycrystalline matrices of alkyl halides. Unfortunately, however, the absorption spectra of the cation and the anion of an aromatic hydrocarbon are, in most cases, very similar to each other. It is, therefore, rather difficult to establish the exstence of either one of these ions with complete definiteness. In spite of such difficulties, however, it seems fairly reasonable to accept the conclusions of Shida and Hamill. It is for this reason that the present work was planned with the hope of establishing the formation and the decay of the radiation-chemical transient species in a solution of an aromatic hydrocarbon in an alkyl halide solvent in the liquid phase.

The present author[2] has studied the effects of additives on the radiolysis of 1,2-dichloroethane. In that study it was shown that those additives with larger reaction-rate constants with hydrated electrons than that of 1,2-dichloroethane decreased the *G*-values of ethylene and HCl, while those additives with smaller rate constants increased the *G*-values of ethylene and HCl, except in the cases of such additives as NH_3. It was also found that there is a parallel relation between the decrease in the *G*-value of ethylene and the increase in the rate constant with hydrated electrons. These facts suggested the existence of both positively- and negatively-charged species as the precursors of the radiolysis products, and also revealed the very quick and efficient charge transfer from the originally-formed solvent cation to the solute molecule.

Arai and Dorfman[3] studied the decay rate and the kinetics of an anion of aromatic hydrocarbon formed in isopropyl alcohol and found that the decay rate curve obeys a first-order reaction rate. This does not agree with a collision-initiated charge neutralization model, which predicts a second-order reaction. They interpreted this phenomenon as possibily resulting from an unknown impurity which still existed in the solution despite the greatest possible efforts at purification. The present author, therefore, also desired to see if such impurity effects are found with alkyl halide solvents.

The rigid-glass method is undoubtedly one of the best ways to take the spectrum of a radiation-chemical transient species, provided that the nature of the species formed is well known. Though in some instances a "fast detection" is equivalent to a "detection after freezing," there are several advantages to the pulse radiolysis method compared to the rigid matrix method. 1) It is possible to ascertain the kinetics of the formation and the decay of the transient species. 2) The successive transformations of the transient species, if any,

1) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 2375 (1966).
2) H. Ueda, *J. Phys. Chem.*, **71**, 3084 (1967).
3) S. Arai and L. M. Dorfman, *J. Chem. Phys.*, **41**, 2190 (1964).

can be traced. 3) More varied types of compounds can be employed as solvents (matrix). 4) The effects of added impurities, which crystallize out if the solution is solidified by cooling, can easily be observed. Because of these considerations, it is important to study again, this time by pulse radiolysis techniques, the kind of system which has already been investigated by the rigid matrix method.

Experimental

The details of the experimental procedures of pulse radiolysis have appeared in many places[4,5] and so will not be particularly described here. Two or three different types of solvents were used after they had been purified. The alkyl halides were shaken with concentrated sulfuric acid and then distilled three times in a vacuum. The ethers, 2,2-dimethoxypropane, 2,5-dimethoxytetrahydrofuran, and 2-methyltetrahydrofuran (abbreviated as MTHF) were treated with sodium, distilled in a vacuum, distilled over a sodium mirror, and then distilled into the cell under a vacuum. The solute hydrocarbons, special reagent grade, were recrystallized twice from alcohol. The polaroid pictures (105 mm×82 mm for 100 mm×60 mm graticule) were enlarged to twice their original dimensions and used for the reaction-rate and absorption-rate analyses.

Results

In Figs. 1—7, Table 1 and Table 2 the results obtained with *trans*-stilbene as the solute are shown. In Fig. 1, the intensity of light absorption by the transient species is plotted as a function of the solute concentration. It may be seen in the figure that the intensity of light absorption is saturated if the solute concentration exceeds 10^{-2} mol/*l*. The effects of the solvents on the intensity of absorption

by the transient species were studied using solutions containing the solute at higher concentrations than this saturating concentration. The results are shown in Table 1. A similar procedure was taken when determining the values in Table 3.

Figures 2 and 3 show the absorption spectra of the transient species of *trans*-stilbene in various solvents. The spectra shown are not the entire absorption corresponding to all the species existing in the system at the time of measurements, but are the differences between the two spectra at 1 and 9 μsec after pulse: (Spectrum at $t=1.0$)—(Spectrum at $t=9.0$ μsec). In Fig. 4 the absorption spectra of the transient species of *trans*-stilbene

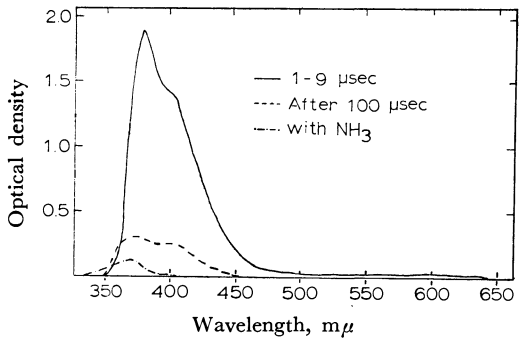

Fig. 4. The absorption spectra of the transient species of *trans*-stilbene in CCl_4. "1—9 μsec," means the difference of the spectra: (absorption at $t=1$ μsec)—(absorption at $t=9$ μsec). "After 100 μsec" means the entire absorption still left at $t=100$ μsec.

in carbon tetrachloride are shown.

It will be seen in Figs. 2, 3, 4, 8, and 9 that there are two types of alkyl halides. The one type consists of *n*-butylchloride (BuCl), 1,1-dichloroethane (11DCE), 1,2-dichloroethane (12DCE), 1,1,2-trichloroethane (112TCE), and 1,1,2,2-tetrachloroethane (TECE). These are called DCE type solvents in this report. The other group consists of 1,1,1-trichloroethane (111TCE), Pentachloroethane (PCE), and carbon tetrachloride. These are called CCl_4-type solvents in this report. The DCE-type solvents give almost identical absorption spectra, which are also quite similar to those reported by Shida and Hamill,[1] when biphenyl and *trans*-stilbene are the solutes, while the CCl_4-type solvents give spectra which are completely different from those observed with the DCE-type solvents.

Figure 5 shows the decay-rate curves of the transient species of *trans*-stilbene in 11DCE at

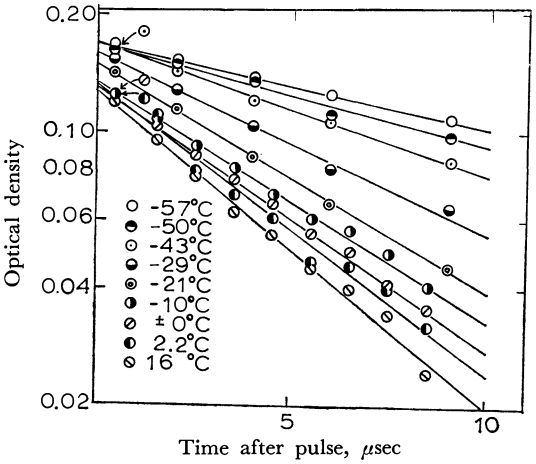

Fig. 5. The decay rate curves of the cations of *trans*-stilbene formed in 1,1-DCE at various temperatures.

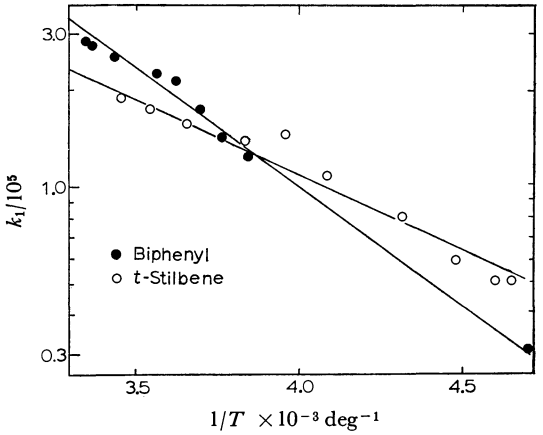

Fig. 6. Arrhenius plots of the 1st order rate constants k_1s in the temperature range between −60°C and +10°C.

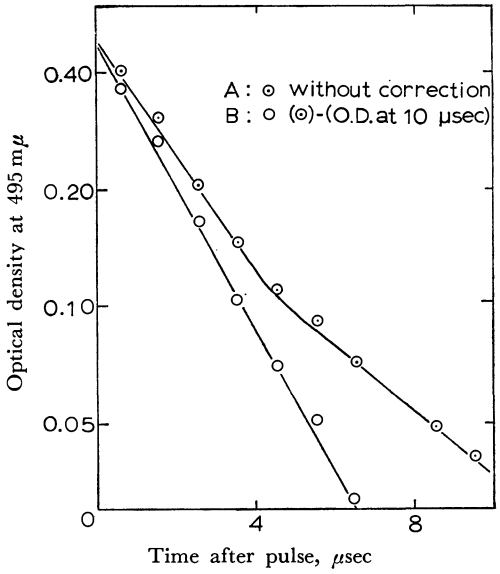

Fig. 7. The decay rate of the anion of *trans*-stilbene in methyltetrahydrofuran.

various temperatures between −60°C and +20°C. The intensity of absorption was observed at 490 mμ. The Arrhenius plots of the rate constants are shown in Fig. 6. The activation energy for the first-order rate constant, k_1, was 1.27 kcal/mol.

In Fig. 7 the decay rate of the transient species in MTHF observed at 495 mμ is shown. The A curve indicates that the absorption curve does not obey the first order decay. However, the absorption spectra showed a clear change in shape after 10 μsec. This means that the species existing during an initial 1—9 μsec, and the species existing after 10 sec, are somehow different. In view of this fact, the optical densities until 9 μsec were corrected by subtracting the value at 10 μsec. The corrected optical densities fall along the straight

line B, which indicates a first-order decay. Such is also true with most of the transient species of *trans*-stilbene in various solvents at 25°C. In other words, all the decay-rate curves, after correction, obey the first-order rate and are identified by the initial optical density at $t=0$, and the rate constant, k_1. Table 1, therefore, shows the initial optical density, at $t=0.5$ μsec, and the k_1.

Though it seems to be beyond question that the effects of the DCE-group solvents on the formation of the transient species are all the same in quality, the present author tested this point by mixing many pairs of the solvents in the group. For example, the results obtained by mixing BuCl and 11DCE are shown in Table 2. However, the effects of 12DCE and CCl_4 are not added to each other when these two solvents are mixed and used. As is shown in Fig. 2, the optical density of the transient species which is qualitatively the same as that obtained by 12DCE is greatly reduced by adding CCl_4. Also, MTHF and TECE have opposite effects. The mixing of 0.08 mol of MTHF with 0.92 mol of TECE reduced the optical density of the transient species of *trans*-stilbene at 490 mμ from the 0.750 of pure TECE to 0.066, as is shown in Table 1.

Figures 8 and 9 show the absorption spectra by the transient species formed from biphenyl in various solvents. In Fig. 10 the decay curves of the transient species of biphenyl in 11DCE at various temperatures between −60°C and 20°C are shown. The intensity of absorption was measured at 370 mμ. The results show first-order rate curves, and the temperature dependence

of the rate constant, shown in Fig. 6, gives 3.62 kcal/mol as the activation energy. Figure 11 shows the various decay rates of the transient species of biphenyl in several alkyl halide solvents. Figure 12 shows the decay rate of the transient species of biphenyl in MTHF. The absorption was measured at 625 mμ. The formation and the decay of the radiation-chemical transient species of biphenyl in various solvents are summarized in Table 3.

Though *trans*-stilbene and many other aromatic hydrocarbons give almost identical spectra[6] in both types of solvents, *i.e.*, alkyl halides and aliphatic ethers, biphenyl gives different spectra, as shown in Fig. 8 and Fig. 9. For a reason to be discussed later, *o*-terphenyl was also expected to give two different spectra in the two types of solvents. Figure 13, therefore, shows the absorption spectra of the transient species of *o*-terphenyl in 112TCE and in MTHF.

Discussion

The light absorption of positive and negative ions of aromatic hydrocarbons have already been studied. Hoijtink[7] studied the negative ions formed with metallic sodium in tetrahydrofuran and the positive ions formed in concentrated sulfuric acid. In most cases the spectra of the cation and the anion were similar to each other. A simple Hückel MO calculation does not predict any difference in the values of the differences in energy levels corresponding to the light absorption by a cation and by an anion.[8] The rigid matrix method used by Shida and Hamill[1,9] also gave many spectra of the unstable species trapped in the matrices of MTHF and alkyl halides (mostly CCl_4 and *s*-butyl chloride) at 77°K. In these cases, however, it is not possible to conclude strightforwardly the pure existence of either a cation or an anion.

There are many possible ways to detect an ion of an aromatic compound in the liquid phase by using some of its physical properties. One of them is the visible-light absorption method, and another is the ESR method. The transient species to be predicted for a system subjected to an ionizing radiation are not limited to only one. For example, the aromatic compound C_nH_m would form $C_nH_m^+$, $C_nH_m^-$, $C_nH_{m-1}\cdot$, $C_nH_{m+1}\cdot$ and so on, generally speaking, there is no reason to deny the existence of any one of them. If this system is investigated in the liquid phase by the use of the ESR method, the difference in the number of protons of the paramagentic species may be found rather easily. Thus the difference between $C_nH_m^+$ or $C_nH_m^-$ and $C_nH_{m-1}\cdot$ or $C_nH_{m+1}\cdot$ will be clear. In addition, some modified or improved MO calculations can predict some difference in the spin density distributions between $C_nH_m^+$ and $C_nH_m^-$, a difference which is to be observed as the difference in the spacings of the lines in the ESR spectrum. At any rate, the information obtained by the ESR method in the liquid phase is normally more useful than that obtained by light absorption specetroscopy. Therefore, if it be possible to apply ESR method to the liquid-phase pulse radiolysis studies, it would be quite powerful.

In the case of the rigid glass method, the ESR method is less powerful than the absorption spectroscopy because of the averaging out of the anisotropy of the resonance lines. Therefore, the results of this method cannot be precisely compared in detail with any MO calculations.

It has already been established that the negative ion of biphenyl is formed by the action of alkali metal in pure tetrahydrofuran or similar solvents. According to Hoijtink,[7] the absorption maximum appears at 625 mμ. Absorption maximum at the same wavelength was also obtained by the pulse radiolysis of biphenyl in ethanol.[3] The present results show that the absorption maximum of 625 mμ is observed only from the solution of biphenyl in MTHF. In the DCE-type solvents, the maximum is 690 mμ. These facts suggest that the species formed in MTHF is the same as that formed in ethanol and that, therefore, it is the anion. However, they do not necessarily indicate that the species formed in 12DCE is the cation. Nevertheless, the effects of gases on the formation of the transient species, Table 3, indicate that only NH_3 affects the formation. The decay kinetics, in all cases, are simple first-order rates, showing that only one short-lived species exists. Such a short-lived species, the origin of which is effectively cancelled by NH_3, must be a species with a positive charge. The only question left is whether or not it is a protonated biphenyl. However, the elimination and transfer of a proton from a DCE-type solvent at these velocities must be doubted.

The absorption spectra for the cation and the anion of *trans*-stilbene have not yet been established. The only available information is that reported by Shida and Hamill.[1] They obtained an absorption spectrum by the use of a rigid glass of *trans*-stilbene in *s*-butylchloride, they ascribed it to the cation. The present pulse-radiolysis results show that there is no considerable difference between the spectrum in MTHF and that in an alkyl halide of the DCE type. The only difference, as may be seen in Fig. 3, is the position of the absorption maximum, which is at 500 mμ for MTHF and 2,5-dimethoxy tetrahydrofuran and at 490 mμ for the alkyl halides of the DCE type. As in the case of biphenyl, it is not easy to decide on the nature of the transient species of *trans*-stilbene formed in each type of solvent. However, the first-order rate curve suggests that there can be only one species which gives the spectrum. The results from the effects of gases, Table 1, show that the transient species formed in DCE type alkyl halides are not much affected by any added N_2O or SO_2, but completely disappear if NH_3 is added. This, it seems, is strong evidence for the formation of the cation in these solvents. Therefore, the species giving rise a spectrum with the peak absorption at 490 mμ can be concluded to be the cation. The mixing of two solvents such as 11DCE and BuCl shows that the effects of the two solvents are added in the mixed solvent. On the other hand, a mixture of 8 mol% of MTHF and 92 mol% of TECE decreased the optical density at 490 mμ to only 9% of that observed with pure TECE. The latter fact indicates that MTHF scavenges the species formed in TECE. Therefore, the electronic nature of the transient species formed in MTHF seems to be exactly the reverse of that formed in TECE. Hence, it is highly probable that the species with the absorption maximum at 500 mμ is the anion.

In the studies of the effect of additives on the radiolysis of 1,2-dichloroethane,[2] it was shown that the *G*-value of ethylene goes down if those additives with larger rate constants with hydrated electrons are added. It was, therefore, concluded that ethylene is formed through a negative ion of 12-DCE. On the other hand, MTHF and tetrahydrofuran, which have smaller affinities with hydrated electrons, increase the *G*-value of ethylene from 2.1 to 3.6 and 5.2 respectively. The explanation of this was that the holes formed in pure 12DCE are normally neutralized by the negative ions. If MTHF or tetrahydrofuran exists, a hole is neutralized by this compound before a negative ion comes into contact with it. The result is an increase in the number of the negative ions which spontaneously disintegrate into ethylene and Cl_2. The conclusion of the product analysis method, therefore, agrees very well with the present pulse-radiolysis results.

The difference between the spectra of the cation and the anion of biphenyl seems to be due to a steric electronic interaction between the *o*-positions in two different benzene rings. If so, a stronger steric effect should be observed in the cation and the anion of *o*-terphenyl. The two spectra from the solutions of *o*-terphenyl in 112TCE and in MTHF are different, as shown in Fig. 13. Therefore, the above explanation may be worth consideration. The electronic charge is conducted through the systems under investigation very well in spite of the insulating nature of both the aromatic solutes and the solvents used, all of which contain only covalent bonds. The concentration dependence of the optical density, Fig. 1, shows that the optical density will be zero at a solute concentration of 10^{-4} mol/*l*. This concentration is equivalent to a cubic lattice model with a unit dimension of 255 Å, one in which all the lattice points are occupied by a *trans*-stilbene molecule while the space inside the lattice is filled with solvent molecules. Therefore, if a cation (hole) of the solvent molecule is formed, at least one of the solute molecules is within less than 220 Å from this hole. The positive charge must travel this distance in order to be transferred to the solute molecule.

A covalently-bonded insulator becomes a semiconductor if some excess electric charge is injected into the lattices. The present system during and immediately after pulsed irradiation seems to be such a semiconductor. This does not mean, however, that a measurable macroscopic

conductivity is observed with an aid of some external circuit connected to the cell. The hole travels only 220 Å before it is captured by the anion. If a solute molecule with a lower ionization potential exists within this range from the hole of the solvent molecule, the hole will migrate to the solute molecule.

Such a semiconduction process also explains the charge transfer within a rigid glass matrix. Unless there is such a conduction, it will be difficult to trap the holes and electrons formed in the matrix molecules completely with less than 10^{-1} mol/l of the solute molecules.

The electricity in the present systems is carried in two ways, by an electron and by a hole. The total conductivity is the sum of the two conductivities, σ_h and σ_e. These quantities are functions of the ionization potential, the electron affinity, the temperature, and so on. In the case of MTHF, the σ_h is small due to the low ionization potential. As a result, the conductivity by the electron traps, σ_e, is dominant, and a negative ion is formed far more easily than a positive ion. The slowly-travelling holes, therefore, are mostly caught by the solvated electrons before they meet a solute molecue. In the case of 12DCE, the σ_h is larger as a result of the high ionization potential. Therefore, only the cation of the solute molecule is formed. In some media in which the σ_h and σ_e are comparable, the simultaneous formation of both the ionic species can be expected. Such is the case with 3-methyl pentane.

To ignore the minor conductivity, however, is not possible, especially more than 1 μsec after a pulse. The ionic species of the solute molecule formed begin to meet the counter electric charge, which is conducted by the minor conductivity. This is observed as the decay of the solute ions. Another piece of experimental evidence to support such a conductivity theory is, then, the kinetics of the decay of the optical densities resulting from the ionic species of the solute.

By analogy with the recombinations of free radicals in the gas-phase photolysis, it has been generally believed that a cation or an anion disappear by the recombination process and that the charge carriers are individual ions. In the present theory, the movements of each molecule are ignored; rather the entire solution is handled as one continuous system. The rate-determining step in the collision-recombination theory is the movement of each molecule, while in the present theory the activation energy for the neutralization of the hole and the trapped electron (or the electron itself) determines the rate. The transportation of a hole or an electron trap is not considered to be rate-determining. It will be helpful to use an ion-pair model to interpret this theory. By, say 0.5 μsec after a pulse, each electron trap has already moved and occupied one of the lattice points which are close to or next to the site which is occupied by a solute cation. By 10 μsec after a pulse all the ion pairs have recombined by going over the activated state. This activation energy is supplied thermally by the surrounding lattices. This theory, therefore, predicts a first-order decay rate of the solute cation. Actually the rate is first-order. Arai and Dorfman[3] suggested the first-order decay rates of the solute anions in isopropyl alcohol with some unknown impurities. It may not have been correct, and the evidence may more properly be interpreted by the present theory.

Though in Shida and Hamill's experiments CCl_4 was a good matrix for observing a cation, in the present study it has been found that CCl_4 gives something else. The fact that a cation is not formed in CCl_4 has already been postulated.[10] The effect of NH_3 on the CCl_4 - *trans*-stilbene system has indicated that the transient species, whose spectrum is entirely different from that of the cation, is also effectively quenched by NH_3. This result can be explained as follows. The initial radiation-chemical product of CCl_4 will be an e^- and a cation, CCl_4^+. CCl_4^+ is, however, extremely unstable. Before a solute cation is formed by a hole conduction started from CCl_4^+, it decomposes to CCl_3 and Cl^+. As Cl^+ is quite different in shape from the matrix molecules, the hole conduction from it to a CCl_4 molecule is rather difficult, and Cl^+ is a stable hole. The transient species observed will have been formed through a direct molecule-to-molecule reaction of Cl^+ and the solute. If NH_3 exists, Cl^+ will react with NH_3 leaving almost nothing to be detected in the visible region. For the cases of other CCl_4-type solvents, namely, 111TCE and PCE, the instability of CCl_3-CH_3^+ and $CCl_3CCl_2H^+$ will explain the odd transient species formed.

CCl_4, CCl_3CH_3 and, CCl_3CCl_2H all have a CCl_3 group, and none of them gives a cation of an aromatic compound in the liquid phase. However, it seems that $CHCl_3$[11] gives a solute cation. Therefore, it is possible to say that a -CCl_3 group without a hydrogen atom connected to it makes the original cation very unstable. In a frozen solid, all the Cl atoms are rigidly fixed by the surounding lattice, as a result, the lifetime of CCl_4^+ is long enough to allow a charge transfer by the hole conduction. If CCl_4 is added to 12DCE, the hole conduction through 12DCE lattice points is greatly disturbed by the presence of CCl_4 molecules. One possible reason is that the conducting holes are not in their ground state (the shallowest holes), but that some deeper holes are contributing to the conduction. Therefore, if the hole arrives at a site of the lattice which is occupied by a CCl_4 molecule, which may have a higher ionization

10) R. E. Bühler and T. Gäumann, p. 279, Ref. 4.
11) S. Arai, private communication.

potential than 12DCE, such an "excited" hole will become a "ground-state" hole of CCl_4 and no longer contribute to the conduction. This impurity effect can also serve to explain the effects of added N_2O and CCl_3CCl_3 on the formation and decay of the cation of *trans*-stilbene in 112TCE, shown in Table 1. As N_2O has a large rate constant with hydrated electrons, it is expected that it will fix negatively-charged species and, as a result, the life of the cation will become longer. This actually happens. However, N_2O also reduces the formation of the solute cation. This indicates that the hole conduction is also reduced by the presence of the N_2O molecule in the system. N_2O^+ as well as N_2O^- is, probably formed, and the charge transfer from a N_2O^+ to a 112TCE molecule is, like that from a N_2O^- to a 112TCE molecule, not easy. This is what the postulate in the previous work of the present author has meant[2]: all electron scavengers would undoubtedly behave both as electron scavengers and as hole scavengers, but after the overall competetion with the solvent molecules, they will behave as electron scavengers. In the case of CCl_3CCl_3, the formation of the cation is not distrubed much, but the decay rate is considerably lower.

The generally-accepted idea of the dissociative attachement process in the gas phase can be doubted in the liquid phase. If the negative charge (or an electron) is permanently trapped in the form of Cl^-, no semiconductivity by the negative charge, σ_e, can be expected. As a result, the decay curve must obey a second-order rate because of the collision-initiated nature of the neutralization. Therefore, the formation of a negative ion, $(RCl)^-$, is more suitable as an explanation of the formation of the cations in these solvents in either the solid or the liquid phase.

The author is greatly indebted to Mr. E. G. Wendell for his technical assistance in this work. He also wishes to thank Dr. L. M. Dorfman for his interest. The helpful opinions of Dr. S. Arai are also appreciated.

Calorimetric Study of the Glassy State. III.*1 Novel Type Calorimeter for Study of Glassy State and Heat Capacity of Glassy Methanol*2

Masayasu SUGISAKI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 16, 1968)

An adiabatic Nernst-Type calorimeter with a cell for condensing a sample vapor as an amorphous state was constructed. By making use of this calorimeter, the heat capacities of the glassy, supercooled liquid, and crystalline states of methanol were measured from 20°K to 120°K. It was found that the state of methanol deposited on the chilled substrate at about 95°K from its vapor state shows a glass transition phenomenon at about 103°K accompanied with the sudden increase of heat capacity, ΔC_P, amounting to 26 J/(mol°K). The drastic crystallization with the exothermic effect coming to 1.54 kJ/mol was observed near 105°K. The residual entropy for the glassy methanol was found to be 7.07 J/(mol°K). Based on these results it seems very plausible to propose that any non-crystalline solid deposited on the chilled substrate from the vapor state will show the glass transition phenomenon.

Usually, a glassy state is considered as a non-crystalline solid which can be obtained by supercooling a liquid sample without any crystallization phenomenon. When the supercooled liquid goes further into a glassy state, a glass transition phenomenon is necessarily found out at a definite temperature characteristic of the sample.

Nowadays, we are able to obtain the non-crystalline solids by using other various kinds of method[1] including the method of the supercooling of liquid. These methods are, *e. g.*, shock wave

*1 Our papers on isopentane (This Bulletin, **41**, 593 (1968)) and on cyclohexanol (*ibid.*, **41**, 1073 (1968)) may be denoted as 1st and 2nd papers of our series of investigation on the glassy state hereafter.

*2 Read before The Third Japanese Calorimetry Conference held at Osaka in 1967. Part of this paper was reported as the short communication in this Bulletin (**40**, 2984 (1967)).

treatment, neutron bombardment, vapor condensation, solution method (hydrolysis and anodization), and dehydration of hydrated crystal, *etc.* These non-crystalline solids prepared by these different methods have common features that they exhibit a crystallization phenomenon on heating.

Are they also plausible to be called as a glass? In order to reply this question, it seems to be most decisive to find out their glass transition phenomena, because the glass transition phenomenon is of characterisitc to the glassy state.

Up to the present time, there has been reported no successful and quantitative work which confirms the glass transition phenomena for such non-crystalline solids prepared by the above cited uncommon methods.

In order to find out the glass transition phenomenon of the non-crystalline state prepared by the vapor condensation method, we have constructed a novel type of calorimeter which involves the sample cell for condensing the sample vapor. By making use of this calorimeter, the heat capacities of the glassy, supercooled liquid, and crystalline states of methanol were measured successfully.

Experimental

Apparatus. The calorimeter consists of a filling tube made of monel and soft copper, a copper cell with a platinum resistance thermometer, inner and outer adiabatic shields, a copper block as thermal station, and a vacuum jacket and others. The filling tube, two adiabatic shields and the copper block are all wound closely with constantan heaters.

The total view of the constructed calorimeter and the sketch of the sample cell are given in Figs. 1 and 2. As is shown in Fig. 2, a part of the filling tube enters into the sample cell. During the procedure of sampling, this part of the filling tube is warmed by the heat conduction from the upper part of the filling tube which is wound closely with the constantan heater. The part of the filling tube inside the cell can be kept at about 15°C, when the temperature of the wall of the sample cell is adjusted to be about 80°K and the outer part of the filling tube is warmed around 30°C under high vacuum condition of about 10^{-6} mmHg inside the cell. In this case the heat conduction between the filling tube and the sample cell occurs spontaneously through the outer short stainless steel tubing put on the top of the cell. The amount of this heat conduction is estimated as 1.3 (J/s), when the above cited temperature difference is maintained. Therefore the effect of the thermal switch is necessitated whose power of the heat exchange is at least larger than 1.3 (J/s). For this purpose the conduction gas method by using helium gas is sufficiently adequate when the apparatus is operated above the boiling point of liquid nitrogen.

In order to carry out the heat capacity measurement under a good adiabatic condition, the adequate combination of monel and copper metals for the filling tube outside the cell is designed for preventing the heat leak through this tube.

Measurements of temperature are made with the platinum resistance thermometer calibrated in terms of International Temperature Scale between 90°K and 500°K and the provisional scale of the National Bureau of Standards between 11°K and 90°K. Measurement of heat capacity is made in quite a same fashion as that reported by Suga and Seki.[2)]

It is found that a heat capacity of the empty cell is about 8.5 (J/degK) at room temperature, and that the attainment of the thermal equilibrium after the finish of energy input takes about 25 min at all temperature region between 13 and 330°K, and that the values of heat capacity deviate from the smoothed curve within 0.1% in the temperature region between 13 and 330°K.

Next, the procedures for condensing the vapor of a sample into the calorimeter as an amorphous state will be described. Firstly the vacuum jacket is immersed into the liquid nitrogen, and helium gas at about one atmospheric pressure is then introduced as a conduction gas into the vacuum jacket, the filling tube and the copper block being simultaneously warmed up at the desired temperature with the constantan heaters wound around them. Their temperatures are registered by the seven chromel P-constantan thermocouples, one of which is attached on the copper block, all the

others being attached on the filling tube (see Fig. 1). The temperature of the sample cell is watched by recording the resistance of the platinum thermometer on the "Speedomax" recorder (Type G, Leeds & Northrup Co.). Under such an operation of the heaters, only the wall of the sample cell is chilled down to sufficiently low temperature, because the heat exchange between the filling tube and the sample cell is pressed down. The temperature difference between them can be easily regulated at any desired values up to about 200°C by changing the level height of liquid nitrogen or by changing the amount of electric current through the heater wound on the filling tube. When the temperature distribution of the calorimeter becomes to be steady, the vapor of the sample is slowly condensed into the calorimeter by opening the needle valve situated at the upper part of the calorimeter (see Fig. 1). The rate of condensation must be regulated to be very slow, since the surface of the amorphous sample produced in the cell may be warmed up above a crystallization temperature with the accumulation of the heat of condensation if the rate of condensation is pretty high. Usually the preparation of the vitreous sample needs about 10—20 hr and a total amount of condensed vitreous substance is of about 1—2 g. After the sampling is over, the heaters of the filling tube and of the copper block are switched off, and the total parts of the calorimeter are chilled down to 80°K, then helium gas (20 mmHg at 80°K) being introduced in the calorimeter cell in order to facilitate the attainment of the thermal equilibrium. Finally the conduction gas in the vacuum jacket is evacuated down to 10^{-6} mmHg for the realization of the adiabatic condition. With this adiabatic calorimeter measurements of the heat capacities can be carried out from 13°K to 330°K.

When the measurement is over, the calorimeter cell is heated up and the sample in the cell is gathered into the glass tube out of the calorimeter and its total amount is determined by measuring its weight.

Purification of Methanol. The commercial extra pure methanol (Wako Chemical Industries, Ltd.) was dried by magnesium metal (Lund and Bjerrum method). This product was distilled twice in high vacuum (10^{-6} mmHg) and the final product was degassed very carefully by repeating melting and freezing of the sample under high vacuum (10^{-6} mmHg). This final product was then introduced into the calorimeter in high vacuum (10^{-6} mmHg) as an amorphous state.

Preparation of Glassy Methanol. For this material, the outer jacket of the calorimeter was removed so that the temperature of the sample cell may be kept as low as possible. During the vitrification process, the temperature of the sample cell was kept between 94 and 97°K, and the filling tube around 220°K. Two kinds of rate of condensation were adopted as given in the second column of Table 1.

Heat Treatment adopted for the Heat Capacity Measurement. For the sample (1) heat capacities of glassy state were measured from 94°K to just above the glass transition temperature, and this sample was again chilled down slowly to 80°K as soon as the sample reached just above the glass transition temperature, and heat capacities were measured again from 80°K to 104°K. When the temperature of the sample reached about 105°K, a drastic crystallization took place and the temperature of the sample rises spontaneously due to the exothermic effect. For the sample (2) the measurements were made for the glassy state from 20°K to 104°K. After the crystallization, the crystalline sample was chilled down to 20°K and the measurements were made from 20 to 120°K.

Experimental Results

Results of Heat Capacity Measurement. *(a) Heat Capacity of the Crystalline State.* The numerical data for the sample (2) are given in

Table 2A, and are represented by hollow circles in Fig. 3. In this figure the smoothed curve above 120°K is drawn on the basis of Kelley's data.[3] It is found that our present data below 120°K agree with his data within the experimental error of 1.3% in the temperature region of liquid hydrogen, and 0.5% in the temperature region of liquid nitrogen.

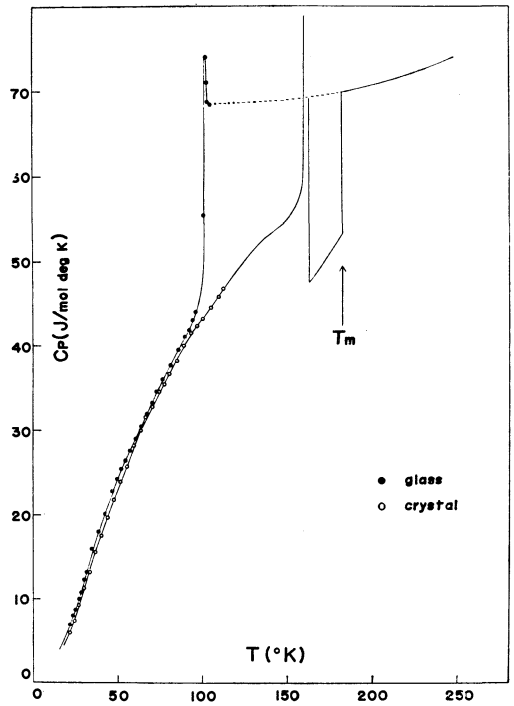

Fig. 3. Heat capacity curve of methanol.

The filled circles represent glassy and supercooled liquid states, and the hollow circles a crystalline state.

(b) Heat Capacities of the Glassy and Supercooled Liquid States. The results of the samples (1) and (2) are given in Table 2B and illustrated by the filled circles in Fig. 3. In this figure, the values for the sample (1) are plotted around the glass transition point and those for the sample (2) are plotted below 80°K (see Table 2A). As is seen in this figure it is found that the state of aggregation of methanol obtained by the present method of vapor condensation shows a glass transition phenomenon at about 103°K. On further heating, we found a drastic crystallization phenomenon at about 105°K just above this glass transition point. The dotted line represents the assumed heat capacity curve for the supercooled liquid which is obtained by an extrapolation of those of the normal liquid. The jump height of heat capacity (ΔC_P) at the glass transition point (T_g) and the total amount of exothermic effect accompanying the crystallization are given in Table 1. By comparing the heat of crystallization with the magnitude of ΔC_P at T_g for both samples, it is easily concluded that the sample (1) is in almost complete glassy state while the sample (2) is in partial glassy state. In Table 1 the amorphous part of the samples are also estimated by comparing the heat of crystallization with each other by assuming that the sample (1) is composed of 100 per cent amorphous material.

Thermodynamic Properties and Residual Entropy. The values of heat capacity, entropy, and also the enthalpy and Gibbs energy functions of methanol at selected temperatures are listed for the glassy and supercooled liquid states in Table 3.

$H°_0(gl)-H°_0(c)$**$=1538$ J/mol.

The values in parentheses are extrapolated by means of the Debye function.

*: (gl) indicates glassy state.

**: (c) indicates crystalline state.

The residual entropy, $S°_0$, which amounts to 7.07J/(mol°K), was also determined by using the results of heat capacity measurement. We could not measure unfortunately the heat of capacity 100 per cent glassy sample of methanol below 80°K, so the heat capacities of the glassy methanol below 80°K were calculated on the assumption that the additivity of the heat capacities of crystalline and glassy states holds as follows,

$$C_P(obs) = \alpha C_P(gl) + (1-\alpha)C_P(cryst),$$

here $C_P(obs)$ is the actually measured heat capacity of the sample, $C_P(gl)$ the heat capacity of completely glassy sample, $C_P(cryst)$ that of the crystalline sample and α the mole fraction of the glassy part of the sample. In the case of sample (2) α was estimated as 0.374, so the heat capacity of the glassy state below 80°K was calculated by using the values of the sample (2).

In passing, the entropy of the crystalline state is based on the Kelley's data.[3]

3) K. K. Kelley, *J. Am. Chem. Soc.*, **58**, 1144 (1936).

Discussion

Design of the Calorimeter. In the past, there has been known no successful work on the precise measurement of heat capacities for an amorphous material deposited directly onto the wall of a calorimeter cell from its vapor state.[4] This fact is due to some difficulties for constructing the calorimeter which fulfills the following few rather severe requirements.

(a) The calorimeter must be equipped with the filling tube, through which vapor of a sample passes, kept at a sufficiently higher temperature above the melting point of the sample, and with the calorimeter cell into which the vapor of the sample is condensed as an amorphous state, kept at a sufficiently lower temperature far below a glass transition temperature of the amorphous sample. For instance, the temperature of the filling tube should be higher about 100—200°C than that of the calorimeter cell if the glass transition point of the sample used situates around 100°K. (b) In order to hold the above cited steady distribution of large temperature difference in the calorimeter, a thermal switch is required whose power of heat exchange is sufficiently large enough. (c) It seems very difficult to obtain a considerable amount of a condensed amorphous substance, so a good adiabatic conditioning of the calorimeter is needed in order to perform precise measurements.

In order to satisfy the condition (a), all previous workers[4] have adopted the method of construction that a sample cell is directly immersed into the liquid nitrogen. This method is, however, inadequate to satisfy the condition (c), because a contamination during the sampling obstructs a realization of an adiabatic conditioning by high vacuum. By taking into consideration the above cited three conditions we have constructed the calorimeter with following devices.

(a) In order to maintain the steady temperature difference between the sample cell and the filling tube, the heat conduction between them is sufficiently reduced by joining them through a thin stainless tube (3 mm in diameter, 0.15 mm in thickness and 10 mm in length). (b) For simplicity of the handling of the apparatus, a conduction gas method was chosen as the thermal switch. If we adopt a mechanical thermal switch which has a comparable efficiency of heat exchange with that of the conduction gas thermal switch, the apparatus becomes to be very complicated. This complication necessarily causes an increase of heat capacity of the sample cell itself, so the mechanical switch is inadequate for the precise measurement.

4) J. A. Pryde and G. O. Jones, *Nature*, **170**, 685 (1952); H. J. de Nordwall and L. A. K. Staveley, *Trans. Faraday Soc.*, **52**, 1061 (1956); R. H. Beaumont, H. Chihara and J. A. Morrison, *J. Chem. Phys.*, **34**, 1456 (1961).

(c) In order to realize a good adiabatic condition, it seems preferable to design the calorimeter equipped with two adiabatic jackets; the structure satisfies the conditions that the convection current of the conduction gas is facilitated, and that a heat leak due to radiation is completely precluded.

Glass Transition Phenomenon of Methanol. Van Thiel and Pimentel[5] observed that methanol deposited on the chilled substrate between 4.2 and 120°K gives an infrared absorption spectrum resembling that of the normal liquid methanol, and that once this deposited state was heated up above 120°K, the spectrum disappeared and changes to that characteristic of the crystalline state. Based on the above observation, they have conjectured that this deposited state of methanol might be a glass. However, their conclusion seems too hasty, because a glass transition phenomenon, which necessarily accompanies the glassy state, has not been discovered yet. Therefore, our present finding of the glass transition phenomenon certifies for the first time that the methanol condensed onto the chilled substrate below 105°K exists as a glassy state. Moreover, it is to be noted that the vitreous methanol of the sample (1) is composed of about 100 per cent amorphous material judging from the heat of crystallization as well as the jump height of heat capacity, ΔC_P, at T_g.

In general, it seems very difficult to obtain the completely vitreous state by the method of vapor condensation. In fact there has been no quantitative work of obtaining completely vitreous material by this method. In the case of our calorimetry, the temperatures of several parts of the apparatus can be regulated accurately and finely and also the rate of condensation can be controlled very precisely during the vitrification process, so that it is rather easy to obtain a completely vitreous material, when the suitable condition for the adjustment of temperature distribution is established. The fact that the sample (2) contains the appreciable crystalline part seems to be due to the warming up of the surface of the sample above the crystallization point by the high rate of condensation.

Judging from the results of our experiment on methanol it seems very plausible to propose that any non-crystalline solid deposited on the chilled substrate from the vapor state will show the glass transition phenomenon.

The authors would like to express their sincere thanks to the Toyo Rayon Co., Ltd. who defraid a part of the financial support for the present investigation.

Calorimetric Study of the Glassy State. IV. Heat Capacities of Glassy Water and Cubic Ice

Masayasu SUGISAKI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 16, 1968)

By making use of the vapor-condensation type calorimeter, the heat capacity measurements of amorphous, cubic and hexagonal ices were made between 20°K and 250°K. The glass transition phenomenon was found near 135°K with the sudden change of the heat capacity amounting to 35 J/(mol°K). The drastic crystallization with the exothermic effect which amounts to 1.64 kJ/mol was then followed at this temperature. The transformation of the cubic crystal to the hexagonal one was confirmed to occur in the temperature region from 160 to 210°K and to proceed in two steps with the activation energies of 21.3 and 44.7 kJ/mol, respectively. The amount of the exothermic effect accompanying this transformation was found to be about 160 J/mol.

In the previous paper,[1] we have reported the construction of the novel type of calorimeter for studying a glassy state and the experimental data on the glassy state of methanol. In the present paper we should like to report our results of investigation on water.

1) M. Sugisaki, H. Suga and S. Seki, This Bulletin, **41**, 2586 (1968).

Since the work by Burton and Oliver[2] in 1935, it has been reported by many workers[2-12] that so-called amorphous state of water may be obtained when the water vapor is condensed onto the chilled substrate below about 140°K. In 1952 Pryde and Jones[4] have first tried to find out the glass transition phenomenon of the amorphous state deposited on a chilled substrate, and several such trials have been followed by many other workers. They are, for example, Ghormley (1956),[5] de Nordwall and Staveley (1956),[6] and McMillan and Los (1965).[12] Nevertheless, there had been no successful work before the study with a differential thermal analysis method by McMillan and Los who have found an endothermic effect at 139°K just below a crystallization temperature for an amorphous ice. Furthermore, many other workers have reported by use of the X-ray or electron diffraction methods that the amorphous ice crystallizes into a cubic form when it is heated up to about 140°K, and that the cubic ice transforms into the hexagonal one very sluggishly and irreversibly around 200°K.[7-11,13] McMillan and Los have also found that this transformation is accompanied with the exothermic effect. Although there have been thus accumulated considerable number of data on the glassy state of this material, it may be said that there is no quantitative and conclusive evidence about the presence of the glassy state of water.

In the present investigation, we have tried to perform the quantitative heat-capacity measurements of the amorphous, cubic and hexagonal ices, and further to obtain some thermodynamical data of the glass transition phenomenon of the amorphous ice, of its crystallization effect and further of the phase transformation of the cubic form to the hexagonal one.

Experimental

Apparatus. An adiabatic Nernst-type calorimeter with a cell for condensing a sample vapor as an amorphous state was used. The detailed structure of the calorimeter and of the experimental procedures were already reported in the previous paper.[1]

Purification of Water. The water treated by ion-exchange resin was distilled under atmospheric pressure, and then this product was distilled twice in high vacuum (10^{-6} mmHg). After the final product was degassed very carefully by repeating melting and freezing of the sample under high vacuum (10^{-6} mmHg), the sample was condensed into the calorimeter in high vacuum (10^{-6} mmHg) as an amorphous state at about 120°K.

Preparation of the Vitreous Water. Four kinds of sample of water were vitrified by condensing their vapor into the calorimeter cell in quite a same fashion as reported in the previous paper.[1] During the vitrification, the temperature of the sample cell was kept first between 103°K and 106°K [sample (1)] and between 120 and 123°K in the other three cases of sample [(2), (3) and (4)]. The filling tube was kept around 300°K in each case for all samples. The rate of condensation and the total amount of the sample used for the measurements are given in Table 1.

Experimental Results

Heat Treatment Adopted for the Heat-capacity Measurement. *Sample (1).* The measurements of heat capacities of the glassy state were made in the region between 118 and 136°K covering the glass transition temperature, through which some exothermic effect was always traced above 115°K. The drastic crystallization was observed at about 135°K which is just above the glass transition point.

Sample (2). The measurements for the glassy state were made in the region from 118 to 136°K including the glass transition temperature. In this case the exothermic effect was observed above 123°K. The drastic crystallization was observed at about 135°K. After the crystallization was over this sample was chilled down to 110°K and measurements were carried out again from 180 to 237°K. The appreciable exothermic effect accompanying the phase transition was observed between 180 and 210°K. After the previous series of measurement was completed, this sample was chilled down once more to 180°K and the measurements were made from 180 to 225°K for the hexagonal phase.

Sample (3). Prior to the measurement of the glassy state, the sample was annealed at 128°K for 12 hr. The measurements of the glassy state were made from 20 to 135°K. After the crystallization was performed, this sample was chilled down to 20°K, and the measurements were made again from 20 to 240°K, an appreciable exothermic effect being also observed between 160 and 210°K during this series of measurement. This sample was again chilled down to 60°K and the measurements were carried out from 60 to 240°K.

Sample (4). After the measurement on the glassy state between 60 and 125°K was over, the sample was annealed at 128°K for 12 hr, and then for this annealed sample the measurements were made between 120 and 135°K in which the drastic crystallization was observed at about 135°K.

● Amorphous ○ Hexagonal ice

After the completion of this crystallization, the sample was chilled down to 60°K and the measurements were repeated from 60 to 240°K.

Determination of a Number of Mole of the Sample. A total amount of the sample, which was condensed into the calorimeter cell for the heat-capacity measurement, was determined first by measuring the weight of the sample collected into the glass tube equipped outside the calorimeter. However, the heat capacities of the hexagonal ice calculated based on this value of the number of mole were smaller than those of Giauque's data[14] by 10%. This seems to be due to the fact that some amount of water were condensed in the filling tube situated out of the sample

cell, because the sample in the filling tube does not take part in the heat-capacity measurement, so the number of mole of the sample in the cell was over-estimated than the true value. In this respect, the number of mole of the sample was determined by fitting our values of hexagonal ice to those of Giauque's data between 100 and 140°K.

The accuracy of our calorimeter was checked already in the case of methanol, and so this method of determination may be reasonable and satisfactory for the present purpose. So that, in place of the value determined by direct measurement of the weight of the sample collected into the glass tube, the number of mole based on the Giauque's data was adopted in the following.

and (4) are given in Table 2 and are represented by the hollow circles in Fig. 1. The deviation of the values around the smoothed curve is within 3% in the vicinity of the boiling point of liquid nitrogen and within 1% around 200°K.

Glass and Supercooled Liquid. The results for the samples (1), (2), (3) and (4) are all given in Table 3. The temperature-dependence of the heat capacity in the vicinity of the glass transition point is drawn for each case of the samples in Fig. 2. Amongst the filled circles given in Fig. 1 the values on the sample (1) are plotted around T_g and those of the sample (3) for the temperature region below 80°K. As is seen in these figures the amorphous solid of water obtained by the method of vapor condensation was found to show a glass transition phenomenon at about 135°K. On further heating the drastic crystallization was found to occur just above the glass transition point. The jump of heat capacity at the glass transition point and the total amount of the exothermic effect accompanying the crystallization are given in Table 1.

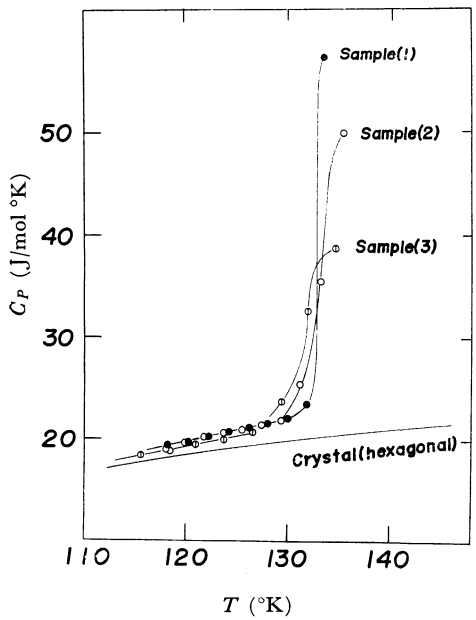

Fig. 2. Heat capacity curve of water near the glass transition temperature.

Cubic Ice. The results for the samples (2), (3) and (4) are given in Table 4, and are illustrated in Figs. 3 and 4 in comparison with those of the hexagonal ice. The total exothermic effect was observed in the temperature region from 160 to 210°K, and in particular we can recognize the remarkably anomalous region of heat capacities between 190 and 210°K. The corresponding enthalpy amount of this exothermic effect was estimated between 160 and 210°K for each sample as is given in Table 5.

Table 5. Total amount of exothermic effect accompanying irreversible transformation of the cubic ice to the hexagonal one

2	158.9	±15
3	164.4	
4	159.5	

Discussion

Realization of Glassy State. From the results of our heat-capacity measurement, it is quite clear that the amorphous water condensed

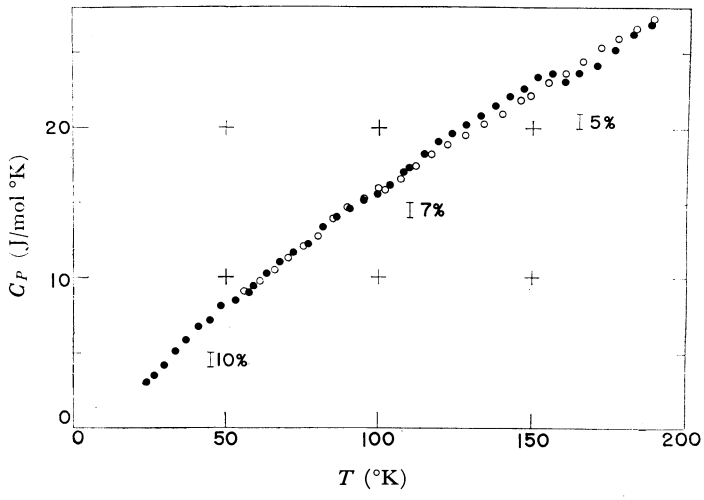

Fig. 3. Heat capacity of ice. The filled circle represents the cubic ice and the hollow circle the hexagonal one.

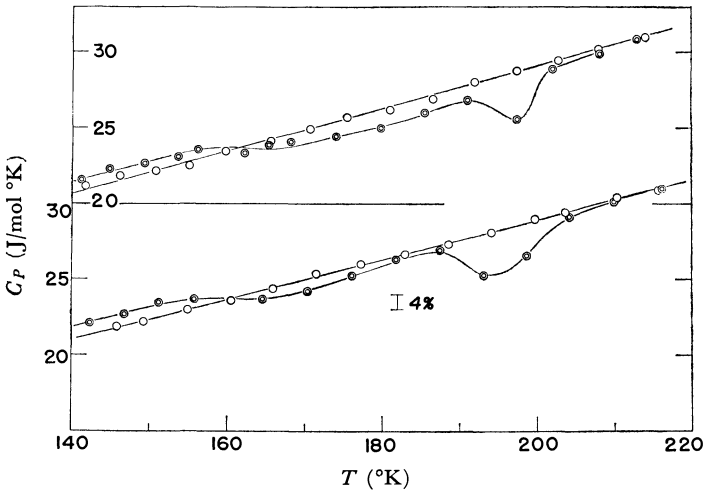

Fig. 4. Heat capacity of ice near the transformation temperature. The lower figure is results for the sample (3) and the upper for the sample (4).
◎ Cubic ○ Hexagonal

from the vapor onto the substrate chilled below 135°K shows a glass transition phenomenon. This fact shows that the condensed amorphous water exists in the glassy state below 135°K. This new finding of the glass transition phenomenon gives a definite resolution to the question whether the non-crystalline solid obtained by the vapor-condensation method is really a glass or not.

It is to be noted that the jump height of heat capacity at the glass transition point, and the heat of crystallization have different four values from sample to sample (see Table 1). This fact suggests that each of samples contains a few amount of a crystalline part. This crystalline part of the sample is considered to appear during the process of annealing. This is evidenced by the fact that the exothermic effect was observed even after the annealing at 128°K for 16 hr, and that the heat of crystallization gets smaller as the time of duration for annealing is longer (see Table 1), and further that the heat capacity curves of two series do not agree with each other in the case of the sample (4), as is shown in Fig. 5, where one series of measurements is made prior to annealing and the other after annealing at 128°K for 13 hr.

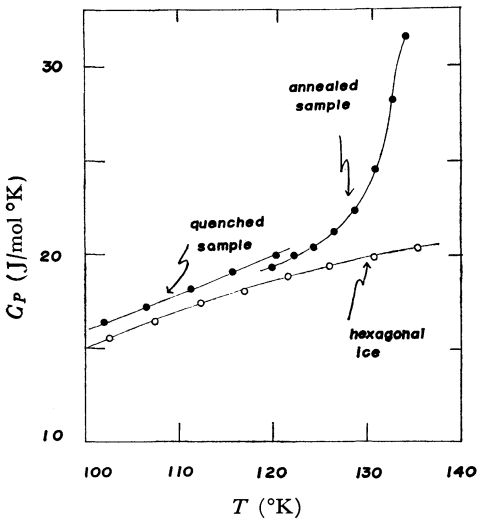

Fig. 5. Heat capacity of the glassy state of water.

In the case of sample (1), the jump height of heat capacity ΔC_P at T_g is of the highest value among all samples (see Table 1 and Fig. 2). The heat capacity just above T_g of this sample is, however, appreciably smaller than that of the supercooled liquid at the same temperature assumed by the extrapolation of the heat capacity of the liquid above the melting point. This fact is, at the first glance, considered to be due to the existence of crystalline part in the vitreous sample. This interpretation seems, however, to be inadequate because of some thermodynamical contradiction as will be described below. If C_P values of the supercooled liquid are assumed to be extended like a dotted line in Fig. 1, the corresponding enthalpy curve of the supercooled liquid comes out to be drawn in Fig. 6. At first sight of this figure it is shortly understood that the curve of the supercooled liquid intersects that of the crystal far above 135°K($=T_g$). This circumstance is evidently incompatible with the fact that the crystallization is necessarily accompanied by the exothermic effect. Consequently, it turns out to be inappropriate to assume that the C_P values of the supercooled liquid is equal to those obtained with extrapolating the C_P values of the liquid above the melting point.

Now, water has been known as a typical anomalous liquid. For example, its C_V values are

much higher than those of other normal liquids composed of triatomic molecules. In order to interpret the remarkably abnormal physical properties, Eucken[15] has proposed that water is an equilibrating mixture of several kinds of associated species (*e. g.*, H_2O, $(H_2O)_2$, $(H_2O)_4$ and $(H_2O)_8$), and that the anomalous large value of heat capacity is caused by the dissociation of the associated species with the rise of temperature. Recently, Wada[16] has calculated the heat capacity of water reduced to a normal liquid assuming the existence of two states in water such as icy and packed states. According to his calculation, the C_P value of water reduced to the normal liquid is smaller than that of crystal at 0°C. Although his result does not directly stand for our present results, the hypothetical C_P value of water consisting of exclusively monomer molecules might be smaller than the observed one. Based on this consideration, it seems to be supported that the vitreous water obtained in the present work (in particular sample (1)), may be nearly 100 per cent amorphous state.

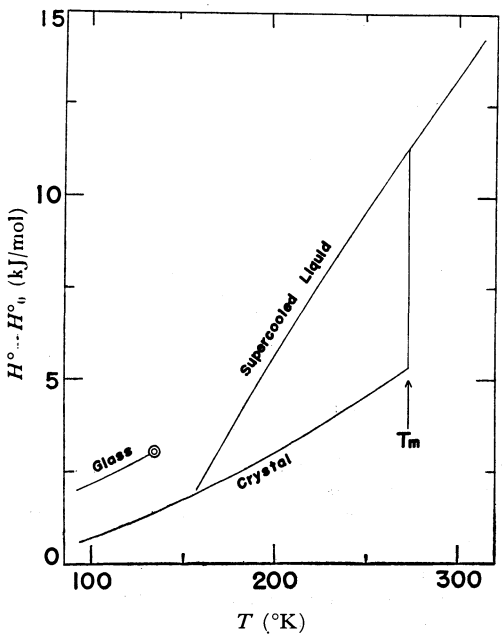

Fig. 6. Enthalpy relation of various states of water.

Appearance of the Cubic Ice and Its Transformation into the Hexagonal Ice. During past many years, a great deal of investigations[7-11,13] have been reported concerning the appearance of the cubic ice and its transformation to the hexagonal ice. As the results of these studies it is now well known that the cubic form of ice can be obtained either as a product of crystallization of amorphous ice or as a kind of high pressure form. In this section, we should like to concern only with the cubic ice prepared by the former method.

Up to the present, the existence of sluggish and irreversible transformation of the cubic ice to the hexagonal one has been observed by several workers. There has been, however, no quantitative experiment on the sample at the thermodynamically equilibrium state, so there remains still a confusion about the temperature interval of the appearance of the cubic ice, and also a more important problem whether the cubic ice is more stable than the hexagonal ice or not in the lower temperature region.

According to our present heat capacity measurements, the cubic ice transforms sluggishly and irreversibly into the hexagonal ice with an appreciable exothermic effect between 160 and 210°K. The average total amount of the exothermic enthalpy change, 160 J/mol, is close to the value, 150 J/mol, previously reported by McMillan and Los. This agreement seems, however, to be fortuitous, because their experiment was of dynamical nature and their results were based on the Ghormley's value (1.26 kJ/mol)[5] for the heat of crystallization which does not agree with our present data (1.64 kJ/mol).

As is well known, the hexagonal ice has a center of symmetry in the direction vertical to *c*-axis and a mirror of symmetry in the direction parallel to this axis with regard to the conformation of oxygen atoms in the lattice. On the other hand the cubic ice has the center of symmetry in these two directions, *i. e.*, a diamond structure.

The enthalpy change of the transformation amounting to about 160 J/mol, which is obtained in the present experiment, is considered to be due to the difference of the lattice energy between these two structures. Such an exothermic phenomenon seems to be concordant with the result calculated by Bjerrum[17] *i. e.*, the hexagonal ice is more stable than the cubic ice with regard to its lattice energy.

Now, the kinetics of this transformation has been studied by several previous workers who have interpreted this phenomenon in terms of the activation energy.[12,18] McMillan and Los have reported that this irreversible transformation may be characterized by the activation energy of about 7.4 kcal/mol, which is calculated based on the X-ray data by Dowell and Rinfret.[9] On the other hand Nozik and Kaplan,[18] by use of the Mössbauer resonance method for the ice doped with ferrous ion, have reported that the transformation occurs at least in two stages with a certain intermediate

18) A. J. Nozik and M. Kaplan, *Chem. Phys. Letters*, **1**, 391 (1967).

state, and that the activation energy for the process of the cubic-to-intermediate comes to about 29 kcal/mol.

We have also estimated the activation energy for this irreversible phenomenon from the results of heat-capacity measurement. When the cubic ice transforms into the hexagonal one with the exothermic effect, the temperature of the sample rises spontaneously if an adiabatic condition is well maintained. Concerning this phenomenon, the following equations were assumed to hold,

$$\dot{T} = (\Delta H/C_P)\cdot\dot{x} = 1/\tau(\Delta H/C_P)\cdot x,$$
$$\dot{x} = (1/\tau)\cdot x \qquad \tau \propto \exp(E/RT)$$

here $\dot{T}$ is the time-derivative of the temperature of the sample, C_P the heat capacity of the sample including the sample-container, ΔH enthalpy change accompanying the cubic-hexagonal phase transition, $\dot{x}$ the time-derivative of the mole number of the cubic ice, τ the relaxation time characteristic of this phenomenon, x the mole number of the cubic ice, E the activation energy for this rate process. The values of $\dot{T}$, C_P, ΔH, and x are all obtained as a function of the temperature from the results of heat capacity measurement, so τ is easily calculated for all temperatures. The obtained relation between $\log \tau$ and $1/T$ is drawn in Fig. 7. From this figure we see that this rate process may be separated into two processes, one of which is characterized with the activation energy of about 5 kcal/mol, the other with the activation energy of about 11 kcal/mol. The fact that this phenomenon occurs in two stages in our study is quite concordant with the results by Nozik and Kaplan, but the values of the activation energy are different from each other. Taking into consideration the difference that our experiments are based on the pure ice, whereas Nozik and Kaplan's works are based on the frozen solution, it is not quite clear to what extent such a comparison is plausible.

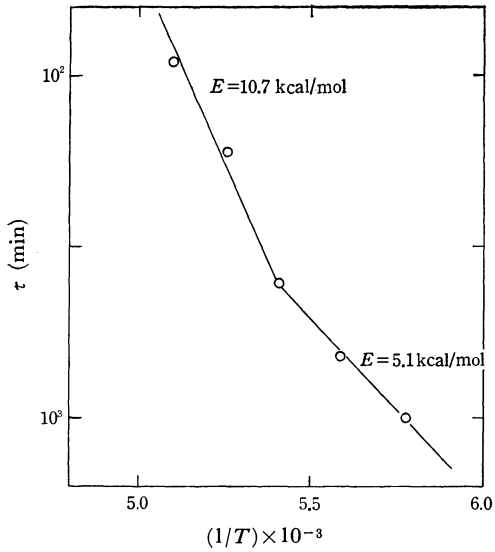

Fig. 7. Relaxation time characteristic of the irreversible transformation of cubic to hexagonal ice.

It is to be noted here that the activation energy of about 11 kcal/mol concerning the higher-temperature process is concordant with the result of Dowell and Rinfret. As their experiment was carried out with the X-ray analysis method, it may be possible that they have observed mainly the higher-temperature process for which the rate of transformation is pretty high.

Definition of the Glassy State. As to the difinition of the glassy state, no unequivocal conclusion has been given hitherto, so there has been still a few confusions concerning the usage of the term "glassy state."[19] This seems to be due to the fact that the past definitions of the glassy state are almost concerned with the chemical composition of the glass or with the methods of obtaining the glassy state.

Commonly, a glassy state has been considered to be equivalent to a non-crystalline or amorphous solid obtained by supercooling the liquid. However, the non-crystalline solid can be obtained also by using other rather uncommon methods, such as vapor condensation, neutron bombardment, and others. Such a non-crystalline solid has been observed to crystallize on heating. For this kind of solid, the glass transition phenomenon has not ever been verified. As far as the glass transition phenomena are not observed, we may feel a certain hesitation to call this non-crystalline solid as a glass. However, our previous finding of the glass transition phenomena of methanol[1] and the same result for water prepared by the vapor condensation method in the present study afford the conclusion that the non-crystalline solids of these materials prepared by this uncommon method must be called as a glass. On the basis of our new observation we may propose a more general properties of the glassy state as follows: (a) The glassy state must be distinguished from other states only by the fact that the thermodynamically equilibrium state is never attained. (b) The glassy state must show the glass transition phenomenon which characterizes the boundary between

19) D. R. Secrist and J. D. Mackenzie, "Modern Aspect of the Vitreous State," Vol. 3, ed. by J. D. Mackenzie, Butterworths Scientific Publication, Ltd., London (1964), Chapter 6.

Note added in proof: Quite recently J. A. Ghormley [*J. Chem. Phys.*, **48**, 503 (1968)] has re-investigated the glass transition phenomenon of water by use of the method of thermal analysis and suspected the observation of T_g by J. A. McMillan and S. C. Los cited in this text. I. Yannas has pointed out also the elusive nature of the glass transition point of water and estimated the glass transition point of water to be 127±4°K indirectly by the extrapolation of T_g for glycerol with the increase of water content [*Science*, **160**, 298 (1968)].

the glassy and the supercooled liquid states. (c) The glassy state is established irrespective of either the method of preparation or the chemical composition of the material.

The authors would like to express their sincere thanks to the Toyo Rayon Co., Ltd. who defraid a part of the financial support for the present investigation.

The Fluorescence Spectrum of Benzene in Solution at 77°K

Yoshio MURAKAMI and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka, Japan

(Received April 25, 1968)

The fluorescence spectrum of benzene in methylcyclohexane at 77°K has been analyzed in detail. The forbidden 0–0 band appeared weakly, and all the bands were interpreted as allowed bands except for the 0–992 band. The fluorescence spectrum has also been studied in carbon tetrachloride; the anomalous vibrational structure has been found in solutions as dilute as 10^{-3} M, irrespective of the cooling procedure. The correlation with the absorption and with the phosphorescence spectrum of benzene reported previously has been discussed.

Ivanova and Sveshnikov[1] studied the fluorescence spectrum of benzene in an alcoholic solution at 77°K and gave a tentative vibrational analysis. The 0–0 band was not observed, and the 992-cm^{-1} progression appeared from bands separated by 606 and 1178 cm^{-1} from the assumed position of the 0-0 band. The $606+n\times992$ series was much stronger in intensity than the $1178+n\times992$ cm^{-1} series. Wolf[2] also gave a simple analysis of the fluorescence spectrum of crystalline benzene at 77°K. The forbidden 0–0 band appeared weakly, while the $606+n\times992$ series appeared strongly. The 992-cm^{-1} progression was also seen to start from the 0–0 band with quite a strong intensity. The crystal spectrum at 77, 20.4, and 4.2°K has also been reported on by Shpak, Solov'ev, and Sheremet[3] and by Vatulev, Sheremet, and Shpak.[4]

We studied the fluorescence spectrum of benzene in solutions in ethanol, cyclohexane, and methylcyclohexane and of the crystal at 77°K in order to check if all the analyses previously reported were correct.

We also studied the fluorescence spectrum in carbon tetrachloride at 77°K. In previous papers[5] we have found anomalous vibrational structures in the phosphorescence spectrum of benzene in carbon tetrachloride and in the absorption spectrum in a rapidly-cooled carbon tetrachloride solution. Here we experimented in order to check if any anomalous feature was also present in the fluorescence spectrum.

Experimental

Benzene was purified according to a method previously described.[5] In the course of study toluene was found to be an impurity in benzene, since it emitted a characteristic fluorescence spectrum overlapping the benzene spectrum. The toluene in the benzene was therefore removed through oxidation with a potassium permanganate solution acidified with sulfuric acid. This operation was repeated several times before the ordinary purification operation of benzene.

Ethanol, cyclohexane, methylcyclohexane, and carbon tetrachloride were purified by methods previously described.[6] A super-high vapor pressure mercury arc lamp of the ORC 1 kW type, CHM-621, was used as the light source, and Hg 2537 Å was introduced into the cell through a filter system.[7] A RIKEN medium quartz spectrograph corresponding to a Hilger E2 was used throughout the work. The optical setup was exactly the same as that described previously except for a phosphoroscope.[5] Here it was unnecessary. The surface of a frozen sample was oblique to the incident light. The concentration was fixed at 10^{-3} M for all the solutions. The slit-width was 50 μ, and Eastman Kodak plates 103a-0 were used. Exposure

times ranged from 2 to 15 h. The accuracy of measurement was about $\pm 3\ cm^{-1}$ for sharp bands and about $\pm 20\ cm^{-1}$ for broader bands.

Results and Discussion

The fluorescence spectrum of benzene in solutions in ethanol, methylcyclohexane, cyclohexane, carbon tetrachloride and in the crystal was studied at 77°K; some of the tracing curves are shown in Figs. 1 and 2. The spectrum in ethanol appears broad in comparison with that in methylcyclohexane; the vibrational analysis has been made with the latter at the beginning. The results are given in Table 1. A band at $37820\ cm^{-1}$ is ascribed to the 0–0 band of the spectrum, a band which is forbidden by symmetry but which is allowed weakly by solvent perturbation. The $992\text{-}cm^{-1}$ progressions appear, perturbed by vibrations of $606(e_{2g})$, $405\times 2(e_{2u}\times e_{2u})$, $405+671$ $(e_{2u}\times a_{2u})$, $1178(e_{2g})$, $405\times 2+606(e_{2u}\times e_{2u}\times e_{2g})$, $849\times 2(e_{1g}\times e_{1g})$, $970\times 2(e_{2u}\times e_{2u})$ or $606+1326$ $(e_{2g}\times a_{2g})$, and $606+703\times 2(e_{2g}\times b_{2g}\times b_{2g})$, and $606+849\times 2(e_{2g}\times e_{1g}\times e_{1g})$. Therefore, all the bands in the progressions are allowed except for two bands, those at 37820 (0–0) and $36830\ cm^{-1}$ (0–992). The spectrum in ethanol looks smoothed out of that in methylcyclohexane. The progression assigned to $1178+n\times 992$ by Ivanova and Sveshnikov must be interpreted as the overlap of the $405\times 2+n\times 992$, $405+671+n\times 992$, $1178+n\times 992$, $970\times 2+n\times 992$ *etc.*, series. They did not find the 0–0 band of the fluorescence spectrum and assumed an unobserved position at $37780\ cm^{-1}$ as the band origin. That the differences between the observed and calculated values are greater for the $1178+n\times 992$ series than those for the $606+n\times 992$ series means that their assignment, $1178+n\times 992$, was not complete enough.

The fluorescence spectrum of benzene in cyclohexane was analyzed in the same way as that in methylcyclohexane. Cyclohexane undergoes a phase transition at −87°C, and the spectrum of a rapidly frozen sample contains bands from the high- and low-temperature phases. By the use of a careful annealing technique, the low-temperature-phase spectrum (the 0–0 band at 37705 cm^{-1}) was separated from the high-temperature one (the 0–0 band at $37790\ cm^{-1}$). Only the low-temperature spectrum is shown in Fig. 1.

The fluorescence spectrum of crystalline benzene was analyzed in comparison with the solution spectra. A weak band at $37713\ cm^{-1}$ looked like the band origin of the spectrum. However, reabsorption must be taken into account, and an unobserved position at $37814\ cm^{-1}$ was assumed here to be the 0–0 band of the spectrum. This really corresponds to the band at $37811\ cm^{-1}$, one of the components of the 0–0 band of the absorption spectrum of the benzene crystal at 90°K suggested by Bronde, Medvedev, and Prikhot'ko.[8] The spectrum photographed at 77°K

in this experiment is essentially the same as that reported by Shpak, Solov'ev, and Shermet[3] and will not be reproduced here. It is to be discussed elsewhere.[9] However, we would like to propose here a suggestion concerning the interpretation of the 0–0 band of the fluorescence spectrum of the benzene crystal they studied.

If we use the data in Fig. 2 in Ref. 3 and add the vibrational frequencies of 607 and 990 cm^{-1} to 37221 and 36838 cm^{-1} respectively, we obtain 37828 cm^{-1} for both cases. This must be the band origin; it corresponds to one of the 0–0 bands of the absorption spectrum. The band at 37775 cm^{-1} may be a band from a trap or a remainder band due to reabsorption. The same interpretation can be applied to the spectra at 20.4 and 4.2°K in Fig. 1 in the paper by Vatulev, Sheremet, and Shpak.[4]

No bands corresponding to the III series in Figs. 1 and 2 of Ref. 8 were found in our spectrum. They were not in Fig. 1 in Ref. 10 either and so must be ascribed to an impurity.

The fluorescence spectrum of benzene was also studied in carbon tetrachloride. In previous papers[5] we have reported an anomalous vibrational structure in the phosphorescence spectrum of benzene in carbon tetrachloride and have examined the absorption spectrum of benzene in carbon tetrachloride with rapidly- and slowly-cooled samples. The spectrum of a rapidly-cooled solution has a strong and broad 0–0 band, while that of a slowly-cooled solution gives weak and split 0–0 bands. No difference was found between the phosphorescence spectra of rapidly- and slowly-cooled samples; this phenomenon may tentatively be ascribed to the mixing of the rapidly-cooled phase in the slowly-cooled phase. The phosphorescence spectrum of weak intensity of the slowly-cooled sample might have been overshadowed by the phosphorescence spectrum of strong intensity of the rapidly-cooled sample. In the absorption experiment, the concentration was as high as 10 mol% since a thin-layer sample had to be used. For the phosphorescence spectrum the concentration was of the order of 10^{-3} M and the volume was about 2 *ml*. These incoincidences in concentrations and in the sample mounting may sometimes be crucial for the interpretation of the spectrum. Therefore, it is necessary to study the fluorescence spectrum at various concentrations. Concentrations were chosen according to a phase diagram of the CCl_4-Benzene System. While a phase diagram designed by Kapustinskii and Drakin[10] was used in the previous papers,[5] a new diagram recently suggested by

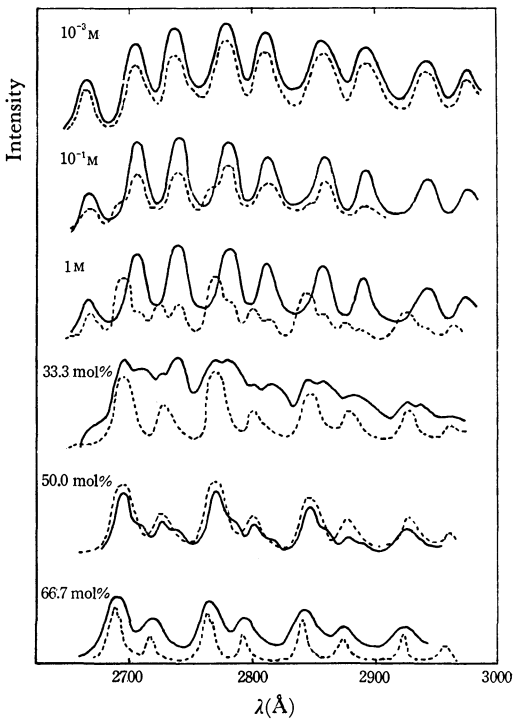

Fig. 2. Fluorescence spectra of benzene in carbon tetrachloride at 77°K.
——: Rapid cooling ·····: Slow cooling

Ott, Goates and Gudge[11] has been used in this work. Samples were mounted as thin layers between quartz plates at 77°K. The results are shown in Fig. 2.

It is interesting to see that there is no difference between the fluorescence spectra of the rapidly- and slowly-cooled solutions at 10^{-3} M; this is in agreement with the results in the phosphorescence spectrum. In one of our previous papers[5] we assumed the mixing of the rapidly-cooled phase in the slowly-cooled phase, but this interpretation proves untenable. At such a low concentration both samples have the same phase and give an anomalous vibrational structure due to a strong environmental effect. At concentrations such as 33.3 and 50.0 mol%, the fluorescence spectrum of the slowly-cooled samples gives a weak 0–0 band (hereafter we will call this the H-spectrum), unlike the spectrum at concentrations as low as 10^{-3} M, which has a strong 0–0 band (hereafter we will call this the L-spectrum). A question arose whether the H-spectrum of the slowly-cooled samples of 33.3 and 50.0 mol% solutions could be the spectrum of the benzene crystal crystallized out of the solution during the cooling processes. However, this is not the case, since the wavelength of each band was different from that of the benzene crystal.

9) A. Nakahara, M. Koyanagi, Y. Murakami, T. Edamura and Y. Kanda, to be published.
10) A. F. Kapustinskii and S. I. Drakin, *Bull. acad. sci. U.S.S.R. classe sci. chim.*, 475 (1947); *Chem. Abstr.*, **42**, 1902 (1948).
11) J. B. Ott, J. R. Goates and A. H. Gudge, *J. Phys. Chem.*, **66**, 1387 (1962).

The spectra of the slowly-cooled samples at 10^{-3} and 1 M (the latter corresponding to about 10 mol%) and that of the rapidly-cooled samples at 33.3 and 50.0 mol% show an overlapping of the L- and H-spectra. The species giving the H-spectrum is considered to be C_6H_6-$2CCl_4$ on the basis of the finding that the H-spectrum appears in the slowly-cooled samples over the wide range from 10^{-1} M to 50.0 mol% (of benzene) and the results of the study of the molecular complex of carbon tetrachloride with benzene from the far infrared spectrum by Chantry, Gebbie, and Mirza.[12]

12) G. W. Chantry, H. A. Gebbie and H. N. Mirza, *Spectrochim. Acta*, **23A**, 2749 (1967).

The spectrum of the slowly-cooled sample at much higher concentrations, such as 66.7 mol%, is the same as the spectrum of the benzene crystal, and the spectrum of the rapidly-cooled sample is an overlapping of the H-spectrum and the spectrum of the benzene crystal. These results show that benzene was crystallized out of the solution during the cooling process; the presence of the C_6H_6-CCl_4 complex, which is indicated by the freezing-point method, is not clearly shown in the fluorescence spectrum.

The authors wish to express their hearty thanks to Assistant Professor Ryoichi Shimada and Dr. Motohiko Koyanagi for their kind support and helpful discussions.

Quenching of the Scintillation from a γ-Irradiated Cyclohexane Solution Containing *p*-Terphenyl by Electron Scavengers, Positive Ion Interceptors and Some Hydrocarbons

Tsunenari SAITO, Koji TAKAHASHI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 1, 1968)

The luminescence from a cyclohexane solution containing *p*-terphenyl irradiated with ^{60}Co γ-rays has been quenched by various compounds. The quenching efficiencies were found to be in the following order; sulfur hexafluoride$\sim$carbon tetrachloride$>$nitrous oxide$>$ethanol$>$ammonia$>$carbon dioxide. These compounds are known in radiation chemistry as electron scavengers or as positive-ion interceptors. Cyclopropane and ethylene have also shown an appreciable quenching ability, but *n*-butane has shown scarecely any. These results have been explained by assuming that ionic reactions are responsible for the luminescence from a cyclohexane-*p*-terphenyl scintillator.

The mechanism of energy transfer occurring in a liquid organic scintillator has been a concern of many investigators.[1,2] The type of energy transfer seems to depend upon many factors, such as the kind of solvent molecule and the mode of excitation.

In an earlier short communication,[1] we have suggested the possibility that emission from a cyclohexane solution of *p*-terphenyl irradiated by γ-rays of ^{60}Co results from the ionic reactions occurring in the system. Such an ionic process had already been suggested by Kropp and Burton[3] as a possible mechanism, but the insight had not been pursued because the excitation-energy-transfer process was thought to be more plausible at that time.

In this paper, we intend to enlarge our remarks in the short communication[1] and to show more evidence for the participation of an ionic process in the formation of the scintillating state of *p*-terphenyl in cyclohexane.

Experimental

Research-grade cyclohexane purchased from the Wako Chemical Co. was passed through a 1 m column packed with silica gel and distilled twice at 80.8°C prior to use. Scintillation-grade *p*-terphenyl was purchased from the Nakarai Chemical Co. and used as supplied. The other compounds used as quenchers were all of a research grade and were used after usual purifications, such as bulb-to-bulb distillation.

c, Scintillator solution d, γ-Rays source
(1 m Ci-^{60}Co).

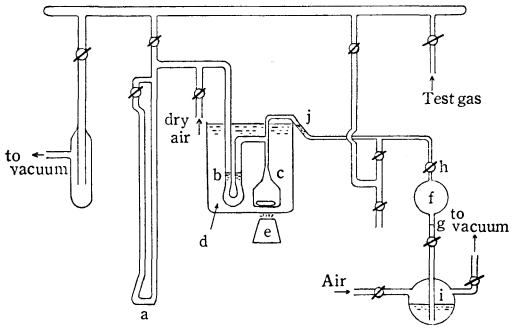

Fig. 2. Apparatus for measuring solubility.
a, Mercury manometer. b, Mercury-filled U-tube, which balances the pressures of both sides. c, A flask of known volume (82 m*l*). d, Water bath. e, Magnetic stirrer. f, A glass flask (Volume is calibrated from the mark g to the stopcock h.). i, Mercury leveling bulb (Mercury goes up to the mark j when introducing a gas.).

A schematic diagram of the apparatus for the measurement of scintillation is shown in Fig. 1. Cyclohexane containing a constant amount of *p*-terphenyl was degassed by repeated freeze-pump-thaw cycles. At least five cycles were needed to obtain a constant emission intensity. Quencher gases were introduced with the aid of a liquid nitrogen trap after the pressure had been measured in a calibrated volume.

Since the solubilities of most gases in cyclohexane are not known, a separate apparatus was constructed for this measurement. A schematic diagram of it is shown in Fig. 2. The method is almost the same as that proposed by Loprest.[4] The apparatus for the preparation of scintillator solutions was constructed so as to be mercury free to avoid the possibility of the participation of dissolved mercury in the scintillation.

Results

Figure 3 shows the Ostwald absorption coefficients of five quencher gases (NH_3, N_2O, C_2H_4, CO_2, and SF_6) in cyclohexane as a function of the temperature. The other quenchers used (C_2H_5OH, CCl_4, cyclo-C_3H_6, and n-C_4H_{10}) were assumed to be completely soluble in cyclohexane. The values with nitrous oxide, carbon dioxide, sulfur hexafluoride, and ethylene were in good agreement with those previously measured.[5,6]

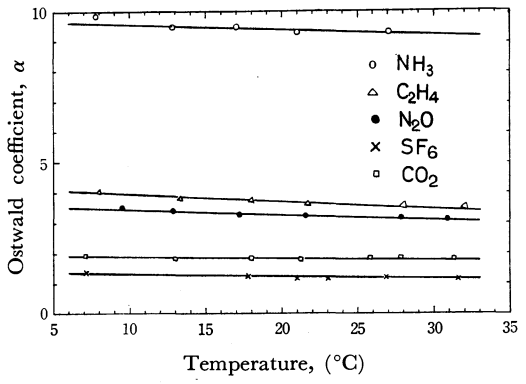

Fig. 3. Ostwald coefficients of quencher gases in cyclohexane as a function of temperature. (at 200 Torr)

In Fig. 4 the reciprocal of the emission intensity is plotted against the reciprocal of the concentration of *p*-terphenyl in cyclohexane. Such a linear relationship as has previously been reported by

many investigators[7,8] is obtained. The slope/intercept ratio has been calculated to be 1.6×10^{-2} mol l^{-1}, a value which agrees reasonably well with the 1.3×10^{-2} mol l^{-1} reported by Burton *et al.*[7] Here, the emission from the quartz vessel and pure solvent has been substracted from the total emission. In the case of a 5.7×10^{-3} mol l^{-1} *p*-terphenyl solution, the emission from the vessel was 8.5%, and that from pure solvent was 6.9%, of the total emission.

In Figs. 5, 7, and 8, the relative emission intensities are plotted as a function of the mole fraction of the quenchers. The quencher gases in Fig. 5 are known in radiation chemistry as electron scavengers. An abnormal curve has been obtained with carbon tetrachloride; *i. e.*, the intensities of the emission from cyclohexane solutions containing high concentrations of carbon tetrachloride were lower than that from pure cyclohexane. The

details are shown in Fig. 6, where the observed currents from the photomultiplier are plotted as a function of the concentration of carbon tetrachloride. Sulfur hexafluoride, which is as effective in quenching as carbon tetrachloride at low concentrations, did not have such an effect. In Fig. 7, the data with ammonia and ethanol are plotted. Their effects are obviously much weaker than strong electron scavengers, such as sulfur hexafluoride, carbon tetrachloride, and nitrous oxide. Figure 8 compares the quenching efficiencies of aliphatic hydrocarbons with those of electron scavengers. Since hydrocarbons were not effective in quenching, a low concentration of *p*-terphenyl was used. The quenching efficiencies of the hydrocarbons used are in the following order; cyclopropane, ethylene, and *n*-butane.

By using the amplification factor of the photomultiplier and the geometry of the apparatus, the *G*-value of the luminescence has been estimated roughly. The values obtained range from 0.01 to 0.1 with a solution containing 5.7×10^{-3} mol·l^{-1} *p*-terphenyl.

Discussion

Dependence on the Concentration of *p*-Terphenyl. If the excitation-energy-transfer is operative as the mechanism of energy transfer occurring in the present system, a linear relationship between $1/I_0$ and $1/N_s$ can easily be obtained by the steady-state treatment, as Lipsky and Burton have already done.[9] Here, I_0 denotes the emission intensity, and N_s, the concentration of *p*-terphenyl. However, this linear relationship does not necessarily mean that the excitation-energy-transfer is the real mechanism. As has been stated in the earlier communication,[1] *p*-terphenyl molecules are known to capture electrons

7) M. Burton, P. J. Berry and S. Lipsky, *J. chim. phys.*, **52**, 48 (1955).
8) M. Burton, M. A. Dillon, C. R. Mullin and R. Rein, *J. Chem. Phys.*, **41**, 2236 (1964).
9) S. Lipsky and M. Burton, *J. Chem. Phys.* **31**, 1221 (1959).

in cyclohexane[10] and the negative ions formed may become precursors of excited *p*-terphenyl molecules. The reaction scheme is:

$$C \text{ -}\!\!\wwvy\!\!\rightarrow C^+ + e \quad (1)$$

$$e + T \longrightarrow T^- \quad (2)$$

$$C^+ + T^- \longrightarrow C + {}^1T^* \text{ (or } {}^3T^*) \quad (3)$$

$${}^1T^* \longrightarrow T + h\nu \quad (4)$$

Here, C and T denote cyclohexane and *p*-terphenyl molecules respectively. $^1T^*$ and $^3T^*$ denote excited singlet and triplet states of *p*-terphenyl. The former is responsible for the luminescence from the solution, while the latter may be deactivated without radiation to the ground state.[11]

For discussing the kinetics of the reactions occurring in a γ-irradiated solution, the steady-state treatment is not adequate, because the charged species produced are believed not to be distributed homogeneously in the solution.[12] A tentative treatment for such a system has recently been developed by Freeman[13] and this laboratory.[5,12] Using the formulation already described[12] with a little modification of the distribution function of the charged species, a linear relationship between $1/I_0$ and $1/N_s$ can be derived; the procedure is shown in the Appendix. In this treatment, the k ratio, which is the slope/intercept ratio of the linear relationship in Fig. 4, has the following relation:

$$k = \alpha/(zn^0_-)$$

while

$$r_{av} = \alpha^{-1/3}\Gamma(4/3)$$

Here, n^0_- is the number of jumps which a "solvated" electron[5] makes when diffusing a unit distance. z is the coordination number, and r_{av} is the average initial distance between an electron and its parent ion. By substituting the observed value, 1.6×10^{-2} mol l^{-1} for k, we can obtain 70 Å for r_{av}. This value is in good agreement with the value, 50—60 Å, estimated previously from the data of an experiment using a different approach.[12]

The Effects of Electron Scavengers. In the previous communication[1] we have reported the effects of sulfur hexafluoride, nitrous oxide, and carbon dioxide. The reinvestigated data of these compounds agree well with the previous data. The quenching efficiencies are in the following order: sulfur hexafluoride, carbon tetrachloride, nitrous oxide, and carbon dioxide. This order seems to correspond to the order of the efficiency of electron scavenging in the gas phase.[14,15]

On the other hand, we have shown that the $G(H_2)$ from cyclohexane is suppressed by the addition of sulfur hexafluoride, nitrous oxide, or carbon dioxide, and that the concentration dependence of the effect is almost constant with any of the three electron scavengers.[5] This discrepancy may be explained as follows. In the scintillator system, we have *p*-terphenyl together with a quencher. Since the *p*-terphenyl molecule is known to capture an electron in cyclohexane,[10] a competition for electrons will occur between the two reactions, (2) and (5):

$$S + e \rightarrow S^- \quad (5)$$

Here, S denotes an electron scavenger. In such a system, electron-transfer reactions must occur when the electron affinities of T and S are different.

$$T^- + S \rightleftharpoons T + S^- \quad (6)$$

If sulfur hexafluoride and carbon tetrachloride, which have high electron affinities, undergo a forward reaction, and carbon dioxide, which has a low electron affinity, does the reverse, the order of efficiencies shown in Fig. 5 can be explained.

If this reasoning is correct, the present experiment provides a method of determining the order of the electron affinities of some compounds. However, as will be seen below, complications airse.

At high concentrations of carbon tetrachloride, the luminescence from a cyclohexane solution of *p*-terphenyl was weaker than that from pure cyclohexane (Fig. 6). Since the origin of the luminescence from pure cyclohexane is difficult to explain,*1 the mechanism of the quenching observed is far beyond our speculation. Obviously, further experiments using different approaches are needed on this problem.

Recently, Holroyd has shown that nitrous oxide in a cyclohexane solution is decomposed by light irradiation at 1470 Å and has concluded that the excitation-energy transfer occurs from an excited cyclohexane molecule to nitrous oxide.[16] According to his estimation, the *G*-value of excited cyclohexane molecules in the γ-radiolysis of cyclohexane is 1.2, if the *G*-value of charge separation is assumed to be 3. In the present system, therefore, the process suggested by Holroyd may play a part in the reaction, especially at high concentrations of quenchers. However, since we are concerned with a qualitative correlation between the quenching of the scintillation and the electron or positive-ion scavenging of quenchers, we neglect the energy-transfer process for the sake of simplicity.

The Effects of Positive-ion Interceptors. Ammonia and ethanol are known to behave as

15) J. M. Warman, *J. Phys. Chem.*, **71**, 4066 (1967).
*1 The possibility that impurities in cyclohexane play a role in the scintillation of pure cyclohexane cannot be excluded.
16) R. A. Holroyd, *ibid.*, **72**, 759 (1968).

proton scavengers in the radiation-induced reaction of hydrocarbons.[17,18] The reaction in cyclohexane may be described as follows:

$$RH + C_6H_{12}^+ \rightarrow RH_2^+ + C_6H_{11} \quad (7)$$

Here, RH denotes ammonia or ethanol. In the present case, the reaction which interferes with the formation of excited *p*-terphenyl molecules may be as follows:

$$RH_2^+ + T^- \rightarrow RH + HT \quad (8)$$

The radicals produced (HT) would not luminescence. The fact that ethanol is more effective than ammonia in quenching (Fig. 7) is consistent with the order of their efficiencies as proton scavengers.[18]

The Effects of Ethylene, Cyclopropane, and *n*-Butane. Recently, Stephenson *et al.* have shown that some diolefins can quench the fluorescence from excited aromatic compounds in *n*-hexane.[19] Therefore, ethylene could behave as a quencher as has been observed in the present experiment (Fig. 8). However, the concentration of dienes used in the above experiment is much higher than ours. Moreover, as is shown in Fig. 8,

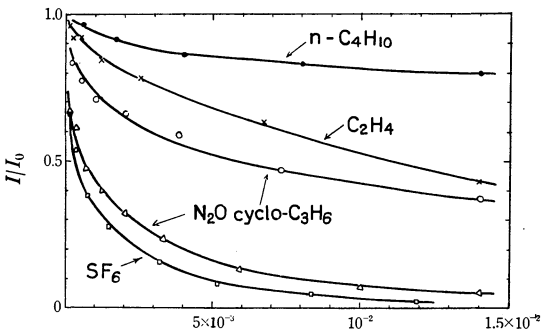

Fig. 8. Relative emission intensity from a 1.9×10^{-3} mol l^{-1} *p*-terphenyl solution as a function of the concentrations of some hydrocarbons and electron scavengers.

cyclohexane has been shown to quench the luminescence as much as ethylene. Cyclopropane is a paraffin and is not expected to quench an excited *p*-terphenyl molecule efficiently. On the other hand, *n*-butane is found to be much less effective even in quenching.

Ausloos *et al.*[20] have recently uncovered a series of ion-molecule reactions occurring in the liquid phase:

$$C_6H_{12}^+ + RH \rightarrow C_6H_{11}^+ + RH_2 \quad (9)$$

$$\searrow C_6H_{10}^+ + RH_3 \quad (10)$$

Here, RH represents cyclopropane or ethylene. If these reactions occur in the present system, quenchings observed with cyclopropane and ethylene may be explained by a combination of the reactions (9) and (10) and the reaction (11):

$$C_6H_{11}^+ + T^- \rightarrow C_6H_{10} + HT \quad (11)$$

Reaction (11) interferes with the formation of excited *p*-terphenyl. In the case of *n*-butane, reactions such as (9) and (10) have not been reported. Probably, they would not occur efficiently.

Alternative Ionic Reactions to Form the Excited *p*-Terphenyl. So far, we have addopted *p*-terphenyl negative ions as the precursors of excited *p*-terphenyl molecules. However, since *p*-terphenyl has an ionization potential lower than cyclohexane, alternative ionic processes can be constructed for the formation of the excited *p*-terphenyl. One of these reaction schema is:

$$C \rightsquigarrow C^+ + e \quad (1)$$

$$C^+ + T \rightarrow C + T^+ \quad (12)$$

$$T^+ + e \rightarrow {}^1T^* \text{ (or } {}^3T^*) \quad (13)$$

However, if this mechanism is the only process producing the excited *p*-terphenyl, the difference in quenching efficiency of the four electron scavengers cannot easily be explained. Therefore, reactions (12) and (13), should they occur, should be taken into account, along with the series of reactions from (1) to (4). In that case, the reaction (14) should probably be included also:

$$T^+ + T^- \rightarrow {}^1T^* \text{ (or } {}^3T^*) + T \quad (14)$$

The data obtained in the present paper cannot make a possible decisive choice of a reaction scheme, but they do show that ionic processes seem to play an important role in the scintillation from a cyclohexane solution of *p*-terphenyl.

The authors are grateful to Professor S. Shida for his valuable suggestions.

Appendix

Electrons ejected into a cyclohexane solution by γ-ray irradiation drift toward the parent positive ions by means of the Coulombic interaction. On the way, a part of electrons will be scavenged by *p*-terphenyl. If the reaction is diffusion-controlled, the fraction (f_T) of electrons scavenged by *p*-terphenyl may be expressed as follows:[12]

$$f_T = 1 - \frac{1}{N}\int_0^\infty \phi(r)(1-N_s)^{zn}\mathrm{d}r$$

$$= 1 - \frac{1}{N}\int_0^\infty \phi(r)\exp(\beta r^3)\mathrm{d}r$$

where N_s is the mole fraction of *p*-terphenyl, z is

the coordination number, and n_- is the number of jumps which an electron makes in diffusion to the parent ion ($n_- = n_-{}^0 r^3$).

$$\beta = \left(\frac{2z}{\sigma^2 r_c}\right)\left(\frac{D_-}{D_+ + D_-}\right)\log(1 - N_s)$$
$$\simeq -\left(\frac{2z}{\sigma^2 r_c}\right)\left(\frac{D_-}{D_+ + D_-}\right)N_s$$

The symbols used here have been discussed in a previous paper;[12] σ is the diameter of the cyclohexane molecule, r_c is defined by the $r_c = e^2/\varepsilon \boldsymbol{k} T$ relation, and D_- and D_+ are the diffusion coefficients of an electron and the parent positive ion in cyclohexane. $\phi(r)$ is the distribution function for ion pairs, for which we used the $r^2\exp(-\alpha r^2)$ function in the previous paper.[12] With this function, the integration shown above cannot easily be carried out. Here, a modified function, $r^2\exp(-\alpha r^3)$,*2 is tentatively introduced for $\phi(r)$, so that the integration can easily be performed. The relation obtained is as follows:

$$f_T = \beta/(\beta - \alpha)$$

According to the preceding discussion, I_o is proportional to f_T:

$$1/I_o \propto 1/f_T = 1 - \alpha/\beta = 1 + k/N_s$$
$$k = \left(\frac{\sigma^2 r_c}{2z}\right)\left(\frac{D_+ + D_-}{D_-}\right)\alpha$$

Obviously, a linear relationship between $1/I_o$ and $1/N_s$ is obtained.

*2 The distribution expressed by this function corresponds to that between $r^2\exp(-\alpha r^2)$ and the function calculated by Freeman.[13]

The Ultraviolet Absorption Spectrum of Quinazoline Vapor Due to the n–π^* Transition

Yoshinori HASEGAWA,*1 Yoshito AMAKO and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received May 2, 1968)

The ultraviolet absorption spectrum of quinazoline vapor due to the n–π^* transition was photographed and analysed. The lowest n–π^* transition has its origin at 27581 cm^{-1}, and consists of two strong and prominent progressions, 515 and 784 cm^{-1}. The vibrational analysis of the strong bands is reported on.

The visible and ultraviolet absorption spectra of azanaphthalenes in solutions have been reported on by Hirt *et al.*,[1] Mason,[2,3] Favini *et al.*,[4] Müller and Dörr,[5] and Wait and Grogan.[6] In general, the weak bands at the longest wavelength in their spectral measurements have been assigned to the n–π^* transitions, on the basis of their blue shift in polar solvents, while the much stronger bands at the shorter wavelength have been assigned to the lowest π–π^* transitions, similar to the 3200 Å system of naphthalene.

The n–π^* and the lowest π–π^* absorption spectra of cinnoline(1,2-diazanaphthalene) vapor have been reported on by Wait and Grogan.[6] It has been found that the n–π^* transition of cinnoline has its origin at 22711 cm^{-1}, and that the vibronic structure of the n–π^* transition consists primarily of a strong prominent progression of 516.0 cm^{-1}, upon which singly-excited vibrations are superimposed, while the lowest π–π^* transition has its origin at 31542 cm^{-1}.

The n–π^* absorption spectrum of quinoxaline-(1,4-diazanaphthalene) vapor has been observed by Ito and Shiratsuchi[7] and by the present authors[8] independently. They all observed that the n–π^* absorption bands of quinoxaline consists of two band systems, one sharp and one broad band system. The broad bands have their origin at 26017 cm^{-1}, and the 525 cm^{-1} progression with the origin is very prominent. On the other hand, the sharp bands have strong false origins at 27496 and 27670 cm^{-1}, and also the 525 cm^{-1} progressions are very prominent.*2

*2 Further work on quinoxaline is now in progress by Ito and Shiratsuchi and by the present authors.

The present authors have previously assigned the broad band system to the allowed $n-\pi^*$ transition and the sharp band system to the "forbidden"[9,10] bands in the allowed $n-\pi^*$ transition.

The electronic absorption spectra of the other azanaphthalenes in the vapor phase have never been reported on. The present investigation is concerned with the $n-\pi^*$ absorption spectrum of quinazoline(1,3-diazanapthalene) vapor.

Experimental

The vapor spectrum of quinazoline was photographed with a Shimadzu Littrow quartz spectrograph with a dispersion of 8.9 Å/mm at 3700 Å, and with a Shimadzu GE-100 grating spectrograph (Ebert type) with a dispersion of 2.7 Å/mm in the third order. The bands were measured on microphotometer tracings of the plates. The wavelength calibration was made by an iron arc. The wavelengthes of the bands were converted into frequencies *in vacuo*. The frequencies are estimated to be accurate about $\pm 2\ cm^{-1}$ for the strong bands, and to about $\pm 5\ cm^{-1}$ for the weak and broad bands. The light source was a 500 W Xenon arc lamp. A Toshiba UV-D2 filter was used to eliminate all the radiation in the higher orders and lower orders. The absorption cell with quartz windows was helically wound with Nichrome wire over an asbestos sheet and covered with an asbestos sheet. The light-pass length of the absorption cell was 60 cm. The cell temperature could be regulated between room temperature and 250°C. The solution spectrum of quinazoline was obtained using a Cary automatic recording spectrometer, Model 14.

The quinazoline used in this study was prepared by following the method described by Riedel[11] and by Bogert and McColm[12]; it was recrystallized repeatedly, and finally sublimated before the experiment. The *n*-hexane was purified according to the procedure described by Morgan and Lowry.[13]

Results and Discussion

The ultraviolet absorption spectra of quinazoline have been reported on in solutions of heptane, ethanol, and an acidic solvent by Müller and Dörr,[5] and in a solution of cyclohexane by Mason.[3] The 3650 Å band system has been assigned to the $n-\pi^*$ transition, and the 3100 Å band system, to the lowest $\pi-\pi^*$ transition. The results of the present investigation in *n*-hexane are shown in Fig. 1, which corresponds well to that in heptane reported by Müller and Dörr.

The $n-\pi^*$ absorption spectrum of quinazoline vapor under a low dispersion consists of a number of band groups. Each of the strong band groups under a moderate dispersion consists of a principal band and of associated $15\ cm^{-1}$ sequence bands, which appear with up to two or three members.

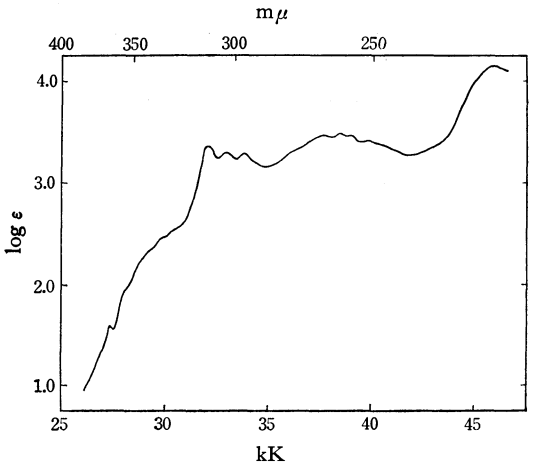

Fig. 1. The ultraviolet absorption spectrum of quinazoline in *n*-hexane.

The $n-\pi^*$ absorption spectrum of quinoxaline vapor has been observed by Ito and Shiratsuchi and by the present authors, as has been stated above. The spectrum consists of two systems, one sharp and one broad, as is shown in the Plate. The $n-\pi^*$ absorption spectrum of quinazoline vapor, however, does not show such two band systems.

The vibronic structure shown in Fig. 2 consists of three progressions with their origins*3 at 27581 cm^{-1}; the members are separated by 515, 784, and 879 cm^{-1} respectively. On their progressions are superimposed a number of singly-, doubly- or triply-excited vibrations. The band at 27581 cm^{-1}, which is the first member of their progressions, was assigned to the 0–0 band. The frequecies and assignments of the principal bands are shown in Table 1. No bands could be observed below 27494 cm^{-1}, and so the frequencies corresponding to the ground state vibrations could not be obtained.

The quinazoline molecule has two nitrogen atoms in the "meta" position of the naphthalene-like ring, and belongs to the C_s point group in the ground state. Because of the interaction between the respective nonbonding orbitals of these nitrogen atoms,[14-16] two allowed $n-\pi^*$ transitions of the $^1A' \rightarrow {}^1A''$ type may be expected to appear. However, no suggestion with respect to the "$n-\pi^*$

*3 With moderate dispersion the origin shows several broad structures, probably due to its sequence bands. Unfortunately, under the conditions used, they do not have intensities sufficient for definite assignments to be made. Therefore, the apparenly strongest peak on the microphotometer tracing was taken as the 0-0 band, which might be one of the sequences of the true origin.

a) Symbol * denotes that the corresponding frequencies are accurate to about 5 cm^{-1}.
b) Usual abbreviation for intensities is taken as; v=very, w=weak, m=moderate and s=strong.
c) The assignments shown by parenthesis are less certain.

splitting" could be obtained under the experimental conditions used; further studies under better conditions will be necessary.

The totally symmetric vibrational intervals, 515 and 784 cm^{-1}, are very prominent. Superimposed on 0-0, 0+879 cm^{-1} and other bands, the 515 and 784 cm^{-1} progressions appear with up to two or three members. According to Wait and Grogan,[6] the interval, 516.0 cm^{-1}, in the n-π^* transition of cinnoline is very prominent. The interval, 525cm^{-1}, in the n-π^* transition of quinoxaline is also very prominent, as has been mentioned above. This normal mode of quinazoline with the 515 cm^{-1} frequency probably corresponds to the same type of mode of cinnoline and quinoxaline with frequencies of 516.0 and 525 cm^{-1} respectively.

In the case of azines,[15,16] the ring breathing vibrations of ~900 cm^{-1} dominate the progressions

in the $\pi-\pi^*$ transitions, while the ring angle bending modes, notably the ν_{6a} of $\sim$600 cm^{-1}, are prominent in the $n-\pi^*$ transitions. These normal modes of the $n-\pi^*$ states of these three diazanaphthalenes with $\sim$520 cm^{-1} are probably ring angle bending modes, or ring deformation modes. The other prominent frequency, 784 cm^{-1}, will be a skeletal stretching mode.

At the present time no further detailed attempts to assign these and other frequencies have been carried out for lack of experimental data.

The authors wish to express their sincere thanks to Misses M. Nyugaku and Y. Kato for their assistance in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2612—2615 (1968)

The Analysis of the Solubility of Hydrocarbons in Water

Kōzō SHINODA and Masamichi FUJIHIRA

Department of Chemistry, Yokohama National University, Ookamachi, Minamiku, Yokohama

(Received May 2, 1968)

Enthalpy and entropy of solution of non-polar solutes in water diverge strikingly from the normal behavior established for regular solutions. This abnormality has been considered mostly due to the iceberg formation around solute molecules in water. The abnormal solubility and enthalpy and entropy of solution of non-polar solutes in water have been explained coherently by the extension of the regular solution theory, taking into account the iceberg formation of water molecules. Unlike currently accepted views on the hydrophobic bonding, it is concluded that the enthalpy of mixing (interchange) of non-polar solute with water is large, but the enthalpy decrease due to the iceberg formation of water largely cancels the enthalpy increase of mixing (interchange). Thus, the apparent enthalpy of solution is small or negative at low temperature. It is concluded that 1) the small solubility of non-polar solutes in water is not an entropy effect, and 2) the solubility of non-polar solutes is promoted by the iceberg formation of water molecules.

Frank and Evans[1] analyzed the entropy of solution of non-polar molecules in water which diverges strikingly from the normal behavior established for regular solutions. The small or negative enthalpy of solution and large negative unitary entropy of solution lead them to the idea that the water forms frozen patches or microscopic icebergs around such solute molecules, the extent of the iceberg increasing with the size of the solute molecule. (More ordered structure formation around the solute molecule may express the phenomenon better than iceberg formation.)

In the present paper, the apparently abnormal solubility and enthalpy and entropy of solution of hydrocarbons in water due to the iceberg formation of water molecules will be explained coherently by the extension of the regular solution theory.[2]

The Enthalpy and Entropy of Solution in Regular Solutions. It is necessary to explain the dissolution in regular solutions in order to understand the dissolution of hydrocarbons in water. The enthalpy and entropy of solution of solute (2nd component) in liquid state in solvent (1st component) in regular solutions is[2];

$$\Delta\bar{S}_2 = -R\ln X_2$$

liquid(2 nd component) → solute, (1)

$$\Delta\bar{H}_2 = V_2\phi_1^2B'$$

liquid(2 nd component) → solute, (2)

where X_2 is the solubility of 2nd component in mole fraction unit, V_2 the molar volume, ϕ_1 the volume fraction of solvent, B' the experimental constant. In the case when the 1st component is sparingly soluble in 2nd component, the 2nd component in pure liquid state and in solute state are in an equilibrium, so that the Gibbs free energy is equal, $\Delta\bar{G}_2=0$, and we obtain,

$$V_2\phi_1^2B' = -RT\ln X_2 . \quad (3)$$

If the 2nd component is a pure solid which does not form solid solution with solvent, the enthalpy and entropy of solution is expressed as follows,

$$\Delta\bar{H}_2 = V_2\phi_1^2B' + \Delta H_2^f$$

solid(2nd component) → solute, (4)

$$\Delta\bar{S}_2 = -R\ln X_2 + \Delta S_2^f$$

solid(2nd component) → solute, (5)

where ΔH_2^f and ΔS_2^f are the enthalpy and entropy of fusion of solid at the temperature of solution. The solid (2nd component) melts at this temperature and mixes with solvent in the process of dissolution. Additional term due to the melting is incidental to the solution of solid in liquid.[3,4] As the 2nd component in solid state and in solute state are in equilibrium, the partial molal Gibbs free energy of solution is zero.

$$\Delta\bar{G}_2 = 0, \qquad \Delta\bar{H}_2 = T\Delta\bar{S}_2 . \quad (6)$$

If we express the vapor pressure of solid by p_2^s and that of supercooled liquid by p_2^l, the Gibbs free energy change of fusion is expressed as,

1) H. S. Frank and M. W. Evans, *J. Chem. Phys.*, **13**, 507 (1945).
2) J. H. Hildebrand and R. L. Scott "Regular Solutions," Prentice Hall, Inc., Englewood Cliffs, New Jersey (1962).
3) J. H. Hildebrand, *J. Phys. Chem.*, **64**, 370 (1960).
4) K. Shinoda and J. H. Hildebrand, *ibid.*, **62**, 292 (1958).

$$\Delta G_2^f = \Delta H_2^f - T\Delta S_2^f = RT\ln(p_2^l/p_2^s) . \quad (7)$$

Combining Eqs. (4), (5) and (6), we obtain

$$T\Delta S_2^f - \Delta H_2^f = RT\ln X_2 + V_2\phi_1^2 B' . \quad (8)$$

Substituting Eq. (7) into (8), we obtain

$$RT\ln(p_2^s/p_2^l) = RT\ln a_2 = RT\ln X_2 + V_2\phi_1^2 B' . \quad (9)$$

The enthalpy of solution and the temperature dependence of solubility is related as follows,

$$-R\left(\frac{\partial \ln a_2}{\partial \ln X_2}\right)_T\left(\frac{\partial \ln X_2}{\partial 1/T}\right)_{sat} = \Delta\bar{H}_2 = T\Delta\bar{S}_2 , \quad (10)$$

where $(\partial \ln a_2/\partial \ln X_2)_T \approx 1$ in dilute solution.

It is clear from Eqs. (10) and (4) that the temperature dependence of the logarithm of solubility is proportional to the enthalpy of solution and increases discontinuously by the amount ΔH_2^f below the melting point of solute. However, the enthalpy and entropy of fusion cancel each other, so that the solubility is scarcely affected by the increased enthalpy of solution slightly below the melting point.

The Enthalpy and Entropy of Solution of Non-polar Solutes in Water. In the process of solution of non-polar solutes in water the iceberg formation[1] and hydrogen bond breaking occurs around the hydrocarbon chains. In dilute solution of this system, the amount of water which forms icebergs and the hydrogen bond breaking increases proportionally to the number of moles of solute, but does not increases with the amount of added solvent. Thus, the iceberg formation of water and the hydrogen bond breaking affect the partial molal quantity of solute, but they little affect that of solvent in dilute solution. This statement is clear from the general partial molal equation for a binary system,

$$n_1 d\bar{Y}_1 + n_2 d\bar{Y}_2 = 0,$$

where Y is any extensive property of the solution. According to the equation, $d\bar{Y}_1$ is negligibly small in dilute solution, because n_2/n_1 is very small (about 10^{-3} at the present system). If n mol of water form icebergs and n' units of hydrogen bonds are destroyed per mole of solute, the enthalpy and entropy of solution of non-polar solutes in water is expressed as fcllows,

$$\Delta\bar{H}_2 = V_2\phi_1^2 B' - n\Delta\bar{H}_i^f + n'\Delta\bar{H}_h$$

non-polar liquid $\rightarrow$ solute in H_2O, (11)

$$\Delta\bar{S}_2 = -R\ln X_2 - n\Delta\bar{S}_i^f + n'\Delta\bar{S}_h$$

non-polar liquid $\rightarrow$ solute in H_2O, (12)

where $-n\Delta\bar{H}_i^f$ $(-n\Delta\bar{S}_i^f)$ is the partial molal enthalpy(entropy) change of 2nd component due to the iceberg formation of n moles of the surrounding water and $n'\Delta\bar{H}_h$ $(n'\Delta\bar{S}_h)$ is the partial molal enthalpy(entropy) change due to the hydrogen bond breaking. As the effect of iceberg formation seems predominant in aqueous solution, only the iceberg formation may be taken into account as an abnormality in the present paper. The iceberg formation proceeds with the temperature decrease and n increases with the temperature depression. On the other hand, the solubility and the enthalpy of solution approach to the regular values at higher temperature.

Analysis of the Temperature Dependence of the Solubility of Alkanes in Water. The solubility of alkanes (C_1—C_4) at 1 atm as a function of temperature has been published.[5-7] In order to gain an insight into the dissolution phenomena, the solubility of alkanes at 1 atm pressure was recalculated to that of hypothetical liquid alkanes. The recalculation has been performed as follows. The fugacity of liquid alkanes divided by the critical pressure of respective alkanes, f°/p_c, at various temperature was obtained from the empirical diagram drawn by Prausnitz based on the principle of corresponding state.[8] The solubility at 1 atm multiplied f° is the solubility of hypothetical liquid alkanes. The recalculated solubility was plotted in Fig. 1.

As the iceberg formation decreases with the temperature rise, n in Eqs. (11) and (12) decreases

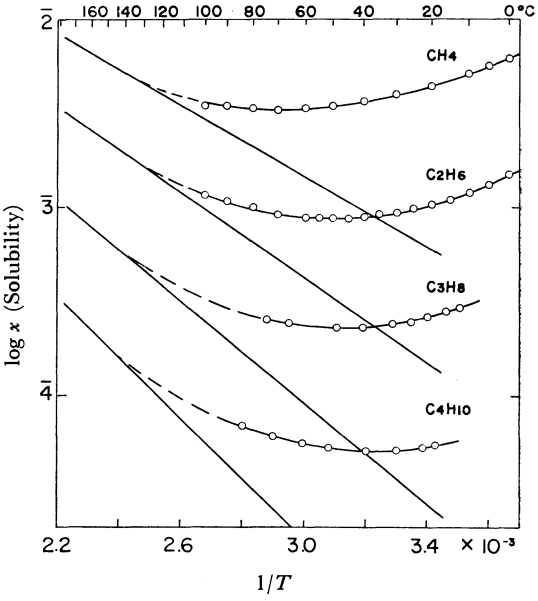

Fig. 1. The solubility of hypothetical liquid alkanes in water as a function of temperature. Calculated from the data at 1 atm (Refs. 5, 6 and 7).

Table 1. The analysis of the enthalpy and entropy of solution of liquid hydrocarbons in water at 25°C

Enthalpy of solution $=\Delta\bar{H}_2=-\boldsymbol{R}\left(\frac{\partial \ln X_2}{\partial\, 1/T}\right)_{\text{sat}}$; Entropy of solution $=\Delta\bar{H}_2/T$

Enthalpy of mixing $=V_2\phi_1^2B'$ (estimated); Entropy of mixing $=-\boldsymbol{R}\ln X_2$

Enthalpy of iceberg formation $=-n\Delta\bar{H}_i^f$; Entropy of iceberg formation $=-n\Delta\bar{S}_i^f$

Solute	$\Delta\bar{H}_2=V_2\phi_1^2B'-n\Delta\bar{H}_i^f$ (cal/mol)	$\Delta\bar{S}_2=-\boldsymbol{R}\ln X_2-n\Delta\bar{S}_i^f$ (cal/deg/mol)	$\Delta\bar{H}_i^f/\Delta\bar{S}_i^f$ (°K)
CH_4	$-1900=4300-6200$	$-6.4=10.8-17.2$	360
C_2H_6	$-2000=5100-7100$	$-6.7=13.7-20.4$	348
C_3H_8	$-1880=6100-7980$	$-6.3=16.5-22.8$	350
C_4H_{10}	$-820=7200-8020$	$-2.7=19.6-22.3$	359
C_6H_6	$+580=5100-4520$	$+1.9=15.4-13.5$	335
$CH_3C_6H_5$	$+640=6050-5410$	$+2.2=17.9-15.7$	345
$C_2H_5C_6H_5$	$+390=7000-6610$	$+1.4=20.4-19.0$	348

and the slope of $-\partial \ln X_2/\partial(1/T)$ increases with the temperature rise as shown in Fig. 1. The change of the slope with temperature, $-[\partial^2 \ln X_2/\partial(1/T)^2]$, decreases with temperature and is almost zero at 120—160°C at which the iceberg formation seems mostly disappear. We can evaluate the solubility at this temperature by extrapolation and then calculate the enthalpy of solution by the aid of Eqs. (2), (3) and (10). The straight lines in Fig. 1 express the hypothetical solubility of alkanes in water assuming no iceberg formation. The temperature dependence of solubility, $-(\partial \ln X_2/\partial 1/T)$, decreases with the temperature depression as shown in Fig. 1 and the solubility increases relatively with the iceberg formation of water. Similar relation is observed for aromatic hydrocarbons[9,10] and the analysis of the data is listed in Table 1.

The straight line and the experimental solubility curve approaches asymptotic at high temperature. This is an important finding, because the entropy of solution of hydrocarbon from the pure liquid state to the solute state in water is then given by,

$$\Delta\bar{S}_2 = -\boldsymbol{R}\ln X_2 = \bar{S}_2 - S_2^\circ. \tag{13}$$

As the partial molal entropy of hydrocarbon (2nd component) in aqueous solution, $\bar{S}_2$, and the hypothetical standard entropy of hydrocarbon in which the mole fraction is formally taken as unity, $\bar{S}_2^\circ$, are related as,

$$\bar{S}_2 = \bar{S}_2^\circ - \boldsymbol{R}\ln X_2, \tag{14}$$

the fact implies the assertion that the hypothetical standard entropy of the 2nd component as a solute is equal to the standard entropy of that component as a pure liquid,

$$\bar{S}_2^\circ = S_2^\circ. \tag{15}$$

This relation holds in regular liquid-liquid mixtures regardless the difference between δ_1 and δ_2, as can be derived from Eq. (1) or (13),

$$\bar{S}_2^\circ = \bar{S}_2 + \boldsymbol{R}\ln X_2 = \bar{S}_2 - (\bar{S}_2 - S_2^\circ) = S_2^\circ. \tag{16}$$

Namely, the enthalpy of mixing in regular solutions is purely energetic and the cratic entropy compensates the enthalpy change to give $\Delta G_2=0$. If the dissolution involves phase change such as the melting of solute, both the enthalpy and entropy changes with the process of melting as shown in Eqs. (4) and (5). In this case both changes largely cancel each other and the cratic entropy to compensate the difference, $\Delta H_2^f - T\Delta S_2^f$, is small. It is evident from Eq. (5) that

$$\bar{S}_2^\circ - S_2^\circ = \Delta S_2^f \quad (\text{solid} \rightarrow \text{solute}). \tag{17}$$

The iceberg formation resembles to the phase change. Both enthalpy and entropy are lost due to the process as expressed in Eqs. (11) and (12). Standard entropy of solute decreases due to the iceberg formation of water, but this abnormality diminishes gradually with the temperature rise. The hydrogen bond breaking on the other hand, increases the enthalpy and entropy of solute. These two abnormalities decrease with the temperature and cancel each other at 120—160°C. Because, the experimental entropy of solution at this temperature is equal to $-\boldsymbol{R}\ln X_2$ (*cf.* Eq. (12)). As the effect of iceberg formation is so large at lower temperature that $n'\Delta\bar{S}_h$ and $-n\Delta\bar{S}_i^f$ (at 120°C) were neglected from the following discussion.

Estimation of Respective Factors to the Enthalpy and Entropy of Solution of Hydrocarbons in Water at 25°C (First Approximation). The enthalpy and entropy of solution of liquid hydrocarbons in water at 25°C are calculated from the temperature dependence of the solubility

9) R. L. Bohon and W. F. Claussen, *J. Am. Chem. Soc.*, **73**, 1571 (1951).
10) D. M. Alexander, *J. Phys. Chem.*, **63**, 1021 (1959).

and shown in Table 1. The enthalpy of solution assuming regular behavior is obtained from the slope of straight lines in Fig. 1, then the enthalpy change of iceberg formation, $n\Delta\bar{H}_i^f$, is readily obtained by the aid of Eq. (11). The entropy of mixing is calculated from the solubility,[11] and $n\Delta\bar{S}_i^f$ is obtained by the aid of Eq. (12) assuming $-n\Delta\bar{S}_i^f$ (at 120°C)$+n'\Delta\bar{S}_h$ (25°C) is small. All these values are summarized in Table 1.

The enthalpy of mixing is approximately proportional to the molal volumes of respective alkanes, and the ratio of $\Delta\bar{H}_i^f/\Delta\bar{S}_i^f$ (mean freezing point of iceberg formation) is nearly constant, 350°K, for all hydrocarbons examined. As the iceberg formation proceeds at above room temperature, this is a reasonable value as a first approximation. These relations support the consistency of the present theory. Unlike currently accepted views,[12,13] it is evident from Fig. 1 and Table 1 that the enthalpy of mixing is a large positive value as would be expected on the basis of the intermolecular forces. Small negative enthalpy of solution, $\Delta\bar{H}_2$, is resulted from a large positive enthalpy of mixing and a large negative enthalpy of iceberg formation.

Introducing the relation $\Delta\bar{H}_2=T\Delta\bar{S}_2$ in Eqs. (11) and (12), (and neglecting $n'\Delta\bar{H}_h-n'T\Delta\bar{S}_h$ as a first approximation,) we obtain,

$$n\Delta\bar{H}_i^f - nT\Delta\bar{S}_i^f = \boldsymbol{R}T\ln X_2 + V_2\phi_1{}^2B' . \quad (18)$$

The left hand side of Eq. (18) corresponds to the free energy term of 2nd component, $\boldsymbol{R}T\ln a_2$. Unlike the process of solid (2nd component) in liquid, the relative activity is larger than 1 in the process of mixing liquid in liquid accompanied with iceberg formation. Equation (18) is useful to understand that the small solubility of hydrocarbons in water is mainly resulted from the large positive enthalpy of mixing and the enthalpy decrease of the iceberg formation is largely cancelled[1,14] by the accompanying entropy decrease (about 83% cancelled) at 25°C, and that the solubility increases as much as $\exp(n\Delta\bar{H}_i^f-n\Delta\bar{S}_i^f)/\boldsymbol{R}T$ times due to the iceberg formation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2615—2619 (1968)

Diffuse Reflection Spectra of Some Würster Salts

Yôichi IIDA and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 6, 1968)

Nine Würster salts derived from *p*-phenylenediamine, benzidine, and their *N*-methyl derivatives were examined for diffuse reflection spectra and classified into three groups, namely, those showing a strong charge-transfer band similar to that in the solution's dimer spectrum, those showing a strong α-band characteristic of the monomer and a relatively weak charge-transfer band, and, finally, those showing a spectrum which bears no resemblance to either the monomer or dimer spectrum. The mode of intermolecular interaction in these cation-radical salts was speculated upon on the basis of the spectra and the magnetic susceptibilities.

Prior to about 1960 the chief emphasis in studies of solid ion-radical salts was on measuring the magnetic susceptibilities of Würster salts, cation-radical salts obtained by the one-electron oxidation of aromatic diamines.[1-4] However, since the appearance of a series of TCNQ anion-radical salts, which are more stable and easily obtainable in the form of single crystals, studies of the electron spin resonance and the electrical conductivity have been among the most fruitful of pursuits.[5-8] The application of these physical methods has

thus far revealed that intermolecular interactions in such solids are often more-than-by-pairs. The electronic spectrum, which has been traditionally the most popular tool for elucidating the electronic structures of molecules and solids, should be able to produce some information concerning the interactions in solid ion-radical salts. It is the purpose of this paper, the first of our attempts along this line, to report the results of our electronic spectrum measurements of nine solid Würster salts and to make a tentative classification of the salts on the basis of their optical and magnetic properties.

The cation-radicals in solution have been known to be in monomer-dimer equilibria.[9] For example, the cation radical derived from *p*-phenylenediamine shows a visible spectrum comprising the α, β, and γ-bands, a doublet at 20.4 and 21.1, a broad shoulder at 27.6, and a strong band at 30.5 kK, when the concentration is low.[10] If the solution is more concentrated or cooled, a new broad band appears at 16.4 kK. This band has been ascribed to the charge-transfer absorption in the dimer by Hausser and Murrell.[11] According to their theory, the cation-radicals in a dimer are stacked face-to-face and the spin exchange interaction leads to a singlet ground state and an excited triplet state. Then, we must take into consideration the fact that intermolecular charge-transfer may make a significant contribution to stabilizing the ground singlet state of the dimer. The low-energy absorption characteristic of the dimer arises from a transition from the thus-stabilized ground state to an excited singlet state expressed by an antisymmetric combination of the wave-functions for charge-transfer structures, $R\text{-}R^{+}{}^{+}$.

Both the present cation-radicals and TCNQ anion-radicals are platelike, and, to the best of our knowledge, they are stacked in the solid salts flat upon one another to form parallel chains.[6,12-15] Any individual radical may interact most strongly with one or two other radicals. In the former case, the interaction is predominantly pair-by-pair; therefore, we may speculate that the solid-state spectrum will be close to the solution's dimer spectrum. If the singlet-triplet excitation energy, to which both the spin exchange and charge-transfer interactions contribute, is rather small, the triplet state may become thermally accessible and paramagnetism may be observed. Secondly, when a radical interacts equally strongly with two neighbors, the following two extreme cases may be conceived. With a weak interaction, the solid-state spectrum may bear some resemblance to the monomer spectrum and paramagnetism of close to 100% free radicals may be exhibited. If any charge-transfer absorption is observable, the paramagnetism may decrease accordingly. On the other hand, if the more-than-by-pairs interaction is strong enough, the salt may be considered to be a linear antiferromagnet. Here again, the charge-transfer interaction may contribute to the stabilization of the state where spins are antiparallel. Therefore, the spectrum may have no similarity to either the monomer or dimer spectrum and the susceptibility may be low or even negative. These speculations clearly represent oversimplified cases; however, we have found that they are well followed in the Würster salts.

Experimental

Materials. The following Würster salts were prepared according to the methods of Michaelis and Granick[1] and of Hughes and Hush[2]; *p*-phenylenediamine bromide,[1] *N,N*-dimethyl-*p*-phenylenediamine (Würster's red) bromide,[1] Würster's red ferrocyanide,[2] *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (Würster's blue) perchlorate,[1] Würster's blue ferrocyanide,[2] Würster's blue iodide prepared in aqueous methanol (high-susceptibility form),[2] Würster's blue iodide prepared in methanol - ether (low-susceptibility form),[2] benzidine bromide,[2] and *N,N,N',N'*-tetramethylbenzidine bromide.[2] They were assumed to exhibit the magnetic behavior reported in the references.

Measurements. The solid bromide was diluted with potassium bromide in a ratio of about 1 : 200 by grinding it to obtain a reasonable reflectance. The spectra were recorded as the difference in reflectance between the mixture and pure potassium bromide in the range from 4.0 to 30.8 kK by a Beckman DK-2A spectroreflectometer, and were then plotted using the Kubelka-Munk function $f(R)=(1-R)^2/2R$, where R is the reflectance. To avoid anion-exchange between the salt and the diluent, the iodide was ground with potassium iodide, and the perchlorate and ferrocyanide, with naphthalene. (With the last diluent, the measurements are reliable only in the range from 10 to 25 kK because of absorption due to the hydrocarbon.)

Results and Discussion

***p*-Phenylenediamine Bromide (Fig. 1, Curve a).** The low-energy band in the solid-state spectrum is found at 12.7 kK, which is much lower than the 16.4 kK value for the charge-transfer band in the dimer spectrum and also the 20.4 and 21.1 kK values for the α-band in the monomer spectrum. Although no information is available on the crystal structure, we suppose that the intermolecular interaction in this salt is

strong and more-than-by-pairs. The magnetic susceptibility reported by Michaelis and Granick is $-(109\pm10)\times10^{-6}$ emu/mol, which is in agreement with the estimated diamagnetic term, $-(98\pm16)\times10^{-6}$.[1]

Würster's Red Bromide (Fig. 1, Curve b). The solid-state spectrum has absorptions at 10.4 and 14.8 kK. The charge-transfer band in the dimer is located at 14.7 kK, and the α-band in the monomer, at 18.0 and 19.4 kK.[10,16] Again, the spectrum is different from either the dimer or monomer spectrum and extends to the lower-energy region. The crystal structure has been examined by Tanaka *et al.*[14] The cation-radicals are equally spaced in a linear chain at the remarkably short distance of 3.135 Å. These pieces of evidence indicate that the intermolecular interaction here is more-than-by-pairs and is strong. The salt is diamagnetic, the reported values being -102×10^{-6} by Michaelis and Granick[1] and -130×10^{-6} emu/mol by Hughes and Hush.[2] This is in accordance with our conclusion. Tanaka *et al.* have reported that the low-energy absorption is polarized out of the molecular plane, presumably in the direction to connect the centers of neighboring molecules.[14]

Würster's Red Ferrocyanide (Fig. 1, Curve c). Unlike the dark-green bromide, this salt shows only one broad absorption in the low-energy region, at 14.8 kK. This energy is in good agreement with the 14.7 kK value for the charge-transfer band in the solution's dimer spectrum.[16] According to the measurements by Hughes and Hush, this salt is paramagnetic; $+1098\times10^{-6}$ emu/mol at 293°K.[2] A cation-radical in this salt appears to interact predominantly with one neighbor, but merely weakly.

Würster's Blue Perchlorate (Fig. 2, Curve a). The crystal is known to be orthorhombic and to be built up from linear chains of equivalent cation-radicals at room temperature. A phase change into the monoclinic form occurs at 186°K, and the radicals pair up to form dimers. The singlet-triplet energy separation in the latter phase has been estimated as 0.246 kK.[6] Thus, the salt at room temperature has been considered to be a normal paramagnet. In accordance with this view, the strong band at 16.7 kK in the solid-state spectrum corresponds well with the α-band in the monomer spectrum, 16.4 and 17.8 kK.[10] However, the presence of a shoulder around 12 kK must be noted. This is the place where the charge-transfer band appears in the solution's dimer spectrum[16] and also in the solid-state spectrum at low temperatures.[17] The paramagnetic susceptibility above the transition temperature has been reported to be consistent with a Curie-Weiss law; however, the observed paramagnetism is often short of the expected 100% free radical value. For example, Duffy has found it to be 94% and Okumura, as low as 81%.[3,4] It is difficult to see how these deviations from 100% free radicals are related with the weak charge-transfer absorption in the solid-state spectrum. At any rate, both the optical and magnetic pieces of evidence clearly indicate that the interaction in Würster's blue perchlorate is weak at room temperature.

Würster's Blue Ferrocyanide (Fig. 2, Curve b). Although the main bands, located at 16.4 and 18.2 kK, again correspond well with the α-band in the monomer spectrum, the charge-transfer band at 12.3 kK is clearly recorded. The susceptibility reported by Hughes and Hush is as high as $+1031\times10^{-6}$ emu/mol at 291°K,

16) K. Suzuki, Y. Ooshika, Y. Seo, K. Uemura and S. Nakayama, Paper presented at the Symposium on Molecular Structure, Nagoya, October, 1965.

17) T. Sakata and S. Nagakura, *Technical Report of ISSP*, Ser. A, No. 244, March, (1967), published by the Institute for Solid State Physics, the University of Tokyo.

which is only a little bit lower than the $+1114\times10^{-6}$ emu/mol value for the perchlorate.[2] As is indicated by the strong charge-transfer absorption and lower susceptibility, the cation-radicals in the ferrocyanide must interact with each other slightly more strongly than those in the perchlorate; otherwise, the situations in these two substances seem to be very much alike.

Würster's Blue Iodide (Fig. 3, Curves a and b). Judging from the spectrum and the susceptibility (as high as $+1004\times10^{-6}$ emu/mol at 289°K),[2] the high-susceptibility form is similar to the perchlorate and ferrocyanide discussed above. The charge-transfer band at 11.4 kK and the band at 25.8 kK are very much intensified in the low-susceptibility form, for which a value of $+51\times10^{-6}$ emu/mol at 289°K has been found by Hughes and Hush.[2] On the other hand, the α-band at 16.4 kK and the γ-band at 30.6 kK almost disappear. This feature is the one expected for the dimer spectrum.[16] Therefore, it is likely that the cation-radicals pair up strongly in the low-susceptibility form. However, the possibility that the sample for the high-susceptibility form is contaminated with a small amount of the low-susceptibility form, or *vice versa*, can not be excluded.

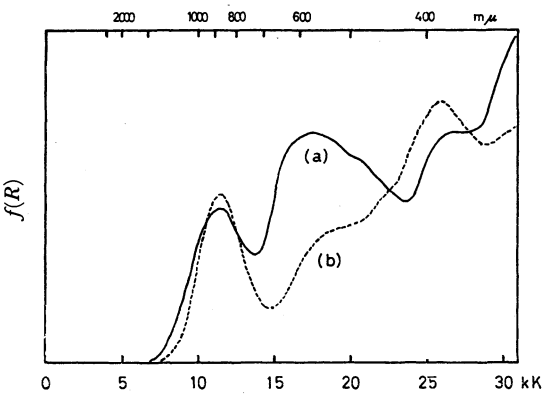

Fig. 3. Diffuse reflection spectrum of Würster's blue iodide, high-susceptibility form (curve a) and low-susceptibility form (curve b).

Mizuno *et al.* have studied the crystal structure of a dark-green Würster's blue bromide recrystallized from methanol.[15] The perpendicular separation between the molecular planes has been found to be as great as 3.515 Å. It is interesting to note that the spectrum reported by them is similar to that of the high-susceptibility form of the iodide.

Benzidine Bromide (Fig. 4, Curve a). The monomer spectrum comprises bands at 11.6 and 13.1, and shoulder at 14.3, and a strong band with some vibrational structures around 21.6 kK, while at low temperatures these absorptions are diminished and new bands appear at 12.4, 16.4, and 27.8 kK.[18] They have been assigned to the dimer. Unfortunately, the lower-energy region, in which we are most interested, could not be examined because of absorption due to the solvent. Consequently, there are not enough data for comparison and we cannot choose between a pair-by-pair and a more-than-by-pairs charge-transfer interaction as the cause of the absorption at 6.7 kK in the solid-state spectrum. The salt is known to be diamagnetic (-123×10^{-6} emu/mol);[2] therefore, the interaction is certainly strong.

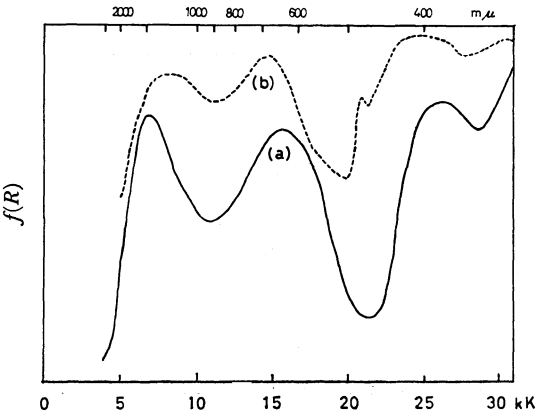

Fig. 4. Diffuse reflection spectra of benzidine bromide (curve a) and *N,N,N',N'*-tetramethylbenzidine bromide (curve b).

***N,N,N',N'*-Tetramethylbenzidine Bromide (Fig. 4, Curve b).** The solution study by Takemoto *et al.*, although valuable as an example of monomer-dimer equilibrium, does not provide us with a complete dimer spectrum for comparison.[19] The solid-state spectrum is very much like that of the afore-mentioned benzidine bromide except for the shift of the low-energy absorption to 8.0 kK. The salt has a susceptibility of -173×10^{-6} emu/mol.[2]

General Remarks. Summarizing the above-mentioned results, we may note that the Würster salts can tentatively be classified into the following three groups:

(I) The paramagnetic Würster's red ferrocyanide and the low-susceptibility form of Würster's blue iodide are in this group. The solid-state spectrum has a strong low-energy absorption near the place where the charge-transfer band is located in the solution's dimer spectrum. The intermolecular interaction seems to be predominantly pair-by-pair. A possible candidate for this group is the monoclinic form of Würster's blue perchlorate provided that the measurements are made well

below the transition temperature. The diamagnetic benzidine and tetramethylbenzidine bromides may be classified into this group or the third group.

(II) The group is represented by Würster's blue perchlorate, ferrocyanide, and iodide (the high-susceptibility form). All of them are highly paramagnetic, containing over 80% free radicals. In addition to a strong absorption corresponding to the α-band in the monomer spectrum, a relatively weak low-energy absorption, almost corresponding to the charge-transfer band in the dimer spectrum, is observed in the solid-state spectrum. The intermolecular interaction is supposed to be perfectly symmetric, but so weak that the absorption process is confined to a region no wider than a single pair.

(III) The *p*-phenylenediamine and Würster's red bromides belong to this group; both are diamagnetic. The solid-state spectrum bears no resemblance to either the monomer or dimer spectrum and extends to a lower-energy region. A strong, more-than-by-pairs interaction is expected to cause such behavior.

Now we have to say a few words why we took only the extremes into consideration for the more-than-by-pairs interaction. The intermediate case may be observed only when the temperature of the measurement is comparable with the interaction. This condition may be fulfilled by Würster's blue perchlorate near the transition temperature. However, carrying out the measurements at room temperature, we can scarcely ever meet with such an intermediate case.

Discussing paramagnetic excitons in solid free radicals, McConnell and Lynden-Bell have speculated that, as linear chains of $S=1/2$ atoms or molecules are unstable with respect to distortions that produce an alternation in the distances between the interacting units, one individual radical can interact equally strongly with two others only at temperatures large compared to the exchange interaction.[20] The Würster salts in the second group apparently fit this speculation; however, we must remark that the very presence of a third group violates their speculation.

The mode of interaction depends naturally on the stacking of the cation-radicals, which is in turn affected not only by the size and shape of the cation itself, but also by those of the counter ion. Understandably, methyl substitution on the cation and a counter ion as bulky as ferrocyanide are unfavorable factors for a strong intermolecular interaction.

The authors wish to express their thanks to Mr. Nobuhiko Miyajima for his technical assistance throughout the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2619—2623 (1968)

β-Diketonates of a Few Lanthanide Elements

M. HASAN, K. KUMAR, S. DUBEY and S. N. MISRA*[1]

Chemical Laboratories, University of Jodhpur, Jodhpur, India

(Received September 11, 1967)

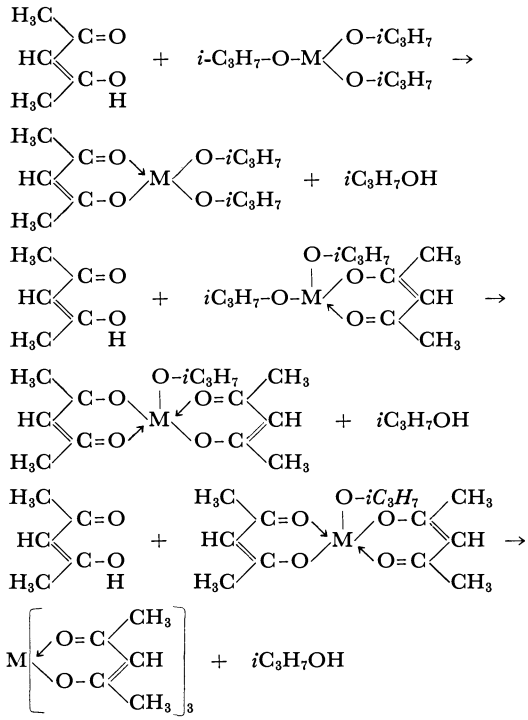
The reactions of isopropoxide of praseodymium and neodymium with benzoylacetone, dibenzoylmethane have been studied and the derivatives of the type $M(O\text{-}iPr)_2(lig.)$, $M(O\text{-}iPr)(lig.)_2$ and $M(lig.)_3$ (where lig.=benzoylacetone or dibenzoylmethane) have been isolated. The isopropoxide-diketonates on treatment with tertiary butanol interchange their isopropoxide group with tertiary butoxide group. Anhydrous acetylacetonates of lanthanum, praseodymium, neodymium and samarium have been prepared from the reactions of the alcoholic solution of the chlorides with alcoholic solution of ammonium acetylacetonates. The molecular weights of these β-diketonates and alkoxides β-diketonates have been measured ebullioscopically in boiling benzene.

In recent years there has been considerable interest in the preparation and properties of metal acetylacetonate derivatives. An extensive study of literature reveals that an appreciable amount

of work has been done on the acetylacetonates of lanthanide elements.[1-9]

In almost all the methods, the reactions were carried out in an aqueous medium (hydrated organic solvents were also employed), by taking hydrated metal chloride and the mono- and trihydrated acetylacetonates were isolated.

Recently the anhydrous acetylacetonates and alkoxide acetylacetonates of praseodymium and neodymium[10] have been synthesised from the reactions of their isopropoxides with acetylacetone in different stoichiometric ratios in benzene: The raction mechanism appears most probably of S_N2 type:



In view of the above, it was considered of interest to study the reactions of praseodymium and neodymium isopropoxides with benzoylacetone and dibenzoylmethane in benzene.

All these derivatives are coloured microcrystalline solids, soluble in benzene and ethanol from which the pure samples could be crystallised.

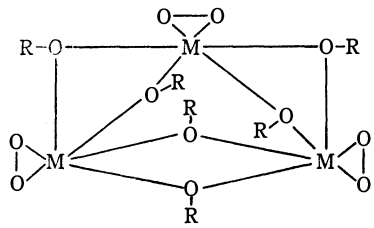
The alkoxide β-diketonates interchange their isopropoxide group with tertiary butoxide group, when refluxed with tertiary butanol in benzene, isopropanol produced in the reaction was fractionated out azeotropically with benzene:

$$M(O\text{-}iC_3H_7)_2L + 2tC_4H_9OH = M(\text{-}O\text{-}tC_4H_9)_2L + 2iC_3H_7OH$$

$$M(O\text{-}iC_3H_7)L_2 + tC_4H_9OH = M(\text{-}O\text{-}tC_4H_9)L_2 + iC_3H_7OH$$

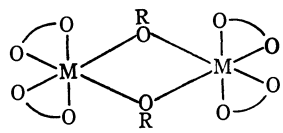
The synthesis of anhydrous acetylacetonates of lanthanum, praseodymium, neodymium and samarium has been followed by another route. Ammonium acetylacetonate (prepared by passing a controlled slow current of ammonia through the solution of acetylacetone in benzene when a crystalline solid separated out; it was filtered) was dissolved in ethanol and this solution was added to the alcoholic solution of metal chloride, when a white precipitate of ammonium chloride separated out leaving clear liquor. The product was obtained after evaporating off the solvent under reduced pressure. The product was recrystallized from refluxing benzene and thus could be obtained in a high grade of purity.

The molecular weight determination of the di-isopropoxide monoligand derivative showed that the molecule is a trimer and thus can be represented-most probably by the following structure:



Where we have three metal octahedra with two edges in common. In this structure the coordination number of the metal appears to be six.

The mono alkoxide diligand derivative has been found to be dimeric and thus can be represented by the following structure:



Where two metal octahedra are bridged through alkoxide oxygen bridges.

The triligand derivative has been found to be dimeric and thus the following structure appear to be a probable one:

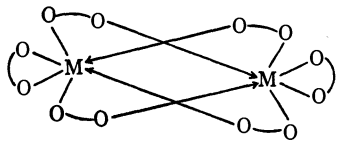
Where two metal octahedra are bridged through oxygen atoms of ligand molecule. The probability of following structure, however, could not be ruled out:



Where the oxygen atoms of ligands are donating electrons to empty d_π orbital of the metal.

Experimental

Glass apparatus with interchangeable joints was used. Anhydrous lanthanum, praseodymium, neodymium and samarium chlorides were prepared as described in earlier publications.[11] Pure lanthanum, praseodymium and neodymium isopropoxides were prepared by sodium alkoxide method already reported[12]; solvents dried as described in earlier communication.[11]

Molecular Weights. The molecular weights of these derivatives were determined ebullioscopically by semi-micro gallenkemp ebulliometer using thermistor sensing in refluxing benzene. The experimental

technique was the same as described in our earlier communication.[13]

Analytical Methods. Praseodymium was estimated as oxinate while lanthanum, neodymium and samarium were estimated by precipitating them as oxalate followed by the ignition to corresponding oxide. The isopropanol content of benzene-isopropanol azeotrope was determined by an oxidimetric method.[14]

Reaction between Praseodymium Isopropoxide and Benzoylacetone (Molar Ratio 1 : 3) in Benzene. The mixture of praseodymium isopropoxide (1.32 g) benzoylacetone (2.01 g) and benzene (84 g) was shaken thoroughly when a clear green solution was obtained. The reaction mixture was refluxed and the liberated isopropanol was fractionated out azeotropically with benzene. The product was obtained after distilling off excess solvent under reduced pressure.

13) S. N. Misra, T. N. Misra and R. C. Mehrotra, *J. Inorg. Nucl. Chem.*, **25**, 195 (1963); **25**, 201 (1963).
14) D. C. Bradley and W. Wardlaw, *J. Chem. Soc.*, **1950**, 3450.

Reaction of Praseodymium Di-isopropoxide Mono-benzoylacetonate with *t*-Butanol in Benzene. Praseodymium di-isopropoxide monobenzoylacetonate (1.43 g) benzene (83 g) and tertiary butanol (2.43 g) were refluxed under the column. After the removal of binary azeotrope (benzene - isopropanol), excess solvent was distilled out under reduced pressure and at the room temperature leaving a green micro-crystalline solid (Yield 1.56 g).

For brevity the reaction of isopropoxides of praseodymium and neodymium with benzoylacetone and dibenzoylmethane are summarised in Table 1, and those from the reaction between above derivatives and tertiary-butanol and summarised in Table 2.

Anhydrous Acetylacetonates of Lanthanum, Praseodymium Neodymium and Samarium. *a) Preparation of Ammonium Acetylacetonate.* Acetylacetone (18.3 g) was dissolved in benzene (150 g) and a current of anhydrous ammonia was slowly passed through the solution. The reaction was exothermic and a white crystalline solid separated out from the solvent. The completion of the reaction was indicated by cooling of

TABLE 3.

Reaction mixture in g		Nature of the product	Analysis % Metal Found	Analysis % Metal Calcd

acetylacetone	10.0			
in ethanol	190.0			

the reaction mixture. It was filtered, washed thoroughly with benzene and dried under reduced pressure (Yield 19.0 g).

b) Preparation of Lanthanum Triacetylacetonate. Lanthanum chloride (2.47 g) was dissolved in ethanol (87 g) when a clear solution was obtained. Ammonium acetylacetonate (3.41 g) taken in ethanol (89 g) containing 10.0 g of acetylacetone, was added to alcoholic lanthanum chloride solution when a white solid separated out. Excess acetylacetone most probably checks the alcoholysis of the product. On evaporating off the excess solvent a faint yellow crystalline solid sparingly soluble in benzene but soluble in refluxing ethanol and benzene was obtained (Yield 4.09 g).

The preparation of the anhydrous acetylacetonates of lanthanum, praseodymium, neodymium and samarium is summarised in Table 3.

The authors wish to express their deep gratitude to Professor R. C. Mehrotra for his valuable suggestions. They are also thankful to Professor R. C. Kapoor, Head of the Department of Chemistry, University of Jodhpur, Jodhpur, and Professor A. B. Sen, Head of the Department of Chemistry, University of Lucknow, Lucknow, for providing research facilities and encouragement throughout the work. They thankfully acknowledge the helpful criticism of Drs. C. S. Pande and R. C. Agarwal of Chemistry Department, Lucknow University, Lucknow. One of us (K. K.) is grateful to the Ministry of Education, Government of India for providing research scholarship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2624—2627 (1968)

Synthesis of Copper(II) Complexes with Maleic Acid[1]*

Kazuo GORA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 12, 1967)

Three copper(II) complexes with maleic acid, [Cu mal(H_2O)] (I) (mal=$C_2H_2(COO)_2$), [Cu(Hmal)$_2$(H_2O)$_4$] (II) and [Cu_2(Hmal)$_4$]·H_2mal·4EtOH (III) (EtOH=C_2H_5OH), were synthesized. Compound I was prepared from an aqueous solution of copper(II) sulfate pentahydrate and sodium hydrogenmaleate at room temperature as fine blue crystals. Compound II was prepared by adding little by little copper(II) hydroxide or copper(II) hydroxycarbonate to an aqueous solution of maleic acid at a temperature below 0°C in an ice-salt bath, obtaining light-blue powdered crystals. Compound III was prepared by heating a mixed alcoholic solution of maleic acid anhydride, copper(II) sulfate pentahydrate and sodium carbonate anhydride (3 : 1 : 1) in a flask with a reflux condenser for two hours. Fine bluish-green crystals were obtained. By using copper(II) hydroxide instead of copper(II) sulfate in the above preparation, a better yield can be obtained. The effective magnetic moments of I and II were 2.00 B. M. (20°C) and 1.97 B. M. (20°C), respectively, which are relatively close to the spin-only value of the divalent copper ion. On the other hand, the magnetic moment of III was subnormal, being 1.12 B. M. (18°C). The reflection spectrum of III gave a shoulder near 370 mμ, which is specific to green copper complexes. The product (IV) obtained by the thermal decomposition of I at 220°C and the product (V) obtained from II at 160°C, which are presumed to have the chemical formula [Cu-mal(H_2O)$_{0.1}$] and [Cu(Hmal)(mal)$_{1/2}$], respectively, gave normal magnetic moments, 1.91 and 1.89 B. M. (20°C). However, product (VI), obtained by expelling the alcohol from III had a magnetic moment of 1.31 B. M. (17°C). Different from the corresponding copper(II) phthalate complexes, no green copper complexes having subnormal magnetic moments could be obtained through dehydration of the blue maleate complex I or the light-blue complex II having normal magnetic moments.

Maleate anions coordinate to metal ions as seven-membered chelate ligands in the same way as succinate and phthalate anions. The fact that the copper(II) succinate complex has a subnormal effective magnetic moment, 1.40 B. M., has already been reported by Kubo *et al.*[1]

The copper(II) complexes with phthalic acid have been prepared and discussed for dimer or monomer structures with respect to two copper atoms in an earlier paper.[2] It was found by the authors that, in an aqueous solution at low temperature below 79°C, monomer phthalate complexes were produced preferably, whereas the dimer began to crystallize at temperatures above 79°C. On the basis of these results, it is assumed that the tendency of hydration of copper(II) ion in an aqueous solution would decrease steadily as the temperature is elevated. Instead of the use of an aqueous medium, some suitable organic solvents have been known to be effective for the preparation of several complexes having subnormal magnetic moments.[3,4]

Although the properties of the copper(II) complexes with maleic acid are partly known,[5] further investigation has not progressed. The present study is an attempt to prepare new copper(II) complexes with maleic acid in different media and to discuss their properties.

In the case of copper(II) phthalate complexes, a green complex having a dimer structure with respect to two copper atoms was obtained by the thermal decomposition of the blue and light-blue complexes. This was ascertained through reflection spectra and X-ray diffraction measurements carried out in an earlier paper.[2]

Despite great interest in the color and structural changes which take place in the thermal decomposition process of copper(II) phthalate complexes as above, such a study has rarely been made for other copper(II) complexes. A further purpose of this study is to find whether or not green copper maleate complex can be obtained through thermal

decomposition of the blue or light-blue complex in the similar way as in the thermal preparation of the corresponding green copper(II) phthalate complexes described in an earlier paper.[2]

Experimental

Syntheses. *Maleatoaquocopper(II)*, [Cu mal(H_2O)] (I). A solution of copper(II) sulfate pentahydrate (25 g; 0.1mol) in 100m*l* of water was mixed with a solution containing maleic acid (20g; 0.2mol) and sodium carbonate (11g; 0.1mol) in 2000m*l* of water. On allowing the mixed solution to stand for a while at room temperature, fine blue crystals precipitated out. After filtration, the precipitate was washed with a small amount of water, ethanol and ether in that order and then dried in a silicagel desiccator. The results of chemical and thermal analyses were: Found: Cu, 32.54; C, 24.58; H, 1.96%. Calcd for $[Cu(C_4H_2O_4)(H_2O)]$: Cu, 32.48; C, 24.56; H, 2.06%.

Bis(hydrogenmaleato)tetraaquocopper(II), $[Cu(Hmal)_2 \cdot (H_2O)_4]$ (II). When copper(II) hydroxycarbonate (12 g; 0.05mol) or copper(II) hydroxide (9.8g; 0.1mol) was added little by little to 300m*l* of an ice-cold aqueous solution containing maleic acid (20g; 0.2mol), a light-blue powder was obtained. It was washed several times with a mixture of ethanol and water (1 : 2), ethanol and ether and then air-dried. Found: Cu, 17.63; C, 26.96; H, 3.93%. Calcd for $[Cu(C_4H_3O_4)_2(H_2O)_4]$: Cu, 17.37; C, 26.28; H, 3.86%.

Tetra(hydrogenmaleato)dicopper(II) Maleate Tetraalcoholate $[Cu_2(Hmal)_4] \cdot H_2mal \cdot 4EtOH$ (III). By refluxing a mixed solution of maleic acid anhydride (30g; 0.3mol), copper(II) sulfate pentahydrate (25g; 0.1mol) and sodium carbonate (11g; 0.1mol) in alcohol (300m*l*) for two hours, a green solutuon was obtained. On allowing the solution to stand for a while at room temperature, green powdered crystals precipitated out. Through recystallization with a saturated ethanol solution, fine green crystals were obtained with a good yield. They were washed with a mixture of ethanol and water (1 : 2), ethanol and ether in a similar way as described above and air-dried. Found: Cu, 14.46; C, 38.28; H, 4.77%. Calcd for $[Cu_2(C_4H_3O_4)_4] \cdot (C_4H_4O_4) \cdot 4C_2H_5OH$: Cu, 14.31; C, 37.88; H, 4.54%.

Thermal Decomposition Product (IV) from I. When complex I was heated to 220°C, a violet compound was obtained. It was thought to have the formula [Cu mal$(H_2O)_{0.1}$] after thermogravimetric (TG) analysis.

Thermal Decomposition Product (V) from II. Complex II was also heated at 160°C in the similar way as described above. The resulting blue powder was assigned to $[Cu(Hmal)(mal)_{1/2}]$ on the basis of its TG analysis. This formula was also confirmed through elementary analysis: Found: Cu, 27.17; C, 31.16; H, 1.69%. Calcd for $[Cu(C_4H_3O_4)(C_4H_2O_4)_{1/2}]$: Cu, 26.96; C, 30.58; H, 1.71%.

Thermal Decomposition Product (VI) from III. Complex III was heated at 100°C in the same way. After TG analysis, the resulting compound was thought to corresponding to $[Cu_2(Hmal)_4] \cdot H_2mal$. It was also confirmed by an analysis of the copper content. Found: Cu, 17.95%. Calcd for $[Cu_2(C_4H_3O_4)_4] \cdot (C_4H_4O_4)$: Cu, 18.07%.

Measurements. Thermal analysis was carried out with a Shimadzu Thermano Balance. Magnetic susceptibilities were measured by the Gouy method using powdered sample at room temperature. The measurements of visible and UV absorption spctra were carried out in an ethanol solution with a Hitachi EPU-2A Spectrophotometer; reflection spectra of finely powdered solid samples were obtained with the same spectrophotometer equipped with a standard Hitachi reflection attachment. With a Nippon-Bunko DS-301 IR Spectrometer, the IR spectra of these complexes were measured in a Nujol or HCB mull state and in a KBr disk. The X-ray diffraction patterns were obtained with a Rigaku-Denki Geiger-flex X-ray Analyzer.

Results and Discussion

Conditions for the Formation of These Copper(II) Maleate Complexes. Complex I was obtained at room temperature, but complex II was prepared at a lower temperature in an ice-salt bath. However, II was sometimes contaminated with a small amount of I even at the low temperature when copper(II) salt was added in relatively larger amounts at a time. The use of copper(II) hydroxide instead of copper(II) hydroxycarbonate, in general, led to rather good yields.

Complex III could not be obtained in a medium consisting of ethanol and water (1 : 1), but was obtained only refluxing an alcoholic solution of the materials required for preparation. On the other hand, I was formed preferably in aqueous media at approximately 100°C and III was transformed to I in the presence of water. These results suggest that the existence of water obstructs the formation of III.

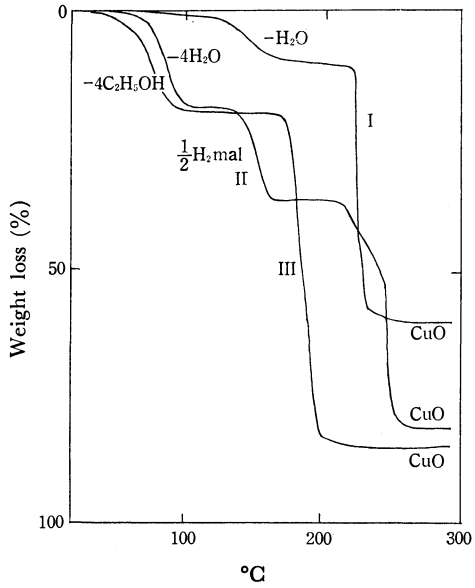

Fig. 1. TG curves for copper(II) maleate complexes.
I $[Cu\ mal(H_2O)]$
II $[Cu(Hmal)_2(H_2O)_4]$
III $[Cu_2(Hmal)_4] \cdot (H_2mal) \cdot 4EtOH$

Thermal Decomposition. Figure 1 shows the TG curves for complexes I, II and III. The thermal decomposition processes in these complexes are expressed as follows:

$$\mathrm{I} \xrightarrow{220^\circ\mathrm{C}} [\mathrm{Cu\ mal}(\mathrm{H_2O})_{0.1}] \xrightarrow{235^\circ\mathrm{C}} \text{decompose}$$

$$\mathrm{II} \xrightarrow{100^\circ\mathrm{C}} [\mathrm{Cu(Hmal)_2}] \xrightarrow{160^\circ\mathrm{C}} [\mathrm{Cu(Hmal)(ma)_{1/2}}] \xrightarrow{260^\circ\mathrm{C}} \text{decompose}$$

$$\mathrm{III} \xrightarrow{100^\circ\mathrm{C}} [\mathrm{Cu_2(Hmal)_4}]\cdot\mathrm{H_2mal} \xrightarrow{200^\circ\mathrm{C}} \text{decompose}$$

The complexes I and II have already been prepared by Pickering,[5] who, however, found the composition of the complex to be $[\mathrm{Cu(Hmal)_2}]\cdot 8\mathrm{H_2O}$, which loses four hydrated water molecules upon heating at 100°C and then loses the remaining four water molecules at 170°C, differing from complex II obtained by the present authors.

Although transformation from complex III to I in the presence of water easily took place as described above, the reverse reaction *via* thermal decomposition was not achieved, apart from the case of the corresponding phthalate complexes.[2]

Magnetic Susceptibility. The effective magnetic moments of these complexes evaluated from magnetic susceptibility measurements are given in Table 1. It is seen in the table that complexes I and II and their thermal decomposition products have normal magnetic moments of a spin-only value for divalent copper ion, exhibiting no specific interactions between two copper atoms, whereas both complex III and its thermal decomposition product possess a subnormal magnetic moment, probably due to a strong interaction between Cu(II)-Cu(II) atoms in a molecule.

Table 1. Magnetic moments, μ_{eff}, of copper(II) maleate complexes

Complex	μ_{eff} B.M. (°C)
I	2.00 (20)
II	1.97 (20)
III	1.12 (18)
IV	1.91 (20)
V	1.89 (20)
VI	1.31 (17)

IR Spectra. The wave numbers of the band assigned to C=O stretching and of the specific absorption band concerning the maleate ion in IR spectra are listed in Table 2. In complexes II and III and their thermal decomposition products both free and coordinated carboxyl groups are found to coexist from the appearance of two strong bands in the regions 1720—1700 and 1660—1620 cm^{-1} assigned to both groups, respectively, whereas in complex I and its thermal decomposition product only one broad band is found in the range of 1660—1620 cm^{-1}, showing that all carboxyl groups are coordinated to the central metal ion in the molecule.

Table 2. IR spectra of copper(II) maleate complexes (cm^{-1})

$\nu_{(COOH)}$ and $\nu_{(COOM)}$ are stretching vibration of free and coordinated COO group; δ, specific absorption band of maleate

Complex	$\nu_{(COOH)}$	$\nu_{(COOM)}$	$\delta_{(mal)}$
I	—	1665, 1620	854, 838
II	1700	1660	835
III	1715	1660—1620	863, 838, 822
IV	—	1660—1620	851, 832
V	1720	1650—1615	835, 825, 810
VI	1720	1650—1615	835, 825, 810

The fact that all the complexes show a specific band assigned to the maleate anion in the region 860—810 cm^{-1} confirms that the complex molecules hold maleate coordinated, not fumarate, in themselves.

Reflection Spectra. The reflection spectra of the complexes, I, II, III and IV are shown in Fig. 2. The absorption bands of I and II are found near $14.5\times10^3\ cm^{-1}$, whereas IV gives a new, relatively strong band near $17.0\times10^3\ cm^{-1}$ instead of the depression of the former band at $14.5\times10^3\ cm^{-1}$. This suggests that the new band can be assigned to the ligand field produced by maleate anion only coordinated to copper as a result of the liberation of coordinated water.

On the other hand, in complex III, there are two bands near 14.7 (d–d transition band) and at $27.0\times10^3\ cm^{-1}$, the latter band appearing at almost the same position as that observed in the

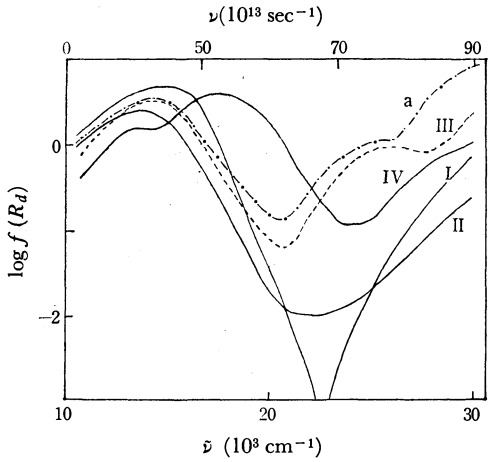

Fig. 2. Reflection spectra of copper(II) maleate complexes.
I $[\mathrm{Cu\ mal}(\mathrm{H_2O})]$
II $[\mathrm{Cu(Hmal)_2}(\mathrm{H_2O})_4]$
III $[\mathrm{Cu_2(Hmal)_4}]\cdot\mathrm{H_2mal}\cdot 4\mathrm{EtOH}$
IV $[\mathrm{Cu\ mal}(\mathrm{H_2O})_{0.1}]$
a, $[\mathrm{Cu_2ph_2}]$ (for reference)

green copper(II) phthalate complex as already described in an earlier paper,[2] which is also shown by (a) in Fig. 2 for reference.

X-Ray Powder Pattern Measurement. Complexes I, II and III give essentially different X-ray powder patterns showing that their structures are different. In the copper(II) phthalate complexes, the interesting fact that the green complex, which has a subnormal magnetic moment, is also produced by the thermal decomposition of the blue or lightblue complex was verified from X-ray powder diffraction patterns in an earlier paper.[2] However, in the copper(II) maleate complexes, such a phenomenon has never been observed. Information on crystal structure was found only for I, which is a hexagonal system with the axial parameters $a=8.10$ Å and $c=10.59$ Å, and of chemical units $Z=4$ with a density $\rho=2.16$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2627—2631 (1968)

The Separation of the Cerium-group Rare Earth Elements by Ion Exchange using a Citrate-acetate Mixed Solution as Eluting Agent*[1]

Muraji SHIBATA,*[2] Isao TANABE, Kinnosuke OKUDA and Kazuo KADOTA

Takaoka Factory, Azuma Kako Company, Noo-machi, Takaoka, Toyama

(Received August 3, 1967)

The separation of rare earth elements by ion exchange was studied. The new eluting agent consists of an aqueous solution of diammonium hydrogencitrate and an aqueous ammonia-acetic acid mixture; the two solutions were mixed in definite ratios. Using a column of Dowex 50 W resin, the separation of Sm, Nd, Pr, Ce and La was successfully achieved. As practical samples, mixed chlorides obtained from monazite concentrates were used. Both the purities and the yields of the recovered rare earths were greater than 99%. This eluting agent was applied to the separation of yttrium-group rare earths such as Dy, Er, Yb and Y, but the attempt was not successful.

During the past twenty years, a great number of papers have been published on the separation of rare earths by ion-exchangers. In the earlier papers, citric acid solution buffered with ammonia was widely used as eluting agent. Initially, 5% citrate at pH 2.5—3.0 was used, but this concentration was found costly in large scale operations.[1,2] Subsequently, 0.5% citrate at pH 3.9 was applied to pilot plant scale separations of the cerium-group rare earths.[3] Systematic studies on the effects of such variables as temperature, pH, size of resin particles and flow rate were also made with the same concentration of eluting agent.[4] Furthermore, certain workers used 0.1% citrate at pH 5.0—8.0 and found that the eluting agent was useful for macro separations of the cerium-group in kilogram quantities.[5] Shiokawa *et al.*[6-9] used 0.1% citric acid at pH 6.0 to separate cerium-group rare earths. Their experiments indicated yields of La, Pr, Nd and Sm at 96.2, 70.3, 90.0 and 77.2%, respectively.

A number of complexing agents beside citrate have also been used for analytical purposes. These are lactate, glycolate, malate, α-hydroxyisobutylate, *etc.* For commercial separation, aminopolycarboxylates such as ethylenediaminetetraacetate and nitrilotriacetate have now been used in conjunction with Cu(II)- or Zn(II)-resin retaining beds. Detailed reviews of such developments of ion exchange methods are described in a book edited by Spedding and Danne.[10]

The present paper deals with a new eluting agent. The eluting agent consists of a mixed system of citrate and acetate solutions. The minor component, acetate, greatly affects the rapid and sharp separation of the cerium-group elements (La, Ce, Pr, Nd and Sm). Successful separations on an analytical scale were provided with practical samples from monazite concentrates.

Experimental

The Eluting Agent. Two hundred grams of citric acid monohydrate and 50 g of diammonium hydrogencitrate were dissolved in water and diluted to 4000 m*l*. Hereafter, this solution is called the "A" solution for convenience. On the other hand, aqueous ammonia (40 m*l* of 28% ammonia diluted to 160 m*l*) was mixed with aqueous acetic acid (100 m*l* of glacial acetic acid diluted to 300 m*l*). This solution is called the "B" solution. Both the "A" and "B" solutions were mixed in definite ratios and used as eluting agents.

The Samples. Stocks of rare earths of 99% or higher purity were available for La, Pr, Nd and Sm as oxides. These were weighed in amounts to produce 10 mg per m*l* of solution. The calculated amount of nitric acid necessary to dissolve the oxide and to produce a final excess of 0.1 M acid was added, and each stock solution was brought to a definite volume with water. For cerium stock solution, cerium(III) nitrate hexahydrate was used. These solutions were used individually or as mixtures for determining optimum conditions for the separation of cerium-group rare earths.

For practical separation of the cerium-group, concentrates from monazite sand were obtained from our company. The concentrates were mixed chloride hydrates of the cerium-group rare earths. Furthermore, mixed oxides prepared from the mixed chlorides were also available for analytical separation. Further details of these separations will be described for each experimental result.

Some of yttrium-group rare earths were used: Stock solutions of Dy, Er and Yb were made from their oxides and that of Y, from the nitrate.

General Procedure. A few preliminary experiments comparing Dowex 50 W X8 resin with Amberlite IR-120 indicated the former to be superior. Therefore, unless otherwise noted, the Dowex resin of 100—200 mesh was used. Prior to elution, the column was washed with the "B" solution and then regenerated to hydrogen-form with 2 N hydrochloric acid. After removing excess acid with water, a sample solution was introduced into the column, the column was again rinsed with water and then eluted with a mixture of the "A" and "B" solutions. Other conditions, such as column dimensions, resin-bed length, flow rate and composition of rare earths are given in each experimental result.

The rare earths were recovered from the eluate as oxalates by adding 5% oxalic acid. The oxalates were ignited to oxides for weighing. Fractions which seemed to be contaminated with adjacent elements were spectrophotometrically analyzed according to the method described by Spedding *et al.*[4] Sm was measured at 401 mμ, Nd at 740 mμ and Pr at 444 mμ. The values for the molar extinction coefficients of Sm, Nd and Pr at the above wavelengths were 3.09, 6.53 and 10.07, respectively. For portions which seemed to be recovered in pure states, characteristic absorption spectra were taken by means of a recording spectrophotometer over the visible range (350—700 mμ).

Results and Discussion

Optimum Composition of the Eluting Agent. In the beginning of the present work, it was found that the "B" solutions show much greater effects on the elution of the rare earth ions than the "A" solutions. When "A" solution was applied alone to a column ($\phi = 1.6$ cm, 10 g the Amberlite resin) which was charged with *ca.* 10 mg of Sm, the elution of Sm ranged from 300 to 700 m*l* of the eluate. In the case of "B" solution, the corresponding elution completed within 50 m*l* of the eluate. This fact suggested that mixing solutions "A" and "B" would be favorable. Then, a few experiments on the elution of Sm-Nd mixtures were made in order to find a suitable composition for the mixed solution. The results indicated that a solution consisting of one volume of "B" and forty volumes of "A" is effective. From this, a set of experiments was made to determine the optimum composition of the eluting agent for the separation of Sm, Nd and Pr. The parts of "A" to be mixed with one part of "B" were varied, maintaining other conditions constant. The results are shown in Figs. 1—3. It is clear from these figures that the best separation of Sm, Pr and Nd was achieved with an eluting agent having a 50 : 1 ("A" : "B") ratio by volume.

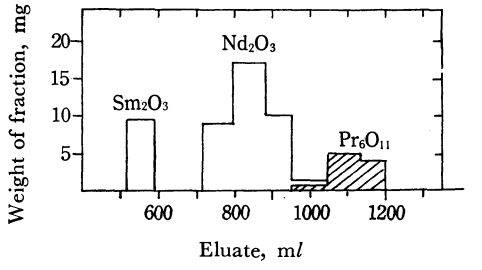

Fig. 1. Elution of Sm, Nd and Pr mixture with 40 : 1 eluting agent.
Weight of sample: Sm_2O_3 10 mg, Nd_2O_3 40 mg, Pr_6O_{11} 10 mg; column diameter 1.6 cm; resin height 19.3 cm (20 g); 1 fraction of eluate 20 m*l*.

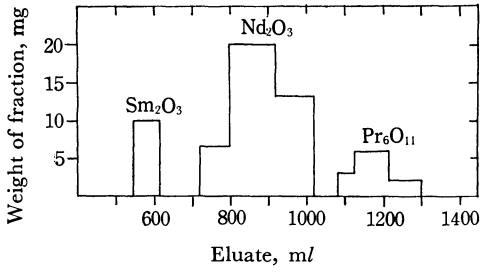

Fig. 2. Elution of Sm, Nd and Pr mixture with 45 : 1 eluting agent.
All the other conditions are the same as in Fig. 1.

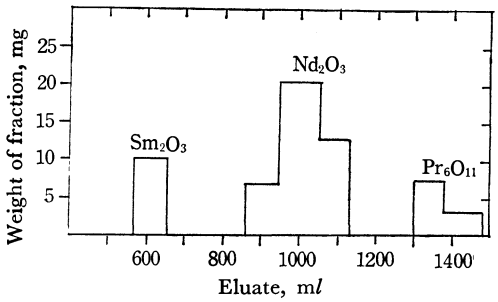

Fig. 3. Elution of Sm, Nd and Pr mixture with 50 : 1 eluting agent.
All the other conditions are the same as in Fig. 1.

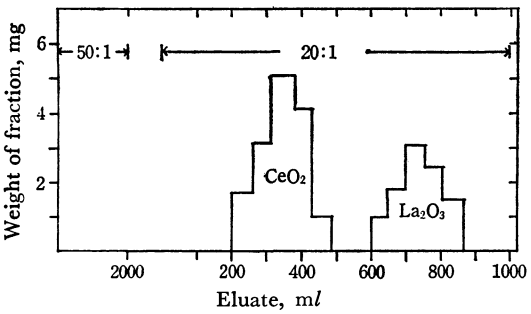

Fig. 4. Elution of Ce and La with 20 : 1 eluting agent.
Weight of sample: CeO_2 20 mg, La_2O_3 20 mg; The other conditions are the same as in Fig. 1.

Similar experiments were made with a mixture of Ce and La. When eluting agent consisting of a 50 : 1 ratio was applied, neither species of Ce nor La appeared in the eluate even when the eluate was 2000 ml. With decreasing the "A" component, each breakthrough volume of both elements was more and more reduced, and complete separation was obtained by using 20 : 1 eluting agent (Fig. 4).

The Elution of Mixed Chlorides of the Cerium-group Rare Earths. Conditions for this separation, based on the above results using Dowex 50W X8 (100—200 mesh), are;

Diameter of column: 2.2 cm
Height of bed: About 22.5 cm
Sample: Two kinds of $LnCl_3 \cdot nH_2O$ (Ln represents rare earths) were available and denoted as sample A and sample B for convenience; two grams of each sample was dissolved in 50 ml of 1 N HCl.
Flow rate: 0.7 cm/min.

The column in hydrogen-form was loaded with sample and washed with water (500 ml). Elution was started with 50:1 eluting agent. With progress in the elution process, movements of colored Nd and Pr bands were clearly observed visually. When the pale greenish band of Pr disappeared from the column, the eluting agent was changed to a 20 : 1 mixture for the elution of Ce and finally to 5 : 1 for the effective removal of La. Typical elution curves are shown in Figs. 5 and 6 and approximate compositions obtained by weighing as oxides are given in Table 1.

Table 1. Elution results of mixed chlorides

	Sample A		Sample B	
	Ln_2O_3 recovered mg	Composition as oxides %	Ln_2O_3 recovered mg	Composition as oxide %
Sm	42.6	6.1	67.0	7.6
Nd	135.1	19.3	184.3	20.8
Pr	42.4*	5.8	40.4*	4.6
Ce	327.4**	44.5	404.7**	45.6
La	170.5	24.3	189.3	21.4

* as Pr_6O_{11} ** as CeO_2

As is shown in Fig. 5, complete separation of Sm, Nd, Pr, Ce and La is obtained for sample A, while a little overlapping of the Nd fraction with Pr is observed in Fig. 6 for sample B. This somewhat poorer separation arises from the higher content of Nd in sample B as compared with that in sample A.

Our elution method was developed for larger scale separation; the sample A absorbed corresponded to 10 g of $LnCl_3 \cdot nH_2O$. The resin was 50—100 mesh in size, and its 540 ml was put into a column 3.0 cm in diameter; the flow rate was 1.5 cm/min, and the results are shown in Fig. 7.

Analyses of Rare Earth Oxides. Samples "C" and "D" were obtained from our company in the form of mixed chlorides after removing almost all the Ce from the other rare earths; these mixed chloride hydrates were first converted to mixed oxides and the oxides were treated with dilute nitric acid to remove the remaining cerium as an insoluble residue. The other rare earths in the solution were precipitated as oxalates and converted to oxides by ignition. The experimental conditions employed were: sample, about 1 g; column, 2.0×50 cm; Dowex 50W X8 (100—200 mesh), 40 g; bed length, about 22 cm; flow rate, 1.0 cm/min.

Elution was started with 50 : 1 eluting agent for Sm. Then the eluting agent was changed to 30 : 1 solution for the effective elution of Nd, where contamination of the Nd fraction with Pr was not observed. The elutions of Pr and Ce were carried out with 20 : 1 and 10 : 1 solutions in turn. Finally, 5 : 1 eluting agent was used for La. The eluates were collected for each fraction and tested for the presence of rare earth species by adding oxalic acid to the fractions placed at intervals of five fractions. The portions containing each species were brought together and evaporated to

a suitable volume. A large excess of oxalic acid was added to the concentrated solution and its pH adjusted to about 1.5 with ammonia. After heating for about 20 min, the whole was allowed to stand overnight. The precipitated oxalate was converted to oxide at 900°C. Typical results are given in Table 2.

TABLE 2. ELUTION RESULTS FOR MIXED OXIDES

Sample	C		D

Total	1051.0	99.72	824.5	99.48

* Qualitative test for its presence was also negative.

Behavior of the Yttrium-group Rare Earths. The utility of the new eluting agent for the cerium-group directed our attention to the separation of the yttrium-group rare earths, and some experiments were carried out in order to investigate the possibility. The individual elutions of Dy, Er, Yb and Y with 50 : 1 eluting agent are presented for comparison (Fig. 8). It is seen from the results that these elements show similar behavior. When 70 : 1 eluting agent was used, the nature of the elution was slightly improved, but it was still hopeless to separate these elements.

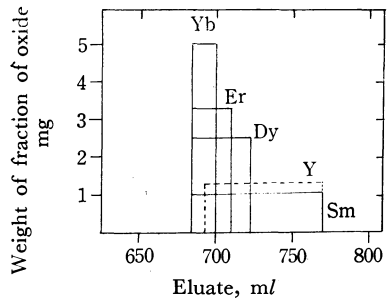

Fig. 8. Individual elution for the yttrium-group rare earths.
Weight of each sample, 10 mg as oxide; column diameter, 1.8 cm; bed height, 18 cm; flow rate 1.0 cm/min; eluting agent, 50 : 1; 1 fraction of eluate, 20 ml

On the Eluting Agent. A distinctive feature of our eluting agent is that the solution contains acetate anions in addition to citrate anions. Both anions may be responsible for the separation of the rare earths in the manner of complex formation. Tompkins and Mayer[11] mentioned that three H_2Cit^- ions are predominantly complexed with a rare earth ion under the condition of 0.25 M (5%) citrate at a pH lower than 3.2. In our eluting agent, the citrate concentration is about 6% and the pH values are 2.9 in 50 : 1 and 3.0 in 30 : 1 eluting agents. Therefore, formation of such complex species as $R(H_2Cit)_3$ should be considered in the elution process. On the other hand, the effect of the "B" component on the separation also suggests the formation of acetate-complex species. Kolat and Powell[12] reported the first two formation constants of acetate anions with rare earths. According to their data, a regular increase in stability is observed in the La-Sm region, while a decrease appears for the heavier elements. This decrease in stability reflects the failure to separate the yittrium-group rare earths.

Summary

A mixed system consisting of citric acid - ammonium citrate and acetic acid - ammonia was found to be a new eluting agent for the separation of La, Ce, Pr, Nd and Sm. The essential feature of this eluting agent is that the solution contains acetate anions in addition to citrate anions, and the former greatly affects the separation. As examples of separation, mixed chlorides obtained from monazite concentrates were eluted on an analytical scale. Mixed oxide samples were also analyzed successfully by this elution method.

Application of this eluting agent to heavier rare earths (yttrium-group) was unsuccessful.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2632—2636 (1968)

The Chelate Formation of *o*-Substituted Phenylazochromotropic Acids with Alkaline Earth Metals*[1]

Susumu NAKASHIMA,*[2] Haruo MIYATA and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received April 24, 1968)

The acid dissociation constants of phenyl, *o*-, *m*-, and *p*-sulfophenyl-, *o*-carboxyphenyl-, *o*-phenol- and *o*-arsonophenylazochromotropic acid and the formation constants of their 1 : 1 metal chelates with alkaline earth metals have been measured by potentiometric titration. The measurements have been carried out at 25°C and $\mu=0.10$ (KNO_3). The influence of these substituents on the acid dissociation constants of the reagents, and on the chelate formation constants was discussed. The dissociation constants of the naphtholic protons of the *o*-substituted reagents increase as follows: *o*-OH <*o*-$AsO(OH)_2$ <*o*-COOH <*o*-SO_3Na <*o*-H. The metal chelate stabilities of *o*-phenol-, phenyl- and *o*-arsonophenylazochromotropic acids decrease as follows: Mg> Ca> Sr> Ba, while for chelates of *o*-carboxyphenyl- and *o*-sulfophenylazochromotorpic acids the order is Mg> Ca> Sr≈Ba. The sulfonic group in *o*-sulfophenylazochromotropic acid, in spite of its remarkable electron-withdrawing effect, depress the acid dissociation, and form more stable barium chelate than phenyl-, *m*- and *p*-sulfophenylazochromotropic acid do. The plot of the formation constants, log *K*, against the sum of the dissociation constants, pK_A ($=pk_{a_1}+pk_{a_2}+pk_{a_3}$), was approximately linear.

A variety of azo dyestuffs have found a wide application in analytical chemistry, especially many azo derivatives of chromotropic acid are well known as colorimetric reagents and as metal indicators in chelatometry.[1] In the authors' laboratory numerous azo compounds showing a high sensitivity for metal ions were synthesized, and the acid dissociation constants of these reagents and the formation constants of thorium chelates were measured spectrophotometrically.[2] The present authors have extended the studies to alkaline earth metal chelates with seven substituted phenylazochromotropic acids, namely phenyl-, *o*-, *m*-, and *p*-sulfophenyl-, *o*-carboxyphenyl-, *o*-phenol- and *o*-arsonophenylazochromotropic acid, and investigated the effect of substituents on the dissociation constants and the chelate formation constants by means of potentiometric titration method.

Experimental

Reagents. Phenylazochromotropic acid [2-(phenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid disodium salt], *o*-sulfophenylazochromotropic acid [2-(2-sulfophenylazo)-1, 8-dihydroxynaphthalene - 3, 6 - disulfonic acid trisodium salt], *m*-sulfophenylazochromotropic acid ([2-(3-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid trisodium salt], *p*-sulfophenylazochromotropic acid [2-(4-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid trisodium salt], *o*-carboxyphenylazochromotropic acid [2-(2-carboxyphenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid disodium salt], *o*-phenylazochromotropic acid [Acid Chrome Blue K, 2-(2-hydroxyphenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid disodium salt] and *o*-arsonophenylazochromotropic acid [Neo-Thorin, Arsenazo, 2-(2-arsonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid disodium salt] were synthesized by the coupling reaction of chromotropic acid with diazobenzene, *o*-diazobenzenesulfonic acid, *m*-diazobenzenesulfonic acid, *p*-diazobenzenesulfonic acid, *o*-diazobenzoic acid, *o*-diazophenol and *o*-diazophenylarsonic acid, respectively. These reagents are all fine crystals. They were dried at 60°C *in vacuo*, and cooled in a phosphorus pentoxide desiccator. The

analytical data of sodium content by the flame analysis are given in Table 1.

The stock solutions of these reagents were standardized by potentiometric titration with standard 0.10 M potassium hydroxide.

Analytical grade $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $Sr(NO_3)_2$ and $Ba(NO_3)_2$ are used to make stock solutions and the solutions are standardized by chelatometric titration.

Potentiometric Titration. The apparatus for potentiometric titration is presented in Fig. 1. The hydrogen ion concentration was measured by using a Metrohm pH meter E 388 [Metrohm A. G., Herisau, Switzerland] with a combined glass electrode. The pH meter was calibrated with an acetate buffer and with potassium hydroxide. Ten milliliters of solution were titrated by addition of 0.10 M potassium hydroxide from a calibrated 0.50 ml Agla micrometer syringe. All measurements were made at 25.0±0.1°C, and the ionic strength was maintained at 0.10 M with potassium nitrate. Solutions under titration were kept in a nitrogen atmosphere.

Calculations of Acid Dissociation Constants and Chelate Formation Constants. The dissociation constants, k_{a_1}, k_{a_2} and k_{a_3} and the formation constant, K, were evaluated by similar equations to those described elsewhere.[3]

k_{a_1}, k_{a_2}, k_{a_3} and K are expressed as follows:

$$k_{a_1} = \frac{[H][HL]}{[H_2L]}, \quad k_{a_2} = \frac{[H][H_2L]}{[H_3L]},$$

$$k_{a_3} = \frac{[H][H_3L]}{[H_4L]}, \quad K = \frac{[MHL]}{[M][HL]}$$

where the ionic charge was neglected for the sake of convenience.

The formation constant of o-arsonophenylazochromotropic acid chelate was calculated by the following equations:

$$K = \frac{T_L - F}{[L^{5-}]\{F + T_M - T_L\}}$$

where

$$[L^{5-}] = \frac{3T_L - T_{OH} - [H^+] + [OH^-]}{\frac{[H^+]}{k_{a_1}} + \frac{2[H^+]^2}{k_{a_1}k_{a_2}} + \frac{3[H^+]^3}{k_{a_1}k_{a_2}k_{a_3}}}$$

$$F = [L^{5-}]\left\{1 + \frac{[H^+]}{k_{a_1}} + \frac{[H^+]^2}{k_{a_1}k_{a_2}} + \frac{[H^+]^3}{k_{a_1}k_{a_2}k_{a_3}}\right\}$$

where T_L, T_M and T_{OH} represent the total concentration of ligand, metal ion species and alkali added, respectively. These equations can be simplified for the calculations of the other chelate formation constants.

These constants were calculated by an NEAC-2203 computer (the Nippon Electric Co., Ltd) in the Electronic Computer Center of Okayama University.

Results and Discussion

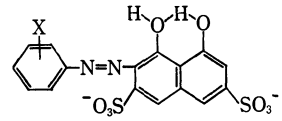
alkaline earth metal ions are illustrated in Figs. 2—6. The clear inflections at $a=1$ in the titration curves of the ligands in Figs. 4 and 5 show the dissociation of carboxyl and hydroxyl protons of the reagents, respectively, and similarly the inflections at $a=1$ and $a=2$ in Fig. 6 correspond to the dissociation of two arsonic protons. No inflection is observed at all on the neutralization of the naptholic protons of the above three reagents. Modification of the titration curves in the presence of metals is due to the chelate formation giving rise to free protons.

Acid Dissociation Constants. Substituted phenylazochromotropic acid is shown in the following structure:



X: *o*-H, *o*-SO_3^-, *o*-COOH, *o*-OH, *o*-$AsO(OH)_2$, *m*-SO_3^-, *p*-SO_3^-

The acid dissociation constants of the above seven derivatives are calculated from the titration curves and summarized in Table 2. As the pk_{a_3} value of *o*-arsonophenylazochromotropic acid is low, it is determined by titrating the reagent solution of 2.06×10^{-3} M. The constants obtained by this apparatus are in good agreement within experimental error with previous results[3] for the dissociation constants of *o*-phenolazochromotropic acid and the formation constants of its magnesium and calcium chelates.

In Table 2, the pk_{a_1} value corresponds to the dissociation of one of the naphtholic hydroxyl groups; the other naptholic hydroxyl group is not dissociated under ordinary experimental conditions, owing to a strong hydrogen bridge between two oxygen atoms of chromotropic acid as shown in the above structure. These ligands may be considered to be monobasic acids for phenyl-, *o*-, *m*-, and *p*-sulfophenylazochromotropic acids, dibasic acids for *o*-carboxyphenyl- and *o*-phenolazochromotropic acids and tribasic acid for *o*-arsonophenylazochromotropic acid.

The pk_a's of benzoic acid, phenol and phenylarsonic acid are 4.17,[4] 9.98[5] and 8.25 and 3.39 (obtained from potentiometric titration) respectively, whereas those of the corresponding azochromotropic acids are smaller. On the other hand, the pk_a's of the naphtholic hydroxyl groups in the azo compounds are much larger than that of chromotropic acid (5.44).[6] This implies that the formation of the intramolecular hydrogen bonding between the naphtholic hydroxyl group and the azo nitrogen atom adjacent to the phenyl group forms a stable six-membered ring.

TABLE 2. ACID DISSOCIATION CONSTANTS OF SUBSTITUTED PHENYLAZOCHROMOTROPIC ACIDS AND FORMATION CONSTANTS OF THEIR CHELATES

(t=25°C, μ=0.10; KNO_3)

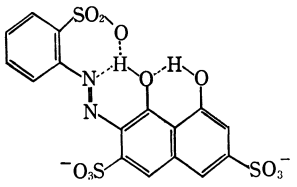
Substituent X	Acid dissociation constant			Formation constant, log K			
	pk_{a_1}	pk_{a_2}	pk_{a_3}	Mg	Ca	Sr	Ba
o-H	9.15			3.64	2.70	1.78	1.06
o-SO_3Na	9.35			3.58	2.91	2.58	2.66
o-COOH	9.94	3.71		4.55	3.40	2.81	2.81
o-OH	10.60	7.60		6.15	5.01	3.49	2.73
o-$AsO(OH)_2$	9.98	7.57	2.97	5.58	5.09	4.41	4.15
m-SO_3Na	8.85						1.44
p-SO_3Na	8.90						1.58

where $k_{a_1}=\frac{[H][HL]}{[H_2L]}$, $k_{a_2}=\frac{[H][H_2L]}{[H_3L]}$, $k_{a_3}=\frac{[H][H_3L]}{[H_4L]}$

Owing to the formation and the stabilization of the ring, the dissociation of the substituents in *o*-COOH, *o*-OH and *o*-$AsO(OH)_2$ compounds is easier than those of the corresponding phenyl compounds, meanwhile the dissociation of naphtholic hydroxyl groups is much more difficult than chromotropic acid.

Electron-withdrawing sulfonic group enhances the ligand acidity and thus the pk_a values of *m*- and *p*-sulfophenylazochromotropic acids are lower than that of phenylazochromotropic acid. However, the contribution of the sulfonic group in *o*-sulfophenylazochromotropic acid leads to the depression of the dissociation of the naphtholic proton as seen in Table 2.

This suggests that the sulfonic group in the ortho position for the azo group forms a hydrogen bond with the naphtholic proton in aqueous solution as the following structure shows:



Formation Constants. The formation constants of the 1 : 1 chelates of substituted phenylazochromotropic acids with alkaline earth metals are also tabulated in Table 2. The formation constant, log K, is plotted *versus* the sum of the disscoiation constants, pK_A ($=pk_{a_1}+pk_{a_2}+pk_{a_3}$), in Fig. 7. An approximately linear correlation between pK_A and log K is obtained for the chelates of a series of alkaline earth metals.

It is of interest that the log K values are nearly proportional to the pK_A values in spite of the complicated chelate structures and the differences of the numbers of the chelate ring formed. In barium chelates, however, a considerable deviation from the linearity is observed in comparison

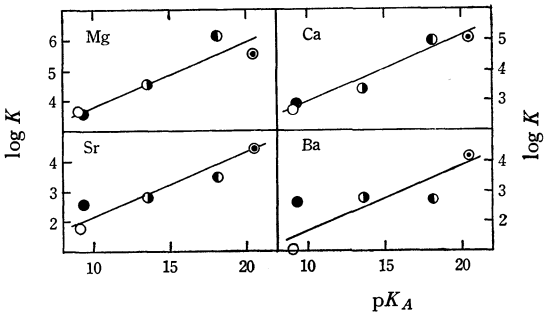


Fig. 7. Relation between pK_A of *o*-substituted phenylazochromotropic acids and log K of their metal chelates.

$pK_A = pk_{a_1} + pk_{a_2} + pk_{a_3}$

○ -H, ● $-SO_3^-$, ◑ -COOH, ◐ -OH, ⊙ $-AsO(OH)_2$

with the other metal chelate systems.

It should be noted that the formation constants of *o*-sulfophenylazochromotropic acid chelates are larger than those of phenylazochromotropic acid chelates except the magnesium chelate. It seems that the sulfonic group takes part in the chelate coordination. Particularly, its stability for barium chelate is much higher than that for *m*-, *p*-sulfophenyl- and phenylazochromotropic acid chelates. This result suggests that the sulfonic group at the ortho position has a strong coordination ability to barium ion. The order of decreasing stability of the metal chelates of phenyl-, *o*-phenol- and *o*-arsonophenylazochromotropic acid, magnesium> calcium> strontium> barium, agrees with the orders already reported for a large number of other ligands. However, in *o*-carboxyphenylazochromotropic acid chelate, the orders of decreasing stability is magnesium> calcium> strontium= barium and furthermore in *o*-sulfophenylazochromotropic acid it is magnesium> calcium> barium> strontium.

The relation of the formation constants, log K, of the chelates of *o*-substituted phenylazochromotropic acids to the reciprocal of the effective

radii, $1/r$, for alkaline earth metal ions, which were calculated by Latimer,[7] is given in Fig. 8. Latimer suggests that these effective radii give a good estimate of ionic size in solution. Figure 8 shows two different trends on the chelates of the ligands investigated. The one is a straight line shown by a solid line on which lie chelates of phenyl-, *o*-phenol- and *o*-arsonophenylazochromotropic acid, but the log K values of the calcium chelates show a larger deviation from that line. The other includes *o*-sulfophenyl- and *o*-carboxyphenylazochromotropic acid, for which another linear relationship is observed from strontium to magnesium as shown by a dotted line, but the log K values of the barium chelates are equal to or larger than that of the strontium chelates.

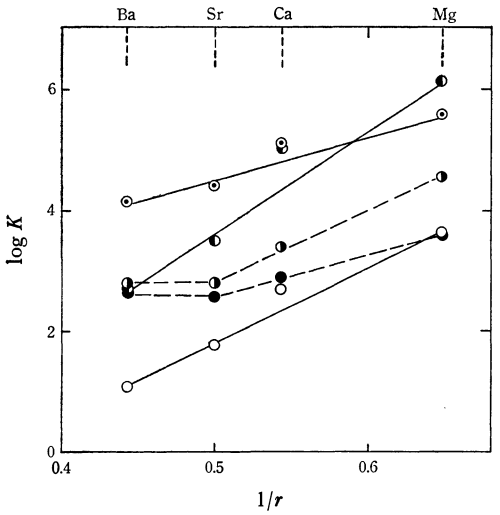

Fig. 8. Correlation of log K for *o*-substituted phenylazochromotropic acid chelates against $1/r$ of metal ions.

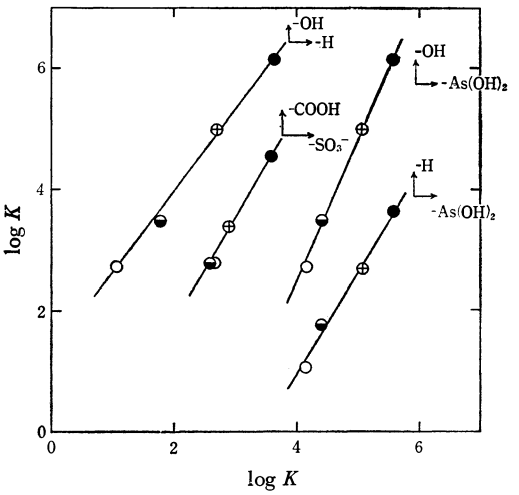

Fig. 9. Relation between log K's for pairs of ligands.
●: Mg, ⊕: Ca, ◒: Sr, ○: Ba

The plot of the log K value of one reagent against that of another reagent is given in Fig. 9. A good linear relationship is obtained among phenyl-, *o*-phenol- and *o*-arsonophenylazochromotropic acid chelate systems and between *o*-carboxyphenyl- and *o*-sulfophenylazochromotropic acid chelate systems.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2637—2640 (1968)

Mass Spectrometry of Organometallics. I. Titanium Cyclopentadienyl Complexes*[1]

Yoshinobu TAKEGAMI, Toru UENO, Toshimitsu SUZUKI and Yuichi FUCHIZAKI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received April 23, 1968)

The possibility of mass spectral analysis of less volatile and air sensitive organometallic compunds has been studied with an electron-impact, Muttauch-type mass spectrograph. Several organotitanium compounds, $(C_5H_5)_2Ti$, $(C_5H_5)_2Ti$-methylacetylene complex, $(C_5H_5)_2Ti$-allylchloride and $(C_5H_5)_2TiCl_2$-$AlEt_2Cl$ complex, have been subjected to mass spectral analysis, and the parent ion has been detected for each compound. The $(C_5H_5)_2Ti$-methylacetylene complex gave a parent ion of $(C_5H_5)_2Ti(C_3H_4)_2^+$; NMR and IR suggested the structure as a five-membered cyclic diene complex of $(C_5H_5)_2Ti$. The $(C_5H_5)_2Ti$-allylchloride gave a parent ion of $(C_5H_5)_2Ti(C_3H_5)^+$ which proves the existence of allyl complex of $(C_5H_5)_2Ti$. The $(C_5H_5)_2TiCl_2$-$AlEt_2Cl$ complex gave a parent ion of $(C_5H_5)_2TiCl_2AlEtCl^+$ which is in agreement with the composition reported in the literature.

There has been considerable interest in mass spectra of organometallics of transition metals in recent years. It has been felt that the mass spectral study should shed direct light on the composition of the organometallic catalysts. Although a variety of the organo transition metal compounds have been subjected to mass spectral analysis, these compounds, in most cases, are either stable to air and moisture or sufficiently volatile to use the conventional reservior inlet system. Relatively few studies on the mass spectral analysis of organometallic compounds which are less volatile and sensitive to air and moisture have been reported in the literature. The work described in this report resulted from our interest in learning whether less volatile, air sensitive organotitanium compounds would be detected by a mass spectrograph.

Experimental

The mass spectra were determined with a Japan Electron Optics Lab. double-focusing mass spectrograph (JMS-01SG). Since the compounds were not sufficiently volatile to use the conventional reservior inlet system, samples were introduced directly into the ion source from a glass tube. In the cases of the compounds which were sensitive to air and moistrue, all operations were carried out under argon or nitrogen atmosphere and samples were introduced as dilute solutions. The solvents were removed in the pre-evacuation chamber of the direct sample inlet system. Ions were formed by the electron bombardment with 75 V electrons and were accelerated at 6000 V. Ions were detected by the Ilford Q2 photographic plate. Perfluorokerosene was used as an internal reference.

Bis(cyclopentadienyl)titaniumdichloride was obtained from Arapahoe Chem. Co. and used without further purification. Bis(cyclopentadienyl)titanium was prepared by the reduction of bis(cyclopentadienyl)titaniumdichloride with sodium amalgam according to the direction of Shikata.[1)]

A 10 m*l* portion of benzene solution (0.075 mol/*l*) of bis(cyclopentadienyl)titanium was stirred under methylacetylene atmosphere at 50°C for 2 hr. The solution turned immediately from green to reddish one. The excess methylacetylene was removed under reduced pressure and the complex was subjected to IR, NMR and mass spectral analysis.

Bis(cyclopentadienyl)titanium solution was also treated with allylchloride in the molar ratio of 1 : 2; the color of the solution turned from green to red. The reaction mixture was subjected to mass spectral analysis.

Bis(cyclopentadienyl)titanium dichloride-diethylaluminumchloride complex was obtained by the reaction of these two reagents at 50°C in the Al/Ti ratio of 4. The solvent (*n*-heptane) was removed under reduced pressure (4 mmHg) at 20°C and the complex was subjected to mass spectral analysis.

Results and Discussion

Bis(cyclopentadienyl)titaniumdichloride. Inasmuch as the usual organotitanium compounds are very sensitive to air and moisture, initial experiments were carried out with the air stable bis(cyclopentadienyl)titaniumdichloride to see the possibility of accurate mass determination. As may be seen in Table 1, nine lines were observed at *m/e* 246—254, the region of which corresponds to the molecular ion of bis(cyclopentadienyl)-titaniumdichloride. Since titanium, chlorine and carbon atoms have five, two and two appreciable isotopes respectively, forty masses might be written in combination with these isotopes. It is impossible, however, to distinguish the masses which

*1 This report was presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

* RI: relative intensity, judged by the degree of blackening of the photographic plate.
** RA: relative abundance, calculated from the natural abundance of isotopes.

belong to the same *m/e* value, *e.g.* $^{48}Ti^{35}Cl_2C_{10}H_{10}$ (247.964 m. u.), $^{47}Ti^{35}Cl_2{}^{13}CC_9H_{10}$ (247.971 m.u.), $^{46}Ti^{35}Cl^{37}ClC_{10}H_{10}$ (247.966 m.u.), *etc.* Among these, only the principal masses with their assignments for isotopes are listed in Table 1. From the agreement between the experimental data and the calculated ones, the nine lines can be reasonably assigned to the molecular ion of bis(cyclopentadienyl)titaniumdichloride. The limit of error in determining of these masses can be drawn within 0.009 m.u. In the present work, ions were detected only by the photographic plate and no attempt was made to achieve quantitative fragmentation patterns (pattern coefficients); the object instead was to determine accurate masses of the parent ions.

Bis(cyclopentadienyl)titanium and Its Complexes. The mass spectra of cyclopentadienyl complexes of several transition metals have been reported.[2] The mass spectral data on bis(cyclopentadienyl)titanium, however, has not been reported, whereas it has been well known that bis(cyclopentadienyl)titanium can be prepared by sodium amalgam reduction of bis(cyclopentadienyl)-titaniumdichloride[1] or by the decomposition of bis(cyclopentadienyl)dimethyltitanium with hydrogen.[3] Difficulty in introducing the bis(cyclopentadienyl)titanium into a mass spectrograph because of its sensitivity to air and moisture appears to be responsible, in part, for the paucity of data on bis(cyclopentadienyl)titanium. Then, in this work, a dilute solution of bis(cyclopentadienyl)titanium was handled under nitrogen atmosphere. Solvent was removed in the pre-evacuation chamber of the direct sample inlet system and the bis(cyclopentadienyl)titanium was introduced directly into the ion source. Table 2 represents the mass spectrum of bis(cyclopentadienyl)titanium thus analyzed. The molecular ion was detected concerning to five isotopes of titanium. Various

fragment ions were also detected. The assignments of these ions are somewhat uncertain, however, by the fact that the isotope lines which belong to the same *m/e*, *e. g.* $^{48}TiC_6H_6^+$ and $^{49}TiC_6H_5^+$, *etc.* could not be distinguished, since the spectrum was determined at resolution of 12000. The assignment was done by the qualitative relative intensities. Under these conditions, the accuracy of determination somewhat diminished because of broadening of the lines; a probable limit of error can be taken as 0.012 m.u.

Ions which could be taken as support for the existence of bis(cyclopentadienyl)titanium dimer have never been detected; bis(cyclopentadienyl)-titanium appears to vaporize as a monomer. On the other hand, several oxygen-containing ions which might come from the reaction of bis(cyclopentadienyl)titanium with air and moisture were detected at *m/e* of 129, 130, 194, 195 and 372. From these ions, it appears to be reasonable to conclude that oxygen-containing compounds such as $(C_5H_5)_2$-TiO, $(C_5H_5)_2TiOH$ and $(C_5H_5)_4Ti_2O$ existed in the sample; it is noteworthy that oxygen-containing bis(cyclopentadienyl)titanium dimer exists in the vapor phase.

When the benzene solution of bis(cyclopentadienyl)titanium was treated with methylacetylene at 50°C, the color of the solution turned green to reddish. Mass spectral analysis of this solution gave a line at 258.092 m.u., which can be assigned to $(C_5H_5)_2Ti(C_3H_4)_2^+$ (258.089 m.u.). Infrared spectra of bis(cyclopentadienyl)titanium and its methylacetylene complex are shown in Fig. 1. The complex exhibited absorption bands at 1580 and 1410 cm^{-1} which are characteristic of a conjugated diene system, and did not exhibit any absorption bands at 2100—2260 cm^{-1} which corresponds to a carbon-carbon triple bond. It can, therefore, be concluded that the two molecules of methylacetylene bond to bis(cyclopentadienyl)-titanium as a conjugated diene. The 60 Mc NMR spectrum of the complex exhibited rather broad signals at δ(benzene)=335 cps and δ(benzene)=354 cps.

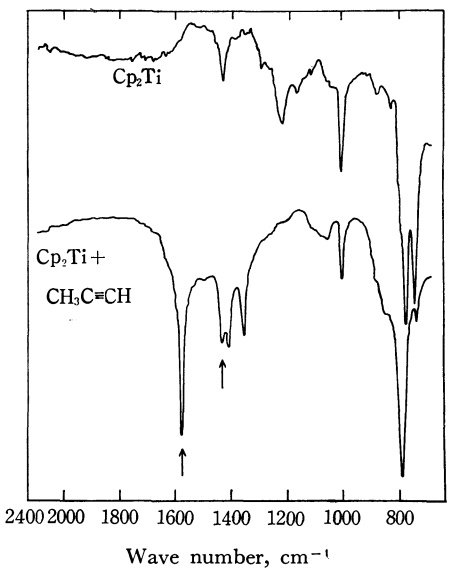

Fig. 1. Infrared spectra of $(C_5H_5)_2Ti$ and $(C_5H_5)_2Ti$-methylacetylene complex.

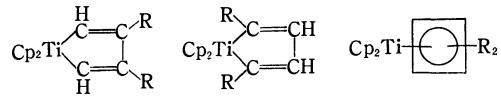
Vol'pin and his co-workers[4] studied the complex of bis(cyclopentadienyl)titanium with phenylacetylene and assumed the structures of I and II. Sonogashira and Hagihara[5] also investigated this complex by means of NMR, IR and electronic absorption spectra and supported the structure I.



Ia Ib II

The present work supports the structure I and NMR (60 Mc) signals at δ(benzene)=335 cps and δ(benzene)=354 cps can be assigned to the methyl groups of Ia and Ib. The fact that $C_6H_8^+$ which is expected from structure II was not detected in the mass spectrum may support the structure I rather than the structure II.

In connection with the cyclic diene complex, a reaction mixture of bis(cyclopentadienyl)titanium with allylchloride was subjected to mass spectral analysis to see the possibility of the formation of allyl complex of bis(cyclopentadienyl)titanium. The results are presented in Table 3. As may be seen in Table 3, the predominant product of the reaction was bis(cyclopentadienyl)titaniumdichloride. A line was, however, observed at 219.062 m.u. which can be taken as a support of the formation of allyl complex of bis(cyclopentadienyl)titanium. Besides the titanium-containing ions, $C_6H_{10}^+$ was also observed.

detail by Natta and Mazzanti,[6] the mass spectral data on this complex has never been reported. Then, the mass spectral analysis was carried out in the same manner as described for bis(cyclopentadienyl)titanium. The lines observed in the highest mass region was *m/e* 339—342, which are shown in Fig. 2. These ions can be assigned to $(C_5H_5)_2TiCl_2$-$AlEtCl^+$ and its isotopic ions, as may be seen in the first four entries of Table 4. Besides $(C_5H_5)_2TiCl_2$-$AlEtCl^+$, a weak line was observed at 333.019m.u.

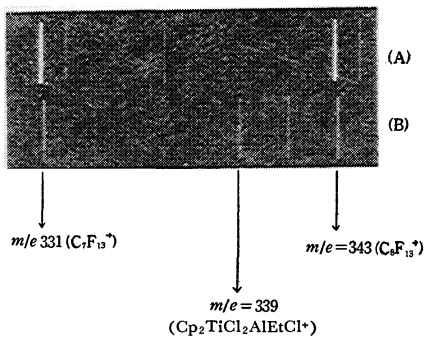

Fig. 2. Partial spectrum of $(C_5H_5)_2TiCl_2AlEtCl^+$.

6) G. Natta and G. Mazzanti, *Tetrahedron*, **8**, 86 (1960).

which corresponds to $(C_5H_5)_2TiCl_2AlEt_2^+$. This is not, however, conclusive in establishing proof for the existence of the complex in the form of $(C_5H_5)_2TiCl_2AlEt_2$, because diethylaluminumchloride unfortunately gives a line at 333.021 m.u.*2 Although it is not clear whether the line at 333.019 m.u. is due to the existence of $(C_5H_5)_2TiCl_2AlEt_2^+$ or whether the diethyaluminumchloride also plays a part, it is more likely that the complex is predominantly in the form of $(C_5H_5)_2TiCl_2AlEtCl$, because the line at *m/e* 339 is much more intense than that at *m/e* 333 as may be seen in Fig. 2. This composition of the complex agrees with that reported by Natta and Mazzanti.[6] Fragment ions of the complex are also included in Table 4. The only observable fragment ions are $(C_5H_5)_2$-$TiCl_2AlCl^+$ and $(C_5H_5)_2TiCl_2AlEt^+$, which correspond to (P-Et) and (P-Cl), respectively.*3 Absence of other fragment ions which contain both titanium and aluminum appears to suggest the weakness of chlorine-bridged titanium-aluminum cluster.

*2 Diethylaluminumchloride gives a variety of oxygen-containing ions at *m/e* 150—400; Preprints for the 21st Annual Meeting of the Chemical Society of Japan (Osaka, 1968), III, p. 1959.

*3 $(C_5H_5)_2TiEt^+$ and $TiEt^+$ would not be the fragment ions of the complex but come from an ethyltitanium compound produced presumably by the exchange reaction between $(C_5H_5)_2TiCl_2$ and $AlEt_2Cl$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2641—2645 (1968)

Synthesis of Sulfosodalite, an Ultramarine-Relating Phase

Goro YAMAGUCHI and Yasushi KUBO*1

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received April 25, 1968)

A sulfur-containing sodalite-type aluminosilicate, $6NaAlSiO_4 \cdot Na_2S$ (designated sulfosodalite in this paper), was synthesized in the system $NaAlSiO_4$-Na_2S at temperatures 850 to 950°C in an H_2 or N_2 atmosphere. All of the sulfur in this substance was contained as sulfide ion S^{2-}, and its equilibrium content in a unit cell increases with temperature from 1.5 S at 850°C to 1.8 S at 950°C. This substance was only pale colored, yellowish or pinkish, but the partial substitution of Si for Al produced a deep vermilion red color.

By heating the system $NaAlSiO_4$-Na_2S in an H_2 or N_2 atmosphere at temperatures 850 to 950°C, a sulfur-containing aluminosilicate phase of sodalite-type was obtained. This phase was found to contain sulfur only in the form of monosulfidic sulfur ion S^{2-}, and thus gave an X-ray diffraction pattern closely resembling that of sodalite, $6NaAlSiO_4 \cdot 2NaCl$. Differing from ultramarine, which contains disulfidic sulfur ion,[1] this substance is only very lightly colored, yellowish or pinkish.

Kirk has already synthesized a sodalite solid-solution of the composition $6NaAlSiO_4 \cdot xNaCl \cdot yNa_2S$ in his study of the luminescence of sodalite.[2,3] The phase synthesized in the present study corresponds to the Na_2S-end member, and thus the name of sulfosodalite may be given. The essential difference between this substance and sodalite, however, is that its composition is not constant as with sodalite but varies considerably with synthetic conditions; also this phase contains usually more than eight Na ions. The synthetic conditions and the composition will be reported in this papaer.

Experimental

Starting Materials. The starting material $NaAlSiO_4$ was prepared by heating a mixture of kaolinite and Na_2CO_3 at about 700°C. The actual composition of this material was $Na_{0.98}Al_{0.98}Si_{1.02}O_4$ because of the composition of the kaolinite employed as raw material. To examine the effect of substitution of Si for Al, SiO_2 (Merck's silica gel for chromatographic use, ignition loss 3.68%) was added to the kaolinite - Na_2CO_3 mixture and the same heat-treatment made. The starting materials $Na_uAl_uSi_{2-u}O_4$ (u=0.90, 0.80 and 0.66) were thus prepared.

The starting mixtures $NaAlSiO_4 + aNa_2S$ (a=0.50, 0.75, 1.00, 1.25 and 1.50) and $Na_uAl_uSi_{2-u}O_4 +$ Na_2S were made with sufficient caution against the oxidation of Na_2S.

Details on these raw materials and on the mixing method are described in another paper.[1]

Apparatus. A silica glass tube set perpendicularly in a cylindrical electric furnace was used as the heating apparatus. H_2 or N_2 gas, which was purified by passage through active copper and water absorbent, was passed through this pipe. The starting mixture, which was put in a silica crucible, was hung from a molybdenum wire into the heating zone kept at the predetermined temperatures between 850 and 950°C. After heating for 1 hr, the crucible was removed rapidly to a cool zone for quenching.

Method of Analysis. *a) Treatment of the Synthesized Specimen.* The synthesized specimen was fully washed with water until no alkali was detected by phenolphthalein indicator, and was dried at 110°C. Then carbon disulfide extraction was carried out to completely remove any free sulfur which condensed on the specimen.

b) Chemical Analysis. The specimen was decomposed by dilute sulfuric acid and the analyses of SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO and alkalis were carried out following the usual procedure of silicate analysis. Fe_2O_3 was determined colorimetrically using sulfosalicylic acid. CaO+MgO, the total content of which was about 1%, was removed on the way and was not determined. The alkalis were determined as residual sulfates where the ratio of K_2SO_4/Na_2SO_4 was determined to be less than 0.005 by flame photometry. The alkali content can also be determined indirectly by the charge balance to the ionic sulfur content. Since the former residual sulfate method always gave a lower result, the latter more reliable method was actually adopted.

Total sulfur content was determined through $BaSO_4$ precipitation. In this case, the specimen was decomposed by a Br_2+HCl solution.

For the analysis of ionic sulfur, the specimen was suspended in a solution of $AgNO_3$ and decomposed with dilute sulfuric acid. To decompose the specimen completely, warming in a hot-water bath was necessary. After the Ag_2S precipitate formed was filtered off, the residual $AgNO_3$ was back-titrated with a KCNS solution.

c) Determination of the Sodalite-type Phase Content. Usually the complete formation of the sodalite-type phase

TABLE 1. DETERMINATION OF THE COMPOSITION OF SODALITE-TYPE PHASE

Sample	Phase content, %	SiO_2	Al_2O_3	Fe_2O_3	Ionic S	Non-ionic S	Na
		37.6	30.4	0.4	4.88	0.26	19.5
H-F	Neph. 6	2.6	2.1		—	—	1.0
	Sod. 94	35.0	28.7		4.88	0.26	18.5

was not achieved and unreacted nepheline phase coexisted in the specimen. Quantitative analyses of both phases were made by powder X-ray diffraction. As internal standard, 1 part (by weight) of MgO powder was added to 2 parts of the specimen. The diffraction intensity of the peak (20·2) of nepheline at $2\theta=29°38'$ (Cu$K\alpha$), I_N, that of the peak (211) of the sodalite-type phase at $2\theta=$about 24°, I_S, and that of the peak (220) of magnesia at $2\theta=62°18.5'$, I_{MgO}, was measured using a diffractometer. A calibration curve between the nepheline content in the mixture and the value I_N/I_{MgO} was made. Another calibration curve between the sodalite-type phase content and the value I_S/I_{MgO} was also made. Strictly speaking, however, the diffraction intensity of the sodalite-type phase may vary in every specimen differeing in composition. Therefore, the calibration was made using the former calibration curve for the nepheline content as far as possible. Thus the sodalite-type phase content was determined from 100(%)−Nepheline(%). In the specimens where SiO_2 was added, an amorphous phase coexisted in addition to nepheline. In this case, calibration had to be made based on the latter calibration curve.

d) Determination of the Composition of Sodalite-type Phase. Components present due to unreacted nepheline were calculated using the nepheline content determined from X-ray diffraction analysis. Then, these values were subtracted from those obtained from the total chemical analysis and the rest was considered to be in the sodalite-type phase. Impurities such as Fe_2O_3, CaO and MgO were neglected.

e) An Example. An Example of this analytical procedure is given for one of the specimens. The results obtained from the total chemical analysis are given in the first line of Table 1. From an X-ray diffraction analysis, the coexisting nepheline and sodalite-type phase components of this specimen were determined as 6% and 94%, respectively. The components due to coexisting nepheline, as given in the second line, were subtracted from values obtained from the total chemical analysis given in the first line, and components in the sodalite-type phase were obtained as given in the third line. The chemical formula for a unit cell of the sodalite-type phase is calculated from this result as $Na_{8.43}Al_{5.89}Si_{6.11}O_{24}\cdot 1.60\,S^{2-}\cdot 0.08\,S$ (the Na ion content required from charge balance with the S^{2-} ion content is 9.08.).

Results and Discussion

Product Composition. The molar compositions which were determined, based on an analysis of total components are shown in Table 2 for several specimens. The values for a unit cell of sodalite-type structure are given. The analytical data for all specimens which were synthesized under conditions given in columns 2 to 4 of Table 3, are shown in columns 5 to 8 of the same table; Al number in the product, sodalite-type phase content and total and ionic sulfur contents are given.

Now, the average valences of sulfur ions (defined as 2×Ionic S/Total S) were calculated as given in column 9 of Table 3, and were also plotted in Fig. 1.

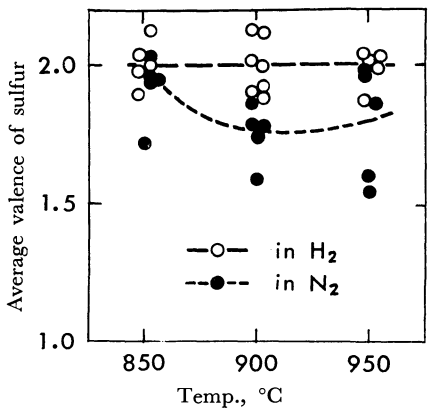

Fig. 1. Average valence of sulfur for specimens synthesized in H_2 and N_2 atmospheres.

As seen in Fig. 1, the average valence of sulfur ions for specimens synthesized in an H_2 atmosphere is equal to 2 within an error of ±5%, while that for specimens synthesized in an N_2 atmosphere ranges from 1.8 to 2. Thus, the former specimens which completely form sulfide may be expressed by the formula $6NaAlSiO_4\cdot xNa_2S$, while the latter, containing some polysulfidic ions, may be expressed by the formula $6NaAlSiO_4\cdot xNa_2S\cdot yS$. When variation in the Si/Al ratio or Al number is taken into consideration, the general formula is given by $6Na_uAl_uSi_{2-u}O_4\cdot xNa_2S\cdot yS$ for a unit cell of a sodalite-type structure.

Based on the general formula, the numbers of ionic sulfurs and non-ionic sulfurs per unit cell (x and y, respectively) were calculated using analytical data on the Al number in the product, u_P, and the total and ionic sulfur contents given in Table 3. The results are shown in columns 10 and 11 of the same table, respectively. When comparison is made between the values (x and y) of Tables 2 and 3, those of Table 2, which were calculated based on an analysis of total components, are in good agreement with those of Table 3, which were calculated based on only the total and ionic sulfur contents according to the general formula. This justifies the general formula, and

TABLE 2. MOLAR COMPOSITION OF SULFOSODALITE FOR A UNIT CELL

the values x and y can be used as characteristic values of the specimen.

Relationships between Synthetic Conditions and Product Composition. Figure 2 shows the variation in the number of ionic sulfurs (or total sulfurs) per unit cell (x), with the amount of Na_2S mixed in the reaction system (a) for specimens synthesized in an H_2 atmosphere at 900°C. The value x increases with increase in a for a less than 1.0, and reaches a constant value for a greater than 1.0. This indicates that the system has not reached equilibrium in a reaction time of 1 hr, until the amount of Na_2S mixed in the reaction system, a, was increased to greater than 1.0 which corresponds to about three times the Na_2S content of the product phase. A similar tendency was observed in specimens synthesized at other temperatures.

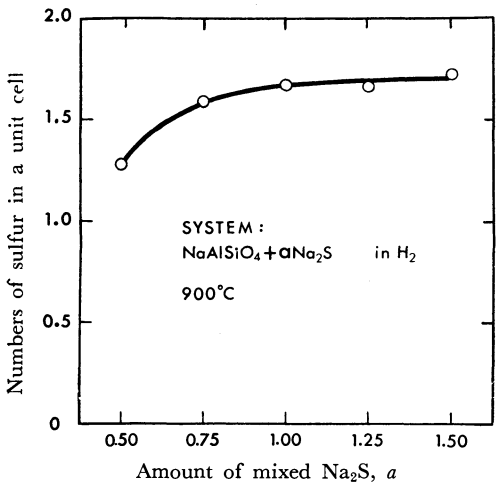

Fig. 2. Variation of sulfur content expressed by numbers in a unit cell with the amount of Na_2S mixed in the reaction system.

Figure 3 shows the change in the value x for a equal to 1.0 with reaction temperature. The value x increases with temperature; the higher the temperature, the more sulfur ions are pressed into

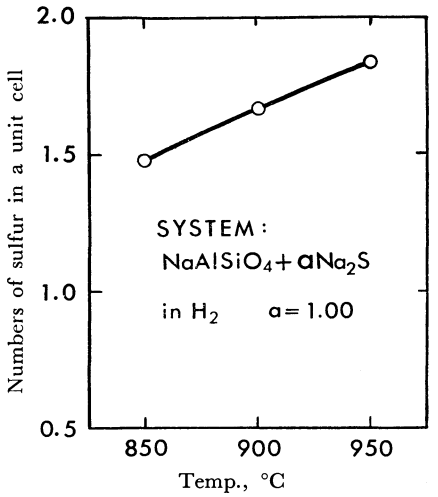

Fig. 3. Variation of sulfur content expressed by numbers in a unit cell with reaction temperature.

the sodalite-type structure. This means that the increase in chemical potential of the Na_2S component with temperature is larger in the Na_2S phase than in the sodalite-type phase.

For specimens synthesized in an N_2 atmosphere, the composition is similar to that of specimens synthesized in an H_2 atmosphere, but the data do not show a constant tendency. Some oxidation of sulfur ion has occurred, giving rise to a small amount of non-ionic sulfur. This may be due to an error caused by residual O_2 in the N_2 gas stream.

Effect of Si Substitution for Al. It must be noted that in this experiment only a small portion of the added SiO_2 has been taken up in the product phase. As shown in columns 4 and 5 of Table 3, the Al number in the reaction system (u_R) and that in the product (u_P) differ considerably; 0.90 *vs.* 0.97, 0.80 *vs.* 0.92 and 0.66 *vs.* 0.76, respectively. Thus, the substitution of Si for Al has taken place only to a small extent compared with the amount of SiO_2 added to the reaction system. This may

be due to the method of preparation of the starting material, and more well-prepared starting material would result in a more complete substitution of Si for Al.

With increase in the Si substitution for Al, an amorphous phase as a coexisting phase in the specimen increased. This increases the error in the determination of the sodalite-type phase content by X-ray diffraction, since the detarmination is based on only the diffraction peak of the sodalite-type phase. Therefore, a detailed discussion can not be made only these data. As a general tendency, the sulfur content increased or did not change up to an Si fraction, Si/(Si+Al), of 0.52 (u_P of 0.97), and decreased with further increase in the Si fraction. However, it is not clear whether equilibrium had been reached in this system.

It is a noteworthy fact that, as the Si fraction increases, specimens synthesized in both H_2 and N_2 atmospheres turned vermilion red. This color faded gradually upon washing with water for a long time.

Crystal Structure. As regards the ionic valence of the anion which is contained in the sodalite-type aluminosilicic framework, the present substance is similar to noselite which contains SO_4^{2-} ion. Since the number of anions per unit cell of noselite ($Na_8Al_6Si_6O_{24}SO_4$) is half that of sodalite ($Na_8Al_6Si_6O_{24}Cl_2$), the crystal structures are not completely homo-structural.[4] In the X-ray diffraction pattern of noselite, diffractions with $h+k+l=$odd appeare, while in that of sodalite the diffractions vanish due to the extinction rule.

The present substance usually contains more than one but less than two S^{2-} ions per unit cell, and the diffraction pattern is identical with that of sodalite. It is noteworthy that the same characteristics of the diffraction pattern are maintained even in specimens which contain almost one or less than one S^{2-} ion per unit cell, though a noselite-like structure is expected in this case. This means that the anion vacancy distributes at random on the anion sites in the structure. The ionic radius of S^{2-} ion being smaller than that of SO_4^{2-} may account for the difference in the structure. Based on the characteristics of its diffraction pattern, the present substance may be named sulfosodalite.

It is a well-known fact that ultramarine abounds in varieties which have various sulfur contents and various colors. Sulfosodalite may perhaps be a phase corresponding to an end-member of a variety of ultramarine.

Ultramarines Synthesized under Controlled Sulfur Vapor Pressures

Goro YAMAGUCHI and Yasushi KUBO*1

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo

(Received April 25, 1968)

Ultramarine was synthesized in the systems $NaAlSiO_4$-Na_2S and $NaAlSiO_4 \cdot aNa_2O$-Carbon under a sulfur vapor pressure controlled between 0 and 1 atm. The average valence of sulfur contained in ultramarine changed from 2.0 to 1.0 with increase in sulfur vapor pressure. This was due to the formation of a sulfide containing monosufidic sulfur ion at 0 atm and of a polysulfide containing disulfidic ion at elevated sulfur vapor pressures. Sigmoidal characteristics were observed in the relationships between the sulfur content of ultramarine and the sulfur vapor pressure.

It is well known that ultramarine, a blue sodium aluminosilicate containing sulfur, is a non-stoichiometric compound with its composition varying to a large extent in ionic and non-ionic sulfur contents and in sodium content, as well as in alumina-silica ratio. The various chemical and physical properties of ultramarine as revealed by previous investigators[1-3] are related to its non-stoichiometric characteristics. However, the most fundamental problem, by what factor and in what range the composition of ultramarine is varied, has not yet been elucidated. The greatest reason for this is that the composition of ultramarine is so complicated that the preparation of well-characterized specimens under well-controlled conditions is

quite difficult. The circumstances may be common to almost all sulfide minerals, the study of which has progressed much less.

It may help to understand this situation to overlook the manufacturing process of ultramarine. In principle, the manufacture of ultramarine consists of heating a mixture of kaolin or alumino-silicic gel, sulfur or sodium sulfate and carbonaceous reducing agents to about 800°C in the absence of air. A yellow-green mass containing pale-colored ultramarine is thereby obtained, and successive reheating in air causes a deepening of the blue color; finally a dark blue product is obtained. Soluble sodium salts are then leached out, leaving blue ultramarine. It must be stressed here that, though a product excellent for practical use can be thus obtained, the meaning of these processes is not always understood. The system and the reactions are too complicated to permit a scientific approach.

In this study, an attempt was made to reduce the complicated synthetic conditions of ultramarine to its essential factors. Thus, synthesis was carried out by controlling the components necessary to produce ultramarine, $NaAlSiO_4$ and Na_2S, the sulfur vapor pressure and temperature. The relationships between the product composition and the synthetic conditions thus simplified, were investigated.

Experimental

Reaction Systems and Raw Materials. In order to strictly control reaction conditions in the production of ultramarine, as simple a reaction as possible is desired. The choice of reaction system, however, is conditioned by the reaction rate; too low a reaction rate makes synthesis practically impossible.

Through preliminary experiments, the following systems were found adoptable. In these systems, the ultramarine phase was formed in tolerable or high yields at the indicated temperatures in the reaction time of 1 hr.

(1) $NaAlSiO_4$ - Na_2S - S_2 (in an S_2+N_2 atmosphere) 950°C

(2) $NaAlSiO_4 \cdot a Na_2O$ ($a \geqq 0.5$) - C(carbon) - S_2 (in an S_2+N_2 atmosphere) 850°C

The oxides $NaAlSiO_4$ and $NaAlSiO_4 \cdot a Na_2O$ ($a=0.50$ and 0.75) were prepared by heating a mixture of Zettlitz kaolinite (chemical composition given in Table 1) and Na_2CO_3 reagent (E. P. grade) at about 700°C. The actual composition of these oxides were $Na_{0.98}Al_{0.98}Si_{1.02}O_4$ and so on, because of the composition of the original kaolinite. These oxides are composed mainly of high-carnegieite (L) phase,[4] and are favorable for use as starting material in respect to homogeneity and activity. As other raw materials, Na_2S reagent (E. P. grade), charcoal for carbon and sulfur reagent (G. R. grade) were used.

The mixtures $NaAlSiO_4+a Na_2S$ ($a=0.50$, 0.75 and 1.00) and $NaAlSiO_4 \cdot a Na_2O + aC$ ($a=0.50$ and 0.75) were prepared by mixing these raw materials with a motor-driven mortar. For the former mixture containing Na_2S, the mixing was done in liquid hexane to prevent Na_2S from being oxidized, and the mixture was heated at 550°C in an H_2 gas stream for 1 hr prior to use in order to reduce completely the partially oxidized Na_2S.

Apparatus. The vapor pressure of sulfur was controlled by making use of the temperature dependence of the vapor liquid equilibrium of sulfur. The main apparatus is shown in Fig. 1. This apparatus made of transparent silica glass, consists of two regions; the sulfur reservoir (lower part of the apparatus)and the reactor (upper part of the apparatus). Two electric furnaces were used to heat the two regions separately. The temperatures at the surface of the liquid sulfur and at the sample holder were detected with a three-forked Pt-PtRh

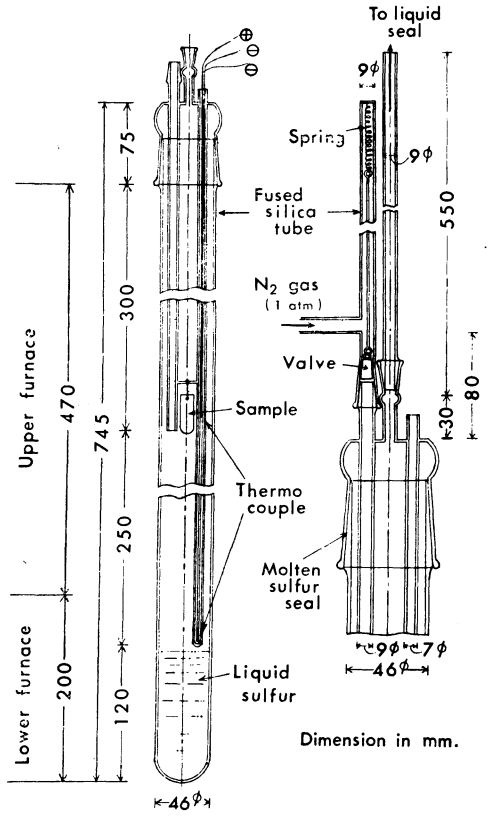

Fig. 1. Apparatus for synthesis under controlled sulfur vapor pressure.

4) Y. Kubo, G. Yamaguchi and K. Kasahara, *Mineral. J.*, **5**, 213 (1967).

thermocouple and were kept by a temperature controller at predetermined values between 380 and 440°C for the sulfur reservoir and between 850 and 950°C for the reactor.

At about 200mm above the ground glass joints, the temperature was held above the melting point of sulfur. Therefore, the condensation of sulfur took place in the perpendicular long thin tube connected to a gas outlet sealed with liquid paraffine. The condensed sulfur was melted away with a hand burner from time to time. The ground glass joints were sealed by molten sulfur.

The apparatus was also connected to an N_2 gas tank of a constant pressure of 1 atm through a valve, in order to remove the contained air before the experiment, as well as to prevent outside air from leaking in during a temporary fall in the inner gas pressure in such an instance as during the cooling process of the sample.

The temperature of the sulfur reservoir could be controlled by a derivative control within ±3°C, which corresponds to a variation in the sulfur vapor pressure of ±0.02 atm around 0.25 atm, and of ±0.04 atm around 0.75 atm. For data on the equilibrium vapor pressure of sulfur, those given by West[5] were used. Except for visual observation at the head of the apparatus, the actual sulfur vapor pressure at the sample holder was not measured. Therefore, agreement between this pressure and that at the surface of the liquid sulfur was not verified. However, since the temperature above the sulfur reservoir was so distributed as to increase towards the sample holder, the stagnation of the sulfur vapor in the lower part of the apparatus could not have occurred.

Experimental Procedures. The starting mixture was put in the sample holder and heated at temperatures of 850 to 950°C for 1 hr. Rapid cooling was carried out by opening the upper electric furnace. The specimen thus obtained was fully washed with water until no alkali was detected by phenolphthalein indicator, and was then dried at 110°C. The free sulfur condensed on the specimen was removed completely by carbon disulfide extraction.

Determination of product composition was made on the specimen by chemical and X-ray diffraction analyses. The methods were described in detail in a previous paper.[6]

Results and Discussion

Product Composition. Analytical data for the specimens which were synthesized under conditions given in columns 2 and 3 of Table 2, are given in columns 4 to 7 of the same table.

Figure 2 shows the variation in the average was valence of sulfur (in column 7) with sulfur vapor pressure, P_{S_2}. As can be seen in the figure, the average valence is 2.0 at no sulfur vapor pressure, and decreases toward 1.0 as the sulfur vapor pressure is increased. This indicates the change from sulfide to polysulfide, and the chemical composition can be expressed conventionally by the formula $6NaAlSiO_4 \cdot xNa_2S \cdot yS$ per unit cell. Based on this formula, the numbers of ionic sulfur, non-ionic sulfur and total sulfur per unit cell, x, y and $x+y$, respectively, were calculated in columns 8 to 10 of Table 2.

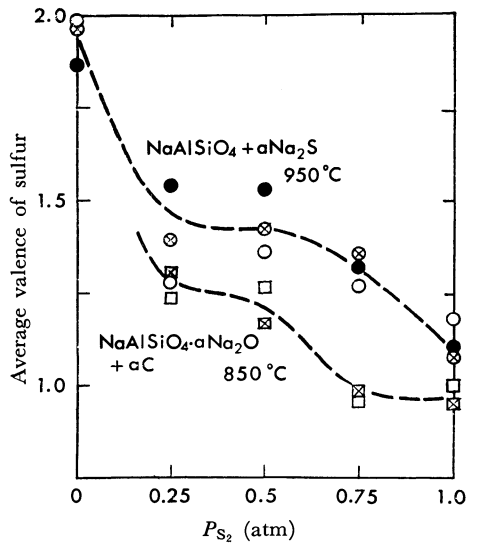

Fig. 2. Variation of average valence of sulfur with sulfur vapor pressure in atmosphere.

Relationships between Synthetic Condition and Product Composition. These values, x, y and $x+y$, change not only with sulfur vapor pressure, P_{S_2}, but also with the amount of Na_2S mixed in the reaction system, a. Changes with the former factor, P_{S_2}, are shown in Figs. 3 and 4; Fig. 3 for the system $NaAlSiO_4+aNa_2S$ at 950°C and Fig. 4 for the system $NaAlSiO_4 \cdot aNa_2O+aC$ at

850°C, respectively. Sigmoidal changes are characteristic of these curves.

Changes with the latter factor, a, are shown in Figs. 5, 6 and 7 for the system $NaAlSiO_4+aNa_2S$ at 950°C. The amount of Na_2S taken up in the product phase correspodns to a value of a of about 0.3. The fact that the product composition expressed by these values varies with the amount of excess Na_2S in the reaction system, indicates that the system has not yet attained equilibrium in a reaction time of 1 hr in the range of a less than 1.0. An increased amount of Na_2S in the reaction system would result in the approach of these values to constant values at equilibrium, as was observed in the sulfosodalite synthesis of the previous paper.[6] However, the tendency of the values at equilibrium can be seen by extrapolating the curves of Figs. 5 to 7; the value x which changes greatly with a, appears to decrease with P_{S_2} at the larger value of a, while the other values, y and $x+y$, increase. The sigmoidal characteristics at equilibrium are strongly seen in Figs. 6 and 7. It is reasonable to conclude that the plateau in the sigmoidal curve corresponds to a stable composition.

Sulfur Ion Species. Now, the sulfur ion species which exist in these specimens and which give the above sulfur composition expressed

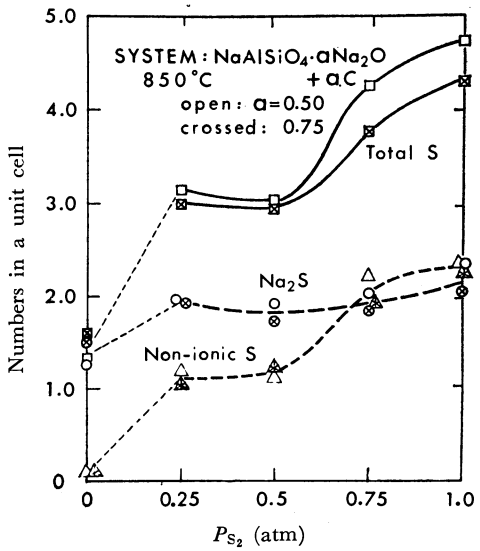

Fig. 4. Variation of numbers of total S, Na_2S, and non-ionic S in a unit cell with sulfur vapor pressure, for specimens synthesized in the system $NaAlSiO_4 \cdot aNa_2O + aC$ in (S_2, N_2) atmosphere at 850°C.

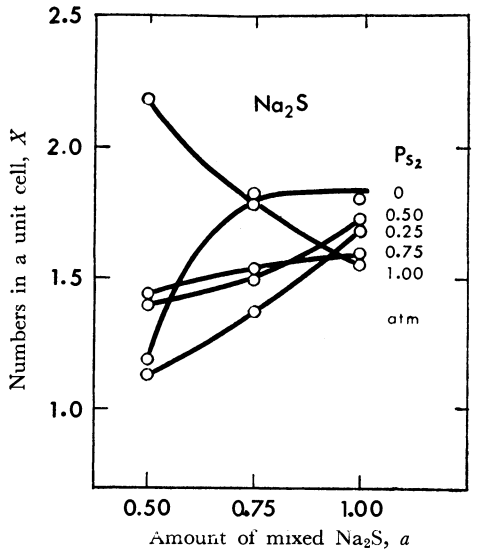

Fig. 5. Variation of numbers of Na_2S in a unit cell with the amount of Na_2S mixed in the reaction system.

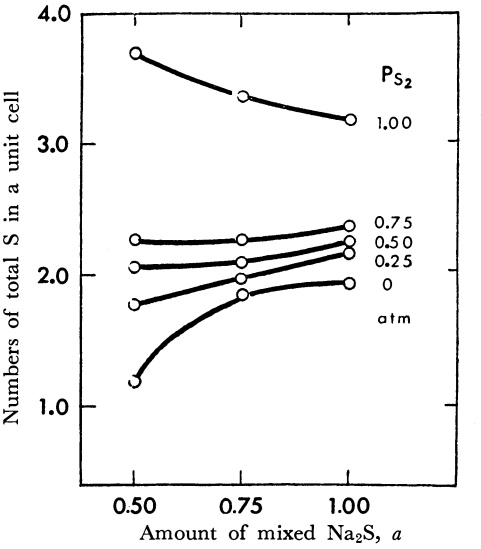

Fig. 7. Variation of numbers of total S in a unit cell with the amount of Na_2S mixed in the reaction system.

conventionally by the numbers of ionic and non-ionic sulfurs (x and y, respectively) should be considered. Here, a criterion is supposed that both the negative charges and the sulfur atoms should distribute as equally as possible on both anion sites (position notation, 2a) in the unit cell of a sodalite-type structure. This supposition is quite reasonable, since it makes anion vacancies as few as possible, as well as to make structural distortion caused by the coexistence of anions with largely different sizes as small as possible. The result of this criterion is that S^{2-} and S_2^{2-} ions coexist in most of the specimens synthesized here. In the results, this model is the same as that supposed by Podschus, Hofmann and Leschewski in their X-ray structure analysis of ultramerine.[7] Thus, the ionic constitutuion at the above-mentioned plateau is given by about $1.2S^{2-}$ $0.6S_2^{2-}$ 0.2 vacancies per unit cell.

7) E. Podshus, U. Hofmann and K. Leschewski, *Z. anorg. u. allgem. Chem.*, **228**, 305 (1936).

Some specimens, however, such as M, V, X and Y, which have either ionic sulfurs or non-ionic sulfurs, or both, more than 2 per unit cell, can not be explained by this model of ionic constitution. The formation of other sulfur ion species must be considered for these specimens. A more detailed discussion on this problem can not be made at present.

Color. In the specimen under no sulfur vapor pressure (namely sulfosodalite), the color is a very pale yellowish or pinkish. With increase in the sulfur vapor pressure, the specimens become more and more blue. This blue is particularly deep in specimens such as N, O, V, W, X and Y, the average valence of sulfur of which is near to or less than 1.0. The color, however, is much more pale than the usual ultramarine deep blue used as pigment. The heat treatment of these specimens in a SO_2 atmosphere at around 350 to 450°C caused a deepening of the blue color, with a great lowering of the average valence of sulfur. Therefore, the specimen in the present experiment is ultramarine of the leuco-form with sulfurs of a high reduction degree.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2650—2656 (1968)

Studies of the Behavior of Trivalent Uranium in an Aqueous Solution. II. Absorption Spectra and Ion Exchange Behavior in Various Acid Solutions

Akiko SATÔ and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received April 26, 1968)

The absorption spectra of trivalent uranium in hydrochloric, sulfuric and perchloric acid solutions were investigated. It was found that there is a possibility of the formation of a chloro-complex from the fact that a large change in absorption spectra was observed at high concentrations of chloride ion. On the basis of the above facts, the behavior of trivalent uranium in those media toward ion exchange resin was studied. It was considered that an anionic complex of trivalent uranium begins to form at concentrations of hydrochloric acid above 7 N, which shows good agreement with results obtained on trivalent ions of plutonium, americium and curium, which are similar actinide elements. However, it was not possible to confirm the existence of a soluble carbonate complex of trivalent uranium, as in the case of trivalent plutonium or americium.

In 1927, Someya[1] first obtained trivalent uranium ion in a hydrochloric acid solution by treating hexavalent uranium with liquid zinc amalgam. Since then, few papers have been reported on its chemical behavior in aqueous solution except for absorption spectra in hydrochloric and perchloric acid solutions[2,3] That is, it was thought that studies on the aqueous chemistry of trivalent uranium would be difficult because trivalent uranium is very unstable and oxidizes rapidly in aqueous solution. One of the authors[4] studied the reduction of hexavalent uranium to the trivalent state and found that reduction with liquid zinc amalgam in hydrochloric, sulfuric and perchloric acid solutions is simple in operation, and gives a high yield within a short period of time and with good reproducibility; almost complete reduction is possible, particularly in 0.5 N hydrochloric acid solution. Next, the stability of trivalent uranium in these acidic solutions was investigated; it was found that trivalent uranium is fairly stable in all hydrochloric, sulfuric and perchloric acid solutions at low acid concentrations in the absence of atmospheric oxygen, but that it becomes unstable as the acid concentration increases. These observations are contrary to the previously-accepted view.[5-10] On the basis of

the above facts, the authors plan to conduct a detailed study of the aqueous chemistry of trivalent uranium.

In this paper, the absorption spectra and ion exchange behavior of trivalent uranium in hydrochloric, sulfuric and perchloric acid solutions were investigated, and the possibility of the existence of a chloro-complex of trivalent uranium in aqueous solutions was discussed through a comparison with results obtained on trivalent ions of plutonium, americium and curium, which are similar actinide elements.

Experimental

Reagents. *Uranium-237 and Various Acid Solutions of Hexavalent Uranium.* The uranium-237 isotope used as a tracer was prepared by the method reported by Ishimori *et al.*[11] Natural uranium dioxide was irradiated for about 2 hr with 20 MeV bremsstrahlung from the linear electron accelerator of the Japan Atomic Energy Research Institute. After irradiation, uranium, containing uranium-237 isotope produced by $(\gamma \cdot n)$ reaction, was separated from the fission products by the TBP-toluene extraction method from a nitric acid solution. The organic substance in the nitric acid solution of the purified uranium was decomposed completely by repeated heating to dryness with nitric acid. The radioactive decay curve of uranium-237 in the purified uranium obtained indicated half lives of 6.5 days for γ-activity and 6.7 days for β-activity, which agreed very well with priviously reported values.[11-15] Energy measurements on the γ-rays of uranium-237 were also carried out, and sharp peaks were found at energies of 59, 163, 210, 265 and 325 keV, which were assigned to γ-rays emitted by uranium-237 in reasonable agreement with the established decay scheme.[12,13] From these observations, uranium-237 thus prepared was thought adequate for use as a tracer. The uranyl nitrate solution thus obtained was heated almost to dryness several times with hydrochloric, sulfuric or perchloric acid in order to convert the salt into each form completely. The residue was then dissolved in an appropriate quantity of hydrochloric, sulfuric or perchloric acid solution in order to prepare acid solutions of various concentrations. The concentration of uranium was determined by first reducing the hexavalent uranium to the tetravalent state in the air with liquid zinc amalgam, then by titrating the tetravalent uranium with a standard solution of 0.01 N potassium dichromate, using sodium diphenylamine sulfonate as an indicator.[16]

Ion Exchange Resins. Dowex-50X8 (100—200 mesh) and Dowex-1X4 (50—100 mesh) were used for the cation and anion exchange experiments, respectively. Before use, they were conditioned sufficiently in the usual manner, converted to the desired forms (Dowex-50 to the hydrogen form; Dowex-1 to the chloride, sulfate or perchlorate form), washed with distilled water and then dried in air.

The liquid zinc amalgam was prepared by a method reported previously.[4] All other chemicals used were of the highest-purity grade.

Apparatus. For the reduction of hexavalent uranium to the trivalent state with liquid zinc amalgam, the reduction apparatus was that described in a foregoing report.[4] A Hitachi EPS-3 recording spectrophotometer and a 1 cm quartz cell with a glass stopper were used in measuring the absorption spectrum. The γ-radioactivity was measured with a Kobe-Kogyo well-type scintillation counter and a $1\frac{3}{4}''$ ida. $\times 2''$ NaI(Tl) well-type detector coupled to a Kobe-Kogyo 100 channel pulse-height analyzer, Model AN-100.

Procedures. A plastic globe-box was used throughout and all experiments were carried out in an argon, nitrogen or carbon dioxide atmosphere in order to prevent the oxidation of trivalent uranium at room temperature, which was 20—25°C.

Trivalent Uranium Solution. An acid solution of hexavalent uranium was reduced to the trivalent state by the liquid-zinc-amalgam method described in a previous paper.[4]

Absorption Spectrum. After reduction of the hexavalent uranium to the trivalent state, the uranium solution was put into the spectrophotometer cell and stopperd in an inert gas atmosphere. The absorption spectrum of 400—1400 mμ was immediately measured with reference to an acid solution of the same concentration as the sample.

Ion Exchange. The apparent distribution coeffcient was determined by equilibrating 500 mg of air-dried ion exchange resin with 25 m*l* of a 10^{-5} M trivalent uranium solution under the desired conditions with shaking. An aliquot of the supernatant liquid was taken for the measurement of γ-radioactivity. The radioactivity in the resin after equilibration was estimated from the difference between the total activity and the final activity present in the solutions.

The apparent distribution coefficient was calculated by means of the usual relationship.

$$K_{d'} = \frac{\left(\frac{\text{Radioactivity of } U^{3+} \text{ in resin}}{\text{Amount of resin (g)}}\right)}{\left(\frac{\text{Radioactivity of } U^{3+} \text{ in solution}}{\text{Volume of solution (m}l\text{)}}\right)}$$

However, the reduction of the hexavalent uranium to the trivalent state does not proceed completely, depending on the acid and its concentration, as described in a previous paper,[4] and although slowly, the trivalent uranium in the solution which has once been reduced is oxidized to the tetravalent state. Therefore, tetravalent uranium is also contained in the sample solution. Consequently, it is necessary to correct for this. The results, given in Tables 1 and 3 mentioned later, indicate that the apparent distribution coefficient

is almost constant, even when the time of standing or the amount of resin present is varied. Therefore, it is thought that cation or anion exchange resin has no effect on the re-oxidation rate of trivalent uranium in our experiments. On the other hand, it was found from our latest study to be published in the near future, that tetravalent uranium is completely extracted with 0.1 M DBP (di-*n*-buthyl phosphate)-benzene solution from a hydrochloric acid solution in an acid concentration range above 0.35 N. However, trivalent uranium can not be extracted at all under the same condition as above. Therefore, the re-oxidation rate of trivalent uranium in hydrochloric acid solutions at acid concentrations above 0.35 N can be determined by the DBP-benzene extraction method. It was also found that the concentration of uranium in the range of 10^{-3}—10^{-5} M has no effect on the re-oxidation rate of trivalent uranium as long as all atmospheric oxygen is excluded.

On the basis of the above facts, it is thought that the percentage of reduction of hexavalent uranium to the trivalent state and the quantity of trivalent uranium present after a fixed time can be calculated by knowing the kind of acid used and its concentration in the sample solution and using the results reported in the previous paper.[4] Corrections to the radioactivity in the solution can be made on the basis of these values. Namely, the radioactivity corrected through calculating the quantity of tetravalent uranium actually present in solution is the radioactivity of trivalent uranium actually present in the solution. Next, the radioactivity of trivalent uranium adsorbed in the resin should also be corrected by obtaining the apparent distribution coefficient of tetravalent uranium under the same conditions and by calculating the cocentration of tetravalent uranium in the solution by the same method as above. That is, the radioactivity corresponding to tetravalent uranium adsorbed in the resin is deducted from the apparent radioactivity of trivalent uranium adsorbed in the resin. The value thus obtained is taken as the actual radioactivity of trivalent uranium adsorbed in the resin.

Results

The Absorption Spectra of Trivalent Uranium. The absorption spectra of trivalent uranium obtained in perchloric and sulfuric acid solutions at 400—1400 mμ are shown in Fig. 1. Even when the concentration of perchloric acid is changed in the range 0.01—6 N and the concentration of sulfuric acid in the range of 0.01—10 N, there is no change in both absorption spectra and they remain completely the same. The absorption spectra are about the same as those reported by Jörgensen[2] and Stewart[3], as the positions of the main peaks are at 455, 526, 619, 639, 740, 890, 910, 980, 1075 and 1230 mμ. The 4 peaks at 526, 890, 910 and 1230 mμ are particularly characteristic, as they are strong, and when the relation between their heights and the concentration of trivalent uranium was obtained, it was found that Beer's law is obeyed. The molar extinction coefficients, E_m, at 526, 890, 910 and 1230 mμ under the above conditions were 171, 222, 226 and 175, respectively. For reference, the absorption spectra of tetravalent uranium under the same conditions are also shown in Fig. 1. Since trivalent uranium becomes unstable as the acid concentration of perchloric or sulfuric acid increases, the experiment was not carried out with higher acid concentrations than those mentioned above.

In a hydrochloric acid solution, the absorption spectra of trivalent uranium, when the concentration is in the range 0.001—6 N, are nearly the same as those in sulfuric acid and perchloric acid solutions, as shown in Fig. 2. However, the positions of peaks at 740, 890 and 980 mμ have shifted 5 mμ to 745, 895 and 985 mμ, respectively. Furthermore, these spectra show marked changes as the hydrochloric acid concentration increases; the peak at 526 mμ shows a sudden increase in height as the acid concentration increases and at the same time, becomes broad and is shifted to 532 mμ at 11 N, and to 548 mμ at 12 N, *i. e.*, to longer wavelengths. On the other hand, the peak at 619 mμ is shifted to 618 mμ at 11 N and to 615 mμ at 12 N, to shorter wavelengths. The peak at 639 mμ does not change up to 11 N hydrochloric acid, but shows a large shift up to 654 mμ at 12 N. In order to study this phenomenon, the hydrochloric acid concentration was maintained below

6 N and the chloride ion concentration increased gradually by adding chloride salts such as lithium chloride, by which a marked change was observed in the absorption spectra similar to that indicated above. It is inferred from the above fact that trivalent uranium forms a chloro-complex in solutions of very high chloride ion concentration. Furthermore, the rate of decrease of the absorption peak at 526 mμ was obtained as a fuction of time and the stability of trivalent uranium in the various acidic solutions was also obtained, by which similar results to those reported in the previous paper[4] were obtained.

Finally, in order to study the formation of a soluble carbonate complex of trivalent uranium, an experiment was carried out by adding potassium or ammonium carbonate to a trivalent uranium solution to a concentration of several % or several tens of %, and also by changing the pH. However, a dark violet, insoluble precipitate was formed under all conditions and it was not possible to confirm the presence of a soluble carbonate complex even from the absorption spectra of the supernatant liquid.

The Ion Exchange Behavior of Trivalent Uranium. *Rate of Exchange.* To evaluate the time of standing necessary for batch experiments, the rate of exchange was investigated by almost the same method as in the K_d determination. The experimental accuracy becomes poor with increase in the time of standing, because the reoxidation of trivalent uranium occurs gradually, even in the absence of atmospheric oxygen; this must be avoided as much as possible. Therefore, the change in the apparent distribution coefficient was measured for anion exchange resin in a concentrated hydrochloric acid solution which is assumed to be adsorbed most. As shown in Table 1, it was found that equilibrium is reached after approximately 45 min. An almost similar result was obtained in the experiment using cation exchange resin. From the above investigation, a standing period of 1 hr is recommended for this batch equilibrium experment.

Amount of Resin. As the trivalent uranium prepared by reduction with liquid zinc amalgam, a considerable quantity of zinc dissolves, particularly in the case of hydrochloric acid solution. As Table 2 shows, the zinc concentration in the solution after reduction is 1×10^{-2} M in a 0.5 N hydrochloric acid solution and 9×10^{-1} M in a 12 N hydrochloric acid solution. It has been known that zinc ion is adsorbed on an anion exchange resin in a hydrochloric acid solution.[17] Therefore, in order to find out whether it affects the apparent distribution coefficient of trivalent uranium or not, an experiment was carried out to investigate whether the apparent distribution coefficient changes with the quantity of resin using anion exchange resin in a similar manner to that mentioned above. As seen from Table 3, the apparent distribution coefficient is almost constant in the range 0.1—5 g of resin, and there is no effect due to the liquid zinc amalgam used in the reduction. A similar experiment was carried out using cation

exchange resin and it was found that, as in the case of the anion exchange resin, there is no effect. From the above results, 0.5 g of the resin is recommended for use in this experiment.

Apparent Distribution Coefficient. The apparent distribution coefficient of trivalent uranium was determined for cation and anion exchange resins at various concentrations of hydrochloric, sulfuric and perchloric acids, using 0.5 g of the resin and 1 hr of standing. However, experiments above 6 N in the case of sulfuric acid solution and above 2 N in the case of perchloric acid solution were not carried out, because trivalent uranium becomes unstable as the acid concentration increases. The apparent distribution coefficient of tetravalent uranium under exactly the same conditions is also determined for reference.

As is clear from Table 4, in a hydrochloric acid solution trivalent uranium is adsorbed on the cation exchange resin to a considerable extent, and the apparent distribution coefficient increases with decrease in the concentration of hydrochloric acid, reaching a maximum at about 0.1 N; in the range 0.1 N to 0.01 N, the apparent distribution coefficient shows an approximately constant value of 500. In the case of tetravalent uranium, the apparent distribution coefficient increases with decrease in the concentration of hydrochloric acid, similar to trivalent uranium. However, the value is larger by nearly one order of magnitude than in the case of trivalent uranium, especially in the low acidity range. Also, the apparent distribution coefficient for the anion exchange resin is low for both trivalent and tetravalent uranium in low concentrations of hydrochloric acid, but increases gradually with increase in the concentration of hydrochloric acid. At any rate, their values are small and that for trivalent uranium is smallest.

In the case of sulfuric and perchloric acid solutions, as shown in Tables 5 and 6, trivalent uranium is not entirely adsorbed on the anion exchange resin in the range of acid concentration of the experiment. In contrast to this, a larger value than that for tetravalent uranium was obtained in the case of cation exchange resin. A very large value of the apparent distribution coefficient was indicated, particularly in a low acid solution, as it became about 7000 even at 0.1 N and is almost completely adsorbed on the cation exchange resin.

Discussion

On the basis of the above experimental results, complex formation of trivalent uranium in sulfuric, perchloric and hydrochloric acid solutions was compared with that of trivalent plutonium, americium or curium ion, which are relatively stable in aqueous solution, from among the same

actinide elements. That is, as prevoiously described[18] for trivalent plutonium, both cationic and anionic complexes are formed in sulfate solutions, negatively charged complexes exist predominantly in concentrated sulfuric acid solutions and trivalent plutonium has a greater tendency to form sulfate complexes than trivalent americium; however, even in solutions where sulfate complexes are definitely known to exist, for example, in a 16 M sulfuric acid solution, changes in the absorption spectra of these solutions are very slight. According to experiments in sulfuric acid solutions, there is no formation of an anionic complex of trivalent uranium, at least at acid concentrations below 6 N, because the absorption spectra show almost no change and trivalent uranium ion is not adsorbed on the anion exchange resin over the entire range of acidity used.

Also, an investigation of complex formation by trivalent plutonium and americium in 1—5 M perchloric acid solution showed no appreciable changes in absorption spectra, and hardly any noticeable changes in absorption spectra of trivalent plutonium were observed at higher concentrations of perchloric acid.[19] Results concerning absorption spectra and the ion exchange behavior of trivalent uranium in a perchloric acid solution hitherto obtained indicate the absence of anionic complex formation at acid concentrations below 2 N, similar to the above results for a sulfuric acid solution.

In the literature, there are quite definite examples of the existence of chloride complexes of trivalent plutonium.[20-22] Changes in the absorption spectra of trivalent plutonium in hydrochloric acid solutions at acid concentrations right up to 4.4 M indicate the formation of complexes of trivalent plutonium with chloride ions.[20] In an ion exchange investigation, Diamond, Street and Seaborg[21] found that at high hydrochloric acid concentrations trivalent transuranium elements form complexes with chloride ions to a greater extent than lanthanides. Quantitative data on the composition and stability of complex chloride ions of Me^{3+} (where Me^{3+} is Pu^{3+}, Am^{3+} and Cm^{3+}) were obtained by Ward and Welch[22] through the ion exchange method. They established the formation of complex ions $MeCl^{2+}$, and at hydrochloric acid concentrations above 1 M, also complexes $MeCl_2^{+}$. Apparently, complex ions of the type $MeCl_3^{0}$ are also formed in more concentrated hydrochloric acid solutions, *i. e.*, in solutions with a large excess of chloride ions. In 12.6 M hydrochloric acid solution complex anions are formed, whose relative stabilities go as $Pu \gg Am > Cm$.

From the results of our study on absorption spectra and ion exchange behavior, it is thought that an anionic chloride complex of trivalent uranium begins to form at hydrochloric acid concentrations above 7 N, showing good agreement with results obtained on trivalent states of plutonium, americium and curium. However, in the case of trivalent plutonium, the stability of anionic chloride complexes increased rapidly at 12.6 N. On the other hand, from results obtained by the present authors, a sudden change occurred in the absorption spectra when the concentration of hydrochloric acid became greater than 10 N in the case of trivalent uranium, and similar to the case of trivalent plutonium, it can be expected that the stability of an anionic complex of trivalent uranium will increase suddenly above 10 N. However, according to results from the ion exchange experiment, a large change in the apparent distribution coefficient for anion exchange resin in high concentrations of hydrochloric acid solutions in the case of trivalent americium or curium was not indicated, contrary to expectation.

In general, the tendency of ions of a given element to form complexes increases with decrease in ionic radius and increase in charge, *i. e.*, with increase in the ionic potential,

$$\varphi = \frac{Z}{r},$$

where Z is the ionic charge and r the ionic radius. In accordance with this, it is to be expected that the ion U^{4+} will have a greater tendency to form complexes with acid anions than the ion U^{3+}. The results of investigating complex formation by uranium in tri- and tetravalence forms are in agreement with this. Also, by analogy with the lanthanides and from the known behavior of the transuranium elements, the relative strengths of the multichloride complex ions of trivalent plutonium, americium and curium should decrease in that order. In dilute hydrochloric acid solutions, the order of the relative strengths of the multichloride complex ions of trivalent uranium, plutonium, americium and curium was found to be identical, while in the case of concentrated hydrochloric acid solutions, the order of uranium and plutonium was reversed.

Finally, it was reported with respect to the formation of carbonate complexes that carbonate ions form soluble anionic complexes in 40% potassium carbonate solution in the case of actinide elements such as trivalent plutonium and americium. That is, it was reported that the absorption spectra of carbonate complexes of trivalent plutonium showing absorption maxima at wavelengths of 565, 600, 835 and 920 mμ were observed,[23] and the formation of anionic complexes confirmed by the study of the electromigration in carbonate solutions.[24,25] It is expected that there is a possibility of the formation of a soluble carbonate complex in the case of trivalent uranium, similar to the case of plutonium and americium, and consequently, this was studied from various points of view. However, in the case of trivalent uranium, a precipitate with a low solubility which is believed to be an insoluble carbonate always formed, and it was not possible to confirm the presence of a soluble carbonate complex from the absorption spectra of the supernatant liquid.

This work was partly supported by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2656—2660 (1968)

Studies on Adduct Formation of β-Diketone Chelates with Heterocyclic Bases

Tsunenobu SHIGEMATSU, Masayuki TABUSHI, Masakazu MATSUI and Megumu MUNAKATA

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received April 27, 1968)

Stability constants of the 1 : 1-adducts with heterocyclic Lewis bases on copper chelates of six β-diketones and two ethylesters of β-ketoacids ($Cu(ligand)_2 \cdot base$) were determined by spectrophotometric measurements in visible region and the effects of β-diketone substituents, Lewis bases and organic solvents on the stability constants were studied. Terminal alkyl groups of β-diketones hardly hindered the adduct formation, because the adducts of β-diketone chelates except acetylacetone chelate had similar stability constants. Solvent effect was due to the formation of the solvates of the chelates or the solvation of N-base with solvent. This is related to the abnormal position of chloroform in the order of the adduct stability compared with oxygen-containing solvents. Infrared spectra indicate that the metal-oxygen bonding, as well as the basicity of Lewis bases is considered as an essential factor in the adduct formation of metal β-diketone chelates.

As already stated by many investigators, the adduct-formation of metal β-diketonates plays an important role in the synergistic enhancement of the solvent extraction, and therefore the adduct-forming reaction and the structure of the adducts have the interest for analytical and coordination chemists. Recently, many adducts of transition metal acetylacetone (AA) chelates were prepared and their properties studied. Nakamoto and his coworkers[1] suggested from the infrared spectra that adduct-forming Lewis bases coordinated directly to the central metal atom in the adduct of metal acetylacetonates such as $Ni(AA)_2$, $VO(AA)_2$ and $UO_2(AA)_2$. Adducts of copper(II) β-diketonates have been extensively investigated. The behavior of Lewis base, chelate ligand and solvent on the adduct-formation were studied by Graddon and Watton[2] using nitrogen-containing heterocyclic bases (N-bases), and by Rao and Li[3] using some organo-phosphorus compounds. They mentioned that (i) the base effect reflected partly donor power of the base and partly steric effect; (ii) the ligand effect related to the transfer of negative charge from the ligand to metal ion, and consequently to the residual positive charge on the metal

atom; and (iii) the solvent effect was attributed to change in the solvation energy.

The present research was carried out in order to ascertain and to discuss Graddon's conclusion. Copper chelates were prepared by using six β-diketones and two methylesters of β-ketoacids; the stability constant of the 1 : 1-adducts with several N-bases (Cu^{II}(chelate ligand)$_2$N-base) was determined by means of spectrophotometric measurements, and various factors affecting the stability of the adduct were investigated. Especially, the solvent effect seemed to result from the change in the thermodynamic concentration of the Lewis base and from the solvation which took place between some oxygen-containing solvents and β-diketone chelates with CF_3 terminal group. Furthermore, the chelates were prepared, and the problem on metal ligand bonding, which had not been clarified, was discussed from the results of infrared absorption.

Experimental

Apparatus. A Hitachi Perkin-Elemer 139 UV-VIS spectrophotometer and a Shimadzu automatic recording spectrophotometer, model IV-50, were used for the visible spectrophotometeric measurements. Infrared spectra were obtained by the KBr disk method with a Perkin-Elmer, Model 521 infrared spectrophotometer.

Materials. Acetylacetone (AA), ethylacetyl acetate (EAA), ethylbenzoyl acetate (EBA), trifluoroacetylacetone (TAA) and benzoyltrifluoroacetone (BFA) were obtained from the Dojindo Co. Ltd., Research Laboratories or from Tokyo Kasei Kogyo Co., Ltd. Dipropionylmethane (DPrM), diisobutyrylmethane (DIBM) and pivaloylacetone (PvA) were prepared by the acylation of methylketones with the ethyl esters of carboxylic acids in the presence of sodium amide or sodium methoxide. These β-diketones were precipitated as copper chelates, and recrystallized from benzene. The analytical data are listed below (calculated values are shown in parentheses):

$Cu(DPrM)_2$	C: 52.88 (52.69)	H: 6.92 (7.05)
$Cu(PvA)_2$	C: 55.80 (56.70)	H: 7.69 (7.52)
$Cu(DIBM)_2$	C: 57.37 (57.80)	H: 8.27 (8.03)

Preparation of Metal Chelates. Copper chelates were prepared in the following manner: To 50 m*l* of 0.5 M copper(II) chloride solution, 20 m*l* of 2.5 M β-diketone methanol solution and 25 m*l* of 2 M sodium acetate solution were successively added under continuous stirring. After heated for a short while on a hot plate, the mixture was allowed to stand in a refrigerator for several hours. The crystalline solid was filtered off on a Buchner funnel, washed with water and dried in a desiccator. After recrystallized from benzene, the crystalline chelate was dried overnight at 60°C in an evacuated vessel. The results of elementary analysis of the chelates are shown in Table 1.

Table 1. Analysis of metal compounds

$Cu(TAA)_2$	32.39(32.43)	2.21(2.16)
$Cu(BFA)_2$	48.54(48.57)	2.39(2.43)

Calculated values are in parentheses.

Results and Discussion

It has been reported that copper β-diketonates react with one mole of N-base to form 1 : 1-adducts in solution. The fact is supported by the fact that a distinct isosbestic point is observed in Fig. 1. Since the visible band shifts to longer wavelength

by coordination of the N-base (see Fig. 1), the stability constant of the adducts can be determined spectrophotometrically by the following equation[2];

$$K = \frac{[E_\infty - E_0][E - E_0]}{B_0[E_\infty - E] - C_0[E - E_0]} \times \frac{1}{E_\infty - E}$$

where E is the absorbance measured at a definite wavelength, such as that is indicated in Table 2,

and E_0 the absorbance obtained in the absence of the N-base, at the same wavelength. The value of E_∞ is that found, by trial and error, to give the most reproducible value of the stability constant, K. B_0 and C_0 are total concentrations of the base and the copper chelate, respectively.

Effect of Alkyl Group of β-Diketones. It was expected that the adduct formation would be influenced by the steric effect of the terminal groups of chelate ligands.[4] The stability constants of the adducts involving AA, DPrM, DIBM and PvA as β-diketone were measured: Each copper chelate of these β-diketones except that of AA seems to have stabilities of the same magnitude. The results presented in Table 3 indicate that the terminal alkyl group scarcely affects the adduct formation. It must be noted that the steric hindrance does appear not in the chelate ligand but in the adduct forming base, as described below.

Effect of N-Base. Tables 3 and 4 show that for each copper chelate and in each solvent, the stability constants of the adducts increased in the following order:

2-methylpyridine < pyridine < 4-methylpyridine,
2-methylpiperidine < piperidine < 4-methylpiperidine

The former order was already observed by Graddon and Watton in the copper(II) β-diketone chelates,[2] and they stated that the higher stability of the 4-methyl pyridine adducts reflected the increased donor property of nitrogen atom due to substitution, and the unexpected low stability of the 2-methyl pyridine adducts was probably caused by the steric interference. The latter order supports this concept. Namely, the ability to form adducts is enhanced by the increasing basicity of the base, but weakened by the steric hindrance.

Solvent: Benzene

Effect of Organic Solvents. The effect of the solvent is shown in Table 5, which indicates that the order of the adduct stability partly depends on the presence of CF_3 terminal group of the chelate ligand. The general orders of increasing stability for $Cu(EBA)_2$ are

chloroform < butyl acetate < acetone < MIBK < benzene < cyclohexane.

While for $Cu(TAA)_2$ and $Cu(BFA)_2$ acetone < butyl acetate < MIBK < chloroform < benzene < cyclohexane.

Toluene and monochlorobenzene situate in the same position as of benzene. The stabilities of the $Cu(AA)_2$ adducts were obtained only in chloroform, acetone and benzene, because of their low solubility in the other organic solvents, and the order is quite the same with that reported by Graddon and Watton. They measured the stability of the pyridine adducts of $Cu(AA)_2$. $Cu(EAA)_2$ and Cu(benzoylacetone)$_2$ in chloroform, acetone and benzene, and stated that the increasing order of the adduct stabilities, chloroform < acetone < benzene, did not agree with the order of the dipole moments, the dielectric constants or the splitting energy of ligand-field of the solvents, but it agreed with the decreasing order in the interaction between the solvents and the copper chelates or in the solvation energy of N-bases. However, it was thought to be difficult to distinguish these two effects, although they showed some evidence in favor of the latter.

In the two kinds of order found in this experiment, the solvation to the chelates may be discriminated from that of N-bases. The relative position of chloroform to MIBK, butyl acetate and acetone may bring a solution of this interesting problem. Clarke *et al.*[5] reported that the bonding energies of chloroform solvates of tervalent metal acetylacetonates were rather small, ranging from 2 to 6 kcal/mol, which lay in the region of hydrogen bonding or dipole-dipole interaction, and with copper(II)-, zinc(II)- and cadmium(II) acetylacetonates, even such weak solvates were not produced. Graddon and Watton pointed out that considerable heat was evolved on dissolving N-bases in chloroform. Such circumstances may lead to the conclusion that the large solvation energy of the N-bases loweres the stability of the adducts of Cu-$(EAA)_2$, Cu $(EBA)_2$ and $Cu(AA)_2$ in chloroform. In other words, the thermodynamic concentration of the bases decreases by the interaction with chloroform through the hydrogen bonding.

On the contrary, for the adducts of $Cu(TAA)_2$

Base: Pyridine

and $Cu(BFA)_2$, the stability in chloroform is comparatively large: At least, the adducts in this solvent are more stable than those in MIBK, butyl acetate and acetone. The phenomena may be now explained by the solvation to the copper chelates. The electron-withdrawing CF_3 group in the chelating ligands decreases the electron density around the central copper atom, but at the same time, it enhances the ability to form the solvates with some oxygen-containing solvents. Consequently, the adduct formation with N-base is weakened owing to the competition reaction with the solvents. This fact must be an important reason for the phenomena that in MIBK, butyl acetate and acetone, the adducts containing CF_3 group in the chelate ligands show lower stabilities than that in chloroform.

Effect of Metal to Ligand Bonding. Table 5 shows that irrespective of the solvents used, the stability of the adducts increases in the order:

$$Cu(AA)_2 < Cu(EAA)_2 < Cu(EBA)_2 < Cu(TAA)_2 \simeq Cu(BFA)_2$$

Graddon and Watton concluded that this was the decreasing order of effect of ligand field and the increasing order of the residual positive charge on the copper atom; but they did not carry out systematic studies. In the present work, the infrared absorptions attributed to the M–O (metal to ligand bonding), C=O and C=C stretching, were obtained to ascertain their conclusion. The spectra of the copper chelates were measured as KBr disks, and the results were summarized in Table 6. The bands for these chelates were assigned on the basis of the data of metal(II) β-diketone chelates, which had been presented by Nakamoto *et al.*[6]

It is important to examine the relationship between the stability constant of the adduct and the M–O or the C=O stretching frequencies and it will be expected that decrease in the M–O frequency reflects the increase in the stability constant of the adduct. Table 6 indicates that the order of both

TABLE 6. M–O, C=O AND C=C FREQUENCIES OF COPPER(II) β-DIKETONE CHELATES(cm^{-1})

Complex	$\nu_{C=O}$	$\nu_{C=C}$	ν_{M-O}
$Cu(AA)_2$	1575	1550 1526	455
$Cu(EAA)_2$	1595	1555 1530	452
$Cu(EBA)_2$	1595	1565 1545	460
$Cu(TAA)_2$	1604	1590	445
$Cu(BFA)_2$	1602	1590	443

the C=C and the C=O stretching frequencies is

$$Cu(BFA)_2 \simeq Cu(TAA)_2 > Cu(EBA)_2 \simeq Cu(EAA)_2 > Cu(AA)_2,$$

but the order of the M–O stretching frequency is

$$Cu(BFA)_2 \simeq Cu(TAA)_2 < Cu(EAA)_2 < Cu(AA)_2 < Cu(EBA)_2.$$

The M–O stretching frequency, except that of $Cu(EBA)_2$, is just in the reversed order to that of the C=C and C=O frequency, and decreased M–O frequency is closely concerned with the higher stability constants of the adducts as presented in Table 5. The M–O stretching frequency of $Cu(EBA)_2$ is abnormally high. The metal-oxygen bonding is weakened by the resonance between carbonyl group and lone pair electrons of ester oxygen in ketoesters such as EAA and EBA. In fact, effect of ligand field of EAA and EBA are lower than that of acetylacetone.[2] From the phenomena, the low M–O frequency must be anticipated for $Cu(EAA)_2$ and $Cu(EBA)_2$, and actually, the frequency of $Cu(EAA)_2$ is somewhat lower that of $Cu(AA)_2$. However, as described above, the M–O band of $Cu(EBA)_2$ shows higher frequency contrary to expection, and this is contradictory also to the fact that the higher C=O and C=C frequency results in the lower M–O one.[7] Then, it seems reasonable to consider that the M–O band of Cu

7) K. Nakamoto, P. J. McCarthy, A. Ruby and A. E. Martell, *J. Am. Chem. Soc.*, **83**, 1066 (1961).

$(EBA)_2$ is not the pure metal-oxygen mode, but the M–O streching band couples with other band and subsequently, it shifts to higher frequency. It can be concluded, therefore that the chelates showing lower M–O stretching frequencies form the more stable adducts with N-base.

The results of this investigation led to the conclusion that (i) metal-oxygen (ligand) bonding—the localization of electron in the chelate ring and (ii) the basicity of Lewis bases are considered as the essential factors in the adduct formation of metal β-diketone chelates.

Furthermore, the stability constant of the adducts was influenced by (iii) steric factors of Lewis base and (iv) solvent effect due to the formation of the solvates of the chelates or the solvation of N-base.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2660—2662 (1968)

A Study on the Yield of (γ, α) Reactions with 20 MeV Bremsstrahlung

Yoshinaga OKA, Toyoaki KATO, Koichi NOMURA, Tatsuya SAITO and Hui-Tuh TSAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 2, 1968)

The yields of the (γ, α) reactions on 7 elements up to an atomic number of 49, irradiated with 20 MeV bremsstrahlung, have been obtained through gamma-ray spectrometric measurements of the resultant activities. The yield values, as measured in absolute disintegration rates at the end of irradiation per mole per roentgen, have been plotted against atomic number of the target nuclides. The yield curve shows a maximum in the region of copper and zinc, and drops rapidly with increasing atomic number. The shape of this yield curve is similar to that for the photoalpha yield as a function of atomic number. It can be seen that the yield levels off in the region of silver and indium. A mechanism such as the direct photoelectric effect is thought to be responsible for this behavior. The yield of the (γ, α) reaction of an element amounts to only a small fraction, at most a few tenths of a per cent, of the total photonuclear yield.

When bremsstrahlung photons with energies in the giant resonance region are attenuated by various target elements, the main nuclear events are the emission of one neutron or one proton. In previous work,[1-4] the yield of the (γ, n) and (γ, p) reactions have been determined with 20 MeV bremsstrahlung as a function of target nuclear charge, and the applicabilities of these reaction products to activation analyses have also been discussed from the data thus obtained. Since the binding energy of alpha-particles is rather low, it is expected that the (γ, α) processes, apart from (γ, n) and (γ, p) processes, can occur in the energy region of 20 MeV bremsstrahlung. Especially for medium weight nuclei, the resultant activities due to (γ, α) processes are expected to be an appreciable fraction of the total resultant activity, because of the relatively low Coulomb barriers. Greenberg *et al.*[5] reported on the yields of alpha-particles emitted from 9 elements up to an atomic number of 58 in the energy region of 23 MeV bremsstrahlung. Some additional details have been clarified by several workers,[6-9] but not studied sufficiently.

In this report, the yields of (γ, α) reactions produced by irradiation of several medium weight nuclei with 20 MeV bremsstrahlung have been given through gamma-ray spectrometric measurements of the resultant activities.

Experimental

Samples and Irradiation. Samples of the target materials with high chemical purity, either in the form of the element or some simple compound, were irradiated for 1 hr with bremsstrahlung gamma-rays of 20 MeV maximum energy produced by the linear electron accelerator of the Japan Atomic Energy Research Institute. Each sample had a weight of 100 mg and was contained in a small quartz tube having an internal diameter of

4 mm. The experimental method involving bremsstrahlung flux monitoring and details on irradiation are essentially described in detail in previous papers.[1-4]

Chemical Separation. For the vanadium target, gamma-ray spectrometric measurements of the scandium activities were performed non-destructively after cooling. The other seven targets were processed radiochemically by the following procedures. In each case, the final precipitate was packed in a small glass tube having an internal diamter of 4 mm to determine the chemical yield and for gamma-ray counting.

Cobalt from Copper. After the addition of cobalt carrier (20.0 mg), the copper target was dissolved in nitric acid and evaporated nearly to dryness. The residue was dissolved in 6 N hydrochloric acid and subjected to anion exchange separation. Cobalt was eluted from a Dowexl X8 column with 6 N hydrochloric acid, and precipitated from this eluate by the addition of an aqueous solution of α-nitroso-β-naphthol. The precipitate was centrifuged and ignited to obtain cobalt(II) oxide. Almost complete recovery was attained.

Copper from Gallium. A gallium(II) oxide target was brought into solution by adding nitric acid along with copper carrier (67.3 mg). After evaporating nearly to dryness, the residue was made 3.5 N in hydrochloric acid, and precipitated from this solution by the addition of aqueous ammonium sulfide. After separation with a centrifuge, the sulfide was ignited to obtain copper(II) oxide. The chemical yield was 88.8%.

Zinc from Germanium. An irradiated germanium dioxide target was transferred to a 50 m*l* distilling flask, and brought into solution by adding 7 N hydrochloric acid along with gallium (269 mg) and Zinc (27.0 mg) carriers. Almost all germanium activity was removed by distillation. From the resultant solution, gallium was extracted with isopropyl ether. The aqueous layer was neutralized by the addition of a dilute aqueous sodium hydroxide solution, and the zinc hydroxide precipitate was separated by centrifugation. The precipitate was ignited to obtain zinc(II) oxide. The chemical yield was 12.9%.

Arsenic from Bromine. To the aqueous solution of an irradiated lithium bromide target arsenic(III) and arsenic(V) carriers (total 30.2 mg) were added. Arsenic was precipitated from this solution in the form of the elemental powder by reduction with tin(II) chloride in concentrated hydrochloric acid on warming. After separation by centrifugation, the precipitate was washed repeatedly with water, and dried in a vacuum. The chemical yield was 72.5%.

Rhodium from Silver. An irradiated silver target was dissolved in nitric acid with the addition of rhodium(III) and rhodium(IV) carriers (total 72.9 mg). An aqueous solution of sodium chloride was added to this solution to precipitate silver chloride. The filtrate was further purified by repeated silver chloride scavenging. Finally, metallic rhodium was precipitated by reduction with the addition of zinc dust. The precipitate was washed with dilute nitric acid and with water, and subsequently dried in a vacuum. The chemical yield was 20.4%.

Silver from Indium. After the addition of silver carrier (35.9 mg), an irradiated indium target was dissolved in nitric acid. Silver chloride was precipitated from this solution by the addition of dilute hydrochloric acid. The precipitate was purified by repeated reprecipitations involving dissolution with aqueous ammonia and precipitation with dilute hydrochloric acid. Finally, the silver chloride was washed with water and dried at 110°C. The chemical yield was 80.5%.

Yield Determination. Yield has been defined as the production rate of a given radioactive nuclide per mole of target nuclide per roentagen. The initial rates of the various activities produced were determined from their photopeak areas from decay curve analyses of the counting rates, and the corresponding saturation rates computed. After correcting for chemical yields, counting efficiencies, branching ratios and internal conversion electrons, the data has been expressed in the form of yields. The decay schemes used were those listed in the Nuclear Data Sheets.[10] A table of internal conversion coefficients[11] was also used.

Measurement of radioactivity was carried out with a 3″ dia.×3″ NaI(Tl) detector coupled to a TMC 400-channel pulse-height analyzer.

Results

Table 1 lists the characteristics and experimental results obtained from 7 gamma-ray emitting products for (γ, α) reactions of the elements studied. The threshold energies for these reactions were

a) The value corrected at the end of 1 hr irradiation (9.4×10^{6} R/min).

calculated on the basis of the mass differences.[12] The yield value, shown in the last column of Table 1, are expressed as the disintegration rate at the end of irradiation per mole of target nuclide per roentgen. This can be taken as the number of (γ, α) processes which occurred during irradiation. The yield values were also plotted against atomic number of the parent nuclides in Fig. 1 in which the symbol noted near each plot indicates the parent nuclide. The yield curve exhibits a maximum in the region of copper and zinc, and drops rapidly with increasing atomic number. It is seen that the yield levels off in the region of silver and indium.

Discussion

The shape of the yield curve, shown in Fig. 1, is very similar to that of the curve for the photo-alpha yield as a function of atomic number with 23 MeV bremsstrahlung presented by Greenberg *et al.*[5] The curve is also similar to that for the (γ, p) reaction yield reported previously.[2] The (γ, α) reaction yield is lower by a factor varying from 20 to 10^3 in the region of $Z<50$. The absorption cross-section for gamma-rays increases with increasing atomic number, and the potential barrier also increases. From the relative effects of these factors, the yield curve shows an initial rise and then, through a maximum point, drops rapidly with increasing atomic number. For silver and indium targets, however, the yields are much higher than those expected from the rapid drop untill the bromine target. The presence of direct effects in the photoproduction of alpha-particles from heavier elements has been suggested by several workers.[8,9] Erdös *et al.*[6] reported that the photoalpha yield curve levels off at a roughly constant value for elements with atomic number greater than 50. Furthermore, disagreement between the calculated evaporative spectra of emitted photoalpha particles and the experimental ones was pointed out by Meneghetti *et al.*[9] An excess of energetic alpha-pariticles, especially in indium and gold irradiated with 35 MeV bremsstrahlung gamma-rays, has been attributed to direct effects. The leveling-off behavior of the yield curve in the region of silver and indium obtained in this experiment suggests that a mechanism such as the direct photoelectric effect becomes more important for heavier elements.

Experimental results show that the (γ,α) reaction yield of an element amounts to only a small fraction of the total photonuclear yield. The relative yields of the (γ, α) reaction to those of the (γ, p) and (γ, n) reactions in the region of copper and zinc have been determined as

$$Y_{(\gamma,\alpha)} : Y_{(\gamma,p)} : Y_{(\gamma,n)} = 1 : 20 : 500$$

In the region of silver and indium, the relative yields are

$$Y_{(\gamma,\alpha)} : Y_{(\gamma,p)} : Y_{(\gamma,n)} = 1 : 10^3 : 3\times10^5$$

Since the yield of a photonuclear reaction is a strong function of the maximum bremsstrahlung energy, the relative probability of producing each activity as the result of photonuclear processes with various energies is to be investigated in detail through further experiments.

12) Nuclidic mass values used were those listed in G. Friedlander, J. W. Kennedy and J. M. Miller, "Nuclear and Radiochemistry," 2nd Ed., John Wiley & Sons, New York (1964), p. 533.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2663—2668 (1968)

Free Radical Reactions in Organic Electrode Processes. V*1 Anodic Cyanation of Some Monosubstituted Benzenes*2

Tosaku SUSUKI,*3 Kikuhiko KOYAMA, Akira OMORI and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received December 28, 1967)

The anodic reaction between cyanide ions and monosubstituted benzenes in methanol has been investigated. An examination of the products has indicated that the reaction proceeded by means of the formation of nucleus-cyanated products. The solvent perhaps also participates concurrently in this anodic reaction leading to the formation of methoxylated compounds. The results offer a striking contrast in isomer distribution between these two substitutions. The substituents on the benzene rings had a pronounced effect on the yield of the cyano compounds. The reactivity of the aromatic compounds toward the anodic cyanation decreased in the following order:

anisole ≫ toluene > ethylbenzene > cumene ≫ benzene ≫ methyl benzoate.

These results have been interpreted as resulting from the generation of an aromatic ion radical at an anode by the loss of a π-electron from each molecule.

In a previous paper,[1] we have demonstrated that the anodic reaction of sodium cyanide with some aromatic hydrocarbons, leading to the formation of cyano compounds, could be carried out in methanol by using a platinum anode. The anodic cyanation occurred only on the aromatic nuclei. The situation in this substitution closely resembles that of the electrophilic aromatic substitutions, even though napthalene and anthracene are reactive at the same position in their respective molecules toward both homolytic and electrophilic substitutions.

Two possible intermediates, *i.e.*, an electrophilic cyano radical or an aromatic cation radical, were conceivable for this anodic aromatic cyanation, but at that time we had not found conclusive evidence for making any particular choice between these two species.

In the present work, monosubstituted benzenes were chosen as the organic substrates, and the effect of substituents on the yield and on the variety of the products formed in the electrochemical reaction was investigated in order to elucidate the mode of the anodic cyanation.

Results and Discussion

All the electrolyses were conducted between a platinum anode and a mercury-pool cathode in an undivided cell under essentially similar conditions.

In the experiment with anisole added, a mixture (3 g) of *o*- and *p*-anisnitriles was obtained. From the gas chromatographic analysis, an isomer distribution of 40% *ortho* and 60% *para* was obtained. The *meta* isomer was not detected. The fractional crystallization of the mixture from ethanol led to the isolation of the *p*-isomer. The saponification of the mother liquor with alcoholic potassium hydroxide afforded *o*-anisic acid. These isolated compounds were identified by a mixed melting-point test, elemental analyses, and a study of the infrared spectra.

When toluene was added as an organic substrate, the anodic reaction proceeded by means of the formation of tolunitirles (0.78 g), methoxytoluenes, and an isonitrile. A sharp infrared absorption band at 2180 cm^{-1} and the foul odor of the crude product suggested the formation of an isonitrile. Gas chromatography indicated that the isomer distribution for tolunitriles consisted of 27% *ortho*, 5.4% *meta*, and 67.5% *para*. It yielded no indication of the formation of benzyl cyanide. Among these products, *o*- and *p*-tolunitriles could be separated by chromatography; they were identified, after treatment with alcoholic potassium hydroxide, as *o*-toluamide and *p*-toluic acid respectively.

Table 1. Isomer distribution in the product obtained from the anode reaction of cyanide ion with ethylbenzene

	Isomer distribution			
	Methoxyethylbenzene		Cyanoethylbenzene	
	Retention time* min	%	Retention time* min	%
α-	4.3	80.3	—	—
o-	6.3	3.3	13.5	33
m-	7.4	8.4	21.2	10
p-	8.1	8.0	24.3	57

* Conditions: 3 m-column of 25% polyethyleneglycol 6000 on Shimalite; carrier gas, He, 46 ml/min; column-temp.. 180°C.

A detailed study of isomer distributions, including those of methoxylated products, was made by experiments with ethylbenzene added. The results obtained are summarized in Table 1.

As is indicated in Table 1, it is quite evident that there is a marked difference in isomer distribution between methoxyethylbenzenes and cyanated products. Side-chain methoxylation took place in preference to nuclear methoxylation, while hydrogen atoms on the aromatic ring preferred to undergo substitution with the cyano group. This product analysis was performed by gas chromatography. Several other unidentified peaks were observed on the gas chromatogram; some of them might be assignable to those of isonitriles. The precipitation of silver cyanide in an aqueous silver nitrate solution, through which evolved gases were passed, may provide evidence for the formation of hydrogen cyanide.

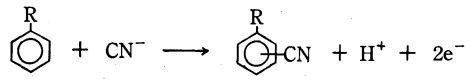
The anodic reaction of cyanide ions in the presence of cumene gave considerable amounts of a product arising from the side-chain substitution of cumene with the methoxy group, but it failed to give any side-chain cyanation product. The isomer distribution of the nucleus-cyanated products consisted of 35.6% *ortho*, 13.8% *meta*, and 50.6% *para*. *p*-Cumic acid was isolated from the saponification products obtained by treatment with alcoholic potassium hydroxide.

The anodic reaction of cyanide ions with benzene in methanol afforded a small amount of benzonitrile, together with anisole, but it failed to yield any cyano product when benzene was replaced with methyl benzoate.

The results obtained from the present work are summarized in Table 2.

The substituent on the aromatic ring had a pronounced effect on the yield of aromatic cyano products. The order of the reactivity of the aromatic compounds toward this anodic aromatic cyanation decreases as follows:

Table 2. Current yields of nitrile formation



Substituent R	Half-wave oxidation potential* $E_{1/2}$(ox), V	Current yield (Y), %	Current yield for		
			Ortho	Meta	Para
$-OCH_3$	1.76[a]	12.1	4.9	—	7.2

anisole ≫ toluene > ethylbenzene > cumene > benzene ≫ methyl benzoate.

This order is in good agreement with that of the ability of the substituents to supply electrons to the ring. The results indicate that the substitution reaction took place at electron-rich sites in the ring. In addition, the isomer distributions in the cyano products are in striking contrast to those in the methoxylated compounds obtained together with nitriles.

In order to elucidate the mode of the anodic aromatic cyanation, a graphical plot of the logarithms of current yield against the half-wave polarographic oxidation potential is represented in Fig. 1.

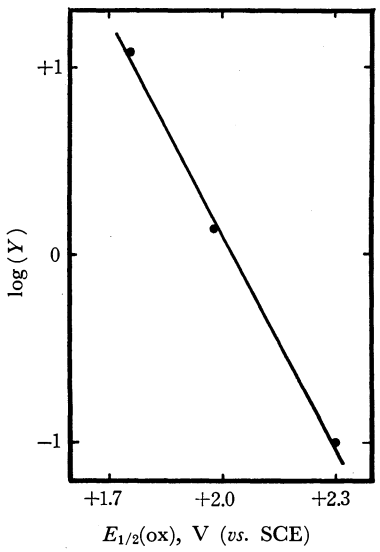

Fig. 1. Correlation of log (Y) and $E_{1/2}$(ox) for the anodic aromatic cyanation.

If cyano radicals are formed at the anode, then diffuse into the bulk solution, and finally attack the aromatic substrates, the current yield would not be expected to be related to the half-wave polarographic oxidation potential. Therefore, the good linear correlation with the half-wave oxidation potential suggests that the electrochemical behavior of the aromatic compounds at the anode plays an important part in the formation of the nitriles.

The reaction has a high sensitivity to substituent influence. The substituent-effect seems larger than that expected for homolytic reactions, even if electrochemically-generated cyano radicals behave as strong electron acceptors. This suggestion is derived from plotting the relative current yield as a function of the σ-constant (Fig. 2), even though competition experiments should be used in the evaluation of the relative current yields.[2]

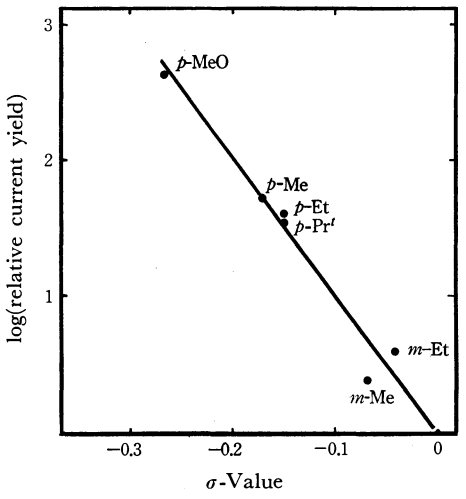

Fig. 2. Correlation of log (relative current yield) and τ for the anodic aromatic cyanation.

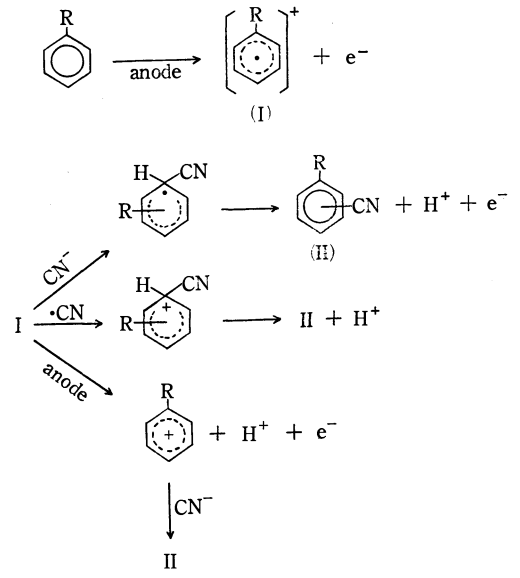
From the considerations described above, we would like to suggest that such good linear correlations are not to be interpreted as resulting from the attack of an electrophilic cyano radical on the aromatic substrate, but as resulting from the direct reflection of the electrochemical behavior of the aromatic compounds at the anode. The aromatic ion radical generated on the anode surface reacts immediately, or through the formation of as aryl or benzyl cation by the loss of a proton and an electron, with either cyanide ion or the radical, resulting in the formation of an aromatic cyano compound. However, if the two anodic substitution reactions, *i. e.*, cyanation and methoxylation, occurs concurrently in this reaction system, and if they proceed *via* a common intermediate, the difference in the isomer distribution between these two substitutions will have to be ascribed to the differences in the electrochemical and chemical behavior of cyanide and methoxide anions.



Experimental

All the melting points and boiling points are uncorrected. The infrared spectra were obtained with a Shimadzu infrared spectrophotometer IR-27C. Gas chromatograms were obtained with a Shimadzu gas chromatograph GC-2A, and a Toyo gas chromatograph GC-S-7.

Materials. Commercially-available methanol (special grade) was dried over calcium hydride and then distilled (bp 64.5°C). Anisole was obtained commercially, washed with aqueous sodium hydroxide, then with water, dried over anhydrous magnesium sulfate, and distilled from sodium; bp 154°C, n_D^{15} 1.5196. Benzene, toluene, ethylbenzene, and cumene were treated with sulfuric acid in a usual manner, and were distilled from sodium through a helices-packed column. The fractions collected had bp's of 80, 111, 135—136, and 151—153°C respectively. Methyl benzoate was obtained commercially, and then distilled; bp 78.5°C/11 mmHg.

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Anisole. A solution of sodium cyanide (8.6 g) and anisole (36 g, 0.33 mol) in methanol (200 m*l*, 160 g) was electrolyzed between a platinum anode (2.5×6.0 cm²) and a mercury-pool cathode (surface area: *ca.* 50 cm²), at 0—5°C with an applied potential of 6 V, at a current of 0.5 A for 20 hr while a slow stream of nitrogen was passed through the solution. The electrodes were spaced *ca.* 1.3 cm apart. At the end of the electrolysis, the current passed through amounted to 9.92 A-hr. Additional sodium cyanide was introduced, portion by portion, as the electrolysis proceeded, until finally 14.9 g of the cyanide had been added by the time the current was stopped. After a

2) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Henry Holt and Co., Inc., New York (1960), pp. 220—230, 434.

usual work-up of the electrolyzed solution, the residue (18 g) was distilled to yield the following fractions: (A), wt 9.7 g, bp 47—49°C at 15 mmHg; (B), 4.1 g, bp 50—125°C at 15 mmHg.

The former fraction was found by gas chromatography to consist of unreacted anisole. The infrared spectrum of the latter fraction exhibited a characteristic absorption band at 2240 cm^{-1}. The cyano products present in fraction B were determined by gas chromatography, and found to be *o*- and *p*-anisnitriles. The yields of *o*- and *p*-anisnitriles were 1.2 and 1.8 g respectively. The gas chromatography was carried out by using a 3 m column packed with 20% polyester DA on fire brick C-22, and hydrogen carrier gas, at a column temperature of 175°C. The retention times of *o*- and *p*-anisnitriles were 24.2 and 22.5 min respectively. The *m*-isomer, whose retention time would be 14.6 min under the conditions employed, could not be detected. The re-distillation of fraction B under reduced pressure gave 2.0 g of an oily distillate; bp 100—128°C at 12 mmHg. The distillate was partially crystallized on cooling, and then separated on a filter.

The solid melted at 59—60°C after recrystallization from ethanol; it was identified as *p*-anisnitrile by a mixed melting point measurement and by a comparison of its infrared spectrum with that of an authentic sample. (Found: C, 72.00; H, 5.48%. Calcd for C_6H_7NO: C, 72.16; H, 5.30%.)

The filtrate was saponified with alcoholic potassium hydroxide to give, after recrystallization from aqueous ethanol, a small amount of *o*-anisic acid, mp 94—96.5°C; mixed mp with authentic *o*-anisic acid, 99—100°C. (Found: C, 63.84; H, 5.82%. Calcd for $C_8H_8O_3$: C, 63.15; H, 5.30%.)

No further attempt was made to investigate other products, *e.g.*, the methoxylated compounds.

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Toluene. A solution of sodium cyanide (12.2 g) and toluene (46.1 g, 0.5 mol) in methanol (300 m*l*, 240 g) was electrolyzed between a platinum foil anode (6.0×5.0 cm^2) and a mercury-pool cathode (*ca.* 50 cm^2) at 0—5°C with an applied potential of 7 V and at a current of *ca.* 1 A for 24 hr. By the end of the electrolysis, the additionally-used sodium cyanide amounted to 22.1 g and the current passed through, to 26.8 A-hr.

The solvent and the bulk of the toluene were removed from the electrolyzed solution and collected in a trap immersed in a dry ice-acetone bath. The gas chromatography of the low-boiling fraction indicated that it contained 39 g of unreacted toluene. The residue emitted a foul odor, and gave an infrared spectrum displaying an absorption band at 2180 cm^{-1}. However, treatment with diluted hydrochloric acid destroyed the odor and gave an infrared absorption band at 3300—3500 cm^{-1}, while the band at 2180 cm^{-1} disappeared. The residue was extracted with ether, and an ether-insoluble solid was removed by filtration. The solid separated on a filter was found to be unchanged sodium cyanide. The filtrate was distilled under reduced pressure to yield, after the removal of the solvent, the following fractions: (A), wt 3.1 g, bp 63—75°C at 13 mmHg; (B), 3.9 g, bp 76—110°C at 13 mmHg; (C), 2.8 g, bp 70—120°C at 0.6 mmHg; (D), 4 g of higher-boiling residue.

The infrared spectroscopic examination of these fractions revealed the presence of some cyano compounds (2240—2260 cm^{-1}), together with methoxylated compounds (1095—1110 and 1250 cm^{-1}) and isonitriles (2180 cm^{-1}). The gas chromatography was carried out by using two columns. The conditions employed and the retention times of the three isomeric tolunitriles identified are listed in Table 3.

TABLE 3. GAS-CHROMATOGRAPHIC ANALYSIS OF ISOMERIC TOLUNITRILES

	P. E. G. 6000, 3 m Column temp., 163°C H_2, min	Polyester DA, 3 m 175°C H_2, min
o-Tolunitrile	8.7	22
m-Tolunitrile	10.4	25.8
p-Tolunitrile	11.4	28.8

The quantitative determination of these three isomers was accomplished by an internal standard method; it indicated that they amounted to 0.221 g (*ortho*), 0.044 g (*meta*), and 0.515 g (*para*), respectively.

Fraction B was chromatographed over alumina. Elution with benzene gave two fractions. The first-eluted oil was heated under reflux with 10% potassium hydroxide in ethanol to yield trace amounts of a white solid, mp 137—140°C. After recrystallization from water, the solid melted at 139—140°C, and it failed to depress the melting point of authentic *o*-toluamide. Moreover, the infrared spectrum was identical with that of an authentic sample. (Found: C, 70.63; H, 6.35%. Calcd for C_6H_9NO: C, 71.09; H, 6.71%.)

The hydrolysis of the second fraction with alcoholic potassium hydroxide gave *p*-toluic acid, mp 178—179°C, undepressed by admixture with an authentic sample. The infrared spectrum was in good agreement with that of an authentic sample. (Found: C, 70.98; H, 5.86%. Calcd for $C_8H_8O_2$: C, 70.57; H, 5.92%.)

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Ethylbenzene. A solution of sodium cyanide (14.2 g) and ethylbenzene (0.5 mol) in methanol (300 m*l*) was electrolyzed at a temperature of 0.5°C with an applied potential of 6—7 V and at a current of 1 A under a slow stream of nitrogen. The nitrogen, accompanied by the gases evolved, was washed with a 1 N acidic silver nitrate solution, and then with a 2 N aqueous sodium hydroxide solution. Additional sodium cyanide (25.8 g) was introduced, portion by portion, into the solution during the electrolysis. The electrolysis was continued until 1.016 faraday had been passed through the solution. As the reaction proceeded, a white precipitate was formed in the silver nitrate solution when portions of it were placed in a washing bottle. After the electrolysis has stopped, the alkaline solution was acidified with diluted nitric acid and silver nitrate was added, thus yielding trace quantitites of silver cyanide.

The electrolyzed solution was worked up in a manner similar to that used for toluene. Distillation gave the following fractions: (A), wt 3.4 g, bp 60—62°C at 14 mmHg; (B), 2.0 g, bp 80—85°C at 14 mmHg; (C), 8.9 g of a residue.

The compounds in each fraction were examined by gas chromatographic and infrared analyses. The infrared spectra of fractions A and B exhibited characteristic absorption bands at 1100—1120, 1250 (C-O-C),

and 2260 (-C≡N) cm^{-1}. The infrared analysis also indicated the presence of some cyano products in the residue. The gas chromatographic analysis was accomplished by using a 3 m column of 25% polyethyleneglycol 6000 on Shimalite, the carrier gas was He (flow rate: 46 ml/min) and the column-temperature, 180°C.

The product distributions in all the fractions are summarized in Table 4.

Table 4. Product distribution in the electrolysis of methanol solution of sodium cyanide in the presence of ethylbenzene

	Weight (g) in		
	Fraction A	Fraction B	Residue
α-Methoxyethylbenzene	2.708	0.086	—
o-Methoxyethylbenzene	0.078	0.036	—
m-Methoxyethylbenzene	0.095	0.199	—
p-Methoxyethylbenzene	0.073	0.205	—
o-Cyanoethylbenzene	0.044	0.18	0.043
m-Cyanoethylbenzene	0.013	0.043	0.022
p-Cyanoethylbenzene	0.037	0.175	0.243

Authentic cyanoethylbenzenes were prepared by the Sandmeyer reaction of aminoethylbenzenes. The infrared spectrum of authentic o-cyanoethylbenzene exhibited characteristic absorption bands at 760 and 2260 cm^{-1}, while p-cyanoethylbenzene showed them at 840 and 2260 cm^{-1}. These two samples were further characterized by gas chromatography. The aminoethylbenzenes used in the Sandmeyer reaction were synthesized by the high-pressure catalytic hydrogenation of a nitroethylbenzene or by the action of zinc on a nitrobenzene in hydrochloric acid. These had bp's of 100—101°C at 17 mmHg (*ortho*) and 57°C at 2 mmHg (*para*). α-Phenylpropionitrile was prepared from hydratripic aldehyde *via* the oxime according to the procedure of Newman and Closson.[3] The nitrile was distilled at 113—116°C at 18 mmHg.

α-Methoxyethylbenzene bp 56—57°C at 9 mmHg, was prepared from methylphenylcarbinol, n-buthyllithium, and dimethyl sulfate. The infrared spectrum showed absorption bands at 700, 750, and 1110 cm^{-1}, and the gas chromatogram displayed a single peak. Ring-methoxylated ethylbenzenes were prepared from the corresponding ethylphenols by methylation with dimethyl sulfate.

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Cumene. A solution of sodium cyanide (15.3 g) and cumene (0.5 mol) in methanol was electrolyzed under conditions similar to those described for toluene. By the end of the electrolysis, 1.033 faraday had been passed through the solution. The total of sodium cyanide used was 40 g. After the electrolyzed solution had been sorked up in a manner similar to that used with toluene, the following fractions were obtained by vacuum-distillation: (A), wt 4.3 g, bp 40—44°C at 8 mmHg; (B), 3.4 g of residue. The infrared spectrum of fraction A exhibited absorption bands at 1100 and 2260 cm^{-1}. The gas chromatography was carried out by using a 3 m column packed with 25% Polyethyleneglycol 6000 on Shimalite; He was the carrier gas (40 ml/min), and the column temperature, 180°C. No evidence for the presence of α-cyanocumene in any fraction could be obtained from the gas chromatographic analysis. The product distributions in all the fractions are given in Table 5.

Table 5. Product distribution in the electrolysis of methanol solution of sodium cyanide in the presence of cumene

	Retention time min	Product (g) in	
		Fraction A	Residue
α-Methoxycumene	6.3	0.09	0.12
o-Cyanocumene	18.8	—	0.31
m-Cyanocumene	24.3	—	0.12
p-Cyanocumene	28.4	—	0.44

A portion (2.2 g) of the residue was chromatographed over silica gel. The fractions eluted with benzene were examined by thin-layer chromatography, and were combined on the basis of their thin-layer chromatographic behavior. The combined oil (0.4 g) was saponified in an autoclave with 10% alcoholic potassium hydroxide at 140°C for 14 hr; it gave, after recrystallization from benzene, a small amount (less than 0.1 g) of p-cumic acid, mp 116—118°C, undepressed by admixture with an authentic sample. (Found: C, 73.35; H, 7.18%. Calcd for $C_{10}H_{12}O_3$: C, 73.14; H, 7.37%.)

Authentic o- and p-cyanocumenes were synthesized by a route similar to that used for the preparation of cyanoethylbenzenes, but the Sandmeyer reaction was carried out using the method given in "Organic Syntheses"[4] for the preparation of o- and p-tolunitriles. α-Cyanocumene was prepared according to the directions of Hauser *et al.*[5,6] These samples were characterized by gas chromatography and infrared analysis. The method used for the preparation of α-methoxycumene, bp 65—68°C at 8 mmHg, was virtually identical with that described for α-methoxyethylbenzene. The other isomeric methoxycumenes were also prepared by the action of dimethyl sulfate on the corresponding sodium phenolates.

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Benzene. A solution of sodium cyanide (15.5 g) and benzene in methanol was electrolyzed until 1.0 faraday had been passed through the solution. Additional sodium cyanide (29.2 g) was then added. A usual work-up of the electrolyzed solution left an oil (0.15 g), bp 30—120°C at 10 mmHg. The infrared spectrum of the oil showed characteristic absorption bands at 700, 760, 1250, and 2250 cm^{-1}. Gas chromatography (columns: 20% Polyester DA on fire brick C-22, 3 m, 25% Apiezon L on Shimalite, 3 m; carrier gas, H_2, 0.5 kg/cm^2; column temperature, 170°C) indicated the presence of benzonitriles with retention times of 5.6 and 2.2 min

3) M. S. Newman and R. D. Closson, *J. Am. Chem. Soc.*, **66**, 1553 (1944).

4) H. T. Clarke and R. R. Read, "Organic Syntheses," Coll. Vol. I, 2nd Ed., 514 (1956).

5) A. Brodhang and C. R. Hauser, *J. Am. Chem. Soc.*, **77**, 3024 (1955).

6) C. R. Hauser and W. R. Brasen, *ibid.*, **78**, 494 (1956).

under these two sets of conditions respectively. Moreover, it gave a peak with the same retention time as that of anisole on the gas chromatogram. The yield of the nitrile was 0.05 g. The treatment of the oil with an alcoholic potassium hydroxide solution under reflux for 24 hr afforded, after purification by sublimation, a trace amount of benzoic acid; mp 121—122°C, undepressed by admixture with an authentic sample. The infrared spectrum of this derivative was identical in all respects with that of an authentic sample.

Electrolysis of Methanol Solution of Sodium Cyanide in the Presence of Methyl Benzoate. The electrolysis was conducted in a manner similar to that used in the experiment with benzene until 1.0 faraday had been passed through the solution. The total amount sodium cyanide used was 39.4 g. After a usua work-up, the following fractions were obtained; (A), wt 3.0 g, bp 44—47°C at 0.8 mmHg; (B), 18.6 g, bp 47—50°C at 0.8 mmHg; (C), 1.6 g, bp 50—90°C at 0.8 mmHg; (D), 5 g of a residue.

The gas chromatographic and infrared analyses of these fractions indicated the absence of any cyano product. Each fraction gave a negative Lassigne sodium decomposition test for nitrogen,[7] and unreacted methyl benzoate was recovered from all of the fractions except the higher-boiling residue.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2668—2671 (1968)

Free Radical Reactions in Organic Electrode Processes. VII.*1 Anodic Reaction of Benzoic Acid with Aromatic Hydrocarbons*2

Kikuhiko KOYAMA, Tatsuyoshi EBARA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Suita, Osaka

(Received December 28, 1967)

The anodic reaction of benzoic acid in acetonitrile containing tiethylamine was carried out in the presence of toluene, ethylbenzene, cumene, and tetralin. The amounts of carbon dioxide evolved during the electrolyses were smaller than those expected to be produced through the spontaneous decomposition of the benzoyloxy radical. An examination of nongaseous products indicated that the anodic reaction proceeds by means of the formation of the benzoyloxylates and phenylates of the aromatic hydrocarbons present. The occurrence of the nuclear benzoyloxylation, to a relatively great extent, suggested that the aromatic hydrocarbons were oxidized at the anode.

In a previous paper from this laboratory, it has been shown that the anodic reaction of some aromatic carboxylic acids in the presence of anisole resulted in the formation of *o*- and *p*-methoxyphenyl esters of the corresponding acids in fairly good yields, together with traces of the Kolbe dimer and of carbon dioxide.[1] The results were interpreted as being due to a simultaneous oxidation of anisole at the anode, leading to the formation of its cation radical.

As has been pointed out by Zweig *et al.*,[2] the aromatic compounds with electron-rich molecular π-orbitals, such as methoxybenzenes, easily lose an electron and so form their cation radicals.

$$ArH \xrightarrow{-e^-} ArH\cdot^+$$

$$ArH \xrightarrow{-2e^-} ArH^{2+} \xrightarrow{+ArH} 2ArH\cdot^+$$

In fact, recent studies of the polarographic oxidation of aromatic compounds have indicated that the half-wave polarographic oxidation potential of aromatic hydrocarbons decreases with an increase in the number of electron-releasing substituents on the benzene ring, or with an increase in the number of fused rings in a series of polynuclear aromatic hydrocarbons.[3,4]

On the other hand, recent studies concerning the

anodic substitution reactions[1,5-10] have indicated that the organic substrates participate in the electrochemical process, generating the cationic intermediates (either the cation radical or the dication), which then react with anions to give the substitution products.

$$ArH \xrightarrow{-e^-} ArH\cdot^+ \xrightarrow{+Y^-} ArHY\cdot \longrightarrow ArY + H^+ + e^-$$

or

$$ArH \xrightarrow{-2e^-} ArH^{2+} \xrightarrow{+Y^-} ArY + H^+$$

The present investigation was undertaken to see if such a mechanism could also be operative in the anodic reaction of benzoic acid with aromatic hydrocarbons with relatively high polarographic oxidation potentials.

Results and Discussion

The electrolyses were carried out in acetonitrile containing triethylamine in the presence of toluene, ethylbenzene, cumene, and tetralin at a temperature of 18—25°C, at a current of 0.08—0.11 A, and with a relatively high applied potential (40—65 V), until a calculated amount of current (2.6—3.0 A-hr) had been passed through the solution.

The gaseous products were then collected, and analyzed by means of a column packed with silica gel. The non-gaseous products, after having been worked up in the usual ways, were separated into unchanged benzoic acid and benzene-soluble and benzene-insoluble materials. The chromatographic separation of the benzene-soluble products yielded a mixture of phenylated and benzoyloxylated aromatic compounds; the mixture was then saponified with alcoholic potassium hydroxide. The products obtained after the saponification were analyzed by vapor-phase chromatography. On the basis of the structure of those characterized phenols and hydrocarbons, the products formed during the electrolysis were determined. In all cases, considerable amounts of benzene-insoluble polymeric residues were produced. Their IR spectra suggested that they had an ester function, but they could not be completely hydrolysed. The results are summarized in Table 1.

The percentage yields given for the non-gaseous products are based on the amounts of benzoic acid not recovered at the end of the electrolysis; the Coulombic yields were calculated for the hydrogen and carbon dioxide evolved.

If the over-all electrode reaction of the carboxylic acids proceeds in exactly the following manner:

$$2RCOO^- \rightarrow 2CO_2 + R\text{-}R + 2e^- \quad (1)$$

$$2H^+ + 2e^- \rightarrow H_2 \quad (2)$$

the quantity should approach two moles of unrecovered carboxylic acid, two moles of carbon dioxide, and one mole of hydrogen per two faradays. However the results, apparently indicate that the addition of aromatic hydrocarbons alters the course of the reaction; the evolved hydrogen reaches 86—100% of the theoretical amount, while the amounts of carbon dioxide are very small. This diminished evolution of carbon dioxide may be

Table 1. Electrolysis of benzoic acid in the presence of aromatic compounds

Acid: Benzoic acid (0.05 mol)
Aromatic compound: 0.4 mol
Solvent: MeCN (50 m*l*) containing Et_3N (2.8 m*l*)

interpreted as being due to the suppressed decarboxylation of an anodically-adsorbed benzoyloxy radical or as being due to the participation of other electrode reactions in which the discharge of the benzoate anion is not significantly operative. From a consideration of the quantitative relationship between hydrogen and the unrecovered acid, it may be suggested that a considerable portion of the hydrogen is not supplied from the electrolysis of benzoic acid, but is, rather supplied from the aromatic substrate present.

Two primary electrode reactions (Eqs. (3) and (4)) are possible in the Kolbe electrolysis:

$$RCOO^- \rightarrow R\cdot + CO_2 + e^- \quad (3)$$

(simultaneous bond-breaking)

$$RCOO^- \rightarrow RCOO\cdot + e^- \quad (4)$$

On the basis of the calculations of the standard potentials and rate constants for the two reactions, Eberson has suggested that, in the anodic reaction of benzoic acid, the latter reaction (Eq. (4)) is probable, and that it is followed by radical decomposition to the phenyl radical and carbon dioxide.[11] A sequent electrode reaction (Eq. (5)) can be ruled out since the ionization potential (9.2 eV)[12] of the phenyl radical is above the critical potential of 8 eV.

$$Ph\cdot \rightarrow Ph^+ + e^- \quad (5)$$

At least three active species, *i.e.*, $PhCOO^-$, $PhCOO\cdot$, and $Ph\cdot$, which can participate in the anodic substitution may be generated from benzoic acid in these systems. Of these however, only the phenyl radical can take part in the phenylation. Thus, the observed phenylation appears to proceed in a free radical manner, while the formation of biphenyl suggests the generation of phenyl radicals:

$$ArH + Ph\cdot \rightarrow Ar(H)(Ph)\cdot \rightarrow Ar\text{-}Ph + H^+ + e^-$$

The other two species, $PhCOO^-$ and $PhCOO\cdot$, can participate in the anodic benzoyloxylation. Homolytic benzoyloxylation has been observed when benzoyl peroxide decomposes in benzene,[13] chlorobenzene,[14,15] nitrobenzene,[14,16] and biphenyl.[13,16] With the mono-substituted benzenes, the extent of the benzoyloxylation is small. Even if the anodically-produced benzoyloxy radical is stabilized by adsorption of the electrode surface, it can undergo spontaneous decomposition; thus, the homolytic phenylation should still proceed as the main reaction. The yields of benzoyloxylates in this anode reaction are, however, rather larger than those expected to be produced by the homolytic processes.

Therefore, it is reasonable to assume that the majority of the benzoyloxylates arise from the reaction of the benzoate anion with a cationic intermediate generated from the aromatic substrate at the anode.

$$ArH \xrightarrow{-e^-} ArH\cdot^+ \xrightarrow{+PhCOO^-} ArOCOPh + H^+ + e^-$$

or

$$ArH \xrightarrow{-2e^-} ArH^{2+} \xrightarrow{+PhCOO^-} ArOCOPh + H^+$$

Experimental

All the melting and boiling points are uncorrected. The IR spectra were obtained with a Shimadzu IR spectrophotometer IR-27C. A Toyo GC-S-7 (gas chromatograph) apparatus was employed in the analysis of the products. The electrolyses were carried out in an undivided cylindrical cell (*ca.* 100 m*l*) fitted with a reflux condenser and a thermometer. Two platinum electrodes (15×20 mm; space, 10 mm apart) were inserted into the center of the cell through a ground-glass joint at the top. The cell was connected through the condenser to a gas-collection apparatus.

Materials. Commercially-availlable benzoic acid (mp 121°C), toluene (bp 110—111°C), ethylbenzene (bp 136°C), cumene (bp 152°C), tetralin (bp 77°C/10 mmHg), acetonitrile (bp 82°C), triethylamine (bp 90°C), and methanol were purified by the usual ways.

Electrolysis of Benzoic Acid in the Presence of Toluene. A solution of benzoic acid (6.1 g, 0.05 mol) and toluene (36.8 g, 0.4 mol) in acetonitrile (50 m*l*) containing triethylamine (2.8 m*l*) was electrolyzed at 18—24°C (current: 0.08—0.11 A, voltage: 40—65 V, total current passed: 2.73 A-hr).

The gas evolved during the electrolysis was then analyzed by using a silica gel column at 20—40°C; it was found to consist of hydrogen (1140 m*l*) and carbon dioxide (80 m*l*). The non-gaseous product was distilled under reduced pressure to recover the solvent and the bulk of the uncharged toluene (22.6 g, 0.25 mol). The residue (9.1 g) was separated into unchanged benzoic acid (2.6 g, mp and mixed mp 120—121°C) and benzene-soluble (2.8 g) and benzene-insoluble (0.9 g) portions. The benzene-insoluble solid (mp over 250°C) displayed IR bands assignable to the ester function at 1240—1280 and 1740 cm^{-1}; it was treated with alcoholic potassium hydroxide under reflux for 15 hr. However, it could not saponified completely. The saponification gave an acid (0.23 g), phenolic compounds (0.1 g) and other materials (0.44 g). These substances were not investigated further.

The benzene-soluble portion gave at least three major spots on TLC and was subjected to chromatographic separation (adsorbent: silica gel; eluent:

11) L. Eberson, *Acta Chem. Scand.*, **17**, 2004 (1963).
12) I. P. Fisher, T. F. Palmer and F. P. Lossing, *J. Am. Chem. Soc.*, **86**, 2741 (1964).

benzene). On the basis of the IR spectra and the results of TLC analysis, the collected fractions were combined after the evaporation of the eluent. The main combined residue (0.5 g) was saponified with alcoholic potassium hydroxide under reflux for 15 hr to give an acid (0.1 g) phenolic compounds (0.09 g) and a neutral portion (0.2 g). The latter two portions were analyzed by vapor-phase chromatography (column: 3-m Cu-column packed with 25% Silicone HV on a fire brick; carrier gas: He, 70 and 37 ml/min respectively; column temperature: 180 and 210°C respectively). The phenolic portion consisted of *m*- and/or *p*-cresol (30.4%), *o*-cresol (9.7%), and other materials. The neutral fraction consisted of *m*- and/or *p*-methylbiphenyl (16.5%), *o*-methylbiphenyl (2.1%), biphenyl, and at least two other unidentified substances.

Additionally, the electrolysis of benzoic acid (6.1 g, 0.05 mol) in methanol (50 ml) containing sodium methoxide (1.1 g) was examined in the presence of toluene (36.8 g, 0.4 mol) under similar conditions (19—24°C; 0.12 A, 15—16 V, 4 A-hr). The gaseous product consisted of hydrogen (1320 ml) and carbon dioxide (110 ml). The benzene-soluble residue (4.3 g) was separated after saponification into acid (1.1 g), a phenolic (0.1 g), and a neutral (0.9 g) portions. The phenolic portion consisted of *m*- and/or *p*-cresol (17.3%), *o*-cresol (8.8%), and other, unidentified substances. The neutral portion consisted of *m*- and/or *p*-methylbiphenyl (1.4%), *o*-methylbiphenyl (0.5%), biphenyl, and other materials.

Electrolysis of Benzoic Acid in the Presence of Ethylbenzene. A solution of benzoic acid (6.1 g, 0.05 mol) ethylbenzene (42.4 g, 0.4 mol) in acetonitrile (50 ml) containing triethylamine (2.8 ml) was electrolyzed at 16—28°C, at a current of 0.07—0.11 A and with an applied potential of 48—69 V, for 25 hr.

The gaseous product consisted of hydrogen (980 ml) and carbon dioxide (170 ml). The non-gaseous product was worked up in manners similar to those employed for toluene, and gave unchanged ethylbenzene (30 g, 0.23 mol), benzoic acid (1.5 g), a benzene-soluble portion (3.2 g), and a benzene-insoluble polymeric solid (0.7 g). The chromatographic separation of the benzene-soluble portion gave a hydrocarbon - benzoate mixture (0.7 g) and a dark-brownish residue. The mixture was treated with alcoholic potassium hydroxide to give benzoic acid (0.17 g), phenolic (0.19 g), and neutral (0.37 g) portions. The phenol portion was found to consist of *o*-ethylphenol (6.6%), *p*-ethylphenol (16.2%), and other materials. The vapor-phase chromatographic analysis of the neutral substances showed it to contain *o*-ethylbiphenyl (21.5%), *p*-ethylbiphenyl (49.8%), biphenyl (traces), α-phenylethanol, and at least two other substances.

Electrolysis of Benzoic Acid in the Presence of Cumene. A solution of benzoic acid (6.1 g) and cumene (48 g, 0.4 mol) in acetonitrile containing triethylamine was electrolyzed under similar conditions (17—25°C, 0.04—0.11 A, 54—60 V, 2.97 A-hr). A mixture of hydrogen (1100 ml) and carbon dioxide (120 ml) was obtained as the gaseous product. From the electrolyzed mixture, unchanged cumene (33.5 g, 0.28 mol) and residual tar (8.8 g) were obtained. The residue was spearated into benzoic acid (1.7 g), benzene-soluble (3.1 g), and insoluble (1.2 g) portions. A hydrocarbon - benzoate mixture (0.57 g) was obtained from the benzene-soluble portion. The mixture gave, after saponification, benzoic acid (0.2 g), phenol (0.1 g) and neutral (0.32 g) portions. The characterized components of the phenol portion were *o*-isopropylphenol (8.7%) and *p*-isopropylphenol (37.6%). *o*-Isopropylbiphenyl (7%), *p*-isopropylibiphenyl (19.7%), biphenyl (traces), and α-cumenol (traces) could be identified as the components of the neutral fraction.

Electrolysis of Benzoic Acid in the Presence of Tetralin. The electrolysis was carried out by using tetralin (47.8 g, 0.35 mol) under similar conditions (18—28°C, 0.08—0.11 A, 56—68 V, and 2.63 A-hr).

The gaseous product consisted of hydrogen (990 ml) and carbon dioxide (40 ml). Tetralin (14 g, 0.31 mol) and a residual oil (13.7 g) were obtained from the crude product. The residual oil gave benzoic acid (2.6 g), benzene-soluble (5.2 g), and insoluble (0.6 g) fractions. Portions (2 g) of the benzene-soluble fraction were chromatographed on silica gel and eluted with a benzene - methanol mixture to give a hydrocarbon - benzoate mixture (1.06 g) The saponification of the mixture yielded benzoic acid (0.2 g), phenolic (0.15 g) and neutral (0.3 g) parts. The VPC analysis of the neutral part failed to show the presence of 1-hydroxy-1,2,3,4-tetrahydronaphthalene.

Episulfones. IV. The Decomposition Reaction of Episulfones by Bases

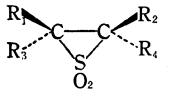
Shoichi Matsumura, Toshikazu NAGAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received January 25, 1968)

The present paper deals with the decomposition reaction of episulfones in the presence of several bases. The treatment of *cis*-stilbene episulfone (I) with 2 N NaOH gave *trans*-stilbene in a 92% yield, and a hydrogen-deuterium exchange experiment using NaOD showed that 66% of the methine protons of the episulfone were exchanged. On the other hand, the reaction of *n*-butyllithium yielded *cis*-stilbene predominantly, along with *trans*-1,2-diphenylvinyl sulfinate in about a 20% yield. Styrene episulfone (II) gave styrene (80%) and a trace of benzyl methyl sulfone when II was treated with alkali. Tetraphenylethylene episulfone (III) afforded tetraphenylethylene almost quantitatively. The cleavage mechanism by bases is then discussed on the basis of the above results. Ethylene episulfone (IV) is oligomerized by tertiary-amine catalysis.

We have been studying the physical and chemical behavior of episulfones (thiirane 1,1-dioxide) and have previously reported some new reactions.[1a,b] In the present paper, we wish to report on the base-catalyzed decompositions of episulfones and on their mechanisms. The reaction of episulfones with a base to give olefins has been investigated by several workers,[1c,2] but the reaction mechanism has not yet been clarified. In this paper, we will describe the decompositions of several episulfones (I—IV) with various bases and suggest the reaction mechanism.



(I) $R_1=R_2=C_6H_5$ $R_3=R_4=H$
(II) $R_1=C_6H_5$ $R_2=R_3=R_4=H$
(III) $R_1=R_2=R_3=R_4=C_6H_5$
(IV) $R_1=R_2=R_3=R_4=H$
(V)[2] $R_1=R_2=CH_3$ $R_3=R_4=H$

The results of the decomposition of *cis*-stilbene episulfone (I) by various bases are summarized in Table 1.

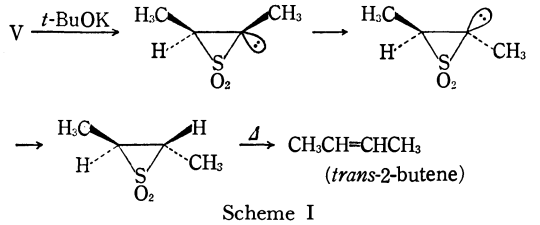
cis-Stilbene episulfone was decomposed to *trans*-stilbene predominantly by the reaction with alkali, while the treatment of I with *n*-butyllithium afforded *cis*-stilbene predominantly. Triethylamine did not cleave the episulfone under the same conditions (0°C, 6 hr).

Recently, Neureiter[2] has proposed a mechanism in which the elimination of α-protons of V by a stronger base is followed by the epimerization to the α-sulfonyl carbanion of the *trans*-form during the process of exchange forming *trans*-olefin by a thermal process; treatment with the *t*-butoxide ion, the strong, hindered base (in *t*-BuOD), resulted in the formation of *trans*-2-butene in a 80% yield, with complete deuteration at the 2 and 3-positions (Scheme 1).

TABLE 1. DECOMPOSITION OF *cis*-STILBENE EPISULFONE (I) BY SEVERAL BASES

Base	Solvent	Temp. (°C)	*cis*-Stilbene	*trans*-Stilbene (%)
2 N NaOH	40%THF-H_2O	0	7	92
2 N LiOH	40%THF-H_2O	0	5	90
2 N KOH	40%THF-H_2O	0	2	89
n-BuLi	THF	0	70	6
$N(Et)_3$	THF	0	No Decomposition	

cis-Butene was favored when V was treated with a weaker base, suggesting that the α-hydrogens were not eliminated in this case.



Scheme I

However, a thermal process to give the *trans*-olefin from the *trans*-episulfone can not be accepted, since the *trans*-episulfone of I or V could not be isolated, even at a low temperature. For this reason, we have tried to isolate the intermediate of the reaction in order to clarify the mechanism.

In order to trap the intermediate, we tried to treat the episulfone (I) with *n*-butyllithium at a low temperature (0°C). We chose the 1,2-diphenyl derivatives because of the ability of the phenyl group to stabilize the system by conjugation.

When I was treated with *n*-butyllithium in

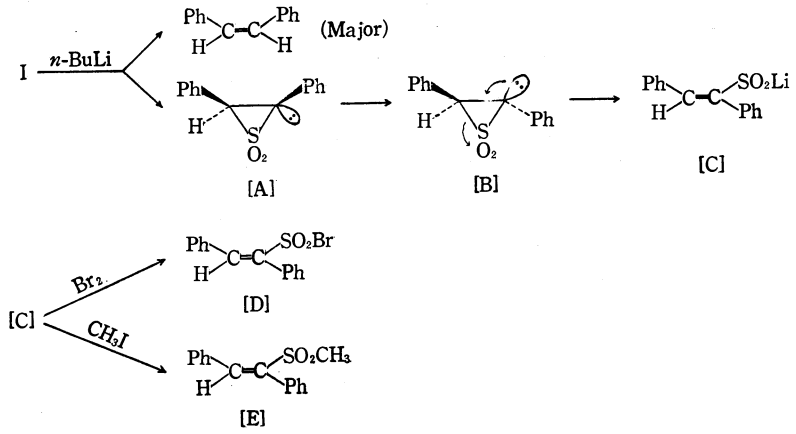
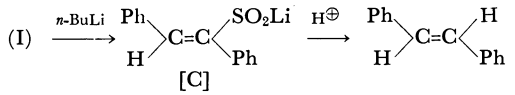


Scheme II

THF, and then with bromine or methyl iodide, *trans*-1,2-diphenylvinylsulfonyl bromide [D] and *trans*-1,2-diphenylvinyl methyl sulfone [E] were formed in 16 and 9% yields respectively, even at 0°C.[3]

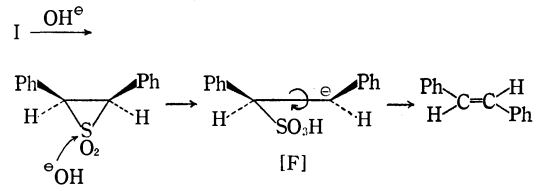
These products were obviously generated through the ring-opening compound, *trans*-1,2-diphenylvinyl sulfinate [C], which was itself formed through [A], and then converted to [B]. The reactions described are outlined in Scheme II.[4]

The above-mentioned results suggest that the formation of *trans*-stilbene or *trans*-2-butene passes through Schemes II and III, if the bases which can eliminate the α-hydrogens but can not attack the sulfur atom of the episulfone, are used.[5] [C] did decompose to *trans*-stilbene when treated with acid.[6]



Scheme III

On the other hand, as there was a 66% hydrogen-deuterium exchange of I in the NaOD-D_2O system, the α-hydrogens are certainly eliminated prior to the formation of the [C] intermediate (Scheme III). The [C] intermediate is not unstable at 0°C, so it might be trapped by bromine or methyl iodide if the reaction followed Scheme III. However, our attempts to trap the [C] intermediate were unsuccessful. Therefore, we assumed a mechanism in which the olefinic product (*trans*-stilbene) arose as a result of a nucleophilic attack on the sulfur atom of the episulfone.[7] (Scheme IV).



Scheme IV

The difference between *n*-BuLi and $OH^{\ominus}$ may be ascribed to the fact that *n*-BuLi is rather sterically hindered to attack the sulfur atom. (The H–D exchange reaction might be fast, and the α-sulfonyl carbanion intermediate [A], considerably stable.) Although the [F] intermediate is stable enough to rotate around the C–C single bond, the similar intermediate which arises in the case of V seems to be unstable, giving *cis*-2-butene predominantly before the rotation.

In this connection, it is interesting to note that these results demonstrate that the isomerization of α-sulfonylcarbanion in a three-membered system would also occur.[8]

As may be seen in Table 1, *cis*-stilbene was favored over the *trans*-isomer when *n*-butyllithium was used as the base. This may be interpreted in terms of the finding[1a] that the carbanion formation of I with *n*-butyllithium is slower than the thermal

3) The geometrical configurations of these two compounds, [D] and [E], were decided on the basis of a comparison of their mp's with those of an authentic specimen [E]. (M. Ōki and A. Kimura, This Bulletin, **38**, 682 (1965)).

4) Recently, L. A. Carpino and R. H. Rynbrondt (*J. Am. Chem. Soc.*, **88**, 5682 (1966) have proposed that, in vinylene sulfones, α-hydrogen is eliminated to give acetylene. However, this reaction has no relation to the stereochemical correlation.

5) Since the isomerization from [A] to [B] would be fast, [A] would not decompose to *cis*-stilbene. However, we cannot completely exclude a mechanism in which *trans*-stilbene is formed through [B], accompanied by the thermal elimination of sulfur dioxide, as has similarly been suggested by Neureiter.[2]

6) W. E. Truce and J. R. Norell, *J. Am. Chem. Soc.*, **85**, 3036 (1963).

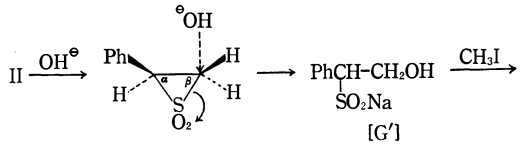
7) A similar mechanism was recently presented by L. A. Paquette and L. S. Wittenbrook, *ibid.*, **89**, 4483 (1967).

8) E. J. Corey, H. Konig and T. H. Lowy, *Tetrahedron Letters*, **1962**, 515.

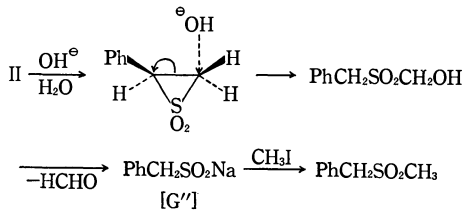
decomposition[1c] of I. *trans*-2-Butene was formed predominantly when V was treated with *t*-butoxide ion, because the carbanion formation was faster than the thermal elimination of sulfur dioxide (Scheme I).[2]

When styrene episulfone (II) was treated with alkali (2 N NaOH), styrene (80%), and a trace of the sulfinate, [G'] or [G''] (identified as benzyl methyl sulfone (0.4%)) was produced. The process of the formation of styrene may be analogous to the mechanistic route described in Scheme IV, and the benzyl sulfone may be formed according to either Scheme V or VI.[9]

Scheme V shows a C–S bond fission, and Scheme VI involves an interesting C–C bond cleavage.[1a,b] It is not yet clear which of the two schemes is correct.

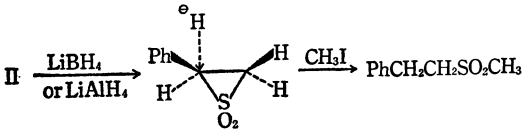


Scheme V



Scheme VI

The hydroxide-ion attack on the β-carbon of II essentially resembles the reaction of styrene oxide. It is interesting to compare with findings previously reported;[1a] the α-carbon of II was selectively attacked by the hydride ion ($LiBH_4$ or $LiAlH_4$) (Scheme VII). The sterically larger molecule, $OH^{\ominus}$, should attack a less hindered site.



Scheme VII

Recently, Desiderate and Sass[10] reported on the crystal structure of *cis*-2-butene episulfone V and showed that the C–C bond length is, surprisingly, 1.60 Å (which is much longer than those of epoxide (1.47 Å) and episulfide (1.49 Å)). Our previous proposal[1a] concerning this abnormal bond length is thus confirmed; however, we are now studying this point in detail.

Tetraphenylethylene episulfone (III) gave tetraphenylethylene exclusively (92%) when III was treated with 2 N NaOH, probably by attacking the sulfur atom as is described in Scheme IV.

These results suggest that the sulfur atoms of episulfones are attacked by $OH^{\ominus}$, giving olefins.

Ethylene episulfone (IV) was first synthesized by Hesse *et al.*, and several reactions toward the episulfone have been reported on; for example, when IV was treated with NaOH, unidentified products were produced. We used *t*-amines, such as pyridine, triethylamine, and 2,6-lutidine, and found that an oligomerization occurs. The elemental analyses of these products are summarized in Table 2. The products were insoluble in almost all solvents except for an alkali solution, while there was an accompanying decomposition. (The oligomers did not dissolve in concentrated H_2SO_4.)

It is well known that the olefins containing strong electron-withdrawing groups are polymerized even by *t*-amines such as triethylamine. Compared with other heterocyclic three-membered rings, episulfones are easily attacked by nucleophilic reagents because of having a strong electron-withdrawing sulfone group.

The structure of the oligomers would seem to be:

$$-(-CH_2CH_2-SO_2-)_{\overline{n}}$$

However, these products were all insoluble in the solvents, and only the IR spectra and elemental analysis gave any information, however little, about the structures. Because of the insolubility, the molecular weights could not be measured, but if the terminals are *t*-amines, the degrees of polymerization can not be very high.

TABLE 2. ELEMENTAL ANALYSES, DECOMPOSITION POINTS, AND YIELDS OF THE POLYMER (25°C, Base/IV = 1/4).

Base	C	H	N	S	D.P.	Yield (%)
	27.44	4.32	2.00	23.48	270	57

Experimental

Materials. The *cis*-stilbene episulfone (I), styrene episulfone (II), tetraphenylethylene episulfone (III), and ethylene episulfone (IV) were synthesized as has described in a previous paper.[1a]

9) D. C. Dittmer and M. E. Christy, *J. Am. Chem. Soc.*, **84**, 399 (1962).
10) R. Desiderate and R. L. Sass, *Acta Cryst.*, **23**, 430 (1967).

The sodium deuteroxide and deuterium oxide were obtained from Ciba Ltd.

The tetrahydrofuran was purified by refluxing it with sodium for two days, followed by distillation in the presence of lithium aluminum hydride.

All the melting points and boiling points are uncorrected. The infrared absorption spectra were determined on a Hitachi Infrared Spectrophotometer. The NMR Spectra were run on a Nihondenshi Spectrometer at 60 Mc. Tetramethylsilane was used as an internal standard, and *d*-chloroform was used as the solvent (Ciba Ltd.). Vpc analysis was carried out on a Yanagimoto Model GCS-100 Instrument.

Reaction of Episulfones with Alkali (General Procedure). A mixture of an episulfone (about 0.002 mol) and aqueous 2 N alkali (40%) in a THF-solution (50 m*l*) was stirred for 20 min at 0°C. The reaction mixture was then added to ice water (50 m*l*) and extracted twice with 50 m*l* of ether. After the combined ether layer had been dried over sodium sulfate (anhydrous), the ether was removed under reduced pressure. The products were identified as follows. The *cis*- and *trans*-stilbene were separated by fractional crystallization. (The *cis*-stilbene was identified as has been described in a previous paper,[1c] while the *trans*-form was a solid material which melted at 124°C.) The styrene was determined by Vpc. The benzyl methyl sulfone and tetraphenylethylene were identified by comparison with authentic specimens (mp 123°C and 222°C respectively).

A deuterium exchange experiment was carried out under nitrogen; the procedure was similar to that described above. The *d-trans*-stilbene was analysed by means of the NMR spectra. The ratio of the area of the peak due to phenyl protons to that area due to olefin protons was 15 : 1, showing that 70% of the olefin protons were deuterated (τ(phenyl) 2.6, (olefin 2.85)).

Reaction of *cis*-Stilbene Episulfone (I) with *n*-Butyllithium. *n*-Butyllithium (about 0.002 mol) was prepared in dry THF, and to this solution *cis*-stilbene episulfone (1.0 g; 0.004 mol) in THF (10 m*l*) was added slowly at 0°C. After the reaction mixture had then been stirred for 30 min, bromine (3.0 g) or methyl iodide (3.0 g) was added, drop by drop; the solvents were then evaporated under reduced pressure. The products were separated on the basis of their solubility; that is, *trans*-1,2-diphenylvinylsulfonyl bromide was soluble in petroleum ether, while the residue (dibromostilbene) was sparingly soluble in petroleum ether. *trans*-1,2-Diphenylvinyl methyl sulfone was also separated and recrystallized from ether-petroleum ether.

The product [D], *trans*-1,2-diphenylvinylsulfonyl bromide, was identified on the basis of the following data: mp 122—124°C, NMR (in $CDCl_3$) τ=2.88 (5H, multiplet, aromatic) 2.53 (5H, singlet, aromatic) 2.21 (1H, singlet, olefinic porton), IR ν_{max}^{KBr} 1620, 818 (tri-substituted olefin) 1350, 1148 cm^{-1} (ν_{SO_2}), UV $\lambda_{max}^{95\%EtOH}$ 287 (14700), 270 (14800), 216 mμ (ε 20300). Found: C, 51.94; H, 3.23%. Calcd for $C_{14}H_{11}BrO_2S$: C, 52.02; H, 3.43%.

trans-1,2-Diphenylvinyl methyl sulfone [E] was identified on the basis of the following data: mp 118—119°C, NMR (in $CDCl_3$) τ=7.21 (3H, singlet, CH_3), 2.84 (5H, multiplet, aromatic), 2.56 (5H, singlet, aromatic), 2.17 (1H, singelt, olefinic proton), IR ν_{max}^{KBr} 1645, 825 (tri-substituted olefin) 1308, 1315, 1132 cm^{-1} (ν_{SO_2}). UV $\lambda_{max}^{95\%EtOH}$ 267 (17400), 217 mμ (ε 23000).

Found: C, 69.81; H, 5.61%. Calcd for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46%.

Reaction of Ethylene Episulfone (IV) with *t*-Amines (General Procedure). A mixture of ethylene episulfone (0.023 mol) and *t*-amines (0.005 mol) in THF (20 m*l*) was allowed to stand for two days at room temperature. The resulting precipitates were washed three times with 95% ethanol, and then three times with water, and dried in a desiccator.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2676—2682 (1968)

The Acylation of 2,3-Dimethyl-*bz*-hydroxybenzofurans and the Syntheses of Di- and Tri-methylfuroisoflavones*[1]

Yoshiyuki KAWASE, Mutsumu NANBU and Fumihisa MIYOSHI

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received March 2, 1968)

The acylation of 2,3-dimethyl-4-hydroxybenzofuran (1) with acetic acid, phenylacetic acid, 2-methoxyphenylacetic acid or 2,4,5-trimethoxyphenylacetic acid, and polyphosphoric acid gave a mixture of the 5- and 7-acyl compounds (2a, b, c, d, and 3a, c, d respectively). Analogously, the isomeric 2,3-dimethyl-6-hydroxybenzofuran (6) gave the 5-acyl compounds (7a, b, c, d), two (7a, b) of which were also obtained by the Friedel-Crafts acylation of the methyl ether of 6 (9), followed by demethylation. On the other hand, the formation of a dimethylfuran ring on 2,4-dihydroxyphenyl ketones by the action of polyphosphoric acid on their 4-(α-acetylethoxy) derivatives (11a, b, c) also afforded mixtures of the ketones (7a, b, c) and isomeric ketones (2a, b, c). The benzofuranyl ketones (2 and 7) thus obtained were converted to the corresponding 4'',5''-dimethyl-furo[2'',3'':7,8]isoflavones (12b, c, d) and isomeric -furo[3'',2'':6,7]isoflavones (14b, c), and also their 2-methyl derivatives (13b, c, d and isomeric 15b, c), by the general method utilizing ethyl orthoformate, piperidine and pyridine, or acetic anhydride and sodium acetate. The furoisoflavones (12b, c and 13b, c) were also prepared by building up the dimethylfuran ring on 7-hydroxyisoflavones by the action of polyphosphoric acid or sulfuric acid on their 7-(α-acetylethoxy) derivatives (16b, c and 17b, c respectively). The alkaline degradation of these furoisoflavones (12 and 13) also gave the benzofuranyl ketones (2)

Previously, furo[2'',3'':7,8]isoflavones[1,2] and the 4''-methyl derivative[2a] were prepared by building up the furan ring on 7-hydroxyisoflavones, while the 5''-alkyl derivatives[3] and isomeric furo[3'',2'' : 6,7]isoflavones[4] were prepared by the dehydrogenation of the corresponding dihydrofuroisoflavones. The furoisoflavones were also prepared by the pyrone ring formation on hydroxybenzofuranyl ketones.[1-3]

In the present experiments, 2,3-dimethyl-4- and isomeric -6-hydroxy-5-benzofuranyl ketones (2 and 7), which had been prepared by the acylation of the corresponding hydroxy- or methoxybenzofurans (1 and 6 or 9), were converted to furo[2'',3'' : 7,8]isoflavones (12 and 13) and isomeric furo[3'',2'':6,7]isoflavones (14 and 15) respectively by the formation of a pyrone ring on them. Two furoisoflavones (12 and 13) were also prepared by building up the dimethylfuran ring on 7-hydroxyisoflavones; the alkaline degradation of these furoisoflavones also gave the benzofuranyl ketones (2).

Previously, 4-hydroxy- or 4-methoxy-5-benzofuranyl ketones were prepared by the interaction of benzofurancarbonyl chloride with ethyl phenylacetate[2a] or with dibenzylcadmium[5]; also, these ketones as well as the isomeric 6-hydroxy-5-benzofuranyl ketones were prepared by the alkaline degradation of furoisoflavones,[1,4] for the direct acylation of hydroxybenzofurans to give the ketones was not successful. On the other hand, the 2-substituted 6-hydroxy-[6] or 6-methoxy-5-benzofuranyl methyl ketones[7] were obtained by the acetylation of the corresponding benzofurans,

*1 A part of this work was presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1967.

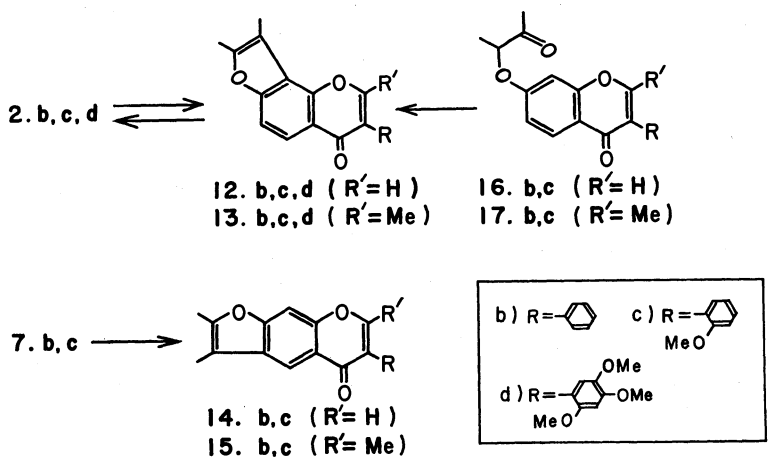

Chart 2

while the acetylation of isomeric 4-methoxy-2-methoxycarbonylbenzofuran afforded the 7-acetyl compound.[7] It has also been reported[8] that the acetylation of 2,3-dimethyl-6-methoxybenzofuran (9) by the Friedel-Crafts reaction gave the 5-acetyl compound (10a), which was then demethylated to the hydroxyketone (7a), while that of isomeric 2,3-dimethyl-4-methoxybenzofuran (4) gave the 7-acetyl compound (5).

8) R. Royer, E. Bisagni, A.-M. Laval-Jeantet and J.-P. Marquet, *Bull. Soc. Chim. France*, **1965**, 2607.

In the present experiments, 2,3-dimethyl-4-hydroxybenzofuran[8] (1) was acylated with acetic acid, phenylacetic acid, 2-methoxyphenylacetic acid or 2,4,5-trimethoxyphenylacetic acid, and polyphosphoric acid to give a mixture of the 5- and 7-acyl compounds (2a, b, c, d and 3a, c, d respectively), analogously to the case of 2,3-dihydro-4-hydroxybenzofuran.[9] The 5-acyl compounds (2) were separated from the isomers (3) by the extraction of the latter from the mixture with aqueous sodium hydroxide.

The similar acylation of isomeric 2,3-dimethyl-6-hydroxybenzofuran[8] (6) gave the 5-acyl compounds (7a, b, c, d); 7a and 7b were also prepared by the Friedel-Crafts acylation of methoxybenzofuran (9), followed by demethylation. In the case of the 2-methoxyphenylacetyl derivative (7c), a small amount of an isomeric 7-acyl compound (8c) was also obtained; the structure of this was assigned on the basis of its positive ferric chloride color reaction and the analogous formation of 7-substituted compounds in the acetylation of 6-methoxy-2-methoxycarbonylbenzofuran[7] and in the condensation of 2,3-dimethyl-6-hydroxybenzofuran with ethyl phenylmalonate.[10]

On the other hand, 2,4-dihydroxyphenyl ketones were converted to 4-(α-acetylethoxy)-2-hydroxyphenyl ketones (11a, b, c) by the action of 3-chlorobutanone-2 and potassium carbonate; the subsequent dehydro-cyclization of these ethers (11) by the action of polyphosphoric acid afforded mainly the 6-hydroxy-5-benzofuranyl ketones (7a, b, c), the dimethylfuran ring being formed towards the unhindered 5-position of the ketones, and also gave small amounts of isomeric 4-hydroxy-5-benzofuranyl ketones (2a, b, c). These experiments confirmed the structures of these ketones (2 and 7).

The *o*-hydroxybenzofuranyl ketones (2a, b, c and 7b, c) thus obtained were converted to the corresponding 4'',5''-dimethylfuro[2'',3'':7,8]-isoflavones (12b, c, d) and 4'',5''-dimethylfuro-[3'',2'':6,7]isoflavones (14b, c) by the action of ethyl orthoformate and piperidine in pyridine, and were also converted to 2,4'',5''-trimethylfuro-[2'',3'':7,8]isoflavones (13b, c, d) and 2,4'',5''-trimethylfuro[3'',2'':6,7]isoflavones (15b, c) by the action of acetic anhydride and sodium acetate.

The furo[2'',3'':7,8]isoflavones (12 and 13) were also obtained by building up the dimethylfuran ring on 7-hydroxyisoflavones. 7-Hydroxyisoflavones were converted to 7-(α-acetylethoxy) derivatives (16b, c and 17b,c) by the action of 3-chlorobutanone-2 and potassium carbonate; the subsequent dehydro-cyclization of these ethers with polyphosphoric acid or concentrated sulfuric acid afforded the furoisoflavones (12b, c and 13b, c). In this case, the dimethylfuran ring is formed towards the 8-position of isoflavones, because this position is not as hindered as the 3-position of 4-(α-acetylethoxy)-2-hydroxyphenyl ketones (11), for the one hydroxyl group of the latter is blocked by the formation of the pyrone ring in the former, and because the position is the most reactive site in such electrophilic substitutions as chloromethylation,[11] Mannich reaction,[12] Claisen rearrangement,[3a] Fries rearrengement,[2a] and formylation.[1,2a]

The alkaline degradation of the furo[2'',3'':7,8] isoflavones (12 and 13) also afforded the 4-hydroxy-5-benzofuranyl ketones (2); this method is another route for the preparation of the ketones (2).

In the infrared spectra, the di- (12b, c, d and 14b, c) and tri-methylfuroisoflavones (13,b c, d and 15b, c) exhibit an absorption at about 1655—1640 cm^{-1} (ν_{CO}), much as the furoisoflavones without dimethyl groups have an absorption at about 1650—1634 cm^{-1}.[1,4,9]

In the ultraviolet spectra, the furo[2'',3'':7,8]-isoflavones (12b, c and 13b, c) have two bands, a strong band, I, at about 247—255 mμ and a weak band, II, at about 313—320 mμ, while the isomeric furo[3'',2'':6,7]isoflavones (14b, c and 15b, c) have corresponding bands at about 248—254 mμ and at 330—338 mμ respectively. These data show that the band II of furoisoflavones with a linearly-fused furan ring is at a wavelength longer by 17—18 mμ than is that of the isomers with an angularly-fused furan ring, but the band I is at almost the same wavelength. These figures are comparable to those of furoisoflavones without dimethyl groups[1,4,9]; this proves that the introduction of dimethyl groups to the furan ring of furoisoflavones causes a bathochromical shift of 10—13 mμ in the band II and one of 2—7 mμ in the band I.

Experimental*2

The Preparation of Benzofuranyl Ketones. *a) By the Acylation of 2,3-Dimethyl-hydroxybenzofurans (1 and 6) with Carboxylic Acid and PPA.**3 A mixture of 2,3-dimethyl-4-hydroxybenzofuran[13] (1) (5 g), acetic acid (2.2 g, 1.2 mol equivalents), and PPA (n=1.5, 125 g) was heated at 90°C for 1 hr with stirring. The cooled mixture was then poured into ice water and extracted with ether. The ethereal solution was washed with

aqueous sodium carbonate and then extracted with aqueous sodium hydroxide. The product obtained from the ethereal solution was recrystallized from ethanol to give 2,3-dimethyl-4-hydroxy-5-benzofuranyl methyl ketone (2a), which had a positive ferric chloride color reaction in ethanol. The alkaline solution was acidified, and the crystalline product formed was collected and recrystallized from ethanol to give the isomeric 2,3-dimethyl-4-hydroxy-7-benzofuranyl methyl ketone (3a), which had a negative ferric chloride color reaction in ethanol.

Similarly, the 2,3-dimethyl-4-hydroxy-5-benzofuranyl

benzyl ketones (2b), the 2,3-dimethyl-4-hydroxy-5-benzofuranyl 2-methoxybenzyl ketones (2c), the 2,3-dimethyl-4-hydroxy-5-benzofuranyl 2,4,5-trimethoxybenzyl ketone (2d), the isomeric 2,3-dimethyl-4-hydroxy-7-benzofuranyl 2-methoxybenzyl ketone (3c), and the 2,3-dimethyl-4-hydroxy-7-benzofuranyl 2,4,5-trimethoxybenzyl ketone (3d) were obtained by this procedure.

Further, the acylation of isomeric 2,3-dimethyl-6-hydroxybenzofuran[13] (6) by this procedure gave the 2,3-dimethyl-6-hydroxy-5-benzofuranyl methyl ketone (7a), the 2,3-dimethyl-6-hydroxy-5-benzofuranyl benzyl ketone (7b), the 2,3-dimethyl-6-hydroxy-5-benzofuranyl 2-methoxybenzyl ketone (7c), and the 2,3-dimethyl-6-hydroxy-5-benzofuranyl 2,4,5-trimethoxybenzyl ketone (7d). The ketone 7a has a mp of 121—123°C (from ethanol) (lit.[8] mp 122°C) and ν_{max}: 1650 cm^{-1} (CO). In the case of the ketone 7c, a small amount of the isomeric 2,3-dimethyl-6-hydroxy-7-benzofuranyl 2-methoxybenzyl ketone (8c) was also obtained.

b) By the Acylation of 2,3-Dimethyl-6-methoxybenzofuran (9), Followed by Demethylation. i) Methoxy-ketone 10b: Powdered anhydrous aluminum chloride (2 g) was added to a solution of 9[13] (2.6 g) and phenylacetyl chloride (2.4 g) in benzene (15 m*l*); the mixture was stirred at room temperature for 2 hr and then poured into ice water and extracted with benzene. The benzene was distilled off, and the residual product was recrystallized from ethanol to give the 2,3-dimethyl-6-methoxy-5-benzofuranyl benzyl ketone (10b), which had a negative ferric chloride color reaction in ethanol.

ii) Demethylation: Amixture of 10b (1.5 g), benzene (10 m*l*), and aluminum chloride (1 g) was refluxed for 10 min. The cooled mixture was poured into ice water and extracted with benzene. The benzene was distilled off, and the residue was recrystallized from ethanol to give the ketone 7b, which had a positive ferric chloride color reaction in ethanol. Some 10b was recovered from the mother solution.

c) By the Acylation of 9 in One Step. Aluminum chloride (3.1 g) was added to a solution of 9 (2.6 g) and phenylacetyl chloride (2.4 g) in benzene (15 m*l*); the mixture was stirred at room temperature for 2 hr and then refluxed for 10 min. The cooled mixture was treated much as has been described above to give the ketone 7b.

The ketone 7a was also prepared by this procedure.

d) By the Furan-ring Formation on 2,4-Dihydroxyphenyl Ketones through 4-(α-Acetylethoxy)-2-hydroxyphenyl Ketones (11). A mixture of the 2,4-dihydroxyphenyl methyl ketone (6.8 g), 3-chlorobutanone-2 (5.2 g), anhydrous potassium carbonate (15 g), potassium iodide (0.5 g), and acetone (60 m*l*) was refluxed for 7 hr. The cooled mixture was treated with water and extracted with ether. The ethereal layer was washed with aqueous sodium hydroxide, and then the ether was distilled off. The residual product was distilled to give the 4-(α-acetylethoxy)-2-hydroxyphenyl methyl ketone (11a); bp 148—153°C/2.5 mmHg, 5.9 g (59%). In the case of 11a, the analytical sample was recrystallized from petroleum ether.

A mixture of this crude ether 11a (1.5 g) and PPA

a) A: Ethyl acetate, E: Ethanol, P: Petroleum ether. b) These of homologous compounds are: furo-(2'',3'':7,8)isoflavone, 1640; 2'-methoxy-, 1650; 2-methyl, 1635; 2'-methoxy-2-methyl-, 1640.

(n=1.5, 40 g) was heated at 80°C for 1 hr with stirring. The cooled mixture was poured into ice water and then extracted with ether. The ethereal layer was washed with aqueous sodium carbonate, and the ether was distilled off. The residual product was crystallized to give the ketone 7a. A small amount of the isomeric ketone 2a was also obtained from the mother solution of the crystallization of 7a.

Similarly, the ketone 7b and a small amount of isomeric 2b were also obtained by this procedure through the 4-(α-acetylethoxy)-2-hydroxyphenyl benzyl ketone (11b); bp 180—220°C/4 mmHg (yield 76%), ν_{max}: 1720 and 1620 cm^{-1} (CO). The ketone 2c and the isomeric 7c were also obtained through the 4-(α-acetylethoxy)-2-hydroxyphenyl 2-methoxybenzyl ketone (11c); bp 200—250°C/10 mmHg (yield 79%).

e) By the Alkaline Degradation of Furoisoflavones. A mixture of the furoisoflavone, 12b (1.1 g), 50% aqueous potassium hydroxide (5 g), and ethanol (60 m*l*) was refluxed for 3 hr, and then most of the ethanol was distilled off. The residue was diluted with water and acidified. The crystalline product formed was collected and recrystallized from ethanol to give the ketone 2b.

Similarly, the ketones 2b and 2c were obtained from the furoisoflavones 13b and 13c respectively.

The Preparation of Furoisoflavones. *a) By the Furan-ring Formation on 7-Hydroxyisoflavones through 7-(α-Acetylethoxy)isoflavones (16). i) The Preparation of 16*: A mixture of 7-hydroxyisoflavone (10 g), 3-chlorobutanone-2 (4.5 g), anhydrous potassium carbonate (17 g), and acetone (150 m*l*) was refluxed for 5 hr. The cooled mixture was filtered, the solvent was distilled off, and the residue was treated with water and then heated for a while on a water-bath. The precipitates

formed on cooling were collected and recrystallized to give 7-(α-acetylethoxy)-isoflavone (16b).

ii) The Dehydro-cyclization of 16 by PPA: A mixture of 16b (1.3 g) and PPA (n=2.5, 30 g) was poured into ice water; the crystalline product thus formed was collected and recrystallized from ethanol to give 4'',5''-dimethylfuro[2'',3'':7,8]isoflavone (12b).

iii) The Dehydro-cyclization of 16 by Sulfuric Acid: The isoflavone 16b (2 g) was gradually added to concentrated sulfuric acid (20 g) at about 30°C; the mixture was allowed to stand at that temperature for 1.5 hr, and then poured into ice water. The crystalline product thus formed was recrystallized from ethanol to give 12b.

Similarly, 4'',5''-dimethyl-2'-methoxyfuro[2'',3'':7,8]isoflavone (12c), 2,4'',5''-trimethylfuro[2'',3'':7,8]isoflavone (13b), and 2'-methoxy-2,4'',5''-trimethylfuro[2'',3'':7,8]isoflavone (13c) were also prepared by this procedure through 7-(α-acetylethoxy)-2-methylisoflavone (17b) and its 2'-methoxy derivative (17c).

b) By the Action of Ethyl Orthoformate on the Benzofuranyl Ketones. A mixture of the ketone 2b (0.2 g), ethyl orthoformate (2 g), piperidine (1 drop) and pyridine (8 ml) was refluxed for 8 hr. Dilute hydrochloric acid was added to the cooled mixture, and the crystalline product formed was collected and recrystallized from ethanol to give 12b.

Similarly, 12c and 4'',5''-dimethyl-2',4',5'-trimethoxyfuro[2'',3'':7,8]isoflavone (12d) as well as the isomeric 4'',5''-dimethylfuro[3'',2'':6,7]isoflavone (14b) and 4'',5''-dimethyl-2'-methoxyfuro[3'',2'':6,7]isoflavone (14c) were also prepared by this procedure.

c) By the Action of Acetic Anhydride and Sodium Acetate on the Benzofuranyl Ketones. A mixture of the ketone 2b (0.2 g), sodium acetate (2 g), and acetic anhydride (10 ml) was refluxed for 12 hr, and then the cooled mixture was poured into ice water and left overnight. The crystalline product formed was collected and recrystallized from ethanol to give 13b.

Similarly, 13c and 2',4',5'-trimethoxy-2,4'',5''-trimethylfuro[2'',3'':7,8]isoflavone (13d), as well as the isomeric 2,4'',5''-trimethylfuro[3'',2'':6,7]isoflavone (15b) and 2'-methoxy-2,4'',5''-trimethylfuro[3'',2'':6,7]isoflavone (15c), were also prepared by this procedure.

The authors are grateful to Messrs T. Kida, T. Kishi, J. Masahashi, N. Shimizu, H. Yanagihara and H. Kawamura for their assistance, and to the Members of the Laboratory of Microanalysis, the Faculty of Pharmacology of this University, for their microanalyses. This work was supported in part by a grant from the Ministry of Education, for which the authors are also grateful.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2683—2689 (1968)

The Syntheses of Dimethylfuro Derivatives of 4-Hydroxycoumarins and Benzofuro[1]benzopyranones*[1]

Yoshiyuki KAWASE, Mutsumu NANBU, Fumihisa MIYOSHI and Hiroshi KAWAMURA

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received Mach 2, 1968)

4′,5′-Dimethyl-4-hydroxyfuro[2′,3′:7,8]coumarin (2) and its 3-phenyl, 3-(2-methoxyphenyl), and 3-(2,4,5-trimethoxyphenyl) derivatives (4, 5 and 6), and also their isomers, 4′,5′-dimethyl-4-hydroxyfuro[3′,2′:6,7]coumarins (14, 15, 16 and 17), were prepared by the action of ethyl carbonate or of ethyl chlorocarbonate on the corresponding 2,3-dimethyl-4- or isomeric 6-hydroxy-5-benzofuranyl ketones. Two furocoumarins (2 and 14) were also obtained in poor yields by the condesnation of 2,3-dimethyl-4- or 6-hydroxybenzofuran with malonic acid. The action of hydroiodic acid on the furocoumarins 5 and 6 afforded 2,3-dimethyl-5*H*-benzofuro[3,2-*c*]furo-[2,3-*h*][1]benzopyran-5-one (8) and its 7,8-dihydroxy derivative (9) respectively; 8 was also synthesized by building up the dimethylfuran ring on 3-hydroxy-6*H*-benzofuro[3,2-*c*][1]benzo-pyran-6-one, while 9 was also synthesized by the oxidative coupling of 2 with catechol. On the other hand, the action of pyridine hydrochloride on 5 caused the closure of the furan ring towards the 2-position, giving 1,2-dimethyl-6*H*-benzofuro[2,3-*b*]furo[2,3-*h*][1]benzopyran-6-one (11), which had a new pentacylic ring system; the only demethylated compound (12) was also obtained. The structure of 11 was confirmed by its IR and UV spectra and by the formation of 12 upon its alkaline hydrolysis. The action of aluminum chloride on 5 also gave 12. Analogously, isomeric 1,2-dimethyl-6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]benzopyran-6-one (20) and its 8,9-dihydroxy compound (21) were also synthesized.

Several derivatives of benzofuran,[1)] 4-hydroxy-coumarin,[1)] furocoumarins,[1,2)] and benzofuro-coumarin[1,2)] were obtained from natural sources; some of them have biological activities. In the present experiments, some furo-derivatives of 4-hydroxycoumarins and of benzofurocoumarin are synthesized in order to test their pharmacological activities, for convenient starting compounds for the synthesis of these compounds could be obtained readily.[3)] Concerning the synthesis of these compounds, the present authors have reported previously[4)] on the synhesis of 4-hydroxyfuro[2′,3′:7,8]-coumarins and 5*H*-benzofuro[3,2-*c*]furo-[2,3-*h*][1]-benzopyran-5-one, while the synthesis of isomeric 4-hydroxyfuro[3′,2′:6,7]coumarins[5-7)] and 6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]benzopyran-6-one derivative (erosnin)[6)] has been reported on by Fukui and Nakayama and others, and that of dimethylfuro-derivatives of 4-hydroxy-3-phenylfuro-coumarin has been reported on by Royer *et al.*[8)]

In the present experiments, 4′,5′-dimethyl-4-hydroxy-furo[2′,3′:7,8]coumarins (2—6) and isomeric -furo[3′,2′:6,7]coumarins (14—17) were synthesized from the corresponding hydroxybenzo-furanyl ketones (1 and 13); some of them (2, 5, and 6, and isomeric 14, 16, and 17) were converted to derivatives of 5*H*-benzofuro[3,2-*c*]furo-[2,3-*h*][1]benzopyran-5-one (8 and 9), 6*H*-benzo-furo[2,3-*b*]furo[2,3-*h*][1]benzopyran-6-one(11) and 6*H*-benzofuro[3,2-*c*]furo[3,2-*g*] [1] benzopyran-6-one (20 and 21), one (11) of these ring systems form-ing a new pentacyclic ring system.

4-Hydroxyfurocoumarins had been prepared previously by the action of ethyl carbonate and sodium on hydroxybenzofuranyl ketones[4-6)] and by the dehydrogenation of dihydrofurocou-marins,[5-7)] while the 4′,5′-dimethyl-3-phenyl com-pounds had been prepared by the thermal con-densation of dimethyl-hydroxybenzofurans with

ethyl phenylmalonate.[8] In the present exeriments, 4',5'-dimethyl-4-hydroxyfuro[2',3':7,8]-coumarin (2) and its 3-phenyl, 3-(2-methoxyphenyl), and 3-(2,4,5-trimethoxyphenyl)derivatives (4, 5, and 6) as well as the isomeric 4',5'-dimethyl-4-hydroxyfuro[3',2': 6,7]coumarins (14, 15, 16, and 17) were synthesized in good yields from the corresponding 2,3-dimethyl-4- or -6-hydroxy-5-benzofuranyl ketones (1 or 13), the preparation of which has been reported on in a preceding paper,[3] by the action of ethyl carbonate and sodium[9] or of ethyl chlorocarbonate and potassium carbonate[10] according to the general method for the synthesis of 4-hydroxycoumarins. In the case of 2, a small

amount of its 3-ethoxycarbonyl derivative (3) was also obtained as a by-product, much as in the case of furocoumarin without dimethyl groups;[4] its formation is probably due to the double ethoxycarbonylation of the ketone 1a, followed by cyclization. The 3-phenyl compound (4) thus obtained was identical with the furocoumarin which had been obtained by the above-mentioned thermal condensation of 2,3-dimethyl-4-hydroxybenzofuran (7) with ethyl phenylmalonate[8]; the furocoumarin 15 was an isomer of 4′,5′-dimethyl-4-hydroxy-3-phenylfuro[2′,3′:5,6]coumarin (19), which had been obtained by a similar thermal condensation from 2,3-dimethyl-6-hydroxybenzofuran (18). The condensation of hydroxybenzofurans (7 and 18) with malonic acid to obtain the corresponding 4-hydroxycoumarins directly was also attempted by the action of polyphosphoric acid[11a] or of phosphoryl chloride and zinc chloride,[11b] but such attempts resulted in the formation of furocoumarins (2 and 14) in only poor yields; this is comparable to the unfavorable results of the thermal condensation of the unsubstituted malonic ester with phenols.[12]

Then, the 4-hydroxyfurocoumarins (2, 5, 6 and isomeric 14, 16, 17) thus obtained were converted to benzofuro-furo[1]benzopyranones by procedures analogous to those reported previously. The reported procedures involve the demethyl-cyclization of 4-hydroxy-3-(2-methoxyphenyl)furocoumarins with hydroiodic acid, with pyridine hydrochloride, or with aluminum chloride,[4] or involve the oxidative coupling of 4-hydroxyfurocoumarin with catechol.[6] In the present experiments, the action of hydroiodic acid in acetic acid on the furocoumarins 5 and 6 caused demethyl-cyclization, thus giving 2,3-dimethyl-5*H*-benzofuro-[3,2-*c*]furo[2,3-*h*][1]benzopyran-5-one (8) and its 7,8-dihydroxy derivative (9) respectively. The compound 8 was also obtained by building up the furan ring on 3-hydroxy-6*H*-benzofuro[3,2-*c*]-[1]benzopyran-6-one[13,14] through the action of 3-chlorobutanone-2 and potassium carbonate to give the 3-(α-acetylethoxy) compound (10), which was then cyclized by the action of polyphosphoric acid. The compound 9 was also prepared by the oxidative coupling of the furocoumarin 2 with catechol by means of potassium ferricyanide. On the other hand, the action of pyridine hydrochloride on 5 gave 1,2-dimethyl-6*H*-benzofuro[2,3-*b*][1]-benzopyran-6-one (11), a compound with a new pentacyclic ring system, and a small amount of a merely-demethylated 3-(2-hydroxyphenyl) compound (12), which was also obtained by the action of anhydrous aluminum chloride in nitrobenzene on 5. The compound 11 has ν_{CO} at 1650 cm^{-1}, which is in the region characteristic of that of the chromone type.[3-5,14,15] The pattern of its UV spectrum, showing a strong absorption at about 250 mμ and only a weak absorption at 315 mμ, is different from that of the benzofuro[3,2-*c*][1]-benzopyranones; rather, it is comparable to that of furoisoflavones.[3-5,16] Its alkaline hydrolysis gave the hydroxyfurocoumarin 12. The structure of 11 was assigned on the basis of these observations and was confirmed by comparing it with that of lisetin,[17] a compound recently isolated from a natural source; this compound has a tetracyclic ring system, 11*H*-benzofuro[2,3-*b*][1]benzopyran-11-one, which is also included in the compound 11. The formation of 11 from 5 is probably a result of the closure of the new furan ring at the 2-hydroxy group of the 2-hydroxyisoflavone derivative, a tautomeric form[14,15] of the 4-hydroxycoumarin 12, but the attempted dehydro-cyclization of 12 by refluxing it with methanolic hydrogen chloride was unsuccessful.

Analogously, the isomeric furocoumarins (16 and 17) were converted to 1,2-dimethyl-6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]benzopyran-6-one (20) and its 7,8-dihydroxy derivative (21) by the action of hydroiodic acid; 21 was also obtained by the oxidative coupling of 14 with catechol. The action of both aluminum chloride and pyridine hydrochloride on 16 gave the demethylated compound (22).

In the IR spectra, the furocoumarins and benzofuro-furobenzopyranones prepared have the ν_{CO} at 1740—1670 cm^{-1}, which is in the region characteristic for those of the coumarin type,[4-6,14,15,17] except that the ν_{CO} of the compounds 4, 12, 14 and 22 are at 1655—1645 cm^{-1}, which is rather in the region characteristic for those of the chromone type,[3-6,14,15,17] moreover, the wave numbers of these ν_{CO} are in general smaller by about 20 cm^{-1} than those of homologues without dimethyl groups.[4-6]

In the UV spectra, the furocoumarins and benzofuro-furobenzopyranones have two bands, the band I and the band II; the band I is in general at 235—240 mμ, while the band II of the compounds with an angularly-fused furan ring is at 320—330 mμ, which is longer by about 20—25 mμ than those of the isomers. These UV spectra are almost identical with those of the compounds without dimethyl groups.[4-6]

Experimental*2

Materials. *Benzofuranyl Ketones 1a, b, c, d and Isomeric 13a, b, c, d.* These compounds were prepared by a previously-reported procedure.[3]

Hydroxybenzofurans 7 and 18. These compounds were prepared by the procedure reported by Royer *et al.*[18]

3-Hydroxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one was prepared, in the present experiments, by the action of ethyl chlorocarbonate and potassium carbonate[10] on the 2,4-dihydroxyphenyl 2-methoxybenzyl ketone to give hydroxycoumarin, which was then converted to the compound by demethyl-cyclization as follows:

4,7-Dihydroxy-3-(2-methoxyphenyl)coumarin. A mixture of the 2,4-dihydroxyphenyl 2-methoxybenzyl ketone[19] (10 g), ethyl chlorocarbonate (14 m*l*), acetone (100 m*l*), and anhydrous potassium carbonate (90 g) was refluxed for 3 hr. The cooled mixture was treated with water (1 *l*) and acidified, and the precipitates thus formed were collected and heated with 1 N aqueous sodium hydroxide (500 m*l*) for 1 hr. The resulting solution was acidified, and the precipitates formed were collected and recrystallized from ethanol; yield 6 g (54.5%). (See Tables 3 and 4).

3-Hydroxy-6H-benzofuro[2,3-c][1]benzopyran-6-one. A mixture of the coumarin (4 g), hydroiodic acid (d=1.7,

*2 All melting points are uncorrected; the IR spectra were measured in the form of KBr disks, while the UV spectra were measured in ethanol. The detailed data are summarized in the tables and figures.

b) A small amount of 12 was also obtained.

100 ml), acetic acid (40 ml), and acetic anhydride (35 ml) was refluxed gently for 1 hr under a stream of nitrogen. The cooled mixture was poured into ice water containing a small amount of sodium bisulfite, and the precipitates formed were collected and recrystallized from ethanol. Mp 276—277°C (lit mp 285°C[13] or 276—277°C[14]); yield 1.6 g (45%).

The Preparation of Furocoumarins from Benzofuranyl Ketones (Table 1). *a) By the Action of Ethyl Carbonate and Sodium.* Small pieces of metallic sodium (2 g) were added to a solution of 1b (1.4 g) in ethyl carbonate (30 ml), and the mixture was heated gradually to 100°C. The mixture was heated at that temperature for 1 hr, and then methanol was added to the cooled mixture to destroy the excessive sodium. The resulting solution was diluted with water, washed with ether, and then acidified. The crystalline product formed was collected and recrystallized from ethanol to give 4',5'-dimethyl-4-hydroxy-3-phenylfuro[2',3':7,8]-coumarin (4); mp 272—273°C (lit.[8] mp 271°C) (Found: C, 74.08; H, 4.34%).

Similarly, 4',5'-dimethyl-4-hydroxyfuro[2',3':7,8]-coumarin (2) and its 3-(2-methoxyphenyl) and 3-(2,4,5-trimethoxyphenyl) derivatives (5 and 6), as well as isomeric 4',5'-dimethyl-4-hydroxyfuro[3',2':6,7]-coumarin (14) and its 3-phenyl, 3-(2-methoxyphenyl), and 3-(2,4,5-trimethoxyphenyl) derivatives (15, 16, and 17), were prepared by this procedure. In the case of 2, a small amount of ethyl 4',5'-dimethyl-4-hydroxyfuro[2',3':7,8]coumarin-3-carboxylate (3) was also obtained from the mother solution of the crystallization of 2.

b) By the Action of Ethyl Chlorocarbonate and Potassium Carbonate. A mixture of 1b (0.5 g), ethyl chlorocarbonate (0.5 g), acetone (15 ml), and anhydrous potassium carbonate (3.0 g) was refluxed for 3 hr. The cooled mixture was treated in a manner similar to that described in the case of 4,7-dihydroxy-3-(2-methoxyphenyl)-coumarin to give the furocoumarin 4.

Similarly, the furocoumarin 15 was also synthesized by this procedure.

c) By the Action of Ethyl Chlorocarbonate and Pyridine. Ethyl chlorocarbonate (0.6 g) was added gradually, with stirring and cooling, to a solution of 1b (0.6 g) in pyridine (10 ml), after which the mixture was allowed to stand overnight. The resulting mixture was poured into ice water and extracted with ether. The ether solution was washed with dilute hydrochloric acid, and the ether was distilled off. The residual product was heated with 10% aqueous sodium carbonate (40 ml) for 2 hr, and the cooled mixture was washed with ether and then acidified. The crystalline product formed was collected and recrystallized from ethanol to give 4.

The Preparation of 4-Hydroxycoumarins and 4-Hydroxyfurocumarins (2 and 14) Directly from Hydroxy-compounds (Table 1). *a) By the Action of Polyphosphoric Acid (PPA).* A mixture of the hydroxybenzofuran 7 (5 g), malonic acid (3.5 g), and PPA (n=2.5, 100 g) was heated at 100°C for 2 hr with stirring. The cooled mixture was poured into ice water and extracted with ethyl acetate. The ethyl acetate solution was extracted with 5% aqueous sodium hydroxide, and the alkaline solution was acidified. The crystalline product thus formed was collected and recrystallized from ethanol to give the hydroxyfurocoumarin 2; mp 287°C (dec.), yield 0.1 g (1.5%).

Analogously, the furocoumarin 14 was also obtained by this procedure from the hydroxybenzofuran 18, while the reaction of resorcinol or its monomethyl ether and malonic acid gave 4,7-dihydroxycoumarin[11a] or 4-hydroxy-7-methoxycoumarin, mp 264.5°C (dec.) (lit.[20] mp 265°C (dec.)) and mp 252.5°C (dec.) (from ethanol) (lit.[20] mp 256°C (dec.)) respectively, in yields of 5% and 9.5%.

b) By the Action of Phosphoryl Chloride and Zinc Chloride. A mixture of 18 (5 g), malonic acid (3.5 g), anhydrous zinc chloride (12.5 g), and phosphoryl chloride (8.5 ml) was heated at 60—70°C for 8 hr

a) s: shoulder.
b) 4,7-Dihydroxy-3-(2-methoxyphenyl)coumarin.

with stirring. The cooled mixture was poured into ice water, and the precipitates formed were collected and dissolved in aqueous sodium carbonate and then filtered. The filtrate was acidified and extracted with ethyl acetate. The ethyl acetate was distilled off, and the residue was recrystallized from ethanol to give the furocoumarin 14.

The Formation of 3-(2-Hydroxyphenyl)coumarins (12 and 22) (Table 1). *a) By the Action of Aluminum Chloride on Methoxyphenylcoumarins (5 and 16).* Anhydrous aluminum chloride (1.1 g) was added to a solution of 5 (0.5 g) in nitrobenzene (30 m*l*), and the mixture was heated on a water bath for 2 hr. The cooled mixture was poured into ice water containing hydrochloric acid, and then the nitrobenzene was removed by steam-distillation. The residual product was recrystallized from acetone to give 4',5'-dimethyl-4-hydroxy-3-(2-hydroxyphenyl)furo[2',3':7,8]coumarin (12).

Analogously, 4',5'-dimethyl-4-hydroxy-3-(2-hydroxyphenyl)furo[3',2':6,7]coumarin (22) was obtained from 16 by this procedure.

b) By the Action of Pyridine Hydrochloride on 5 and 16. A mixture of 16 (0.4 g) and anhydrous pyridine hydrochloride (2 g) was refluxed for 30 min, after which the cooled mixture was treated with dilute hydrochloric acid. The precipitates formed were collected and recrystallized from ethyl acetate and then from ethanol to give the hydroxycoumarin 22.

In the case of 5, a small amount of the hydroxycoumarin 12 was obtained from the mother solution of the crystallization of the major product (11), the preparation of which will be described bellow.

c) By the Alkaline Hydrolysis of 11. A mixture of 11 (64 mg), 10% aqueous potassium hydroxide (10 m*l*), and methanol (20 m*l*) was refluxed for 2 hr. The cooled mixture was acidified with dilute hydrochloric acid, and the precipitates formed were collected and recrystallized from ethyl acetate to give the hydroxycoumarin 12.

The Preparation of Benzofuro-furo[1]benzopyranones (Table 2). *a) By the Action of Hydroiodic Acid on the Methoxyphenyl-furocoumarins.* A mixture of 5 (0.5 g), hydroiodic acid (d=1.7, 11m*l*), acetic acid (4.5 m*l*), and acetic anhydride (5 m*l*) was refluxed gently for 45 min under a stream of nitrogen. The cooled mixture was treated much as has been described in the case of 3-hydroxybenzofuro-benzopyranone; this gave 2,3-dimethyl-5*H*-benzofuro[3,2-*c*]furo[2,3-*h*]-[1]benzopyran-5-one (8).

Similarly, the 7,8-dihydroxy derivative of 8 (9), 1,2-dimethyl-6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]benzopyran-6-one (20), and its 8,9-dihydroxy derivative (21) were also obtained by this procedure.

b) By the Action of Pyridine Hydrochloride on the Furocoumarin 5. A mixture of 5 (0.4 g) and anhydrous pyridine hydrochloride (2 g) was refluxed for 20 min, after which the cooled mixture was treated much as has been described in the case of hydroxycoumarins. The crude product was recrystallized from ethyl acetate to give 1,2-dimethyl-6*H*-benzofuro[2,3-*b*]furo[2,3-*g*][1]-benzopyran-6-one (11); the hydroxycoumarin 12 was also obtained from the mother solution by the method described before.

c) By the Oxidative Coupling of 2 or 14 with Catechol. A solution of potassium ferricyanide (1.2 g) and sodium acetate (1 g) in water (10 m*l*) was added to a solution of 2 (0.3 g) and catechol (0.12 g) in a mixture of acetone (30 m*l*) and water (4.5 m*l*), after which the mixture was allowed to stand at room temperature for 2 hr. The resulting mixture was filtered from the inorganic precipitates formed, the filtrate was treated with formic acid (46%, 3 m*l*), and then the acetone was removed *in vacuo*. The precipitates formed were collected and recrystallized from acetone to give the compound 9.

d) By Building Up the Furan Ring on 3-Hydroxybenzofurobenzopyranone. i) 3-(α-Acetylethoxy)-6H-benzofuro[3,2-c][1]benzopyran-6-one (10): A mixture of 3-hydroxy-6*H*-benzofuro[3,2-*c*][1]benzopyran-6-one (1.3 g), 3-chlorobutanone-2 (0.6 g), the methyl ethyl ketone (50 m*l*), and anhydrous potassium carbonate (2.5 g) was refluxed for 10 hr. The cooled mixture was filtered, the solvent was distilled off, and the residual product was recrystallized from ethyl acetate to give the compound 10; yield 1.2 g (74%).

ii) The Ring Closure of 10: A mixture of 10 (0.5 g) and PPA (n=2.5, 20 g) was heated on a water bath for 2 hr. The cooled mixture was poured into ice water, and the precipitates formed were collected and crystallized from ethyl acetate to give the compound 8 in an impure form; mp 210—230°C, 0.4 g. A part of it (0.1 g) was purified through chromatography, using alumina and benzene as a solvent; the product obtained from the elute was recrystallized from ethyl acetate to give the pure 8.

The Isokinetic Temperature of the Acylation of *l*-Menthol

Fuminori AKIYAMA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received March 23, 1968)

The acylations of *l*-menthol with *p*-substituted benzoyl- and substituted acetyl chlorides were carried out, and it was found that the electron-releasing substituents accelerate the reaction rate in chloroform even though the reaction is completely of the S_N2 type. This result is interpreted in relation to the low isokinetic temperature, the reaction itself being carried out above that temperature. Such a phenomenon is discussed in terms of the configurational and the solvent effects on the entropy of activation.

The mechanism of the solvolysis of the acyl halides has been studied comprehensively. The substituent effect of such a reaction has been discussed by Hudson *et al.*[1] in relation to the mechanism of the solvolysis of the substituted benzoylchloride. In S_N1 solvolysis the acyl chloride which has an electron-releasing substituent reacts faster than the acyl chloride which has an electron-attracting substituent. However, the reverse trend has been observed in S_N2 solvolysis, where an electron-releasing substituent retards the reaction rate. These trends are quite generally accepted for nucleophilic substitutions.[2]

The present authors have studied the acylation of *l*-menthol and observed a reverse substituent effect in the reaction despite the S_N2-character of this acylation. An abnormal change in the substituent effect is often explained as the result of a shift of the reaction mechanism from S_N1 to S_N2 or from S_N2 to S_N1.[2] However, an alternative explanation, which may be reasonable in view of the present results, in that the reaction is carried out above the isokinetic temperature.[3]

Such a phenomenon is usually accompanied with a low isokinetic temperature of the acylation. The configurational and the solvent effects are discussed with regard to the cause of the anomaly.

Experimental

Solvents. The solvents—chloroform, benzene, liquid sulfur dioxide, tetrahydrofuan and acetonitrile—were purified by the methods described in earlier papers.[4,5]

Materials. Extra-pure-grade *l*-menthol was used without further purification. *p*-Substituted benzoyl chlorides were obtained by the chlorination of the corresponding *p*-substituted benzoic acids with thionyl chloride. Propionyl, monochloroacetyl, dichloroacetyl, and trichloroacetyl chlorides were commercial materials and were used after distillation.

The Identification of the Esters. The reaction mixture after the acylation was concentrated *in vacuo*, and the residual oil was fractionated. *l*-Menthyl monochloroacetate: bp 116°C/5 mmHg. Found: C, 61.89; H, 9.25%. Calcd for $C_{12}ClH_{21}O_2$: C, 61.92; H, 9.09%. *l*-Menthyl dichloroacetate: bp 128°C/5 mmHg. Found: C, 53.68; H, 7.64%. Calcd for $C_{12}Cl_2H_{20}O_2$: C, 53.94; G, 7.54%. *l*-Menthyl trichloroacetate: bp 113°C/3 mmHg. Found: C, 47.59; H, 6.50%. Calcd for $C_{12}Cl_3H_{19}O_2$: C, 47.78; H, 6.35%. *l*-Menthyl benzoate: bp 151°C/4 mmHg. Found: C, 77.73; H, 9.27%. Calcd for $C_{17}H_{24}O_2$: C, 78.41; H, 9.29%. *l*-Menthyl *p*-methylbenzoate: bp 170°C/2 mmHg. Found: C, 79.00: H, 9.93%. Calcd for $C_{18}H_{26}O_2$: C, 78.78; H, 9.55%. *l*-Menthyl *p*-chlorobenzoate: bp 187°C/3 mmHg. Found: C, 69.41; H, 7.71%. Calcd for $C_{17}ClH_{23}O_2$: C, 69.25; H, 7.86%.

Kinetic Procedure. The polarimetric procedure was used for the measurement of the reaction rate. A graphic representation of the apparatus and the details of the kinetic procedure have been given in earlier papers.[3,4] Equimolar concentrations of *l*-menthol and acyl chloride were used. The second-order reaction rate constant was given by the slope of the linear plot of:

$$\frac{1}{\alpha_\infty - \alpha} \text{ vs. the time } t,$$

since:

$$\frac{1}{\alpha_\infty - \alpha} - \frac{1}{\alpha_\infty - \alpha_0} = \frac{kt}{l\{[R]^\circ_E - [R]^\circ_A\}} \quad (1)$$

where $[R]^\circ_A$ and $[R]^\circ_E$ are the specific optical rotations of *l*-menthol and of the ester, rotations which were measured beforehand and which are listed in Table 1, where l, α, α_0, and α_∞ are the length of the cell, dm, and the rotations of the solutions at time t, zero, and infinity, respectively. The second-order plots of typical runs are shown in Fig. 1.

Results

The reactions of *l*-menthol with *p*-substituted benzoyl chlorides were studied in chloroform at various temperatures. The same reactions in liquid sulfur dioxide and in acetonitrile were also performed with substituted benzoyl chlorides. However, the results were complicated and difficult to interpret, since in both solvents the S_N1 reaction was predominant under the same conditions. The second-order rate constants in chloroform are listed in Table 2, while the activation parameters of these reactions are listed in Table 3. An isokinetic relationship is observed in the linear plot of the activation enthalpy, $\Delta H^{\ddagger}$, *vs.* the activation entropy, $\Delta S^{\ddagger}$, as is shown in Fig. 2.

This result demonstrates the abnormal trend of the substituent effect and the extraordinarily low isokinetic temperature. The tendency of the rate constant in connection with the substituent is in the order:

$$p\text{-}CH_3O > p\text{-}CH_3 > H > p\text{-}Cl$$

which is the reverse of the ordinary order in an S_N2 reaction, whereas the activation enthalpy is characteristic of the S_N2 acylation, the values of $\Delta H^{\ddagger}$ being in the order:

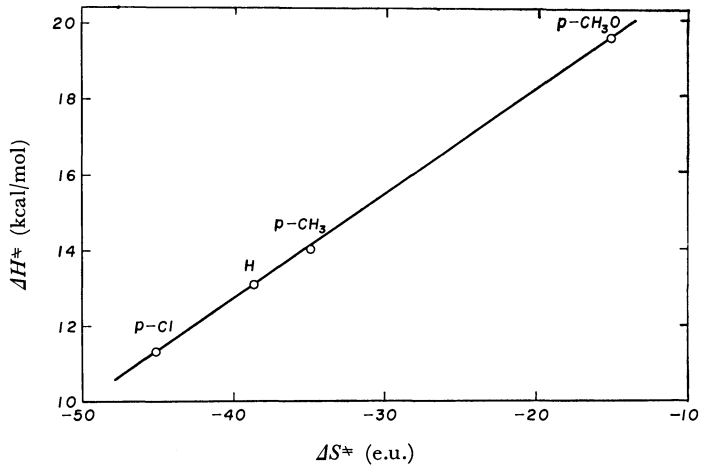

Fig. 2. The isokinetic relation of the reaction of *l*-menthol with *p*-substituted benzoyl chlorides in chloroform.

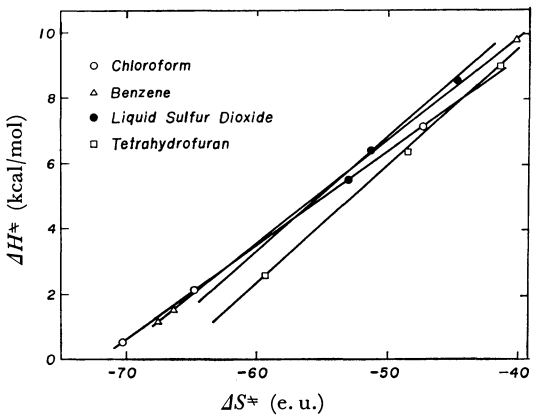

Fig. 3. The isokinetic relation of the acetylations of *l*-methanol in various solvent.

$$p\text{-}CH_3O > p\text{-}CH_3 > H > p\text{-}Cl$$

The reactions of *l*-menthol with substituted acetyl chlorides are relatively faster than with substituted benzoyl chlorides. The second-order rate constants of the acetylations of *l*-menthol in various solvents, such as chloroform benzene, liquid sulfur dioxide, and tetrahydrofuran, are listed in Tables 4, 5, 6, and 7. The isokinetic relationships obtained in these solvents are visualised in Fig. 3. From this figure the isokinetic temperatures can be estimated to be as listed in Table 9.

The trend of the activation enthalpies is also characteristic of an S_N2 reaction. However the rate in chloroform is in an anomalous order:

propionyl > monochloracetyl > dichloroacetyl

whereas in benzene, liquid sulfur dioxide, and tetrahydrofuran the order is:

trichloroacetyl > dichloroacetyl > monochloroacetyl > propionyl

Discussion

According to the absolute reaction rate theory, the reaction rate constant, k, is expressed as a function of the activation enthalpy, $\Delta H^{\neq}$, and of the activation entropy, $\Delta S^{\neq}$:[6] Since $\Delta F^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}$ (2):

$$k = \frac{kT}{h} e^{-\Delta F^{\neq}/RT} = \frac{kT}{h} e^{\Delta S^{\neq}/R} \cdot e^{-\Delta H^{\neq}/RT} \quad (3)$$

where k and h are the Boltzmann and the Planck constants respectively. Empirically, the isokinetic relation holds:[3,7]

$$\Delta H^{\neq} = \Delta H_0^{\neq} + \beta \Delta S^{\neq} \quad (4)$$

where β is an isokinetic temperature and $\Delta H^{\neq}$ is the activation enthalpy at the standard state. As a result, k is expressed as a function of β, $\Delta H^{\neq}$, and $\Delta S^{\neq}$.

From Eqs. (2) and (3), as has been derived by Leffler:[3]

$$\Delta F^{\neq} = \Delta H^{\neq} + (\beta - T)\Delta S^{\neq} = \frac{T}{\beta}\Delta H_0^{\neq} + \frac{(\beta - T)}{\beta}\Delta H^{\neq} \quad (5)$$

$$k = \frac{kT}{h} \exp -\left\{\frac{T}{\beta}\Delta H_0^{\neq} + \frac{(\beta - T)}{\beta}\Delta H^{\neq}\right\} \Big/ RT \quad (6)$$

Therefore, provided

$$\beta > T$$

then:

$$\Delta F^{\neq} \propto \Delta H^{\neq}$$

and if,

6) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Process," McGraw Hill Co., New York (1941).

7) J. E. Leffler, *J. Org. Chem.*, **20**, 1202 (1955).

$$\beta < T$$

the situation is reversed:

$$\Delta F^{\neq} \propto -\Delta H^{\neq}$$

Thus, the above discussion allows one to understand that the reaction will be accelerated (or suppressed) below the isokinetic temperature and suppressed (or accelerated) above the isokinetic temperature, as long as the isokinetic relationship is sustained.

The reaction temperatures adopted here are in the range between 15 and 49°C; actually the reactions were undertaken near the isokinetic temperatures. As may be seen in Figs. 2 and 3 and in Table 9, the isokinetic temperatures of the acylation of *l*-menthol are low, being 285° in chloroform, 315° in benzene, 344° in liquid sulfur dioxide, and 357°K in tetrahydrofuran. In general, the isokinetic temperatures of the solvolyses of substituted benzoyl chlorides are as high as 450°K[8] in ether-ethanol and over 600°K in aceton-water,[1] as Fig. 4 shows.

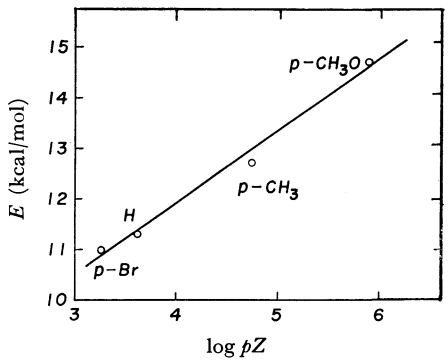

Fig. 4. The isokinetic relation of the hydrolysis of the *p*-substituted benzoylchloride in 95% acetone-5% water.[1] β=652°K

The present results indicate that the substituent effect in this reaction is contrary to the expected order in the S_N2 acylation, and that the rate decreases in the order:

$$p\text{-}CH_3O > p\text{-}CH_3 > H > p\text{-}Cl$$

Such a reversal may adequately be explained by the fact that the reaction was undertaken above isokinetic temperature, the large entropy-controlled reaction operating throughout the acylation (*vide infra*).

Such a phenomenon, encountered for the first time in acylations by the present authors, will be discussed further below.

By the definition of Eq. (3), as long as the isokinetic relation is sustained, the value of β can be rewritten as:

$$\beta \frac{\Delta\Delta H^{\neq}}{\Delta\Delta S^{\neq}} \qquad (7)$$

where $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ are the differentials of the activation enthalpies and entropies. As the $\Delta\Delta S^{\neq}$ becomes larger, or as the reaction becomes more entropy-controlled, the isokinetic temperature, β, will become smaller, whereas a larger value of β will be obtained when the $\Delta\Delta H^{\neq}$ becomes larger or when the reaction is enthalpy-controlled. Thus, the small value of β is attributable to the entropy-controlled reaction.

Two factors which may have a predominant influence on the low isokinetic temperature are the steric configuration of the activated complex in the reaction medium and the nature of the solvent applied.

The term $\Delta\Delta S^{\neq}$ may be divided into two parts, the change in the activation entropy of the reactant molecules, $\Delta\Delta S_R^{\neq}$, which is characteristic of the reactants, and the change in the activation entropy of the solvent molecules, $\Delta\Delta S_S^{\neq}$, which is the solvent effect. Assuming the additivity of the entropies, $\Delta\Delta S^{\neq}$ may be expressed as:

$$\Delta\Delta S^{\neq} = \Delta\Delta S_R^{\neq} + \Delta\Delta S_S^{\neq} \qquad (8)$$

The difference between the acylations of *l*-menthol and ordinary alcohols may be largely due to the difference in the transition states of the acylation, which is illustrated in Fig. 5, the value of $\Delta\Delta S_R^{\neq}$ in the acylation of *l*-menthol being much larger by steric reasons.

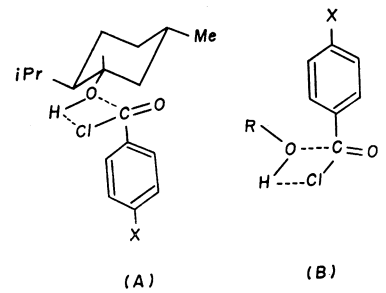

Fig. 5. The transition state of the acylation of *l*-menthol (A) and the ordinary alcohol (B).

At a lower energy state, the internal motion in the transition state of the acylation of *l*-menthol is inhibited. However, at a higher energy state the internal rotation comes into action against the steric restriction. In the acylation of ordinary alcohols, the steric inhibition to the internal motion is not as large as in the menthol. Consequently, the $\Delta\Delta S_R^{\neq}$ in the acylation of menthol may be larger than that of ordinary alcohol.

The dependency of the isokinetic temperature on the solvent is indicated in Table 9. The relative rate of the acylation of *l*-menthol with substituted acetyl chlorides at 35°C undergoes an almost complete reversal in order as the solvent is changed from chloroform to benzene, liquid sulfur dioxide, or tetrahydrofuran.

Suppose two circumstances, 1 and 2, where the

	Trichloroacetylation	6.1	5.5	−53.0
Tetrahydrofuran	Propionylation	10.6	10.0	−43.8
	Monochloroacetylation	9.6	9.0	−4.15
	Dichloroacetylation	6.9	6.3	−48.5
	Trichloroacetylation	3.2	2.6	−59.4

Table 9. The isokinetic temperature of the acetylations in various solvents

Solvent	β°K
Chloroform	285°K
Benzene	315°K
Liquid sulfur dioxide	344°K
Tetrahydrofuran	357°K

activation enthalpies and entropies are indicated as $\Delta H_1^{\neq}$, $\Delta H_2^{\neq}$, $\Delta S_1^{\neq}$ and $\Delta S_2^{\neq}$, respectively. The suffixes 1 and 2 indicate the respective cases of 1 and 2. The entropy differences, $\Delta S_1^{\neq}$ and $\Delta S_2^{\neq}$, can then be expressed as:

$$\begin{aligned}\Delta S_1^{\neq} &= \{l-(m+n)\}(S_{AB}^{\neq}-S_S) + m(S_{AB}^{\neq}-S_A) \\ &\quad + n(S_{AB}^{\neq}-S_B) \\ &= l(S_{AB}^{\neq}-S_S) - m(S_A-S_S) - n(S_B-S_S)\end{aligned} \tag{9}$$

$$\begin{aligned}\Delta S_2^{\neq} &= \{l'-(m'+n')\}(S'_{AB}{}^{\neq}-S_S) \\ &\quad + m'(S'_{AB}{}^{\neq}-S'_A) + n'(S'_{AB}{}^{\neq}S'_B) \\ &= l'(S'_{AB}{}^{\neq}-S_S) - m'(S'_A-S_S) \\ &\quad -n'(S'_B-S_S)\end{aligned} \tag{10}$$

The l, m, and n symbols are the solvation numbers of the solvents to the transition state AB$^{\neq}$, the reactants being A and B in case 1. S_A, S_B, and $S_{AB}^{\neq}$ are the entropies of the solvent molecules which solvate to A, B, and AB in case 1. All the symbols with dashes correspond to case 2. S_S is the entropy of the unsolvated solvent.[9] Since $\Delta\Delta S_R^{\neq}$ is a constant in both cases:

$$\begin{aligned}\Delta\Delta S_S^{\neq} &= \Delta S_2^{\neq} - \Delta S_1^{\neq} = l(S'_{AB}{}^{\neq}-S_{AB}^{\neq}) \\ &\quad - m(S'_A-S_A) - n(S'_B-S_B) \\ &\quad - (l-l')(S'_{AB}{}^{\neq}-S_S) - (m-m')(S'_A-S_S) \\ &\quad - (n-n')(S'_B-S_S)\end{aligned} \tag{11}$$

Equation (11) may then be rewritten as:

$$\Delta\Delta S_S^{\neq} = \Delta\Delta S_C^{\neq} + \Delta\Delta S_P^{\neq}$$

where:

$$\begin{aligned}\Delta\Delta S_C^{\neq} &= l(S'_{AB}{}^{\neq}-S_{AB}^{\neq}) - m(S'_A-S_A) \\ &\quad - n(S'_B-S_B)\end{aligned} \tag{12}$$

$$\begin{aligned}-\Delta\Delta S_P^{\neq} &= (l-l')(S'_{AB}{}^{\neq}-S^{\neq}) \\ &\quad + (m-m')(S'_A-S_S) + (n-n')(S_B'-S_S)\end{aligned} \tag{13}$$

Equation (11) indicates that $\Delta\Delta S_S^{\neq}$ consists of two components, the *solvent coordinate* and the *solvent polarity factors*, $\Delta\Delta S_C^{\neq}$ and $\Delta\Delta S_P^{\neq}$.

The $(S'_{AB}{}^{\neq}-S_{AB}^{\neq})$, (S'_A-S_A), and (S'_B-S_B) terms mean the change in the entropy of the solvent molecules with the changes in the energy state of the activated complex and the reactant molecules respectively, and may be defines as the *solvent coordinate factor*, $\Delta\Delta S_C^{\neq}$. The $(S'_{AB}{}^{\neq}-S_S)$, (S'_A-S_S), and (S'_B-S_S) terms indicate the change in the entropy of the solvent molecules with the transfer of the solvent molecules from the solvent layer to the solvation shell. These terms may be called the *solvent polarity factor*, $\Delta\Delta S_P^{\neq}$. The *solvent coordinate factor* is related to the solvent effect on the activation entropy within the solvation shell, while the *solvent polarity factor* correlates with that of the solvation of the solvent molecules.

As the non-polar solvents associate with each other more loosely than as the polar solvents in the solvent layer, the *solvent polarity factor* is larger in a non-polar solvent than in a polar solvent. Therefore, the $\Delta\Delta S^{\neq}$ value is larger in a non-polar solvent than in a polar solvent.

As a result, if the $\Delta\Delta H^{\neq}=\Delta H_2^{\neq}-\Delta H_1^{\neq}$ change is not as pronounced as the $\Delta\Delta S^{\neq}$ change, the isokinetic temperature is lower in the case of benzene and chloroform than in tetrahydrofuran and liquid sulfur dioxide.

The high isokinetic temperature in tetrahydrofuran may be due to the *solvent coordinate factor*. The change in the entropy with the change in the energy state is larger in the liquid sulfur dioxide than in tetrahydrofuran. While tetrahydrofuran is a cyclic molecule with only one solvation center, liquid sulfur dioxide has three centers, one sulfur and two oxygen atoms.

9) S_S is assumed to be constant under any circumstances.

Long-Range Spin Coupling between the Methoxyl and Ring Protons in 2-Methoxytropone Derivatives and Its Applications*[1]

Shuichi SETO, Kyozo OGURA, Hiroko TODA (SASAKI), Yusaku IKEGAMI and Tsuneo IKENOUE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received March 26, 1968)

Bromination of 5-amino-2-methoxytropone and 2-amino-7-methoxytropone afforded 5-amino-4-bromo-2-methoxytropone and 2-amino-3,5-dibromo-7-methoxytropone, respectively, as expected from the consideration of the effect of amino group in 2-methoxytropone system. Long-range spin coupling between the methoxyl group and a neighboring ring proton was observed in 2-methoxytropone derivatives. This information was applied to elucidation of the structure of the bromination products. The comparison of their NMR spectra gave the reasonable assignment for the ring protons of 5-amino-2-methoxytropone.

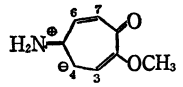
Long-range spin coupling involving methoxyl groups in aromatic compounds has been reported on the derivatives of *o*-hydroxyacetophenone and salicylaldehyde by Forsén and his co-workers.[1,2] They observed that the methyl protons are coupled to a neighboring ring proton with coupling constant of 0.24—0.31 Hz in these compounds.

During the course of our study of the reaction of amino derivatives of 2-methoxytropone, long-range spin coupling was observed between the methoxyl group and a ring proton. The fact is applicable to confirm the direction of the substitution reaction.

Results and Discussion

Bromination of 5-Amino-2-methoxytropone. It is well known that the substitution in the bromination of tropolone[3-5] and 2-aminotropone[6] takes place at 3-, 5- and 7-positions of the tropone ring, and that 2-methoxytropone is subject to addition rather than substitution on its treatment with bromine.[7] Bromination of 5-amino-2-methoxytropone (I)[8] is of interest from the standpoint of the effect of the amino group on electrophilic substitution of the 2-methoxytropone system. In the NMR spectrum of I (Fig. 1), the quartet at the highest field in the ring proton region must be due to H_4 proton or H_6 proton since it has spacings 2.5, 9.0 and 2.5 Hz due to *ortho* and *meta* couplings, respectively.[9]

It seems likely that the electron density at the position 4 of I is raised by mesomeric effect of the amino group and that such an effect is not conceivable as to the position 6. Therefore, this quartet is reasonably assigned to H_4 proton, and the other signals for ring protons can be tentatively assigned as illustrated in Fig. 1. These considerations lead to an anticipation that the substitution of bromine may occur exclusively at the position 4.



Treatment of I with bromine in methanol caused a transitory red color to appear, and then yellow crystals of a monobromo derivative (II) separated out in a high yield. The NMR spectrum of II (Fig. 2) in DMSO-d_6 shows a pair of AB type doublet (δ=6.97 and 7.13 ppm) with coupling constant of 13.9 Hz due to two adjacent ring protons and a signal with small splittings at 7.22 ppm probably due to H_3 proton. The signals corresponding to H_4 proton in I disappear in the monobromo derivative (II) and no splitting by *meta*-coupling is observed, suggesting the substitution occurred at the position 4. The splitting of the signal at 7.22 ppm was found to be due to the coupling with the methoxyl protons (J=0.5 Hz) by spin decoupling experiment; namely double irradiation at around 223 and 433 Hz sharpened the signal at 7.22 ppm and the signal for the methoxyl protons, respectively. The positional relation between methoxyl and H_3

proton in II is the same as that of methoxyl derivatives of 2-hydroxyacetophenone and salicylaldehyde[2] in which a coupling between methoxyl and its adjacent ring proton is reported. Accordingly, the observation of this long-range coupling also affords a strong support for the structural elucidation of II as 5-amino-4-bromo-2-methoxytropone.

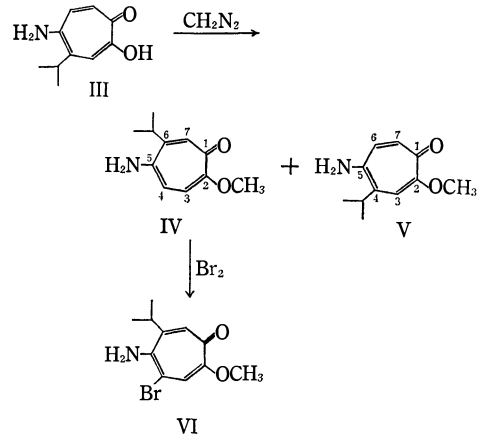
(in DMSO-d_6)
For the sake of comparison of each spectrum, Figs. 1—4 are expressed illustratively.

Two Methyl Ethers of 5-Amino-4-isopropyltropolone. Reaction of 5-amino-4-isopropyltropolone (III)[10] with diazomethane gave two methyl ethers (IV: mp 220°C, V: mp 140°C). As shown in Fig. 3, the NMR spectrum of IV has a pair of AB type doublet (δ=6.32 and 6.82 ppm) with coupling constant of 12.0 Hz, which means an existence of two adjacent ring protons in its structure. It is noticed, moreover, that two peaks at lower fields in the pair showed further a small splitting. Spin decoupling at frequencies of 220 and 409 Hz sharpened those aromatic and methyl proton signals, respectively, indicating that the lower-field peaks in the pair of AB type doublet is assigned to a ring proton neighboring with the methoxyl group. So, the structure of IV was determined as 5-amino-6-isopropyl-2-methoxytropone. A signal at 7.00 ppm in Fig. 3 is reasonably assigned to a H_7 proton.

Isomeric methyl ether, V, is naturally assumed to be 5-amino-4-isopropyl-2-methoxytropone. The following decoupling study of its NMR spectrum supported the structure. In the spectrum shown in Fig. 4, a signal (6.84 ppm) due to an isolated ring proton appears, overlapping with a line at 6.87 ppm of a pair of doublet (δ=6.86 and 6.95 ppm, J=13.0 Hz) of two adjacent ring protons. Decoupling at frequencies of methyl protons and isolated ring-proton resonances afforded sharp and intense signals for a line at 6.84 ppm and methyl proton signal at 3.67 ppm, respectively. The phenomenon indicates that an isolated ring proton exists at a position adjacent to methoxyl group in the structure of V.



III IV V VI

Monobromo derivative (VI) of IV was obtained by its bromination, while the isomer, V, did not give any bromo derivative. Since the NMR spectrum of VI does not show any signal in the region corresponding to H_4 proton signals of IV, it is clear that the bromination of IV has occurred at 4-position similarly to the case of 5-amino-2-methoxytropone (I).

Dibromo Derivative of 2-Amino-7-methoxytropone. Reaction of 3-aminotropolone (VII) with diazomethane affords 2-amino-7-methoxytropone (VIII), together with a small amount of isomeric methyl ether (IX). The structure of VIII was confirmed by the fact that the compound (VIII) reacted with diketene giving an authentic

10) T. Nozoe, Y. Kitahara, E. Kunioka and K. Doi, *Proc. Japan Acad.*, **26**, 38 (1950).

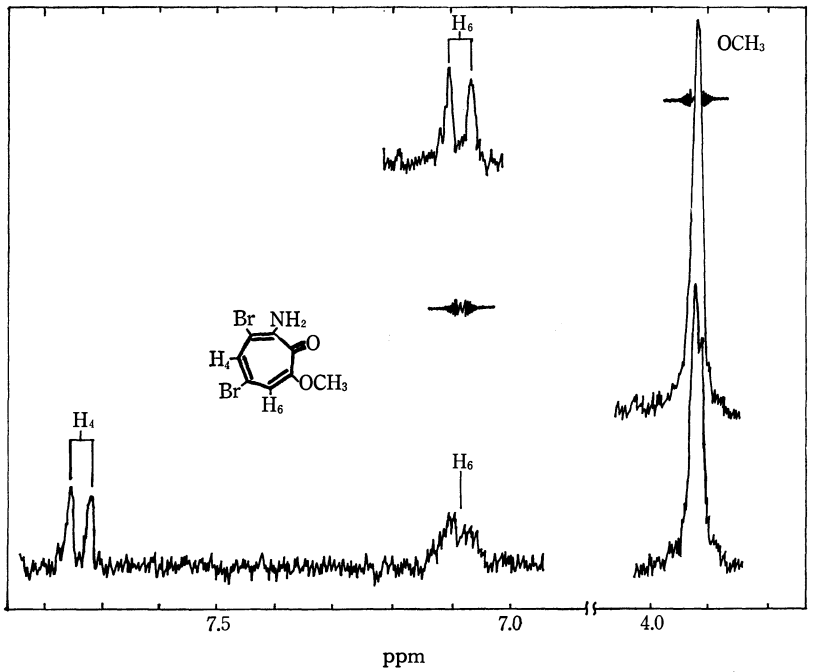


Fig. 5. NMR spectra of 2-amino-3,5-dibromo-7-methoxytropone (X) in DMSO-d_6 showing results (top two spectra) of spin decoupling experiments.

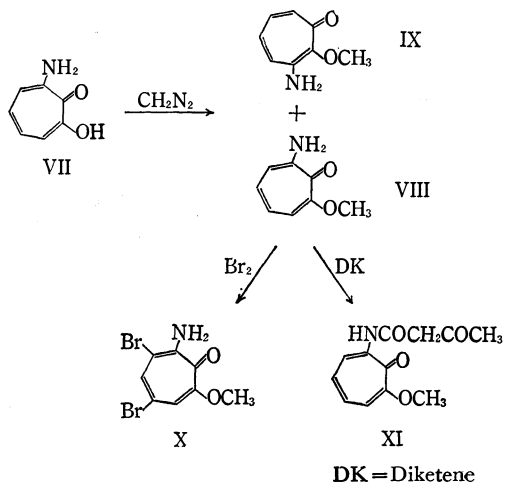
2-acetoacetamino-7-methoxytropone (XI), which had been obtained in the reaction of VII with diketene followed by methylation.[8]



Long-range spin coupling between methoxyl and ring proton was also applied to the determination of the structure of 2-amino-3,5-dibromo-7-methoxytropone (X) which is a bromination product of VIII, as follows. Since the ultraviolet and infrared spectra of the product show the existence of tropone skeleton, the dibromo derivative of VIII should be one of the six possible isomers. Analysis of the NMR spectrum excluded the structure having two adjacent ring protons, as shown in Fig. 5. The further study by proton magnetic double resonance chose a structure of X because the double resonance spectra clearly demonstrated the existence of a splitting due to long-range coupling between methyl protons and H_6 proton, the signal of which appears at 7.10 ppm, and H_6 proton couples to H_4 proton with coupling constant of 1.9 Hz.

The formation of 3,5-dibromo derivative of VIII shows that VIII has a behavior as 2-aminotropone derivative that gives 3,5,7-tribromo-2-aminotropone derivative on bromination.

Comparison of these spectra gave a confirmation of the assignment of every signal of 5-amino-2-methoxytropone (I) as given in Fig. 1. The results obtained here suggest that the long-range coupling between methoxyl and neighboring ring protons will be widely useful for the study of structural elucidation.

Experimental*2

Bromination of 5-Amino-2-methoxytropone (I). Into a cooled solution of I (100 mg) in 1 m*l* of methanol, a solution of bromine (110 mg) in 1 m*l* of methanol was added dropwise slowly. After bromine was added, the solution was stirred for 10 min and then the crystals that separated out were collected (140 mg). When the

*2 All melting points are uncorrected. The microanalyses were carried out by Misses Noriko Matsukawa, Emiko Yoshida and Hiroko Hosokawa of this Institute, to whom the authors are indebted.

crystals were dissolved in water and the solution was neutralized with sodium carbonate, yellow crystals separated out. The recrystallization of these from ethanol gave 5-amino-4-bromo-2-methoxytropone (II); yield, 90 mg. Mp 182°C (dec.). ν_{max}^{KBr} cm^{-1}: 3290, 3160, 1632, 1615, 1550, 1488, 1450, 1240. λ_{max}^{MeOH} $m\mu$ (log ε): 242 (4.32), 354 (4.02), 390 (4.02).

Found: C, 39.18; H, 4.50; N, 5.47%. Calcd for $C_8H_8O_2NBr \cdot H_2O$: C, 38.70; H, 4.02; N, 5.60%.

Two Methyl Ethers of 5-Amino-4-isopropyltropolone (III). To a suspension of III (500 mg) in a small amount of methanol, an ethereal diazomethane was added until portions of the solution were no longer colored with ferric chloride, and then the solution was allowed to stand at room temperature overnight. Yellow needles that separated out were collected by decantation and washed with benzene - methanol. A brownish yellow oil obtained by evaporation of solvent from the supernatant was dried well and chromatographed on alumina by elution with chloroform. The first fraction gave 5-amino-6-isopropyl-2-methoxytropone (IV) as yellow crystals. The third fraction, which was obtained by elution with 1% ethanolic chloroform, gave a yellow oil that crystallized by addition of benzene. The resulting yellow needles were 5-amino-4-isopropyl-2-methoxytropone (V). The second part was chromatographed again to give IV and V.

IV: mp 224—225°C; yield, 200 mg. ν_{max}^{KBr} cm^{-1}: 3740, 3320, 3200, 1640, 1610, 1576, 1500.

Found: C, 68.32; H, 7.72; N, 7.49%. Calcd for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25%.

V: mp 138—140°C; yield, 100mg. ν_{max}^{KBr} cm^{-1}: 3410, 3350, 3240, 2970, 1644, 1622, 1578, 1530, 1490.

Found: C, 68.50; H, 7.83; N, 7.10%. Calcd for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25%.

Bromination of 5-Amino-6-isopropyl-2-methoxytropone (IV). Into a solution of IV (50 mg) in 1 m*l* of methanol, a solution of bromine (50 mg) in 0.5 m*l* of methanol was added dropwise on being cooled with ice-salt. After the solution was stirred for 10 min, the removal of the solvent gave a small amount of pale yellow crystals of 5-amino-4-bromo-6-isopropyl-2-methoxytropone (VI).

Two Methyl Ethers of 3-Aminotropolone (VII). A methanolic solution of VII (670 mg), to which ethereal diazomethane was added until the solution became negative to ferric chloride coloration, was held to stand overnight. After evaporation of the solvent, the resulting hygroscopic crystalline mixture was dried in a desiccator and chromatographed on alumina with chloroform. The removal of the solvent from the first eluate gave yellow crystals of 2-amino-7-methoxytropone (VIII), which were recrystallized from benzene - ether. A yellow oily mixture of VIII and IX was obtained by the elution with 5% ethanolic chloroform. Addition of a small amount of benzene to this mixture afforded yellow prisms, which were recrystallized from benzene-methanol to give 3-amino-2-methoxytropone (IX).

VIII: mp 118—119°C; yield, 160 mg. ν_{max}^{KBr} cm^{-1}: 3370, 3290, 3150, 1613, 1588, 1525. λ_{max}^{MeOH} $m\mu$(log ε): 250(4.44), 263(4.25), 273(4.14), 340(4.14), 400(3.97).

Found: C, 62.74; H, 5.98; N, 9.72%. Calcd for $C_8H_9O_2N$: C, 63.56; H, 6.00; N, 9.29%.

IX: mp 157°C; yield, 30 mg. ν_{max}^{KBr} cm^{-1}: 3370, 3300, 3170, 1630, 1578, 1512. $\lambda_{max}^{H_2O}$ $m\mu$ (log ε): 264 (4.52), 313(3.90), 323(3.83), 365(3.30).

Found: C, 63.35; H, 5.81; N, 9.10%. Calcd for $C_8H_9O_2N$: C, 63.56; H, 6.00; N, 9.29%.

Bromination of 2-Amino-7-methoxytropone (VIII). To a solution of VIII (200 mg) in 2 m*l* of methanol that was cooled with ice-water, 220 mg of bromine in methanol was added. After the mixture was allowed to stand in a refrigerator overnight, the solvent was removed off. The crystalline residue (HBr salt of X) was dissolved in water and the pH of the solution was adjusted to 4 with sodium bicarbonate, and then extracted with chloroform. The extract that had been dried over anhydrous sodium sulfate was passed through an alumina column. Yellow crystals that were obtained from the first fraction were recrystallized from methanol to give yellow prisms of 2-amino-3,5-dibromo-7-methoxytropone (X); 45 mg, mp 172°C. ν_{max}^{KBr} cm^{-1}: 3440, 3310, 1555, 1530, 1450, 1229. λ_{max}^{MeOH} $m\mu$(log ε): 266(4.26), 350(3.91), 418(3.70).

Found: C, 30.88; H, 2.73; N, 4.55%. Calcd for $C_8H_7O_2NBr_2$: C, 31.09; H, 2.27; N, 4.53%.

Spectral Measurements. Measurements of the normal NMR spectra were carried out by using a Varian A-60 NMR spectrometer. Decoupling experiments were carried out by the frequency sweep method, using a Hitachi H-60 NMR spectrometer with a decoupling unit. The saturating field intensities were 1.0—2.0 milligauss. The spectra were taken at 34°C. In the decoupling experiments coupling constants and chemical shifts were determined with an error of ± 0.1 Hz by a frequency counter in hexadeuterodimethyl sulfoxide with concentration of *ca.* 0.3 mmol per milliliter utilizing tetramethylsilane as an internal standard. The chemical shifts were given in ppm unit.

The present authors wish to express their thanks to Messrs. Yoshiharu Utsumi and Go Miyashima of Hitachi Co., Ltd., Naka Work for the measurement of NMR spectra and to Sankyo Co., Ltd., who defrayed a part of expense for the present work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2700—2703 (1968)

The Absolute Configuration of Pinocarvone Oxide

Jun KATSUHARA

Sun Star Dentifrice Company, Research Laboratory, Takatsuki, Osaka, Japan

(Received March 30, 1968)

The conversion of (−)-pinocarvone oxide derived from (+)-pinocarvone into (−)-(1R : 2S : 3R : 5R)-*cis*-2-hydroxypinocampheol and the conversion of (+)-pinocarvone oxide in (+)-(1R : 2R : 3R : 5R)-*trans*-2-hydroxyneoisopinocampheol and (−)-(1R : 2R : 3R : 5R)-*cis*-2-hydroxyisopinocampheol are described. With the knowledge of the absolute configurations of these glycols, it was concluded that (−)-pinocarvone oxide and (+)-pinocarvone oxide have the (1R : 2S : 5R)- and (1R : 2R : 5R)-configurations, respectively.

Although Djerassi and coworkers[1] have determined the ORD curve of a mixture of diastereomeric pinocarvone oxides, the separation of the diastereomeric pinocarvone oxides and then ORD curves have not yet been described. It seemed of interest to undertake the isolation of these epoxides and to examine the ORD and CD curves of these compounds, in order to determine the applicability of the Octant Rule to oxirane systems. We wish, at this time, to report the assignment of the absolute configuration of the pinocarvone oxides by means of unequivocal chemical transformations into diols of established configuration.

(+)-*trans*-Pinocarveol (I) was oxidized with chromic acid anhydride pyridine-complex to (+)-(1S : 5R)-pinocarvone (II) which, on the Treibs epoxidation, afforded a mixture of trans-, (III) and *cis*-pinocarvone oxide (IV) in an isomer ratio of 35.5 : 64.5 as indicated by vpc analysis. The mixed isomers were separated by means of preparative vpc followed by silica gel column chromatography, and chemically pure (−)- and (+)-pinocarvone oxides were obtained.

The diastereomeric pinocarvone oxide III gave, upon the lithium aluminum hydride reduction, (−)-2-hydroxypinocampheol (V), whose IR spectrum indicated the presence of *cis*-glycol by the absorption bands of free (3628 cm^{-1}) and bonded hydroxyl (3572 cm^{-1}; $\Delta\nu$ 56 cm^{-1}).

The (+)-diastereomer (IV) was reduced with lithium aluminum hydride to give (+)-*trans*-2-hydroxyneoisopinocampheol (VIII) and (−)-*cis*-2-hydroxyisopinocampheol (IX).

(+)-2-Hydroxypinocamphone (X) derived from (−)-α-pinene, was reduced with lithium aluminum hydride to give the diol (XI). The identity of the diol (VIII) melting at 158° with the diol XI of the same melting point was established by direct comparison of the melting points and the IR spectra. The IR spectrum of the diol XI exhibited an absorption band at 3628 cm^{-1} corresponding to a free hydroxyl group and one 3612 cm^{-1} ($\Delta\nu$ 16 cm^{-1}) of the neighboring two hydroxyl groups. The NMR spectra of XI and of monoacetate of XI also substantiated the structure.

As for the geometry of 2-hydroxypinocamphone, Schmidt[2] concluded that (−)-2-hydroxypinocamphone derived from (+)-α-pinene should be assigned the *cis*-configuration (relative to the carbon-7 bridge carrying geminal dimethyl and 10-methyl group). Accordingly, the (1R : 2R : 3R : 5R)-configuration VIII may be assigned to (+)-2-hydroxyneoisopinocampheol (XI).

The Meerwein-Ponndorf-Verley reduction of (+)-X gave a diol XII, whose IR spectrum exhibited absorption bands at 3620 cm^{-1} (free hydroxyl) and at 3552 cm^{-1} ($\Delta\nu$ 68 cm^{-1}; bonded hydroxyl), suggesting the *cis*-arrangement of the two hydroxyl groups. It was shown by tlc comparison that the diol XII was identical with the diol IX, and consequently the (1R : 2R : 3S : 5R)-*cis*-structure may be assigned to (−)-*cis*-2-hydroxyisopinocampheol (IX).

For the purpose of comparison, another diastereomeric diol VI was prepared through (−)-pinocarveyl acetate from (+)-*trans*-pinocarveol (I) as follows: Hydroxymercuration[3] of (−)-*trans*-pinocarveyl acetate yielded the corresponding hydroxy acetate VII which on alkaline hydrolysis gave the diol VI. IR spectrum of VI indicated the presence of *trans*-diol by the absorption bands of free (3625 cm^{-1}) and bonded hydroxyl (3610 cm^{-1}; $\Delta\nu$ 15 cm^{-1}). With the knowledge of absolute configuration of the starting (+)-*trans*-pinocarveol, the (1R : 2S : 3S : 5R)-configuration can be assigned for (+)-*trans*-2-hydroxyneopinocampheol (VI).

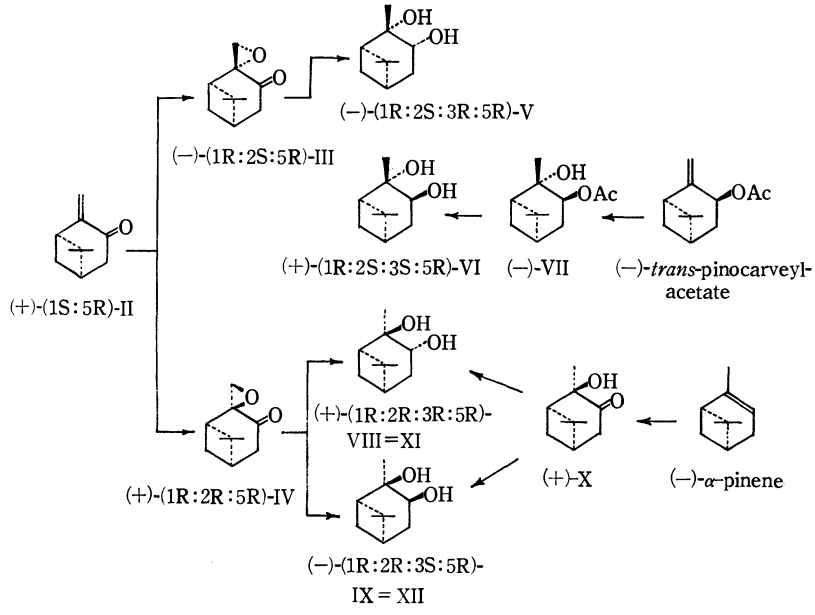


Scheme 1

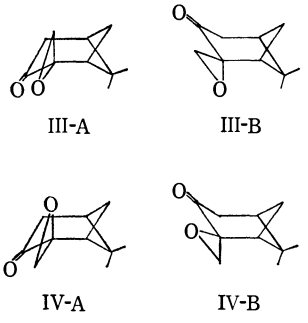
The comparison of IR spectra, R_f values and physical properties proved that neither VI, VIII nor IX was identical with the diastereomeric *cis*-diol V. Since VI, VIII and IX are excluded, it may be concluded that the diol V, the product resulting from the lithium aluminum hydride reduction of (−)-epoxide III, must have the sole remaining configuration, *i. e.*, (1R : 2S : 3R : 5R).

It naturally follows that the parent (−)-pinocarvone oxide (III) from which the levorotatory diol V was derived, should have the *trans*-(1R : 2S : 5R)-configuration.

In the consequence, (+)-pinocarvone oxide (IV), the parent compound of both VIII and IX, is assigned to the *cis*-(1R : 2R : 5R)-configuration. (See Scheme 1).

The ORD and CD curves of the isomeric pinocarvone oxides whose absolute configuration is now clarified seem to permit one to speculate with some certainty on the preferred conformation of these epoxides. The red shift at 323 mμ($\Delta\nu$=20 mμ) in the CD curve of (−)-III strongly suggests the axial disposition[4] would be expected to assume the III-B conformation rather than the other possibility, III-A, as implicit in Scheme 2. In contrast, however, the isomeric (+)-epoxide IV may reasonably be expected to exist largely in the IV-A conformation with the oxirane oxygen disposed in an axial position as cogently supported by the red shift ($\Delta\nu$=20 mμ) in the observed positive Cotton curve.

If one accepts conformation III-B for (−)-III and conformation IV-A for (+)-IV, one finds,



Scheme 2

with the knowledge of the absolute configurations and the experimentally determined Cotton effects, that the "reversed" Octant Rule is applicable to these oxirane systems, in agreement with the previous deduction.[1]

Experimental[5]

Preparation of Pinocarvone (II). Chromic acid anhydride (65 g) was carefully added to 1 *l* of dried pyridine at 0°. The resulting mixture was added to

4) C. Djerassi, O. Halpern, V. Halpern, O. Schindler and Ch. Tamm, *Helv. Chim. Acta*, **41**, 250 (1958).

5) Infrared spectra were recorded on a Shimadzu Model 27-G spectrophotometer. Optical rotatory dispersion and circular dichroism measurements were made on a Nippon Bunko Spectropolarimeter Model ORD/UV-5. Optical rotation measurements were recorded on a Perkin-Elmer Model 141 with 10 cm cell. Gas-liquid partition chromatography analyses were carried out using a Shimadzu 2-C gas chromatograph. A 3 mm×2.25 m column of 20% Hyporose-80 on Celite-545 served for vpc analyses. Nuclear magnetic resonance spectra were recorded with a Varian A-60 spectrometer.

30.0 g of I,[6] $[\alpha]_D^{22}$ +51.8°±1.0 (*c* 0.94, methanol), optical purity 71%, *trans*-pinocarveyl *p*-nitrobenzoate mp 91°C, in 50 m*l* of pyridine and was kept at room temperature for 18 hr. Water was then added to the mixture and was extracted with benzene - ether (1 : 1) solution. The combined benzene - ether extract was washed with 2 N hydrogen chloride solution, 3% hydrogen sodium carbonate solution and water, and dried over anhydrous sodium sulfate. After removal of solvent *in vacuo*, the crude product (26.0 g, 88% yield) was distilled to yield II[7]; bp 84—86°C/8 mmHg, (14.5 g). The IR spectrum exhibited the following characteristic absorptions (cm^{-1}): 1700s, 1680m, 1620s, 1390m, 1380m, 930s, 920s; λ_{max} 234 mμ (ε 6030) (in ethanol); $[\alpha]_D^{22}$ +48.0°±1.0 (*c* 0.84, methanol), optical purity 70%.

Preparation of Pinocarvone Oxide Mixture. A mixture of 10.0 g of pinocarvone in 65 m*l* of methanol and 22 m*l* of 30% hydrogen peroxide was cooled to −15°C, and a solution of 1.25 g of sodium hydroxide in 6 m*l* of water was added dropwise with stirring over a 15 min period. Stirring was continued for 4 hr, the temperature being maintained at 20—25°C. The reaction mixture was poured into 100 m*l* portions of ethyl ether. After the combined ether extract was washed and dried, the solvent was removed under reduced pressure and the residue was analyzed by vpc. The crude product, 8.0 g (yield 75%), consisted of 35.5%, III and 64.5%, IV.

Isolation and Properties of Pure Pinocarvone Oxides III and IV. Isolation of the pure diastereomer was effected by preparative vpc, of the fraction of distillation through a 30 cm concentric column, boiling at 98°C/5 mmHg. Further purification of the fraction on silica gel column chromatography gave III: the IR spectrum showed the following peaks (cm^{-1}): 1720s, 1390m, 1370m, 1275m, 1250m, 940w, 890m, 870m, 840m, 785m; $[\alpha]_D^{20}$ −22°±5 (*c* 0.10, dioxane); ORD mμ ([ϕ] in dioxane): 400 (−154), 340 (−789), 328sh(−369), 316sh(+478), 307(+921), 303 (+856), 300(+895), 265(−1000), 228(−3268): CD mμ ([θ] in dioxane): 333 (−668), 322.5 (−985), 313 (−788), 302 (−255); IV, IR spectra main bands (cm^{-1}): 1725s, 1385m, 1370m, 1275m, 1260m, 940m, 900m, 885m, 840m, 820m, 800m, $[\alpha]_D^{20}$ +74°±7 (*c* 0.27, dioxane): ORD mμ ([ϕ] in dioxane): 400 (+493), 340 (+2051), 332.5 (+1417), 327 (+1807), 318.5 (+390), 314 (+629), 306 (−383), 302.5 (−171), 297 (−500), 291.5 (−276), 290 (−293), 224 (+6829), 210 (−850); CD mμ ([θ] in dioxane): 336 (+967), 323 (+1781), 311 (+1628), 302 (+1018), 292 (+545), 275 (+143), 252 (+50).

Lithium Aluminum Hydride Reduction of (−)-Pinocarvone Oxide (III). The oxide III (37.0 mg) dissolved in 3 m*l* of absolute ether was added dropwise with stirring to a chilled (−10°C) slurry of 100 mg of lithium aluminum hydride in 3 m*l* of absolute ether. Upon completion of addition, the solution was stirred at 0°C for an additional hour, stirring was continued at room temperature (15—20°C) for 10 hr and finally, the reaction mixture was refluxed on water bath and cooled. Excess hydride was decomposed by addition of the ether saturated with water under cooling, and the organic layer was separated, filtered and dried. Removal of the solvent gave the diol V, $[\alpha]_D^{22}$ −17.6±1.4 (*c* 0.40, methanol), and its NMR spectrum indicated a three hydrogens singlet (τ 8.94) for methyl, a six hydrogens singlet (τ 8.78) for the geminal dimethyl, and one hydrogen AB quartet (τ_A 6.22; τ_B 6.06, J=7 Hz) for the hydrogen on the carbon bearing the hydroxyl group.

Lithium Aluminum Hydride Reduction of (+)-Pinocarvone Oxide (IV). The oxide IV (60.4 mg) was reduced with lithium aluminum hydride (100 mg) in 5 m*l* of absolute ether, in the same way as mentioned above, to give a mixture of VIII and IV, yield 54.6 mg (yield 88%). Diols VIII and IX were separated by means of silica gel column chromatography: VIII, mp 158°C, $[\alpha]_D^{22}$ −42.5°±1.0 (*c* 0.57, methanol) and oily crude (−)-IX.

Preparation of Hydroxypinocamphone (X).[2] To a solution of 28 g of (−)-α-pinene ($[\alpha]_D^{20}$ −26.8° ±1.0, *c* 0.67, methanol, optical purity 52%) in 250 m*l* of 90% acetone was added 56 g of potassium permanganate with stirring at 0—5°C for 8 hr. The manganese dioxide was filtered off, and the acetone was removed under reduced pressure to afford a crude product 20 g (58%) of (+)-X.

Reduction of Hydroxypinocamphone (X). Lithium aluminum hydride reduction of 513 mg of **X** in the same way as mentioned above gave 508 mg (98%) of XI, mp 158°, $[\alpha]_D^{22}$ −39.1° ±3.0 (*c* 0.21, methanol).

Found: C, 70.68; H, 10.67%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

The NMR spectrum of the monoacetate of XI indicated a three hydrogens singlet (τ 9.04) for methyl, a six hydrogens doublet (τ 8.75) for geminal dimethyl, a three hydrogens singlet (τ 7.87) for acetoxy and one hydrogen AB quartet (τ_A 5.02: τ_B 4.84, J=7 Hz) for the hydrogen on the carbon bearing the acetoxy group.

The Meerwein-Ponndorf-Verley reduction of 3.0 g of **X** was carried out with 10 g of aluminum isopropylate in 20 m*l* of absolute isopropanol in the usual manner.[2] There were obtained 2.9 g of the diol XII (95%).

Preparation of (+)-*trans*-2-Hydroxyneopinocampheol (VI). A mixture of 2.0 g of (+)-I and 0.4 g of anhydrous sodium acetate in 2 m*l* of acetic anhydride was heated at 140°C for 1 hr and the reaction mixture was poured into water. The reaction mixture was extracted with ether and the solvent was removed under reduced pressure to give 1.6 g (63%) of *trans*-pinocarveyl acetate, $[\alpha]_D^{22}$ −7.5°±0.7 (*c* 0.69, methanol). A mixture of 1.6 g of mercuric acetate in 10 m*l* of aqueous-tetrahydrofuran (1 : 1 by volume) was added dropwise to 0.5 g of *trans*-pinocarveyl acetate with stirring for 4 hr and then kept at room temperature for 16 hr. Then 5 m*l* of 3 M sodium hydroxide was added, followed by 6 m*l* of 0.5 M sodium borohydride in 3.0 M sodium hydroxide. The water layer was saturated with sodium chloride. The upper layer of tetrahydrofuran was separated. It contained 0.45 g (81%) of VII $[\alpha]_D^{22}$ −15.9°±0.9 (*c* 0.62, methanol).

The acetate VII (0.4 g) was refluxed in 10 m*l* of methanol with 0.2 g of potassium hydrioxide on a water bath (95°C) for 1 hr. The reaction mixture was poured

6) (+)-*trans*-Pinocarveol (I), derived from (−)-α-pinene, by means of photo-oxidation method using Rose Bengal as a photosensitizer in methanol, was supplied by Takasago Kogyo Co., Ltd. Research Laboratory.

Herz of Florida University, Dr. M. Kobayashi, Mr. K. Hashimoto and Mr. H. Watanabe of Sun Star Research Laboratory, for many helpful discussions and suggestions during this work, and to Takasago Perfumery Co., Ltd. for their generous gifts of authentic samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2703—2706 (1968)

Convenient Method for the Preparations of Carboxylic Thiolester and Acid Anhydride

Teruaki MUKAIYAMA and Harumi KATSUYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 11, 1968)

The reactions of mercuric carboxylates with bivalent sulfur compounds, such as aralkyl sulfides and mercaptoles, were investigated. When mercuric acetate and aralkyl sulfides were refluxed in benzene, mercury mercaptides and aralkyl acetates were obtained. It was made clear that the reactivity of the sulfides depends on the stability of carbonium ions given by elimination of the mercapto group. Next, it was found that acetic anhydride, benzophenone and mercury phenylmercaptide were obtained in high yields by the equimolar reaction of benzophenone diphenylmercaptole with mercuric acetate. Further, the reaction was extended to the preparative method of carboxylic acid anhydrides from free acids by treating the carboxylic acids with diphenylmercury and the mercaptole. On the other hand, *S*-phenyl thioacetate, benzophenone and mercury mercaptide were produced in good yields when benzophenone diphenylmercaptole (2 mol) was treated with mercuric acetate (1 mol). Further, it was established that thiolesters were exclusively produced in good yields along with benzophenone and the mercury mercaptide by the reaction of benzophenone diphenylmercaptole or bis(*p*-chlorophenyl)mercaptole (2 mol) with free carboxylic acids (2 mol) and diphenylmercury (1 mol).

In the preceding paper,[1] it has been shown that acetic anhydride, *N,N*-dimethylbenzamide and mercury ethylmercaptide were obtained in good yields by treating *N,N*-dimethylbenzamide diethylmercaptole with mercuric acetate at room temperature. This reaction was reasoned by considering facile elimination of the mercapto group from *N,N*-dimethylbenzamide diethylmercaptole by an attack of the mercuric acetate yielding a reactive intermediate, acyloxyimmonium ion. In the present experiment, the reactions of phenyl aralkyl sulfides with mercuric acetate were tried first in order to find out the facility of elimination of phenylmercapto group from the sulfides by the attack of the mercuric salt. For example, when phenyl trityl sulfide was treated with mercuric acetate in boiling benzene for 3 hr, mercury phenylmercaptide and trityl acetate were obtained in good yields. It was found that the reaction of phenyl benzhydryl sulfide with mercuric acetate under the same conditions yields only a small amount of benzhydryl acetate and phenylmercapto mercury acetate. But, benzhydryl acetate and mercury phenylmercaptide were obtained in good yields by carrying out the reaction in the presence

Table 1. The reaction of phenyl aralkyl sulfides with mercuric acetate[a]

Aralkyl group	Catalyst	Yield, %		
		Aralkyl acetate	$(C_6H_5S)_2$-Hg	C_6H_5SHg-$OCOCH_3$
$(C_6H_5)_3C$-	—	70	90	—
$(C_6H_5)_2CH$-	—	33	—	86
$(C_6H_5)_2CH$-	$BF_3 \cdot O(C_2H_5)_2$	83	85	—
$C_6H_5CH_2$-	$BF_3 \cdot O(C_2H_5)_2$	30	—	

a) These reactions were carried out in refluxing benzene for 3 hr.

1) T. Yamaguchi and T. Mukaiyama, This Bulletin, **40**, 1952 (1967).

of a catalytic amount of boron trifluoride etherate (see Table 1).

$$C_6H_5SR + \tfrac{1}{2}(CH_3CO_2)_2Hg \rightarrow CH_3CO_2R + \tfrac{1}{2}(C_6H_5S)_2Hg$$

R: Aralkyl

These results show that the reactivity of the aralkyl sulfides decreases in the following sequence: $(C_6H_5)_3C- > (C_6H_5)_2CH- > C_6H_5CH_2-$. This order also suggests that the ease of carbon-sulfur bond fission[2] is dependent on the stability of carbonium ions formed by elimination of the mercapto group.

Next, the reactions of the mercaptoles with mercuric carboxylates were tried with the assumption that acid anhydrides, the ketone and mercury mercaptide would be produced as in the case of the reaction of mercuric acetate with *N,N*-dimethylbenzamide diethylmercaptole.

Concerning the reactions of mercaptals with heavy metal salts, Painter reported[3] that one of the ethylmercapto group of penta-*O*-acetyl diethylmercaptals of some hexoses was substituted by an acetoxy group when the mercaptals were treated with mercuric acetate. Bourne also reported[4] that the reaction of benzaldehyde dibenzylmercaptal with lead tetraacetate gave benzylidene diacetate, dibenzyl disulfide and lead acetate.

It was established that acetic anhydride, benzophenone and mercury phenylmercaptide were obtained in good yields by treating benzophenone diphenylmercaptole with mercuric acetate in boiling benzene in the presence of a catalytic amount of boron trifluoride etherate, as expected. Benzophenone diphenylmercaptole was chosen as the mercaptole with the expectation that it would readily eliminate the mercapto group, activated by two phenyl and a phenylmercapto groups attached to the same carbon.

$$(C_6H_5)_2C(SC_6H_5)_2 + (CH_3CO_2)_2Hg \rightarrow (CH_3CO)_2O + (C_6H_5)_2CO + (C_6H_5S)_2Hg$$

68% 96% 96%

Next, the reactions of carboxylic acids, diphenylmercury and the mercaptole were tried to explore a convenient method for the synthesis of acid anhydrides starting from free acids with the consideration that the mercuric carboxylates would be produced from free acids and diphenylmercury. Indeed, various acid anhydrides, benzophenone and mercury phenylmercaptide were obtained in good yields by refluxing 2 mol of free carboxylic acids, 1 mol of diphenylmercury and 1 mol of the mercaptole in anhydrous benzene for a few hours in the presence of a catalytic amount of boron trifluoride etherate. The results are listed in Table 2.

$$(C_6H_5)_2C(SC_6H_5)_2 + 2RCO_2H + (C_6H_5)_2Hg \xrightarrow{-2C_6H_6} (RCO)_2O + (C_6H_5)_2CO + (C_6H_5S)_2Hg$$

TABLE 2. THE REACTIONS OF BENZOPHENONE DIPHENYLMERCAPTOLE (1 MOL) WITH FREE CARBOXYLIC ACIDS (2 MOL) AND DIPHENYLMERCURY (1 MOL)[a]

Carboxylic acid	Yield, %		
	Acid anhydride	Benzophenone	$(C_6H_5S)_2Hg$
Acetic	67	94	85
Propionic	55	88	94
n-Butyric	63	94	80
Cinnamic	74	75	80
Benzoic[b]	51	90	87

a) These reactions were carried out in refluxing benzene for 4 hr in the presence of a catalytic amount of boron trifluoride etherate.

b) In the case of benzoic acid, 11% yield of *S*-phenyl thiobenzoate based on benzoic acid was also obtained.

On the other hand, it was found that *S*-phenyl thioacetate, benzophenone and mercury phenylmercaptide were produced in high yields by treating 2 mol of benzophenone diphenylmercaptole with 1 mol of mercuric acetate under the same conditions.

$$2(C_6H_5)_2C(SC_6H_5)_2 + (CH_3CO_2)_2Hg \rightarrow 2CH_3COSC_6H_5 + 2(C_6H_5)_2CO + (C_6H_5S)_2Hg$$

63% 92% 97%

The use of diphenylmercury extended this reaction to a preparative method of thiolesters starting from free carboxylic acids on the basis of the similar consideration as mentioned above. The reactions of benzophenone diphenylmercaptole or bis(*p*-chlorophenyl)mercaptole (2 mol) with free carboxylic acids (2 mol) and diphenylmercury (1 mol) in boiling benzene in the presence of a catalytic amount of boron trifluoride etherate gave *S*-phenyl or *S*-*p*-chlorophenyl thiocarboxylates, benzophenone and the mercury mercaptide in high yields. The results are listed in Tables 3 and 4.

$$2(C_6H_5)_2C(SC_6H_4\text{-}X\text{-}p)_2 + 2RCO_2H + (C_6H_5)_2Hg \xrightarrow[-2C_6H_6]{} 2RCOSC_6H_4\text{-}X\text{-}p + 2(C_6H_5)_2CO + (p\text{-}X\text{-}C_6H_4S)_2Hg$$

X: H or Cl

The formation of acid anhydrides or thiolesters can be explained by considering an initial formation of an intermediate (1) from mercuric carboxylates

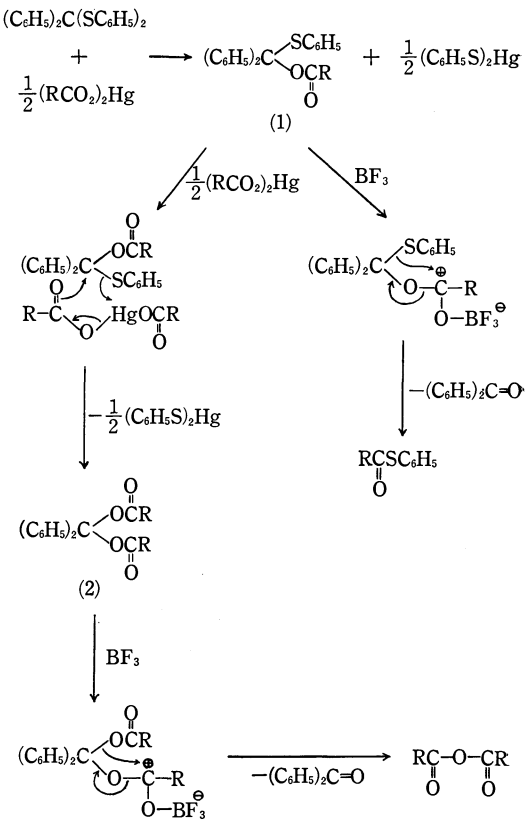
b) In the case of *p*-nitrobenzoic acid, only 37% yield of *p*-nitrobenzoic anhydride resulted.

Table 4. The reactions of benzophenone bis(*p*-chlorophenyl)mercaptole (2 mol) with free carboxylic acids (2 mol) and diphenylmercury (1 mol)[a]

Carboxylic acid	Yield, %		
	S-*p*-Chlorophenyl thiocarboxylate	Benzophenone	$(C_6H_5S)_2Hg$
Acetic	84	88	98
n-Butyric	75	98	98
n-Stearic	60	73	92
Benzoic[b]	21	44	98
p-Anisic	79	93	98
Cinnamic	88	96	98

a) These reactions were carried out in refluxing benzene for 2 hr in the presence of a catalytic amount of boron trifluoride etherate.
b) In the case of benzoic acid, 34% yield of benzoic anhydride based on benzoic acid was obtained together with the thiolester.

and the mercaptole. When one half mole of mercuric carboxylates are used, thiolesters are exclusively produced from the intermediate (1) by an intramolecular nucleophilic displacement. On the other hand, in the presence of an additional half mole of mercuric carboxylates, the intermediate (1) further reacts with them to give the second intermediate (2), an acylal, by a nucleophilic attack of the mercapto group on the mercury atom. The second intermediate (2) then yields benzophenone and acid anhydrides by the aid of boron trifluoride.



Experimental

Reaction of Phenyl Trityl Sulfide with Mercuric Acetate. A solution of phenyl trityl sulfide (3.52 g, 0.01 mol) and mercuric acetate (1.59 g, 0.005 mol) in 20 m*l* of anhydrous benzene was refluxed for 3 hr. After cooling the reaction mixture, the precipitate was filtered off to give mercury phenylmercaptide, 1.76 g (82%), mp 150°C. The filtrate was evaporated *in vacuo*. The addition of 10 m*l* of anhydrous ether-petroleum ether mixture (1 : 1 v/v) to this residue gave the precipitate containing the mercury salt, and the sulfide was recovered. It was filtered off and the filtrate was concentrated under reduced pressure. To the resulted oil a small amount of anhydrous petroleum ether was added and this mixture was heated until it became a homogeneous solution. Trityl acetate was obtained as colorless crystals from the solution, 2.10 g (70%), mp 83°C (Found: C, 82.81; H, 6.06%).

Reaction of Phenyl Benzhydryl Sulfide with Mercuric Acetate in the Presence of a Catalytic Amount of Boron Trifluoride Etherate. A solution of phenyl benzhydryl sulfide (2.76 g, 0.01 mol) and mercuric acetate (1.59 g, 0.005 mol) in 20 m*l* of benzene was refluxed for 3 hr in the presence of a catalytic amount of boron trifluoride etherate. After cooling the reaction mixture, the precipitate of mercury phenylmercaptide (1.76 g, 85%) was filtered off and the filtrate was evaporated *in vacuo*. The residue was distilled to give benzhydryl acetate, 1.95 g (86%), bp 124°C/1 mmHg (Found: C, 79.40; H, 5.96%).

Equimolar Reaction of Benzophenone Diphenylmercaptole with Mercuric Acetate. A solution of benzophenone diphenylmercaptole (7.64 g, 0.02 mol) and mercuric acetate (6.36 g, 0.02 mol) in 40 m*l* of anhydrous benzene was refluxed for 0.5 hr in the presence of a catalytic amount of boron trifluoride etherate. After cooling the reaction mixture, the precipitate was filtered off to give mercury phenylmercaptide, 8.10 g (97%). The filtrate was concentrated and distilled to give 1.39 g (68%) of acetic anhydride, bp 70—72°C/90 mmHg, and 3.32 g (92%) of benzophenone.

Reaction of Benzophenone Diphenylmercaptole (1 mol) with Cinnamic Acid (2 mol) and Diphenylmercury (1 mol). A solution of benzophenone diphenylmercaptole (3.82 g, 0.01 mol), cinnamic acid (2.96 g, 0.02 mol) and diphenylmercury (3.54 g, 0.01 mol) in 40 m*l* of anhydrous benzene was refluxed for 4 hr in the presence of a catalytic amount of boron trifluoride etherate. After the reaction mixture was cooled, the precipitate was filtered off to give mercury phenylmercaptide, 3.33 g (80%), and the filtrate was evaporated *in vacuo*. The addition of 10 m*l* of alcohol to this residue gave the precipitate of cinnamic anhydride, 2.05 g (74%), mp 136°C (Found: C, 77.92; H, 5.10%). The filtrate was evaporated *in vacuo* and the residue was distilled to give benzophenone, 1.39 g (75%) and a small amount of cinnamic acid recovered.

Reaction of Benzophenone Diphenylmercaptole (2 mol) with Mercuric Acetate (1 mol). A solution of benzophenone diphenylmercaptole (3.82 g, 0.01 mol) and mercuric acetate (1.59 g, 0.005 mol) in 20 m*l* of anhydrous benzene was refluxed for 0.5 hr in the presence of a catalytic amount of boron trifluoride etherate. After the reaction mixture was cooled, the precipitate was filtered off to give mercury phenylmercaptide, 1.92 g (92%). The filtrate was evaporated *in vacuo* and the residue was distilled to give *S*-phenyl thioacetate, 0.96 g (63%), bp 63°C/0.3 mmHg and benzophenone, 1.69 g (92%) (Found: C, 62.85; H, 5.58%).

Reaction of Benzophenone Bis(*p*-chlorophenyl)-mercaptole (2 mol) with Acetic Acid (2 mol) and Diphenylmercury (1 mol). A solution of benzophenone bis(*p*-chlorophenyl)mercaptole (3.82 g, 0.01 mol), acetic acid (0.60 g, 0.01 mol) and diphenylmercury (1.77 g, 0.005 mol) in 20 m*l* of anhydrous benzene was refluxed for 2 hr in the presence of a catalytic amount of boron trifluoride etherate. After the reaction mixture was cooled, the precipitate was filtered off to give mercury *p*-chlorophenylmercaptide, 2.07 g (98%). The filtrate was evaporated *in vacuo* and the residue was distilled to give *S*-*p*-chlorophenyl thioacetate, 0.78 g (84%), bp 142—144°C/20 mmHg, and benzophenone, 1.60 g (88%).

Found: C, 51.71; H, 3.78%. Calcd for C_8H_7OClS: C, 51.49; H, 3.78%.

Reaction of Benzophenone Diphenylmercaptole (2 mol) with *p*-Toluic Acid (2 mol) and Diphenylmercury (1 mol). A solution of benzophenone diphenylmercaptole (3.84 g, 0.01 mol), *p*-toluic acid (1.36 g, 0.01 mol) and diphenylmercury (1.77 g, 0.005 mol) in 20 m*l* of anhydrous benzene was refluxed for 5 hr in the presence of a catalytic amount of boron trifluoride etherate. After the reaction mixture was cooled, the precipitate was filtered off to give mercury phenylmercaptide, 1.98 g (95%). The filtrate was evaporated *in vacuo* and the crystalline residue was washed with 2 portions of 10 m*l* of anhydrous pentane. The crystalline product was *S*-phenyl *p*-thiotoluate, 1.80 g (79%), mp 91.5—92°C (from alcohol).

Found: C, 73.38; H, 5.31%. Calcd for $C_{14}H_{12}OS$: C, 73.67; H, 5.30%.

The pentane solution was evaporated *in vacuo* and the resulting oil was distilled to give benzophenone, 1.71 g (94%).

The authors wish to express their hearty thanks to Mr. Khoichi Wada for his help during this experiment. Grateful acknowledgment is also made to Miss Kazuko Isojima for her microanalyses.

(Received April 15, 1968)

Reaction of α-carboxy-β-carbethoxy-γ,γ-dimethylbutyrolactone (**3**) with equimolar amount of nitrous acid gave ethyl α-hydroxyaminoaconate (**7**). However, the nitrosation of **3** using excess nitrous acid afforded a variety of compounds such as α-diazo (**4** and **5**), α-nitro (**8**), and α-azoxybutyrolactone (**9**) derivatives. Each of the products (**4**, **5**, **8**, and **9**) could be synthesized from **7**, independently. By the action of phosphoric acid, α-diazolactones (**4** and **5**) were converted into ethyl α,β-epoxyparaconate (**6**). The nature of the product **7** was demonstrated through its conversion into ethyl α-hydroxyaconate and through its thermal decomposition to ethyl α-aminoaconate and α-isopropylidenecyanoacetic acid derivatives. A possible mechanism for the formation of **6** through **4** and **5** is described.

All of the previous reports concerning the nitrosation of α-substituted butyrolactones (**1**)[2] have only described the formation of α-hydroximinobutyrolactones (**2**) as a main product. However, we found that nitrosation of α-carboxy-β-carbethoxybutyrolactones,[3] readily prepared from α,β-dicarbethoxybutyrolacetones,[4] afforded a mixture of complex substances, some of which can be used as a potential intermediate in the synthesis of α,β-epoxyparaconic acid.

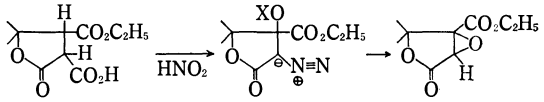
2

R=R'=H, Alkyl;
R''=CH_3, OC_2H_5, OH

In this paper, nitrosation of a model compound, α-carboxy-β-carbethoxy-γ,γ-dimethylbutyrolactone (**3**)[3] with sodium nitrite in an aqueous acetic acid, which leads ultimately to the formation of the corresponding ethyl α,β-epoxyparaconate (**6**) *via* α-diazolactones (**4** and **5**), is described.



3 **4** X=Ac, **5** X=H **6**

The nitrosation of **3** with an approximately equimolar amount of sodium nitrite in an aqueous acetic acid at 0—5°C, or with a large excess of sodium nitrite at about −5°C for a short reaction period, gave mainly ethyl α-hydroxyamino-γ,γ-dimethylaconate (**7**), white crystals, mp 73°C, which showed an intense band in the 3500—3100 region, consistent with NH and OH functions, 1775, 1695 (lactone, conjugated ester C=O), and 1655 cm^{-1} due to double bond.[5] The ultraviolet spectrum of **7** had λ_{max} 224 mμ (ε 11000) and 258 mμ (ε 760) in ethanol. The NMR spectrum of **7** showed one hydroxy proton at τ 6.10, six gamma dimethyl protons at 8.44 and 8.50, three methyl protons centered at 8.73, two methylene protons centered at 5.78, and one imino proton, as a multiplet form centered at −0.90.

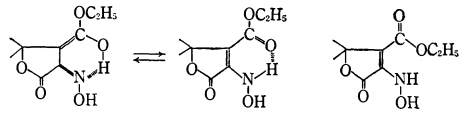
7

On the other hand, when the lactone acid **3** was allowed to react with a large excess of sodium nitrite in an aqueous acetic acid at 5—10°C for 4—5 hr, a mixture having a sharp band in the infrared at 2100 cm^{-1} was obtained together with **7**. Thin-layer chromatography (tlc) on silica gel G (E. Merck), developed by acetone - benzene mixture (1 : 8), revealed that this mixture consisted of more than four components which corresponded to R_f values: 0.70, 0.35, 0.26, and 0.16. Separation of each constituents was carried out by the extraction of the crude product with the alternate use of saturated aqueous sodium bicarbonate and saturated aqueous sodium carbonate, or by collecting each spots on silica gel plates individually. The compound corresponding to the third spot (R_f 0.26) was found to be identical with **7** by the comparison of their infrared and NMR spectral data. The top and the second constituents (R_f 0.70 and 0.35) gave total yield of 65—70% and have a sharp absorption at 2100 cm^{-1}. The elongated oval shape of the fourth spot (R_f 0.16) suggested the presence of two components.

The structure of the compound, pale yellow oil, of the top spot (R_f 0.70) is considered to be **4**, since the infrared spectrum of **4** had a sharp band at 2100 cm^{-1} due to diazo group[6] and a broad band at 1760—1750 cm^{-1}, corresponding to lactone and ester carbonyls. The NMR spectrum of **4** showed three acetoxy protons at τ 7.80 as a singlet.

5) Dr. H. Wamhoff of Bonn University suggested that from the NMR data of the compound (**7**) provided by us, there is a H-bridge from the NH-proton to the neighboring C=O group and this causes a shift of NH-proton signal to lower field down to τ −0.64 in deuterochloroform. Furthermore, he mentioned that the infrared spectrum of **7** in chloroform showed three peaks between 1600—1800 cm^{-1}: 1780 (lactone C=O), 1740 (ester C=O), and 1660 cm^{-1} (C=C), and these values are similar to those of the saturated lactones. These facts reveal that concerning the α,β-unsaturated ester group, **7** may have structures such as A or B in chloroform in contrast to the solid state in Nujol mull, which may not undergo a solvation and have a structure of C.

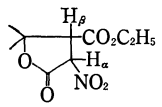


B A C

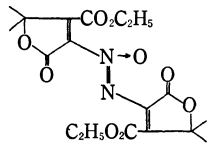
6) Diazo carbonyl compounds have a sharp infrared absorption in the 2100—2150 cm^{-1} region: G. R. Harvey, *J. Org. Chem.*, **31**, 1587 (1966); D. Hauser and H. P. Sigg, *Helv. Acta Chim.*, **50**, 1327 (1967); S. Julia, G. Cannic and G. Linstrumelle, *Compt. Rend.*, **264**, 1890 (1967).

The structure of the second component (R_f 0.35), pale yellow oil, was assigned to **5**, whose infrared spectrum showed a sharp band at 2100 cm^{-1} and a characteristic broad band at 3500—3000 cm^{-1} due to diazo and hydroxy group, respectively. It was observed that the NMR spectrum of **5** has a band at τ 5.60 due to hydroxy proton in place of a band at 7.80 due to acetoxy group of **4**. Nitrosation of **7** by treating with an excess sodium nitrite in an aqueous acetic acid at 3—7°C for 3 hr gave a major product (**5**) and a minor product (**4**) (*ca.* 5 : 1).

From the head part of the fourth constituents (R_f 0.16) was obtained the white crystals, mp 65.5—66.5°C, which exhibited sharp absorptions at 1565 and 1378 cm^{-1} due to nitro group[7] and was assigned to **8**. Its infrared spectrum exhibited two absorption bands at 1785 and 1728 cm^{-1} due to lactone and ester carbonyls. The NMR spectrum of **8** showed an AB pattern of two bands (doublet, $J_{\alpha,\beta}$ 9—10 cps) centered at τ 4.10 ($\underline{H}_\alpha$) and 5.96 ($\underline{H}_\beta$), indicating that the dihedral angle between two protons is close to 180° from the Karplus curve.[8] Confirmation of the structure of **8** was provided by an independent synthesis involving oxidation of **7** with excess sodium nitrite or nitric acid in an aqueous acetic acid at 0—2°C for about 30 min.



8



9

The last component, amorphous pale yellow solid, mp 120—123°C, was obtained from the tail part of the oval spot (R_f 0.16)on the tlc plate and purified by repeating tlc on the silica gel G plates. The infrared spectrum indicated the absence of nitro group. Its structure was assigned to **9**, which have absorptions at 1780, 1750 (lactone, ester C=O), 1635 (C=C), and strong bands at 1260 and 1300 cm^{-1}, one of which may be due to azoxy group.[9] The NMR spectrum of **9** showed no absorption except for bands in the regions of 8.9—9.3(*gem*-$C\underline{H}_3$, $C\underline{H}_3$-C-O) and 6.0—5.3 (C-$C\underline{H}_2$-O). The ultraviolet spectrum of **9** had λ_{max} 226 mμ (ε 12000) in ethanol. Considering the preparative methods of the azoxy compound such as the oxidation of hydroxyamine derivatives in neutral media[10]

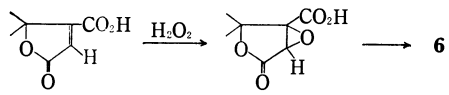
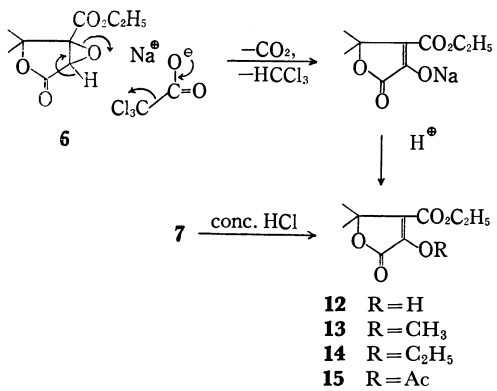
and the reaction of nitroso group with hydroxyamine,[11] we attempted the oxidation of **7** with manganese dioxide in acetone for 2 days and obtained **9** in quantitative yield.

Treatment of α-diazolactone (**4** and **5**) with phosphoric acid gave the α,β-epoxybutyrolactone (**6**), bp 100°C/2 mmHg, in excellent yield (*ca.* 90%). A proof of the structure of **6** was obtained by epoxidation[12] of aconic acid (**10**),[13] followed by esterification of α,β-epoxyparaconic acid (**11**) with ethyl orthoformate.[14]



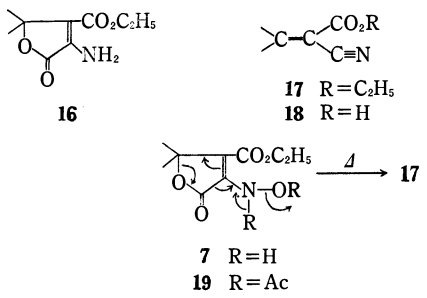
10 **11**

Several aspects of the chemical property of the *intermediates (**6** and **7**) are of particular interest.* Namely, ethyl α-hydroxyaconate (**12**)[15] was obtained readily in good yield by the treatment of **7** with concentrated hydrochloric acid at room temperature. Treatment of **6** with sodium trichloroacetate at 90—130°C also gave **12** in excellent yield along with the evolution of carbon dioxide and chloroform.[16] The structure of **12** was inferred from its spectral data[15] and microanalysis. A mechanism of the formation of **12** is given in Scheme I. The physical constants of a series of the derivatives (**12**, **13**, **14** and **15**) are shown in experimental part and Table 1.



Scheme I

On the other hand, ethyl α-aminoaconate (**16**) was obtained in 15—20% yield together with isopropylidenecyanoacetic acid derivatives (**17**[17] and **18**[18]), when **7** was subjected to thermal decomposition at 140—160°C under reduced pressure. Pyrolysis of diacetate (**19**), prepared by boiling **7** with acetic anhydride, gave only **17**, indicating that normal thermal decomposition may proceed *as below, and formation of **16** may be due to a* disproportionation.



The structure of **16** was proven by its spectral data and microanalysis. Thus, mass spectrum of **16** exhibited a peak at *m/e* 199, corresponding to molecular ion. The infrared spectrum showed two bands at 3350—3450 (NH_2), two bands at 1760 and 1686 (lactone, ester C=O) and a band at 1640 cm^{-1} (C=O). The NMR spectrum showed the following absorptions: τ 4.40 (broadened, NH_2), 8.76 and 5.65 (triplet and quartet, CH_3CH_2O–), and 8.30 (singlet, 2 CH_3).

The possible mechanism of the formation of the

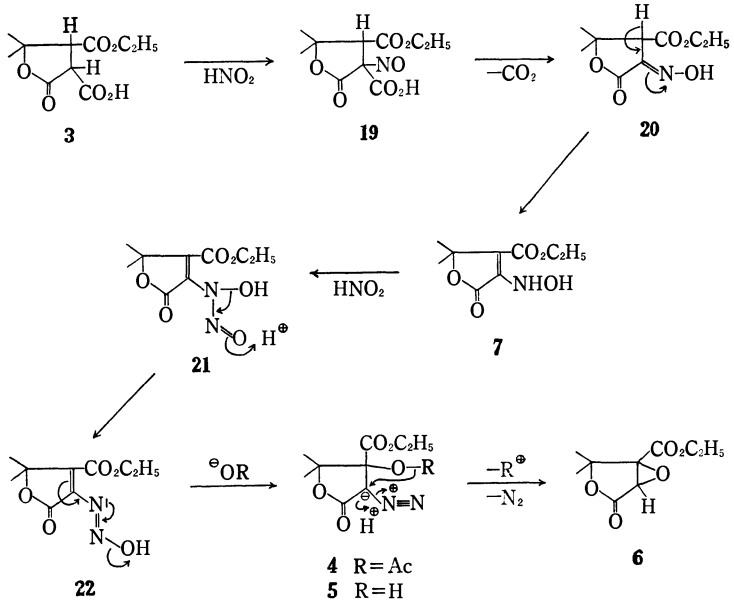

Scheme II. Mechanism of the formation of the epoxylactone.

epoxylactone (**6**) are depicted in Scheme II. The presence of the carbethoxy group at the β-position of the lactone ring would have effected a rapid transformation of the transient intermediates (**19** and **20**) to the α-hydroxyaminoaconate (**7**), which may be stabilized by forming a conjugated ring system in an acidic media. It is considered that the compound (**7**) would be the key intermediate for the present reaction, since **7** can be converted into the α-diazolactones (**4** and **5**) by the action of excess nitrous acid *via* **21** and **22**, which were affected by phosphoric acid to afford the epoxylactone (**6**), as a result of electrophilic attack of a proton to the α-carbon atom along with the elimination of a nitrogen molecule, followed by the intramolecular nucleophilic attack of the oxygen atom attached to the β-position of **4** and **5**.

Experimental[19]

Ethyl α-Hydroxyamino-γ,γ-dimethylaconate (7). To a solution of α-carboxy-β-carbethoxy-γ,γ-dimethylbutyrolactone (**3**)[3] (5 g) in glacial acetic acid (10 m*l*) sodium nitrite (1.5 g) in water (3 m*l*) was added. The reaction mixture was stirred for 30 min at 0—2°C and then diluted with water (34 m*l*) with stirring for 1 hr. The mixture was extracted with ether and the extract was washed with aqueous sodium chloride. After drying over Na_2SO_4 and concentrating by evaporation, the residue, when scrubbed, solidified and afforded 3.2 g (68.1%) of **7**, mp 71.5°C (*n*-hexane - benzene); IR (Nujol mull) 3280, 3100, 1778, 1700, 1655, 1400, 1375, 1340, 1260, 1195, 1090, 990, 910, 870, and (ethanol or chloroform) 1780—1775 (lactone C=O), 1745—1740 (ester C=O), 1660 cm^{-1} (C=C); UV max (95% EtOH) 224 mμ (ε 11000) and 258 mμ (ε 760); NMR ($CHCl_3$) τ −0.90 (m, NH), 5.77 (q, C-CH$_2$-O), 6.10 (s, OH), 8.44 (s, CH$_3$), 8.50 (s, CH$_3$), and 8.72 (t, CH$_3$-C-O).

Found: C, 50.18; H, 6.08; N, 6.47%. Calcd for $C_9H_{13}NO_5$: C, 50.23; H, 6.09; N, 6.51%.

Nitrosation of α-Carboxy-β-carbethoxy-γ,γ-dimethylbutyrolactone (3). A solution of sodium nitrite (10 g) in water (20 m*l*) was added to a solution of **3** (20 g)[3] in glacial acetic acid (36 m*l*) with stirring at 0—5°C. After the mixture had been stirred for 30 min at 10—15°C, it was diluted with water (170 m*l*), stirred for an additional 1 hr, and the organic layer was taken up in ether. The extract was washed several times with aqueous sodium chloride, once with a small portion of 5% aqueous sodium bicarbonate, twice with aqueous sodium chloride, and dried over Na_2SO_4. Removal of the solvent gave 16.0 g of slightly greenish yellow, neutral liquid (Mixture I), which showed a strong band at 2100 cm^{-1}. The tlc of the Mixture I showed four spots (R_f values: 0.70, 0.35, 0.26, and 0.16).

Separation of each components of the Mixture I was carried out as follows: the ethereal solution of the Mixture I (16.0 g) extracted several times with 5% aqueous sodium bicarbonate (2.5 *l*), washed with aqueous sodium chloride, and dried over Na_2SO_4. Evaporation of the solvent gave 4.0 g of pale greenish yellow liquid (Mixture II) which was chromatographed on thin layer

19) All melting and boiling points are uncorrected. Infrared spectra were determined on a Hitachi EPI-S$_2$ and ultraviolet spectra on a Hitachi ESP-3T spectrophotometer. Thin layer chromatography (tlc) on baked silica gel G (E. Merck) as the support with acetone-benzene (1 : 8) as the solvent and with iodine for detection purposes was employed throughout the experiments. The NMR spectra were obtained on Japan Electron Optics Laboratory spectrometer (JNM-C-60) in chloroform with TMS as internal standard. The molecular weight determinations were made on a Hitachi RMU-6E mass spectrometer using a cold injection port. Microanalyses were performed by Miss H. Nisino of our laboratory.

plate to give two spots (R_f: 0.70 and 0.16). The Mixture II (4.0 g) dissolved in ether was extracted with aqueous sodium carbonate (100 ml), washed with aqueous sodium chloride, and dried over Na_2SO_4. Removal of the ether gave slightly colored liquid (**4**) (2.5 g) which gave a spot (R_f 0.70) on silica gel plate. Analytically pure sample of **4** was obtained from the spots (R_f 0.70) on silica gel plates arranged to 0.8 mm thickness. The spectral data were as follows: IR 3000—2850, 2100, 1765—1740, 1390, 1375, 1360, 1305, 1240, 1080, 1050, 1020, 980, 930, 910, 730 cm^{-1}; UV max (95% EtOH) 217 mμ (ε 4230) and 255 mμ (ε 7050); NMR ($HCCl_3$) τ 5.27 (q, C-C$\underline{H}_2$-O), 7.84 (s, C$\underline{H}_3$COO), 8.40 (s, C$\underline{H}_3$), 8.62 (s, C$\underline{H}_3$), 8.68 (t, C$\underline{H}_3$-C-O).

Found: C, 49.26; H, 5.42; N, 9.97%. Calcd for $C_{11}H_{14}N_2O_6$: C, 48.89; H, 5.22; N, 10.37%.

The extracts with aqueous sodium carbonate were acidified with dilute sulfuric acid to pH 6.5—7 and extracted with ether. The extracts were washed with aqueous sodium chloride and dried over sodium sulfate, and the solvent was removed *in vacuo*. The remaining viscous oil (1.0 g) (Mixture III) gave an elongated elliptical spot (R_f 0.16). From the head part of the tlc spot of the Mixture III, α-nitrolactone (**8**) (0.3 g), white solid, mp 66.5°C was obtained, after repeated purification by tlc on silica gel G plates (0.8 mm thickness). The spectral data of **8** were as follows: IR (Nujol mull): 1785, 1727, 1656, 1470—1445, 1395—1390, 1375, 1315, 1300, 1265, 1245—1220, 1200, 1175, 1115, 1095, 1025, 955, 900, 860, 845, 820, 790, 765, 705 cm^{-1}; NMR ($HCCl_3$) τ 4.11 (d, $\underline{H}_\alpha$), 5.62 (q, C-C$\underline{H}_2$-O), 5.92 (d, $\underline{H}_\beta$), 8.22 (s, C$\underline{H}_3$), 8.60 (s, C$\underline{H}_3$), and 8.67 (t, C$\underline{H}_3$-C-O).

Found: C, 46.63; H, 5.84%. Calcd for $C_9H_{13}NO_6$: C, 46.75; H, 5.60%.

From the tail part of the tlc spot (R_f 0.16) of the Mixture III, azoxylactone (**9**) (0.7 g), pale yellow solid, mp 120—123°C, was obtained, after repeated purification by tlc on silica gel G plates (0.8 mm thickness). The spectral data of **9** were as follows: IR (Nujol mull): 1785, 1750, 1640, 1480, 1470, 1450, 1395, 1375, 1305—1200, 1105—1010, 960, 935—930, 900, 865, 830, 780, 740 cm^{-1}; NMR ($HCCl_3$) τ 8.9—8.2 (*gem* C$\underline{H}_3$, C$\underline{H}_3$-C-O) and 5.4—6.1 (C-C$\underline{H}_2$-O).

Found: C, 52.77; H, 5.65; N, 6.86%. Calcd for $C_{15}H_{24}N_2O_9$: C, 52.42; H, 5.86; N, 6.79%.

The alkaline extracts (2.5 *l*) from the Mixture I were neutralized with dilute sulfuric acid to pH 6.5—7 and extracted with ether. The ethereal extracts were washed with aqueous sodium chloride, dried, and concentrated. The tlc of the residual pale yellow oil (Mixture IV) (11.0 g) showed the presence of two components (R_f 0.35 and 0.26). Separation was carried out by extracting the ethereal solution of the Mixture IV with aqueous sodium carbonate. From the ether layer there was obtained 1.0 g of pale yellow, neutral oil (R_f 0.35). The analytical sample was obtained by passing the crude oil through an aluminum oxide G (E. Merck) column using acetone to remove a trace of the impurity (R_f 0.26). The spectral data of **5** were as follows: IR 3500—3000 (broad), 3000—2800, 2100, 1740—1715, 1470, 1385, 1355, 1255, 1190, 1090—1070, 1027, 905, 735 cm^{-1}; NMR ($HCCl_3$) τ 5.60 (s, O$\underline{H}$), 5.62 (q, C-C$\underline{H}_2$-O), 8.46 (s, C$\underline{H}_3$), 8.65 (s, C$\underline{H}_3$), and 8.65 (t, C$\underline{H}_3$-C-O).

Found: C, 47.61; H, 5.55; N, 11.70%. Calcd for $C_9H_{12}N_2O_5$: C, 47.37; H, 5.35; N, 12.28%.

On the other hand, the alkaline layer was neutralized with dilute sulfuric acid, washed, and dried over Na_2SO_4. Removal of the solvent gave 8.0 g of slightly colored oil (R_f 0.26), which was solidified upon standing for several days, to white crystals (**7**), mp 71.5—73°C (benzene - *n*-hexane). The structure was confirmed by comparison of the infrared spectrum with that of authentic **7**.

Ethyl α-Diazoparaconates (4 and 5). These were obtained from the α-hydroxyaminolactone (**7**) in 85—90% yield by treating with sodium nitrite (2 mol) in an aqueous acetic acid at 3—7°C for 3 hr. Separation of **4** and **5** was carried out in a manner described above. Both **4** and **5** (estimated to be 5 : 1) were identified by their R_f values of tlc and their infrared spectra, which were in good agreement with those of the reference compounds (**4** and **5**) obtained in the above experiment.

Ethyl α-Nitro-γ,γ-dimethylparaconate (8). To a solution of concentrated nitric acid (0.3 ml) and glacial acetic acid (3 ml) ethyl α-hydroxyamino-γ,γ-dimethylaconate (**7**) (200 mg) was added at 2—5°C with stirring for 20 min. The cooled mixture was poured into 50 ml of ice water. After 15 min of stirring, the precipitate was filtered, washed with water, and dried. Recrystallization from *n*-hexane - benzene (4 : 1) gave 65 mg (*ca.* 30%) of **8**, white crystal, mp 66.0—66.5°C, whose infrared spectrum was identical with that of the reference compound obtained as described in the above paragraph.

Azoxylactone (9) from Ethyl α-Hydroxyamino-γ,γ-dimethylaconate (7). A mixture of **7** (200 mg) and manganese dioxide[20] (1.0 g) in acetone (10 ml) was kept at room temperature for 2 days. The manganese dioxide was filtered off and the filtrate was concentrated under vacuum to give 150 mg of **9**, pale yellow solid, mp 118—123°C, identified by comparison with the authentic sample obtained as described in the preceding paragraph.

Ethyl α,β-Epoxy-γ,γ-dimethylparaconate (6) from α-Diazolactones (4 and 5). A mixture of **4** and **5** (5 : 1) (500 mg) was dissolved in phosphoric acid (0.5 ml) at room temperature, and immediately colorless gas was evolved. When the gas evolution was ceased, the mixture was poured into 50 ml of saturated aqueous sodium chloride with stirring, and extracted with ether. The extract was washed with water, dried over Na_2SO_4 and the solvent was stripped *in vacuo*. Upon distillation of the residual oil, there was obtained 340 mg (89.1%) of **6**, bp 100°C/2 mmHg, n_D^{20} 1.4458; IR 1780 (lactone C=O), 1740 (ester C=O), and 1250 and 865 (epoxy) cm^{-1}; NMR ($HCCl_3$) τ 5.63 (q, C-C$\underline{H}_2$-O), 5.83 (s, $\underline{H}$), 8.33 (s, C$\underline{H}_3$), 8.42 (s, C$\underline{H}_3$), and 8.67 (t, C$\underline{H}_3$-C-O).

Found: C, 54.03; H, 6.16%. Calcd for $C_9H_{12}O_5$: C, 54.00; H, 6.04%.

α,β-Epoxy-γ,γ-dimethylparaconic Acid (11). To a solution of γ,γ-dimethylaconic acid (**10**)[13] (2.4 g) in methanol (36.6 ml) and 15% hydrogen peroxide solution (20.4 ml) 16% aqueous sodium hydroxide (34.2 g) was added at 20—25°C. The mixture was kept at room temperature for overnight, then poured into water (200 ml), acidified with diluted sulfuric acid,

20) J. Attenburrow, A. F. B. Cameron, J. H. Chapman, R. M. Evans, B. A. Hems, A. B. A. Jansen and T. Walker, *J. Chem. Soc.*, **1952**, 1094.

and extracted with ether. The extracts were washed with water, dried over Na_2SO_4, and evaporated to dryness to give 1.8 g (71%) of **11**, white needles, mp 120°C (methanol-benzene); IR 1740 (lactone, carboxylic acid C=O) and 1250, 920, and 860 (epoxy) cm^{-1}.

Found: C, 48.49; H, 4.79%. Calcd for $C_7H_8O_5$: C, 48.84; H, 4.68%.

Esterification of α,β-Epoxy-γ,γ-dimethylparaconic Acid (11). A solution of α,β-epoxyparaconic acid (**11**) (300 mg) in ethyl orthoformate (2 m*l*) was refluxed for 8 hr and then distilled *in vacuo* to give **6** (250 mg), bp 100°C/2 mmHg, whose infrared spectrum was in good agreement with that of the reference compound **6** obtained as described in the preceding paragraph.

Ethyl α-Hydroxy-γ,γ-dimethylaconate (12). Method A. A solution of ethyl α-hydroxyamino-γ,γ-dimethylaconate (**7**) (2.0 g) in concentrated hydrochloric acid (20 m*l*) was kept at 25—30°C for 3 days. Then, the mixture was neutralized with 2 N aqueous sodium hydroxide to pH 4—5 and extracted with ether. The extracts were washed with saturated aqueous sodium chloride, dried over $MgSO_4$, and evaporated to dryness to give **12** (1.0 g, 55%), mp 71.0°C (lit.[15] mp 73.0—73.5°C); IR (Nujol mull) 1750 (lactone C=O), 1710 (ester C=O), and 1660 (C=C) cm^{-1}; NMR ($HCCl_3$) 2.62 (s, O<u>H</u>), 5.62 (q, C-C<u>H</u>$_2$-O), 8.38 (s, *gem* C<u>H</u>$_3$), and 8.60 (t, C<u>H</u>$_3$-C-O), 8.38 (s, *gem* C<u>H</u>$_3$), and 8.60 (t, C<u>H</u>$_3$-C-O). The microanalysis of **12** gave good result for carbon and hydrogen.

Method B. A mixture of ethyl α, β-epoxy-γ,γ-dimethylparaconate (**6**) (500 mg) and sodium trichloroacetate (500 mg) was heated to 97—135°C for 15 min, then poured into water (30 m*l*), and extracted with ether. The aqueous layer was acidified to pH 4—5 with diluted sulfuric acid and extracted with ether. This extracts were washed with saturated aqueous sodium chloride, dried over $MgSO_4$, and evaporated to dyness to afford **12** (300 mg, 60%), mp 71°C, which was identified by its infrared spectrum and by comparison with that of the authentic specimen obtained by Method A.

Preparation of the Derivatives (13, 14, and 15) of 12. The compounds (**13**, **14**, and **15**) were prepared as follows: **13** was obtained by treating **12** with diazomethane; **14** was prepared by refluxing **12** with ethyl orthoformate; **15** was prepared by refluxing **12** with acetic anhydride. The physical constants, microanalyses, and spectral data of these compounds are listed in Table 1.

Thermal Decomposition of Ethyl α-Hydroxyamino-γ,γ-dimethylaconate (7). The thermal decomposition of **7** (1.0 g) carried out at 140—160°C/25 mmHg for 3 hr and then the mixture was taken up in ether. The ether layer was extracted with aqueous sodium bicarbonate, washed with water, and dried over Na_2SO_4. After removal of the solvent, the residue was distilled to give 380 mg (53%) of ethyl isopropylidenecyanoacetate (**17**), M^+ 153 *m/e*, bp 99—100°C/8.5 mmHg (lit.[17] 116—118°C/11 mmHg), which was identical in all respects with authentic specimen (**17**).[17] Small amount of the distillate, bp 100—130°C/2 mmHg, solidified in the side tube of Claisen flask or in the receiver as colorless needles. This was recrystallized from ethanol to afford ethyl α-amino-γ,γ-dimethylaconate (**16**) as colorless needles, yield 160 mg (17%), M^+ 199 *m/e*, mp 120°C; UV max (95% EtOH) 297.5 mμ (ε 11600); IR (Nujol mull) 3450 and 3350 (NH_2), 1760 (lactone C=O), 1690 (ester C=O), 1635 (C=C), and 1583 (NH_2) cm^{-1}; NMR ($HCCl_3$) τ 4.42 (broad N<u>H</u>$_2$), 5.71 (q, C-C<u>H</u>$_2$-O), 8.40 (s, *gem* C<u>H</u>$_3$), and 8.65 (t, C<u>H</u>$_3$-C-O).

Found: C, 54.22; H, 6.63; N, 7.11%. Calcd for $C_9H_{13}NO_4$: C, 54.26; H, 6.58; N, 7.03%.

The alkaline extract was acidified with dilute sulfuric acid to pH 6.5—7 and extracted with ether. The extracts were washed with saturated aqueous sodium chloride and dried over Na_2SO_4. After removal of the solvent, there was obtained 130 mg (23%) of isopropylidenecyanoacetic acid (**18**), mp 129—130.5°C (lit.[18] 137°C). The confirmation of the structure was made based on the spectral data and from the conversion of **18** into **17** by the action of ethyl orthoformate.[14]

Ethyl α-(*N*-Acetoxy-*N*-acetyl)amino-γ,γ-dimethylaconate (19). A solution of **7** (500 mg) in acetic anhydride (3 m*l*) was refluxed for 4 hr. The solvent was removed under reduced pressure. Distillation of the residue gave 700 mg (*ca.* 95%) of **19**, bp 145°C/2.5 mmHg; IR 1805 and 1775 (lactone C=O), 1725 (ester C=O), and 1650 (C=C) cm^{-1}; NMR ($HCCl_3$) τ 5.81 (q, C-C<u>H</u>$_2$-O), 7.75 (s, C<u>H</u>$_3$-CO-O-N), 7.88 (s, C<u>H</u>$_3$CO-N), 8.37 (s, *gem* C<u>H</u>$_3$), and 8.68 (t, C<u>H</u>$_3$-C-O).

Found: C, 52.39; H, 5.97%. Calcd for $C_{13}H_{17}NO_7$: C, 52.17; H, 5.73%.

Thermal Decomposition of 19. The thermal decomposition of **19** (500 mg) was carried out at 140—160°C/ 25 mmHg for 2 hr to give exclusively a fraction boiling at 98—100°C/8.5 mmHg, whose infrared spectrum was superimposable in very fine detail with that of the authentic sample (**17**) obtained in the above paragraph.

We are indebted to Dr. Shigezo Shimokawa, Hokkaido University, for the measurement of the NMR spectra.

Photochemical Hydrolysis of Barbitals*1

Yoshio OTSUJI, Tokuyuki KURODA and Eiji IMOTO

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received April 19, 1968)

The irradiation of barbital (BA) and *N,N'*-dimethylbarbital (DMBA) in aqueous alkaline media gave diethylacetylurea and *N,N'*-dimethyldiethylmalonamide respectively. On the basis of the results of kinetic studies, the above photochemical hydrolyses of BA and DMBA were shown to be an attack of the hydroxide ion on the singlet excited states of BA monoanion and DMBA respectively. Such nucleophilic reagents as amines, mercaptide, and cyanide ions retarded the photochemical hydrolyses by quenching the excited state of the substrates.

A few examples of photochemical solvolysis reactions have hitherto been reported in the literature. Zimmerman and his co-workers[1] have observed that certain benzyl acetates and trityl ethers are readily solvolyzed upon irradiation in aqueous media. Havinga and his co-workers[2] have reported that the hydrolysis of certain aromatic phosphate and sulfate esters is accelerated by light. Recently, Barltrop and Schofield[3] have found that the substituted aromatic carbamate esters of glycine are hydrolyzed upon the irradiation of the aqueous solutions. The driving force of these photochemical solvolysis reactions has been supposed to be a decrease in electron density around the reaction center through the $\pi \rightarrow \pi^*$ excitation process of aromatic compounds.[4]

During the course of our studies of the chemistry of barbitals, we found that barbital is readily hydrolyzed to diethylacetylurea upon the irradiation of its aqueous sodium hydroxide solution with ultraviolet light. This photochemical reaction constitutes a very rare example of a photochemical solvolysis in which an aromatic ring is not involved as an entity of the excitation. This paper will describe our investigation of the photochemical reactions of barbital and its derivatives in aqueous media.

Results and Discussion

Photoproducts. When a solution of barbital (BA) in a 0.1 N aqueous sodium hydroxide was irradiated with a low-pressure mercury arc at room temperature, crystals gradually appeared on the wall of the reaction vessel. After several hour's irradiation, the collection of the deposited crystals and their recrystallization gave diethylacetylurea (**1**) in a 95% yield. The structure of the compound **1** was confirmed by a comparison of its physicochemical properties with those of an authentic sample and by elemental analysis. However, even when the solution was heated at 80°C in the dark for two periods of time the same as the light reaction period, the starting material was recovered in an almost quantitative yield. These facts clearly demonstrate that the hydrolysis of barbital is accelerated by irradiation with ultraviolet light. The urea, **1**, is supposed to be formed by the attack of the hydroxide ion on the carbonyl carbon atom at the 4 position of BA. The first intermediate produced by this reaction would be the keto acid (**2**). This keto acid **2** might be unstable under the reaction conditions and might be decomposed spontaneously to the isolable product **1**.

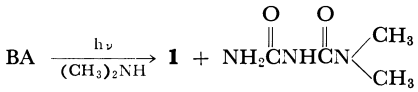
Table 1. The photoreaction products of BA in the presence of various nucleophilic reagents

Irradiated compound	Nucleophile	Product	Yield %	Irradiation time, hr
BA	0.1 N NaOH	Diethylacetylurea	95	14
	$(CH_3)_2NH$	Diethylacetylurea	35	66
		N,N-Dimethylbiuret	35	
	$C_2H_5NH_2$	Diethylacetylurea	30	66
	KCN	Diethylacetylurea	75	110
	C_2H_5SNa	Diethylacetylurea	—	90
DMBA	0.1 N NaOH	*N,N'*-Dimethyldiethylmalonamide	67	68

Since we suspected that this photochemical hydrolysis would have the nature of a nucleophilic solvolysis of BA, the photoreactions of BA were undertaken in the presence of various nucleophilic reagents. The results are summarized in Table 1.

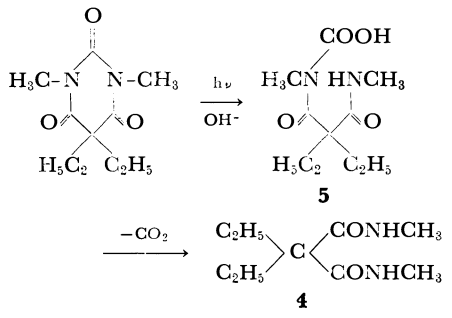
No photochemical reaction was observed upon the irradiation of BA in water or in an aqueous hydrochloric acid, BA being recovered in both cases. The irradiation of an aqueous solution of BA in the presence of ethylamine, potassium cyanide, and sodium ethylmercaptide produced the same product, diethylacetylurea, as that obtained in the photoreaction of BA and sodium hydroxide. However, when an aqueous solution of BA in the presence of dimethylamine was irradiated, a 1 : 1 mixture of the urea **1** and *N,N*-dimethylbiuret (**3**) was obtained in a 70% yield.



3

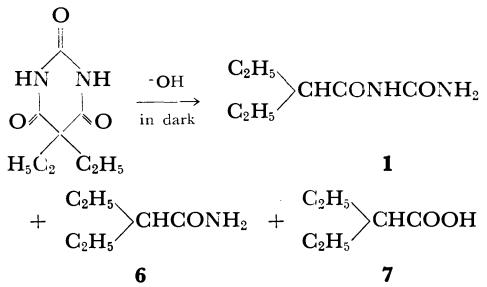
Unfortunately, the mechanism of the formation of the biuret, **3**, could not be elucidated in this investigation; therefore, it will not be discussed further here.

The photoreaction of *N,N'*-dimethyl barbital (DMBA) was also investigated. The irradiation of a suspension of DMBA in a 0.1 N aqueous sodium hydroxide with stirring afforded *N,N'*-dimethyl diethyl malonamide (**4**) in a 67% yield. This compound is supposed to be formed by the attack of the hydroxide ion on the carbonyl carbon at the 2 position of DMBA.



5 **4**

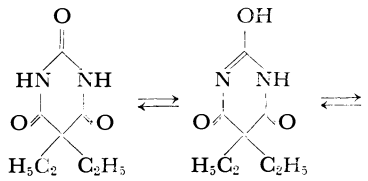
The hydrolysis of BA has been known to proceed with some difficulty in the dark to give **1** along with diethylacetamide (**6**) and diethylacetic acid (**7**), the relative yields of these compounds depending on the reaction conditions.[5] For this reason, the



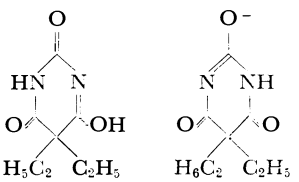
1 **6** **7**

photochemical reactions reported in this paper will provide a convenient method for the preparation of the compounds of the **1**, **6**, and **7** types.

Light-absorbing Species during the Photochemical Hydrolysis of BA and DMBA. There exist tautomeric equilibria for BA in an aqueous solution; the plausible tautomeric forms include **8**, **9** and **10**, among others:



8 **9**



10 **11**

Sato[6] has concluded, on the basis of his molecular orbital calculations, that **9** is the most likely form in

5) a) H. Ruhkopf, *Ber.*, **73**, 938 (1940); b) E. H. Volwiler and D. L. Tabern, *J. Am. Chem. Soc.*, **58**, 1352 (1936); c) M. Freifelder, A. O. Geiszler and G. E. Stone, *J. Org. Chem.*, **26**, 203 (1961).

6) Y. Sato, *Nippon Kagaku Zassi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **78**, 924 (1957).

an aqueous solution. Furthermore, since $pK_1=7.85$ and $pK_2=12.7$ for BA,[7] BA would exist exclusively in the form of a monoanion of **9**, *i. e.*, **11** in a 0.1 N sodium hydroxide solution (pH ~11.3), in which most of the present experiments were carried out.

The spectral properties of BA were also studied in some detail. Figure 1 shows the ultraviolet spectra of $\sim 1\times10^{-4}$ M of BA in buffered aqueous solutions of various pH values. The absorbance at an absorption maximum of 240 mμ, As_{240}, decreased with a decrease in the pH values of the solutions. When As_{240} values were plotted against the concentrations of the monoanion of BA (BA^-) present in the solutions (the concentrations of BA^- were calculated from the pK_a of BA), a straight line passing through the origin was obtained, as is shown in Fig. 2. These results indicate that the only species which shows the absorption at 240 mμ is BA^-. From the data in Fig. 2, the molar extinction coefficient of BA^- was calculated to be 1.03×10^4.

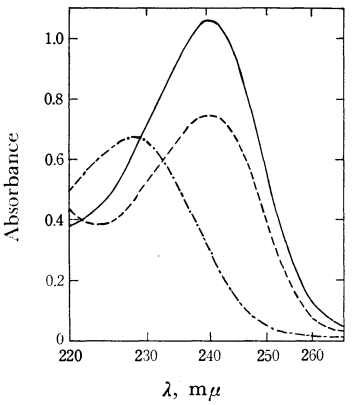


Fig. 1. Absorption spectra of BA and DMBA.
—— BA in 2×10^{-4} M NaOH
·—· DMBA in 2×10^{-4} M NaOH
---- BA in buffer solution at pH 8.27

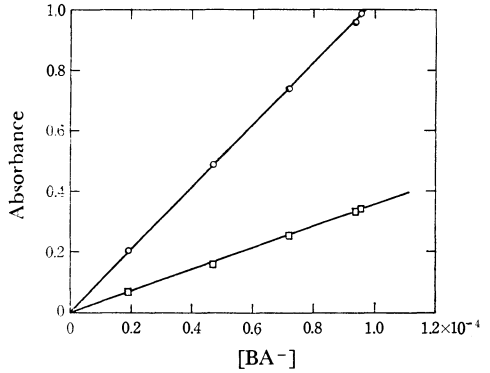

Fig. 2. Plots of absorbance *vs.* concentration of BA^-.
-○- at λ 240 mμ -□- at λ 254 mμ

The hydrolysis products of BA have no appreciable absorption at $\geq$240 mμ under the present reaction conditions, and the illuminating light used in our experiments was practically that of the wavelength at 254 mμ. Therefore, the above results also indicate that the only light-absorbing species during the photochemical hydrolysis of BA in an aqueous solution (pH>7.0) is BA^-.

The light-absorbing species of DMBA during the photochemical hydrolysis is apparently DMBA itself, since DMBA does not exhibit the tautomeric equilibria and its absorption maximum lies at 229 mμ ($\varepsilon_{229}=6.74\times10^3$); also, the hydrolysis products of DMBA has no absorption at $\geq$229 mμ under the present reaction conditions.

Kinetic Studies. In order to get some clue to the mechanism of the photochemical hydrolysis, kinetic studies of the hydrolysis of BA in the aqueous solutions were made under a variety of conditions.

If the rate of hydrolysis of BA is assumed to be proportional to the light intensity absorbed by BA^- (the only light-absorbing species present in the reaction system), then the rate of the reaction (and, hence, the rate of the disappearance of BA^-) is given by Eq. (1):

$$-\mathrm{d}[BA^-]/\mathrm{d}t = \Phi K I_{abs} \quad (1)$$

where Φ is the quantum yield for the reaction, and where K is a unit conversion factor which transforms the number of photons absorbed per second into moles per liter per photons absorbed. I_{abs} is expressed in terms of Lambert and Beer's law:

$$I_{abs} = I_0(1 - e^{-\varepsilon[BA^-]d}) \equiv I_0 A \quad (2)$$

where I_0 is the incident light intensity, ε is the molar extinction coefficient of BA^- at the wavelength band incoming from the illuminating light source, and d is the thickness of the reaction vessel through which the incident light passes. The combination of Eqs. (1) and (2), and the integration of the resulting equation, lead to:

$$[BA^-]_t + (\ln A)_t/\varepsilon d = -\Phi K I_0 t + C \quad (3)$$

where C is the integration constant.

If our assumption is correct, the plot of the values on the left side of Eq. (3) against the time should give a straight line. Thus, the relative quantum yield, Φ', defined by Eq. (4) can be calculated from the slope of the straight line:

$$\Phi' = \Phi K I_0 \quad (4)$$

In our experiments the values of $[BA^-]_t$, the concentrations of BA^- at a given time, t, were determined from the readings of As_{240} (see the previous section):

$$[BA^-]_t = (As_{240})_t/\varepsilon_{240} \quad (5)$$

The term of $(\ln A)_t/\varepsilon d$ was calculated by the use of Eq. (6):

7) Y. Sato, *ibid.*, **78**, 382 (1957).

$$(\ln A)_t/\varepsilon d = 2.303 \log (1 - e^{-\varepsilon[BA^-]_t d})/\varepsilon d \quad (6)$$

$\varepsilon = 3.55 \times 10^3$ was obtained from the data represented in Fig. 1 as the molar extinction coefficient of BA^- at 254 mμ (see the previous section and also the Experimental section). The d was measured as 3.5 cm.

The rate measurements for the hydrolysis of BA were carried out in buffered aqueous solutions of various pH values and in a 0.1 N sodium hydroxide solution. The plot of the $[BA^-]_t + (\ln A)_t/\varepsilon d$ function against the time furnished a straight line in every case. Typical data are shown in Fig. 3. The relative quantum yields, Φ', calculated from the slopes of the straight lines are summarized in Table 2. When a reciprocal of Φ' was plotted against a reciprocal of the hydroxide ion concentration, a straight line was obtained, as is shown in Fig. 4. This result demonstrates that the hydroxide ion may be involved in the rate-determining step of the reaction.

Table 2. Relative quantum yield, Φ'

I) Φ' for BA in aqueous solutions at various pH values

pH	$1/[OH^-]$	Φ'	$1/\Phi'$
7.70	200×10^4	1.47×10^{-6}	6.80×10^5
8.03	58.1×10^4	2.29×10^{-6}	4.38×10^5
8.46	34.7×10^4	2.59×10^{-6}	3.87×10^5
8.87	13.5×10^4	2.83×10^{-6}	3.53×10^5
9.50	3.16×10^4	3.01×10^{-6}	3.32×10^5

II) Φ' for the reactions of BA and DMBA with various nucleophiles

Irradiated compound	Nucleophile	Concn. mol/l	Φ'
BA	NaOH	2×10^{-4}	3.18×10^{-6}
	NaOH	2×10^{-4}	3.13×10^{-6}*
	C_2H_5SNa	3×10^{-3}	3.01×10^{-6}
	KCN	1×10^{-2}	2.79×10^{-6}
	KCN + NaOH	1×10^{-2} + 2×10^{-4}	2.85×10^{-6}
	$C_2H_5NH_2$	1×10^{-2}	0.552×10^{-6}
	$C_2H_5NH_2$ + NaOH	1×10^{-2} + 2×10^{-4}	0.552×10^{-6}
	$(CH_3)_2NH$	1×10^{-2}	0.333×10^{-6}
	$(CH_3)_2NH$ + NaOH	1×10^{-2} + 2×10^{-4}	0.333×10^{-6}
DMBA	NaOH	2×10^{-4}	0.367×10^{-6}

* This value was obtained under bubbling nitrogen.

The rates of the photochemical reactions of BA with various nucleophiles were also measured. The shapes of the spectra of BA in the presence of nucleophiles were similar to those in the buffered solutions represented in Fig. 1. Thus, the rates of the disappearance of BA^- were followed by measuring the As_{240} of BA^-, and the relative quantum yields were obtained as has been described for the reactions in the buffered solutions. A typical datum is shown in Fig. 3, while the results are summarized in Table 2. The Φ' decreased in the order of hydroxide ion $\geq$ sodium mercaptide $\geq$ potassium cyanide $>$ ethylamine $>$ dimethylamine. However, when the reactions of BA with various nucleophiles were carried out in the presence of sodium hydroxide, the relative quantum yields of the reactions remained at the same values as those in the absence of sodium hydroxide, as is shown in Table 2. This observation can be explained by noting that the excited state of BA^- may be partially quenched in a characteristic manner determined by the nature of the nucleophiles, and that the only attacking reagent in these photochemical reactions is actually the hydroxide ion, which does not practically quench the excited state of BA^- and which would have its strongest affinity for the excited state of BA^-.

A further important observation was that when the photochemical hydrolysis of BA in 0.1 N sodium hydroxide was carried out in a nitrogen stream, no change in the relative quantum yields

was observed (Table 2). This finding suggests that the photochemical hydrolysis of BA starts directly from its singlet excited state.

A kinetic study of the photochemical hydrolysis of DMBA was also made in a 0.1 N sodium hydroxide solution. The rate was measured by following the decrease in the As_{229} of DMBA. The relative quantum yield was obtained by the use of Eqs. (3) and (4). In this case ε was estimated to be 2.02×10^2 from the spectral data (ε was taken to be equal to the molar extinction coefficient of DMBA at 254 mμ under the present reaction conditions). The approximate ratio of the relative quantum yield of BA$^-$ to DMBA was 1 : 0.1 (see Table 2).

Mechanistic Pathways. The results and discussion presented earlier suggest that the pathways outlined in Chart 1 are involved in the photochemical hydrolysis reactions of BA in aqueous solutions. The symbols used in Chart 1 have the usual meanings, while Q represents any quencher participating in the reactions. The reactions probably start from the singlet excited state of BA$^-$ (BA$^-$*). The BA$^-$* reacts with hydroxide ion to give a 1 : 1 complex of the type X. The complex may be formed by the addition of the hydroxide ion to the carbonyl carbon atom at the 4 position rather than the 2 position of BA$^-$, since the accumulation of a negative charge around the carbonyl group at the 2 position prevents the addition of the hydroxide ion to that group. The complex thus formed collapses spontaneously to the hydrolyzed product, **1**, through the keto acid, **2**. The nucleophilic reagents other than hydroxide ion act as quenchers for BA$^-$* and partially prevent the formation of the complex.

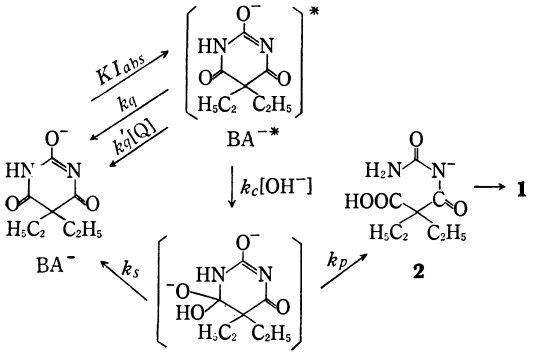

Chart 1

Making the usual steady-state assumption for BA$^-$* and the complex X, the rate equation (7) can be obtained from the above reaction scheme:

$$-\frac{d[BA^-]}{dt}=\frac{d(\mathbf{2})}{dt}=\frac{k_ck_p[^-OH]KI_{abs}}{(k_s+k_p)[k_q+k'_q[Q]+k_c[^-OH]]} \quad (7)$$

The quantum yield and the relative quantum yield defined in this investigation for the disappearance of BA$^-$ become, then, Eqs. (8) and (9) respectively:

$$\Phi=\frac{k_ck_p[^-OH]}{(k_s+k_p)[k_q+k'_q[Q]+k_c[^-OH]]} \quad (8)$$

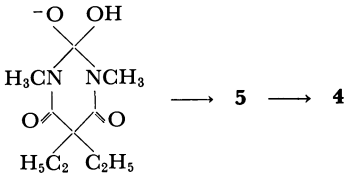
$$\Phi'=\frac{k_ck_p[^-OH]}{(k_s+k_p)[k_q+k'_q[Q]+k_c[^-OH]]}\times KI_0 \quad (9)$$

When $[Q]\simeq0$, *i. e.*, when the photochemical hydrolysis is carried out in buffered solutions, the relation of Eq. (10) is obtained:

$$\frac{1}{\Phi'}=\frac{1}{KI_0}\frac{k_s+k_p}{k_p}+\frac{k_q(k_sk_p)}{k_ck_p[^-OH]} \quad (10)$$

Our observations are consistent with this theoretical relationship (see Fig. 4). Since at present we do not have much information about the quenching ability of the nucleophiles, no detailed discussion is given in this paper. However, amines are often known to act as effective quenchers of excited-state molecules.

In the case of DMBA, the reaction proceeds similarly except that a complex of the type of (**12**)



12

may be formed between the carbonyl carbon atom at the 2 position and the hydroxide ion. There is no reason for preventing the addition of the hydroxide ion to that position, because no tautomeric equilibrium exists in this compound and, hence, no accumulation of negative charge around the carbonyl group at the 2 position can be expected. The complex thus produced collapses to the expected product.

Experimental

The melting points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-S2 infrared spectrometer. The ultraviolet spectra were obtained with a Hitachi recording spectrophotometer. The microanalysis were performed with a Yanagimoto MT-1 CHN Corder.

Materials. Barbital (BA) was of a Nakarai reagent grade and was purified by recrystallization from ethanol before use. *N,N'*-Dimethylbarbital (DMBA) was prepared by the method of Dox.[8] The other reagents were purchased from various companies and were purified by recrystallization or distillation.

Photochemical Hydrolysis of Barbital (BA). A solution of 500 mg of BA in 100 m*l* of 0.1 N aqueous sodium hydroxide in a quartz vessel was irradiated for 14 hr with a 15-W low-pressure mercury arc placed at

8) W. Dox, *J. Am. Chem. Soc.*, **58**, 1633 (1936).

a distance of 10 cm. During irradiation, the product deposited out on the surface of the vessel as crystals. After irradiation, the crystals thus produced were collected by filtration and recrystallized from ethanol, mp 205—206°C. The product, 400 mg (95%), was identified as diethylacetylurea by the elemental analysis and by comparison with an authentic sample prepared by the method of Volwiler and Tabern,[9] which was found to be identical in every respect.

Found: C, 53.29; H, 9.17; N, 17.81%. Calcd for $C_7H_{14}N_2O_2$: C, 53.14; H, 8.92; N, 17.71%.

An aqueous solution of BA containing ethylamine, potassium cyanide, or sodium ethylmercaptide was irradiated similarly. The product isolated was diethylacetylurea in all of the above cases.

A solution containing 1 g of BA, 5 m*l* of 40% dimethylamine, and 100 m*l* of water was also irradiated in a similar manner. After 66 hrs' irradiation, the crystals which had deposited on the surface of the vessel were collected by filtration and identified as diethylacetylurea. The filtrate was evaporated to dryness under reduced pressure; the recrystallization of the residue gave 250 mg (35%) of *N,N*-dimethylbuiret, mp 170—171°C. The structure of this compound was confirmed by the elemental analysis and by comparison with an authentic sample prepared by the method of Davis and Blanchard,[10] which was found to be identical in every respect.

Found: C, 36.89; H, 7.14; N, 32.02%. Calcd for $C_4H_9N_3O_2$: C, 36.63; H, 6.92; N, 32.05%.

Hydrolysis of Barbital in the Dark. A solution of 500 mg of BA in 30 m*l* of 0.1 N aqueous sodium hydroxide was allowed to stand at 80°C for 17 hr. The mixture was then acidified with a dilute hydrochloric acid under cooling. The precipitated crystals were collected by filtration and found to be barbital. The evaporation of the filtrate also gave barbital. The total amount of barbital recovered was 350 mg (70%).

Photochemical Hydrolysis of *N,N'*-Dimethylbarbital (DMBA). Since the solubility of DMBA in water was too small to make a homogeneous aqueous solution with a relatively high concentration, the experiment was carried out as follows. A mixture of 1.2 g of DMBA in 100 m*l* of 0.1 N aqueous sodium hydroxide in a quartz vessel, where a small amount of DMBA remained insoluble as an oil, was irradiated in a manner similar to that described above, while being stirred with a magnetic stirrer. The oil, DMBA, went into solution with irradiation. After 68 hr's irradiation, although a very small amount of the oil still remained insoluble, the reaction mixture was neutralized with a dilute hydrochloric acid, and extracted with ether and then with chloroform. Both extracts were dried over sodium sulfate. The evaporation of the ether extract gave 100 mg (8%) of the starting materials, DMBA. The evaporation of the chloroform extract under reduced pressure afforded, after recrystallization from benzene, 0.7 g (67%) of *N,N'*-dimethylmalonamide; mp 149—150°C, IR 3300, 1650, 1530 cm^{-1} (KBr).

Found: C, 58.07; H, 9.91; N, 14.80%. Calcd for $C_9H_{18}N_2O_2$: C, 58.03; H, 9.74; N, 15.04%.

A mixture of 1.1 g of DMBA in 100 m*l* of water was irradiated for 63 hr in a manner similar to that described above. When the mixture was then worked up similarly, the starting material, DMBA, was recovered in almost a quantitative yield.

Kinetic Measurements. An aqueous solution (100 m*l*, 10^{-4} M) of BA or DMBA was placed in a quartz tube of 3.5 cm in diameter and 10 cm long. The solutions were irradiated at room temperature with a 15 W low-pressure mercury arc placed 30 cm from the samples. Four-m*l* portions of the solutions were pipetted into a spectrophotometric cell at intervals. The hydrolysis rates for the samples were followed by measuring the decreases in the absorbance at 240 mμ in the case of the BA's, and at 229 mμ in the case of the DMBA's with a Hitachi Perkin-Elmer 139 UV-Vis spectrophotometer. Special care was taken to fix a relative position between the reaction vessel and the light source so that the irradiation was carried out by the light beam of a constant intensity throughout a whole series of samples for which the kinetic studies were made. For this reason, the kinetic data obtained in this investigation were always reproducible.

Since an unfiltered light beam was used for irradiation, no attempt was made to calculate the exact quantum yields for the reactions. However, it was found from the spectral examination that the light source used radiates mostly the light beam at 2537Å in the region where the absorption spectra of the samples were detected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2719—2722 (1968)

Synthesis of 3-Vinylpyrene by Wittig's Reaction, and Syntheses and Electrical Properties of Polyvinylpyrene and Its Charge Transfer Complexes

Kiyoshi TANIKAWA, Takashi ISHIZUKA, Kojiro SUZUKI, Shigekazu KUSABAYASHI and Hiroshi MIKAWA

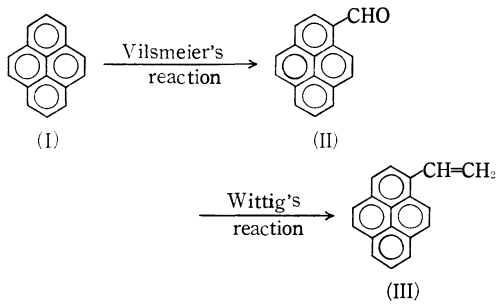
Department of Chemical Technology, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima, Osaka

(Received April 19, 1968)

Using Wittig's reaction, we synthesized 3-vinylpyrene from pyrene-3-aldehyde in 76% yield. 3-Vinylpyrene monomer was polymerized by benzoylperoxide or di-*t*-butylperoxide catalysts. Each polymer had a melting point, being observed by the method of polarizing hot stage microscopic examination. X-ray examination showed that the polymer was crystalline, although rather poor. The charge transfer complexes, containing polyvinylpyrene as an electron donor, and iodine, tetracyanoethylene or tetracyanoquinodimethane as an electron acceptor, were prepared, each having the composition of pyrene nucleus : acceptor=16 : 3, 15 : 2, 15 : 2, respectively. Electrical conductivities of the complexes at 25°C, ρ_{25}, and band gap energies, ε, were 1.3×10^{8} Ωcm, 0.80 eV; 4.5×10^{12} Ωcm, 1.32 eV; 1.1×10^{14} Ωcm, 1.34 eV, respectively. Each complex showed ohmic current-voltage characteristics in an appropriate temperature range.

Electrical properties of several vinyl polymers having large π electron systems and of their charge transfer complexes have been reported.[1,2] In order to investigate the electrical properties[3] of polyvinylpyrene (PVP), a vinyl polymer hitherto known having largest π electron systems on a polymer chain, we synthesized PVP and its charge transfer complexes.

Synthesis of 3-Vinylpyrene. 3-Vinylpyrene monomer is known and synthesized by the dehydration of 3-(1-hydroxyethyl)pyrene with Al_2O_3.[4] The product obtained by this method is, however, difficult to purify and the yield is poor. Al_2O_3 employed by us yielded ethylpyrene (isolated and identified) as a by-product, which was very difficult to be separated from 3-vinylpyrene. As reported in the present paper, we synthesized first pyrene-3-aldehyde (II) from pyrene (I) by Vilsmeier's reaction,[5] and then 3-vinylpyrene (III) by Wittig's reaction from the aldehyde.



Both the yield and the quality of 3-vinylpyrene were much improved by using this synthesis method (76% and mp 88—89°C). Although methylenetriphenylphosphorane was synthesized in ether solution, the betaine intermediate obtained from pyrene and methylenetriphenylphosphorane had moderate stability and the decomposition of the betaine to 3-vinylpyrene was effected only at the boiling temperature of tetrahydrofuran (THF).

Synthesis and Properties of Polyvinylpyrene. The polymerization of 3-vinylpyrene was carried out by radical initiators, benzoylperoxide (BPO) or di-*t*-butylperoxide (DTBP), in benzene, toluene or xylene.

Although the polymerization of 3-vinylpyrene by BPO in benzene at 80°C was slow, the polymer obtained had moderate degree of polymerization ($[\eta]\sim0.1$ in THF at 25°C). By the use of DTBP catalyst in xylene at 140°C, however, the conversion was higher and the polymer began to precipitate in xylene after several hours. The polymer obtained in xylene was somewhat colored and the viscosity was lower, having lower degree

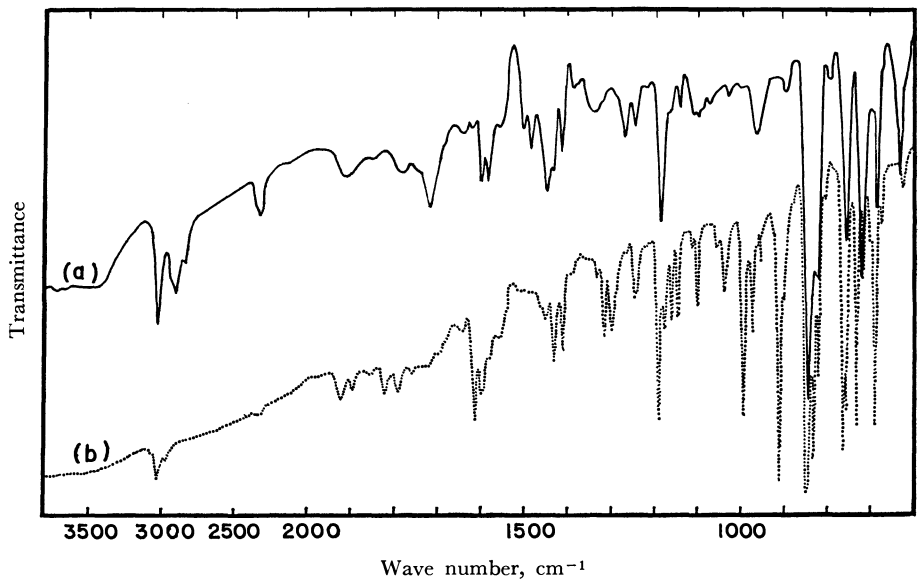

Fig. 1. Infrared spectra of (a) polyvinylpyrene and (b) 3-vinylpyrene in KBr disk.

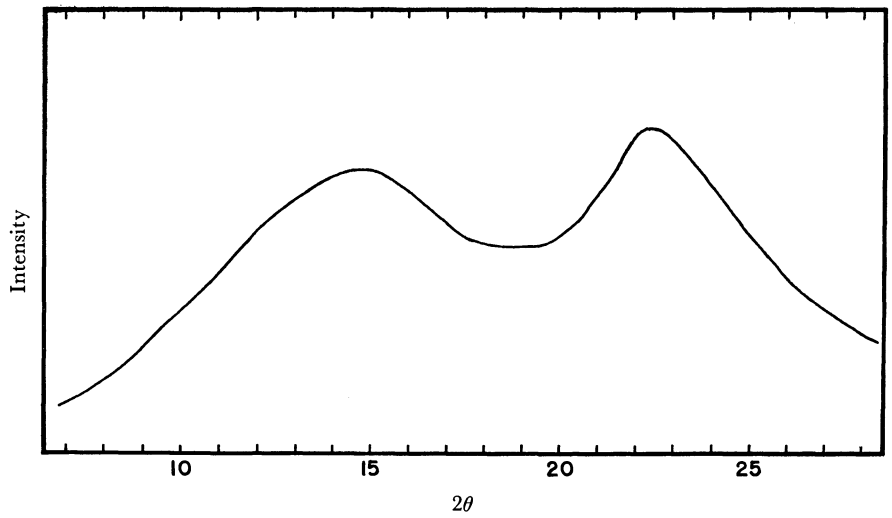

Fig. 2. X-ray diffraction pattern of polyvinylpyrene polymerized by benzoylperoxide catalyst. Rigaku Denki Co.'s X-ray diffractometer, CuK_α (Ni-filtered), 30 kV-20 mA, slit geometry 1°—1°—0.1 mm, scanning speed 1°/min, chart speed 10 mm/min, full scale 400 cps.

of polymerization.

Infrared spectrum of PVP, Fig. 1, shows the disappearance of the absorptions of the end vinyl group (910 and 990 cm^{-1}) in 3-vinylpyrene.

The partially crystalline nature of PVP has been recognized by the examinations with X-ray diffraction and polarizing hot-stage microscope. An X-ray diffraction pattern of PVP polymerized by BPO annealed at 240°C for 4 hr did not show any sharp diffraction peaks as shown in Fig. 2. This X-ray diffraction pattern shows that the polymer is poorly crystallized, if not completely in noncrystalline state.

Examinations of the PVP specimens under the polarizing hot-stage microscope showed the following facts: At room temperature, the polymer powder prepared by precipitation from its solution showed a few birefringent regions as light spots distributed in a dark visual field of crossed Nicols. When this powder is finely powdered in an agate mortar, many light spots appeared along with the considerable amount of weakly light spots. Although the latter weakly light spots may be due to an internal stress *etc.* of PVP sample, the former light spots are believed to be due to the crystalline birefringent regions in the polymer.

Table 1. Properties of charge transfer complexes

Charge transfer complexe	Donor : Acceptor	Softening range* °C	ρ Ωcm	ε eV
PVP-iodine	16 : 3	280—290	1.3×10^{8}	0.80
PVP-TCNE	15 : 2	267—280	4.5×10^{12}	1.32
PVP-TCNQ	15 : 2	230—240	1.1×10^{14}	1.34

* Softening range is observed by pressing the polymer between glass plates under microscope.

Table 2. Polymerization of polyvinylpyrene

	Condition					Product	
	Solvent ml	Monomer g	Initiator mg	Time hr	Temp. °C	Softening range, °C	Yield g
1	Benzene 25	2.3	BPO 9.7	22	80	270—295	0.53
2	Toluene 18	1.7	DTBP 11.0	21	110	230—270	0.4
3	Xylene 32	3.2	DTBP 22.0	18	140	235—250	1.0

When PVP sample is heated very slowly, the light spots disappeared completely at about 254°C (PVP polymerized by BPO in benzene), about 198°C (DTBP in toluene), and about 213°C (DTBP in xylene). These temperatures are believed to be the melting points of the polymers.

It is very interesting that PVP prepared by radical polymerization is crystalline. This may be due to the effect of very large pendant pyrene groups. It is observed that *N*-vinylcarbazole having very large carbazyl groups gives highly crystallized polymer even when polymerized by radical process. Detailed results will be published in the near future.[6]

Preparations of the Charge Transfer Complexes. The charge transfer complexes, having PVP as an electron donor, and iodine, tetracyanoethylene (TCNE) or tetracyanoquinodimethane (TCNQ) as an electron acceptor, were prepared.

The absorption spectra of the charge transfer complexes in film show charge transfer bands as shown in Fig. 3. It is known that pyrene-TCNE complex shows charge transfer bands[7] around 500 and 730 mμ in dichloromethane solution, or around 510 and 830 mμ in crystalline state, and pyrene - iodine complex has the charge transfer band[8] around 420 mμ. As shown in Fig. 3, PVP-TCNQ, PVP-TCNE and PVP-iodine complexes exhibit the absorption band due to charge-transfer excitation around 700—900 mμ. The wavelength of the charge transfer band of the PVP-TCNQ complex, 780 mμ, is much longer than that of poly(*N*-vinylcarbazol) - TCNQ complex,[2] around 620 mμ.

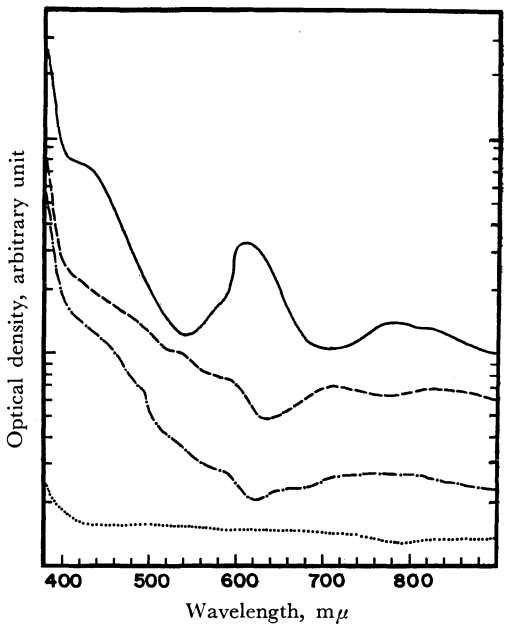

Fig. 3. Absorption spectra of the charge transfer complexes in solid film.
——, PVP-TCNQ; ----, PVP-TCNE;
·—·, PVP-iodine; ·····, PVP

From the elementary analyses of iodine and nitrogen, the compositions of the three complexes were found to be pyrene nucleus : acceptor = 16 : 3, 15 : 2, and 15 : 2, respectively (Table 1).

Electrical Properties of the Charge Transfer Complexes. A sample tablet, 12.5 mm diameter and *ca.* 1 mm thick, was made by pressing about 0.3 g of finely powdered samples of charge transfer complexes at 150—200 kg/cm^2. Silver paste was painted on both sides of the tablet, with a guard ring on one side.

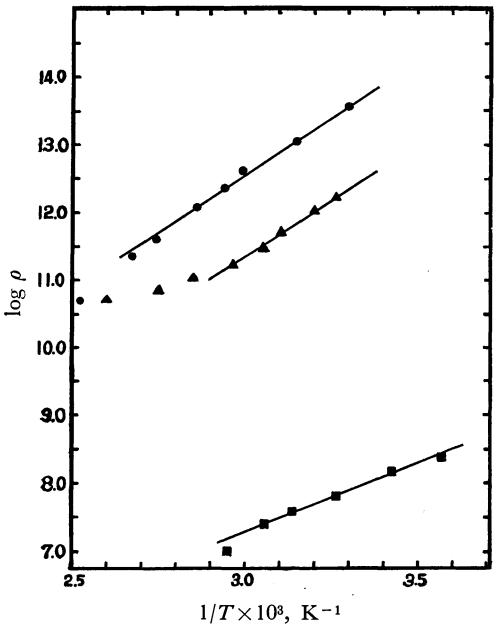

Fig. 4. The relations between resistance and temperature in charge transfer complexes.
—●—, PVP-TCNQ; —▲—, PVP-TCNE; —■—, PVP-iodine.

The electrical conductivity of the tablet thus prepared was measured by the DC method. The sample was put in a well sealed conductivity cell placed in a thermostat. The current was measured by using a Takeda Riken Vibrating Reed Electrometer.[2,9]

Electrical resistivities of these complexes are fairly low. The relation between applied voltage and current obeys Ohm's law.

Figure 4 shows the relations between resistance and temperature. In PVP-iodine complex, at about 80°C, the curve begins to deviate from an equation $\rho = \rho_0 \exp(\varepsilon/2kT)$ (ρ, specific resistance in Ω cm; ρ_0, constant; k, Boltzmann's constant; ε, energy gap of a band model in eV). The deviation may be due to the beginning of decomposition of the complex.

In PVP-TCNE complex, the curve begins to deviate from lineality at about 90°C, showing probably the beginning of decomposition in this case also. PVP-TCNQ complex is most stable to heat.

Among three polymeric charge transfer complexes, PVP-iodine complex has the best electrical conductivity and the smallest band gap energy as shown in Table 1. PVP-TCNQ complex has the best heat stability.

Experimental

Pyrene-3-aldehyde (II).[5] With stirring, 135 g of $POCl_3$ was gradually droped into a mixture of 135 g of *N*-methyl-formanilide and 100 m*l* of *o*-dichlorobenzene during 2 hr at 0—5°C. Into this reaction mixture, 100 g of powdered pyrene was added gradually. After stirring for 3 hr at 90—95°C, the reaction product was decomposed by 1000 m*l* of water containing 480 g of sodium acetate. Both *o*-dichlorobenzene and *N*-methylaniline were steam distilled, and the crude pyrene-3-aldehyde was recrystallized from ethyl alochol. Mp 125—126°C. Yield 56%.

Found: C, 88.67; H, 4.38%. Calcd for $C_{17}H_{10}O$: C, 88.40; H, 4.50%.

3-Vinylpyrene (III). From an injector, ethereal solution (*ca.* 80 m*l*) containing 0.08 mol of phenyllithium[10] was added with stirring into 28.6 g (0.08 mol) of powdered triphenylphosphonium bromide suspended in 250 m*l* of dry ether. The reaction was carried out with stirring in a dry nitrogen stream for about 23 hr at room temperature.[11] After the reaction, 100 m*l* of THF containing 16.1 g (0.07 mol) of pyrene-3-aldehyde was dropped into the reaction solution and 150 m*l* of dry THF was introduced into the solution. After stirring in a dry nitrogen stream at least for about 2 hr at room temperature, ether was removed by distillation and the refluxing of THF was continued for about 24 hr at 65—66°C. THF was distilled and the residue was extracted with benzene, washed by aq. 30% $NaHSO_3$ solution and water. Sometimes triphenylphosphinoxide crystallized out from the solution. 3-Vinylpyrene, showing yellow green fluorescence, was separated from benzene solution by adsorption chromatography (Al_2O_3), 3-vinylpyrene being most weakly adsorbed than the other components. Final recrystallization from ethyl alcohol yielded 3-vinyl pyrene, mp 88—89°C, 76%. 3-Vinylpyrene was stored in nitrogen atmosphere in the dark.

Found: C, 94.69; H, 5.30%. Calcd for $C_{13}H_{12}$: C, 94.20; H, 5.38%.

Polymerization. 3-Vinylpyrene was polymerized by BPO or DTBP in purified benzene, toluene or xylene. The polymerizations were carried out in a dry nitrogen stream under the following conditions (Table 2): The polymer was separated by precipitating with methyl alcohol. The polyvinylpyrene was purified several times by reprecipitation method. $[\eta]$ ~0.1 in THF at 25°C.

Charge Transfer Complexes. Twenty-five milliliters of chloroform containing 0.6 g of sublimed iodine was added into 10 m*l* of chloroform containing 0.5 g of PVP, and the solution was stirred for 5 hr at room temperature, set aside overnight, and poured into petroleum ether, and the very fine precipitate was separated by centrifuge, washed and dried in a desiccator. In the case of both TCNE and TCNQ, the procedures were the same. Found: PVP-iodine, iodine 17.29%; PVP-TCNE, nitrogen 2.93%; PVP-TCNQ, nitrogen 2.89%.

The authors are very much indebted to Associate Professor N. Kasai of the Faculty of Engineering, Osaka University, for his helpful advice and examination with X-ray diffraction.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 41 2723—2726 (1968)

Studies on Amino-hexoses XIV. Preparation of Partially *O*-Carboxymethylated Chitin and Its Component 3-*O*- and 6-*O*-Carboxymethyl-D-glucosamine, and the Corresponding Glucosaminitols

Tsuyoshi MIYAZAKI and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University College of Science, Toyonaka

(Received April 20, 1968)

3-*O*-carboxymethyl-D-glucosamine, 6-*O*-carboxymethyl-D-glucosamine, and the corresponding glucosaminitols are prepared as reference compounds in a study of a lysozyme action on a partially-*O*-carboxymethylated chitin. The preparation of partially-*O*-carboxymethylated chitin, a substrate of hen-egg white lysozyme, is also described.

In our study of a mode of action on a partially-*O*-carboxymethylated chitin of hen-egg white lysozyme, the monomeric *O*-carboxymethylated glucosamines and the corresponding sugar alcohols were essential for characterizing the substrate and the enzymatic reaction products. In order to obtain these reference compounds, 3-*O*-carboxymethyl-D-glucosamine and the corresponding sugar alcohol were prepared *via* the synthetic route shown in Scheme 1. Because the methods we adopted in order to synthesize 6-*O*-carboxymethyl-D-glucosamine were not successful, the acid hydrolysate of the partially-*O*-carboxymethylated chitin was resolved into components by ion exchanger chromatography; a crystalline component was thus obtained which was proved analytically to be 6-*O*-carboxymethyl-D-glucosamine. The corresponding glucosaminitol was obtained by a borohydride reduction as a syrup.

Partially-*O*-carboxymethylated chitin, a substrate of the enzyme,[1] was prepared through partially-*O*-carboxymethylated chitosan,[2] different batches

TABLE 1. COMPONENT OF PARTIALLY-*O*-CARBOXYMETHYLATED CHITIN

Component	Lot No.		
	1	2	3
Unknown-X_1	1.3%	3.6%	3.0%
Unknown-X_2	0.9%	2.5%	5.5%
3-*O*-CM-Glucosamine	2.3%	2.5%	5.5%
6-*O*-CM-Glucosamine	22.6%	33.1%	43.1%
Glucosamine	72.9%	56.9%	43.1%

For the estimation of the unknown components, color yield of the ninhydrin reaction was assumed to be the same with that of 3-*O*-CM-glucosamine.

of which had naturally varying compositions. The compositions of the specimens which we obtained are summarized in Table 1. The specimens are composed mostly of unsubstituted glucosamine, 3-*O*-, and 6-*O*-carboxymethyl-glucosamines. The enzymatic action will be described elsewhere.

Experimental

Methyl 2-Acetamido-2-deoxy-3-*O*-carboxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside (III). To a solution of 6.5 g of methyl 2-acetamido-2-deoxy-4,6-*O*-benzylidene-α-D-glucopyranoside (II,[3] mp 248—250°C) in 400 m*l* of dry dioxane, was added, at 90°C, a suspension of 2.5 g of sodium hydride in 15 m*l* of dioxane under mechanical stirring. After 30 min, 10 g of chloroacetic acid in 30 m*l* of dioxane was added, and then the stirring was continued for 3.5 hr at the same temperature. After an additional 10 g portion of sodium hydride in 50 m*l* of dioxane had been added to the reaction mixture, the heater was removed and the stirring was continued overnight. The excess sodium hydride was decomposed by the careful addition of 30 m*l* of water under ice-water cooling, after which the mixture was evaporated *in vacuo*. The residue was dissolved in 250 m*l* of warm water, and the insoluble matter was removed by filtration. The filtrate gave a colorless precipitate when the pH of the solution was adjusted to 2 by adding 6 N hydrochloric acid under ice-water cooling. The precipitate was washed thoroughly with water and recrystallized in methanol, 3.6 g of colorless crystals which melted at 215—217°C. giving $[\alpha]_D^{20}$ +69.1 (*c* 0.79, methanol).

Found: C, 56.54; H, 6.44; N, 3.54%. Calcd for $C_{18}H_{23}O_8N$: C, 56.68; H, 6.08; N, 3.67%.

An aglycon homologue of III, ethyl 2-acetamido-2-deoxy-3-*O*-carboxymethyl-4,6-*O*-benzylidene-α-D-glucopyranoside, was likewise prepared; it melted at 203—205°C. $[\alpha]_D^{20}$ +92 (*c* 0.90, methanol).

Found: C, 57.64; H, 6.35; N, 3.52%. Calcd for $C_{19}H_{25}O_8N$: C, 57.71; H, 6.37; N, 3.54%.

2-Amino-2-deoxy-3-*O*-carboxymethyl-D-glucose (IV). Three grams of III were hydrolyzed in 35 m*l* of 2.5 N hydrochloric acid at 100°C for 4 hr. The hydrolysate was then washed with ether in order to remove the benzaldehyde that had been released. After the addition of 50 m*l* of water, the pH of the solution was adjusted to 6.1 by the addition of Dowex-1 (OH^- form) resin. The filtrate from the resin was decolorized with a small amount of charcoal, and the solution was concentrated *in vacuo*. The concentrated solution (20 m*l*) gave, after standing in a refrigerator, colorless crystals which melted at 160—162°C (decomp.) after having been once recrystallized in a small amount of water. $[\alpha]_D^{20}$ +108 (*c* 1.36, water, equil.).

Found: C, 40.23; H, 6.63; N, 5.82%. Calcd for $C_8H_{15}O_7N$: C, 40.50; H, 6.37; N, 5.91%.

The physical constants agreed well with those given by Gigg and Carroll,[4] who prepared the compound *via* a different route.

2-Amino-2-deoxy-3-*O*-carboxymethyl-D-glucitol (V). To a solution of 250 mg of IV in 15 m*l* of water, was added a solution of 100 mg of sodium borohydride in 5 m*l* of water, after which the mixture was stirred overnight at room temperature. Then the pH of the mixture was adjusted to 4.5 by the addition of Amberlite IR-120 (H^+ form) resin. The filtrate from the resin was concentrated *in vacuo*. A small amount of methanol was then added to the residue, and the mixture was evaporated. This procedure was repeated six times in order to remove any boric acid. The residue was dissolved in 0.7 m*l* of water, and the subsequent addition of 7 m*l* of methanol gave 150 mg of colorless crystals which melted at 197—198°C. $[\alpha]_D^{23}$ +38 (*c* 2.0, methanol).

Found: C, 39.89; H, 7.25; N, 5.77%. Calcd for $C_8H_{17}O_7N$: C, 40.16; H, 7.16; N, 5.86%.

Methyl 2-Acetamido-2-deoxy-3-*O*-methylcarboxylate-4,6-*O*-benzylidene-α-D-glucopyranoside (VI). An ethereal solution of diazomethane was added to a solution of 300 mg of III in 100 m*l* of methanol. The addition of the reagent was stopped when a persistent yellow color remained. The mixture was then evaporated *in vacuo*, and the residue was dissolved in a small amount of methanol. After an amorphous, insoluble material had been removed, colorless crystals were obtained when the solution was cooled in a refrigerator. The specimen thus obtained (180 mg) melted at 225—226°C. $[\alpha]_D^{20}$ +77 (*c* 0.56, methanol).

Found: C, 57.84; H, 6.44; N, 3.53%. Calcd for $C_{19}H_{25}O_8N$: C, 57.71; H, 6.37; N, 3.54%.

An aglycon homologue (ethyl 2-acetamido-2-deoxy-3-*O*-methylcarboxylate-4,6-*O*-benzylidene-α-D-glucopyranoside) was likewise obtained; it melted at 174—175°C. $[\alpha]_D^{20}$ +79.4 (*c* 0.68, methanol).

Found: C, 58.54; H, 6.51; N, 3.47%. Calcd for $C_{20}H_{27}O_8N$: C, 58.67; H, 6.65; N, 3.42%.

2-Amino-2-deoxy-6-*O*-carboxymethyl-D-glucose. Two grams of *O*-carboxymethylated chitin (Lot 3 in Table 1) were hydrolyzed in a nitrogen atmosphere at 100°C for 5 hr with 200 m*l* of 4 N hydrochloric acid. The hydrolysate was then dried up *in vacuo*, and the residue was dissolved in 50 m*l* of a 0.2 M citrate buffer solution with a pH of 3.11. The solution was placed on an Amberlite IR-120 column (Na^+ form, 3×65 cm) which had been bufferized with the same buffer solution. The column was then also eluted with the same buffer solution. The elution speed was 50 m*l* per hour, and each 8.1 m*l* portion of ninhydrin-positive fraction was collected. At Fraction No. 120, the

buffer solution was changed to 0.2 M citrate with a pH of 4.25. The peak IV in Fig. 1 was evaporated *in vacuo*, and the residue was dissolved in 30 m*l* of water and placed on a column of Amberlite IR-120 (H^+ form, 2.8×12 cm). The column was then washed thoroughly with water and eluted with 0.1 N hydrochloric acid. A ninhydrin-positive fraction was obtained and evaporated *in vacuo*. The syrup thus obtained was dissolved in 50 m*l* of water, and the pH of the solution was adjusted to 6.1 by the addition of Dowex-1 (OH^- form) resin. The filtrate from the resin was decolorized with a small amount of charcoal and evaporated *in vacuo*. The remaining syrup was crystallized in 10 m*l* of ethanol. The yield of faintly yellow crystals which melted at 178—180°C (decomp.) was 430 mg. $[\alpha]_D^{18}$ +72 (*c* 1.03, water, equil.).

Found: C, 39.84; H, 6.50; N, 5.84%. Calcd for $C_8H_{15}O_7N$: C, 40.50; H, 6.37; N, 5.91%.

The position of the carboxymethyl group was determined by the periodate oxidation method. As is shown in Table 2 the specimen did not produce formaldehyde at all after the consumption of the theoretical amount of periodate. This is strong evidence of the position-6 for the carboxymethyl group. The elemental analyses agreed with its identification as a monocarboxymethylated glucosamine; its behavior was

Table 2.

	Consumption of periodate after 46 hr oxidation*	Formation of formaldehyde after 46 hr oxidation**
Glucose	6.7 mol	1.0 mol

quite different from that of synthetic 3-*O*-carboxymethylglucosamine. All these facts indicate that the specimen is 6-*O*-carboxymethylglucosamine.

Partially-*O*-carboxymethylated Chitin. Ten grams of finely-powdered commercial chitin were soaked in 60 g of a 42% sodium hydroxide solution and then kept overnight *in vacuo*. To this mixture crushed ice was then added, portion by portion and under vigorous stirring, until the total volume reached about one liter. A solution of 300 m*l* of 4 N sodium chloroacetate was added to the paste thus obtained, after which the stirring was continued at room temperature for 24 hr. In order to *N*-acetylate the partially-released amino groups, 100 m*l* of acetic anhydride were gradually stirred in, while the pH of the solution was prevented from going below 10 by the addition of sodium hydroxide. Stirring was continued for 24 hr. The mixture was dialyzed against running water for 3 days and against deionized water for 24 hr. The insoluble material was removed in a centrifuge, and the supernatant was lyophilized. The sodium salt of partially-carboxymethylated chitin thus obtained weighed 8.5 g; it contained 14% of water and did not reveal any van Slyke nitrogen. A sample of chromatographic pattern of a specimen (Lot No. 2 in Table 1) derived by component analysis using an automatic amino-acid analyzer is shown in Fig. 2.

The Photochemical Reactions of Fe(III) Complexes with 1,2-Glycols. Dehydration and Dehydrogenation*1

Hiroo INOUE, Nobuyuki KOMAKINE and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received April 20, 1968)

Ferric chloride reacts with 1,2-glycols, when irradiated with light, to afford dehydration and dehydrogenation products. The reaction course is influenced by the structure of the 1,2-glycols, the kind of ligand around the Fe(III) ion, and the solvent in the reaction system. When the number of hydrogen atoms on carbon having a hydroxyl group of 1,2-glycol increases, the yield of the dehydration product increases in comparison with that of the dehydrogenation product; the photochemical reaction of ferric chloride with ethylene glycol or pinacol gives, selectively, acetaldehyde or acetone respectively. The photochemical reaction of ferric acetate with the ethylene glycol shows a highly selective dehydrogenation, giving only formaldehyde, though it is in a good yield. Furthermore, the addition of aniline or acetic acid to the ferric chloride-ethylene glycol system results in an increase in the production of glyoxal or acetaldehyde respectively. In the photochemical reaction of ferric chloride with ethylene glycol or *cis*- and *trans*-1,2-cyclohexanediol, acetonitrile as a solvent causes the formation of the dehydrogenation products, that is, acetoxyacetaldehyde and glyoxal or 1,2-cyclohexanedione respectively.

The photochemical reaction of ethylene glycol with ferric chloride affords, selectively, the dehydration product, acetaldehyde.[1] The ferric chloride - pyridine complex, however, causes the formation of the dehydrogenation product, glyoxal and formaldehyde, from ethylene glycol.[2] The reactions are mediated by a Fe(III) ion - ethylene glycol complex in solution. The selectivity of the reaction may be interpreted in terms of the interaction of a ligand with the hydrogen of either the carbon or hydroxyl group of ethylene glycol, which is close to the ligand. Moreover, the electronic nature of the Fe(III) in a Fe(III) complex may also contribute to the selective reaction. The present paper deals with a study of the effects of the ligand of a complex, of the solvent, and of the structure of 1,2-glycols on the dehydration or dehydrogenation course. Ethylene glycol, propylene glycol, 2,3-butanediol, pinacol, and *cis*- and *trans*-1,2-cyclohexanediol as 1,2-glycols, and ferric chloride and ferric acetate as ferric salts, were used here.

Experimental

Materials. The ethylene glycol, propylene glycol, 2,3-butanediol, aniline, and acetic acid were purchased from commercial sources, while the pinacol and *cis*- and

trans-1,2-cyclohexanediol were synthesized by the methods described in the literature.[3-5] These materials were dried by the usual methods and distilled through a Vigreux column before use. Ethylene glycol: bp 76—77°C/4 mmHg, n_D^{22} 1.4321. Propylene glycol: bp 185—189°C, n_D^{32} 1.4291. 2,3-Butanediol: bp 72—73°C/5 mmHg, n_D^{31} 1.4343. Pinacol: bp 80°C/15 mmHg (lit.[3,6] bp 75°C/13 mmHg). *cis*-1,2-Cyclohexanediol: mp 97—98°C (lit.[4] mp 98°C). *trans*-1,2-Cyclohexanediol: mp 102—104°C (lit.[5] mp 101.5 103°C). The anhydrous ferric chloride and ferric acetate, and thallium oxide (Tl_2O_3) were of a commercial grade; they were dried over phosphorus pentoxide at 100°C under the reduced pressure of 10 mmHg. The acetonitrile was purified by two distillations after having been dried on calcium hydride.

General Procedure of the Photochemical Reaction. The photochemical reactions were carried out by the methods described in previous papers.[1,2] Glycols and ferric chloride or ferric acetate were transferred, under a nitrogen atmosphere, to a vycor tube. The tube was then sealed and irradiated for 20—24 hr at an equidistant place (4 cm) from a 100W mercury lamp, which irradiated waves at 2500, 3200, 3600, 4400, 5500, and 5800 Å at room temperature unless otherwise stated. The reactions of *cis*- and *trans*-1,2-cyclohexanediol with anhydrous ferric chloride or ferric acetate were carried out in an acetonitrile solvent. In the case of pinacol, chelate complexes consisting of pinacol and ferric chloride or cupric chloride were prepared, dissolved in an acetonitrile solvent, and irradiated as has been described above. The concentration of a solution of the chelate complex in acetonitrile was about 22 g/*l*. In order to isolate the reaction products, another procedure was attempted on a large scale by using a cylindrical, 300-m*l* reaction vessel.[1]

Analyses of the Products. The analyses of the products were mainly accomplished by means of gas chromatography, using Hitachi KGL-2 and Yanagimoto 5DH gas chromatographs. A column containing polyethylene glycol-6000 and -20 M and/or high-vacuum silicone grease was used in the gas chromatography analyses. Helium gas was used as the carrier gas.

Acetone, propionaldehyde, acetaldehyde, methyl ethyl ketone, 2-ethyl-4-methyl-1,3-dioxolane, 2,4-dimethyl-1,3-dioxolane, 2,2,4-trimethyl-1,3-dioxolane, 2,4,5-trimethyl-1,3-dioxolane, and 2-ethyl-2,4,5-trimethyl-1,3-dioxolane were identified by a comparison of their retention times with those of authentic materials, and by trapping the materials from the column and by then comparing the infrared spectra of the trapped materials with those of authentic materials. The amounts of these compounds were determined by means of gas chromatography, and by the paper chromatography of their 2,4-dinitrophenylhydrazones. The amounts of the oxolanes are described as those of the corresponding carbonyl compounds in Tables 1, 2, 3 and 4. 1,2-Propanedione, 1,2-cyclohexanedione, adipaldehyde, 2,3-butanedione, and glyoxal were isolated as their 2,4-dinitrophenylhydrazones, which were purified by recrystallization from ethanol or ethanol-ethyl acetate, and which were identified by comparing their infrared spectra and their melting points with those of authentic materials. The diketones were determined by measuring the weights of their 2,4-dinitrophenylhydrazones. Acetoxyacetaldehyde was isolated as the 2,4-dinitrophenylhydrazone, mp 150—151°C (lit.[7] mp 152°C), the infrared absorption spectrum of which has the absorption of the carbonyl group of the ester at 1730 cm^{-1}. Its elementary analysis indicates:

Found: C, 42.40; H, 3.44; N, 19.72%. Calcd for $C_{10}H_{10}N_4O_6$: C, 42.57; H, 3.55; N, 19.86%.

Formaldehyde and the ferrous ion were determined spectrophotometrically by using the Schiff's reagent and the 1,10-phenanthroline methods respectively.[8,9]

Analysis of Fe(III) in Fe(III) Complex. A weighed amount of the Fe(III) complex was decomposed by refluxing it in concentrated nitric acid for 3—4 hr. The solution was then diluted with distilled water, and adjusted to pH 2—3 with 1 N sodium acetate-acetic acid, after which a 2% tiron solution was added. The solution was then titrated with a 0.01 M EDTA solution by a volumetric method.

Preparations of Complexes. *Ferric Chloride-Pinacol.* Ferric chloride (7.1 g) in acetonitrile (20 g) was mixed with a solution of pinacol (10 g) in acetonitrile (2 g). The solution was heated at 70—80°C for 1—2 min, then cooled with dry ice and acetone. Pale green crystals of the complex, which decomposed above 100°C without melting, were filtered off and washed with boiling chloroform (yield, 3.8 g).

Found: C, 26.15; H, 5.26%. Calcd for $C_6H_{14}O_2$-$FeCl_3$: C, 25.70; H, 5.03%.

Ferric chloride content, 4.2×10^{-3} mol/g. Pinacol content, 3.8×10^{-3} mol/g.

The determination of the pinacol present in the complex was carried out by the following method: a portion of 0.3 g of 8-quinolinol was added to a solution of 0.1 g of the complex in 10 m*l* of acetonitrile. The mixture was then allowed to stand at 30°C for 30 min to give the precipitate of the 8-quinolinol-ferric ion complex. The pinacol thus removed was analyzed by means of gas chromatography. The infrared absorption spectrum of the complex showed absorptions at 3270, 2960, 1460, 1380, 1340, 1140, 950, 920, 880, and 690 cm^{-1}, as Fig. 1 shows.

Cupric Chloride-Pinacol. A portion of 1 g of cupric chloride was added to a solution of 2 g of pinacol in 10 g of acetonitrile. The solution was heated at 70—80°C for 1—2 min, and then cooled with a dry ice-acetone mixture. Pale green crystals of the complex, which decomposed above 100°C without melting, were filtered off and washed with boiling chloroform (yield, 1.5 g). Pinacol content, 5.7×10^{-3} mol/g. The infrared absorption spectrum of the complex showed absorptions at 3400, 3125, 3025, 2750, 2550, 2330, 1460, 1375, 1210, 1160, 1140, 1113, 947, 895, and 827 cm^{-1}.

Results

Photochemical Reaction of Ferric Chloride. *Eethylene Glycol.* Ethylene glycol reacts with ferric chloride under the irradiation of ultraviolet light for 24 hr to afford acetaldehyde in a 74% yield,[1] based on the amount of ferric chloride used. The addition of pyridine to the ferric chloride-ethylene glycol system, however, results in the production of glyoxal, formaldehyde, and acetaldehyde in 44, 5 and 6% yields respectively, when 60% of the Fe(III) is photo-reduced to Fe(II).[2] In this paper, aniline or acetic acid was added to a solution of ferric chloride in ethylene glycol, with the molar ratio of aniline or acetic acid to ferric chloride, of 1/2 or 1 respectively, and irradiated in an atmosphere of nitrogen at a distance of 4 cm from the light source for 24 hr at room temperature. As Table 1 shows, the addition of aniline to the reaction system gave glyoxal and acetaldehyde in 12 and 9% yields, while Fe(III) was photo-reduced to Fe(II) in a 84% yield. Thus, the product yields became considerably lower than the photo-reduction yield of Fe(III) to Fe(II). Probably, this means that aniline itself is photo-oxidized by ferric chloride. On the other hand, in the case of acetic acid, acetaldehyde was obtained as the main product in a yield which corresponded to the photo-reduction yield of Fe(III) to Fe(II). Thus, the acidic or basic ligand in the reaction system tends to contribute to the formation of the dehydration or dehydrogenation product respectively.

Propylene Glycol. When a solution of ferric chloride in propylene glycol was heated at about 100°C under a nitrogen atmosphere for 5.5 hr, no product was detected. However, the ultraviolet light irradiation of a solution of ferric chloride in propylene glycol gave mainly acetone, propionaldehyde, acetaldehyde, and formaldehyde, as is shown in Table 2. During the photo-reaction, the Fe(III) is photo-reduced to Fe(II). Acetone or propionaldehyde is produced by the elimination of the primary or the secondary hydroxyl group respectively (dehydration).

The formations of acetaldehyde and formaldehyde mean the occurrence of the oxidative cleavage of

* The amounts of propylene glycol, ferric chloride and hydrogen peroxide were 4.04, 0.19 and 0.18 mol respectively. Irradiation time: 20 hr. Thermal reaction: temperature, 100°C and time, 5.5 hr.

** The yields of CH_3COCH_3, CH_3CH_2CHO, CH_3CHO, CH_2O and Fe(II) ion: (amount of the product)/(amount of $FeCl_3$ or H_2O_2)$\times$100, and the yield of CH_3COCHO: 2$\times$(amount of CH_3COCHO)/(amount of H_2O_2)$\times$100. The total amount of gas evolved was 4×10^{-3} and 1.5×10^{-3} mol for the photo-reactions in the case of ferric chloride and hydrogen peroxide respectively.

*** P and T are the abbreviations for the photochemical and thermal reactions.

TABLE 3. THE PHOTOCHEMICAL AND THERMAL REACTIONS OF 2,3-BUTANEDIOL WITH FERRIC CHLORIDE*

Reaction type	Yield of product (%)			
	$CH_3COCH_2CH_3$	CH_3CHO	$CH_3COCOCH_3$	Fe(II) ion
P	14	24	0	50
T	0	0	0	0

* The starting amounts of 2,3-butanediol and ferric chloride were 0.1 and 5×10^{-3} mol respectively. Irradiated time: 24 hr. Distance of irradiation: 4 cm. Thermal reaction: temperature, 100°C and time, 5.5 hr. The evolution of gas was not observed. The yield of the product was based on the starting amount of ferric chloride.

the bond between 1- and 2-carbons (dehydrogenation). The dehydration occurs twice as easily as does the dehydrogenation and, furthermore, involves twice as much elimination of the secondary hydroxyl group as of the primary hydroxyl group.

The ultraviolet-light irradiation of propylene glycol in the presence of hydrogen peroxide resulted in the formation of acetone in a 83.3% yield. This reaction is initiated by the hydroxyl radical produced by the photo-decomposition of hydrogen peroxide, followed by the abstraction of hydrogen on 2-carbon and the elimination of the primary hydroxyl group. Thus, there were remarkable differences between the photochemical behavior of ferric chloride and hydrogen peroxide in relation to propylene glycol. Probably, this is because the excited ferric chloride reacts with propylene glycol through a complex between them. Furthermore, the fact that the secondary hydroxyl group is more easily eliminated than the primary hydroxyl group supports the interpretation of the elimination mechanism by means of ferric chloride, as will be discussed later.

2,3-*Butanediol.* When a solution of ferric chloride in 2,3-butanediol was heated at about 100°C under a nitrogen atmosphere for 5.5 hr, no product was confirmed. However, the ultraviolet-light irradiation of the solution involving ferric chloride in 2,3-butanediol gave acetaldehyde, methyl ethyl ketone, and Fe(II) in 24, 14 and 50% yields respectively, as is shown in Table 3. That is, the yields of acetaldehyde and methyl ethyl ketone, based on the amount of Fe(III) converted to Fe(II), were 48 and 28% respectively. This would mean that the carbon-carbon bond cleavage occurs in a ratio similar to the elimination of the hydroxyl group.

Pinacol. A complex consisting of ferric chloride and pinacol was isolated as a pale green plate by mixing a solution of ferric chloride in acetonitrile with that of pinacol in acetonitrile. The combination of the elementary analyses of carbon and hydrogen, and the quantitative analyses of Fe(III) and pinacol in the crystals, showed that the molar ratio of the ferric chloride to the pinacol present in the complex is nearly 1, as is shown in Table 4. Furthermore, the infrared absorption spectrum of the crystals had absorptions characteristic of pinacol and ferric chloride.

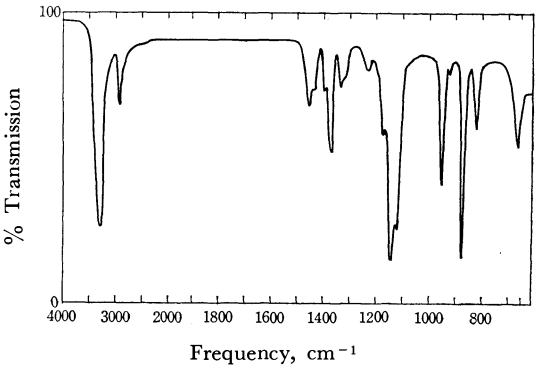

Fig. 1. Infrared spectrum of ferric chloride-pinacol complex (KBr disk).

The ferric chloride - pinacol complex dissolved in acetonitrile was irradiated with ultraviolet light for 24 hr at room temperature. As Table 4 shows, acetone was obtained as the sole product in a nearly 100% yield, based on the amount of ferric chloride in the complex as a starting material. The theoretical amount of the unreacted pinacol was recovered. When water instead of acetonitrile was used as the solvent, pinacol did not react with ferric chloride under the ultraviolet-light irradiation. This must be due to the decomposition of the ferric chloride - pinacol complex by the coordination of water.

On the other hand, when a solution of the complex in acetonitrile or water was refluxed under a nitrogen atmosphere for 6 hr, no product was detected, and pinacol was recovered in an almost 100% yield.

Although the production of pinacolone by pinacol rearrangement was predicted in the photochemical reaction of pinacol with ferric chloride, no pinacolone was detected at all. Pinacol also formed a complex with cupric chloride; the photochemical reaction of the complex gave acetone in a lower yield than in the case of the ferric chloride - pinacol complex, as is shown in Table 4. The photochemical reactions of binary metal salts, such as ferric chloride-cupric chloride and ferric chloride-thallium oxide, with pinacol gave unfavorable results, as Table 4 also shows. Thus, pinacol is photo-oxidized by ferric chloride in acetonitrile

Table 4. The photochemical reaction of pinacol-Fe(II) or Cu(II) ion complex*

Complex pinacol-metal salt	Amount (g)	Component: Metal salt (mol×10³)	Component: Pinacol (mol×10³)	Metal salt added (mol×10³)	Solvent	Reaction type	Yield of CH_3COCH_3 (%)	Recovery % pinacol
$FeCl_3$	0.22	0.7	0.8	0	CH_3CN	P	100	55
$FeCl_3$	0.33	1.4	1.3	0	H_2O	P	0	100

0.11	0.11	158	0	0	1	8	50	80

* Irradiated time: 24 hr in the absence of acetonitrile and 48 hr in the presence of acetonitrile. Reaction method: cylindrical vessel. The yield of the product was based on the starting amount of ferric chloride.

to afford, selectively, acetone in a good yield. This seems to be characteristic of the photochemical action of ferric chloride.

cis- and trans-1,2-cyclohexanediol. As Table 5 shows, the photochemical reaction of ferric chloride with *cis-* and *trans-*1,2-cyclohexanediol in acetonitrile afforded, selectively, a dehydrogenation product, 1,2-cyclohexanedione or 2-hydroxycyclohexanone, in a low yield of about 10%, when Fe(III) was reduced to Fe(II) in about a 40% yield. Although we attempted to recover *cis-* or *trans-*1,2-cyclohexanediol from the reaction mixture, it was difficult to recover it completely because of the formation of a complex between *cis-* or *trans-*1,2-cyclohexanediol and ferric chloride. By means of the ligand-exchange of the complex by 8-quinolinol, about 45—50% of *cis-* or *trans-*1,2-cyclohexanediol was, however, recovered. Thus, the yield of the product was low because of the photochemical reaction of ferric chloride with acetonitrile as a solvent; no remarkable differences were observed in the cases of *cis-* and *trans-*1,2-cyclohexanediol. The coordination of acetonitrile to Fe(III) may affect the selectivity and the yield in the formation of the dehydrogenation product.

Photochemical Reaction of Ethylene Glycol with Ferric Acetate. The photochemical reaction of ethylene glycol with ferric acetate was carried out under conditions similar to those used with ferric chloride. As Table 6 shows, formaldehyde was obtained as the sole product. During the photochemical reaction, white crystals appeared on the wall of the reaction vessel. In the photochemical reaction of 0.17 mol of ethylene glycol and 0.008 mol of ferric acetate, 0.16 g of the crystals was collected by filtration after the reaction. The crystals rapidly turned from white to brown upon exposure to air. The infrared absorption spectrum of the crystals, measured by a KBr disk, shows absorptions at 3400, 2950, 2870, 1555—1530, 1450—1430, 1350, 1055, 1030, 893, and 660 cm^{-1}, absorptions characteristic of those of ferric or ferrous acetate and ethylene glycol. The iron content of the complex was 4.8×10^{-3} mol/g; this corresponded to the amount of ferric acetate required for the formation of formaldehyde. The crystals are probably a complex between ferrous acetate and ethylene glycol.

The next phenomenon concerns the photochemical reaction of a complex consisting of ethylene glycol and ferric acetate (Fe(III) ion content; 1.58×10^{-2} mol/3.8 g) in acetonitrile. The complex was prepared as follows. When a solution of 3.8 g of ferric acetate in 20.1 g of ethylene glycol was allowed to stand at room temperature for a day, there were precipitated 2.4 g of a pale prism, decomposing gradually above 100°C. After this had been filtered and then washed with acetonitrile. it was dried on calcium chloride under the reduced pressure of 10 mmHg at room temperature. The dispersion of the crystals in a solution of 8-quinolinol in acetonitrile removed the ethylene glycol from the crystals. Thus, it was confirmed that no organic compounds other than ethylene glycol and acetate anion were present in the crystals. Furthermore, the infrared absorption spectrum of the crystals, as measured by the use of a KBr disk, had absorptions at 3300—3100, 2950, 2870, 1580—1560, 1455—1420, 1390, 1300, 1245, 1230, 1070, 1040, 910, 895, and 660 cm^{-1}, absorptions characteristic of ferric acetate and ethylene glycol, as Fig. 2 shows. The absorption of the complex at 1560—1580 cm^{-1} was shifted toward a wave number shorter by about 30 cm^{-1} than that of ferric acetate. The determination of the Fe(III) present in the crystals showed the amount to be 4.1×10^{-3} mol/g. These results indicate that the crystals are a complex consisting of ferric acetate and ethylene glycol, with a molar ratio of 6.

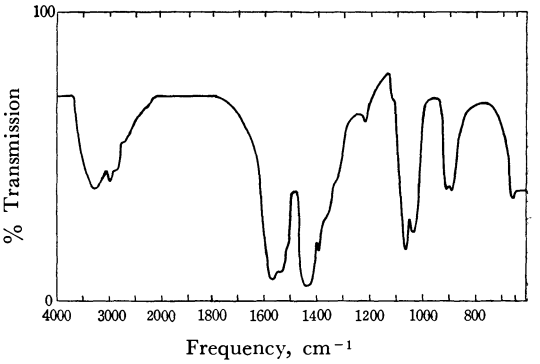

Fig. 2. Infrared spectrum of ferricacetate-ethylene glycol complex (KBr disk).

A dispersed solution of 0.1 g of the ferric acetate-ethylene glycol complex in 10.0 g of acetonitrile was irradiated in an atmosphere of nitrogen at a distance of 4 cm from the light source for 24 hr at room temperature. Formaldehyde was obtained as the sole product in a 100% yield.

It has thus been confirmed that the photochemical reaction of ferric acetate with ethylene glycol shows a highly selective oxidative cleavage of a carbon-carbon bond to formaldehyde. Furthermore, the photochemical action of ferric acetate on *cis-* and *trans-*1,2-cyclohexanediol was also similar to that for ethylene glycol; that is, it resulted in the production of adipaldehyde, as is shown in Table 5.

On the other hand, the thermal reaction of ferric acetate with ethylene glycol afforded only a dehydrogenation product, glyoxal. Thus, there was a remarkable difference between the photochemical and thermal reactions of ferric acetate with ethylene glycol.

Solvent Effect of Acetonitrile. As Table 7 shows, the photochemical reaction of ferric chloride with ethylene glycol in acetonitrile afforded glyoxal and acetoxyacetaldehyde in 1 and 8% yields respectively, while Fe(III) was photo-reduced

to Fe(II) in a 50% yield. About 80% of the ethylene glycol was recovered. Acetaldehyde and formaldehyde, which are the products of the photochemical reactions of ethylene glycol with ferric chloride and ferric acetate respectively, were not detected at all. Furthermore, when the solution of a mixture of ferric chloride and ethylene glycol in acetonitrile was allowed to stand at room temperature without any light irradiation, no acetoxyacetaldehyde was obtained. A reaction (1) involving the formation of hydroxyethyl esters by thermal interaction between nitriles and ethylene glycol has already been reported.[10] In the photochemical reaction

$$RCN + HOCH_2CH_2OH \xrightarrow[\text{reflux}]{} RCOO(CH_2)_2OH \qquad (1)$$

described above, acetoxyacetaldehyde would be produced *via* the following process, that is, by the addition to one hydroxyl group of ethylene glycol to a nitrile group of acetonitrile coordinated to ferric chloride, and by the oxidation of the other hydroxyl group of ethylene glycol by the excited ferric chloride, as is indicated in Eq. (2):

$$CH_3CN + HOCH_2CH_2OH \xrightarrow[FeCl_3]{h\nu} CH_3C(=NH)-OCH_2CHO \xrightarrow{H_2O} CH_3COOCH_2CHO \qquad (2)$$

Discussion

Ferric salts form a complex with 1,2-glycols in the reaction system. The ferric chloride - pinacol and ferric acetate - ethylene glycol complexes were isolated as crystals. The excitation of the Fe(III) of the complex with light resulted in the competition of the dehydration and the dehydrogenation of the 1,2-glycols coordinated with the Fe(III). When the number of hydrogen on carbon with a hydroxyl group increased, the dehydration increased in comparison with the dehydrogenation: the yield of the dehydration product became lower in the order of ethylene glycol> propylene glycol> 2,3-butanediol> pinacol, while that of the dehydrogenation showed the reverse order. Furthermore, in the case of propylene glycol, the secondary hydroxyl group was eliminated more readily than the primary hydroxyl group. In addition, no rearrangement product was obtained in any case. On the other hand, the irradiation of a complex consisting of ferric acetate and ethylene glycol in acetonitrile gave, selectively, the dehydrogenation product, and addition of pyridine or acetonitrile to the ferric chloride - ethylene glycol system resulted in an increase in the formation of the dehydrogenation product. Thus, there were significant effects of the ligand, the solvent, and the structure of 1,2-glycol on the selectivity for the dehydration and the dehydrogenation.

The mechanisms for the two reactions may be explained reasonably by considering the interaction of the ligand or the base with hydrogen of either the carbon or hydroxyl group of 1,2-glycol. That is, for a dehydration mechanism, we assume a mechanism involving the intramolecular abstraction of hydrogen radical or proton by a chlorine radical or anion, followed by the simultaneous elimination of the hydroxyl radical or anion by the excited Fe(III), as is shown in Eq. (3). For the occurrence of the dehydration, the existence

10) B. Robinson, *J. Chem. Soc.*, **1963**, 2417.

of hydrogen on the carbon with a hydroxyl group and an exact stereochemical arrangement of the 1,2-glycol and ferric chloride in the complex are required.

The dehydrogenation by ferric acetate or the ferric chloride - pyridine system resembles Criegee's oxidation of glycols by lead tetraacetate.[11] Furthermore, it has been proposed that the excitation of Fe(III) complexes with OH^-, Br^-, I^-, NCS^- or $C_2O_4^{2-}$ as the ligand results in the transfer of an electron from the ligand to the Fe(III).[12] In a previous paper,[2] we have assumed the interaction of pyridine with the hydrogen of the hydroxyl group of glycol and the transfer of an electron from the oxygen of glycol or the glycol anion to the Fe(III), as is indicated in Eq. (4). The dehydrogenation by ferric acetate may also involve a mechanism similar to that of the case of pyridine, that is, the intramolecular interaction of acetate anion with the hydroxyl group and the oxidation of glycol or the glycol anion by the excited ferric acetate, thus producing formaldehyde *via* the cleavage of a carbon-carbon bond.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2733—2735 (1968)

Synthetic Studies of Sesamol Derivatives. X.*1 Synthesis of Dehydroneotenone

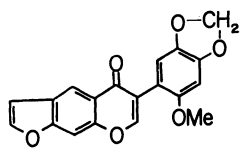
Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

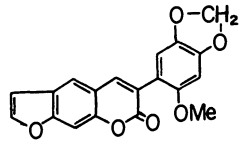
(Received April 27, 1968)

The synthesis of dehydroneotenone has been carried out using 6-hydroxy-5-(2-methoxy-4,5-methylenedioxyphenylacetyl)-2,3-dihydrobenzo[*b*]furan as an intermediate and by subjecting it to cyclization with ethyl orthoformate, followed by dehydrogenation.

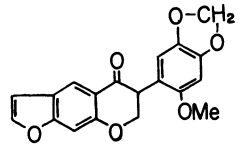
Dehydroneotenone (Erosone),[1] a colorless substance, $C_{19}H_{12}O_6$, is the first naturally-occurring furanoisoflavone (I) which has been isolated, along with pachyrrhizin (II)[2], from *Pachyrrhizus erosus* (Yam bean),[3] as well as from *Neorautanenia edulis*[4] and *N. amboensis*.[4] On the other hand, I has been derived[5] from neotenone (III), a naturally-occurring furanoisoflavanone, by dehydrogenation with manganese dioxide. The present paper will describe the total synthesis of I according to a modification of a procedure reported earlier.[6]



I



II



III

By a modified Hoesch reaction, 6-hydroxy-2,3-dihydrobenzo[*b*]furan (IV)[7] was condensed with 2-methoxy-4,5-methylenedioxyphenylacetonitrile

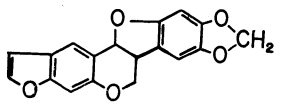
(V)[8] to give 6-hydroxy-5-(2-methoxy-4, 5-methylenedioxyphenylacetyl)-2, 3-dihydrobenzo[*b*]furan (VI). The subsequent treatment of the dihydrobenzofuran VI with ethyl orthoformate - pyridine - piperidine gave dihydrodehydroneotenone (VII). The dehydrogenation of the dihydro-compound VII with either *N*-bromosuccinimide[4,9] or 10% palladium-charcoal gave the isoflavone I. On alkaline hydrolysis, I gave 6-hydroxy-5-(2-methoxy-4,5-methylenedioxyphenylacetyl)benzo[*b*]furan (VIII).[5,9]

The partial synthesis of III had already been carried out from the isoflavone I.[5] Moreover, the racemate of (−)-neodulin (IX),[10] a naturally-occurring pterocarpan, had already been derived from the same isoflavone I *via* the corresponding isoflavanol-4.[4] Thus, the total syntheses of III and (±)-IX have been now accomplished.



IX

The ultraviolet spectra of the isoflavone I and its dihydro-compound VII are shown in Fig. 1. There are two absorption bands, at *ca.* 230—250 mμ (band I) and at *ca.* 300—310 mμ (band II). Band I is due to furano- and dihydrofurano-benzenoid. The dehydrogenation of the dihydrofuranobenzenoid showed a marked hyperchromic effect. Many samples of this same phenomenon have been reported in previous reports.[2,6,11]

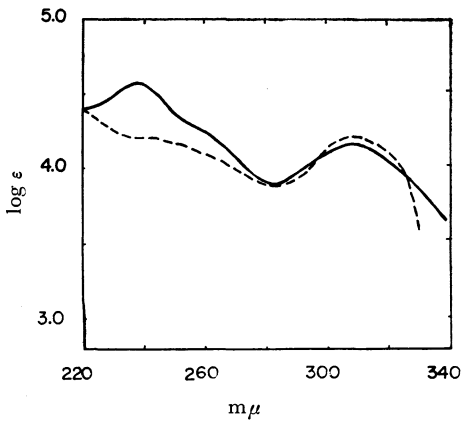


Fig. 1. UV spectra of I (——) and VII (- - -) in ethanol.

Experimental*2

6-Hydroxy-5-(2-methoxy-4,5-methylenedioxyphenylacetyl)-2,3-dihydrobenzo[*b*]furan (VI). To a mixture of 6-hydroxy-2,3-dihydrobenzo[*b*]furan (IV)[7] (4.0 g), 2-methoxy-4, 5-methylenedioxyphenylacetonitrile (V)[8a] (4.0 g), and fused zinc chloride (9.0 g) in dry chloroform (200 m*l*), anhydrous aluminum chloride (7.0 g) was added. Dry hydrogen chloride was passed through this mixture for 30 min at 0°C, and then dry ether (150 m*l*) was added. The resulting mixture was completely saturated with dry hydrogen chloride and then allowed to stand for 4 days in a

*2 All melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

refrigerator. An ether solution was decanted from the ketimine hydrochloride, which had separated. The residue was washed with dry ether and then hydrolyzed with water (350 m*l*) on a steam bath for 1 hr. The precipitates were collected and recrystallized from ethanol to give VI as colorless needles, mp 153—154°C, which gave a brown ferric chloride reaction in ethanol; yield, 2.1 g (31%). IR: 1650 (C=O), 1038, 931 (O-CH_2-O) cm^{-1}. UV: λ_{max} mμ (log ε); 239 (4.21), 284 (4.14), 330 (3.70).

Found: C, 65.67; H, 4.95%. Calcd for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

Dihydrodehydroneotenone(4'',5''-dihydrofurano-(3'',2'':6,7)-2'-methoxy-4',5'-methylenedioxyisoflavone) (VII). To a solution of VI (1.0 g) and ethyl orthoformate (6 m*l*) in pyridine (25 m*l*), piperidine (1 m*l*) was added. The solution was then refluxed for 24 hr. The resulting solution was cooled and acidified with dilute hydrochloric acid. The resulting precipitates were collected, washed with water, and recrystallized from ethanol to give VII as colorless needles, mp 247—248°C; yield, 1.1 g (82%) (lit.[4] mp 255°C (correct.)). IR: 1644 (γ-pyrone), 1040, 919 (O-CH_2-O) cm^{-1}. UV: λ_{max} mμ (log ε); 241_i (4.22),*3 251_i (4.19), 310 (4.23).

Found: C, 67.38; H, 4.47%. Calcd for $C_{19}H_{14}O_6$: C, 67.45; H, 4.17%.

Dehydroneotenone (I). A mixture of VII (500 mg), 10% palladium-charcoal (400 mg), and diphenyl ether (20 m*l*) was refluxed for 10 hr. The catalyst was then filtered off, and the solvent removed by steam distillation. The resulting precipitates were collected and recrystallized from ethanol to give I as colorless needles, mp 234—235°C; yield, 220 mg (44%) (lit. mp 242°C (correct.),[3] 239.5—240.5°C (correct.),[4] 240—241°C[5]). This was identical with an authentic sample (mp 234—235°C) obtained from VII by the *N*-bromosuccinimide method.[9] IR: 1644 (γ-pyrone), 1626, 1589, 1544, 1508 (aromatic), 1040, 942 (O-CH_2-O) cm^{-1} (lit.[5] 1658, 1629, 1592, 1549, 1506 cm^{-1} (chloroform solution)). UV: λ_{max} mμ (log ε); 238 (4.59), 309 (4.20) (lit.[5] 239 (4.61), 308 (4.10)).

Found: C, 68.00; H, 3.84%. Calcd for $C_{19}H_{12}O_6$: C, 67.85; H, 3.60%.

The authors are grateful to Professor Tetsuo Mitsui, Kyoto University, for his microanalyses.

Sur la Structure des Dimères du *N*-Phényl Acétone-D-glycéraldimine

Masuo FUNABASHI et Juji YOSHIMURA

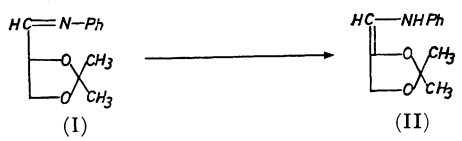
Laboratoire de Chimie des Substances Naturelles, Faculté des Sciences, Institut Téchnologique de Tokio Ookayama, Meguro-ku, Tokio

(Reçu le 30 Avril 1968)

N-phényl acétone-D-glycéraldimine dimérise facilement en présence d'un soupçon de l'acide acétique et donne deux dimères, dont la structure y comprise la configuration absolue partielle a été etablie par l'analyse spectrométrique et la décomposition chimique comme étant un 4-anilino-2-(2',2'-diméthyl-1',3'-dioxolanne-4'-yl)-1,2,3,4-tétrahydroquinoléine-3-spiro-4''-(2'',2''-diméthyl-1'',3'')dioxolanne. Lorsqu'on hydrolyse ces dimères partiellement avec l'acide acétique aqueux à 70%, on peut isoler 1,2,3,4,5,6-héxahydro-4-hydroxy-1,5-méthano-2,6-benzoxazocine-11-spiro-4'-(2',2'-dimethyl-1',3')dioxolanne avec un rendement d'environ 40% et en même temps l'aniline est detaché. Néanmoins, le dérivé *N*-acétyle d'un dimère n'a pas détaché l'aniline à la même condition d'hydrolyse.

En conséquence des recherches sur la synthèse asymétrique entre le *N*-phényl acétone-D-glycéraldimine (I) et les réactifs organométalliques, on a déjà rapporté[1] que le composé d'addition du type de threo se produisait supérieurement dans le cas du phénylllithium et par contre le composé d'addition d'érythro prédominait dans le cas du bromure de phénylmagnesium.

A cette occasion on a aperçu que I perdait graduellement le pouvoir rotatoire et les aiguilles se précipitaient peu à peu pendant quelques semaines. On pensait momentanément que ce phénomène doit à l'isomérisation de l'aldimine (I) en l'énamine (II) en présence d'un soupçon de l'acide:



(I) (II)

1) J. Yoshimura, Y. Ohgo et T. Sato, *J. Am. Chem. Soc.*, **86**, 3858 (1964).

2) M. Funabashi, H. Ando et J. Yoshimura, *Tetrahedron Letters*, No. 1, 115 (1968).

Cependant ces aiguilles ont été confirmées d'être un dimère (III) de I selon le mesurage du poids moléculaire. On a aussi pu isoler un autre dimère (IV, les cristaux cubiques) de dedans du filtrat de III et le rendement total de ces deux dimères est au plus 30% et le rapport de III et IV est environ 2 : 1.

Dans une communication précédente,[2] on a decrit l'isolement de ces deux dimères à l'aide de la chromatographie de colonne et la cristallisation fractionnée et on y a proposé erronément une structure du type de 3-anilino-1,2,3,4-tetrahydroquinoléine (A) seulement en analysant le spectre infra-rouge et de résonance magnétique nuclaire.

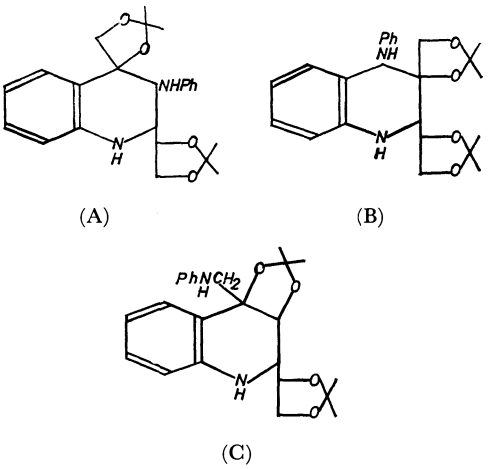
Après un certain temps on a trouvé que la structure raisonable de III était le type de 4-anilino-1,2,3,4-tétrahydroquinoléine (B), en conduisant III au dérivé cétonique plus caractéristique.

Ce rapport se concerne en la vérification que ces deux dimères sont dérivés du 4-anilino-1,2,3,4-tétrahydroquinoléine et en détermination de la configuration absolue partielle de III. On voudrait ici rapporter en détail les résultats d'analyse spectrométrique et la transformation III en un dérivé cétonique.

Résultats et Discussion

Le spectre de masse de III et IV montre, outre un pic moléculaire à *m/e* 410, quelques pics caractéristiques; un pic à *m/e* 395 (M−15), un pic à *m/e* 317 correspondant au départ de $[PhNH_2]^+$, un pic à *m/e* 309 (M−101), et un pic à *m/e* 101 du à l'oxonium-cation du 2,2-diméthyl-1,3-dioxolanne.

Le spectre infra-rouge de III, auquel il y a une grande ressemblance entre III et IV, montre les bandes caractéristiques suivantes: 3410 (NH), 2985, 2935 (CH_3), 1610, 1580, 1500 (phényl), 1485 (CH_3), 1385, 1385, 1217, 1180 cm^{-1} (CMe_2), 750 et 690 cm^{-1} (le benzène monosubstitué et ortho-disubstitué). Le spectre IR du dérivé monoacétyle (V) de III montre aussi une bande amine à 3440 cm^{-1}.



(A) (B)

(C)

Les trois structures cycliques suivantes parmi huit celles-là possibles en théorie sont en accord avec les résultats du spectre IR et de masse.

Le spectre RMN du dérivé deutérié en N de III (Fig. 1) montre les quatre pics à τ 8.46—8.67 dûs aux groupements méthyles géminés sur les cycles de dioxolanne et un multiplet à τ 2.85—3.33 attribuable au phényl correspondant à neuf protons. Les autres sept protons (sauf les duex NH) sont remarqués à τ 5.0—6.5. Il est clair que le doublet (J=2.5 cps) à τ 6.32 doit être dû au proton (He) en C-2 dans le cycle du 1,2,3,4-tétrahydroquinoléine, parce que l'irradiation de ce proton a transformé le sextet d'un proton (Ha) à τ 5.42 en un triplet et l'irradiation inverse a transformé le doublet en

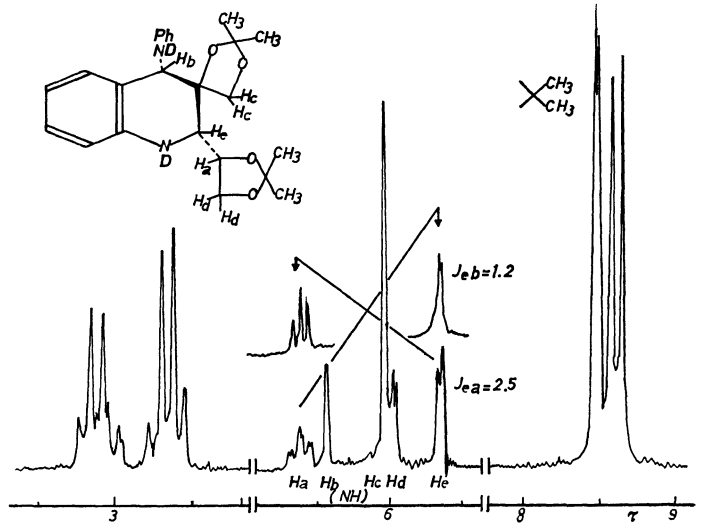


Fig. 1. Spectre RMN du composé deutérié de III et spin-spin découplage (100 Mc, $CDCl_3$).

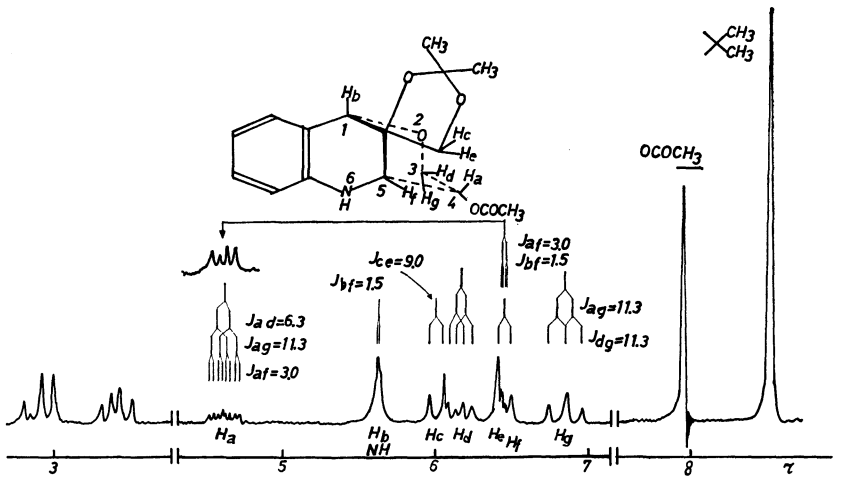

Fig. 2. Spectre RMN du composé IIIb et spin-spin découplage (100 Mc, $CDCl_3$).

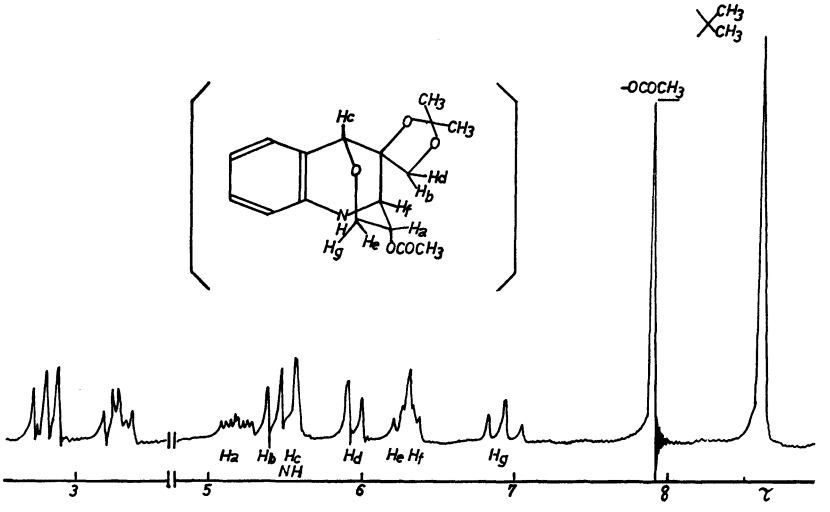

Fig. 3. Spectre RMN du composé IVb (100 Mc, $CDCl_3$).

autre doublet étroit (J=1.2 cps). Le sextet correspond au proton (Ha) de méthine dans le cycle dioxolanne lié au C-2, couplé tant avec le proton (He) à C-2 que avec les deux protons (Hd) du groupement méthylène. Le singulet à τ 5.95 attribuable aux protons d'autre méthylène se superpose avec une partie de Hd.

Comme ces interprétations du spectre RMN peuvent être appliqués à n'importe quelle structure de A, B et C, il est impossible de distinguer ces trois structures seulement par l'analyse du spectre RMN.

C'est pourquoi on a essayé de conduire III et IV au composé plus simple et plus caractéristique. Quand on d'abord hydrolyse III partiellement avec l'acide acétique aqueux à 70%, on obtient des cristaux aiguilles (IIIa) et en même temps l'aniline se détache. Dans le cas de IV, on aussi obtient les aiguillles purifiées par la chromatographie de colonne avec un rendement d'environ 40%. IIIa et IVa correspond à $C_{15}H_{19}O_4N$ selon l'analyse élémentaire et le spectre de masse montre un pic moléculaire à m/e 277 et un pic déshydraté à m/e 259 (M−18). Le spectre IR de IIIa montre les bandes caractéristiques: 3460 (OH), 3400 (NH), 1610, 1500 (phényl), 1380, 1370 (CMe_2) et 760 cm^{-1} (le benzène ortho-disubstitué), mais une bande attribuable au benzène monosubstitué à 690 cm^{-1} est disparue, ce qui est compatible avec le phénomène du détachement de l'aniline au cours de l'hydrolyse.

L'acétylation de IIIa et IVa avec l'anhydride acétique en présence de la pyridine donne les dérivés monoacétylés (IIIb et IVb), dont le spectre IR montre une bande d'éster à 1735 cm^{-1}. Le spectre RMN de IIIb, qui est donné dans la Fig. 2,

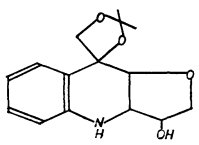
montre un singulet dû au groupement isopropylidène à τ 8.50, un singulet dû au groupement acétyle à τ 7.98 et ensuite un multiplet attribuable au groupement phényle à τ vers 3.0. Le rapport de l'intensité intégrale de ces trois groupement est environ 6 : 3 : 4.

Le spectre RMN de IVb donné dans la Fig. 3 a une ressemblance frappante avec celui-là de IIIb sauf quelques différences du déplacement chimique.

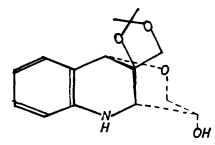
Le résultat du spectre RMN decrit ci-dessus indique qu'il n'y a qu'un seul hydroxyle dans la structure IIIa et IVa et qu'une nouvelle réaction de cyclisation intramoléculaire doit se produire au cours de l'hydrolyse partielle.

La plus possible structure parmi 18 celles-là conduites à partir de A, B et C est l'un ou l'autre des deux structures (A-1, B-1) suivantes qui sont en accord avec les donnés spectrométriques.

Dans le cas de la structure C, le détachement de l'aniline est impossible au point de vue structurale et même si l'aniline se détachait de C au cours de l'hydrolyse, le produit ne pourrait pas montre un singulet dû au grou ement iso ropylidène, mais un doublet selon le rapport de Foster et coll.[3]



(A-1)



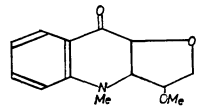
(B-1)

Citons le spectre RMN de IIIb (Fig. 2) encore une fois et distribuons les hydrogènes dans la région de τ 4.55 à τ 6.87 aux positions propres de la structure B-1, qui posséde le cycle 1,5-méthano-2,6-benzoxazocine. Le spectre montre un octet à τ 4.55 attribuable à l'hydrogène (Ha) en C-4 couplé avec trois hydrogènes (Hd, Hg, Hf) en C-3 et C-5, un doublet ($J_{b,f}$=1.5 cps) à τ 5.60 dû à l'hydrogène (Hb) en C-1 se superposant à l'hydrogène de NH, un doublet ($J_{c,e}$=9.0 cps) dû à l'un (Hc) des hydrogènes géminés dans le cycle dioxolanne à τ 5.95, un quadruplet ($J_{a,d}$ =6.3, $J_{d,g}$=11.3 cps) à τ 6.12 attribuable à l'hydrogène (Hd) en C-2 couplé avec les deux hydrogènes en C-3 et C-4, un quadruplet ($J_{a,f}$ =3.0, $J_{b,f}$=1.5 cps) dû à l'hydrogène (Hf) de C-5 à τ 6.46, un doublet ($J_{c,e}$=9.0 cps) dû à l'autre (He) de *gém*-hydrogènes à τ 6.46 et un triplet à τ 6.87 ($J_{d,g}=J_{a,g}$=11.5 cps) dû à l'hydrogène (Hg) en C-3.

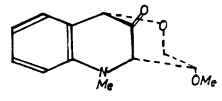
Quoiqu'on peut aussi attribuer ces hydrogènes respectivement aux positions propres de A-1 ayant le squelette furano [3,2-*b*] quinoléine, il reste encore une partie un peu irrationale; c'est à dire que la constante de couplage J=1.5 cps est trop petite pour les hydrogènes vicinaux entre C-2 et C-3, parce qu'on sait[4] que celle-là entre les deux hydrogènes vicinaux à la tête de pont du cycle de cinq atomes fondu en cis au cycle de six atomes est en général 4—5 cps.

Dans le cas de la structure B-1, cette petite constante de couplage correspond au couplage à longue distance entre H-1 et H-5 attribuable au règle de W-lettre et par conséquent tous les deux substituants à C-1 et C-5 doivent être axuels. Il en résulte que la structure B-1 plûtot que A-1 est conforme à l'estimation du spectre RMN. Néanmoins, il est nésessaire de conduire IIIa au composé plus simple et plus caractéristique pour distinguer B-1 de A-1 complètement. Ainsi, IIIa est d'abord conduit au dérivé diméthylé en N, O avec l'iodure de méthyle et l'hydrure de sodium, et ensuite hydrolysé avec l'acide acétique aqueux à 70% et enfin transformé en le dérivé cétonique (IIIc) par l'oxidation avec l'acide périodique.

Si la structure A-1 était raisonable, IIIc correspondrait à A-2 et par contre si la structure B-1 était juste, IIIc s'accorderait avec B-2 comme déssiné ci-dessous.



(A-2)



(B-2)

Le discernement B-2 de A-2 est beaucoup facilité tant par le spectre IR que par le spectre UV, parce que le spectre IR du dérivé cétonique conjugué montra une bande carbonyle conjugée[5] dans la région vers 1660 cm^{-1} et son spectre UV montra un effet bathochrome en conséquence de la conjugaison.

En vérité, le spectre IR de IIIc montre une bande carbonyle non-conjuguée[6] à 1740 cm^{-1} et le spectre UV montre deux maxima d'absorption à 258 et 313 mμ. Par conséquent, la structure A-2 correspondante au dérivé cétonique conjugué peut être rejetée aisement.

Par ailleurs, le dispersion rotatoire optique de IIIc indique l'effect Cotton négatif vers 260 mμ (Fig. 4), ce qui permet de supposer la configuration absolue de IIIc comme déssinée au-dessus d'après le règle d'octant. La configuration absolue de IIIa et III peut être aussi donnée comme déssinée plus haut sauf la partie du carbone de spiro. La configuration absolue de IV et IVa est en cours d'investigation.

D'autre part, le dérivé monoacétylé (V), qui est préparé à partir de III avec le chlorure d'acétyle et de la pyridine, montre un comportement

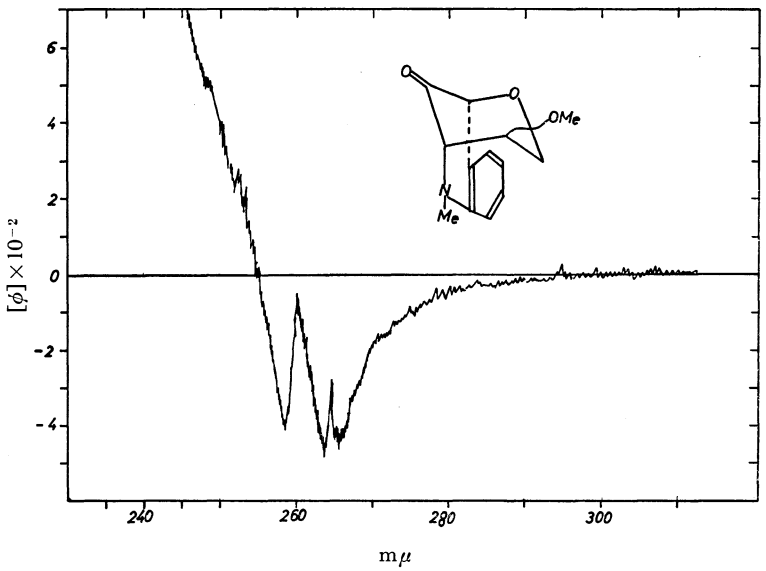

Fig. 4. Spectre DRO du composé IIIc dans le méthanol.

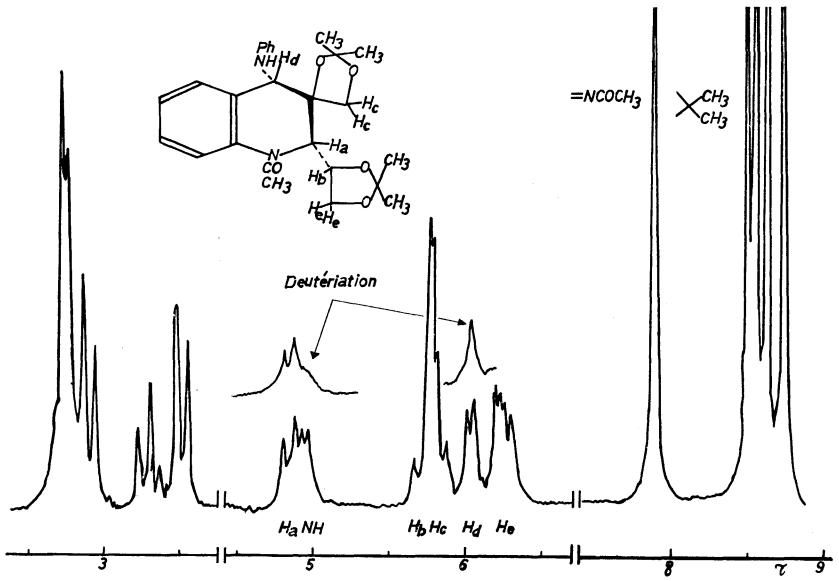

Fig. 5. Spectre RMN du composé V (100 Mc, $CDCl_3$).

différent de III contre l'hydrolyse. Le spectre RMN de V est indiqué dans la Figure 5. Le doublet ($J=7.0$ cps) est attribuable à l'hydrogène en C-2 et la distribution des autres protons est indiquée dans cette figure. Cette grandeur de la constante de couplage ($J=7.0$ cps) indique que le groupement acétyle n'est pas au nitrogène du groupement anilino en C-4, mais au nitrogène dans le cycle 1,2,3,4-tétrahydroquinoléine.

Quand on hydrolyse V à la même condition que III, on ne peut pas obtenir un composé correspondant au dérivé *N*-acétylé de IIIa, mais un composé suivant (Va) qui conserve le groupement anilino.

On ne peut pas s'empêcher de penser que la difficulté de détachement de l'aniline doive à l'éléctronégativité du groupement acétyle. Le spectre RMN (Fig. 6) de Vb (le dérivé acétylé de Va) montre trois pics vers τ 8.0 dû au groupement *O*-acétyle et un pic à τ 7.90 dû au groupement *N*-acétyle et le rapport de l'intensité intégrale de celui-là à celui-ci est 3 : 1, ce qui indique la présence de trois groupements *O*-acétyles. Un singulet d'intensité 1 à τ 6.68 est attribuable au groupement hydroxyle tértiaire, qui est disparu par deutériation. Les autres protons peuvent être distribués comme déssinés dans la figure.

Le dérivé monoacétylé (V) resiste à l'alkali à

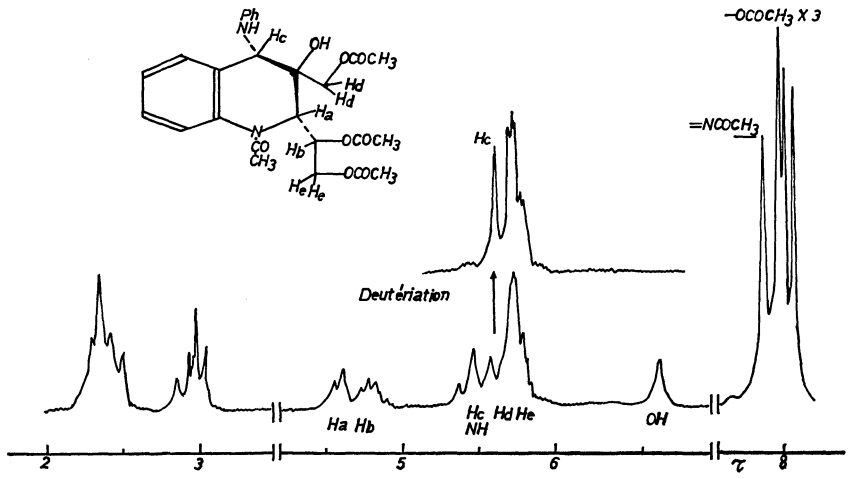

Fig. 6. Spectre RMN du composé Vb (100 Mc, $CDCl_3$).

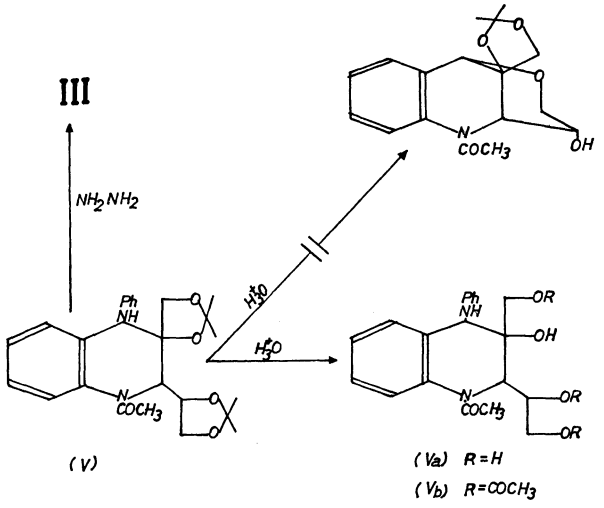
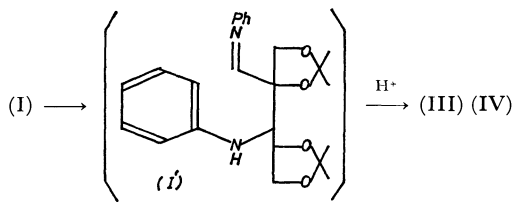


la différence de l'amide tértiaire ordinaire: quand on chauffe V au reflux dans du méthanol contenant de méthylate de sodium, on complètement retire V, qui peut être transformé en III seulement en chauffant V dans du hydrazine anhydre.

Sur méchanisme de réaction de cette dimérisation, on réfléchit maintenant comme suite; c'est à dire que I premièrement dimérise au composé additionné aldolique (I') et ensuite il se cyclise en III et IV en présence d'un soupçon de l'acide.



Partie Expérimentale

Les points de fusion non corrigés ont été déterminés en tube capillaire dans le bain de l'acide sulfurique. Les spectres de masse ont été pris sur Hitachi RMU-6. Les spectres IR ont été pris sur Hitachi EPI-G2 et les spectres UV et DRO ont été pris sur Hitachi EPS-3T et Nihon Bunko ORD/UV-5 respectivement en solution dans le méthanol. Les spectres RMN ont été pris sur JNM-4H-100 en solution dans le deutériochloroforme avec le tétraméthylsilane comme réference interne.

L'isolation de 4-Anilino-2-(2',2'-diméthyl-1',3'-dioxolanne-4'-yl)-1,2,3,4-tétrahydroquinoléine-3-spiro-4''-(2'',2''-diméthyl-1'',3'') dioxolanne (III et IV). A une solution de l'acétone-D-glycéraldehyde (18 g, 0.14 mol) et l'aniline (13 g, 0.14 mol) dans le benzène (20 m*l*) on ajoute l'acide acétique (1 m*l*) et laisse reposer le mélange de réaction pendant 24 h à une température ambiante. De l'eau formée et l'acide

acétique sont eliminés sur le carbonate de potassium anhydre. En chassant le solvant sous vide on obtient le sirop rouge-brun, qui est redissout dans une petite quantité du benzène (environ deux fois le volume du sirop). Les aiguilles (III) se précipitent graduellement, mais quelque fois les cristaux cubiques (IV) se précipitent avant III. En général, on sépare les deux dimères par la chromatographie de colonne du gel de silice (WAKOGEL C-100) en utilisant le mélange ligroin - benzène comme l'agent d'élution. III est un peu plus vite élué que IV. La valeur R_f de III et IV est respectivement 0.91 et 0.85 (benzène : méthanol=3 : 1) sur le couche mince du gel de silice (WAKOGEL-B-O). Le rendement total de ces dimères est au plus de 30% de la théorie et le rapport de III à IV est environ 2 : 1, III cristallise dans l'éther ou le benzène en longues aiguilles soyeuses: F=161—162°C, $[\alpha]_D^{29}=-42.0°$ (*c* 1.0, $CHCl_3$).

Analyse $C_{24}H_{30}O_4N_2$: Calc. %: C, 70.22; H, 7.55; N, 6.82. Tr.%: C, 70.18; H, 7.49; N, 6.98.

IV cristallise dans l'éthanol en cristaux cubiques; F=199—200°C, $[\alpha]_D^{28}=+2.2°$ (*c* 1.2, $CHCl_3$).

Analyse $C_{24}H_{30}O_4N_2$: Tr.%: C, 70.40; H, 7.55; N, 7.00.

1-Acétyl-4-anilino-2-(2',2'-diméthyl-1',3'-dioxolanne-4'-yl)-1,2,3,4-tétrahydroquinoléine-3-spiro-4''-(2'',2''-diméthyl-1'',3'') dioxolanne (V). A une solution du dimère III (0.5 g) dans le solvant mélangé de la pyridine (0.5 m*l*) et du chlorure de méthylène (10 m*l*), on ajoute goute à goute le chlorure d'acéthyle (0.35 m*l*) en maintenant la température au-dessous de 5°C. Après qu'on laisse reposer pendant 5 h, on la lave avec de l'eau du bicarbonate de sodium et séché sur le sulfate de sodium anhydre et puis évaporé sous vide en pourde, qui est dissout dans l'éther, décoloré avec charbon actif et laisse reposer à la température ambiante. Les cristaux cubiques (0.33 g) précipitent graduellement. F=173°C, $[\alpha]_D^{29}=-152°$ (*c* 1.0, $CHCl_3$).

Analyse $C_{26}H_{32}O_5N_2$ (452): Calc.%: C, 69.00; H, 7.13; N, 6.19, Tr.%: C, 69.03; H, 7.16; N, 6.39.

Hydrolyse de III — Preparation de 1,2,3,4,5,6-Héxahydro-4-hydroxy-1,5-méthano-2,6-benzoxazocine-11-spiro-4'-(2',2'-diméthyl-1',3') dioxolanne (IIIa). On chauffe la suspension de III (2 g) dans l'acide acétique aqueux à 70% (20 m*l*) à 100°C pendant 5—10 mn. Après refroidissement avec de l'eau courante, on verse peu à peu la solution réactionnelle sur de l'eau (300 m*l*) du bicarbonate de sodium (20 g) et on filtre le précipitate. Le filtrate est éxtrait au chlorure de méthyléne (30 m*l*×5) et l'éxtrait est lavé avec une petite quantité de l'eau, séché sur le sulfate de soude anhydre et enfin évaporé sous vide. On obtient ainsi les cristaux aiguilles crus (0.42 g), qui sont lavés à l'éther et recristallisés dans l'acétone - méthanol (10 : 1). F=279—280°C (dec.), $[\alpha]_D^{29}=+13.2°$ (*c* 1.0, méthanol).

Analyse $C_{15}H_{19}O_4N$ (277); Calc. %: C, 65.28; H, 7.12; N, 5.15. Tr.%: C, 64.96; H, 6.91; N, 5.05.

Acétylation de IIIa—Préparation de 1,2,3,4,5,6-Héxahydro-4-acétoxy-1,5-méthano-2,6-benzoxazocine-11-spiro-4'-(2',2'-diméthyl-1',3') dioxolanne (IIIb). A une solution de IIIa (100 mg) dans la pyridine (2 m*l*) on ajoute l'anhydre acétique (2 m*l*) et laisse reposer à une température ambiante pendant 24 h. La solution réactionelle est puis versée sur de l'eau glacée et éxtraite au chlorure de méthylène. L'éxtrait est puis lavé avec de l'eau, séché sur sulfate de soude anhydre et évaporé sous vide en un résidu cristallisable, qui est recristallisé dans l'acétone ou l'acétate d'éthyle. On obtient les cristaux plats (85 mg, 81%). F=215—216°C, $[\alpha]_D^{28}=+105°$ (*c* 1.0, méthanol).

Analyse $C_{17}H_{21}O_5N$ (319): Calc. %: C, 63.93; H, 6.63; N, 4.39. Tr.%: C, 63.93; H, 6.82; N, 4.76.

Hydrolyse de IV. *Procédé a.* On hydrolyse IV à la même condition que III et le traitement est aussi même. IVa, qui est plus soluble que IIIa dans les solvants organiques, a difficulté à se cristalliser.

Procédé b. On suspend IV (298 mg) dans l'acide acétique aqueux à 70% et le dissout en chauffant à 100°C pendant 5 mn. On filtre une matière insoluble et on évapore le filtrate sous vide en un sirop brun, qui est purifié par la chromatographie de colonne du gel de silice. De la partie éluée au solvant mélangé (benzène et acétone=10 : 1) on obtient les blanches aiguilles (75 mg, 37%). F=183—185°C, $[\alpha]_D^{19}=+15.0°$ (*c* 0.27, méthanol).

Analyse $C_{15}H_{19}O_4N$ (277): Calc.%: C, 64.96; H, 6.91; N. 5.05. Tr.%: C, 64.37; H, 7.69; N, 4.81.

Acétylation de IVa. IVa est acétylé à la même condition que IIIa. A partir de IVa (62 mg) on obtient les cristaux (IVb) (48 mg, 69%), qui sont recristallisés dans l'acétone. F=192°C, $[\alpha]_D^{16.5}=+17.0°$ (*c* 0.45, méthanol).

Analyse $C_{17}H_{21}O_5N$ (319): Calc.%: C, 63.93; H, 6.63; N, 4.39. Tr.%: C, 63.53; H, 7.06; N, 4.42.

Transformation de IIIa au Dérivé Cétonique (IIIc). A une solution de IIIa (277 mg) dans le diméthylsulfoxide (10 m*l*) on ajoute peu à peu l'hydrure de sodium (150 mg) et on chauffe la solution à 60—70°C pendant 5 mn. Après refroidissement jusqu'à la température ambiante, on ajoute l'iodure de méthyle (0.5 m*l*×3) et on chauffe à 60°C pendant 5 mn. La solution réactionnelle est puis versée sur de l'eau glacée, éxtraite au chlorure de méthylène, lavée à l'eau, séchée sur Na_2SO_4 et enfin évaporée sous vide en sirop. Ce sirop (environ 300 mg) est puis chauffé à 100°C avec l'acide acétique (2 m*l*) aqueux à 70% pendant 30 mn. Après évaporation du solvant sous vide, on obtient les cristaux fondants à 147—150°C.

Analyse $C_{14}H_{19}O_4N\ H_2O$: Calc.%: C, 59.35; H, 7.47; N, 4.94. Tr.%: C, 59.25; H, 7.47; N, 5.08.

Finallement dans le mélange de l'eau distillée (5 m*l*) et du méthanol (5 m*l*), on dissout ces cristaux-là et le périodate de sodium (108 mg) et puis on laisse reposer à une température ambiante pendant une nuit. Après d'élimination du solvant par distillation, le résidu obtenu est rempli sur une colonne du gel de silice (WAKOGEL C-100, 10 g) et élué au benzène ou benzène - acétone (10 : 1). On obtient un sirop (IIIc; 70 mg) par évaporation du solvant. $[\alpha]_D^{19}=107°$ (*c* 0.52, méthanol), UV λ_{max}^{MeOH} 258 mμ (log ε, 4.16), 313 mμ (log ε, 3.60).

Analyse $C_{13}H_{15}O_3N$ (233): Calc.%: C, 66.93; H, 6.48; N, 6.01. Tr.%: C, 66.24; H, 6.53; N, 5.49.

Hydrolyse de V — Préparation de 1-Acétyl-4-anilino-2-(1',2'-dihydroxy) éthyl-3-hydroxy-3-hydroxyméthyl-1,2,3,4-tétrahydroquinoléine (Va). Après qu'on chauffe à 100°C la suspension de V (0.8 g) dans l'acide acétique aqueux à 70% pendant 13 mn, on élimine le solvant sous vide. Le sirop obtenu est purifié par la chromatographie de colonne du gel de silice en utilisant benzène et acétone comme l'éluant successivement. La partie éluée au benzène - acétone

(1 : 1) est évaporée sous vide. Le poudre amorphe (0.5 g) est obtenu. $[\alpha]_D^{22} = -90.5°$ (*c* 0.61, éthanol).

Analyse $C_{20}H_{24}O_5N_2$: Calc.%: C, 64.52; H, 6.50; N, 7.52. Tr.%: C, 64.32; H, 6.54: N, 6.60.

Acétylation de Va — Préparation de 3-Acétoxyméthyl-1-acétyl-4-anilino-2-(1',2'-diacétoxy) éthyl-3-hydroxy-1,2,3,4-tétrahydroquinoléine (Vb). — A une solution du poudre amorphe (0.5 g) obtenu ci-dessus dans la pyridine (10 m*l*), on ajoute l'anhydride acétique (10 m*l*) et on laisse reposer pendant une nuit. La solution réactionnelle est puis versée sur l'eau glacée, éxtraite au chlorure de méthylène, lavée à la solution de $NaHCO_3$, séchée sur Na_2SO_4 et enfin évaporée sous vide. Le poudre amorphe obtenu est dissout dans l'acétone, décoloré avec le charbon actif et reconcentré sous vide. On obtient 0.45 g de produit (poudre amorphe). $[\alpha]_D^{20} = -4.8°$ (*c* 1.1, méthanol).

Analyse $C_{26}H_{30}O_8N_2$: Calcd.%: C, 60.45; H, 6.24; N, 5.42. Tr.%: C, 61.24; H, 5.86; N, 5.29.

Transformation de V en III par l'Hydrazine Anhydre. On met le dérivé monoacétyle (V) (73 mg) et l'hydrazine anhydre à 98% (1 m*l*) dans le tube scellé qui a 1 cm de diamètre et 10 cm de longueur, et on chauffe à 100—120°C pendant 20 hr. Par refroidissement précipitent les aiguilles (51 mg, 77%), qui sont filtrées et lavées à l'éther. Ce produit n'a pas montré l'abaissement du point de fusion à l'examen mixte avec le dimère III.

New Syntheses of Vinyl Sulfides and Unsaturated Nitriles *via* Quaternary Phosphonium Salts

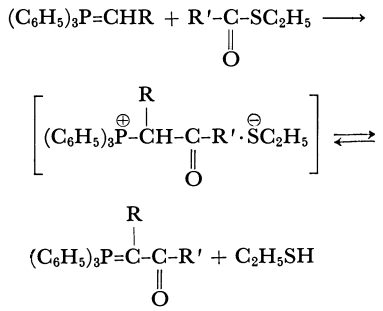
Takanobu KUMAMOTO, Kazuo HOSOI and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

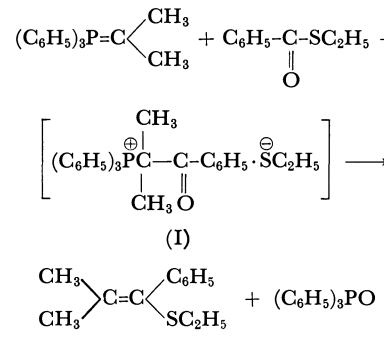
(Received May 1, 1968)

New methods for the syntheses of vinyl sulfides and unsaturated nitriles *via* quaternary phosphonium salts have been established. The reaction of isopropylidenetriphenylphosphorane with *S*-ethyl thiobenzoate or substituted *S*-ethyl thiobenzoates afforded vinyl sulfides and triphenylphosphine oxide in good yields. Further, it was found that the reaction of α-benzoylalkylphosphonium salts with sodium ethylmercaptide or potassium cyanide gave olefins, such as vinyl sulfides or unsaturated nitriles, and triphenylphosphine oxide in good yields, respectively.

The reaction of alkylidenephosphoranes with *S*-ethyl thiocarboxylate affords acylalkylidenephosphoranes in high yields. A removal of ethylmercaptan from an intitially formed phosphonium ethyl mercaptides shifts the equilibrium to the side of the phosphoranes.[1]



It was found by the present experiment that the reaction of thiolester with alkylidenephosphoranes having no hydrogen atom on the methylene carbon resulted in the formation of the Wittig type reaction products, vinyl sulfides and triphenylphosphine oxide. Thus, 1-ethylthio-2-methyl-1-phenylpropene and triphenylphosphine oxide were obtained in 72% and 40% yields, respectively, when isopropylidenetriphenylphosphorane was allowed to react with *S*-ethyl thiobenzoate in boiling tetrahydrofuran.



Similarly, isopropylidenetriphenylphosphorane reacted with *S*-methyl thiobenzoate and substituted *S*-ethyl thiobenzoates, such as *S*-ethyl *p*-chlorothiobenzoate and *S*-ethyl *p*-methoxythiobenzoate,

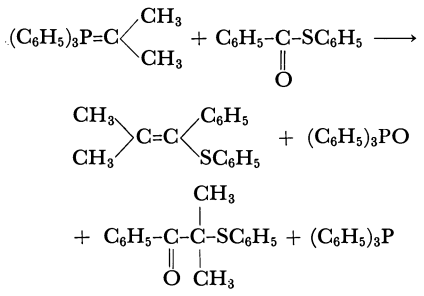
TABLE 1. THE REACTION OF ISOPROPYLIDENETRIPHENYLPHOSPHORANE WITH THIOLESTER

Thiolester	Vinyl sulfide Yield (%)	Bp °C/mmHg	Anal. Found C(%)	Anal. (Calcd) H(%)	$(C_6H_5)_3PO$ (%)
$C_6H_5COSC_2H_5$	72	134—136/28	75.16 (74.97	8.58 8.39)	40
$C_6H_5COSCH_3$	73	118/16	73.87 (74.13	7.89 7.92)	45
p-$ClC_6H_4COSC_2H_5$	83	147/15	63.75 (63.72	6.95 6.67)	52
p-$CH_3OC_6H_4COSC_2H_5$	70	154/16	70.35 (70.24	8.13 8.16)	52

to give corresponding vinyl sulfides and triphenylphosphine oxide in good yields (see Table 1).

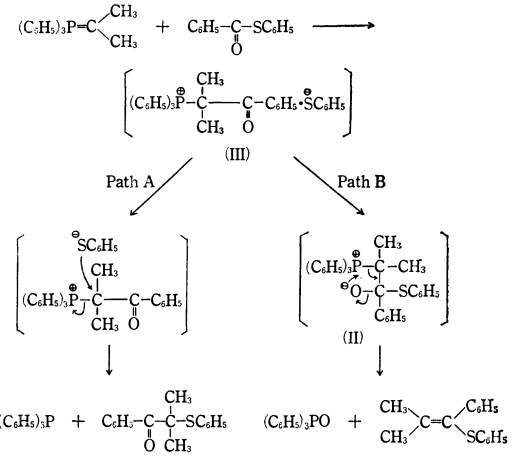
The above mentioned reactions are considered to proceed through an initial formation of phosphonium mercaptide (I). An intramolecular nucleophilic attack of the ethylmercapto anion on carbonyl carbon of (I) yields the vinyl sulfide and triphenylphosphine oxide probably through a betain structure (II) as shown in path B of the following scheme.

On the contrary, vinyl sulfide was not obtained when isopropylidenetriphenylphosphorane and *S*-phenyl thiobenzoate were refluxed in tetrahydrofuran. Instead, only phosphonium phenylmercaptide resulted. The phosphonium salt decomposed to yield 2-methyl-1-phenyl-1-phenylthiopropene (14%), triphenylphosphine oxide (10%), α-phenylthioisobutyrophenone (28%) and triphenylphospine (36%) when it was refluxed in toluene.



The formation of α-phenylthioisobutyrophenone and triphenylphosphine can be explained by assuming a nucleophilic attack of phenylmercapto anion on the α-carbon of the phosphonium salt (III) (Path A). It is noteworthy that, in the case of the *S*-phenyl thiocarboxylate, the nucleophilic attack of reference anion, phenylmercapto anion, occurs competitively on α-carbon and on carbonyl carbon to afford the above mentioned four products.

In the case of the reaction of isopropylidenetriphenylphosphorane with *S*-ethyl thiobutyrate in tetrahydrofuran, triphenylisopropylphosphonium iodide (99%) and *S*-ethyl α-butyrylthiobutyrate



(77%) were obtained. This result shows that ester condensation reaction of *S*-ethyl thiobutyrate preferentially takes place to afford α-butyrylthiobutyrate by the influence of isopropylidenetriphenylphosphorane, a strong basic substance. The formation of triphenylisopropylphosphonium iodide can be explained by assuming the anion exchange reaction of phosphonium salt (IV) with lithium iodide.

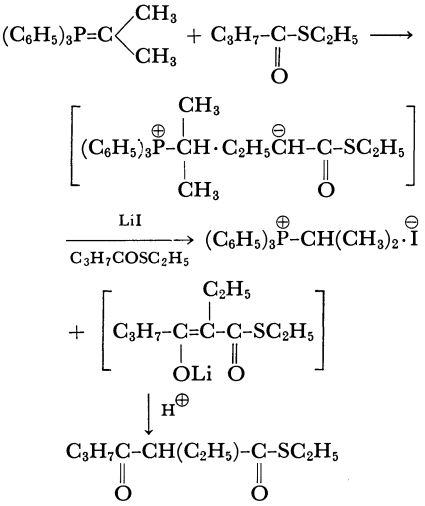


TABLE 2. THE REACTION OF α-BENZOYLALKYLPHOSPHONIUM SALT WITH SODIUM ETHYL MERCAPTIDE

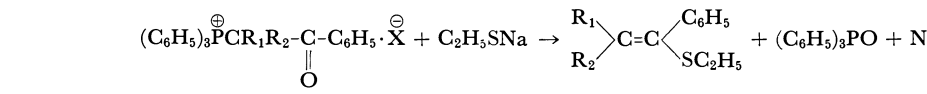

R_1	R_2	Vinyl sulfide Yield (%)	Bp (mp) °C/mmHg	Anal. Found C(%)	Anal. (Calcd) H(%)	$(C_6H_5)_3PO$ (%)

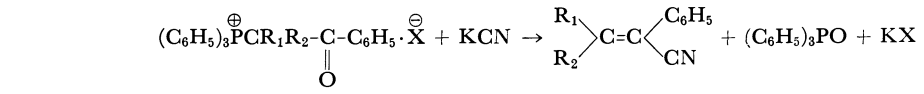
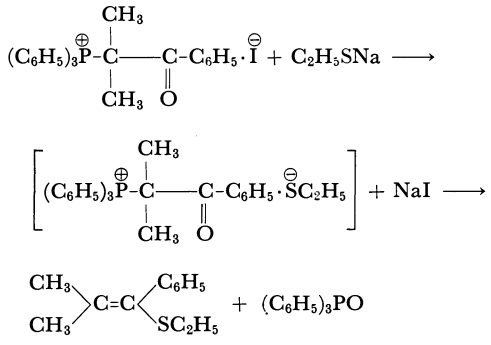
	H	45	150—155/7	77.87 (77.55	8.67 8.68)	47
CH_3	C_6H_5	83	113—115/1 (54)	79.78 (80.28	7.32 7.13)	82

TABLE 3. THE REACTION OF α-BENZOYLALKYLPHOSPHONIUM SALT WITH POTASSIUM CYANIDE



R_1	R_2	Unsaturated nitrile Yield (%)	Bp (mp) °C/mmHg	Anal. Found C(%)	Anal. (Calcd) H(%)	N(%)	$(C_6H_5)_3PO$ (%)
CH_3	CH_3	54	124—125/3	83.51 (84.04	7.06 7.05	8.86 8.91)	52
	H	72	116—117/1	85.33 (85.23	7.37 7.66	6.93 7.10)	82
CH_3	C_6H_5	75	(81)	87.47 (87.64	5.73 5.98	6.63 6.39)	82

Next, the isolation of the key intermediate (I) of the above mentioned reactions forming vinyl sulfide from sodium ethylmercaptide and triphenyl-α-benzoylisopropylphosphonium iodide was attempt. When sodium ethylmercaptide and triphenyl-α-benzoylisopropylphosphonium iodide, formed from isopropylidenetriphenylphosphorane and benzoyl chloride,[2] were refluxed in tetrahydrofuran for 6 hr, 1-ethylthio-2-methyl-1-phenylpropene (52%) and triphenylphosphine oxide (67%) were obtained as expected.

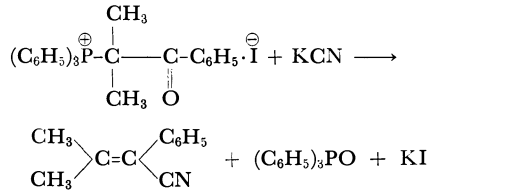


2) H. J. Bestmann and T. Denzel, *Tetrahedron Letters*, **1966**, 3591.

Similarly, the reaction of triphenyl-α-benzoylcyclohexylphosphonium bromide or triphenyl-1-benzoyl-1-phenylethylphosphonium bromide with sodium ethylmercaptide resulted in the formation of corresponding α-ethylthiobenzylidenecyclohexane or 1,2-diphenyl-1-ethylthiopropene and triphenylphosphine oxide in good yields (see Table 2). It is of interest to note that α-ethylthiobenzylidenecyclohexane could not be obtained directly from *S*-ethyl thiobenzoate and cyclohexylidenetriphenylphosphorane because the phosphonium salt, the key intermediate, could not be obtained even when they were refluxed in tetrahydrofuran.

In addition, it was found that the reaction of triphenyl-α-benzoylalkylphosphonium salt with sodium phenylmercaptide or potassium thiocyanate did not afford the expected olefins, such as vinyl sulfides or vinyl thiocyanates.

Finally, this reaction was successfully extended to the synthesis of unsaturated nitriles by reacting triphenyl-α-benzoylalkylphosphonium salts with potassium cyanide. When triphenyl-α-benzoylisopropylphosphonium iodide was allowed to react with potassium cyanide in tetrahydrofuran - water mixed solvent at room temperature, α-phenyl-β-methylcrotonitrile (54%) and triphenylphosphine oxide (52%) were obtained.



In a similar manner, cyclohexylidenephenylacetonitrile or α,β-diphenylcrotonitrile was obtained by the reaction of triphenyl-α-benzoylcyclohexylphosphonium bromide or triphenyl-1-benzoyl-1-phenylethylphosphonium bromide with potassium cyanide in good yields (see Table 3).

Further study on this type of the synthesis of unsaturated compound is now in progress.

Experimental

Reaction of Isopropylidenetriphenylphosphorane with *S*-Ethyl Thiobenzoate. *S*-Ethyl thiobenzoate (1.33 g, 0.008 mol) was added to the solution of isopropylidenetriphenylphosphorane, prepared from triphenylisopropylphosphonium iodide (4.32 g, 0.01 mol) and *n*-butyl lithium (0.01 mol) in tetrahydrofuran (20 m*l*) under nitrogen. The dark red color disappeared soon and a phosphonium salt precipitated. The reaction mixture was further refluxed for 4 hr under stirring. After resulted precipitate was filtered, the filtrate was evaporated under reduced pressure. The distillation *in vacuo* gave 1-ethylthio-2-methyl-1-phenylpropene (1.14 g, 74%), bp 133—135°C/25 mmHg. The precipitate and the residue of the distillation were collected and refluxed in a mixture of aqueous solution of 5% sodium hydroxide (10 m*l*) and benzene (10 m*l*) for 30 min. After precipitated triphenylisopropylphosphonium iodide was filtered, the benzene layer was separated. The removal of benzene gave white crystals. They were recrystallized from carbon tetrachloride, triphenylphosphine oxide was obtained, 1.20 g (40%), mp 154—156°C.

Reaction of Isopropylidenetriphenylphosphorane with *S*-Phenyl Thiobenzoate. A mixture of isopropylidenetriphenylphosphorane (0.02 mol) and *S*-phenyl thiobenzoate (4.28 g, 0.02 mol) was refluxed in toluene for 5 hr. After resulting precipitate was filtered, the filtrate was evaporated under reduced pressure. The residue was chromatographed on silica gel with petroleum ether, benzene and ether. α-Phenylthioisobutyrophenone, 1.00 g (25%) and triphenylphosphine oxide, 0.43 g (10%), mp 155—156°C, along with a mixture of triphenylphosphine and 2-methyl-1-phenyl-1-phenylthiopropene (V) were obtained from the elutate with benzene, ether and petroleum ether, respectively. α-Phenylthioisobutyrophenone was identified by the formation of its 2,4-dinitrophenylhydrazone, mp 155—156°C.

Found: C, 60.19; H, 4.73; N, 12.88%. Calcd for $C_{22}H_{20}N_4O_4S$: C, 60.54; H, 4.62; N, 12.84%. The mixture of triphenylphosphine and V was treated with an excess amount of methyl iodide to give triphenylmethylphosphonium iodide, 2.02 g. From the yield of phonium iodide, the yield of triphenylphosphine was estimated, 31%. The residue was distilled *in vacuo* to give V, 0.53 g (14%), bp 118—120°C/3 mmHg.

Reaction of Isopropylidenetriphenylphosphorane with *S*-Ethyl Thiobutyrate. A mixture of isopropylidenetriphenylphosphorane (0.01 mol) and *S*-ethyl thiobutyrate (1.32 g, 0.01 mol) in tetrahydrofruan (20 m*l*) was refluxed for 5 hr. A resulting white precipitate was filtered and recrystallized from the mixture of alcohol and ether giving triphenylisopropylphosphonium iodide, 4.18 g (99%), mp 195°C. The filtrate was evaporated *in vacuo* to give a white precipitate. After the neutralization with hydrochloric acid, an oily product was obtained. Distillation under reduced pressure gave *S*-ethyl α-butyrylthiobutyrate, 0.79 g (77%), bp 126—128°C/15 mmHg.

Preparation of Triphenyl-α-benzoylisopropylphosphonium Iodide. Benzoyl chloride (14.10 g, 0.10 mol) was added dropwise to the solution of isopropylidenetriphenylphosphorane, prepared from triphenylisopropylphosphonium iodide (43.20 g, 0.10 mol) and *n*-butyl lithium (0.10 mol) in tetrahydrofuran (200 m*l*) under nitrogen. The reaction mixture was refluxed for 5 hr under stirring. The resulting precipitate was filtered and was recrystallized from a mixture of alcohol and ether to give triphenyl-α-benzoylisopropylphosphonium iodide, 47 g (88%), mp 213—215°C.

Found: C, 62.13; H, 4.99%. Calcd for $C_{28}H_{26}IOP$: C, 62.69; H, 4.85%.

Reaction of Triphenyl-α-benzoylphosphonium Iodide with Sodium Ethylmercaptide. A mixture of triphenyl-α-benzoylisopropylphosphonium iodide (5.36 g, 0.01 mol) and sodium ethyl mercaptide (0.84 g, 0.01 mol) was refluxed in tetrahydrofuran for 5 hr under stirring. After removal of the solvent under reduced pressure, a small amount of ether was added to the residue. The precipitated crystals were filtered and the filtrate was distilled *in vacuo* to give 1-ethylthio-2-methyl-1-phenylpropene, 1.00 g (52%), bp 115—123°C/18 mmHg. The precipitate and the residue of the distillation were collected and were treated with aqueous 5% sodium hydroxide to give triphenylphosphine oxide, 2.06 g (74%), mp 153—154°C.

Reaction of Triphenyl-α-benzoylisopropylphosphonium Iodide with Potassium Cyanide. A mixture of triphenyl-α-benzoylisopropylphosphonium iodide (5.36 g, 0.01 mol) and potassium cyanide (0.66 g, 0.011 mol) in 10 m*l* of water and 10 m*l* of tetrahydrofuran was stirred at room temperature for 2 hr. The reaction mixture was extracted with 50 m*l* of ether. After the extract was evaporated under reduced pressure the residue was distilled *in vacuo* to give α-phenyl-β-methylcrotonitrile, 0.85 g (54%), bp 123—124°C/8 mmHg. The residue of the distillation was collected and was recrystallized from carbon tetrachloride to give triphenylphosphine oxide, 1.45 g (52%), mp 155—156°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2746—2747 (1968)

A Convenient Method for the Preparation of Acid Anhydrides from Metallic Carboxylates

Tsujiaki HATA, Kiyohiko TAJIMA and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 2, 1968)

A convenient method for the preparation of carboxylic anhydrides by use of one mole of *N,N'*-dicyclohexylthiourea and two moles of silver or mercurous carboxylate has been established. According to this method, several carboxylic anhydrides were obtained in high yields under mild conditions even by microscale experiments.

In previous papers,[1,2] it has been reported that carboxylic anhydrides were prepared from the corresponding mercuric carboxylates by treatment with the addition compound of dibenzoylethylene and triphenylphosphine, or by treatments with *S*-ethylthioamidium iodide.

In the present study, a general preparative method of acid anhydrides was investigated with the expectation that acid anhydride would be formed by the reaction of *N,N'*-dicyclohexylthiourea with silver carboxylates through an intermediate, imidoyl acylate. Indeed, when one mole of *N,N'*-dicyclohexylthiourea was added to a suspension of two moles of finely pulverized silver benzoate in anhydrous acetone at room temperature, benzoic anhydride was obtained in 93% yield along with *N,N'*-dicyclohexylurea and silver sulfide.

$$2\,RCOOAg + C_6H_{11}NHCSNHC_6H_{11} \xrightarrow{\text{Room temp.}} (RCO)_2O + C_6H_{11}NHCONHC_6H_{11} + Ag_2S$$

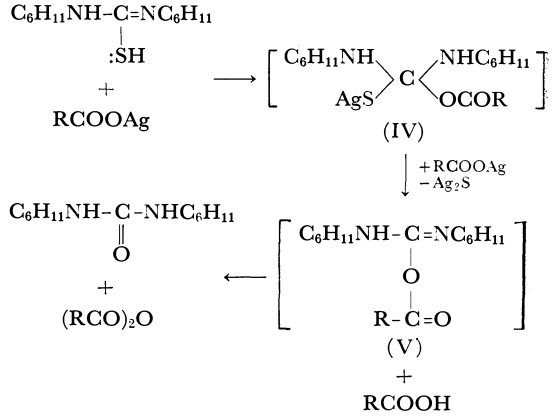
R: C_6H_5

In a similar manner, acetic, propionic, phthalic and succinic anhydrides were obtained from the corresponding silver carboxylates. These data are recorded in Table 1.

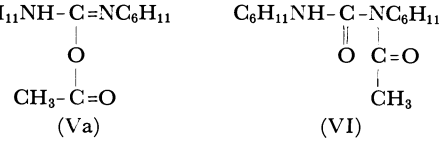
TABLE 1. ACID ANHYDRIDES FROM SILVER CARBOXYLATES

Silver salt (0.04 mol)	Yield of acid anhydride, %	Solvent	m*l*
Acetate	68.0	Acetone	13
Propionate	88.4	Acetone	20
Benzoate	93.0	Acetone	10
Phthalate	86.9	Acetonitrile	30
Succinate	90.0	Chloroform	30

The reaction is considered to proceed through an intermediate (IV), produced from a silver carboxylate and *N,N'*-dicyclohexylthiourea. The IV in turn reacts with another silver carboxylate to form silver sulfide and the imidoyl acylate (V), which further reacts with carboxylic acid to give an acid anhydride and *N,N'*-dicyclohexylurea.



In addition, it was found that mercuric acetate also reacts with *N,N'*-dicyclohexylthiourea to give acetic anhydride, *N,N'*-dicyclohexylurea and mercuric sulfide along with a considerable amount of *N*-acetyl-*N,N'*-dicyclohexylurea (VI), a rearrangement product of imidoyl acylate (Va).



Some mercuric carboxylate, such as mercuric benzoate, contains one mole of water of crystallization, which cannot be removed by the ordinary procedure. Since water reacts with imidoyl benzoate faster than with carboxylate ion, mercuric carboxylates containing water of crystallization cannot be used in this reaction. Next, since anhydrous mercurous carboxylates are easily prepared from sodium carboxylates and mercurous nitrate,

1) I. Kuwajima and T. Mukaiyama, *J. Org. Chem.*, **29**, 1385 (1964).
2) T. Yamaguchi, K. Inomata and T. Mukaiyama, This Bulletin, **41**, 673 (1968).

the reactions of the carboxylates with *N,N'*-dicyclohexylthiourea were tried in order to avoid the above-mentioned trouble. When two moles of mercurous benzoate were allowed to react with one mole of *N,N'*-dicyclohexylthiourea, benzoic anhydride was obtained in a quantitative yield along with mercuric sulfide, metallic mercury and *N,N'*-dicyclohexylurea.

$$(RCOO)_2Hg_2 + C_6H_{11}NHCSNHC_6H_{11} \xrightarrow{\text{Room temp.}} (RCO)_2O + C_6H_{11}NHCONHC_6H_{11} + HgS + Hg$$

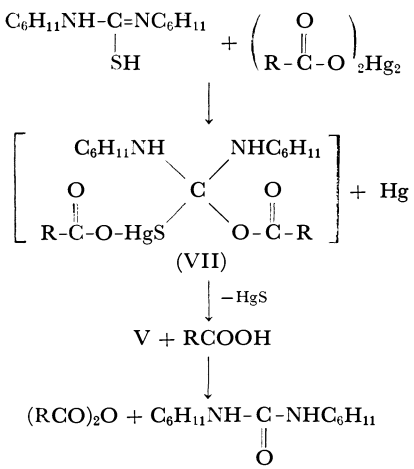
R: C_6H_5

Similarly, acetic, propionic, phthalic and succinic anhydrides were obtained in high yields from the corresponding mercurous carboxylates. The results are listed in Table 2.

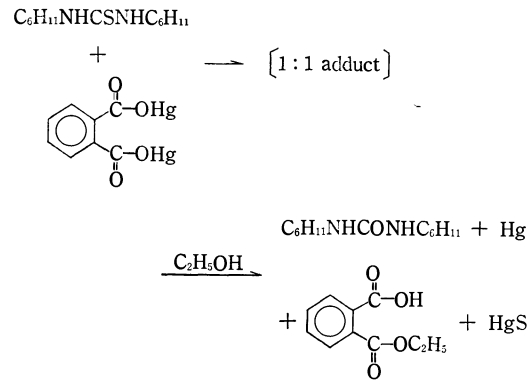
Table 2. Acid anhydrides from mercurous carboxylates

Mercurous salt (0.04 mol)	Yield of acid anhydride, %	Solvent	m*l*
Acetate	69.0	Acetone	15
Propionate	99.2	Acetone	10
Benzoate	98.0	Acetone	30
Phthalate	81.1	Acetonitrile	25
Succinate	95.0	Chloroform	40

The reaction proceeds through an intermediate (VII), which loses mercuric sulfide to form the imidoyl acylate (V), a compound similar to that described in the case of silver carboxylate.



Further, it was found that one of the intermediates (IV), an 1 : 1 adduct, was successfully isolated in a quantitative yield as greenish white precipitates by treating mercurous phthalate (1 mmol) with *N,N'*-dicyclohexylthiourea (1 mmol) in a mixed solvent of anhydrous benzene (4 m*l*) and petroleum ether (1 m*l*). The adduct instantly reacted with ethanol at room temperature to give monoethyl ester of phthalic acid along with *N,N'*-dicyclohexylurea, metallic mercury and mercuric sulfide.



In conclusion, it is noted that mercurous carboxylates react with *N,N'*-dicyclohexylthiourea more easily than mercuric carboxylates and, in each reaction, the yield of acid anhydride markedly depend on the nature and the amount of solvent used as shown in Tables 1 and 2, probably due to the solubility of the intermediate complex (IV).

Experimental

Materials. *N,N'*-Dicyclohexylthiourea,[3] silver carboxylates[4] and mercurous carboxylates[5] were prepared by known procedures. They were ground and dried over P_2O_5 in vacuum desiccator before use.

The Preparation of Propionic Anhydride by the Reaction of *N,N'*-Dicyclohexylthiourea and Silver Propionate. *N,N'*-Dicyclohexylthiourea (4.8 g, 0.02 mol) was added to a suspension of silver propionate (7.24 g, 0.04 mol) in 20 m*l* of dry acetone and was continuously stirred about 15 hr at room temperature. During 2 hr, the suspension changed gradually from white to black. Then the black precipitates were filtered and washed with dry acetone. The filtrate and the washings were combined and evaporated. Propionic anhydride, 2.30 g (88.4%), bp 165—169°C, was obtained by distillation. After distillation, remaining oil solidified at room temperature. Recrystallization from benzene - petroleum ether gave *N*-propionyl-*N,N*-dicyclohexylurea, (0.6 g, 10.7%), mp 127—129°C. The black precipitate was throughly washed with ethanol. After evaporation of ethanol, *N,N'*-dicyclohexylurea, 4.17 g (93%), mp 218°C, was obtained.

Similarly, acetic, benzoic, succinic and phthalic anhydrides were obtained from the corresponding silver or mercurous carboxylates. The reaction conditions and the yields are summarized in Tables 1 and 2. According to this preparative method, except in the cases of acetic and propionic anhydrides, practically pure carboxylic anhydrides were separated by simply removing the black precipitate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2748—2753 (1968)

Selective Chemical Cleavage of Asparagine Peptides[1)]

Tetsuo SHIBA, Akio KODA,*1 Shoichi KUSUMOTO[2]* and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 2, 1968)

Asparagine peptide was selectively cleaved by the Hofmann rearrangement followed by an alkaline treatment at the peptide linkage in which an amino group of the asparagine residue participated. Upon reaction of *N*-benzyloxycarbonyl-L-alanyl-L-asparagine with one equivalent of bromine and three equivalents of aqueous sodium hydroxide solution at 60°C, 1-(*N*-benzyloxycarbonyl-L-alanyl)-2-oxo-imidazolidine-5-carboxylic acid was obtained in quantitative yield. When this was treated with an aqueous methanolic sodium hydroxide solution at room temperature, a cleavage reaction occurred to give *N*-benzyloxycarbonyl-L-alanine and 2-oxo-imidazolidine-5-carboxylic acid. Under the same condition of the rearrangement, *N*-benzyloxycarbonyl-L-asparaginyl-L-phenylalanine was converted to 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carbonylphenylalanine. Since glutamine peptide could not give the corresponding ring compound, this cleavage reaction was found to be specific to asparagine peptide.

For the elucidation of the primary structure of protein, a number of chemical cleavage reactions specific to the particular amino acid residues have been presented as a supplementary method to the enzymic reactions which did not cover all usual amino acids in a sense of selective cleavage.[2)] Nevertheless, neither chemical nor enzymic reaction of asparagine peptide has been known so far. In our previous papers,[3-5)] chemical cleavage reactions of serine and threonine peptides were demonstrated. These reactions were based on formation of oxazolidone derivatives, by action of phosgene, which facilitated the removal of acyl group attached to the ring nitrogen atom by alkaline hydrolysis. It is expected that a similar cleavage reaction would occur readily too in the case of imidazolidone peptide where the ring O atom in oxazolidone peptide is replaced with NH group as shown in Fig. 1. Although α,β-diaminopropionic acid which will give the imidazolidone ring by reaction with phosgene, is not a constituent of natural protein, asparagine derivative can also be converted to the imidazolidone derivative *via* the Hofmann rearrangement reaction. In this respect, *N*-benzyloxycarbonyl-L-asparagine was actually converted to 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carboxylic acid by treatment with sodium hypochlorite at 60°C according to Schneider.[6)] When *N*-acetylasparagine was treated with bromine and barium hydroxide at 90°C by Karrer and Schlosser,[7)] 2-oxo-imidazolidine-5-carboxylic acid was obtained through the Hofmann rearrangement followed by cyclization to the imidazolidone ring and then elimination of acetyl group. Concerning oxidative reaction of peptide with sodium hypobromite, Goldschmidt *et al.*[8-12)] and Carpenter *et al.*[13)] had demonstrated chemical changes of *N*-terminal amino acid residue either to nitrile or to α-ketoacyl group for the purpose of the sequential analysis of peptide from *N*-terminal end. The other use of this rearrangement reaction had been investigated by Kovács *et al.*[14-16)] in order to distinguish α- and ω-acid amide group in aspartic or glutamic acid residue in peptide chain.

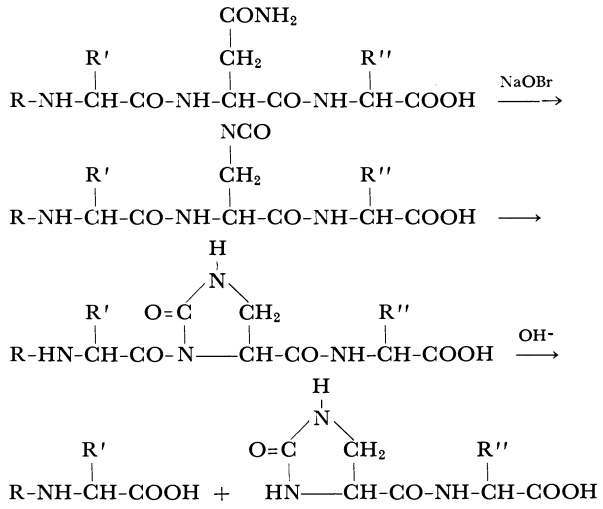

Fig. 1.

However, no attempts have been made to apply the Hofmann reaction to the selective cleavage of asparagine peptide according to a scheme outlined in Fig. 1. Asparagine peptides used in this reaction were prepared either by the mixed anhydride method or by the *p*-nitrophenyl ester method.

As a preliminary experiment *N*-benzyloxycarbonyl-L-alanyl-L-asparagine (I) was treated with one equivalent of bromine and five equivalents of aqueous sodium hydroxide at different temperatures as mentioned in Table 1. Theoretically, four equivalents of alkali are necessary to convert an acid amide to an amine in the usual Hofmann reaction, and one more equivalent should be added to neutralize the carboxyl group of I. From the reaction mixture, *N*-benzyloxycarbonylalanine (III) was obtained in crystalline state as one of the cleavage products. Although another product, *e. g.*, 2-oxo-imidazolidine-5-carboxylic acid (IV) could not be isolated, acid hydrolysis of a residue obtained by evaporation of the mother liquor gave α,β-diaminopropionic acid hydrochloride (V). Among a couple of the reaction conditions, the reaction at 60°C seemed to be most profitable in view of the yields of the products, III and V, as shown in Table 1. Although the results of the preliminary experiments suggest and strongly support the mechanism shown in Fig. 2, a route of the cleavage *via* imidazolidone peptide (II) could not be necessarily ascertained, since α,β-diaminopropionic acid would be possibly formed by the Hofmann reaction followed by the simple alkaline hydrolysis of asparagine residue without formation of imidazolidone ring.

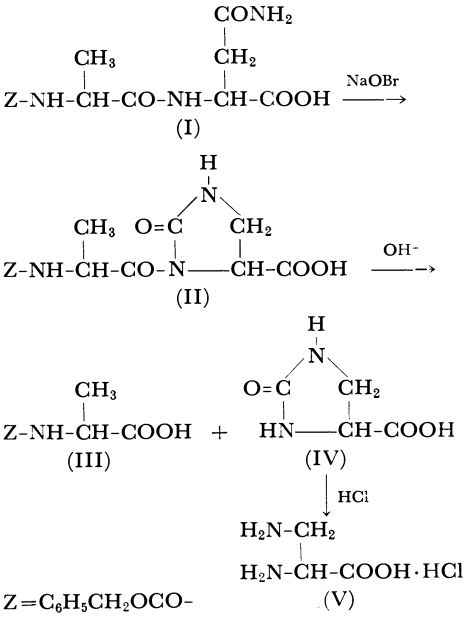

Fig. 2.

Table 1. Effects of temperature to reaction of *N*-benzyloxycarbonyl-L-alanyl-L-asparagine with sodium hypobromite in alkaline medium

Reaction Temp. (°C)	Yield of III (%)	Yield of V (%)
40	39	—

80	44	29

In order to prove the reaction mechanism, an isolation of the intermediate(II) was next attempted. A general mechanism of the Hofmann rearrangement by which a primary acid amide is converted to an amine is shown in Fig. 3. However, in the case of the reaction of *N*-benzyloxycarbonylalanyl-asparagine (I), the isocyanate, as soon as formed on step 4, will attack the nitrogen atom of the amino group of the original asparagine residue because of the electron-withdrawing effect of the

carbon atom of the isocyanate group. As far as the formation of the isocyanate is concerned, only two equivalents of alkali are enough. Therefore, one equivalent of bromine and totally three equivalents of 1 N sodium hydroxide, that is, two for the formation of isocyanate and one for the neutralization of the carboxyl group, were used for the reaction of I. Thus, 1-(*N*-benzyloxycarbonyl-L-alanyl)-2-oxo-imidazolidine-5-carboxylic acid (II) was obtained in a quantitative yield as expected. This compound showed an absorption of the ring carbonyl group at 1760 cm^{-1} in its infrared spectrum.

$$Br_2 + 2NaOH \rightarrow NaOBr + NaBr \quad (1)$$

$$RCONH_2 + NaOBr \rightarrow RCONHBr + NaOH \quad (2)$$

$$RCONHBr + OH^- \rightarrow RCONBr^- + H_2O \quad (3)$$

$$RCONBr^- \rightarrow RNCO + Br^- \quad (4)$$

$$RNCO + OH^- \rightarrow RNHCOO^- \quad (5)$$

$$RNHCOO^- + OH^- \rightarrow RNH_2 + CO_3^{--} \quad (6)$$

Fig. 3.

The compound II was then treated with two equivalents of an aqueous methanolic sodium hydroxide solution at room temperature, giving III and IV in yields of 50 and 10% respectively. From the result of this stepwise reaction, it is now certified that the cleavage reaction takes place through the imidazolidone intermediate without splitting of the peptide linkages by simple alkaline hydrolysis.

When the asparagine residue is located at a position other than carboxyl terminal end, there is another possibility of ring formation; that is, the isocyanate group will link with the nitrogen atom of an amino acid residue adjacent to asparagine residue at its carboxyl side to form a hydrouracil ring instead of an imidazolidone ring. In order to check this possibility, *N*-benzyloxycarbonyl-L-asparaginyl-L-phenylalanine (VII) was treated under the same reaction condition, and 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carbonylphenylalanine (VIII) was obtained as a single product. This compound showed an infrared absorption at 1790 cm^{-1} which was characteristic of the ring carbonyl absorption of the imidazolidone as compared with authentic 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carboxylic acid. Furthermore, the removal of benzyloxycarbonyl group from VIII by catalytic hydrogenation gave a ninhydrin-negative product (IX). These facts indicated that the isocyanate group was not linked with the amino group of the phenylalanine residue, but certainly with that of the asparagine residue.

At the stage of the present investigation, a solubility of longer asparagine peptide in an aqueous alkaline solution gave some restriction for an applicability of this method. For instance, in the reaction of *N*-benzyloxycarbonyl-L-alanyl-L-asparaginyl-L-phenylalanine (XI) with one equivalent of bromine and three equivalents of aqueous 1N sodium hydroxide solution, a large amount of unreacted tripeptide was recovered and no 1-(*N*-benzyloxycarbonylalanyl)-2-oxo-imidazolidine-5-carbonylphenylalanine was obtained. The original tripeptide XI was almost insoluble in this reaction medium. When five equivalents of alkali were used, *N*-benzyloxycarbonylalanine was found in the reaction mixture by a thin-layer chromatography, but could not be isolated as crystals. However, a possibility of non-selective cleavage of the peptide bond by simple alkaline hydrolysis could not be excluded in this case, since ninhydrinpositive spots of amino acids were also found on a thin-layer chromatogram of the reaction mixture.

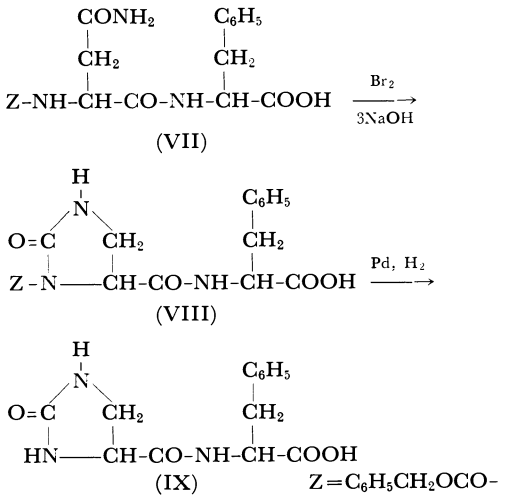

Fig. 4.

It must be investigated whether or not a glutamine residue will react in a similar way under the same condition as that of the cleavage reaction of asparagine peptide. In the Hofmann reaction of *N*-benzyloxycarbonyl-L-glutamine (XIIa), compound XIIIa was obtained as a reaction product. The removal of benzyloxycarbonyl group from XIIIa by catalytic hydrogenation yielded a free amino compound (XIV), which was then hydrolyzed by 6 N hydrochloric acid, giving three amino acids, *e.g.*, α,β-diaminobutyric acid, glutamic acid and glutamine. On the basis of this fact together with the results of the elementary analysis of XIIIa and of the observed molecular weight of dimethyl ester of XIIIa, the structure of this compound XIIIa was assigned as shown in Fig. 5. This may be formed by the intermolecular condensation of the isocyanate derivative with an intact glutamine molecule.

N-Benzyloxycarbonyl-L-alanyl-L-glutamine (XII b) gave also a corresponding product (XIIIb) under the same condition of the Hofmann reaction as mentioned in Fig. 5. This product did not afford *N*-benzyloxycarbonylalanine by treatment

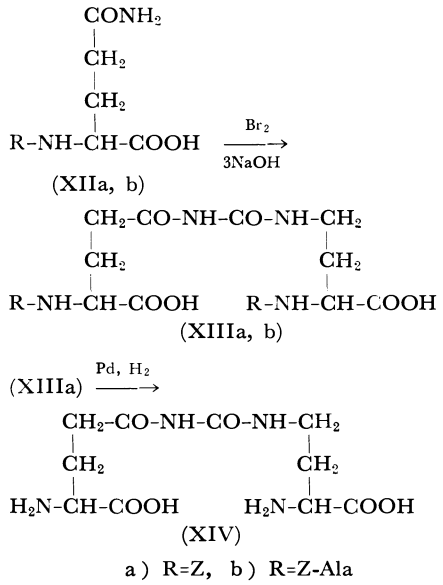

Fig. 5.

with aqueous sodium hydroxide in methanol at room temperature as expected from the structure.

From the results obtained above, it is now concluded that the isocyanate group formed as an intermediate in the Hofmann reaction could be very easily cyclized, giving a five-membered imidazolidone ring, but not a six-membered 2-hydroxytetrahydropyrimidine ring. Therefore, this selective cleavage reaction proceeded specifically only for asparagine peptide whereas glutamine peptide did not react similarly. For application of this reaction to the selective cleavage of asparagine residue in natural peptide or protein, however, the reaction condition should be somehow improved for solubility of the molecule and for prevention of the non-selective alkaline hydrolysis.

Experimental

All melting points are uncorrected. The infrared absorption spectra were obtained in Nujol mull with Nihon Bunko IR-S spectrophotometer. Thin-layer chromatography was carried out on silica gel G.

***N*-Benzyloxycarbonyl-L-alanyl-L-asparagine (I).** To a mixed solution of 13.4 g (0.060 mol) of *N*-benzyloxycarbonyl-L-alanine and 6.0 g (0.060 mol) of triethylamine in 150 m*l* of tetrahydrofuran, there was added 7.1 g (0.066 mol) of ethyl chloroformate at −2°C with stirring. After the reaction mixture had been stirred at −5°C for 20 min, a solution of 9.9 g (0.066 mol) of L-asparagine monohydrate in 66 m*l* of 1N sodium hydroxide solution was added. Stirring was continued at this temperature for 1 hr, and then at room temperature for additional 3 hr. Insoluble crystals of unreacted asparagine were filtered off; wt 2.9 g. The filtrate was acidified to pH 2 with 6 N hydrochloric acid, and an oily substance was obtained. It was extracted with totally 250 m*l* of ethyl acetate. After the extract had been allowed to stand in a refrigerator overnight, crystals formed were filtered; wt 5.5 g, mp 179—180°C (decomp.). Concentration of the mother liquor gave 3.2 g of the same crystals; total yield, 48%. Combined crystals were recrystallized from 94% ethanol to yield 8.3 g of pure crystals; mp 186—187°C (decomp.), $[\alpha]_D^{17}$ +18.7° (*c* 2.09, dimethylformamide).

Found: C, 53.20; H, 5.70; N, 12.29%. Calcd for $C_{15}H_{19}O_6N_3$: C, 53.40; H, 5.68; N, 12.46%.

***N*-Benzyloxycarbonyl-L-asparaginyl-L-phenylalanine *t*-Butyl Ester (VI).** To a solution of 5.16 g (0.020 mol) of *t*-butyl L-phenylalaninate hydrochloride[17,18] in 40 m*l* of dimethylformamide, there was added 2.02 g (0.022 mol) of triethylamine on ice-cooling. After stirring for 30 min, triethylamine hydrochloride formed was filtered off. To the filtrate, a solution of 7.74 g (0.020 mol) of *p*-nitrophenyl *N*-benzyloxycarbonyl-L-asparaginate in 40 m*l* of dimethylformamide was added and the reaction mixture was allowed to stand at room temperature. Crystals formed on addition of water were filtered off after allowing to stand overnight in a refrigerator; yield, 8.29 g (88%), mp 151—152°C. Recrystallization from ethyl acetate gave 7.60 g (81%) of pure crystals; mp 152.0—152.5°C.

Found: C, 64.16; H, 6.92; N, 8.99%. Calcd for $C_{25}H_{31}O_6N_3$: C, 63.94; H, 6.66; N, 8.95%.

***N*-Benzyloxycarbonyl-L-asparaginyl-L-phenylalanine (VII).** To 4.7 g of VI, 25 m*l* of trifluoroacetic acid was added, and the reaction mixture was stirred at room temperature for 1 hr. Crystals formed on addition of 70 m*l* of ether were filtered, washed with ether and then dried *in vacuo* over phosphrus pentoxide; yield, 3.9 g (94%), mp 202.5°C (decomp). Recrystallization from dimethylformamide - water gave needles; mp 210.5°C (decomp.).

Found: C, 60.98; H, 5.67; N, 10.28%. Calcd for $C_{21}H_{23}O_6N_3$: C, 61.01; H, 5.61; N, 10.16%.

***N*-Benzyloxycarbonyl-L-alanyl-L-asparaginyl-L-phenylalanine *t*-Butyl Ester (X).** Through a mixed solution of 14.0 g (0.031 mol) of VI and 3 m*l* of acetic acid in 400 m*l* of methanol, hydrogen gas was passed in the presence of 2 g of 10% palladium on charcoal with stirring for 6 hr. After removal of the catalyst by filtration, the filtrate was evaporated *in vacuo*. To a solution of the residue in 50 m*l* of dimethylformamide, there were added 3 g of triethylamine and a solution of 10.4 g (0.031 mol) of *p*-nitrophenyl *N*-benzyloxycarbonyl-L-alaninate[19] in 50 m*l* of dimethylformamide. The reaction mixture was stirred at room temperature for 24 hr. After addition of water, it was allowed to stand in a refrigerator overnight. Crystals formed were filtered and dried *in vacuo* at 70°C for 3 hr. Recrystallization from dimethylformamide - water gave 14.7 g (91%) of X; mp 164—165°C. Repeated recrystallization from the same solvent raised the melting point to 174—175°C (sintered at 164°C).

Found: C, 62.27; H, 6.80; N, 10.34%. Calcd for $C_{23}H_{36}O_7N_4$: C, 62.20; H, 6.71; N, 10.36%.

***N*-Benzyloxycarbonyl-L-alanyl-L-asparaginyl-L-phenylalanine (XI).** A mixture of 5.4 g (0.010 mol) of X and 30 m*l* of trifluoroacetic acid was stirred at room temperature for 1 hr, and then 100 m*l* of anhydrous

ether was added. A gelatinous precipitate formed was filtered after cooling and washed with ether. It was reprecipitated from dimethylformamide - water, and then dried *in vacuo* over phosphorus pentoxide; yield, 4.7 g (94%), mp 196°C (decomp.). Elementary analysis was carried out after drying *in vacuo* at 90°C for 3 hr.

Found: C, 57.32; H, 5.95; N, 11.13%. Calcd for $C_{24}H_{28}O_7N_4 \cdot H_2O$: C, 57.36; H, 6.02; N, 11.15%.

***N*-Benzyloxycarbonyl-L-alanyl-L-glutamine (XIIb).** A mixed solution of 6.7 g (0.030 mol) of *N*-benzyloxycarbonyl-L-alanine and 3.0 g (0.030 mol) of triethylamine in 75 m*l* of dioxane, there was added 3.6 g (0.033 mol) of ethyl chloroformate at −5°C for 5 min with stirring. After the stirring had been continued at this temperature for 20 min, a solution of 4.8 g (0.033 mol) of L-glutamine in 33 m*l* of aqueous 1 N sodium hydroxide was added. The reaction mixture was stirred at −5°C for 40 min and then at room temperature for 2.5 hr. A small amount of undissolved glutamine was removed by filtration. The filtrate was acidified to pH 1 with 6 N hydrochloric acid, and extracted with ethyl acetate. Crystals formed in the extract were filtered and recrystallized from water to yield 7.1 g (67%) of needles; mp 167.5—168.5°C. Recrystallization from water raised the melting point to 169.0—171.5°C.

Found: C, 54.49; H, 6.18; N, 11.99%. Calcd for $C_{16}H_{21}O_6N_3$: C, 54.69; H, 6.02; N, 11.96%.

The Hofmann Reaction of *N*-Benzyloxycarbonyl-L-asparagine. To a solution of 3.3 g of sodium hydroxide in 70 m*l* of water, 4.4 g of bromine was added dropwise with stirring at 0—5°C. To the solution, 6.7 g (0.025 mol) of *N*-benzyloxycarbonyl-L-asparagine was added, and stirred at 50°C for 1 hr.[20] After addition of sodium thiosulfate on cooling, the reaction mixture was washed with ether, and then acidified to pH 2 with 6 N hydrochloric acid to give an oily material which was crystallized after allowing to stand in a refrigerator overnight. It was filtered and recrystallized from water to yield 4.3 g (65%) of 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carboxylic acid; mp 164—168°C (decomp.). Recrystallization from methanol - ether raised the melting point to 190°C (decomp.), lit.,[6] mp 194°C.

Found: C, 54.24; H, 4.58; N, 10.64%. Calcd for $C_{12}H_{12}O_5N_2$: C, 54.54; H, 4.58; N, 10.60%.

This compound gave crystalline *N,N'*-dicyclohexylammonium salt; mp 200°C (decomp.).

Found: C, 64.19; H, 7.92; N, 9.22%. Calcd for $C_{12}H_{12}O_5N_2 \cdot C_{12}H_{23}N$: C, 64.69; H, 7.92; N, 9.43%.

2-Oxo-imidazolidine-5-carboxylic Acid (IV). Through a mixed solution of 1.32 g (5.0 mmol) of 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carboxylic acid and a few drops of acetic acid in 50 m*l* of methanol, hydrogen gas was passed in the presence of 100 mg of 10% palladium on charcoal for 8 hr. After evaporation of the solvent, a residue obtained was crystallized from methanol - ether; mp 179.5°C (decomp.), lit.,[6] 190—191°C (decomp.), lit.,[7] 184°C (decomp.).

Found: C, 37.14; H, 5.00; N, 21.48%. Calcd for $C_4H_6O_3N_2$: C, 36.93; H, 4.65; N, 21.53%.

This carboxylic acid gave long needles of *N,N'*-dicyclohexylammonium salt; mp 214°C (decomp.) (sintered at 203°C).

Found: C, 61.81; H, 9.46; N, 13.48%. Calcd for $C_4H_6O_3N_2 \cdot C_{12}H_{23}N$: C, 61.71; H, 9.39; N, 13.49%.

Cleavage Reaction of *N*-Benzyloxycarbonyl-L-alanyl-L-asparagine (I). a) A mixture of 3.4 g (10 mmol) of I and a solution of 1.8 g (11 mmol) of bromine in 50 m*l* of aqueous 1 N sodium hydroxide was stirred at 78—80°C for 1 hr. After cooling, it was acidified to pH 2—3 with 6 N hydrochloric acid. Crystals of *N*-benzyloxycarbonyl-L-alanine (III) formed were filtered; wt 0.85 g, mp 77.5—81.0°C. The filtrate was extracted with 45 m*l* of chloroform. To a concentrated extract, petroleum ether was added to give needles of a second crop of III; wt 0.58 g, mp 81.5—84.0°C, total crude yield, 64%. Recrystallization of combined product from chloroform - petroleum ether gave 0.99 g (44%) of pure crystals; mp 84—85°C, $[\alpha]_D^{17}$ −14.6° (*c* 2.2, acetic acid). Lit.,[21] mp 84°C, $[\alpha]_D^{17}$ −14.3° (acetic acid), lit.,[22] mp 87°C (corrected), $[\alpha]_D^{27}$ −13.9° (*c* 2.0, acetic acid).

The aqueous layer from the chloroform extraction was evaporated *in vacuo* to dryness. A residue was triturated with 100 m*l* of anhydrous ethanol to remove insoluble inorganic salts. The solution was evaporated *in vacuo* to a residue which was then dissolved in 15 m*l* of water. The aqueous solution was passed through Dowex 50 (H form) column, and an effluent was evaporated *in vacuo* to give an oil. This oily material was heated with 6 N hydrochloric acid under reflux for 2 hr. Residue obtained by evaporation *in vacuo* was crystallized from 99% ethanol to yield 0.41 g (29%) of L-α,β-diaminopropionic acid monohydrochloride; mp 230—231°C (decomp.). It was recrystallized from water; mp 238—239°C (decomp.), $[\alpha]_D^{16}$ +21.2° (*c* 5.61, 1 N hydrochloric acid). Lit.,[23] mp 245°C (decomp.) (corrected), $[\alpha]_D^{20}$ +25.09° (1 N hydrochloric acid), lit.,[7] $[\alpha]_D^{20}$ +25.0° (1 N hydrochloric acid.).

Reactions at different temperatures shown in Table 1 were carried out by the similar procedure to that mentioned above.

b) To a solution of 2.4 g (0.060 mol) of sodium hydroxide in 60 m*l* of water, 3.2 g of bromine was added dropwise on ice-cooling. To the sodium hypobromite solution prepared above, 6.7 g (0.020 mol) of I was added. The reaction mixture was stirred at 60°C for 1 hr. After cooling and addition of 40 m*l* of water, the reaction mixture was acidified to pH 2 with 6 N hydrochloric acid. An oily material formed was extracted with totally 750 m*l* of ethyl acetate three times. The combined extracts were washed with water, and dried with sodium sulfate. Evaporation of the solvent *in vacuo* gave a solid of crude 1-(*N*-benzyloxycarbonylalanyl)-2-oxo-imidazolidine-5-carboxylic acid (II), which was then dried *in vacuo* over calcium chloride; yield 6.5 g (95%), mp 66°C (decomp.). This compound gave a crystalline dicyclohexylammonium salt

20) In our experiment, crystalline 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carboxylic acid was obtained only when three equivalents of sodium hydroxide and one equivalent of bromine were used, although Schneider carried out the same reaction using much excess amount of sodium hydroxide and bromine.[6]

21) M. Bergmann and L. Zervas, *Ber.*, **65**, 1192 (1932).

22) M. Hunt and V. du Vigneaud, *J. Biol. Chem.*, **124**, 669 (1938).

from anhydrous ether solution; mp 212.5°C (decomp.), ν_{max} 1760 cm^{-1} (ring CO).

Found: C, 62.41; H, 7.94; N, 10.82%. Calcd for $C_{27}H_{40}O_6N_4$: C, 62.77; H, 7.80; N, 10.85%.

To a solution of 0.84 g (2.5 mmol) of II obtained above in 10 m*l* of methanol, there was added 5 m*l* of aqueous 1 N sodium hydroxide solution. The reaction mixture was stirred at room temperature for 2 hr. After acidification to pH 3 with 1 N hydrochloric acid, methanol was removed by evaporation *in vacuo*. Aqueous solution was extracted with chloroform three times. To the dried extract, petroleum ether was added to yield 0.28 g (50%) of needles of *N*-benzyloxycarbonyl-L-alanine (III). Its infrared spectrum and melting point were identical with those of the authentic sample respectively.

The aqueous layer from the chloroform extraction was evaporated *in vacuo*. The residue obtained was dried over phosphorus pentoxide, and dissolved in anhydrous methanol. To the solution, dicyclohexylamine and then anhydrous ether were added giving crystals of dicyclohexylammonium salt. They were filtered and dried. A solution of this salt in a mixture of methanol and water was treated with Dowex 50 (H form) by stirring for 30 min. After removal of the resin by filtration, the solvent was evaporated *in vacuo*. A residue obtained was crystallized from methanol - ether; yield, 30 mg (10%). Its infrared spectrum and melting point were identical with those of 2-oxo-imidazolidine-5-carboxylic acid (IV) respectively.

The Hofmann Reaction of *N*-Benzyloxycarbonyl-L-asparaginyl-L-phenylalanine (VII). To sodium hypobromite solution prepared from 23.3 m*l* of 1 N sodium hydroxide and 0.42 m*l* of bromine, there was added 3.1 g (7.5 mmol) of VII. The reaction mixture was stirred at 60°C for 1 hr. After cooling, crystals formed were filtered and dried *in vacuo* over phosphorus pentoxide; yield 3.1 g (100%), mp 179—181°C (decomp.). Recrystallization from methanol - ether gave pure crystals of 1-benzyloxycarbonyl-2-oxo-imidazolidine-5-carbonylphenylalanine (VIII) containing one mole of methanol as crystallization solvent; mp 191°C (decomp.), ν_{max} 1790 cm^{-1} (ring CO).

Found: C, 59.66; H, 5.79; N, 9.15%. Calcd for $C_{21}H_{21}O_6N_3 \cdot CH_3OH$: C, 59.58; H, 5.68; N, 9.48%.

When 23.645 mg of the crystals was heated at 80°C *in vacuo*, a constant weight of 22.067 mg was obtained after 15.5 hr. The loss in weight corresponds to 92.3% of the theoretical amount of one mole of methanol as crystallization solvent.

Through a solution of 0.75 g (1.8 mmol) of VIII in a mixture of 20 m*l* of methanol, 5 m*l* of acetic acid and 5 m*l* of water, hydrogen gas was passed for 6 hr in the presence of 100 mg of 10% palladium on charcoal. After removal of the catalyst by filtration, the solvent was evaporated *in vacuo*. A residue obtained was dried *in vacuo* over phosphorus pentoxide; yield, 0.40 g (78%). Recrystallization from water gave needles of 2-oxo-imidazolidine-5-carbonylphenylalanine (IX); mp 195°C (decomp.) (sintered at 100°C). This compound gave no ninhydrin reaction.

Found: C, 53.37; H, 5.81; N, 14.16%. Calcd for $C_{13}H_{15}O_4N_3 \cdot H_2O$: C, 52.87; H, 5.80; N, 14.23%.

The Hofmann Reaction of *N*-Benzyloxycarbonyl-L-glutamine (XIIa). To a solution of 4.0 g of bromine in 100 m*l* of 0.75 N sodium hydroxide, there was added 7.0 g (0.025 mol) of *N*-benzyloxycarbonyl-L-glutamine. The reaction mixture was stirred at 60°C for 1 hr. After cooling and addition of sodium thiosulfate, the reaction mixture was acidified to pH 2 with 6 N hydrochloric acid. Crystals formed were filtered off and dried *in vacuo* over phosphorus pentoxide; wt 5.6 g. It was recrystallized from methanol - water, and then from ethanol - water to yield needles of XIIIa; mp 181.5°C (decomp.).

Found: C, 55.96; H, 5.54; N, 9.96%. Calcd for $C_{26}H_{30}O_{10}N_4$: C, 55.91; H, 5.41; N, 10.03%.

This compound gave pure crystals of bis-dicyclohexylammonium salt, mp 192°C (decomp.).

Found: C, 65.11; H, 8.32; N, 9.09%. Calcd for $C_{26}H_{30}O_{10}N_4 \cdot 2C_{12}H_{23}N$: C, 65.19; H, 8.32; N, 9.12%.

The compound IIIa was converted to its dimethyl ester by diazomethane in the usual manner; mp 160—162°C (decomp.), mol wt: Found: 545 (by the Rast method using camphor). Calcd for $C_{28}H_{34}O_{10}N_4$: 586.

Hydrogenation of IIIa by the usual procedure using 10% palladium on charcoal gave compound XIV. It was recrystallized from water; mp 226—227°C (decomp.), R_f, 0.13 on a thin-layer chromatogram (*n*-butanol - acetic acid - water, 4 : 1 : 2).

Found: C, 41.25; H, 6.47; N, 18.87%. Calcd for $C_{10}H_{18}O_6N_4$: C, 41.37; H, 6.25; N, 19.30%.

Compound XIV was then hydrolyzed by refluxing with 6 N hydrochloric acid for 3 hr. The reaction product gave three spots of α,γ-diaminobutyric acid, glutamic acid and glutamine by ninhydrin coloration on a thin-layer chromatogram and a paper chromatogram. Thin-layer chramotography (*n*-butanol - acetic acid - water, 4 : 1 : 2): R_f, 0.16 (α,γ-diaminobutyric acid), 0.22 (glutamine), 0.30 (glutamic acid). Paper chromatography (phenol - water, 4 : 1): R_f, 0.18 (α,γ-diaminobutyric acid), 0.33 (glutamic acid), 0.59 (glutamine).

The Hofmann Reaction of *N*-Benzyloxycarbonyl-L-alanyl-L-glutamine (XIIb). To a mixture of 15 m*l* of 1N sodium hydroxide and 0.80 g of bromine, there was added 1.76 g of XIIb. The reaction mixture was stirred at 60°C for 1 hr. By a procedure similar to that in the reaction of XIIa, 1.49 g of the product XIIIb was obtained. It was recrystallized from methanol - ether - petroleum ether to yield needles; mp 192.5°C (decomp.).

Found: C, 54.29; H, 5.82; N, 11.78%. Calcd for $C_{32}H_{40}O_{12}N_6 \cdot CH_3OH$: C, 54.09; H, 6.05; N, 11.47%.

Even when this product was treated with 1 N sodium hydroxide in methanol at room temperature for 2 hr, the starting material was recovered without formation of *N*-benzyloxycarbonylalanine (III).

The authors are grateful to the Central Research Laboratories of Ajinomoto Co., Inc. for donation of the amino acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2754—2757 (1968)

Studies on the Substrate Specificity of Egg White Lysozyme. II. Mode of the Enzymatic Action on Partially-*O*-carboxymethylated Chitin

Tsuyoshi MIYAZAKI and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University, College of Science, Toyonaka

(Received May 9, 1968)

Partially-*O*-carboxymethylated chitin was found to be a soluble substrate of hen egg white lysozyme. The products of the lysozyme action were analyzed by gel filtration and by ion-exchange chromatography. The reducing ends of the saccharides produced by the enzyme were the *N*-acetyl-glucosamine residue or the 3-*O*-carboxymethyl-*N*-acetyl-glucosamine residue. 6-*O*-Carboxymethyl-*N*-acetyl-glucosamine never appeared as a reducing end. The *O*-substituted disaccharide detected in the reaction products was 6'-*O*-carboxymethyl-di-*N*-acetyl-chitobiose. The results of the reducing-end analyses and the finding that none of the monomers were formed except for the unsubstituted *N*-acetyl-glucosamine, while an *O*-substituted dimer was formed as is mentioned above, are in conformity with the conformation of the enzyme-substrate complex proposed by Blake *et al.* as a result of their X-ray crystallographic investigations.

An elaborate model of a three-dimensional structure of an ES-complex formed between chitin oligosaccharide and hen egg white lysozyme [EC 3.2.1.17.] was presented by Blake *at al.*[1] as a result of thier X-ray crystallographic investigations. When partially-*O*-carboxymethylated chitin is used instead of a natural substrate chitin, it is expected that the fairly bulky *O*-substitutent groups will not permit the substrate molecules to bind freely with the enzyme protein. The enzyme must avoid the steric hindrance exerted by the *O*-substituent groups on the substrate and select some suitable portions of the substrate in order to make an ES-complex. If this is the case, the orientation of the *O*-substituent groups in the enzymatic reaction products will afford information on the conformation of the binding site of the enzyme protein.

Partially-*O*-carboxymethylated chitin was reported by Hultin[2] to be a soluble substrate of chitinase. The present authors prepared the substance by the *N*-acetylation of the *O*-carboxymethylated chitosan reported by Okimasu.[3] This substance was found to be a substrate of hen egg white lysozyme[4] by the release of reducing power when it was incubated with the enzyme. Among the low-molecular-weight compounds produced by the enzyme, there were *N*-acetylglucosamine (I), di-*N*-acetylchitobiose (II), tri-*N*-acetylchitotriose (III), and 6'-*O*-carboxymethyl-di-*N*-acetylchitobiose (IV). None of the *O*-substituted monosaccharides were produced by the enzyme, and the reducing-end residues of the product saccharides were either unsubstituted or 3-*O*-substituted. These findings can be well interpreted when we take into account the conformation of the *O*-substituted groups of the substrate in the ES-complex.

Our results offer chemical evidence for the conformation of the active sites in the Phillips model[1] of the ES-complex of hen egg white lysozyme.

Experimental

The enzyme specimen used was a thrice recrystallized one purchased from Sigma Chemicals.

Abbreviations will be used for glucosamine: GlN, *N*-acetylglucosamine: GlNAc, glucosaminitol: GlNOH, carboxymethyl: CM.

The Enzymatic Action on Partially-*O*-carboxymethylated Chitin. An example of the time course of the enzymatic reaction is shown in Fig. 1. The pH-activity curve is shown in Fig. 2. The molar composition of the substrate is: 56.7% GlNAc, 3.2%

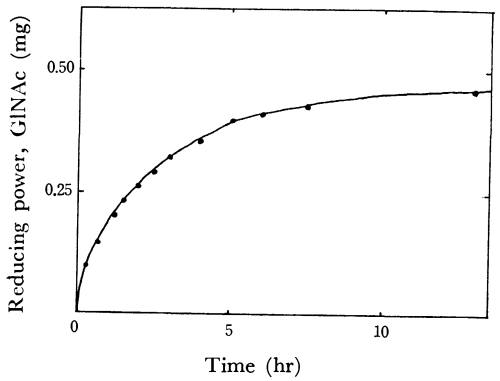

Fig. 1. Incubation mixture: Five mg of the substrate in 1 m*l* of water, 0.5 m*l* of 0.4 M acetate buffer (pH 5.6) and 0.1 mg of the enzyme in 0.5 m*l* of water. Incubation temperature: 37°C. Reducing power measurement: Somogyi-Nelson method.[5]

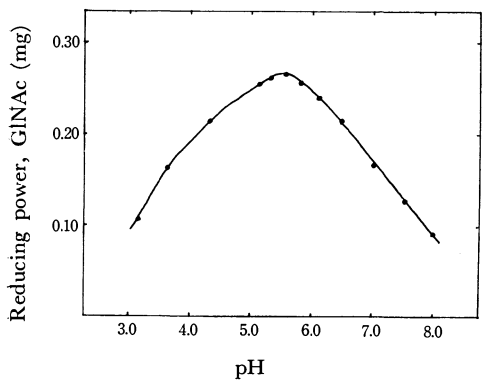

Fig. 2. Incubation mixture: Five mg of the substrate in 1 m*l* of water, 0.5 m*l* of 0.4 M acetate buffer (pH 3.3—5.8) or phosphate buffer (pH 6.0—8.0) and 0.1 mg of the enzyme in 0.5 m*l* of water. Incubation temperature: 37°C. Incubation time: 2 hr. Reducing power measurement: Somogyi-Nelson method.

5) "Methods in Carbohydrate Chem.," Vol. 1, Academic Press, New York and London (1962), p. 368.

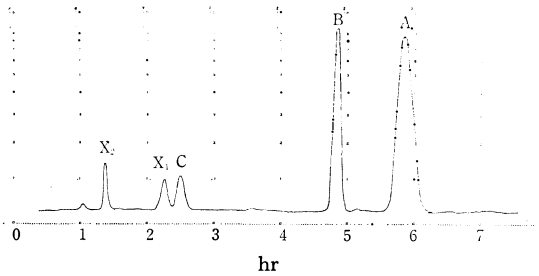

Fig. 3a. The composition of the substrate. The specimen was hydrolyzed in 4 N hydrochloric acid at 105°C for 4 hr. The hydrolysate was evaporated *in vacuo*, and 1 mg of the dried residue was placed on a column of Hitachi Autoanalyzer KLA-3. Elution was performed with 0.2 M citrate buffer (pH 3.11—4.25). The peaks shown are: GlN(A), 6-*O*-CM-GlN(B), 3-*O*-CM-GlN(C) and unknown substances (X_1, X_2). The peaks were identified by using standard specimens.[6]

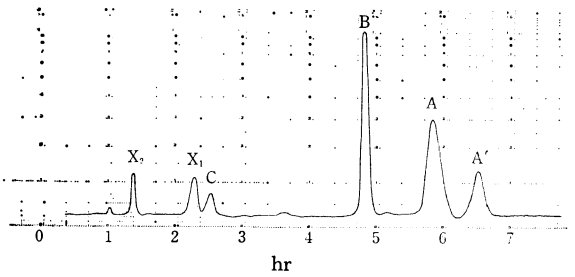

Fig. 3b. The composition of the enzymatic reaction products which was reduced with borohydride before hydrolysis. The peaks shown are: GlNOH(A'), GlN(A), 6-*O*-CM-GlN(B), 3-*O*-CM-GlN(C) and unknown substances (X_1, X_2). The peak of 3-*O*-CM-GlNOH was not recognizable due to a low ninhydrin color yield of the compound, and due to its close vicinity to the peak X_1. The retention time for the peak of 6-*O*-CM-GlNOH, which did not appear, is 4.58 hr.

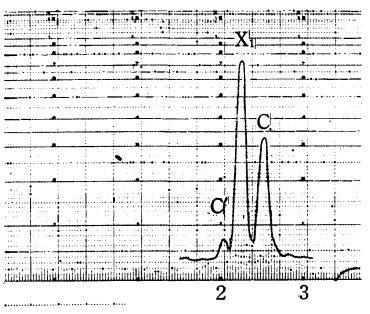

Fig. 3c. The pattern of the early region of Fig. 3b magnified by charging ten times amount (10 mg) of the specimen. The peaks shown are: 3-*O*-CM-GlN(C), an unknown substance (X_1) and 3-*O*-CM-GlNOH(C').

3-*O*-CM-GlNAc, 27.2% 6-*O*-CM-GlNAc, plus unknown components.

Analyses of the Reducing-end Residues Produced by the Enzyme. The whole of the enzymatic reaction mixture was reduced by sodium borohydride, and the mixture was hydrolyzed with hydrochloric acid. The acid hydrolysate contained monosaccharides and sugar alcohols, and the structure (3-*O*-, 6-*O*-, or unsubstituted) of the latter revealed what had been the reducing ends of the oligosaccharides produced by the enzyme. The chromatographic pattern of the acid hydrolysate, after the borohydride reduction, of the enzymatic reaction mixture is shown in Fig. 3(a—c) in comparison with the acid hydrolysate of the sub-substrate.

Fractionation by Dialysis and Gel Filtration of the Enzymatic Reaction Products. Three grams of the substrate were digested by 60 mg of the enzyme in a 100 m*l* of acetate buffer solution (pH 5.6) for 48 hr at 37°C. Sixty milligrams of the enzyme in 25 m*l* of water were then added to the mixture, and the incubation was continued for 24 hr more. The mixture was then dialyzed against 2000 m*l* of deionized water for 24 hr. The dialysis was repeated three times. The dialysate was then concentrated to 200 m*l* *in vacuo*, and the residual solution was passed through a column of Amberlite IR-120 (H^+ form, 3×15 cm) in order to eliminate the sodium ion of the buffer solution. The lyophilization of the solution gave 1.87 g of a mixture of saccharides. An aliquot (260 mg) of the mixture was placed on a column of Sephadex G-15 (3×160 cm) and eluted with 0.1 N acetic acid. The chromatographic pattern obtained is shown in Fig. 4.

Identification of the Fractions in Gel Filtration. *Fraction I.* On a paper chromatogram this fraction gave only one spot that corresponded to GlNAc, as is shown in Fig. 5. The identity was further confirmed by the use of an automatic amino-acid analyzer. The fraction, after it had been hydrolyzed with hydrochloric acid, gave a single peak which corresponded to GlN. After the borohydride reduction and acid hydrolysis, the fraction gave a single peak that corresponded to GlNOH. No trace of *O*-substituted saccharide was observed in this fraction. These results, when consolidated, are evidence for the fraction I being very

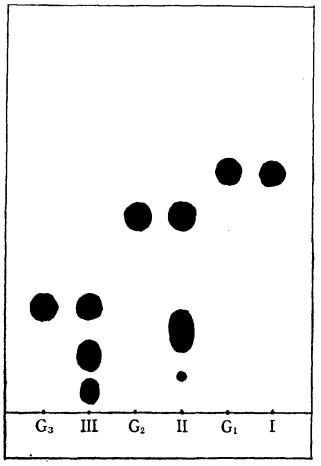

Fig. 5. Solvent system is *n*-butanol : pyridine : water = 6 : 4 : 3 (v/v). G_1: *N*-acetylglucosamine, G_2: di-*N*-acetylchitobiose, G_3: tri-*N*-acetylchitotriose.

Table 1. Molar ratio of the component sugars and sugar alcohols

	Neutral	Acidic
GlN	1.00	0.25
6-*O*-CM-GlN		1.18
GlNOH	1.00	1.00
3-*O*-CM-GlNOH		0.34

pure GlNAc. The recovery of the fraction was 0.118 g (referred to 3.0 g of the substrate).

Fraction II. This fraction was a mixture of disaccharides. As is shown in Fig. 5, the fraction contained at least three components, one of which corresponded to di-*N*-acetylchitobiose. By passing 20.2 mg of the fraction through a column of Dowex-1 (acetate form, 1.2×14 cm), it was resolved into a neutral and an acidic part. The component analyses of these two parts are shown in Table 1. The data for the neutral part demonstrate almost unequivocally the presence of di-*N*-acetylchitobiose in the enzymatic reaction products. The data for the acidic part can be interpreted as showing, along with the paper-chromatographic data, the presence of 6′-*O*-CM-di-*N*-acetylchitobiose (IV) and of 3-*O*-CM-di-*N*-acetylchitobiose, though the analytical values for the latter are not very reliable because of the low color yield in the ninhydrin reaction of 3-*O*-CM-GlNOH. The pattern in the cation-exchanger chromatography of the acidic part is shown in Fig. 6.

Fraction III. A spot corresponding to tri-*N*-acetylchitotriose is shown in Fig. 5. Further investigation of the fractions III—VII remains to be done.

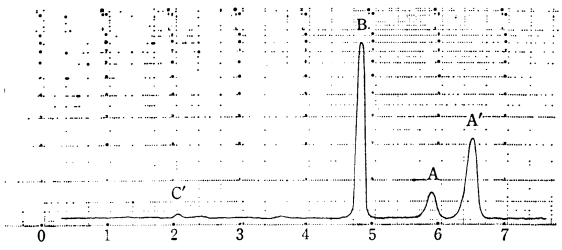

Fig. 6. The peaks are: GlNOH(A′), GlN(A), 6-*O*-CM-GlN(B) and 3-*O*-CM-GlNOH(C′).

Discussion

A three-dimensional model construction according to Blake *et al.*[7] reveals explicitly the orientation of the substituents on the substrate molecule bound to the active site (cleft) of the enzyme protein. The general features are presented in Table 2.

Table 2.

Substituent	Sub-sites A	B	C	D	E	F
3-*O*-	IN	OUT	IN	OUT	IN	OUT
6-*O*-	OUT	IN	OUT	IN	OUT	IN

The notation of the sub-sites is according to Blake *et al.*[1] "IN" means that a substituent group is directed toward inside of the "cleft", thus being ready to suffer steric hindrance, and "OUT" means contrary. Cleavage of a glycosidic bond of the substrate occurs on a residue which has been in the sub-site D. The reducing end of the saccharide chain is directed toward F.

The experimental results can be well interpreted when we take into account the general features shown in Table 2, and when the interpretation is made, as a first-order approach, only in terms of steric circumstances. The 6-*O*-substituted residue will not be able to fit into D because of its substituent group directed toward the inside of the cleft, and so this residue will not be able to be a reducing end of the various saccharides produced by the enzyme. A monosaccharide released by the enzyme must necessarily fit once into D, and once into E. Any *O*-substituted residue will suffer steric hindrance at either of these two subsites, and so can not be released as a monosaccharide. Any disaccharide to be released must fit once into C-D, and once into E-F. The disaccharides identified in the experiments meet this requirement. It seems that the C, D and E sub-sites do not have much room toward the inside of the cleft. The structure determination of the product oligosaccharides larger than disaccharide will afford information in a chemical sense about the "size" of the room of the sub-sites A, B and F. This task is now being undertaken.

This investigation was supported by U. S. Public Health Service Grant AI-04586-05. The authors are also grateful to Mr. S. Kasai for his assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2758—2762 (1968)

Syntheses of 4-Alkylidene- and 4-Aralkylidene-2-chloromethyl-5-oxazolones and *N*-(Chloroacetyl)dehydroamino Acids

Hideaki KURITA, Yasuhiro CHIGIRA, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

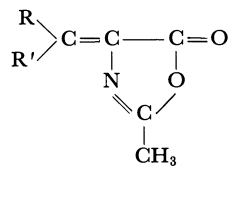
(Received May 11, 1968)

Treatment of *N*-dichloroacetyl amino acids with acetic anhydride at a temperature between 85°C and 130°C yielded 4-alkylidene- and 4-aralkylidene-2-chloromethyl-5-oxazolones, which were readily hydrolyzed to give 2-(2-chloroacetamido)-2-alkenoic acids, *i. e.*, *N*-(chloroacetyl)-dehydroamino acids.

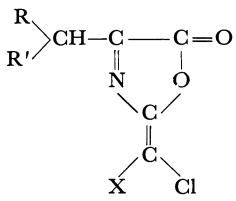
Several synthetic methods of 2-(2-chloroacetamido)-2-alkenoic acid, *i. e.*, *N*-(chloroacetyl)dehydroamino acid have been known, since the acid can be used as one of the most convenient intermediates for dehydropeptide synthesis.[1] Greenstein and his coworkers reported the preparation of several *N*-(chloroacetyl)dehydroamino acids by treating a mixture of α-keto acids and chloroacetonitrile with dry hydrogen chloride.[2] The reaction with pyruvic acid leads to the substantially quantiative formation of 2-(2-chloroacetamido)-acrylic acid, *i. e.*, *N*-(chloroacetyl)dehydroalanine in a pure state,[2a] which can be also prepared by the condensation of pyruvic acid with chloroacetamide in 30% yield.[3] In the condensations of other α-keto acids, such as α-ketovaleric acid or α-ketocaproic acid, with chloroacetonitrile, however, the yields of the products are low and the isolation and purification are difficult.[2b,c] Bergmann and his coworkers described that *N*-(chloroacetyl)phenylserine could be dehydrated under carefully controlled conditions by the action of acetic anhydride to give 4-benzylidene-2-chloromethyl-5-oxazolone, which, upon hydrolysis with dilute alkali, afforded α-2-(chloroacetamido)-cinnamic acid, *i. e.*, *N*-(chloroacetyl)dehydrophenylalanine.[4] Sheehan and Duggins reported the formation of α-(2-chloroacetamido)cinnamic acid in the treatment of *N*-(dichloroacetyl)phenylalanine with acetic anhydride in the presence of pyridine.[5] The formation has been explained by the initial cyclization of *N*-(dichloroacetyl)phenylalanine into 4-benzylidene-2-chloromethyl-5-oxazolone, followed by a hydrolytic fission of the oxazolone ring.

This paper deals with the preparation and characterization of 4-alkylidene- and 4-aralkylidene-2-chloromethyl-5-oxazolones and those transformations into *N*-(chloroacetyl)dehydroamino acids.

The treatment of *N*-(chloroacetyl)phenylalanine or *N*-(chloroacetyl)leucine with acetic anhydride has been known to form readily 4-benzylidene- or 4-isobutylidene-2-methyl-5-oxazolone (I, R=C_6H_5 or *i*-C_3H_7; R'=H) by the elimination of one molecule each of water and hydrogen chloride.[6] On the other hand, the recent report by Steglich *et al.* showed that *N*-trichloroacetyl amino acids, upon treatment with dicyclohexylcarbodiimide or phosphorus trichloride in the presence of pyridine, gave 2-dichloromethylene-pseudo-5-oxazolones (II, X=Cl).[7]



I



II

When *N*-dichloroacetyl-L-leucine (IIIb) was heated in acetic anhydride at 85—90°C for 1 hr, 2-chloromethyl-4-isobutylidene-5-oxazolone (IVb) was obtained in 74% yield. The structure of IVb was determined by its elemental analysis and spectral studies as well as the hydrolysis reaction. The infrared spectrum showed a strong, broad band at 1800 cm^{-1} (C=O), a strong sharp band at 1670 (C=N) and a weak band at 1615 (C=C). The

NMR spectrum exhibited a doublet at τ 3.44, a singlet at 5.64, a multiplet centered at 6.8, and a doublet at 8.85. The peak areas were in the ratio 1.0 : 2.3 : 1.0 : 6.0 (theory 1 : 2 : 1 : 6). The peak pattern corresponds not to the pseudo-oxazolone structure II (R=*i*-C_3H_7; R'=H; X=H), but to 2-chloromethyl-4-isobutylidene-5-oxazolone structure IVb.

Analogous treatments of several *N*-dichloroacetyl amino acids (III) with actic anhydride resulted in the formation of the corresponding 4-alkylidene- and 4-aralkylidene-2-chloromethyl-5-oxazolones (IV). The yields of the oxazolones IV were affected sensitively with the reaction temperature, probably owing to the thermo-unstability of IV. After much repeated experiments under various conditions, the best yields could be obtained only at the temperature described in Experimental. Sheehan and Duggins demonstrated that the treatment of *N*-(dichloroacetyl)phenylalanine (IIId) with acetic anhydride at 100°C for seventy-five min led only to recovery of the starting material.[5] In our experiment, however, 4-benzylidene-2-chloromethyl-5-oxazolone (IVd) was obtained in 61% yield by the treatment at 130°C for 1 hr.

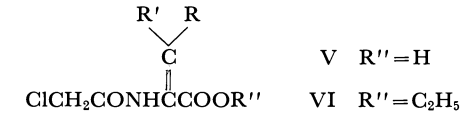
IVf R=*p*-AcO-C_6H_4, R'=H

4-Alkylidene-2-chloromethyl-5-oxazolones were susceptible to undergo hydrolysis. Even when left to stand at room temperature, the oily oxazolones were partially hydrolyzed by atmospheric moisture to afford the crystalline product. Treatment of 2-chloromethyl-4-isopropylidene-5-oxazolone (IVa) with water at room temperature gave 2-(2-chloroacetamido)-3-methylcrotonic acid, *i. e.*, *N*-(chloroacetyl)dehydrovaline (Va) in 80% yield.

In a similar fashion, *N*-(chloroacetyl)dehydroleucine (Vb), *N*-(chloroacetyl)dehydroisoleucine (Vc) and *N*-(chloroacetyl)dehydrophenylalanine (Vd) were prepared by the hydrolysis of the oxazolones (IVb, IVc, IVd). The acids V were characterized by elemental analyses and infrared spectra.[8] In turn, the formation of V also supported the structure of the parent oxazolone IV.

When 2-chloromethyl-4-isopropylidene-5-oxazolone (IVa) was refluxed in ethanol, the ethanolysis product, ethyl 2-(2-chloroacetamido)-3-methylcrotonate (VIa) was obtained in 17% yield. The ester VIa was also obtained in 39% yield by the esterification of the acid Va in the presence of



V R''=H

VI R''=C_2H_5

sulfuric acid and *p*-toluenesulfonic acid. The NMR analysis revealed that the ester has an *N*-acyl-enamine structure VIa and not the tautomeric *N*-acyl-imine structure (see Experimental).

The amination of the crude 2-(2-chloroacetamido)-2-alkenoic acids V with ammonia has been known to give *N*-(glycyl)dehydroamino acids.[2b,c] In order to study the reactivity of the chloroacetyl group, the reactions of *N*-(chloroacetyl)dehydroleucine (Vb) with several amines were carried out.

Piperidine (pK_a=11.22) reacted with Vb immediately at room temperature to afford 4-methyl-2-(2-piperidinoacetamido)-2-pentenoic acid hydrochloride. Analogously, L-leucine ethyl ester (pK_a=7.66) treated smoothly with Vb within half an hour to give 4-methyl-2-[2-(1-ethoxycarbonyl-3-methylbutylamino)acetamido] - 2 - pentenoic acid hydrochloride, while the reaction of Vb with pyridine (pK_a=5.23) occurred in acetonitrile at the refluxing temperature to yield the corresponding pyridinium chloride. The reaction with aniline (pK_a=4.6) was attempted in refluxing tetrahydrofuran or acetonitrile, but the starting materials were recovered.

N-(Chloroacetyl)dehydrophenylalanine (Vd) was again treated with acetic anhydride under the same condition as for the preparation of IVd, but this reaction gave 4-benzylidene-2-methyl-5-oxazolone in 74% yield, instead of the parent oxazolone IVb. The formation of the dechlorinated oxazolone is possibly explained by an exchange of the chloroacetyl group of Vd with acetyl group, followed by the cyclization of the resultant α-acetamidocinnamic acid.

N-Dichloroacetyl amino acids (III) were prepared by treatment of amino acids with dichloroacetyl chloride in ethyl acetate[9] or in aqueous sodium hydroxide.

Treatment of DL-valine with 1.2—1.3 equiv. of dichloroacetyl chloride in refluxing ethyl acetate afforded not only *N*-dichloroacetyl-DL-valine (IIIa), but also *N*-(chloroacetyl)dehydrovaline (Va). The formation of Va could be easily rationalized by transformation of IIIa with dichloroacetyl chloride into the oxazolone IVa, followed by hydrolysis of IVa.

8) There has been no description about the constants of *N*-chloroacetyl derivatives of dehydrovaline, dehydroleucine, and dehydroisoleucine, owing to the difficulties in the purification of the products from the reactions of α-keto acids with chloroacetonitrile.[2b,c]

9) E. Ronwin, *J. Org. Chem.*, **18**, 1546 (1953).

TABLE 1. YIELDS OF PRODUCTS IN THE REACTION OF AMINO ACIDS WITH DICHLOROACETYL CHLORIDE

a) A-1 means the reaction in ethyl acetate where the amino acid and dichloroacetyl chloride were used in the mole ratio 1 : 1.2—1.3. A-2 means the reaction in ethyl acetate where the amino acid and dichloroacetyl chloride were used in the mole ratio 1 : 0.5—0.7. B means the reaction in aqueous sodium hydroxide. (See Experimental)

Analogous treatment of other amino acids with dichloroacetyl chloride in ethyl acetate led to the results summarized in Table 1.

Experimental[10)]

Dichloroacetyl chloride was prepared by using the technique of Boshard *et al.*[11)] for trichloroacetyl chloride. A mixture of dichloroacetic acid (162 m*l*, 247 g, 1.92 mol), thionyl chloride (160 m*l*, 259 g, 2.18 mol) and dimethylformamide (20 m*l*, 18.5 g, 0.25 mol) was heated at 70—85°C for 4 hr, and then distilled to give a colorless liquid (214 g, 76%), bp 104—109°C (lit.[12)] bp 105—107°C).

N-Dichloroacetyl Amino Acids (III). *A) Reaction in Ethyl Acetate.* The procedure was modified from the method of Ronwin.[9)] To a suspension of an amino acid (25 g) in ethyl acetate (300 m*l*) was added the appropriate equiv. of dichloroacetyl chloride, and the mixture was refluxed for 30 min in the case of DL-valine, L-leucine and DL-isoleucine, or for 1 hr in the case of DL-phenylalanine and L-tyrosine. After the removal of the insoluble substance, the resultant solution was concentrated and the residue was treated with a small amount of ether in the case of DL-valine, DL-isoleucine, DL-phenylalanine and L-tyrosine, or with a small amount of carbon tetrachloride in the case of L-leucine: thereby the dichloroacetyl amino acid separated as a crystalline product, which was collected and washed with the same solvent as that of the filtrate.[13)] The product was characterized by the melting point[5,9)] and the infrared spectrum, which exhibited four characteristic sharp bands at 3300—3250, 1730—1715, 1680—1660 and 1560 cm^{-1}. The yields were summarized in Table 1.

The combined filtrate and washing were concentrated to yield *N*-(chloroacetyl)dehydroamino acid in the yield shown in Table 1. The product was characterized by comparison (mp and infrared spectrum) with a sample obtained by the method described below, except *N*-(chloroacetyl)dehydrotyrosine.

B) Reaction in Aqueous Sodium Hydroxide. The procedure was modified from the method for the preparation of *N*-dichloroacetyl-DL-phenylalanine described by Sheehan and Duggins.[5)] To a solution of an amino acid (0.2 mol) in 1 N sodium hydroxide (200 m*l*) were added dropwise, with stirring, dichloroacetyl chloride (30 g) and 1 N sodium hydroxide (210 m*l*) below 0°C. After the additions had been completed, the mixture was stirred for several hr, while being allowed to warm to room temperature. The insoluble substance was removed and the filtrate was acidified to pH 1 with concentrated hydrochloric acid. The crystalline solid was collected, dissolved in ethyl acetate and dried over anhydrous sodium sulfate. Evaporation of the ethyl acetate afforded the *N*-dichloroacetyl amino acid[13)] in the yield shown in Table 1. In the case of L-tyrosine, analogous directions were followed to the procedure for the preparation of *N*-chloroacetyl-L-tyrosine described by Fisher.[14)]

4-Isopropylidene-2-chloromethyl-5-oxazolone (IVa). A suspension of *N*-dichloroacetyl-DL-valine (11.7 g) in acetic anhydride (35 m*l*) was heated at 95—105°C for 1 hr. The resultant red-brown solution was concentrated and the residual oil was distilled to give a pale yellow oil (6.9 g, 78%), bp 93—103°C/2 mmHg.[13)] A colorless fraction, bp 103.5°C/2.5 mmHg, obtained from the redistillation was submitted to analysis.[15)] IR (liquid film): 1800, 1670, 1615 cm^{-1}. NMR ($CDCl_3$): τ 5.65 (s, 2H), 7.62 (s, 3H), 7.71 (s, 3H).

Found: C, 47.50; H, 4.36; N, 7.76%. Calcd for $C_7H_8NO_2Cl$: C, 48.41; H, 4.61; N, 8.07%.

4-Isobutylidene-2-chloromethyl-5-oxazolone (IVb). In a manner analogous to the case of IVa, dichloroacetyl-L-leucine (10 g) was treated with acetic anhydride (60 m*l*) at 85—90°C for 1 hr to give a pale yellow oil (5.7 g, 74%), bp 90—102°C/3 mmHg.[13)] A colorless fraction, bp 90°C/1 mmHg, obtained from the redistillation was submitted to analysis. The spectra data were described in the text.

Found: C, 50.97; H, 5.54; N, 7.66%. Calcd for $C_8H_{10}NO_2Cl$: C, 51.20; H, 5.33; N, 7.47%.

4-*s*-Butylidene-2-chloromethyl-5-oxazolone (IVc). In a manner analogous to the case of IVa, *N*-dichloroacetyl-DL-isoleucine (17 g) was treated with acetic anhydride (30 m*l*) at 115—125°C for 1—1.5 hr to

10) All concentrations and evaporations were carried out by rotary evaporation under reduced pressure. All melting points were determined in a liquid bath, and those and boiling points are uncorrected.

11) H. H. Boshard, R. Mory and H. Zollinger, *Helv. Chim. Acta*, **42**, 1653 (1959).

12) H. C. Brown, *J. Am. Chem. Soc.*, **60**, 1326 (1938).

13) The product was sufficiently pure to be used for a next reaction without further purification.

14) E. Fisher, *Chem. Ber.*, **37**, 2494 (1904).

15) The analytical results were outside the generally accepted limits for C and H, possibly owing that the oxazolone IVa is too sensitive towards atmospheric moisture to be microanalyzed. But the formation was characterized by the spectral data and by the conversion to *N*-(chloroacetyl)dehydrovaline (Va).

give a pale yellow oil (8.9 g, 67%), bp 90—102.5°C/0.8 mmHg.[13] A colorless fraction, bp 113—115°C/3.5 mmHg, obtained from the redistillation was submitted to analysis. IR (liquid film): 1800, 1670, 1615 cm^{-1}.

Found: C, 50.83; H, 5.02; N, 7.84%. Calcd for $C_8H_{10}NO_2Cl$: C, 51.20; H, 5.33; N, 7.47%.

4-Benzylidene-2-chloromethyl-5-oxazolone (IVd). A mixture of *N*-dichloroacetyl-DL-phenylalanine (18.5 g) and acetic anhydride (80 m*l*) was heated at 130°C for 1 hr. The resultant red-brown solution was concentrated and the crystalline residue was treated with methanol (20 m*l*). The collected yellow product was washed twice with methanol (4 m*l*×2). Yield: 8.9 g (61%).[13] A part of the product was recrystallized from ethanol to give yellow plates, mp 109—110°C (lit.[4] mp 114°C). IR: 1785, 1660, 1605 cm^{-1}. NMR ($CDCl_3$): τ 2.0 and 2.7 (m, 6H), 5.65 (s, 2H).

4-(*p*-Acetoxybenzylidene)-2-chloromethyl-5-oxazolone (IVf). In a manner analogous to the case of IVd, *N*-dichloroacetyl-L-tyrosine (5.2 g) was treated with acetic anhydride (20 m*l*) at 105—115°C for 1 hr to give IVf as yellow crystals (3.9 g, 78%). Recrystallization from carbon tetrachloride afforded orange crystals, mp 123.5°C (after sintered at 110°C). IR (KBr): 1790, 1760, 1655, 1605 cm^{-1}.

Found: C, 55.57; H, 3.27; N, 4.95%. Calcd for $C_{13}H_{10}NO_4Cl$: C, 55.81; H, 3.58; N, 5.01%.

The oxazolone IVf is soluble easily in ethyl acetate and tetrahydrofuran, moderately in carbon tetrachloride and slightly in water, ether, benzene and ethanol.

2-(2-Chloroacetamido)-3-methylcrotonic Acid (*N*-(Chloroacetyl)dehydrovaline, Va). A mixture of IVa (7.7 g) and water (15 m*l*) was left to stand at room temperature overnight: thereby the oily oxazolone had been hydrolyzed to give Va as a crystalline solid. The crystals were collected (6.5 g), and the filtrate was concentrated to give additional crystals (0.3 g). Total yield was 6.8 g, 80%.[13] An analytical sample was obtained by recrystallization from acetone, as colorless needles, mp 166—166.5°C (decomp.). IR (KBr): 3250, 1690, 1670, 1640, 1530 cm^{-1}.

Found: C, 44.00; H, 5.32; N, 7.28%. Calcd for $C_7H_{10}NO_3Cl$: C, 43.86; H, 5.22; N, 7.31%.

The acid Va is soluble easily in tetrahydrofuran, ethanol and acetone, moderately in hot acetonitrile, hot ethyl acetate and hot water, and slightly in ether, carbon tetrachloride and benzene.

2-(2-Chloroacetamido)-4-methyl-2-pentenoic Acid (*N*-(Chloroacetyl)dehydroleucine, Vb). The same directions were followed as for Va. From IVb (6.2 g) and water (10 m*l*) there was obtained Vb (5.7 g, 83%). Recrystallization from water afforded colorless needles, mp 128—129°C (decomp.). IR (KBr): 3250, 1695, 1670, 1625, 1525 cm^{-1}.

Found: C, 46.34; H, 5.84; N, 6.61%. Calcd for $C_8H_{12}NO_3Cl$: C, 46.72; H, 5.84; N, 6.81%.

2-(2-Chloroacetamido)-3-methyl-2-pentenoic Acid (*N*-(Chloroacetyl)dehydroisoleucine, Vc). The same directions were followed as for Va. From IVc (5.1 g) and water (15 m*l*) there was obtained Vc (4.1 g, 73%). Recrystallization from ethyl acetate afforded colorless needles, mp 149.5—150°C (decomp.). IR (KBr): 3250, 1690, 1675, 1630, 1530 cm^{-1}.

Found: C, 46.75; H, 5.67; N, 6.82%. Calcd for $C_8H_{12}NO_3Cl$: C, 46.72; H, 5.84; N, 6.81%.

α-(2-Chloroacetamido)cinnamic Acid (*N*-(Chloroacetyl)dehydrophenylalanine, Vd). A solution of IVd (8.86 g) and water (10 m*l*) in tetrahydrofuran (120 m*l*) was refluxed for 3 hr and then left to stand at room temperature overnight. The tetrahydrofuran was evaporated and the residue was treated with ether (50 m*l*) to give an almost colorless crystalline product (8.15 g, 86%).[13] Recrystallization from isopropyl alcohol afforded colorless needles, mp 194—195°C (decomp.) (lit. mp 204.5—206°C,[5] 207°C[4]). IR (KBr): 3250, 1690, 1665, 1635, 1525 cm^{-1}. NMR (CF_3COOH): τ1.35 (s, 1NH), 2.11 (s, 1H), 2.54 (m, 5H), 5.71 (s, 2H).

α-(2-Chloroacetamido)-*p*-hydroxycinnamic Acid (*N*-(Chloroacetyl)dehydrotyrosine, Ve). This compound was obtained from the reaction of DL-tyrosine with dichloroacetyl chloride in ethyl acetate, as described above. Recrystallization from acetonitrile afforded pale yellow needles, mp 185°C (decomp.). IR (KBr): 3375, 3200, 1675 (broad), 1635, 1515 cm^{-1}.

Found: C, 51.82; H, 3.74; N, 5.75%. Calcd for $C_{11}H_{10}NO_4Cl$: C, 51.66; H, 3.91; N, 5.48%.

The acid Ve is soluble easily in tetrahydrofuran, ethanol, hot acetonitrile and hot water, and slightly in ethyl acetate and ether.

4-Methyl-2-(2-piperidinoacetamido)-2-pentenoic Acid Hydrochloride. Colorless needles (from ethyl acetate), mp 110—111°C.

Found: C, 53.72; H, 7.96; N, 9.79%. Calcd for $C_{13}H_{23}N_2O_3Cl$: C, 53.70; H, 7.92; N, 9.64%.

4-Methyl-2-[2-(1-ethoxycarbonyl-3-methylbutylamino)acetamido]-2-pentenoic Acid Hydrochloride. Colorless plates (from ethyl acetate), mp 134—135°C.

Found: C, 53.06; H, 8.09; N, 7.57%. Calcd for $C_{16}H_{29}N_2O_5Cl$: C, 52.67; H, 7.96%; N, 7.68%.

[*N*-(1-Carboxy-3-methyl-1-butenyl)carbamoylmethyl]pyridinium Chloride. Colorless crystals (from isopropyl alcohol), mp 222—223°C (decomp.).

Found: C, 55.25; H, 5.90; N, 9.55%. Calcd for $C_{13}H_{17}N_2O_3Cl$: C, 54.83; H, 5.98; N, 9.84%.

Ethyl 2-(2-Chloroacetamido)-3-methylcrotonate (VIa). *A) From IVa.* A solution of IVa (bp 89—98°C/1.5 mmHg, 6.9 g) in ethanol (20 m*l*) was refluxed for 4 hr. After evaporation of the ethanol, the residue was dissolved in ether and washed successively with a small amount of aqueous sodium bicarbonate and with water. The ethereal layer was dried over anhydrous sodium sulfate and evaporated to give the ester, which was treated with *n*-dibutyl ether and collected (1.45 g, 17%, mp 115—116°C). Recrystallization from water-methanol (11 : 9) and then from *n*-dibutyl ether gave colorless long needles, mp 118—119°C. IR (KBr): 3200, 1715, 1665, 1535 cm^{-1}. NMR ($CDCl_3$): τ 2.07 (s, 1H), 5.77 (q, 2H), 5.86 (s, 2H), 7.80 (s, 3H), 8.15 (s, 3H), 8.72 (t, 3H).

Found: C, 49.41; H, 6.24; N, 6.09%. Calcd for $C_9H_{14}NO_3Cl$: C, 49.20; H, 6.38; N, 6.38%.

B) From Va. A mixture of Va (2 g), ethanol (15 m*l*), benzene (20 m*l*), *p*-toluenesulfonic acid (0.5 g) and concentrated sulfuric acid (0.5 g) was refluxed for 5 hr. After concentration of the solution, ether and water were added to the resultant oily residue. The ethereal layer was spearated and the aqueous layer was extracted further twice with ether. The combined extracts were dried over anhydrous sodium sulfate and concentrated to give the ester (0.9 g, 39%), mp 109—

110°C. Recrystallization raised the mp to the value described in A method. The product was identical (mp and infrared spectrum) with the above sample.

Treatment of Vd with Acetic Anhydride. A suspension of Vd (1 g) in acetic anhydride (30 m*l*) was heated at 120—130°C for 1 hr. After concentration of the resultant solution, the crystalline residue was treated with ethanol (10 m*l*) and collected (0.58 g). Recrystallization from ethanol gave pale yellow needles, mp 152.5°C, which was identical in mp and infrared spectrum with authentic 4-benzylidene-2-methyl-5-oxazolone, mp 151—153°C (lit.[6a] mp 151—152°C).

Stereospecific Synthesis of 1,4-Dienes. IV.[1] The Catalytic Behavior of the Ethylenebis(diphenylphosphine) Complex of Iron(0)

Go HATA and Akihisa MIYAKE

Basic Research Laboratories, Toyo Rayon Co., Ltd., Kamakura

(Received May 16, 1968)

A zerovalent iron complex, $Fe(Ph_2P{\cdot}CH_2CH_2{\cdot}PPh_2)_2{\cdot}C_2H_4$, catalyzes addition of ethylene to butadiene to afford 1 : 1 adducts consisting of 1,*cis*-4-hexadiene, 1,3-hexadiene, 2,4-hexadiene and 1,5-hexadiene, and 2 : 1 adducts. The combination of the iron complex and a Lewis acid (triethylaluminum, diethylaluminum chloride, ethylaluminum dichloride and boron trifluoride etherate) gives 1,*cis*-4-hexadiene much more selectively. The most efficient Lewis acid component for the synthesis of 1,*cis*-4-hexadiene is diethylaluminum chloride.

There are several reports on the preparation of 1,4-dienes by addition of ethylene to 1,3-dienes using the iron-based catalysts.[2-5] The binary system consisting of iron(III) acetylacetonate and triethylaluminum[2], and the ternary system consisting of ferric chloride, ditertiaryphosphine and an organoaluminum compound[3] were reported to catalyze the reaction of ethylene with butadiene to afford 1,4-hexadiene.

In connection with investigation of the reducing property of the organoaluminum compounds in these catalyst systems, the reaction of iron(III) acetylacetonate with ethoxydiethylaluminum was carried out in the presence of ethylenebis(diphenylphosphine), and a zerovalent iron complex, $Fe(Ph_2P{\cdot}CH_2CH_2{\cdot}PPh_2)_2{\cdot}C_2H_4$, was isolated.[6] This fact suggests that one of the functions of the organoaluminum compounds in the catalyst systems is the reduction of the iron compounds to a zerovalent iron complex. It has been confirmed that this diphosphine complex catalyzed the reaction of butadiene with ethylene. This work was undertaken to study the catalytic behavior of the diphosphine complex in this reaction.

Results and Discussion

The diphosphine complex, $Fe(Ph_2P{\cdot}CH_2CH_2{\cdot}PPh_2)_2{\cdot}C_2H_4$ (hereafter the iron complex), was found to catalyze addition of ethylene to butadiene to afford 1 : 1 adducts consisting of 1,*cis*-4-hexadiene, 1,3-hexadiene, 2,4-hexadiene and 1,5-hexadiene, and 2 : 1 adducts. The 2 : 1 adducts were major products. The reaction was carried out at 85°C under ethylene pressure of 40 kg/cm^2. The result is shown in Table 1. 1,5-Hexadiene and the 2 : 1 adducts were not obtained in the iron(III) acetylacetonate-triethylaluminum catalyzed reaction.[2] The former compound was identified by comparison of its infrared spectrum and gas chromatographic retention time with those of an authentic sample. The gas chromatographic analysis of the 2 : 1 adducts using a squalane capillary column (90 m) showed that they contained four components. The molecular weights of these components were determined by mass spectroscopy to be 110 (C_8H_{14}). However, separation of these four components by preparative gas chromatography using a squalane column was unsuccessful, and hence further characterization of the adducts was not possible.

Addition of a Lewis acid to the iron complex changed remarkably the distribution of the products. The results are summarized in Tables 1

8	$BF_3\cdot O(C_2H_5)_2$	(1)	80	100	1.2	0.3

Reaction conditions: $Fe(Ph_2P\cdot CH_2CH_2CH_2\cdot PPh_2)\cdot C_2H_4$ 0.5 mmol, butadiene 0.3 mol, toluene 10 m*l*, ethylene 40 kg/cm².

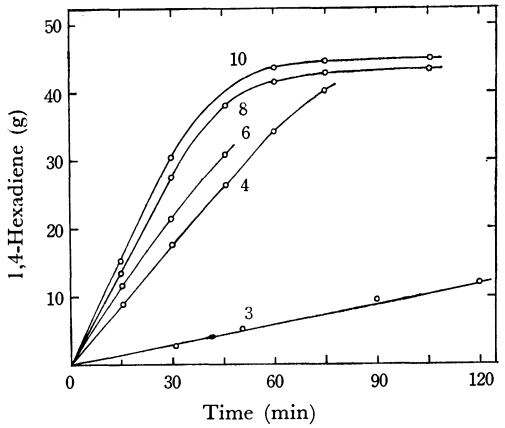

Fig. 1. Reaction of butadiene with ethylene. Reaction conditions: $Fe(Ph_2P\cdot CH_2CH_2\cdot PPh_2)_2\cdot C_2H_4$ 0.5 mmol, toluene 20 m*l*, C_4H_6 0.6 mol, C_2H_4 40 kg/cm², 50°C. The numbers in the table show molar ratios of $(C_2H_5)_2AlCl$ to the iron complex.

and 2. The combination of the iron complex and diethylaluminum chloride catalyzed the reaction of butadiene with ethylene to give 1,*cis*-4-hexadiene in high yield (95%). This reaction occurred at 30°C and proceeded very rapidly at 80°C (Table 2). The effect of the molar ratio of the catalyst components on the catalytic activity is shown in Fig. 1. At the molar ratios larger than 3, the reaction proceeded quickly. The catalyst system containing ethylaluminum dichloride and boron trifluoride etherate also afforded the 1,4-diene selectively. However, these Lewis acids were not so effective components, as compared with diethylaluminum chloride, because of decomposition of the catalyst during the reaction. The decomposition of the catalyst containing ethylaluminum dichloride occurs at the early stage of the reaction. When the reaction was conducted under the same conditions as listed in Run No. 7 of Table 2 except stirring for 20 min before introduction of ethylene (40 kg/cm²), this system showed a quite low activity and only 0.2 g of 1,4-hexadiene was obtained. Almost all of the employed butadiene was recovered. This observation indicates that the catalyst decomposed during the stirring for 20 min. In contrast to these catalyst systems, the system containing triethylaluminum as a Lewis acid component gave the same products as obtained in the reaction catalyzed by the iron complex alone. However, the distribution of the products was different and the formation of 1,*cis*-4-hexadiene increased. The molar ratio of triethylaluminum to the iron complex affected the distribution of the products as shown in Table 1. At a high molar ratio, the behavior of the catalyst resembled that of the combination of the iron complex and diethylaluminum chloride, and the major product was 1,*cis*-4-hexadiene.

The function of the Lewis acids in these catalyst systems is presumably the removal of the coordinated diphosphine from the iron complex to leave a coordination site for butadiene. The stronger Lewis acid should accomplish this removal more effectively. In fact, diethylaluminum chloride is much more effective than triethylaluminum as a catalyst component for the selective synthesis of 1,*cis*-4-hexadiene. The former aluminum compound is a stronger Lewis acid than the latter. Lewis acidity of organoaluminum compounds toward a Lewis base is correlated to the complex formation between both compounds. The easiness of the

complex formation of organoaluminum compounds with a Lewis base is in the following order: $C_2H_5AlCl_2 > (C_2H_5)_2AlCl > (C_2H_5)_3Al > (C_2H_5)_2AlOC_2H_5$.[7] Although ethylaluminum dichloride, the strongest Lewis acid, decomposes the catalyst during the reaction, this organoaluminum compound is more effective than diethylaluminum chloride at the low molar ratio (2 : 1) of the Lewis acid to the iron complex.

The catalyst system consisting of the iron complex and diethylaluminum chloride affords 1,4-hexadiene in a high selectivity as compared with the iron(III) acetylacetonate-triethylaluminum catalyst system.[2] This fact suggests the coordination of one molecule of the diphosphine in the catalyst species, which would interrupt coordination of another molecule of butadiene and suppress oligomerization of butadiene.[8]

The formation of 1,4-hexadiene occurs through transfer of a hydrogen atom of ethylene to butadiene. The mechanism of the hydrogen transfer, however, is not clear.

The mixture of iron(III) acetylacetonate, ethylenebis(diphenylphosphine) and diethylaluminum chloride showed the same catalytic activity as that of the iron complex and diethylaluminum chloride, and gave 1,*cis*-4-hexadiene in 91% yield. This fact indicates that diethylaluminum chloride in the former system acts as a reducing agent as well as a Lewis acid.

The reaction of isoprene with ethylene by the ternary system gave a mixture of 4-methyl- and 5-methyl-1,4-hexadiene in 92% yield. The ratio of the former diene to the latter was 75 : 25 (at 70°C). 1,3-Pentadiene reacted with ethylene to afford 3-methyl-1,*cis*-4-hexadiene and 1,*cis*-4-heptadiene in a ratio of 85 : 15. The preferential addition of ethylene occurs at the methyl substituted side, and this is the characteristic of the reaction by the iron(III) acetylacetonate-triethylaluminum catalyst system.[2] In the reaction catalyzed by the latter system, the above ratios were 57 : 43 and 70 : 30 at 30°C, respectively.

Experimental

Reaction of Butadiene with Ethylene. (1) A 100 m*l* autoclave was flashed with ethylene and then charged with liquid butadiene, a toluene solution of the complex, $Fe(Ph_2PCH_2CH_2PPh_2)_2 \cdot C_2H_4$, which was prepared by the method described previously,[6] and a toluene solution of the Lewis acid. The resultant solution was stirred under ethylene pressure of 40 kg/cm^2. 1,*cis*-4-Hexadiene, 1,3-hexadiene and 1,5-hexadiene were separated by preparative gas chromatography and identified by comparison of their infrared spectra and gas chromatographic retention times with those of authentic samples. 2,4-Hexadiene was characterized by gas chromatographic analysis. The C_8 hydrocarbons were separated by gas chromatography on a squalane capillary column (90 m) at 40°C into four components, which were analyzed by mass spectroscopy. All of their spectra showed parent peaks at $m/e=110$ (C_8H_{14}).

(2) A mixture of 15 m*l* of toluene, 0.3 mol of butadiene, 0.177 g (0.5 mmol) of iron(III) acetylacetonate, 0.478 g (1.2 mmol) of ethylenebis(diphenylphosphine) and 8 mmol of diethylaluminum chloride was stirred at 80°C under ethylene pressure of 40 kg/cm^2 for 30 min. The yield of 1,*cis*-4-hexadiene was 22.5 g (91%).

Reaction of Isoprene with Ethylene. A 100 m*l* autoclave was charged with 21.0 g (0.3 mol) of isoprene, 20 m*l* of xylene, 0.177 g (0.5 mmol) of iron(III) acetylacetonate, 0.478 g (1.2 mmol) of ethylenebis(diphenylphosphine) and 8 mmol of diethylaluminum chloride. The resultant mixture was stirred at 70°C under ethylene pressure of 40 kg/cm^2 for 2 hr. Gas chromatographic analysis showed that the reaction mixture contained 26.6 g (92% yield) of a mixture of 4-methyl-1,*cis*-4-hexadiene and 5-methyl-1,4-hexadiene.[2] The ratio of the products was determined by gas chromatography using a silver nitrate-benzyl cyanide column.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2765—2769 (1968)

Studies of Aminosugars. XIX. Syntheses of O-Benzyl-α-halogeno Derivatives of 3-Acetamido-3-deoxy- and 6-Acetamido-6-deoxy-D-glucose[1]

Shinkiti KOTO, Takayuki TSUMURA, Yoshinori KATO and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May, 23, 1968)

As a part of investigation of the synthesis and reaction of 1-halogeno derivatives of amino-monosaccharides, 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride and 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranosyl chloride have been synthesized. Attempts to prepare α-glycosides from these benzyl derivatives proved to be practical, giving cyclohexyl 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranoside and cyclohexyl 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranoside as main products. Removal of the masking groups gave cyclohexyl α-glucosides of 3-amino-3-deoxy-D- and 6-amino-6-deoxy-D-glucose respectively. A number of related derivatives have been described.

1-Halogeno derivatives of masked monosaccharides are important intermediates for the synthesis of glycosides. However, the corresponding derivatives of aminosugars represents a relatively unexplored territory. In the preceding papers,[2,3] the syntheses of α-acetobromo and β-acetochloro derivatives of 3-carbobenzoxyamino-3-deoxy- and 6-carbobenzoxyamino-6-deoxy-D-glucose have been developed. This paper reports the syntheses of 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucosyl chloride (IV) and 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranosyl chloride (XII). These *O*-benzyl-α-chloro derivatives have been found to be useful for preparing α-glycosides of the aminosugars, as shown here in the preparation of cyclohexyl 3-amino-3-deoxy-α-D-glucoside (VII) and cyclohexyl 6-amino-6-deoxy-α-D-glucoside (XV).

Benzylation of methyl 3-acetamido-3-deoxy-β-D-glucopyranoside[4] with benzyl bromide in the presence of barium oxide and barium hydroxide in *N,N*-dimethylformamide (DMF) gave methyl 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-β-D-glucopyranoside (II) in a 95% yield.

Hydrolysis of II with sulfuric acid in aqueous acetic acid followed by acetylation with acetic anhydride in pyridine gave 3-acetamido-1-*O*-acetyl-2,4,6-tri-*O*-benzyl-α- and β-D-glucopyranose

VIb R^1=Ac, R^2=R^4=H, R^3=OC_6H_{11}

VII R^1=H_2Cl, R^2=R^3=H, R^4=OC_6H_{11}

(IIIa and IIIb) which were separated by fractional crystallization from isopropanol and isopropyl ether, the ratio of α- to β-anomer being 1 : 1.

Chlorination of the α-anomer (IIIa) or β-anomer (IIIb) with dry hydrogen chloride in dioxane containing acetyl chloride gave 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride (IV) in quantitative yield.

On the other hand, the *O*-benzyl-α-chloro derivative of 6-amino-6-deoxy-D-glucose has been synthesized by an analogous route. Methyl 6-acetamido-6-deoxy-α-D-glucopyranoside[5] (VIII) was benzylated with benzyl chloride and sodium

hydride to give methyl 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranoside (IX) in a 83% yield. It should be noted that the primary acetamido group of VIII is further benzylated. Hydrolysis of IX with sulfuric acid in aqueous acetic acid gave 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-β-D-glucopyranose (X) in a 75% yield, which was converted to its acetate (XI). The acetate was chlorinated in like manner as described in the preparation of IV to give 2,3,4-tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-glucopyranosyl chloride (XII) in a 95% yield.

Infrared spectra of the above-mentioned 1-chloro derivatives (IV and XII) of two kinds of aminomonosaccharides showed absorption near 850 cm^{-1} which is characteristic of α-configuration.

Attempts to prepare α-glycosides from IV and XII proved to be practical. When shaken with a mixture of cyclohexanol, mercuric cyanide and mercuric bromide in nitromethane, IV gave cyclohexyl 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D- and β-D-glucopyranoside (Va and Vb), the ratio of α- to β-anomer being 7 : 11. The similar glycosidation of XII gave cyclohexyl 2,3,4-tri-*O*-benzyl-6-(*N*-benzyl-acetamido)-6-deoxy-α-D- and β-D-glucopyranoside (XIIIa and XIIIb), the ratio of α- to β-anomer being about 47 : 5.

Hydrogenolysis over palladium black in methanol smoothly debenzylated Va and Vb to form cyclohexyl 3-acetamido-3-deoxy-α-D- and β-D-glucoside (VIa and VIb) respectively. Similar hydrogenolysis of XIIIa and XIIIb followed by de-*N*-benzylation with sodium in liquid ammonia gave cyclohexyl 6-acetamido-6-deoxy-α-D- and β-D-glucopyranoside (XIVa and XIVb) respectively.

Finally, treatment with hydrazine hydrate de-*N*-acetylated VIa and XIVa to form cyclohexyl 3-amino-3-deoxy-α-D-glucoside and cyclohexyl 6-amino-6-deoxy-α-D-glucoside, which were led to crystalline hydrochlorides (VII and XV) respectively.

Experimental

General Procedures. Thin layer chromatography (TLC) was performed on "Silica-Reider for TLC" (Dai-ich Pure Chemicals Co.). Paper chromatography was carried out on Toyo filter paper No. 51, using a solvent system of *n*-butanol, pyridine, water and acetic acid (6 : 4 : 3 : 1), ninhydrin in pyridine (0.3%) being sprayed on.

Methyl 3-Acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-β-D-glucopyranoside (II). A mixture of methyl 3-acetamido-3-deoxy-β-D-glucopyranoside (I) (5 g), benzyl bromide (50 m*l*), powdery barium oxide (37 g) and finely crushed barium hydroxide octahydrate (17 g) in DMF (100 m*l*) was vigorously stirred at about 0°C for 4 hr and then at room temperature overnight. The reaction mixture diluted with chloroform (250 m*l*) was filtered and the filtrate was dried up under reduced pressure at 60°C to afford a yellow sirup, which was extracted with ethyl acetate (200 m*l*). Evaporation of the extract, followed by treatment with cyclohexane afforded colorless crystals of II; yield, 10.2 g (95%). Recrystallized from isopropanol; mp 163—164°C, $[\alpha]_D^{18}$ +24° (*c* 1.0, chloroform), ε_{258}^{MeOH}=544 (calcd, 558), IR spectrum (KBr): 3290, 1653 and 1576 (NHAc), 1068, 747, 737 and 695 (*O*-benzyl), 907 cm^{-1} (type 2b of pyranose ring.)

Found: C, 70.88; H, 6.63; N, 2.86%. Calcd for $C_{30}H_{35}NO_6$: C, 71.27; H, 6.98; N, 2.77%.

3-Acetamido-1-*O*-acetyl-2,4,6-tri-*O*-benzyl-α- and β-D-glucopyranose (IIIa and IIIb). A mixture of II (13 g), glacial acetic acid (240 m*l*) and 2 N sulfuric acid (63 m*l*) was heated over a boiling water bath for 2 hr. To the resulting mixture was added 2 N sulfuric acid (51 m*l*) and the mixture was further heated for 13 hr. The mixture was poured into a large amount of water to give a colorless precipitate, which was collected and washed thoroughly with water; yield 9.0 g.

The hydrolysis product (8.2 g) was acetylated with acetic anhydride (50 m*l*) and pyridine (50 m*l*) at room temperature overnight. After evaporation the residue was crystallized with isopropanol to afford IIIb; 3.8 g (43%), mp 183—184°C, $[\alpha]_D^{21}$ + 8.1° (*c* 2.6, chloroform), ε_{258}^{MeOH}=534 (calcd, 558), IR spectrum (KBr): 3310, 1659 and 1552 (NHAc), 1744 and 1237 (OAc), 1102, 743 and 697 (*O*-benzyl), 892 cm^{-1} (type 2b of pyranose ring).

Found: C, 69.95; H, 6.74; N, 2.85%. Calcd for $C_{31}H_{35}NO_7$: C, 69.78; H, 6.61; N, 2.63%.

Mother liquor was concentrated and crystallized by treatment with isopropyl ether to give 3.8 g of α-isomer (43%); mp 135—136°C, $[\alpha]_D^{21}$ +62° (*c* 2.2, chloroform), ε_{258}^{MeOH}=549 (calcd, 558), IR spectrum (KBr): 3275, 1658 and 1550 (NHAc), 1757 and 1238 (OAc), 1101, 748 and 697 (*O*-benzyl), 855 cm^{-1} (type 2a of pyranose ring).

Found: C, 69.92; H, 6.67; N, 2.27%. Calcd for $C_{31}H_{35}NO_7$: C, 69.78; H, 6.61; N, 2.63%.

3-Acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl Chloride (IV). To a solution of IIIa (0.5 g) in dioxane (25 m*l*) containing dry hydrogen

chloride (4%) was added acetyl chloride (13 ml) and the mixture was kept standing at 37°C overnight in a tightly stoppered flask. After evaporation at 20°C under reduced pressure, the resulting sirup was subjected repeatedly to co-distillation with absolute toluene *in vacuo* to be freed from hydrogen chloride to give a powdery solid, which was treated with dry petroleum ether to afford the chloride IV; 0.49 g (98%), mp 143—144°C (decomp.), $[\alpha]_D^{23}$ +78° (*c* 0.7, chloroform), $\varepsilon_{258}^{AcOEt}$=530 (calcd, 558), IR spectrum (KBr): 3280, 1655 and 1550 (NHAc), 738 (C-Cl), 696 (phenyl), 856 cm^{-1} (type 2a of pyranose ring). The C=O stretching absorption of acetoxy group in IIIa completely disappeared.

Found: C, 68.01; H, 6.54; N, 2.69; Cl, 7.35%. Calcd for $C_{29}H_{32}NO_5Cl$: C, 68.30; H, 6.32; N, 2.75; Cl, 6.96%.

IIIb also gave quantitatively IV by the above-mentioned chlorination, the result being examined by TLC using a solvent system of toluene and MEK (3 : 1).

Cyclohexyl 3-Acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α- and β-D-glucopyranoside (Va and Vb). A mixture of IV (0.5 g), cyclohexanol (1.3 g), well pulverized mercuric cyanide (0.25 g) and mercuric bromide (0.35 g) in absolute nitromethane (5 ml) was shaken at 27°C for three days under anhydrous conditions. After removal of insoluble matters, the mixture was diluted with chloroform (15 ml) and washed with several 20 ml portions of 20% aqueous potassium bromide and successively twice with 20 ml portions of water. After being dried over anhydrous sodium sulfate, the solution was evaporated to dryness to give sirup, which was subjected to fractional crystallization from isopropanol. First, Va deposited and was recrystallized from isopropanol; 0.16 g (28%), mp 135—136°C, $[\alpha]_D^{28}$ +88°C (*c* 1.0, chloroform), ε_{258}^{MeOH}=539 (calcd, 558), IR spectrum (KBr): 3290, 1652 and 1567 (NHAc), 2925 and 2850 (cyclohexyl), 845 (type 2a of pyranose ring), 735 and 694 cm^{-1} (phenyl).

Found: C, 73.32; H, 7.71; N, 2.57%. Calcd for $C_{35}H_{43}NO_6$: C, 73.27; H, 7.55; N, 2.44%.

From the mother liquor β-isomer (Vb) was obtained after a few days. Recrystallized from isopropanol; yield, 0.25 g (44%), mp 179—180°C, $[\alpha]_D^{28}$ +18° (*c* 1.0, chloroform), ε_{258}^{MeOH}=541 (calcd, 558), IR spectrum (KBr): 3300, 1654 and 1568 (NHAc), 2940 2870 (cyclohexyl), 888 (type 2b of pyranose ring), 733 and 694 cm^{-1} (phenyl).

Found: C, 73.21; H, 7.69; N, 2.42%. Calcd for $C_{35}H_{43}NO_6$: C, 73.27; H, 7.55; N, 2.44%.

Cyclohexyl 3-Acetamido-3-deoxy-α-D-glucopyranoside (VIa). A sample (70 mg) of Va was hydrogenated in methanol (3 ml) containing acetic acid (0.02 ml) over palladium black (50 mg) under 3.5 atm of hydrogen pressure at room temperature. After 5 hr of hydrogenation, the catalyst was filtered off. Evaporation of the filtrate *in vacuo* gave a colorless sirup which was crystallized from acetone; yield, 36 mg (94%), mp 210—211°C, $[\alpha]_D^{23}$ +158° (*c* 1.1, methanol), IR spectrum (KBr): 2925 and 2850 (cyclohexyl), 1658 and 1563 (NHAc), 852 cm^{-1} (type 2a of pyranose ring).

Found: C, 55.64; H, 8.51; N, 4.47%. Calcd for $C_{14}H_{25}NO_6$: C, 55.44; H, 8.31; N, 4.62%.

Cyclohexyl 3-Acetamido-3-deoxy-β-D-glucopyranoside (VIb). A sample of Vb was also hydrogenated to give VIb in like manner as described above; mp 201—202°C, $[\alpha]_D^{23}$ −17°C (*c* 1.3, methanol), IR spectrum (KBr): 2930 and 2855 (cyclohexyl), 1622 and 1565 (NHAc), 888 cm^{-1} (type 2b of pyranose ring).

Found: C, 55.61; H, 8.19; N, 4.58%. Calcd for $C_{14}H_{25}NO_6$: C, 55.44; H, 8.31; N, 4.62%.

Cyclohexyl 3-Amino-3-deoxy-α-D-glucopyranoside Hydrochloride (VII). A sample (36 mg) of VIa was heated with hydrazine hydrate (1.0 ml) in a sealed tube in the boiling water for 16 hr to give a pale brown solution, which was dried up *in vacuo*. The resulting brown sirup was purified on a column of Dowex 1×2 (OH type; 10×50 mm), developing with carbon dioxide-free water. Evaporation of ninhydrin positive fractions afforded a colorless glass, 30 mg, which was took up with a small volume of water and then acidified to pH 2 with 0.1 N hydrochloric acid. After evaporation of excess acid and water, a crystalline residue remained; trituration with acetone; yield, 36 mg (72%), mp 228—230°C (decomp.), $[\alpha]_D^{23}$ +151° (*c* 0.4, water).

Found: C, 48.48; H, 8.26; N, 4.67%. Calcd for $C_{12}H_{24}NO_5Cl$: C, 48.41; H, 8.12; N, 4.71%.

On ascending paper chromatography at room temperature for 16 hr, the R_f value of VII was 0.66. When heated with 3 N hydrochloric acid at 98°C for 3 hr, VII gave 3-amino-3-deoxy-D-glucopyranose being examined by paper chromatography.

Methyl 2,3,4-Tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranoside (IX). A mixture of methyl 6-acetamido-6-deoxy-α-D-glucopyranoside (VIII) (1.0 g, finely powdered), benzyl chloride (20 ml) and sodium hydride (1.0 g) was stirred magnetically under anhydrous conditions for 2—3 hr at 125—130°C. This reaction was exothermic and the mixture became thick and then changed into a thin slurry as the reaction reached completion. Progress of the reaction was followed by TLC and measurement of volume of the evolved hydrogen gas which showed that benzylation was virtually complete after 2 hr. The reaction mixture was passed through a thick bed of Celite and the insoluble matters were washed with a large volume of dry benzene. The combined benzene filtrate and washings were washed with water, dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo* at 90°C to afford a yellow sirup, which was crystallized from *n*-hexane (50 ml); colorless needles, yield, 2.1 g (83%). This product was sufficiently pure for the next preparation as described below. Recrystallization from methanol gave an analytically pure sample; mp 81—83°C, $[\alpha]_D^{25}$ +26°C (*c* 1.0, chloroform), ε_{258}^{MeOH}=760 (calcd, 744), IR spectrum (Nujol): 1637 (NAc), 1090, 733 and 694 cm^{-1} (*O*-benzyl). No absorption appeared in the region of OH or NH stretching.

Found: C, 74.40; H, 6.77; N, 2.53%. Calcd for $C_{37}H_{41}NO_6$: C, 74.60; H. 6.94; N, 2.35%.

2,3,4-Tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-β-D-glucopyranose (X) and Its Acetate (XI). To a solution of IX (5.0 g) in glacial acetic acid (50 ml) and acetic anhydride (8 ml) was added a mixture of concentrated sulfuric acid (1.0 ml) and acetic acid (5.0 ml) at 0°C under stirring in the course of 10 min. The stirring was continued at 0°C for 1 hr under exclusion of moisture and additional 7 hr at 10—20°C. The resulting mixture was poured onto cracked pieces of ice (300 g) under stirring to separate an oily product,

which was extracted with benzene. The benzene solution was neutralized with dilute aqueous sodium bicarbonate (5%) by cautious shaking, washed with water and evaporated to give an oily product, which was not crystallizable. The product was then treated with methanolic sodium methylate (0.003%; 10 ml) at room temperature for 1 hr. After neutralization with acetic acid, the solution was evaporated to fine crystalline X; yield 3.4 g (75%). Recrystallized from methanol; mp 160—161°C, $[\alpha]_D^{18}$ +18° (*c* 1.0, chloroform), ε_{258}^{MeOH} =738 (calcd, 744), IR spectrum (Nujol): The expected absorption of OH stretching was observed at 3190 cm^{-1} and no amido II band appeared; 1624 (NAc), 734 and 696 cm^{-1} (phenyl).

Found: C, 74.51; H, 6.71; N, 2.41%. Calcd for $C_{36}H_{39}NO_6$: C, 74.35; H, 6.76; N, 2.41%.

A sample (10 g) of X was acetylated with acetic anhydride (10 ml) in pyridine (70 ml) at room temperature overnight under exclusion of moisture. The resulting mixture was evaporated to give a sirup which was crystallized with isopropanol. Recrystallized from the same solvent; mp 121—122°C, $[\alpha]_D^{25}$ +12° (*c* 1.0, chloroform), ε_{258}^{MeOH}=726 (calcd, 744), IR spectrum (Nujol): The OH stretching absorption completely disappeared; 1763 and 1240 (OAc), 1658 (NAc), 750, 735 and 701 (phenyl), 917 cm^{-1} (type 2b of pyranose ring).

Found: C, 73.49; H, 6.89; N, 2.39%. Calcd for $C_{38}H_{41}NO_7$: C, 73.17; H, 6.63; N, 2.25%.

2,3,4-Tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α-D-glucopyranosyl Chloride (XII). A solution XI (0.6 g) in a mixture of acetyl chloride (4 ml) and dioxane (23 ml) containing dry hydrogen chloride (4%) was allowed to stand at 37°C overnight in a tightly stoppered flask. After concentration *in vacuo* at 20°C, the resulting product was repeatedly co-distilled with absolute toluene until the product became an amorphous solid. Treatment with dry petroleum ether gave a colorless powder; yield 0.55 g (95%), mp 91—92°C (decomp.), $[\alpha]_D^{23}$ +70° (*c* 1.34, chloroform), $\varepsilon_{258}^{AcOEt}$=738 (calcd, 744), IR spectrum (Nujol): The C-O stretching absorption of OAc was not observed; 1652 (NAc), 845 (broad, type 2a of pyranose ring) and 699 cm^{-1} (phenyl).

Found: C, 71.65; H, 6.24; N, 2.30; Cl 6.51%. Calcd for $C_{36}H_{38}NO_5Cl$: C, 72.06; H, 6.38; N, 2.33; Cl, 5.92%.

Cyclohexyl 2,3,4-Tri-*O*-benzyl-6-(*N*-benzylacetamido)-6-deoxy-α- and β-D-glucopyranoside (XIIIa and XIIIb). A mixture of XII (0.50 g), cyclohexanol (0.25 ml), finely powdered mercuric cyanide (0.20 g) and mercuric bromide (0.23 g) in absolute nitromethane (5 ml) was shaken at 27°C for 48 hr under anhydrous conditions. The resulting pale yellow mixture was filtered and the filtrate was diluted with a large volume of chloroform. The solution was washed with three 20 ml portions of 20% aqueous potassium bromide and successively with three 20 ml portions of water. After drying over anhydrous sodium sulfate, the solution was evaporated *in vacuo* to give an oily product. TLC using a solvent system of toluene and MEK (3 : 1) showed that the product mainly consisted of two substances of R_f values 0.70 (main) and 0.65. The product was chromatographed on a silicagel column (50g) with the same solvent system to separate into the two substances; the former with R_f value 0.70 weighed 0.32 g (47%) and the latter with R_f value 0.65 was 0.04 g (5%). The analytical sample of the main product XIIIa was prepared by chromatography on a small silica-gel column; $[\alpha]_D^{22}$ +43° (*c* 1.7, chloroform), ε_{258}^{MeOH}=765 (calcd, 744), IR spectrum (KBr): 2940 (cyclohexyl), 1650 (NAc), 850 (type 2a of pyranose ring) and 696 cm^{-1} (phenyl).

Found: C, 75.76; H, 7.60; N, 2.41%. Calcd for $C_{42}H_{49}NO_6$: C, 75.99; H, 7.44; N, 2.11%.

The minor product XIIIb crystallized from methanol; mp 143.5—144.5°C, $[\alpha]_D^{27}$ +29 (*c* 1.0, chloroform), ε_{258}^{MeOH}=738 (calcd, 744); IR spectrum (KBr): 2940 (cyclohexyl), 1650 (NAc), 912 (type 2b of pyranose ring) and 695 cm^{-1} (phenyl).

Found: C, 76.46; H, 8.06; N, 2.45%. Calcd for $C_{42}H_{49}NO_6$: C, 75.99; H, 7.44; N, 2.11%.

Cyclohexyl 6-Acetamido-6-deoxy-α-D-glucopyranoside (XIVa). A sample (0.12 g) of XIIIa was hydrogenated over palladium black (0.01 g) in methanol containing a few drops of acetic acid at room temperature under 3.5 atm of hydrogen pressure for 5 hr. After removal of the catalyst, the solution was evaporated to give a sirup, which was dissolved in liquid ammonia (30 ml) and reduced by additions of several pieces of sodium until the developed blue color maintained for 15 min. After quenching the reaction with ammonium chloride (0.2 g), excess ammonia was removed by evaporation and the residue was took up in water. The solution was successively passed through a column of Amberlite IRA-410 (OH type; 5 ml) and Amberlite IR-120 (H type; 3 ml). The deionized solution was evaporated to give a colorless crystalline residue, which was further treated with acetone; yield 0.03 g (53%), mp 113—114°C, $[\alpha]_D^{23}$ +138° (*c* 1.2, methanol), IR spectrum (KBr): 1645 and 1570 (NHAc), 2935 (cyclohexyl), and 846 cm^{-1} (type 2a of pyranose ring).

Found: C, 54.81; H, 8.27; N, 4.55%. Calcd for $C_{14}H_{25}NO_6$: C, 55.43; H, 8.31; N, 4.62%.

Cyclohexyl 6-Acetamido-6-deoxy-β-D-glucopyranoside (XIVb). A sample (20 mg) of XIIIb was hydrogenated over palladium black (5 mg) in methanol containing a few drops of acetic acid at 40—45°C for 4 hr under 3.5 atm of hydrogen pressure to de-*O*-benzylate. The catalyst was filtered off and the solution was evaporated. An oily product was dissolved in liquid ammonia (30 ml) and to the solution was added small pieces of sodium until the blue color survived for 15 min. To the solution was added an excess of ammonium chloride (0.3 g) and ammonia was removed by evaporation. The product was deionized in like manner as described in the preparation of XIVa to give a colorless crystalline residue which was crystallized from acetone; yield 4.5 mg (47%), mp 163—164°C, $[\alpha]_D^{23}$ +1.5° (*c* 0.3, methanol), IR spectrum (KBr): 2850 (cyclohexyl), 1650 and 1550 (NHAc), and 893 cm^{-1} (type 2b of pyranose ring).

Found: C, 55.12; H, 8.23; N, 4.35%. Calcd for $C_{14}H_{25}NO_6$: C, 55.43; H, 8.31; N, 4.62%.

Cyclohexyl 6-Amino-6-deoxy-α-D-glucopyranoside Hydrochloride (XV). XIVa (18 mg) was heated with hydrazine hydrate (80%; 1 ml) in a sealed tube in the boiling water for 20 hr to give a pale brown solution, which was evaporated *in vacuo* at 60°C. The resulting brown sirup was purified on a column of Dowex 1×2 (OH type; 20 ml), irrigating with distilled

water. The ninhydrin-positive fractions were evaporated *in vacuo* to give a colorless glass of XV. The free base was dissolved in a small volume of water and acidified with 0.1 N hydrochloric acid to pH 4. After evaporation of excess acid and water, a crystalline residue was obtained which was treated with acetone; yield 13 mg (75%), mp 184—185°C (decomp.), $[\alpha]_D^{23}$ +120° (*c* 0.4, water).

Found: C, 48.24; H, 7.82; N, 4.84%. Calcd for $C_{12}H_{24}NO_5Cl$: C, 48.41; H, 8.12; N, 4.71%.

On the ascending paper chromatography at room temperature for 16 hr, the R_f value of XV was 0.55. When heated with 3 N hydrochloric acid at 95—98°C for 3 hr, XV afforded 6-amino-6-deoxy-D-glucopyranose, the formation of which was examined by paper chromatography.

The authors are indebted to Mr. Saburo Nakada for his microanalysis, to Mr. Yoshito Koyama for his technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2769—2771 (1968)

Studies of Aminosugars. XX. The Synthesis of 6-O-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine[1]

Shinkiti KOTO, Kuniaki TATSUTA, Eiichi KITAZAWA and Sumio UMEZAWA

(Received June 1, 1968)

6-O-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (3AD) which is a glycoside component of kanamycin A has been synthesized. Amino and hydroxyl groups of 2-deoxystreptamine were masked with carbobenzoxy and isopropylidene groups to give racemic mono-O-isopropylidene-di-N,N'-carbobenzoxy-2-deoxystreptamine, with which 3-acetamido-2,4,6-tri-O-benzyl-3-deoxy-α-D-glucopyranosyl chloride was condensed by a modified Koenigs-Knorr reaction. Removal of all the masking groups followed by N-dinitrophenylation, acetylation and chromatography gave the product identical with an authentic specimen of the penta-O-acetyl-tri-N-(2,4-dinitrophenyl) derivative of the natural 3AD. The synthetic product was further led to 3AD identical with a natural sample.

As a part of the investigation of the synthesis of antibiotic aminoglycosides, we previously reported the syntheses of paromamine,[2] neamine,[3] 5-O-(2-amino-2-deoxy-α-D-glucopyranosyl)-deoxystreptamine,[4] 4,6-di-O-(3-amino-3-deoxy-β-D-glucopyranosyl)-deoxystreptamine,[5] 4,6-di-O-(6-amino-6-deoxy-β-D-glucopyranosyl)-deoxystreptamine,[5] diamino-dideoxy derivative of trehalose,[6] trehalosamine,[7] triamino-trideoxy derivatives of maltose,[6] sucrose[6] and raffinose[8] and hexaamino-hexadeoxy derivative of Schardinger α-dextrin.[8]

In the present paper, the synthesis of 6-O-(3-amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine (IV: abbreviated to 3AD) is described. This is a glycoside component of kanamycin A,[9] an useful antibiotic, and was first isolated by Maeda *et al.*[10] from the hydrolyzate of the antibiotic. Synthesis of this glycoside was undertaken as an approach to the synthesis of kanamycin A which has been briefly communicated.[11]

The key intermediates for the proposed synthesis were the totally O-benzylated derivative of 3-acetamido-3-deoxy-α-D-glucopyranosyl chloride on the one hand, and the monoisopropylidene derivative of N,N'-masked 2-deoxystreptamine on the other hand. A modified Koenigs-Knorr reaction between the two intermediates formed the desired α-glycosidic linkage, though not exclusively.

The preparation of 3-acetamido-2,4,6-tri-O-benzyl-3-deoxy-α-D-glucopyranosyl chloride (I) was

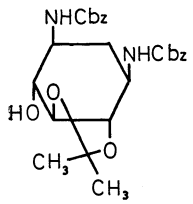
previously reported.[12] Treatment of *N,N'*-dicarbobenzoxy-2-deoxystreptamine[5] with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in *N,N*-dimethylformamide at 110°C gave the monoisopropylidene derivative (II) in racemic form in a quantitative yield.

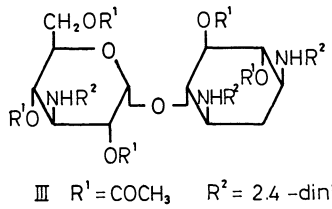
Condensation of I with II in the presence of mercuric cyanide and Drierite in an anhydrous mixture of benzene and dioxane gave a crude product, which was hydrolyzed with 80% acetic acid to remove isopropylidene group and hydrogenated over palladium black to remove benzyl groups. De-*N*-acetylation with barium hydroxide gave a crude ninhydrin-positive product. This was further dinitrophenylated with 2,4-dinitrofluorobenzene and *O*-acetylated. The resulting product showed about five spots including one main (R_f-value 0.3) and four minor spots on a silica-gel thin-layer chromatogram. The product was chromatographed on a silica-gel column and the main fraction was further separated into two fractions (R_f-values 0.30 and 0.28) of nearly equal amounts by preparative thin-layer chromatography. The substance having R_f-value 0.30 was crystallized to give 4,5-di-*O*-acetyl-6-*O*-[2,4,6-tri-*O*-acetyl-3-(2,4-dinitroanilino)-3-deoxy-α-D-glucopyranosyl]-di-*N,N'*-(2,4-dinitrophenyl)-2-deoxystreptamine (III) of mp 195—198°C (decomp.) and $[\alpha]_D$ +24° (*c* 0.9, acetone) in a 12% overall-yield from I.

On the other hand, the natural sample of 3AD was dinitrophenylated and acetylated to give penta-*O*-acetyl-tri-*N*-(2,4-dinitrophenyl) derivative, mp 194—198°C (decomp.) and $[\alpha]_D$ +22° (*c* 1.0, acetone).

The identity of the synthetic derivative III was established by direct comparison with both III and the above-mentioned derivative from natural sample.



II (racemate) Cbz = $COOCH_2C_6H_5$



III $R^1 = COCH_3$ R^2 = 2,4-dinitrophenyl

IV $R^1 = R^2 = H$ (3AD)

V $R^1 = H$, $R^2 = COCH_3$

Hydrolysis of III with methanolic ammonia followed by treatment with Dowex 1*X*2 (OH) resin gave 3AD (IV), whose identity was established by direct comparison with both synthetic IV and natural sample.

Further, the synthetic free aminosugar (IV) was *N*-acetylated with acetic anhydride in methanol to give 6-*O*-(3-acetamido-3-deoxy-α-D-glucopyranosyl)-*N,N'*-diacetyl-2-deoxystreptamine (V), which showed $[M]_{CuAm}$ +1460, by the copper complex method[13] reported from our Laboratory. The observed value agreed with the reported value[14] of the tri-*N*-acetyl derivative of natural 3AD, indicating that IV is the 6-*O*-linked glycoside of 2-deoxystreptamine.

Experimental

General Procedure. Infrared spectra were determined in potassium bromide pellets. Thin layer chromatography (TLC) was performed by "Silica-Rider for TLC" (Dai-ichi Pure Chemicals Co.). Descending paper chromatography was carried out by Toyo filter paper No. 51, using a solvent system of *n*-butanol : pyridine : water : acetic acid = 6 : 4 : 3 : 1, with ninhydrin (0.3% in pyridine) coloration, developing at room temperature for 72 hr.

Racemic Di-*N,N'*-carbobenzoxy-mono-*O*-isopropylidene-2-deoxystreptamine (II). To a solution of 4.3 g of di-*N,N'*-carbobenzoxy-2-deoxystreptamine[5] in freshly distilled *N,N*-dimethylformamide (30 m*l*) was added *p*-toluenesulfonic acid monohydrate (0.06 g) and 2,2-dimethoxypropane (5 m*l*), and the mixture was heated at 110°C for 4 hr to result in a brown solution. After the solution was neutralized with 10 m*l* of Amberlite IRA-400 (OH type) which was washed with methanol before use, the resin was filtered off and the filtrate was evaporated to give a thick sirup, which solidified when treated with water (100 m*l*). Crude product, 4.4 g (94%), was recrystallized from ethyl acetate to give an analytically pure sample of racemic II; yield 4.0 g, 86%, mp 145—146°C; IR spectrum: 3325, 1698 1545 (NHCbz), 1067 cm^{-1} (ketal).

Found: C, 63.63; H, 6.69; N, 5.85. Calcd for $C_{25}H_{30}N_2O_7$: C, 63.82; H, 6.43; N, 5.95%.

4,5-Di-*O*-acetyl-6-*O*-[2,4,6-tri-*O*-acetyl-3-(2,4-dinitroanilino)-3-deoxy-α-D-glucopyranosyl]-di-*N,N'*-(2,4-dinitrophenyl)-2-deoxystreptamine (III). A mixture of II (1.3 g), well dried powdery mercuric cyanide (0.91 g) and Drierite (9.5 g) in a solvent mixture of benzene and dioxane (4 : 1; 40 m*l*) was heated at 110°C for 15 min with stirring and then cooled to room temperature. To this mixture was added dry 3-acetamido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-glucopyranosyl chloride[11] (1.9 g; 1.3 eq.) and stirred at 110°C for 6 hr and additional 4 hr at room temperature under anhydrous conditions. The mixture was passed through a bed of Celite. The filtrate was combined and evaporated to afford a dark-brown residue, which

12) S. Koto, T. Tsumura, Y. Kato and S. Umezawa, This Bulletin, **41**, 2765 (1968).

13) S. Umezawa, T. Tsuchiya and K. Tatsuta, *ibid.*, **39**, 1235 (1966).

14) S. Umezawa, K. Tatsuta and T. Tsuchiya, *ibid.*, **39**, 1244 (1966).

was extracted with ethyl acetate (40 ml). After removal of an insoluble matter, the solution was shaken with four 40 ml portions of 20% aqueous potassium bromide and then 20 ml portions of distilled water, dried over anhydrous sodium sulfate and evaporated to afford a sirup (2.5 g). This was dissolved in warm 80% aqueous acetic acid (25 ml) and the solution was heated at 60°C for 2 hr. Evaporation *in vacuo* gave a sirup residue. The deacetonated product was dissolved in a mixture (15 ml) of dioxane, water and concentrated hydrochloric acid (8 : 3 : 1) and hydrogenated over palladium black (0.5 g) at about 30°C for 35 hr under 3.5 atm of hydrogen pressure with occasional addition of water (total volume, 10 ml). The mixture was filtered and the solution was evaporated at below 30°C and hydrogen chloride was removed by co-distillation with *n*-butanol to give a residue (0.7 g). The ninhydrin-positive sirup was dissolved in 1 N aqueous barium hydroxide (15 ml) and heated on a boiling water bath for 2 hr. The mixture was acidified with 2 N sulfuric acid to pH 2 and filtered. The filtrate was neutralized with 2 ml of Dowex 1×2 (OH type) and evaporated *in vacuo* to afford a colorless sirup (0.5 g) of free base. The crude product was dinitrophenylated with 2,4-dinitrofluorobenzene (1.3 ml) in the presence of sodium bicarbonate (0.7 g) in 50% aqueous ethanol (10 ml) at room temperature under stirring overnight to give a yellow precipitate. To the resulting mixture was added water (10 ml) and further stirred to complete precipitation; yellow powder, 1.4 g, was obtained. The product was acetylated with acetic anhydride (11 ml) and freshly fused sodium acetate (0.5 g) by heating at 110°C for 12 hr with stirring. Evaporation of excess reagent afforded a brown residue, which was extracted with acetone and followed by evaporation of the extract *in vacuo* to give a yellow glass, 1.25 g. The product showed about five spots with R_f values 0.3 (main), 0.37, 0.45, 0.51 and 0.56 on a silica-gel thin-layer chromatogram with a solvent system of benzene and MEK (3 : 1). The product was chromatographed on a silica-gel column (200 g; 47×290 mm) using a solvent system: benzene and MEK (4 : 1), being cut into 10 g each. The main product having an R_f value 0.3 appeared in fractions of Nos. 77—101 which gave a yellow solid by evaporation *in vacuo*. This fraction was further separated into two fractions of nearly equal amount, which have R_f values 0.30 and 0.28 respectively, by preparative TLC (20×20×0.05 cm) using the above-mentioned solvent system. The substance of R_f value 0.30 was collected and recrystallized from the same solvent system to give yellow needles of III, 340 mg (12% overall-yield from II); mp 195—198°C (decomp.), $[\alpha]_D^{18}$ +24° (*c* 0.9, acetone), IR spectrum: 3340, 3100, 1625, 1595, 1340 and 745 (NHDNP), 1760, 1370 and 1225 cm^{-1} (OAc).

Found: C, 46.50; H, 4.25; N, 12.41. Calcd for $C_{40}H_{41}N_9O_{24}$: C, 46.56; H, 4.01; N, 12.22%.

The melting point of III was not depressed by admixture with the penta-*O*-acetyl-tri-*N*-(2,4-dinitrophenyl) derivative of natural 3AD described below. On TLC with a solvent system, toluene-MEK (3 : 1), the synthetic III and the above-mentioned derivative of natural 3AD showed identical mobilities and their IR spectra were superimposable.

6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine (IV). A sample (59 mg) of III was dissolved in methanol (15 ml) saturated with dry ammonia at 0°C and the red solution was kept standing at room temperature overnight. Evaporation of the reaction mixture *in vacuo* gave a yellow residue, which was treated with Dowex 1×2 (OH type; 10 ml of wet resin) in acetone (5 ml) under stirring at room temperature overnight. The resin was filtered off and the filtrate was concentrated *in vacuo* to give a glass, 22 mg, which was chromatographed on a column of Dowex 1×2 (OH type; 2 ml) with carbon dioxide-free water. Evaporation of the middle ninhydrin positive fraction was followed by trituration with aqueous methanol-ethanol to give an analytically pure sample of III; yield 11 mg (60% from III), $[\alpha]_D^{18}$ +98°C (*c* 0.9, water).

Found: C, 44.24; H, 7.51; N, 12.69. Calcd for $C_{12}H_{25}N_3O_7$: C, 44.57; H, 7.79; N, 13.00%.

On the other hand, the natural 3AD showed $[\alpha]_D^{18}$ +98° (*c* 0.10, water). On descending paper chromatography, the R_f values of the synthetic product IV and the natural 3AD were in agreement. IR spectra of IV and natural 3AD were superimposable.

Penta-*O*-acetyl-tri-*N*-(2,4-dinitrophenyl) Derivative of Natural 6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-2-deoxystreptamine. A mixture of natural 3AD (0.33 g) and sodium bicarbonate (0.4 g) in water (15 ml) was stirred for a while, and to the solution was added 2,4-dinitrofluorobenzene (0.62 g) in ethanol (7 ml). The mixture was stirred for about 6 hr at room temperature until the yellow gummy product initially formed became powdery; yield 0.74 g (90%). The crude tri-*N*-(2,4-dinitrophenyl) derivative was acetylated with acetic anhydride (10 ml) and anhydrous sodium acetate (1.0 g) by heating at 110°C for 10 hr with stirring under anhydrous conditions. Evaporation of the excess reagent gave a residue, which was extracted with acetone. Concentration of the extract gave a yellow glass which was crystallized from acetone by the gradual addition of ethanol. Two recrystallization from benzene-MEK (3 : 1) afforded a chromatographically pure product, fine neeldes, mp 194—198°C (decomp.), $[\alpha]_D^{18}$ +22° (*c* 1.0, acetone), IR spectrum: 3340, 3100, 1625, 1595, 1340 and 745 (NHDNP), 1760, 1370 and 1225 cm^{-1} (OAc).

Found: C, 46.44; H, 4.21; N, 12.36. Calcd for $C_{40}H_{41}N_9O_{24}$: C, 46.56; H, 4.01; N, 12.22%.

6-*O*-(3-Acetamido-3-deoxy-α-D-glucopyranosyl)-*N*,*N*′-diacetyl-2-deoxystreptamine (V). To a suspension of IV (20 mg) in methanol (1.2 ml) was added acetic anhydride (0.6 ml) at room temperature. The mixture became clear immediately and after 18 hr, the solution became ninhydrin-negative. The solution was evaporated to give a colorless solid, from which acetic anhydride was removed by co-distillation with ethanol and crystallized from acetone to afford the pure acetate V; yield 23 mg (80%), mp 236—239°C (decomp.), $[\alpha]_{589}^{18}$ +74° (*c* 0.91, water), $[\alpha]_{436}^{18}$ +140° (*c* 0.91, water), $[\alpha]_{436}^{8}$ +465° (*c* 0.80, CuAm), $\Delta[M]_{CuAm}$ +1460, IR spectrum: 3400, 1100—1000 (OH), 3290, 1650, 1560 and 1375 cm^{-1} (NHAc).

Found: C, 47.91; H, 6.99; N, 9.08. Calcd for $C_{18}H_{31}N_3O_{10}$: C, 48.10; H, 6.95; N, 9.35%.

The authors are indebted to Mr. Saburo Nakada for his microanalysis, to Mr. Yoshio Nishimura and Takeshi Umeda for their technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2772—2776 (1968)

Analogs of Oxytocin Containing Leucinamide and Glycylglycinamide in Place of Glycinamide[1]

Haruhiko Aoyagi,[2] Michio Kondo[3] and Nobuo Izumiya[4]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 3, 1968)

Two analogs of oxytocin, [9-leucine]-oxytocin and oxytocinoyl-glycinamide, in which the glycinamide residue at position 9 in oxytocin has been replaced by a leucinamide and glycylglycinamide, respectively, have been synthesized and tested for some of the pharmacological properties characteristic of oxytocin. The protected nona- and decapeptide intermediates were prepared by use of the azide method in a fashion of the fragment condensation. After removal of the protecting groups from the intermediates by means of either sodium in liquid ammonia or anhydrous hydrogen fluoride, the dithiols thus obtained were oxidized to the required analogs. It was found that [9-leucine]-oxytocin possessed approximately 8% oxytocic potency, and oxytocinoyl-glycinamide 0.5% potency compared with oxytocin preparation.

The synthetic approach to the study of structure-activity relationships in oxytocin hormone opens up a wide choice of structural variations.[5] Among the numerous analogs of oxytocin which have been synthesized, very few have involved modifications of the glycinamide residue in position 9; du Vigneaud *et al.* reported the properties of [9-sarcosine]-oxytocin[6] and 9-deamidooxytocin[7] in which the glycinamide residue was replaced by that of sarcosinamide and glycine, respectively. The present paper reports the syntheses and pharmacological properties of two analogs of oxytocin, [9-leucine]-oxytocin[8] and oxytocinoyl-glycinamide[8] in which leucinamide and glycylglycinamide replace the glycinamide residue, respectively. As a peptide for the comparison with these two analogs, oxytocin itself was also prepared *via* the similar reaction-sequence employed for the syntheses of the analogs.

The sequence of reaction employed for the syntheses of oxytocin and its analogs is shown in Fig. 1. For the preparation of the protected nona- and decapeptides for the syntheses of the desired peptides (XV-A, B and C), benzyloxycarbonyl-tripeptide azide which was derived from the corresponding hydrazide (XIII) was allowed to react with hexa- (XI-A and C) or heptapeptide amide (XI-B) in a manner similar to that used by Boissonnas *et al.*[9] The required hexa- or heptapeptide amide (XI-A, B or C) was itself prepared from benzyloxycarbonyl-tripeptide hydrazide (IX) and tri- or tetrapeptide amide (V-A, B or C) followed by removal of the benzyloxycarbonyl group.

The protecting groups of the nona- and decapeptide intermediates (XIV-A, B and C) were removed by treatment with sodium in liquid ammonia by the method of du Vigneaud *et al.*[10] The removal of the protecting groups of the intermediates was also performed by acidolysis with anhydrous hydrogen fluoride as was reported by Sakakibara and Shimonishi.[11] The dithiols so obtained were oxidized in neutral solution by aeration, and the hormonal activities of the products in the solutions were determined by the rat-uterine contracting and avian depressor test.

Total activities of the preparations derived from 0.06 mmol (about 80 mg) of the intermediates are shown in Table 1. The oxytocinoyl-glycinamide (XV-B) possesses a weak activity such as some 0.5% oxytocic potency compared with oxytocin preparation. The relative activities of the analogs XV-B as well as [9-leucine]-oxytocin (XV-A) toward

1) Presented in part at 17th Annual Meeting of the Chemical Society of Japan, April, 1964.

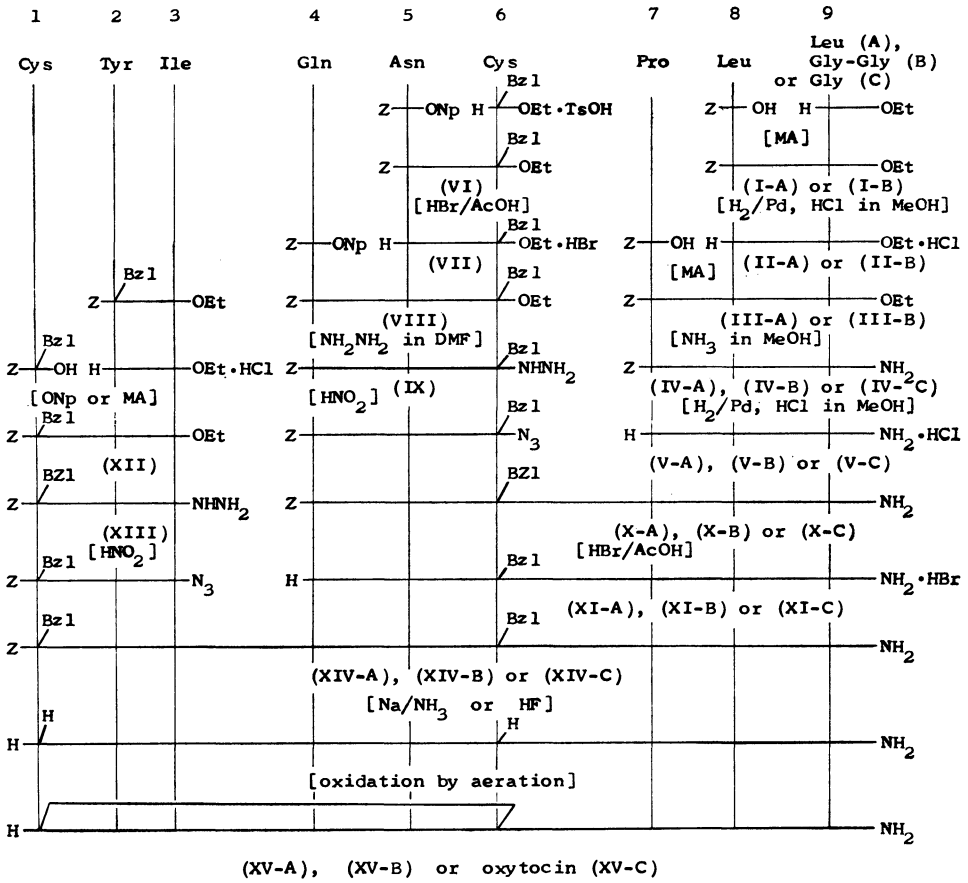

Fig. 1. Schematic diagram of syntheses of oxytocin and its analogs.
Z, benzyloxycarbonyl; Bzl, benzyl; ONp, *p*-nitrophenyl ester; [MA], mixed anhydride method; DMF, dimethylformamide.

Table 1. Total activities (units) of products derived from the protected peptides (0.06 mmol)

Compound	Oxytocic (rat)		Depressor (fowl)	
	Na/NH_3	HF	Na/NH_3	HF
	(%)			
[Leu^9]-oxytocin (XV-A)	1050(8)	225	850	190
Oxytocinoyl-Gly-NH_2 (XV-B)	63(0.5)	15	55	12
Oxytocin (XV-C)	12800(100)	2650	13100	2700

oxytocin should be considered as that of very approximation since the oxidized solution which was subjected to the biological assay might contain several by-products. It would be noteworthy that glycyl-oxytocin[12,13] carrying glycine residue to the amino group of *N*-terminal hemicystine residue showed 0.07% oxytocic potency compared with oxytocin.[13] The [9-leucine]-oxytocin preparation, however, showed appreciable biological activities; thus the replacement of the glycin residue with bulky leucine did not cause a remarkable decrease in the activities. These effects are of considerable significance to the question of the relation of structure to the biological activity of oxytocin molecule. The nature of the effects may become apparent when the role of glycine at position 9 toward the activity will be elucidated in future.

Experimental

All melting points are uncorrected.

Z-Leu-Leu-OEt (I-A). To a chilled solution of benzyloxycarbonyl-L-leucine (4.7 g; 20 mmol) and

triethylamine (2.8 ml) in tetrahydrofuran (40 ml), isobutyl chloroformate (2.6 ml) was added. After 15 min, a mixture of L-leucine ethyl ester hydrochloride (4.7 g; 20 mmol), triethylamine (2.8 ml) and chloroform (40 ml) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated *in vacuo*. The residual oil was dissolved in ethyl acetate, and the solution was washed successively with 4% sodium bicarbonate, 3% hydrochloric acid and water, dried over sodium sulfate and then evaporated *in vacuo*. The residual oil was solidified by the addition of petroleum ether. It was recrystallized from ethyl acetate-ether-petroleum ether; yield, 6.8 g (84%); mp 89—90°C; $[\alpha]_D^{25}$ −31.6° (*c* 1, AcOH).

Found: C, 64.92; H, 8.39; N, 7.09%. Calcd for $C_{22}H_{34}O_5N_2$: C, 65.00; H, 8.43; N, 6.89%.

H-Leu-Leu-OEt·HCl (II-A). The compound I-A (11.0 g; 27 mmol) was subjected to hydrogenolysis in the presence of palladium black and 0.76 N methanolic hydrogen chloride (37 ml). The filtrate from the catalyst was evaporated *in vacuo* leaving an oil; yield, 8.0 g (96%).

H-Leu-Gly-Gly-OEt·HCl (II-B). Z-Leu-Gly-Gly-OEt (I-B)[14] (6.7 g; 16.5 mmol) was treated as described above; yield of a hygroscopic powder, 4.2 g (92%).

Z-Pro-Leu-Leu-OEt (III-A). The mixed anhydride prepared from benzyloxycarbonyl-L-proline (3.8 g; 15 mmol) was coupled with II-A (4.7 g; 15 mmol), following the procedure used in the preparation of I-A. The crude product was recrystallized from ethanol-ether; yield, 5.6 g (73%); mp 138—139°C; $[\alpha]_D^{25}$ −88.6° (*c* 1, AcOH).

Found: C, 64.14; H, 7.96; N, 8.38%. Calcd for $C_{27}H_{41}O_6N_3$: C, 64.39; H, 8.21; N, 8.34%.

Z-Pro-Leu-Gly-Gly-OEt (III-B). The mixed anhydride prepared from benzyloxycarbonyl-L-proline (3.8 g) was coupled with II-B (4.7 g; 15.3 mmol) as has been described for the preparation of I-A. The product was recrystallized from ethyl acetate - ether - petroleum ether; yield, 4.9 g (65%); mp 133—135°C; $[\alpha]_D^{25}$ −64.8° (*c* 1, AcOH).

Found: C, 59.35; H, 7.13; N, 11.19%. Calcd for $C_{25}H_{36}O_7N_4$: C, 59.51; H, 7.19; N, 11.10%.

Z-Pro-Leu-Leu-NH_2 (IV-A). The compound III-A (6.3 g; 12.5 mmol) was dissolved in methanol (60 ml) saturated with ammonia. After it had been allowed to stand for 3 days, the solution was evaporated *in vacuo*. The remaining crystals were collected with the aid of ether. Recrystallization from ethanol-ether gave 3.9 g (66%); mp 190°C; $[\alpha]_D^{25}$ −88.5° (*c* 1, AcOH).

Found: C, 63.13; H, 7.94; N, 11.69%. Calcd for $C_{25}H_{38}O_5N_4$: C, 63.27; H, 8.07; N, 11.81%.

Z-Pro-Leu-Gly-Gly-NH_2 (IV-B). The compound III-B (5.2 g; 10.7 mmol) was converted into the amide as described above. Recrystallization from ethanol-ether gave 4.2 g (84%); mp 192—193°C; $[\alpha]_D^{25}$ −75.0° (*c* 2, AcOH).

Found: C, 57.99; H, 6.93; N, 14.75%. Calcd for $C_{23}H_{33}O_6N_5$: C, 58.09; H, 7.00; N, 14.73%.

H-Pro-Leu-Leu-NH_2·HCl (V-A). The compound IV-A (4.8 g; 10 mmol) was treated as has been described for the preparation of II-A. The product was obtained as a hygroscopic powder; yield, 3.8 g (99%).

H-Pro-Leu-Gly-Gly-NH_2·HCl (V-B). The compound IV-B (2.4 g; 5 mmol) was treated as has been described for the preparation of II-A. The product was obtained as a hygroscopic powder; yield, 1.8 g (95%).

H-Pro-Leu-Gly-NH_2·HCl (V-C). Z-Pro-Leu-Gly-NH_2 (IV-C)[15] (6.7 g; 16 mmol) was treated as described above; yield of a hygroscopic powder (V-C), 5.4 g (99%). Boissonnas *et al.* reported the synthesis of the oily hydrobromide from IV-C with hydrogen bromide-acetic acid.[9]

Z-Asn-Cys(Bzl)-OEt (VI). To a solution of *S*-benzyl-L-cysteine ethyl ester *p*-toluenesulfonate[16] (8.2 g; 20 mmol) in a mixture of dimethylformamide (20 ml) and triethylamine (4.0 ml), benzyloxycarbonyl-L-asparagine *p*-nitrophenyl ester[17] (7.7 g; 20 mmol) was added. The solution was allowed to stand at room temperature and a mass of crystals was deposited within about 1 hr. After 2 hr this mass was triturated with water (300 ml), collected by filtration, and washed successively with 4% sodium bicarbonate, 3% hydrochloric acid and water. It was recrystallized from ethanol; yield, 6.2 g (64%); mp 191°C; $[\alpha]_D^{20}$ −30.2° (*c* 2, DMF).

Found: C, 59.11; H, 6.04; N, 8.73%. Calcd for $C_{24}H_{29}O_6N_3S$: C, 59.13; H, 6.00; N, 8.62%.

H-Asn-Cys(Bzl)-OEt·HBr (VII). The compound VI (6.0 g; 12.3 mmol) was dissolved in acetic acid (40 ml) and 6.9 N hydrogen bromide - acetic acid (30 ml). After it had been allowed to stand at room temperature for 1 hr, the solution was evaporated *in vacuo*. The resulting residue was washed with ether and dried *in vacuo;* yield, 5.0 g (94%).

Z-Gln-Asn-Cys(Bzl)-OEt (VIII). To a solution of VII (5.0 g; 11.5 mmol) and triethylamine (2.5 ml) in dimethylformamide (25 ml), benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester[17] (4.6 g; 11.5 mmol) was added. After it had been allowed to stand at 30°C for 2 hr, the precipitate which formed was triturated with water (300 ml) and treated as has been described for the preparation of VI. It was recrystallized from dimethylformamide-ether; yield, 6.2 g (82%); mp 234—235°C; $[\alpha]_D^{25}$ −21.5° (*c* 2, DMF).

Found: C, 56.80; H, 6.13; N, 11.31%. Calcd for $C_{29}H_{37}O_8N_5S$: C, 56.57; H, 6.06; N, 11.38%.

Z-Gln-Asn-Cys(Bzl)-$NHNH_2$ (IX). To a solution of VIII (3.0 g; 4.8 mmol) in dimethylformamide (30 ml), hydrazine hydrate (2.5 ml) was added. After it had been allowed to stand at room temperature overnight, the mixture which contained crystals was allowed to cool for several hours. The product was then collected by filtration, and washed with water and acetone; yield, 2.7 g (95%); mp 246—248°C. Boissonnas *et al.* reported the synthesis of IX from Z-Gln-Asn-Cys(Bzl)-OMe with hydrazine in methanol by heating for 3 hr; mp 248°C.[9]

Z-Gln-Asn-Cys(Bzl)-Pro-Leu-Leu-NH_2 (X-A). To a chilled solution of IX (0.60 g; 1 mmol) in glacial acetic acid (25 ml) and 2 N hydrochloric acid (2 ml),

1 N sodium nitrite (1.1 ml) was added at 0°C. After 6 min, cold water (80 ml) was added to the solution. The azide which precipitated as a white mass was collected by filtration, washed with 4% sodium bicarbonate and water, and dried *in vacuo* at 0°C. The azide was added to a solution of V-A (0.40 g; 1 mmol) and triethylamine (0.14 ml) in dimethylformamide (10 ml). The mixture was stirred for 1 day at 0°C and further 1 day at room temperature, and then evaporated *in vacuo*. The precipitate which formed upon the addition of water was collected, and washed with 4% sodium bicarbonate, 3% hydrochloric acid and water. It was recrystallized from dimethylformamide - ethyl acetate - ether; yield, 0.59 g (66%); mp 220—221°C; $[\alpha]_D^{17}$ −56.9° (*c* 1, DMF).

Found: C, 58.06; H, 6.98; N, 13.76%. Calcd for $C_{44}H_{63}O_{10}N_9S$: C, 58.07; H, 6.98; N, 13.85%.

Z-Gln-Asn-Cys(Bzl)-Pro-Leu-Gly-Gly-NH_2 (X-B). The azide derived from IX (2.0 g; 3.3 mmol) was condensed with V-B (1.4 g; 3.3 mmol) as was described above. The product was recrystallized from dimethylformamide - ethyl acetate - ether; yield, 1.7 g (56%); mp 188—191°C; $[\alpha]_D^{17}$ −46.1° (*c* 1, DMF).

Found: C, 54.38; H, 6.41; N, 15.08%. Calcd for $C_{42}H_{58}O_{11}N_{10}S \cdot H_2O$: C, 54.29; H, 6.51; N, 15.08%.

Z-Gln-Asn-Cys(Bzl)-Pro-Leu-Gly-NH_2 (X-C). The azide from IX (2.46 g; 4.1 mmol) was condensed with V-C (1.32 g; 4.1 mmol) The product was recrystallized from dimethylformamide - ethyl acetate; yield, 1.68 g (48%); mp 206—208°C; $[\alpha]_D^{17}$ −53.5° (*c* 1, DMF).

Found: C, 55.59; H, 6.47; N, 14.52%. Calcd for $C_{40}H_{55}O_{10}N_9S \cdot \frac{1}{2}H_2O$: C, 55.67; H, 6.53; N, 14.61%.

Rudinger *et al.* reported the synthesis of the similar hemihydrate (mp 209—210°C),[18] and Bodanszky *et al.* reported the synthesis of the compound which has no water of crystallization (mp 233—234°C).[19]

H-Gln-Asn-Cys(Bzl)-Pro-Leu-Leu-NH_2·HBr (XI-A). The compound X-A (1.83 g; 2 mmol) was treated as has been described for the preparation of VII. The product was obtained as a hygroscopic powder; yield, 1.61 g (94%).

H - Gln - Asn-Cys(Bzl)-Pro-Leu-Gly-Gly-NH_2·HBr (XI-B). The compound X-B (0.93 g; 1 mmol) was treated as has been described for the preparation of VII. The product was obtained as a hygroscopic powder; yield, 0.85 g (96%).

H-Gln-Asn-Cys(Bzl)-Pro-Leu-Gly-NH_2·HBr (XI-C). The compound X-C (1.71 g; 2 mmol) was converted to XI-C as a hygroscopic powder; yield, 1.52 g (95%).

Z-Cys(Bzl)-Tyr-Ile-OEt (XII). *(a) ONp Method.* To a solution of H-Tyr-Ile-OEt·HCl[20] (1.9 g; 5 mmol) and triethylamine (0.7 ml) in dimethylformamide (10 ml), benzyloxycarbonyl-S-benzyl-L-cysteine *p*-nitrophenyl ester[17] (2.3 g; 5 mmol) was added at 0°C. The solution was allowed to stand overnight at room temperature. After the addition of water, the precipitate was collected by filtration and treated as has been described for the preparation of VI. It was recrystallized from ethyl acetate - ether - petroleum ether; yield, 2.5 g (80%); mp 143°C. Iselin *et al.* prepared this compound XII by the coupling of benzyloxycarbonyl-*S*-benzylcystein cyanomethyl ester and H-Try-Ile-OEt; mp 141—143°C.[21]

(b) MA Method. The product XII was also prepared from benzyloxycarbonyl-*S*-benzyl-L-cysteine and H-Tyr-Ile-OEt·HCl by the mixed anhydride method using isobutyl chloroformate; yield, 50%; mp 143°C.

Z-Cys(Bzl)-Tyr-Ile-$NHNH_2$ (XIII). The compound XII (5.2 g; 8 mmol) was converted into the hydrazide as has been described for the preparation of IX; yield, 4.0 g (80%); mp 236—238°C. Boissonnas *et al.* prepared the compound XIII from Z-Cys(Bzl)-Tyr-Ile-OMe with hydrazine in methanol; mp 238°C.[9]

Z-Cys(Bzl) - Tyr - Ile - Gln-Asn-Cys(Bzl)-Pro - Leu-Leu-NH_2 (XIV-A). The compound XIII (0.50 g; 0.8 mmol) in glacial acetic acid (40 ml) was converted to the corresponding azide with 1N hydrochloric acid (2.5 ml) and 1N sodium nitrite (0.9 ml). The azide was added to a solution of XI-A (0.69 g; 0.8 mmol) and triethylamine (0.11 ml) in dimethylformamide (8 ml). The mixture was treated in the same manner as has been described for the preparation of X-A. The crude product was recrystallized from dimethylformamide-ether; yield, 0.47 g (44%); mp 213—217°C; $[\alpha]_D^{25}$ −31.2° (*c* 1, DMF).

Found: C, 60.02; H, 6.55; N, 11.98%. Calcd for $C_{69}H_{94}O_{14}N_{12}S_2$: C, 60.07; H, 6.87; N, 12.18%.

Z-Cys(Bzl)-Tyr-Ile-Gln - Asn - Cys(Bzl) - Pro - Leu-Gly-Gly-HN_2 (XIV-B). The azide derived from XIII (0.64 g; 1 mmol) was condensed with XI-B (0.89 g; 1 mmol) as was described above. It was recrystallized from dimethylformamide-methanol-ether; yield, 0.78 g (57%); mp 225—227°C; $[\alpha]_D^{21}$ −42.0° (*c* 1, DMF).

Found: C, 58.02; H, 6.63; N, 12.85%. Calcd for $C_{67}H_{89}O_{15}N_{13}S_2$: C, 58.29; H, 6.50; N, 13.19%.

Z - Cys(Bzl) - Tyr - Ile-Gln-Asn -Cys(Bzl)-Pro-Leu-Gly-NH_2 (XIV-C). The azide from XIII (1.02 g; 1.6 mmol) was condensed with XI-C (1.26 g; 1.6 mmol) as described above; yield, 0.77 g (37%) (found: C, 58.78; H, 6.41; N, 12.55%); mp 235—237°C; $[\alpha]_D^{21}$ −45.5° (*c* 1, DMF). Lit., mp 241°C, $[\alpha]_D$ −51.5° (AcOH);[9] mp 243—245°C, $[\alpha]_D$ −43° (DMF).[22]

Removal of the Protecting Groups from XIV. *(a) Na/NH_3 Method.* Each 0.06 mmol of the protected peptide (83 mg of XIV-A, 83 mg of XIV-B or 80 mg of XIV-C) was dissolved in liquid ammonia (*ca.* 50 ml), and sodium (*ca.* 40 mg) was added until a blue color persisted for 3 min. Ammonium chloride (100 mg) was added to the solution and the ammonia was allowed to evaporate spontaneously. The residue was dissolved in water (100 ml) and the pH was adjusted to 6.5 with acetic acid, and carbon dioxide free-air was bubbled through for about 4 hr until the nitroprusside reaction for sulfhydryl groups was negative. The solution was further acidified to pH 3.5 with acetic acid, and an aliquot of the solution was subjected to the tests of the rat uterine-contracting and avian depressor activities (Table 1).[23]

Oxidation of Propylene over the Tin-Antimony Oxide Catalysts. II. Investigations of Physicochemical Properties of the Catalysts

Katsuhiko WAKABAYASHI,*1 Yoshio KAMIYA and Nobuto OHTA

Department of Fuel, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 26, 1967)

The physicochemical properties of the binary system composed of Sn and Sb oxides have been investigated. The electrical conductivity increased rapidly up to 3 atom% Sb, and subsequently decreased, little by little, as the Sb oxide content in the binary system increased. The surface area also increased rapidly up to 3 atom% Sb, and in the region exceeding this content a dilution effect due to Sb oxide was observed. The behavior of the initial rate of acrolein formation as a function of the catalyst composition was fairly similar to that of the surface area. The apparent activation energies for carbon dioxide formation at first decreased, and then became nearly constant when the Sb content of the catalysts increased. On the other hand, the activation energies for acrolein formation may be considered to be always constant, independent of the catalyst composition, at about 17 kcal/mol. The activation energies for the catalyst reduction by hydrogen were 28 kcal/mol for Sn oxide, 14 for a mixture containing 25 atom% Sb, and 30 for Sb oxide. Consequently, it has been concluded from these results that it may depend on the nature of the chemisorbed oxygen which attacks propylene whether the propylene is oxidized into acrolein or into such complete combustion products as carbon dioxide.

In the studies of the binary system of Sn and Sb oxides, a former paper[1] was concerned with the effect of the catalyst compositon and the calcination conditions on the formation of acrolein, and with an investigation of the X-ray patterns of the catalysts; it was confirmed that Sb oxide was dissolved into Sn oxide and that the solid solutions thus formed were active in the production of acrolein.

The present paper will deal with the physical and catalytic properties of the binary system for the purpose of elucidating why the solid solutions composed of Sn and Sb oxides are active in acrolein formation.

Many works[2-6] have thus far been presented on various binary systems, though few have dealt with the correlation between the reaction activity and the physicochemical properties. Butler *et al.*,[6] however, observed a correlation between the conducitivity and the apparent activation energy for the decomposition of benzene over mixed catalysts of V_2O_5 containing MoO_3 or GeO_2.

From the viewpoint of controlled-valency semiconductivity, the decomposition of N_2O[7-9] and the oxidation of CO[10,11] have thus far been studied,

but the mechanism of the catalysis has not been completely elucidated.

Experimental

The apparatus, experimental procedures, and methods of catalyst preparation were the same as were employed in the previous work.[1)]

The samples used in the measurements of the surface area and of the electrical conductivity were prepared by heating the powder of SnO_2 and Sb_2O_5 at a desired ratio, the two ingredients being thoroughly admixed without any carrier.

The surface areas were measured with nitrogen by the BET method at −196°C; an area of 16.2 Å² was assumed for the nitrogen molecule. The dc resistance of a 2 g portion of the powdered sample was measured with Wheatstone's bridge. The apparatus was similar to that of Griffith *et al.*[12)] The electrodes were platinum disks 12 mm in diameter; two springs applied a constant pressure to the sample between the electrodes.

The reduction of the catalysts was carried out at the atmospheric pressure of hydrogen in the range from 400°C to 500°C by using a thermobalance.

Results

Figure 1 shows the electrical conductivity of the binary system composed of Sn and Sb oxides. The measurements were carried out in air at room temperature. The conductivity increased markedly up to 3 atom% Sb, and then decreased little by little in the region above 3 atom% Sb.

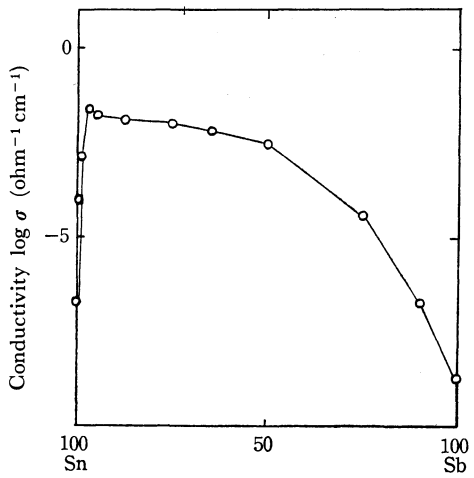

Fig. 1. The conductivity of the Sn and Sb oxide binary system.

Figure 2 shows the surface area as a function of the composition of Sn and Sb oxides. The surface area increased as markedly as may be observed in Fig. 1 up to 3 atom% Sb. However, in the region of higher Sb oxide concentrations the surface area subsequently decreased, and a dilution effect due to Sb oxide was observed.

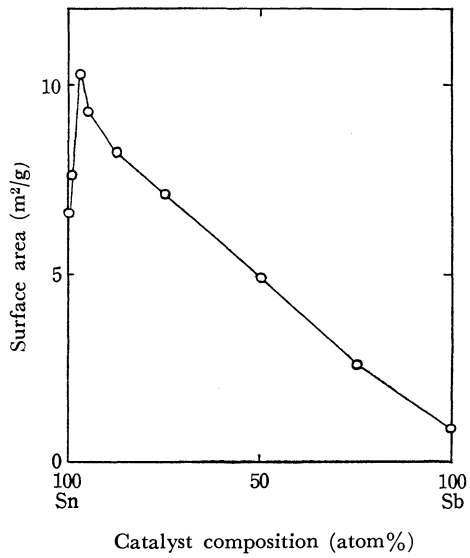

Fig. 2. The surface area of the Sn and Sb oxide binary system.

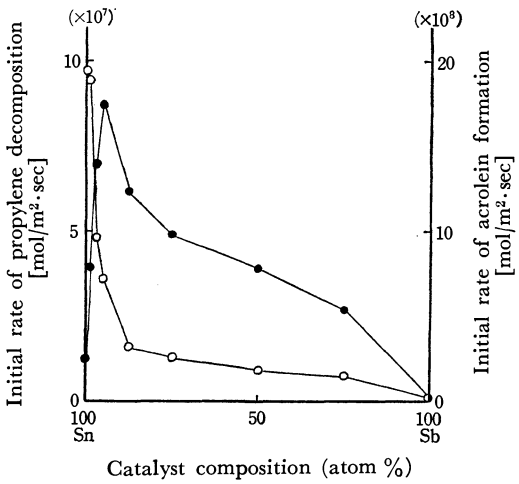

Fig. 3. Initial rate of acrolein formation and propylene decomposition.
Catalyst: calcined at 1000°C for 3 hr
Reaction temperature: 470°C
○: Propylene decomposition
●: Acrolein formation

Figure 3 shows the initial rates of acrolein formation and propylene decomposition at 470°C. A rapid increase in the initial rate of acrolein formation was caused by the addition of Sb oxide; the maximum rate was obtained at a 5 atom% Sb content. In the region of higher Sb oxide concentrations, a dilution effect seems to exist. The initial rate of propylene decomposition fell

off rapidly as Sb oxide was added to Sn oxide. The formation of carbon dioxide was extremely depressed by the addition of Sb oxide, as is summarized in Table 1.

The selectivity to acrolein when the conversion of propylene is about 10% is shown in Fig. 4 as a function of the catalyst composition. The selectivity at first increased upon the addition of Sb oxide, and then it became almost constant in the region of Sn-to-Sb atomic ratios below 3 : 1.

The apparent activation energies for the formation of acrolein (E_{acr}) and carbon dioxide (E_{CO_2}) have been obtained from Arrhenius plots in the temperature range from 400°C to 490°C, using an initial rate, r, which is considered to be proportional to the rate constant, k. These plots of log r against $1/T$ have given a reasonably straight line for all the catalysts of various compositions. In the case of acrolein formation, representative Arrhenius plots are shown in Fig. 5. Figure 6 shows E_{acr} and E_{CO_2} as functions of the catalyst composition. E_{acr} remained constant over the entire range of compositions of the binary system. On the other hand, E_{CO_2} decreased up to 25 atom% Sb, and then became constant in the region of Sn-to-Sb atomic ratios below 3 : 1.

Table 1. Rate of reaction
Reaction temperature: 470°C

Catalyst composition (Sn/Sb)	Rate of reaction (mol/m²·sec)		
	$d(CH_2=CHCHO)/dt$ ($\times 10^8$)	$d(CO_2)/dt$ ($\times 10^8$)	$-d(C_3H_6)/dt$ ($\times 10^7$)
SnO_2	2.6	252	9.9
99/1	7.8	165	9.8
97/3	14.0	59	4.9
95/5	17.4	35	3.5
7/1	12.4	9.3	1.9
3/1	9.8	3.9	1.3
1/1	7.8	1.9	0.98
1/3	5.5	1.4	0.74

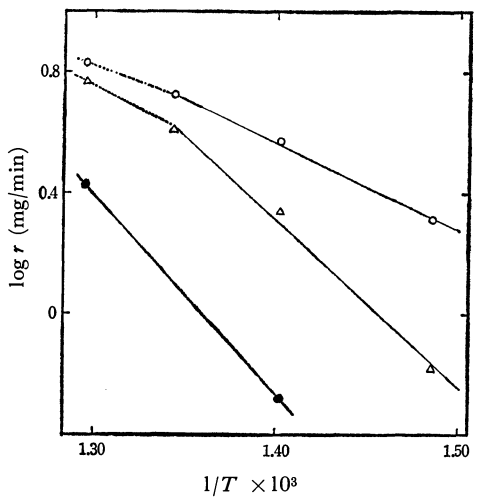

Fig. 8. Arrhenius plots for catalyst reduction by hydrogen.
○: Sample with a Sn-to-Sb atomic ratio of 3 : 1
△: SnO_2
●: Sb_2O_5
Each sample was calcined at 1000°C for 3 hr.

Figure 7 indicates the weight loss during reduction by hydrogen of a mixture with a Sn-to-Sb atomic ratio of 3 : 1. The reduction rate has been represented by the decrease in the weight of a sample between 5 and 15 min after the beginning of the reduction. Arrhenius plots for the reduction are shown in Fig. 8. The diffusion process seems to have an effect upon the reduction rate at temperatures as high as 500°C. The apparent activation energies thus obtained were 28 kcal/mol for Sn oxide, 14 for the mixture with a Sn-to-Sb atomic ratio of 3 : 1, and 30 for Sb oxide.

Discussion

As has been mentioned in the earlier paper,[1] SnO_2 and Sb_2O_5 form a substitutional solid solution. The solid solution is formed as follows:

$$(1-2\delta)SnO_2 + \delta Sb_2O_5 \rightarrow Sn_{(1-4\delta)}^{4+}Sn_{2\delta}^{3+}Sb_{2\delta}^{5+}O_2 + \frac{1}{2}\delta O_2 \quad (1)$$

or

$$Sb_2O_5 \rightarrow 2Sb_{(Sn)}^{+} + 2\ominus + 2SnO_2 + \frac{1}{2}O_2 \quad (2)$$

where $Sb_{(Sn)}^{+}$ indicates Sb^{5+} which has been substituted for Sn^{4+}. SnO_2 acts as a n-type semiconductor; accordingly Sn^{3+}, which may be called anion vacancies, or quasi-free electrons, is produced as is shown above when the lattice of SnO_2 dissolves Sb_2O_5. The Sn^{3+} content is equivalent to the amount of Sb^{5+} substituted for Sn^{4+}. The solid solutions were found, from the X-ray investigations described in the previous paper, to have a homogeneous crystal of the same structure as the original SnO_2, but the dimensions of the unit cell must be larger, as the ionic radius of Sn^{3+} is larger than that of Sn^{4+}. Hence, an expansion of the lattice by the addition of Sb_2O_5 may be expected. This has also actually been observed, as has been shown in the previous paper.

Phase Composition of Sn and Sb Oxide System. How far Sb_2O_5 is dissolved into SnO_2 is dependent upon the calcination temperature and the period. However, it is difficult to determine the solubility by measuring Δd because of the fact that the addition of Sb_2O_5 to SnO_2 does not cause much change in the d-spacings in X-ray patterns; also, it is difficult to ascertain whether Sb_2O_5 is completely dissolved into SnO_2 at a low Sb content because of the fact that the relative intensity of Sb_2O_5 in X-ray patterns is considerably smaller than that of SnO_2. It was shown by the X-ray investigations described in the previous paper that some Sb_2O_5 remains insoluble in SnO_2 in the case of a (Sn/Sb=3, 1000°C, 3 hr) mixture, and that a larger amount of Sb_2O_5 is dissolved into SnO_2 in a (Sn/Sb=3, 1100°C, 3 hr) mixture than in the (Sn/Sb=3, 1000°C, 3 hr) mixture. Here, the description of the (Sn/Sb=3, 1000°C, 3 hr) mixture means that the Sn-to-Sb atomic ratio in

the mixture is 3 : 1 and that the mixture has been calcined at 1000°C for 3 hr. Hence, it is certain that two phases consisting of Sb_2O_5 and the solid solution are present in the (Sn/Sb=3, 1000°C, 3 hr) mixture. However, it remains uncertain whether Sb_2O_5 insoluble in SnO_2 is present in the mixture with a Sn-to-Sb atomic ratio above 3 : 1 when it is calcined at 1000°C for 3 hr, as has been shown in the X-ray patterns in the previous paper.

As quasi-free electrons equivalent to the amount of Sb dissolved into SnO_2 are produced, the conductivity increases upon the addition of Sb_2O_5 to SnO_2, showing a maximum value at a 3 atom% Sb content. It is impossible, however, to determine from the conductivity measurements how far the Sb oxide is dissolved into the Sn oxide, because the conductivity is not necessarily proportional to the concentration of the foreign ion when dissolved in great quantities. Nevertheless, it may be considered, judging from the conductivity data, that the Sb oxide is almost completely dissolved up to 3 atom% Sb. The surface area also increases rapidly upon the addition of a small amount of Sb oxide; it is largest at a 3 atom% Sb content. In the region of the oxide system containing more than 3 atom% Sb, a dilution effect due to Sb oxide has been observed. Taking into consideration the conclusion of the conductivity investigations, the increase in the surface area upon the addition of a small amount of Sb oxide can be attributed to the formation of the solid solutions. As the surface area is regarded as dependent upon the dimensions of the grain size, it seems that the grain size may become small when the lattice of Sn oxide dissolves Sb oxide.

The investigation of the initial rate of acrolein formation, if based on the conclusion drawn from the conductivity and surface area data, shows that the initial rate is mainly dependent upon the amount of the solid solutions formed on the catalyst surface. A dilution effect due to the Sb oxide added seems to be present in the region above a 5 atom% Sb content. The dilution effect in the above two cases can be attributed to the Sb oxide which remains insoluble in Sn oxide. Hence, it may be concluded that the two phases composed of Sb oxide and the solid solutions are present in the system exceeding about a 5 atom% Sb content.

Why the mixtures of Sn and Sb oxides become colored upon being calcined at a high temperature may be due to the Sn^{3+} produced when the lattice of Sn oxide dissolves Sb oxide. Accordingly, the maximum solubility may be qualitatively determined from the depth of the color of the mixtures. As was mentioned in the previous paper, the mixture with a Sn-to-Sb atomic ratio of 3 : 1 is deepest in color of all the mixtures when calcined at 1000°C for 3 hr, but it is less deep than the (Sn/Sb=3, 1100°C, 3 hr) mixture. The maximum solubility of Sb oxide into Sn oxide may, therefore, be regarded as nearly 25 atom%; this value is in good agreement with the value inferred from the measurements of the apparent activation energies for the formation of carbon dioxide and of the selectivity to acrolein. Consequently, it may be concluded that Sb oxide is completely dissolved into Sn oxide up to 3 or 5 atom% Sb when calcined at 1000°C for 3 hr, and that Sb oxide as well as the solid solution is present in the system at a higher Sb content, though the maximum solubility is nearly 25 atom%.

Formation of Acrolein and Carbon Dioxide. Many mixed catalysts, for example, CuO-SeO_2,[13] Fe_2O_3-As_2O_3,[14] Bi_2O_3-MoO_3,[15] and SnO_2-Sb_2O_5,[16] recommended for the oxidation of propylene to acrolein, contain one metal oxide which is considered to produce acrolein selectively by itself, though the rate of formation is slow. The heat of the formation of this oxide from a lower oxide or metal to a higher is relatively small, as Table 2 shows. A pure molybdenum oxide catalyst, as has been reported previously,[17] scarcely oxidizes propylene at all in such a reducing atmosphere as that in this work, nor does a pure antimony oxide catalyst. This may be because these oxides are easily reduced to lower oxides or metals, whose surface is in a reducing atmosphere with a large amount of adsorbed propylene and, accordingly, almost inactive in the oxidation of propylene as a result of the poverty of active oxygen on the surface. Kominami *et*

TABLE 2. THE HEAT OF FORMATION OF THE METAL OXIDES

Metal oxide	(kcal/mol)
SnO_2	137.4
SnO	66.0

al.[18] have proposed the following mechanism with respect to the CuO-SeO_2 system:

$$SeO_2 \text{ (or } CuSeO_3) + C_3H_6 \rightarrow \text{acrolen} + Se \text{ (}CuSeO\text{)} \quad (3)$$

$$Se \text{ (}CuSeO\text{)} + CuO \rightarrow SeO_2 \text{ (}CuSeO_3\text{)} + Cu_2O \quad (4)$$

$$Cu_2O + O_2 \rightarrow CuO \quad (5)$$

This may mean that one oxide in the mixed catalysts is effective in the activation of oxygen, and another, in the activation of propylene. In the binary system composed of Sn and Sb oxides, antimony ions may be effective in the activated adsorption of propylene, as has been investigated with regard to Bi_2O_3-MoO_3[2,5] and Cu_2O[19]. In this discussion, however, only the chemisorption of oxygen will be taken into consideration.

Oxygen is adsorbed on a metal oxide as follows:

$$O_2 \rightleftarrows O_2^- \rightleftarrows O^- \rightleftarrows O^{2-} \quad (6)$$

At a low temperature, the oxygen adsorbed on a metal oxide is considered to be converted to O_2^- or O^-, and at a high temperature, to O^- or O^{2-}. Therefore, under these reaction conditions, it may be assumed that there may be present on the catalyst surface both O^- and O^{2-} ions. The former is an oxygen ion adsorbed on the catalyst, while the latter is an oxygen ion more strongly adsorbed, one which may be of the same nature as the lattice ion.

As is shown in Fig. 6, E_{CO_2} decreases up to about 25 atom% Sb and remains nearly constant hereafter. In the V_2O_5-MoO_3 system,[20] a vanadium-oxygen bond is weakend by the addition of MoO_3. If the SnO_2-Sb_2O_5 system is analogous, a tin-oxygen bond may become weaker as the Sb oxide is dissolved into the Sn oxide. The measurements of the activation energies for the catalyst reduction indicate that a mixture with a Sn-to-Sb atomic ratio of 3 : 1 has an activation energy smaller by 14 kcal/mol than a pure tin oxide. This finding is in fairly good agreement with the difference in E_{CO_2}. Hence, the lattice oxygen is possibly connected with the formation of carbon dioxide.

On the other hand, little change in E_{acr} was observed in spite of the change in the amount of Sb oxide added. This suggests that the formation of acrolein may be dependent upon the O^- ions, according to the report that ethylene oxide is yielded by O_2^- rather than O^- ions in the oxidation of ethylene.[21]

Thus:

Formation of carbon dioxide

$$O^{2-} \text{ (lattice oxygen)} + C_3H_6 \rightarrow \text{complete combustion products} + [O_v^{2+} \cdot 2e] \text{ (oxygen defect)} \quad (7)$$

$$\frac{1}{2}O_2 + [O_v^{2+} \cdot 2e] \rightarrow O^{2-} \text{ (lattice oxygen)} \quad (8)$$

Formation of acrolein

$$\frac{1}{2}O_2 + Sn^{3+} \rightarrow O^- + Sn^{4+} \quad (9)$$

$$O^- + C_3H_6 + Sn^{4+} \rightarrow \text{acrolein} + Sn^{3+} \quad (10)$$

where Sn^{3+} indicates an anion vacancy.

This mechanism explains very reasonably the results of the kinetic measurements and the selectivities of the catalysts as well as the dilution effects. As the amount of quasi-free electrons on the catalyst surface increases when Sb oxide is added to Sn oxide, the increase in the initial rate of acrolein formation, shown in Fig. 3, is observed. On the other hand, an active lattice oxygen ion available for carbon dioxide formation is removed from the system, leaving an anion vacancy, when Sb oxide is dissolved into Sn oxide, so the rate of carbon dioxide formation falls off. That the maximum value of the rate of acrolein formation was obtained at a 5 atom% Sb content suggests that the concentration of anion vacancies avaiable on the catalyst surface is highest at this content. It is due to the more marked decrease in the rate of carbon dioxide formation that the rate of propylene decomposition decreases upon the addition of Sb oxide to Sn oxide and that the selectivity to acrolein increases above 5 atom% Sb even though the rate of acrolein formation falls off.

The selectivity to acrolein was 32% at the contact time of 0.5 sec and 17% at 2.5 sec with a (Sn/Sb= 97/3, 1000°C, 3 hr) catalyst, though it was 74% at 7.5 sec and 68% at 25 sec with a (Sn/Sb=3, 1000°C, 3 hr) catalyst, where Sb oxide is considered to dissolve into Sn oxide almost to the maximum extent of solubility. Therefore, a lattice oxygen ion may also be related to the further oxidation of acrolein.

However, detailed information on the reaction kinetics as well as on the adsorption of oxygen and propylene is necessary before a quantitative reaction scheme can be presented.

The authors wish to express their thanks to Professor Emeritus Shingo Ando for his continued advice and encouragement in this work.

Effect of Pressure on Graphitization of Carbon. V. Electron Spin Resonance in Hard Carbon Heat-Treated under High Pressure

(Received May 6, 1968)

By means of the electron spin resonance (ESR), the graphitization process of a hard carbon (phenolformaldehyde resin char) under a pressure of 5 kbar was investigated in relation to the results of the X-ray diffraction analysis. In the ESR measurement, there is observed only a sharp Lorentzian line having *g*-value of about 2.003 for the products heat-treated at relatively low temperatures. On the other hand, gradual increase in the heat treatment temperature (HTT) leads to the appearance of new 15—20 G wide line having *g*-value of about 2.01, overlapping on the sharp one, and its absorption intensity tends to increase further with HTT. The appearance of the broad ESR line has been found always being accompanied by an abrupt increase of the content of graphitic component deduced from the analysis of (002) diffraction profile. From further investigation of features of these ESR lines as a function of ambient temperature, the sharp one is concluded that it originates from the so-called localized spin centers, while the broad one from the delocalized. The coexistence of these two signals suggests that the turbostratic and graphitic parts have enough extent to prevent the motional mixing of these spin centers, which has also been verified by the X-ray diffraction analysis.

The graphitization process of carbons under high pressure has recently been studied by Noda and his co-workers[1-5] through an analysis of the profiles of (001) X-ray diffraction lines. In their studies,[1,2,5] every kind of carbons examined was found to be graphitized under high pressure at relatively low temperature such as 1500°C. Furthermore, it has been deduced that the graphitization process of a hard carbon under a pressure of 5 kbar is divided into three distinctive stages[5]: In the first stage, there is observed only one component, A_H, having the so-called turbostratic structure. In the second stage, the new components G'_H and G''_H seem to coexist with A_H, and the total content of G_H' and G''_H, which will hereafter be denoted by G_H, shows a gradual increase up to 20% with the increase in heat treatment temperature (HTT). At the beginning of the third stage, *i. e.*, HTT of 1400, 1500 and 1700°C for the residence time of 60, 20 and 3 min, respectively, the content of G''_H increases so abruptly as to exceed 70%, while G'_H disappears and a small amount of A_H remains still unaltered. Therefore, the sum G_H is equal to the content of G''_H in this stage, and still increases gradually with the increase in HTT towards full graphitization. The components G''_H and A_H are concluded to have the three-dimensional graphitic and turbostratic structures, respectively, but G'_H may be of intermediate structure between the turbostratic and the graphitic.

In the present work, it has been intended to study the electron spin resonance (ESR) in the hard carbons heat-treated under high pressure, making a comparison with the results of X-ray diffraction analysis performed on the same samples.

Experimental and Results

The hard carbon sample PH-7 was prepared at 700°C from phenolformaldehyde resin which was made by a conventional method using ammonium hydroxide as catalyst. Heat treatments of this sample under a quasi-hydrostatic pressure of 5 kbar were performed at various temperatures between 1100—1800°C for residence times of 3, 20 and 60 min. The temperature of heat treatment (HTT) was evaluated from the electric input power, for which the relation between temperature and input power had preliminarily been determined by using chromel-alumel thermocouple. The accuracy of the HTT determination in this way was considered to be ±50°C

at 1500°C. Details on the sample treatment, *e. g.*, high pressure apparatus, high pressure cell arrangement and heat treatment procedures *etc.* are the same to those reported elsewhere.[3-5]

Through the heat treatment, the sample was sintered into a cylindrical block about 6 mm in length and 4 mm in diameter. An about 2 mm long piece was cut out of the central part, where the temperature gradient was hardly observed during the treatment.[4] A half of each piece was examined with ESR in this work, and another half with the X-ray diffraction analysis previously reported.[5]

The ESR work was conducted mostly at room temperature for finely-ground samples placed in vacuum. DPPH and Mn^{+2}-doped magnesia were used as primary and secondary standards, respectively, to determine the *g*-value of signals. In Fig. 1, the change of the ESR line shape with HTT is shown for the residence time of 3 min. For HTT below 1670°C, a sharp near-symmetrical line is observed around the *g*-value of 2.003.

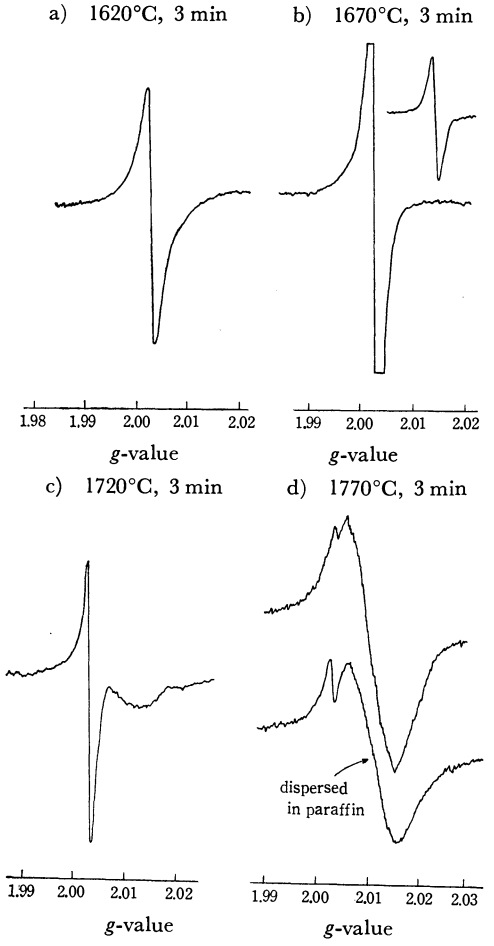

Fig. 1. Change of the line shape of ESR signal of the hard carbon, heat-treated under 5 kbar for 3 min, with HTT.

Above 1720°C, however, a new broad signal centered at $g \fallingdotseq 2.01$ turns up and develops with the increase in HTT. At 1770°C, the broad signal becomes so strong that we have to disperse the sample in solid paraffin for making clear the sharp signal (Fig. 1 d). As to the line shape and the width (w), the sharp signal is of Lorentzian type, giving $w \fallingdotseq 2$G, and the broad one considerably Dysonianized gives $w \fallingdotseq 15$ G to 20 G.

The critical temperature at which the broad signal appears is strongly dependent on the residence time; *e. g.*, about 1500°C for 20 min, and 1400°C for 60 min. It is noticeable that such critical temperatures are coincident with those at which the content of the component G_H shows an abrupt increase. As shown in Fig. 2, a beautiful correspondence between the results of ESR and X-ray analyses, where the *g*-value and the content of G_H are plotted both as functions of HTT, and the critical points are marked by arrows.

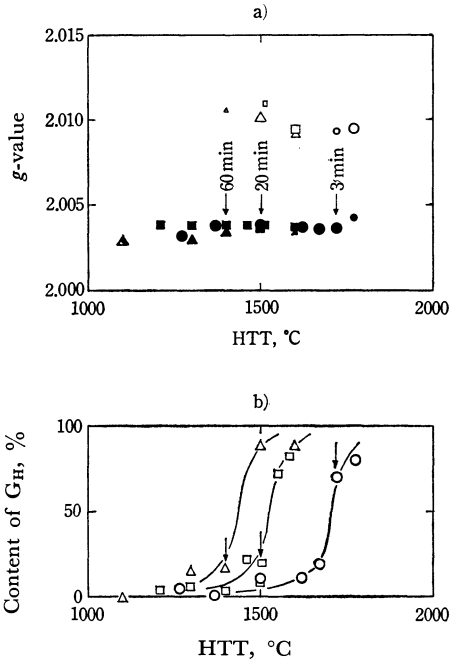

Fig. 2. a) Changes of *g*-values of ESR signals with HTT.

Localized spin	Delocalized spin	
●	○	3 min
■	□	20 min
▲	△	60 min

b) Change of content of the component G_H with HTT.[5]
○ 3 min □ 20 min △ 60 min

In order to obtain further information on the nature of the spin the absorption intensity, line width and *g*-value as functions of ambient temperature were investigated on two typical samples,

say A and B, poorly and highly graphitized, respectively. Sample A heat-treated under 5 kbar at 1370°C for 3 min does not contain the component G_H at all, while for sample B subjected to the same pressure at 1500°C for 60 min the content of G_H amounts to 89%. Ambient temperature was precisely controlled, during the ESR measurement, by suitable ventilation of cold and warm nitrogen gases into the cavity.

The experimental results for these samples are shown together in Fig. 3: Sample A exhibits only the sharp signal. Its relative intensity is found to obey the Curie law, showing an excellent linearity when plotted against $1/T$ (reciprocal temperature in $°K^{-1}$), whereas the line width ($\fallingdotseq$2G) and the g-value ($\fallingdotseq$2.003) are almost independent of temperature in the range from 140°K to 300°K. Such characters are in agreement with those of localized spin centers which have generally been found for various chars on the way of carbonization.[6] On the other hand, behaviors of the broad signal solely displayed by sample B are much different from the above; *viz.*, the line width as well as the g-value decrease with the increase of ambient temperature, while the absorption intensity shows a slightly increasing tendency. Undoubtedly, these trends are associated with the delocalized nature of spins, and hence may conform with the Pauli-McClure type paramagnetism[7] of conduction electrons in graphite which has practically been justified by Wagoner[8] (for single crystal) and further by Singer and Wagoner[9] (for polycrystal).

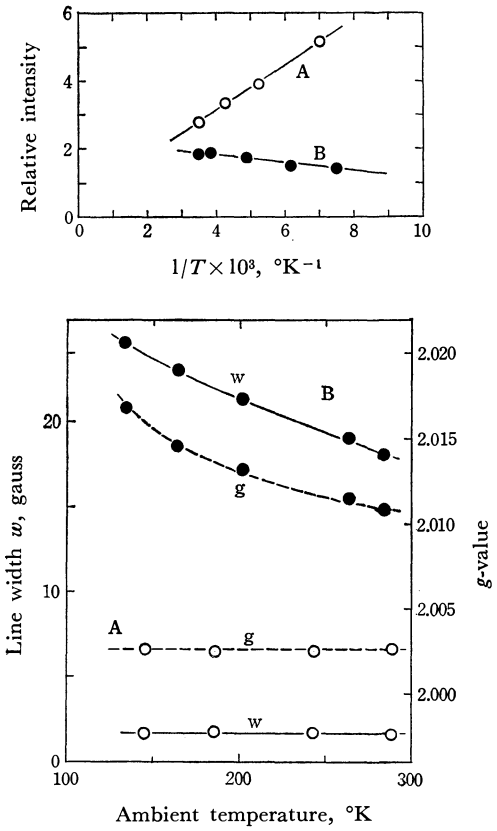

Fig. 3. Dependences of relative intensity, line width and g-value of two kinds of signals on ambient temperature (T).
○ Sample A ● Sample B

Discussion

As shown in Fig. 2, the critical points on HTT axis, at which the broad ESR signal of delocalized nature turns up, coincide with those where the abrupt increase of component G_H is observed in the X-ray analysis. On this basis, we can conclude that the conduction carriers can take part in ESR just through the agency of the three-dimensional graphitic structure. On the other hand, the free spin species giving rise to the sharp signal are mostly distributed, may be bound with some structural defects, in the turbostratic media. However, for the second-stage product in which the content of graphitic part (the component G''_H) is far below 20%, the broad signal due to conduction carriers has not yet been detected. In this sense, the ESR analysis as a tool for detecting the structural change in carbons is likely less sensitive than the well-arranged X-ray diffraction analysis.

Another fact to be remarked in this work is that for some not-fully graphitized sample, there are simultaneously observed two kinds of absorption lines which are due to the localized and delocalized spin centers, respectively. This makes a sharp contrast to the past observations[10,11]; *i. e.*, for usually-treated carbons, one can obtain an ESR line which exhibits intermediate nature between fully localized and delocalized spins as a result of the so-called motional narrowing. Therefore, in our specimens the both structures responsible for such two lines, the turbostratic and the graphitic, have enough extent to prevent such a motional mixing of these spins. This may corresponds to that in the X-ray diffraction either of the turbostratic or of the graphitic portions has enough extent to produce the coherent scattering of X-ray.

Several years ago, Honda *et al.*[12] found double-fold ESR lines for some chars prepared in usual way from phenolformaldehyde resin and its derivatives. However, the broad component observed in their study has the same *g*-value as the sharp one. Therefore it might originate from other mechanism than that outlined in the present work. They did not mention the correspondence between the ESR and X-ray diffraction data.

The authors are indebted to Dr. T. Noda of Mie University for his encouragement and valuable discussions.

An Oxygen Concentration Profile of a MnO_2 Particle after Discharge Service

Kazuhide MIYAZAKI

Central Research Laboratories, Mitsui Mining & Smelting Co., Mitaka-shi, Tokyo

(Received May 6, 1968)

The behavior of oxygen in a manganese dioxide depolarizer discharged in a Leclanche-type test cell down to a cut-off voltage of 0.7 V was visually examined by means of electron probe microanalysis. The oxygen concentration profile of a typical MnO_2 particle of about 50 μ in diameter showed that the relative amount of oxygen at the surface and along the pores inside was evidently reduced due to the discharge reaction invading 5 to 10 μ towards the inner part of the particle, indicating that the discharge primarily took place in these portions and involves a process of releasing oxygen from sites at the outermost surface and along the pores. The region which contains these lower oxide portions was observed to be 20—30% of the total cross-sectional area, implying that the utility factor of MnO_2 as a depolarizer was accordingly of the order of 20—30%. It was suggested that enhancement of the use of pores or cleavages during a discharge would generally be beneficial to the service life as a depolarizer, better than merely reducing the particle size of the material.

The present paper provides results of an electron probe microanalysis of an MnO_2 specimen which was under discharging service as a depolarizer in a Leclanche-type wet cell. The purpose here is to visually examine relative concentrations of oxygen at the surface and the inner part of the MnO_2 particles during the discharge reaction.

Many years ago[1] the "polarization" of MnO_2 in a cell was explained by the formation of discharge products on the surface. In 1931, Keller[2] advanced the view that electric discharge of MnO_2 resulted in the formation of a solid solution of MnO_2 with a lower oxide of manganese and this material would degrade the electromotive force of the original MnO_2. Since then, many basic investigations have been carried out concerning the discharge mechanism of MnO_2 in terms of the primary discharge products of the MnO_2 electrode.[3] Changes in the X-ray diffraction pattern of MnO_2 during discharge were examined, as a means of revealing the reduction stages of the depolarizer in a cell, by various investigators including Matsuno,[4] McMurdie[5] and Copeland and Griffith.[6] These reports describe the formation of lower oxides and hydroxides of manganese as possible products in the discharge of MnO_2.

In recent years, a newly developed technique of electron probe microanalysis has been increasingly used in such fields as metallurgy and earth sciences in determining the nature of very small volumes of polished thin sections of alloys or mineral mounts. The principle is that the X-rays generated by the impact of the electron beam are characteristic of the elements present, and their intensity is an approximately linear function of concentration.[7]

If the MnO_2 during discharge produces a lower oxide or oxides of manganese by releasing the oxygen from MnO_2, a change in the relative concentration of oxygen at the reduced portions of the material may no doubt be visually observable, at least qualitatively, by differentiating the characteristic OK_α rays coming from the cross-sectional area of a thin section of MnO_2.

The present work has been performed in an attempt to observe the coexisting phases of reduced oxygen concentrations more directly by means of the electron probe microanalytical technique, to visualize how and where the reduction of the individual MnO_2 particles will proceed as the discharge takes place.

Experimental

Material. Electrolytically synthesized manganese dioxide was commercially available with an approximately 200 mesh fineness. This material was of a typical γ-type MnO_2 containing more than 91—93% MnO_2, and is currently used as a standard source of battery-grade manganese dioxide.

Procedures. (a) Discharging cell: A 5 g quantity of MnO_2 material was incorporated into a Leclanche-type test cell. The test cell was constructed by a method similar to that described in "Japanese Industrial Standards",[8] where 20 m*l* of a mixed solution of $NH_4Cl + ZnCl_2$ with a pH of 5.4 is provided as an electrolyte. A discharge with this type of wet cell was conveniently employed for the present purpose because of the ease of separating the MnO_2 after discharge from the cathode mix of the MnO_2 and acetylene black, rather than the paste-type cathode mix of a commercial dry battery. The cell construction used is shown in Fig. 1. A continuous discharge was performed on a fixed resistance of 10 Ω from an initial voltage of 1.6 V down to a cut-off voltage of 0.7 V.

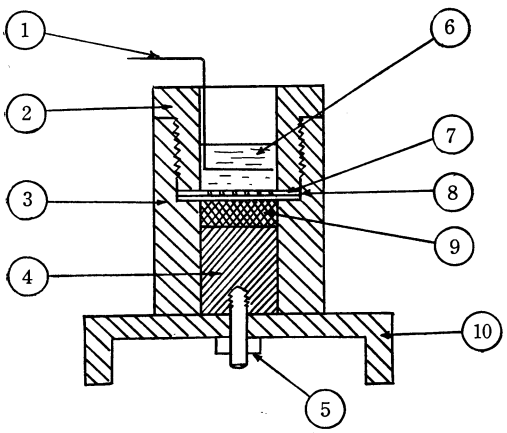

Fig. 1. Construction of the discharge cell used. (1): Zinc anode, (2): Anode bobbin, (3): Cathode bobbin, (4): Carbon rod, (5): Cathode terminal, (6): $NH_4Cl+ZnCl_2$ electrolyte, (7): perforated plate, (8): filter paper, (9): MnO_2 + acetylene black, (10): Bottom plate. (JIS K-1467 (1965))

8) JIS K-1467 (1965).

(b) Electron probe microanalysis: The cathode mix after discharge was washed and air dried. The dried sample was mixed with a polyester resin and set into a shape having a well-polished surface, and was put in an electron probe microanalyzer. This instrument was operated under the following set of conditions: accelerating voltage, 10 kV; average electron beam intensity, 0.04 μA; characteristic X-ray, OK_α; and magnification, 750. A concentration profile of the characteristic OK_α rays, integrated as well as discriminated, was taken by scanning the cross-sectional area of the MnO_2 in parallel with recording the absorbed electron image, focussing on a typical particle about 50 μ in diameter.

Results and Discussion

Figs. 2(a), 2(b) and 2(c) are a series of electron probe microanalyses for the cross-sectional area of a typical MnO_2 particle discharged down to a cut-off voltage of about 0.7 V, where Fig. 2(a) is the absorbed electron image of the profile with a magnification of 750. Figure 2(b) is a discriminated scanning of OK_α with the same magnification, which appears as an ensemble of small light spots across the same cross-sectional area as in Fig. 2(a). It is interesting to note that some darker portions cover the surface of the discharging particle and occurs along cleavages, or pores, near the surfaces of the body in Fig. 2(a), and in a corresponding manner in Fig. 2(b), the discriminated OK_α spots from the oxygen are less distributed at the border area between the cross-section and the background and around the pores in that area, reflecting a reduction in oxygen concentration in these portions. Especially the pores, either closed or open, of Fig. 2(a), are clearly observable as black voids in the upper-left areas lacking in white spots from oxygen in Fig. 2(b).

Fig. 2(c) is a photograph of the integrated intensities of the OK_α rays coming from oxygen

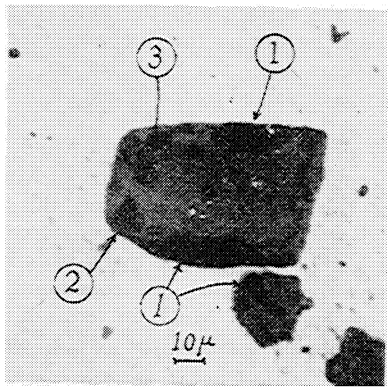

Fig. 2(a). Absorbed electron image of a profile of MnO_2 particle after discharge service. (1): discharged surfaces, (2): discharged open pore, and (3): discharged closed pore near the surface.

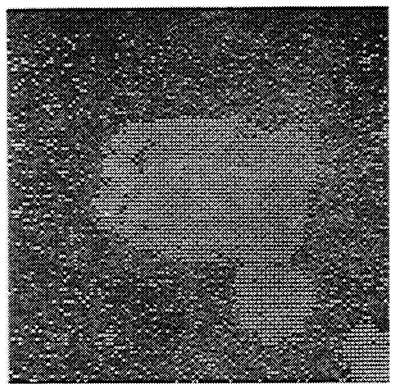

Fig. 2(b). Discriminated characteristc OK_α image scanned across the same profile of Fig. 2(a), showing that the corresponding discharged portions are less distributed with white spots which reflect the relative intensities of the characteristic OK_α rays coming from the oxygen of the cross sectional area. (Background: polyester resin of mounting piece)

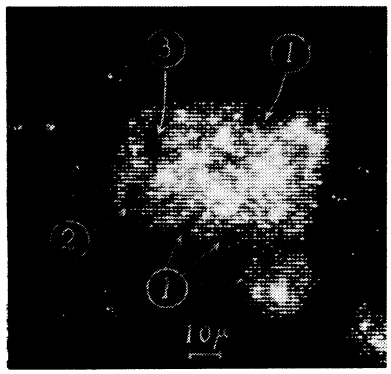

Fig. 2(c). Integrated characteristic OK_α image scanned across the same profile of Fig. 2(a), representing a well-defined light and shade of relative concentrations of oxygen of the profile. (1): discharged surfaces, (2): discharged open pore, and (3): discharged closed pore near the surface.

atoms of the same particle showing a more well-defined light and shade in the concentration profile. From a comparison of Fig. 2(c) with Fig. 2(b), it is clearly seen that the outermost surface of the particle and the vicinity around the pores are observed to contain a lesser amount of oxygen due to the reduction of MnO_2 in those portions, while the inner part of the particle is brighter, showing that the bulk still contains oxygen in the unused MnO_2.

It is noted that the parallel use of Figs. 2(a), 2(b) and 2(c) have provided a visual observation, in a sense, of the result that the discharge took place primarily at the surface and the pores, as previous workers pointed out the importance of the surface characteristics of MnO_2 including the surface area[9,10] and the pore distribution.[11,12] Furthermore, the present example with a 50 μ-particle suggests that the extension of the pores or cleavages in the MnO_2 body is seen to be roughly of the order of 10 μ. The initial pore openings have not been detected here, because the magnitude of a pore diameter is too small, previously calculated to be less than 400 Å by Cahoon[12] and predominantly 180 Å by Kozawa.[11] However, the results of Figs. 2(a), 2(b) and 2(c) show that the region containing a lower oxide of manganese, which was initiated along the micropores as well as at the surface, has invaded about 5 to 10 μ toward the inner part of the MnO_2 particle before decaying to the cut-off voltage of 0.7 V, and these invaded regions became detectable by the microanalytical method.

It also follows from an examination of the pictures that if the utility factor of the MnO_2 particle as depolarizer may be represented as a ratio of the total cross-sectional area of the particle to the darker area of reduced oxygen concentration emerging in the profile, the percentage will be 20—30% in this particular case of discharge down to a cut-off voltage of 0.7 V, which potential is well below that of the terminating voltage employed in most cases[13] when specifying the service life of a cell. This is an important observation as it shows the possibility of revealing changes in the solid phase during discharge in a cell system, provding useful data for industrial applications as well as for basic investigations of MnO_2 depolarizer, suggesting for instance that a treatment of the material to enhance a better use of the functions of cleavages or pores will be more beneficial to the service life as depolarizer than merely reducing the particle size alone.

Summary

Visual observation has been carried out with an oxygen concentration profile of an MnO_2 particle after discharge service down to 0.7 V in a Leclanche-type wet cell, by surveying the relative intensities of OK_α rays by means of an electron probe microanalytical technique. The roles of the pores inside the particle as well as the surface on the discharge process has been established by visually observing that the relative oxygen concentration of these portions becomes less after discharge. A covering of the MnO_2 by these lower oxide portions

is observed in a ratio of 20—30% of the total cross-sectional area. It is indicated that the discharge reaction of an MnO_2 particle involves a process of releasing oxygen from the sites of the outermost surface and along the pores.

The possibility is suggested for the use of the microanalytical examination as a powerful tool in interpreting how and where the discharge reaction proceeds across the cross-sectional area of the MnO_2 particle and in pursuing better performance for the material as a depolarizer in a cell.

The author wishes to thank Mr. H. Nakamura and Mr. S. Nakada for their cooperation in the electron probe microanalytical procedures which brought this work into being.

NOTES

Effects of Substituents of the Chain-transfer Reactivities of Nuclear-substituted Acetophenones toward the Polymethyl Methacrylate Radical

Tadahiro YAMAMOTO,*1 Masaru HASEGAWA and Takayuki OTSU

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka

(Received March 27, 1968)

In previous papers,[1-5] the effects of substituents on the reactivities of substituted cumenes toward polymer radicals have been reported. The observed reactivities were not correlated with the ordinary Hammett equation, but they showed a good correlation with the Hammett equation[6] modified to include the resonance term:

$$\log (k/k_0) = \rho\sigma + \gamma E_R \qquad (1)$$

where $\rho\sigma$ is the polar term and γE_R is the resonance term. The ρ and γ show the degree of polar and resonance contributions of the substituents to the reactivities respectively.

This paper will describe the substituent effects on the chain-transfer reactivities of nuclear-substituted acetophenones toward the polymethyl methacrylate (PMMA) radical. Since the acetophenone has a carbonyl group between the benzene ring and the reacting methyl group, the nuclear-substituent effects on the reactivities of its derivatives toward a radical may be different from those observed in the abstraction of a benzylic hydrogen, as has been reported in previous papers.[1-5]

Experimental

A series of nuclear-substituted acetophenones (see Table 1), but not acetophenone itself, were synthesized. By using the method described in a previous paper,[1] the polymerizations of the methyl methacrylate in each acetophenone derivative were carried out at 60°C in the presence of 2,2'-azobisisobutyronitrile (3.32×10^{-3} mol/l) as an initiator. The polymerizations were performed below 5% conversion.

The number-average degree of the polymerization ($\overline{P}_n$) of the polymers was calculated from their intrinsic viscosities, [η], determined in benzene, according to the following equation[7]:

$$\log \overline{P}_n = 3.420 + 1.13 \log [\eta]$$

The chain-transfer constants (C) of acetophenones were determined by means of Mayo plots[8] between $1/\overline{P}_n$ and the concentrations of the acetophenones.

Results and Discussion

The C values obtained are listed in Table 1, in which the E_R and σ values are the resonance[6] and the Hammett substituent constants[9], respectively.

As may be seen in Table 1, all of the C values for the substituted acetophenones were larger than that (C_0) for the unsubstituted compound. Figure 1 shows the plots using the ordinary Hammett equation and using Eq. (1).

p-Cl	0.227	0.10	0.90
p-Br	0.232	0.12	1.15
m-Cl	0.373	0.08	0.83
p-CH_3CO	0.502	0.24	2.86 (1.43)*
p-CN	0.660	0.24	2.18

* This value indicates the value per CH_3CO group.

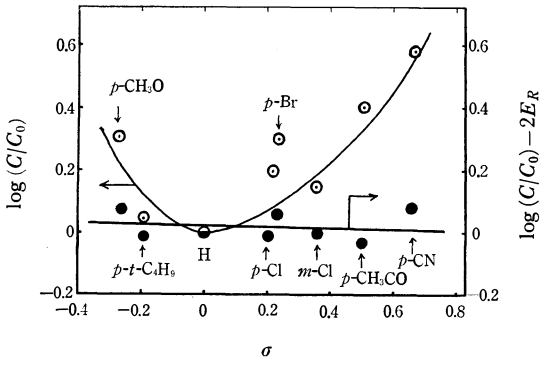

Fig. 1. Application of the Hammett equation and Eq. (1).

As is shown in Fig. 1, the ordinary Hammett plots for this reaction series failed to give a linear relationship. However, when the γ value in Eq. (1) was assumed to be 2.0, the plots with Eq. (1) gave linear relationship. From the slope of this line, the ρ value was obtained as nearly zero.

Table 2. Application of Eq. (1) to the chain-transfer reactions toward the PMMA radical at 60°C

Substrate	ρ	γ	Lit.
Cumenes	0.03	0.9	4)
Toluenes	0.01	0.6	10)
Dibenzoyl disulfides	0.07	0.75	11)
Diphenyl disulfides	0.01	0.75	12)
Phenylacetylenes	0.0	1.7	13)
Acetophenones	−0.01	2.0	This work

Table 2 summarizes the reaction constants obtained from the application of Eq. (1) to the chain-transfer reactions of various substrates toward the PMMA radical.

As can be seen from Table 2, the ρ values in these reactions are very small or are negligible in comparison with the γ values. This finding strongly demonstrates that the polar substitutent effect on the chain-transfer reactivities of these substrates toward the PMMA radical is rather small. On the other hand, the γ value in the present reaction series is much larger than those in the other reaction series. Therefore, it may be considered that the effects of substituents in the acetophenones on the chain-transfer reactivities toward the PMMA radical depend on the contributions of their resonance factors.

Synthesis of Perylene

Satoshi IWASHIMA and Junji AOKI

Tokyo Yushi Ind. Co., Iidabashi, Tokyo,

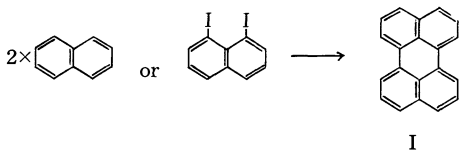
and Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba

(Received April 1, 1968)

Perylene, $C_{20}H_{12}$(I), is of interest in the field of organic and physical chemistry. It is possible to synthesize larger polycyclic aromatic compounds from this hydrocarbon; also, perylene forms molecular compounds with various kinds of electron donors and acceptors, all of which are typical organic semiconductors.

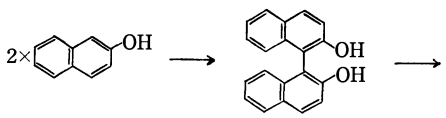
In 1910, perylene was first prepared by heating 1,1'-dinaphthyl or naphthalene with aluminum chloride.[1] However, the yield was extremely poor. Therefore, many studies concerning the synthesis of perylene and its derivatives have been carried out by a number of workers, as is described in Schemes A, B, and C.

1) R. Scholl and R. Weitzenböck, *Mh. Chem.*, **43**, 2202 (1910).

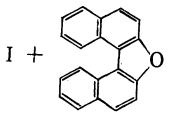


I

Scheme A

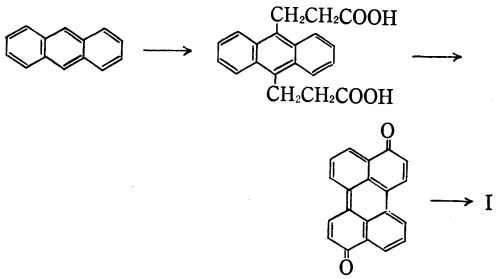


II



III

Scheme B

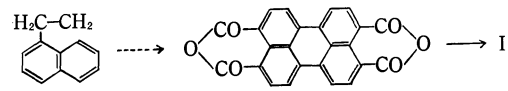


Scheme C

Of these methods, the A and C methods are very difficult to perform, and they yield only small percentages. The B method, in which the zinc-dust distillation is applied to β-dinaphthol (II), is a little easier to perform than the other two, but its yield is also low (3—7%) and purification is very difficult.

In this note, we will describe a method of preparing perylene which gives a good yield and a high purity. At first, we tried to improve the yields of perylene in the previous Schemes, A, B, and C, but we were unsuccessful. Secondly, we found that perylene is produced by the reduction of β-dinaphthylene oxide. This fact is interesting, but the yield is still low.

It has, however, also been found that perylene can readily be prepared by heating perylene tetracarboxylic acid anhydride (VI) with soda-lime in a vacuum. We denote this as Scheme D. This method gives a good yield of 80%, for the crude product has a high purity and purification can be readily carried out.



V VI

Scheme D

In addition, it has been reported that the decarboxylation of VI can also be carried out by heating it with 12% potassium hydroxide under pressure.[2] This method may also be considered a good method of preparing perylene, for it gives a considerable yield.

Experimental

The melting points are uncorrected.

Zinc-dust Fusion of β-Dinaphthylene Oxide (III). A mixture of 24 g of III, 16 g of zinc dust, 100 g of zinc chloride, and 20 g of sodium chloride was fused at 260°C for 20 min. After cooling, the mixture was dissolved in diluted hydrochloric acid. The insoluble part was collected, washed with water, and then dried. Fine, brownish-colored crystallites (2.0 g), extracted by hot xylene from this crude product, were sublimed *in vacuo* (10^{-3} Torr) and then recrystallized from xylene as yellow plates. The melting point of the crystal was 268—269°C (Ref. 1, 264—265°C). Yield, 1.5 g (6.6% of the theoretical amount).

Reduction of III by Martin's Method.[3] A mixture of 50 g of III, 125 g of zinc dust, 160 g of sodium hydroxide, 500 m*l* of xylene, and 2000 m*l* of water was refluxed for 20 hr. After the reaction mixture had cooled, the precipitate, containing zinc dust, was collected; this was then purified by a procedure similar to that described above. Yield, 3.6 g (7.7%) of fine, golden yellow plates; mp, 268—269°C.

Decarboxylation of Perylene Tetracarboxylic Anhydride (VI). A mixture of 1.00 g of VI[4] and 6 g of soda-lime was heated at 350°C for 1 hr; then, under a reducing pressure of 10^{-2} Torr, the temperature was raised to 440°C and kept there for 7hr. By the latter process, 0.60 g of fine, yellow crystals was obtained as a sublimate. This product was recrystallized from toluene, giving golden yellow plates. Yield, 0.51 g (80%); mp, 269.5°C (uncorr.), 280.3°C (corr.).

The authors wish to express their thanks to Professor Hiroo Inokuchi of the Institute for Solid State Physics, The University of Tokyo, for his kind advice.

The Mössbauer Effect in Fe_3Sn_2

Sumio ICHIBA, Hiroshi SAKAI and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received April 1, 1968)

In iron-tin alloys, the following intermetallic compounds have been reported to exist[1]: Fe_3Sn, Fe_2Sn, Fe_3Sn_2, FeSn and $FeSn_2$. Studies of the Mössbauer effect in these compounds, except for Fe_3Sn_2, have been performed by a number of workers,[2-6] because both constituents involve suitable nuclei.

Fe_3Sn_2 was shown to have a monoclinic structure with 40 atoms per unit cell and $a=13.5$Å, $b=5.34$Å, $c=9.20$Å, $\beta=103°$.[1] The Mössbauer parameters of both ^{57}Fe and ^{119}Sn nuclei in Fe_3Sn_2 are reported in this note.

Experimental

The alloy Fe_3Sn_2 was prepared by means of a sintering method. The powders of iron and tin were mixed in the stoichiometric proportion, pressed into a pellet, sealed in an evacuated quartz tube which was then heated at 800°C for a week and subsequently quenched in water. The phases which existed in the sample were identified as Fe_3Sn, Fe_3Sn_2 and β-Sn by X-ray diffractometry.

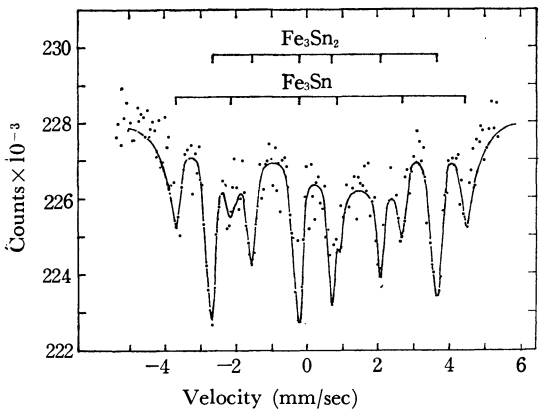

Fig. 1. Mössbauer absorption spectrum of ^{57}Fe in Fe_3Sn_2 at 24°C. The scale of the abscissa was taken toward ^{57}Fe in pure iron.

The ^{57}Fe Mössbauer spectrum of the sample at room temperature (source: ^{57}Co on Pd) is shown in Fig. 1. The spectrum shows the superimposed spectra of Fe_3Sn and Fe_3Sn_2. Table 1 gives the values of the relative velocity v of the source at which the maximum γ-ray absorption is observed for Fe_3Sn_2.

TABLE 1. THE RELATIVE VELOCITIES AND CORRESPONDING HYPERFINE COMPONENTS OF THE ABSORPTION LINE OBTAINED WITH THE SOURCE OF ^{57}Fe IN Pd AND Fe_3Sn_2 ABSORBER

hfs component	Transition	v, mm/sec
1	$+\frac{1}{2} \rightarrow +\frac{3}{2}$	-2.67 ± 0.03
2	$+\frac{1}{2} \rightarrow +\frac{1}{2}$	-1.55 ± 0.03
3	$+\frac{1}{2} \rightarrow -\frac{1}{2}$	-0.27 ± 0.03
4	$-\frac{1}{2} \rightarrow +\frac{1}{2}$	-0.69 ± 0.03
5	$-\frac{1}{2} \rightarrow -\frac{1}{2}$	2.08 ± 0.03
6	$-\frac{1}{2} \rightarrow -\frac{3}{2}$	3.63 ± 0.03

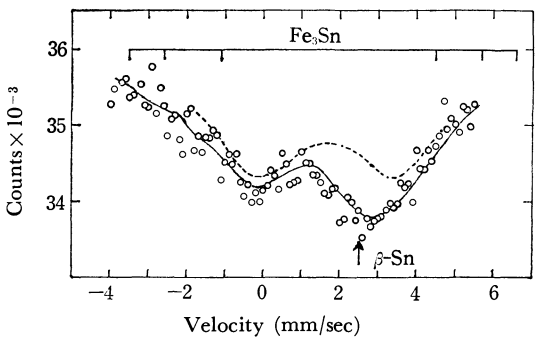

Fig. 2. Mössbauer absorption spectrum of ^{119}Sn in Fe_3Sn_2 at 24°C.

From the data in Table 1 the Mössbauer parameters of ^{57}Fe in Fe_3Sn_2 can be estimated as follows: isomer shift, $\delta=0.37\pm0.01$ mm/sec (relative to pure iron); quadrupole splitting, $2\varepsilon=0.21\pm0.02$ mm/sec; internal magnetic field, $H_i=196\pm3$ kOe; magnetic splitting of the ground level, $\alpha=2.30\pm0.03$ mm/sec; and magnetic splitting of the excited level, $\beta=1.33\pm0.03$ mm/sec. The ratio $\alpha/\beta=1.72\pm0.04$ is in good agreement with the value reported by Nikolaev *et al.*[4] for $FeSn_2$ and also with that by Kistner and Sunyar[7] for Fe_2O_3.

7) O. C. Kistner and A. W. Sunyar, *Phys. Rev. Letters*, **4**, 412 (1960).

Figure 2 shows the ^{119}Sn Mössbauer spectrum of the sample at room temperature for 23.8 keV γ-ray against the $^{119m}SnO_2$ source. This spectrum also shows the superimposed spectra of Fe_3Sn, β-Sn and Fe_3Sn_2. The two peaks in the center of the spectrum are thought to be due mainly to β-Sn and Fe_3Sn_2, because the absorption peaks of Fe_3Sn are situated far from the center. Then, the ^{119}Sn Mössbauer spectrum of Fe_3Sn_2 can be obtained by subtracting the β-Sn absorption from the peak. The resulting spectrum is shown by the dotted line in Fig. 2. In this case, the spectrum cannot be resolved into its hyperfine structure. However, the value of the internal magnetic field can be estimated to be about 38 kOe by using together values for the magnetic moment of -1.0411 ± 0.002 nm for the ground state and $+0.672\pm0.025$ nm for the first excited state of ^{119}Sn obtained by Kistner.[6] The isomer shift δ is found to be about 1.7 mm/sec.

The authors are indebted to Dr. Yutaka Maeda of the Research Reactor Institute of Kyoto University for the measurement of the Mössbauer spectra of ^{57}Fe.

Zone-Refining of Phenanthrene and Studies on the Purity*[1]

Shoichi MATSUMOTO

Central Research Laboratory, Tokyo Shibaura Electric Co., Ltd., Komukai, Kawasaki, Kanagawa

(Received April 9, 1968)

There is no available organic solid from commercial products which is in a state of such purity as is enough for the investigation of semiconductive properties. Thus, the purification of a specimen becomes a matter of special importance in the field of organic semiconductors; there have recently begun to appear many papers handling specimens of the utmost purity obtained by zone-refining.[1-5]

This paper deals with the practice of zone-refining of phenanthrene, which was adopted as the specimen of the experiments in the preceding papers,[6,7] and also studies on the purity of the purified specimen.

Experimental

The starting material was phenanthrene of a chemical purpose-grade obtained from Eastman Kodak Co. This material is henceforward denoted as phenanthrene C.

Phenanthrene C was at first recrystallized from an ethanol solution; phenanthrene R stands for the product after the four times recrystallization.

The zone-refining was carried out by using a modified zone-melting apparatus of the type designed by Herington, Handley and Cook.[8,9] The essential features of our apparatus are given in Fig. 1: the cycle of a slow and fast pass of the heater carriage can be continued automatically in our apparatus.

Phenanthrene R was loaded into a Telex-glass tube with an inner diameter of 10 mm, and the tube was sealed under a vacuum after it had been evacuated at 10^{-5} mmHg for eight hours. Then, the phenanthrene in the tube was automatically subjected to a number of zone-passes by the apparatus described above. The-

molten zone about 5 mm long was controlled to move slowly downward at a speed of 20 mm per hour.

The zone-rod of the phenanthrene after being subjected to 130 zone-passes (denoted as phenanthrene Z), with a total length of 130 mm in a Telex-glass tube, was cut into eight sections with a length of about 15 mm, and the phenanthrene of each section was denoted as phenanthrene Z-0, phenanthrene Z-1, ···, and phenanthrene Z-7 from the bottom of the zone-tube.

Results and Discussion

Purification and Electronic Spectra. All electronic spectra were measured in cyclohexane of a spectro-grade with a Cary Model-14 recording spectrophotometer, using 1 cm quartz cells. The variation of the electronic spectrum of phenanthrene Z observed according to distance along the zone-rod is shown in Fig. 2, where the spectra of phenanthrene Z-0, Z-3, Z-5, and Z-7 are represented, and they are accompanied with the spectrum of anthracene of a zone-grade (Tokyo Kasei Co.).

The electronic spectrum of phenanthrene Z near the bottom of the zone-tube, *e.g.*, phenanthrene Z-0, agrees with the spectrum of phenanthrene reported in the literatures,[10,11] while as for the spectrum of the phenanthrene Z in the distance far from the bottom of the tube, *e.g.*, phenanthrene Z-5 and Z-7, there appear four absorptions at 376, 371, 356, and 352 mμ which are not assigned to the spectrum of phenanthrene. These four absorptions become more intensified according to an increase in distance from the bottom of the zone-tube.

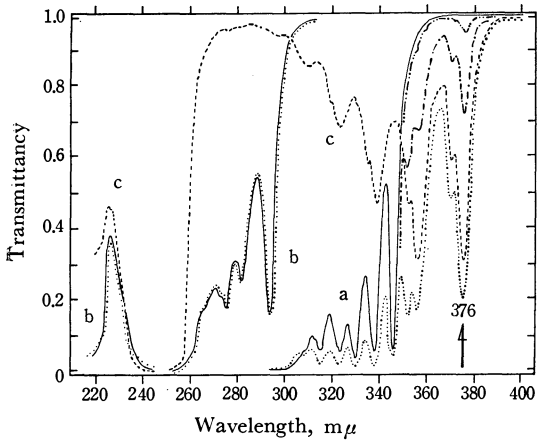

Fig. 2. Variation of the electronic spectrum of phenanthrene Z according to distance along the zone-rod (—— Z-0, —··— Z-3, —·— Z-5, ····· Z-7) and the spectrum of anthracene of a zone-grade purity (----). Symbols a, b for 5.05×10^{-3}, 5.05×10^{-5} mol/l phenanthrene solutions; symbol c for 4.24×10^{-5} mol/l anthracene solution.

Here, it was investigated from which compound among the probable impurities of acenaphthene, anthracene, carbazole, and fluorene, these four absorptions were originated. As a result, these absorptions in question were proved to correspond to the para-bands of anthracene,[11] and further it seemed very improbable spectroscopically that the above-mentioned impurities other than anthracene were present.*2 Therefore, anthracene may be a main impurity in the phenanthrene R.

Purification and Infrared Spectra. The variation of the infrared spectrum of phenanthrene Z according to distance along the zone-rod was investigated further to confirm the preceding results. The representative spectra of phenanthrene Z-0, Z-3, Z-5, and Z-7 are shown in Fig. 3, together with the spectrum of the zone-grade anthracene; it is observed that the absorption to be assigned to the very intensitive absorption at 882 cm^{-1} which is characteristic of anthracene and belongs to out of plane CH-bending vibrations of

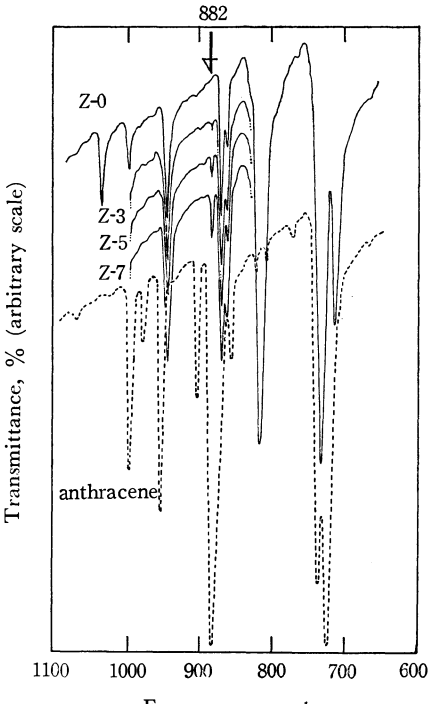

Fig. 3. Variation of the infrared spectrum of phenanthrene Z according to distance along the zone-rod and the spectrum of anthracene of a zone-grade purity.

10) E. Clar, *Spectrochim. Acta*, **4**, 116 (1950).
11) R. A. Friedel and M. Orchin, "Ultraviolet Spectra of Aromatic Compounds," "John Wiley & Sons, Inc., New York (1951).

*2 The relative intensity of the absorption at 352 mμ among the four absorptions seems to be rather stronger, compared with the corresponding one in the parabands of anthracene, but at the present time a reasonable explanation for it is not available.

it,[12] appaers at the same wave number in the spectrum of phenanthrene Z in the distance far from the bottom of the zone-tube, *e. g.*, phenanthrene Z-5 and phenanthrene Z-7.

The intensity of this absorption at 882 cm^{-1} increases with an increase in distance from the bottom of the zone-tube, while the spectrum of each phenanthrene Z is practically identical with each other except at 882 cm^{-1}. All absorptions other than that at the wave number in question in the spectrum of each phenanthrene Z shown in Fig. 3 coincide with those in the spectrum of phenanthrene reported in the literatures. These observations in the infrared spectroscopy are consistent with the result derived from the electronic spectroscopy, that anthracene is a main impurity in the phenanthrene R.*3

The infrared spectra were measured in the region 4000—650 cm^{-1} with a Jasco DS-402 G infrared spectrophotometer, and a potassium bromide disk method was employed.

Concentration-Distribution of Anthracene in the Zone-Rod. The quantity of anthracene as an impurity in each phenanthrene Z was spectroscopically evaluated by employing the absorption at 376 mμ after Beer's law was confirmed to be valid at this wavelength for the cyclohexane solution of phenanthrene containing a minute quantity of anthracene.

Figure 4 shows the resultant concentration-distribution of anthracene in phenanthrene Z; the concentration in moles of anthracene per one mole of phenanthrene (denoted as M) is plotted as the ordinate, and the distance measured from the bottom of the zone-tube is plotted as the abscissa, together with the corresponding position of the section of each phenanthrene Z. As to the concentration of anthracene in phenanthrene Z-0, 7×10^{-6} M was graphically estimated. The result reveals that anthracene travelled in the direction opposite to the direction of zone-travel and aggregated towards the top of the zone-tube.

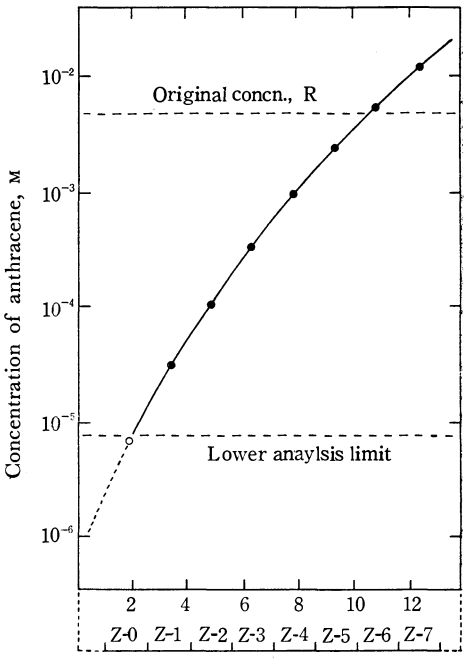

Fig. 4. Concentration-distribution of anthracene in the zone-rod of phenanthrene Z.

As for phenanthrene C and phenanthrene R, the concentration of anthracene was also analyzed spectroscopically; it was evaluated as 1.1×10^{-2} M and 5.6×10^{-3} M, respectively.

The extremely low concentration of anthracene observed at near the bottom of the zone-tube, 10^{-6}—10^{-5} M, indicates the effectiveness of the zone-melting with a sufficient number of zone-passes for the purification of phenanthrene containing anthracene which has been proved to be difficult by the conventional methods of purification.

*3 It should be kept in mind that there is the possible presence of some impurities which could not be spectroscopically detected.

The Formation of Salicylonitrile *via* the Thermal Decomposition of Bis(salicylaldimine)copper

Akira MISONO and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 10, 1968)

It is well known that the bis(salicylaldimine)-copper is a stable chelate. But the thermal properties of this chelate have not been fully studied. The authors have investigated on the preparation of nitriles from aldehydes and ammonia,[1] the reaction catalysed by a copper cation, for example, and also on the thermal properties of copper halide complexes of ketimines.[2] In due course, the bis(salicylaldimine)copper is expected to yield salicylonitrile through the thermal decomposition. Wendlandt *et al.*[3] investigated on the thermal decomposition of this chelate and reported that this chelate decomposed at high temperatures with evolving water, carbon monoxide, carbon dioxide and nitrogen. But they did not studied the fate of the ligand fully. Then, the present authors tried to detect salicylonitrile among the decomposition products.

The differential thermal analysis and thermogravimetric analysis were carried out and the results are shown in the Fig. 1. At about 215—240°C, the decomposition reaction proceeded, as was reported previously by Wendlandt.[3]

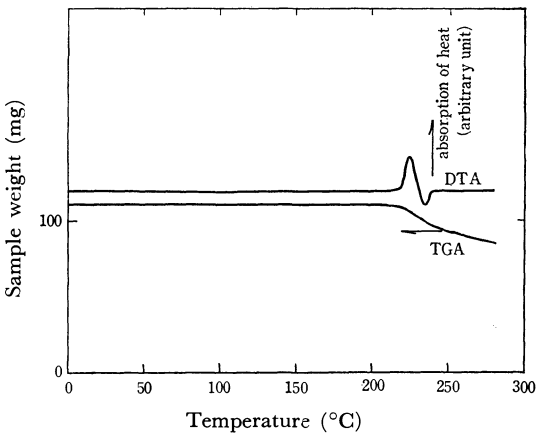

Fig. 1. The differential thermal analysis (DTA) and the thermogravimetric analysis (TGA). Heating rate: 2.5°C/min under a dynamic nitrogen atmosphere the reference: α-alumina.

The chelate was set at the bottom of an ample under reduced pressure at 220°C; the volatile decomposition products were trapped on the water-cooled wall of the upper part of the ample. From the trapped material, a considerable amount of salicylonitrile (nearly the half of the total amount of the ligand contained) was obtained after suitable treatments. Among the trapped material, some resinous products were also found. The unvolatile part was dark purple in color after the decomposition reaction, which contained metallic copper.

The thermal decomposition may proceed through the internal oxidation-reduction, in which the central cation is reduced to its metallic form and the coordinated ligands lose their some hydrogen atoms by oxidation and yield the nitrile as the main product. Some residual products may contain the further reaction products of the nitrile. It has been made clear that the coordinated imino group could be dehydrogenated to the cyano group by the action of the central cation.

Experimental

The bis(salicylaldimine)copper(II) was synthesized according to Tyson and Adams.[4] (Found: C, 55.66; H, 4.05; N, 9.39%)

The chelate, 2.98 g (9.8 mmol) in weight, was set in the bottom of an ample, the upper part of which was cooled with water. The lower part of the ample was heated at about 220°C for 3 hr under reduced pressure (about 1 mmHg). The yellow material trapped on the water-cooled wall was dissolved into acetone (yield, 1.78 g). The infrared spectrum of this material showed a strong absorption signal at about 2220 cm^{-1} assigned as the C≡N stretching (other main signals at about 3400—3000 (broad), 1605, 1460, 1310, 1280, 1240, 1160, 1030, 860, 850, 755 cm^{-1}: KBr disc method), but was not fully identical with that of a pure salicylonitrile. Salicylonitrile as the product was isolated according to the following procedure. The ether solution of the trapped material was treated with aqueous sodium hydroxide, and then the aqueous part was separated and acidified by hydrochloric acid. The aqueous solution thus obtained was again extracted with ether, and from the ethereal part, a yellow solid was obtained after evaporating the solvent. Its infrared spectrum was almost identical with that of a pure salicylonitrile (main signals at about 3290, 2220, 1605, 1505, 1460, 1360, 1310, 1275, 1240, 1160, 1100, 850, 750,

735 cm^{-1}: KBr disc method). Gross yield, 0.98 g (8.2 mmol) Recry. from toluene after the treatment with activated carbon. Mp 95.7—96.5°C (the mixture with an authentic salicylonitrile showed the identical melting point), lit.[5] 96°C.

Found: C, 70.68; H, 4.16; N, 11.95; O, 14.35%. Calcd for C_7H_5NO: C, 70.58; H, 4.23; N, 11.80; O, 13.34%.

5) M. Tanaka, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **78**, 1385 (1957).

In the X-ray diffraction pattern (Rigaku-Denki Co., Ltd., Geigerflex D-8C) of the unvolatile part (yield, about 1 g), strong signals were observed at about 43.5, 50.5, 74.0 and 90.0° of 2θ, which coincide with the signals of metallic copper. No other remarkable signals were observed.

The thermal analyses (TGA, DTA) were carried out with Rigaku-Denki Co., Ltd., differential thermal and thermogravimetric analyser. The decomposition was observed in a dynamic nitrogen atmosphere, at a heating rate of 2.5°C/min. Sample weight, 111 mg.

Short-range Dating of Fresh Nuclear Debris by the Activity Ratio of Iodine-133 to Iodine-131

Takeshi SOTOBAYASHI, Toshio SUZUKI and Seitaro KOYAMA

Department of Chemistry, Faculty of Science, University of Niigata, Niigata

(Received April 10, 1968)

In order to investigate the radiochemical composition at time-zero of short-lived radionuclides in fallout particles and its time variation shortly after a nuclear test explosion, it is necessary to determine as accurately as possible the age of the fallout particles. Fresh nuclear debris particles usually consist mainly of short-lived nuclides, such as ^{97}Zr, ^{99}Mo, ^{143}Ce, ^{132}Te-^{132}I, ^{133}I and ^{239}Np. Recently we proposed a simple method for the short-range dating of fresh nuclear debris;[1] this method was successfully carried out by the determination of the activity ratio of ^{97}Zr to ^{95}Zr at a given time 2—7 days after a nuclear explosion.

Results and Discussion

According to the radiochemical composition of short-lived fission products present in hot fallout particles, the particles can be grouped roughly into two classes. The first is enriched with refractory nuclides, such as ^{97}Zr, ^{99}Mo, and ^{144}Ce, and depleted in volatilely-behaving ones, such as ^{132}Te-^{132}I and ^{133}I. The second shows the reverse trend regarding the enrichment of these nuclides; that is, refractory nuclides are depleted and volatile ones, enriched. In many cases these two different types of particles were not found at the same time among hot particles or in rain samples resulting from a given nuclear test explosion, but one of the two types was detected shortly after a nuclear detonation. The first type of particles was recently found among the fallout particles derived from the May 9, 1966, Chinese nuclear test explosion[2] and the second, in the particles (Fig. 1) and rain samples from the December 28, 1966, Chinese nuclear test. Figure 1 shows three γ-ray spectra of a hot particle collected on December 30, 1966; the spectra, A, B, and C, were measured 9, 28 and 37 days after the explosion, respectively. From these spectra it is obvious that this particle consisted mainly of ^{103}Ru, ^{132}Te-^{132}I, ^{133}I, and ^{239}Np, and that it contained no detectable amounts of ^{95}Zr-^{95}Nb or, hence, of ^{97}Zr-^{97}Nb.

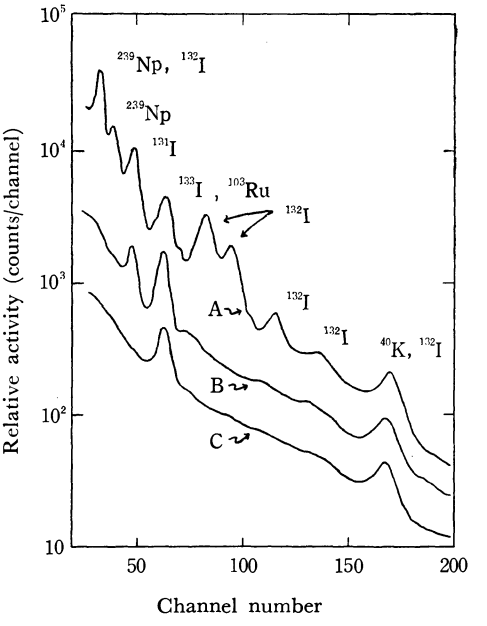

Fig. 1. Gamma-ray spectra of a fallout particle from the December 28, 1966, Chinese nuclear explosion. The spectra A, B and C were measure on January 6, 25 and March 3, 1967 respectively.

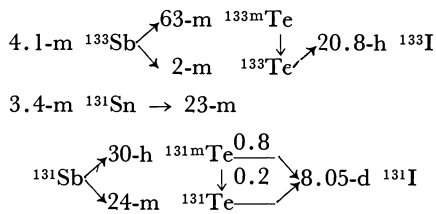
2) T. Sotobayashi, T. Suzuki and S. Koyama, This Bulletin, **40**, 1555 (1967).

The $^{97}Zr/^{95}Zr$ dating method is not suitable for the radioiodine-rich particle shown in Fig. 1 because of the very great trouble needed to collect a number of fallout particles large enough for the activity ratio to be determined with sufficient accuracy. In the present work, therefore, we have especially examined two isotopes, ^{133}I and ^{131}I, present in large quantities in the particles in question. The ^{133}I and ^{131}I isotopes decay, with 20.8-h and 8.05-d half-lives, to ^{133}Xe and ^{131}Xe, respectively. Thus, we can expect the $^{133}I/^{131}I$ activity ratio to provide a radioactive clock very sensitive to small differences in time. The two mass chains, 133 and 131, are relatively complex compared with those for 97 and 95:



At the earlier stages of the formation processes of fallout particles, it seems that the two nuclides, ^{133}I and ^{131}I, still remain in the forms of ^{133}Sb and ^{131}Sn, respectively; this is on the assumption that the time taken for fission products to condense and to form a fallout particle is 40 sec or less after an explosion.[3] The melting points of antimony and tin are 630 and 230°C, respectively, and the solidification temperature of the carrier material (silicate soil) of fallout particles can reasonably be considered to be ~1700°C.[4] Taking these points into consideration, we will show here that the requirements for a successful dating are fulfilled by the ^{133}I and ^{131}I fission fragments extracted from the particles or rain samples resulting from the December 28, 1966, explosion.

Highly-radioactive fallout particles and rain-water samples were collected at Niigata between December 30, 1966, and January 2, 1967. One particle and 3 rain samples were submitted to preliminary treatment for chemical separation. The sample solutions thus obtained (1 M HNO_3) were then analyzed by the HNO_2-CCl_4 extraction method. The activities of the purified radioiodines in the form of silver iodide were measured using a $1\frac{3}{4}$ in $\times$ 1 in NaI(Tl) scintillation detector with a 200-channel pulse-height analyzer, and were determined by measuring the areas of the photopeaks at 0.36 and 0.53 MeV.

Figure 2 shows the activity ratios of ^{133}I to ^{131}I as a function of the time 2—10 days after the explosion. The solid line in this figure was drawn

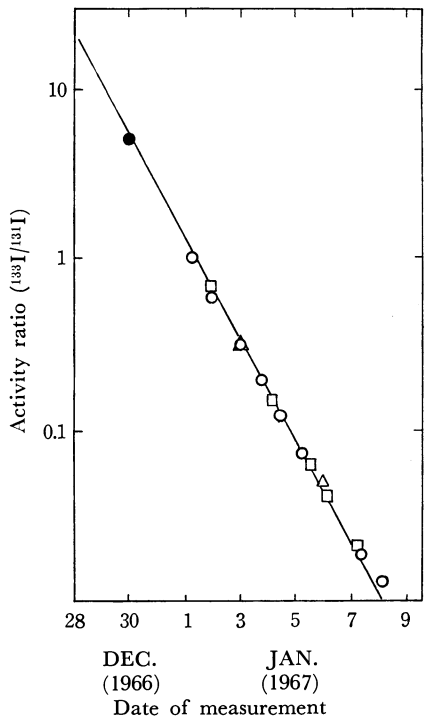


Fig. 2. Activity ratios of ^{133}I to ^{131}I as a function of time 2-10 days after the explosion.
●, a particle sample collected on Dec. 30, 1966
○, a rain sample collected on Dec. 31, 1966
□, a rain sample collected on Jan. 1, 1967
△, a rain sample collected on Jan. 2, 1967

against the time on the assumption that the cumulative fission yields of ^{133}I and ^{131}I are 6.9 and 3.1, respectively.[5] Further, the Chinese nuclear bomb was estimated to have been blasted at 14 : 30 h on December 28, 1966 (Japanese time), by the $^{97}Zr/^{95}Zr$ method.[1] We regarded this estimated time of explosion as the time-zero of the nuclear fission event because the exact time of the explosion was not announced by the Chinese agency responsible. It can clearly be seen in Fig. 2 that most of the measured ratios lie nearly along the assumed line. This finding suggests that, in spite of some differences in the physical and nuclear properties of each first member for the two mass chains, 133 and 131, no significant fractionation occurred between ^{133}I and ^{131}I during the formation of fallout particles. As a result, the dating method by the activity ratio $^{133}I/^{131}I$ is well suited for the short-range dating of fresh nuclear debris of the second type.

In conclusion, when any kind of fresh nuclear debris is found shortly after a nuclear explosion, either of the two dating methods will enable us to determine readily the age of this fresh nuclear debris with sufficient accuracy.

The Intramolecular Hemiacetal Structure of Benzoyl-(2-hydroxybenzoyl)methyl Bromide*1

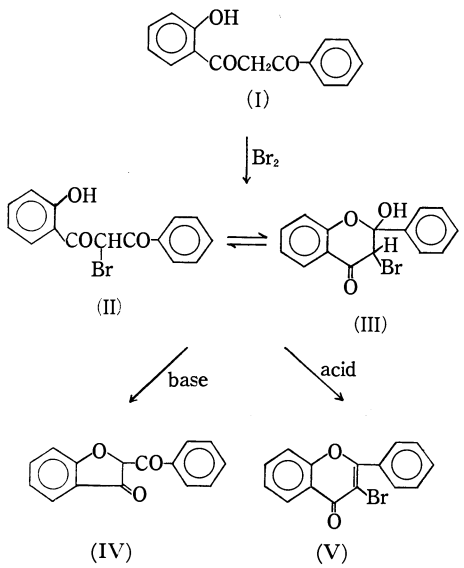
Heitaro OBARA and Jun-ichi ONODERA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received April 12, 1968)

During the course of their studies of the properties of benzoyl(2-hydroxybenzoyl)methyl bromide (II), which was afforded from benzoyl(2-hydroxybenzoyl)methane (I) by bromination in a chloroform solution in the presence of potassium carbonate, the present authors found that a ring-chain tautomerism exists between II and its cyclic hemiacetal structure (III). II was prepared by Hlavka,[1] in 1965, from I by bromination with *N*-bromosuccinimide in a chloroform solution for the purpose of its photolysis, and it has been reported that this bromide converts easily into 3-benzoylcoumaranone (IV)[2] and 3-bromoflavone (V)[3] with a base or an acid respectively.

However, no investigation has been made concerning its cyclic hemiacetal structure. In order to ascertain this tautomerism, the NMR, IR and UV spectra of this bromide and its homologue will be discussed in the present paper.



Results and Discussion

The NMR spectrum of this bromide in $CDCl_3$ exhibits four groups of signals (a, b, c, and d) in addition to the aromatic proton groups (6.65 ppm—8.20 ppm), as is shown Fig. 1. From the fact that the a and d bands disappear after the D_2O exchange, the a peak on the lowfield side of these bands was attributed to the hydrogen bonding phenolic OH proton in II, while the d peak was attributed to the hemiacetal OH proton in III. The c band was assigned by comparing it with the signal due to the -COCHBrCO- proton in dibenzoyl methyl bromide,*2 and the b band was assigned to the -COCHBr- proton in the hemiacetal (III).

From the relative peak areas of a, b, c, and d, the molar ratio of the tautomer II and III in this case was found to be approximately 3 : 11.

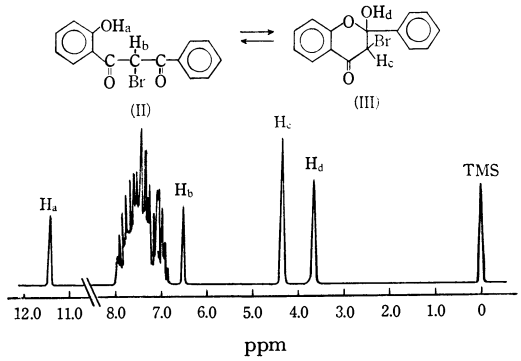


Fig. 1

The IR spectrum of this bromide in a chloroform solution gave an interesting result in the 1600 cm^{-1}—1700 cm^{-1} region. It showed a strong carbonyl absorption band at 1678 cm^{-1} immediately after it had been dissolved in chloroform; however, this absorption band decreased slowly with the lapse of time, and a new absorption band appeared at 1634 cm^{-1} and then remained unchanged for at least 4 hr (Fig. 2). It is considered that this new band is a characteristic absorption band due to the intramolecular chelated carbonyl group in the structure II which is observed in aromatic *o*-hydroxyketones.[4]

4) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules," John Wiley & Sons, Inc., New York (1958), p. 143.

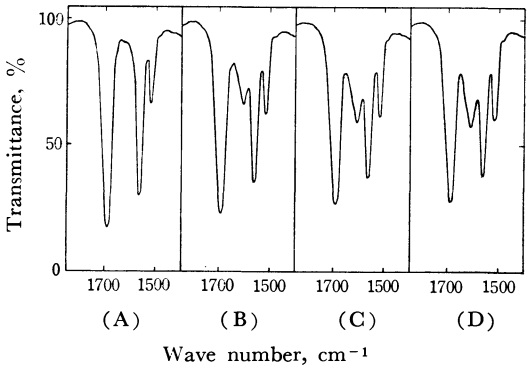

Fig. 2. The variation of the IR spectra of (II) with time in $CHCl_3$.
A: Immediately after dissolving. B: After 10 min. C: After 30 min. D: After 4 hr.

From the results of these IR spectra measurements, it is expected that this bromide has the structureIII before dissolving, and that it reaches equilibrium between II and III in a solution. It seems to be a very valuable result that the variation in such ring-chain tautomerism between II and III was observed in the IR spectrum measurements. On the other hand, the IR spectrum of this bromide in a KBr disk is similar to those of flavanone (VI) and 3-hydroxyflavanone (VII), and there is no chelated carbonyl absorption band near 1634 cm^{-1}, which would be expected if the structure of this bromide were II (Fig. 3).

From these observations, the cyclic hemiacetal structure III rather than II must be given for this bromide in the crystalline state. Accordingly, it is presumed that the strong peak of this bromide shown at 3270 cm^{-1} in Fig. 3 is not a phenolic OH peak but a hemiacetal OH-stretching peak.

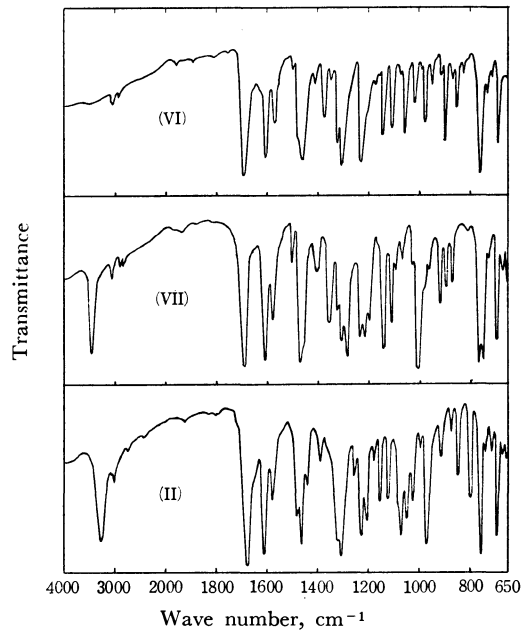

Fig. 3. The IR spectra of flavanone (VI), 3-hydroxyflavanone (VII) and benzoyl(2-hydroxybenzoyl)methyl bromide (II) in KBr disks.

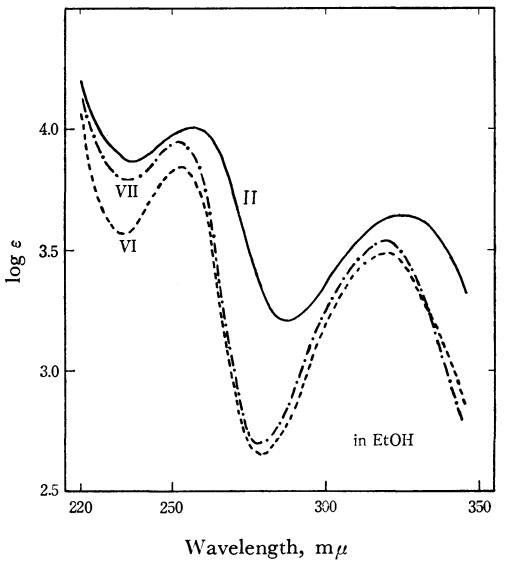

Fig. 4. The UV spectra of benzoyl(2-hydroxybenzoyl)methyl bromide (II); flavanone (VI) and 3-hydroxyflavanone (VII).

The UV spectrum of this bromide exhibits its absorption maxima at 257 mμ and 324 mμ in ethanol; the similarity of the absorption curve with those of flavanone (VI) and 3-hydroxyflavanone (VII) was observed.

Finally, the existence of ring-chain tautomerism in II and III was ascertained by the chemical

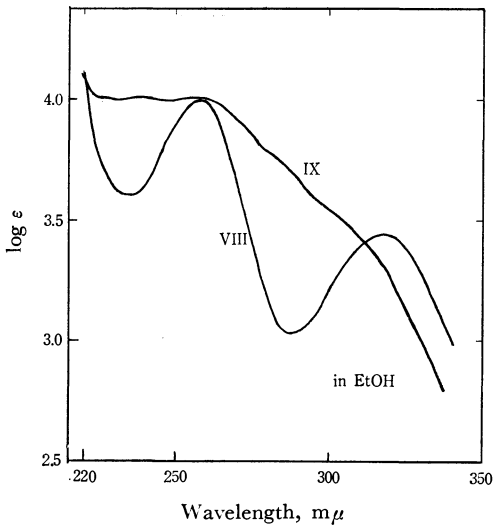

Fig. 5. The UV spectra of benzoyl(2-acetoxybenzoyl)methyl bromide (IX) and 2-acetoxy-3-bromoflavanone (VIII).

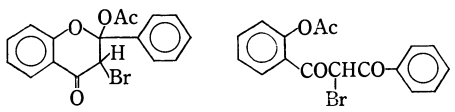
method. Two acetates were obtained from this bromide by acetylation with acetic anhydride in pyridine; one was crystalline (mp 151—152°C), and the other was a viscous oil, while both were analyzed as acetates of II or III.

The UV spectrum of the crystal acetate exhibits its absorption maxima at 257 mμ and 318 mμ, and its absorption curve is similar to those of flavanones (VI and VII); however, the oily acetate is not. (Fig. 5). The IR spectra of both acetates showed the same CO bands due to the acetyl groups at 1766 cm^{-1} and 1767 cm^{-1}, but two different CO bands were observed in the 1670 cm^{-1}—1700 cm^{-1} region (Fig. 6).



(VIII) (IX)

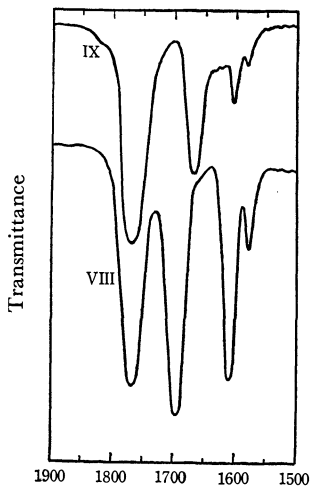


Fig. 6. The IR spectra of benzoyl(2-acetoxybenzoyl)methyl bromide (IX) and 2-acetoxy-3-bromoflavanone (VIII) in $CHCl_3$.

In these experiments, the ring-chain tautomerism between II and III was confirmed by NMR, IR and UV spectra measurements, and by the formation of two isomeric acetates; furthermore, it was proved that this bromide exists as the cyclic hemiacetal structure (III) *i. e.*, 2-hydroxy-3-bromoflavanone in the crystalline state.

Experimental

Benzoyl(2-hydroxybenzoyl)methyl Bromide (II). A solution of 1.0 g of bromine in 8 m*l* of chloroform was stirred into a mixture of 1.40 g of benzoyl(2-hydroxybenzoyl)methane (I) and 2.5 g of anhydrous potassium carbonate in 60 m*l* of chloroform at 0°C. After the addition was completed, the reaction mixture was filtered, and the filtrate was evaporated *in vacuo*. Ligroin was added to the oily residue, which was then allowed to stand overnight in an ice box. By the recrystallization of the resulting pale yellow solid from chloroform-ligroin, 1.29 g of II were afforded as colorless needles. Mp 141°C. Reported mp 145—146°C[1] IR (KBr), 3270 cm^{-1} (ν OH), 1678 cm^{-1} (ν CO). UV λ_{max}^{EtOH} mμ (log ε), 257 (4.01), 324 (3.65).

Found: C, 56.63; H, 3.70%. Calcd for $C_{15}H_{11}O_3Br$: C, 56.45; H, 3.47%.

Formation of 2-Benzoylcoumaranone (IV) and 3-Bromoflavone (V). a) II was converted to yellow crystals by heating it with pyridine at 75°C for 5 min. Recrystallization from methanol gave IV as yellow needles melting at 79—81°C. Reported mp 79—80°C.[2] IR (KBr), 1616 cm^{-1} (ν CO). UV λ_{max}^{EtOH} mμ (log ε), 241(4.05) 258(4.02) 348(4.21). b) To a solution of II in acetic acid, a drop of concentrated sulfuric acid was added, and the mixture was heated for 10 min at 100°C. It was then poured into water. The recrystallization of the resulting crystals from ethanol gave V as colorless needles melting at 124—125°C. Reported mp 126.5°C.[3] IR (KBr), 1660 cm^{-1} (ν CO). UV λ_{max}^{EtOH} mμ (log ε) 249 (4.27) 309 (4.09).

Acetylation of Benzoyl(2-hydroxybenzoyl)-methyl Bromide (II). To a solution of 500 mg of II in 5 m*l* of acetic anhydride, 2 drops of pyridine were added, after which the mixture was allowed to stand at room temperature for 2 days. The resulting yellow solution was poured into cold water, and the oily product was extracted with ether. The ether layer was washed with a dilute sodium hydrogencarbonate solution and water, and was dried over anhydrous sodium sulfate. The ether was removed by distillation, and the residue was chromatographed on a column of silica gel. Elution with ether-petroleum ether (2 : 1) gave 10 mg of 2-acetoxy-3-bromoflavanone (VIII) as colorless prisms. Mp 151—152°C. IR ($CHCl_3$), 1695, 1767 cm^{-1}. UV λ_{max}^{EtOH} mμ (log ε) 257 (4.01) 318 (3.45).

Found: C, 56.62; H, 3.68%. Calcd for $C_{17}H_{13}O_4Br$: C, 56.53; H, 3.63%.

Continuing elution with the same eluents yielded 23 mg of white crystals, which were identified as 3-bromoflavone (V) by means of their IR spectra, their melting points, and a mixed melting point determination with an authentic sample (mp 124—125°C). Using the same procedure from the last eluents 234 mg of benzoyl-(2-acetoxybenzoyl)methyl bromide (IX) were afforded as viscous oil. IR ($CHCl_3$) 1672, 1766 cm^{-1} (ν CO). UV λ_{max}^{EtOH} mμ (log ε) 237 (4.04) 257 (4.03).

Found: C, 56.63; H, 3.91%. Calcd for $C_{17}H_{13}O_4Br$: C, 56.53; H, 3.63%.

The authors wish to express their thanks to Professor Tetsunosuke Nishi for his encouragement and to Professor Ichiro Murata for the NMR spectra. They are also grateful to Mr. Hajime Baba for supplying the flavanones and to Miss Chiyo Itô for her technical assistance.

The Reactions of 4-Thiazone Imine Hydrochlorides with Amines[1]

Shigeru SATO and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 24, 1968)

In the preceding paper of this series,[2] it was reported that mesoionic compounds with an exocyclic imino group such as thiazone imine and sydone imine are stable only in the forms of salts or of *N*-acyl derivatives and do not exist in the form of free bases.

The treatment of 2-phenyl-3-*p*-chlorophenyl-4-thiazone imine hydrochloride (I) with sodium bicarbonate afforded cyanomethyl *N*-(*p*-chlorophenyl)benzthioimidate (II), which could then be converted back into I by treating it with hydrogen chloride, while the treatment of 2,3-diphenylthiazone imine hydrochloride (III) with sodium bicarbonate gave only tarry substances, from which neither the expected cyanomethyl *N*-phenylbenzthioimidate (IV) nor the free base of the corresponding thiazone imine hydrochloride could be obtained. It seems that the nucleophilic attack of a base upon thiazone imine hydrochloride might not be simple; therefore we investigated the behavior of thiazone imine hydrochloride towards the nucleophilic attack of amines.

Results and Discussion

The treatment of III with triethylamine, pyridine, and sodium alkoxide afforded tarry substances in all cases. When the solution of III in aniline was allowed to stand overnight, and was then neutralized with hydrochloric acid, colorless needles (V) were separated out; the results of an elemental analysis of them were consistent with the formula resulting from the removal of hydrogen chloride from III. In the infrared spectrum of V a band at 3300 cm^{-1}, which may be due to an NH stretching vibration, and a band at 1540 cm^{-1}, due to an N=C stretching vibration, appeared. V showed characteristic absorptions at 275 mμ, (ε=36000) and 362 mμ, (ε=4800) in its ultraviolet spectrum, absorptions suggestive of an aromatic heterocyclic system. These spectral analyses suggest that Compound V may be 2-phenyl-4-anilinothiazole. In addition, in the NMR spectrum V had an absorption at 3.85 τ. On the basis that the proton of the 5-position of 2,4-dimethylthiazole exhibits a singlet at 3.34τ,[3] this absorption was attributed to the proton of the 5-position of the above structure for V. Very few 4-aminothiazole derivatives have been found in the literature,[4] and no 4-anilinothiazole derivatives have been known. Although the structure of V was not confirmed by an independent sythesis, it may possibly be supported by the elemental and spectral analyses.

The consideration that the formation of V might proceed through the intermediate IV led us to examine the reaction of IV with aniline. When IV was treated with aniline under the same reaction conditions as in the case of the reaction of III with aniline, V was obtained in a good yield. In order to investigate the role of aniline, other bases were used in the reaction with IV. The treatment of IV with *o*-toluidine also gave V; this fact showed that the anilino group of the 4-position of V was not derived from the aniline used as the solvent, but was rather derived by the rearrangement of IV. When dimethylaniline was used instead of aniline, the starting material was recovered. This fact suggests, further, that aniline participates in the rearrangement by forming an adduct with IV.

As a consequence, the mechanism of the formation of V may be formulated in the way pictured in Scheme I.

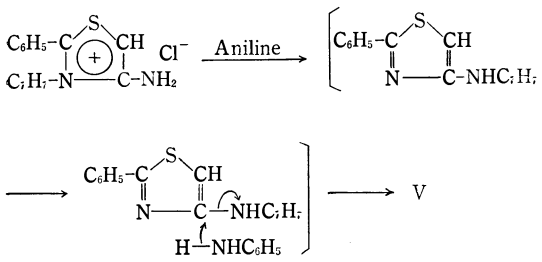
A rearrangement analogous to this was observed in that of *N*-acetyl-sydnone imine hydrochloride into a 5-hydroxytriazole derivative.[5] When 2-*p*-methoxyphenyl-3-phenyl-thiazone imine hydrochloride was treated with aniline, 2-*p*-methoxyphenyl-4-anilinothiazole was obtained, but in the case of II, the corresponding thiazole was not obtained by the treatment of II with aniline. When 2-phenyl-3-benzyl-thiazone imine hydrochloride was treated with aniline, V was obtained. The isolation of this unexpected product may be explained on the assumption that there was an exchange of the benzylamino group of the first-formed 2-phenyl-4-benzylaminothiazole with aniline.

When IV was treated with benzylamine, two substances were obtained; one was *N*-phenyl-*N'*-benzyl-benzamidine, but the structure of the other



Scheme II

was not clear. When IV was allowed to stand in liquid ammonia, thiobenzanilide was isolated.

V formed the hydrochloride and picrate; the former was so unstable that it was converted into polymeric substances within one or two days. When an ethanolic solution of V was boiled with hydrochloric acid, a tarry substance was formed, from which nothing was obtained in a pure state, but when it was boiled with sodium hydroxide for eight hours, V was almost quantitatively recovered unchanged. V was acetylated with acetyl chloride to form 2-phenyl-4-anilino-*N*-acetyl-thiazole. Attempts to form the quaternary salt with benzyl chloride and the *N*-nitroso derivative were not successful. By the treatment of 2-phenylsydnone imine hydrochloride with aniline, an analogous rearrangement product was not obtained, in contrast with the case of thiazone imine hydrochloride, but *N*-nitroso-*N*-phenyl-glycinonitrile was obtained.

Experimental[6]

The Reaction of 2,3-Diphenyl-thiazone Imine Hydrochloride(III) with Aniline. A solution of 1 g of III in 10 m*l* of aniline was allowed to stand overnight at room temperature, and then it was neutralized with 10% hydrochloric acid under ice cooling. The precipitates were collected and recrystallized from ethanol to give colorless needles; mp 102—102.5°C. Yield, 0.4 g. UV: λ_{max}^{EtOH} 275 mμ (ε=36300), 362 mμ (ε=4800). IR: 3200, 1600, 1530 cm^{-1}. Found: C, 71.14; H, 4.59; N, 11.08%. Calcd for $C_{15}H_{12}N_2S$: C, 71.42; H, 4.76; N, 11.11%.

The treatment of 2-*p*-methoxyphenyl-3-phenyl-thiazone imine hydrochloride with aniline gave the corresponding thiazole under the same experimental conditions as have been described. Mp 120—121°C. The yield was 70%. Found: N, 10.23%. Calcd for $C_{16}H_{14}N_2OS$: N, 9.93%.

The Reaction of Cyanomethyl *N*-Phenylbenzthioimidate (IV) with Amines. *With Aniline.* A solution of 1 g of IV in 10 m*l* of aniline was allowed to stand overnight at room temperature, and then it was neutralized with 10% hydrochloric acid under ice cooling. After collection by filtration, the precipitates were recrystallized from ethanol to give colorless needles; mp 102—103°C. No depression of the melting point was observed on admixture with V. The yield was 0.7 g.

With o-Toluidine. The treatment of IV with *o*-toluidine instead of aniline under the above experimental conditions afforded V. The yield was 15%.

With Dimethylaniline. A solution of 1 g of IV in 10 m*l* of dimethylaniline was allowed to stand for a week, and then it was neutralized with 10% hydrochloric acid under ice cooling. The precipitates which separated out were collected and recrystallized from methanol to give colorless needles; mp 65—67°C. No depression of the melting point was observed on admixture with the starting material.

With Liquid Ammonia. A solution of 1 g of IV in liquid ammonia was allowed to stand for four days at room temperature. After the removal of the ammonia, the residue was collected and recrystallized from ethanol to give yellow prisms; mp 96—97°C.

No depression of the melting point was observed on admixture with thiobenzanilide.

With Benzylamine. A solution of 1 g of IV in 10 m*l* of benzylamine was allowed to stand overnight and was then neutralized with 10% hydrochloric acid under ice cooling. From the precipitates which separated out, *N*-phenyl-*N'*-benzyl-benzamidine was isolated by fractional recrystallization from ethanol.

The Reaction of 2-Phenyl-3-benzyl-thiazone Imine Hydrochloride with Aniline. A solution of 1 g of 2-phenyl-3-benzyl-thiazone imine hydrochloride in 10 m*l* of aniline was allowed to stand overnight, and was then neutralized with 10% hydrochloric acid under ice cooling. The precipitates were collected and recrystallized from ethanol to give colorless needles; mp 102—103°C. No depression of the melting point was observed on admixture with V.

The Acetylation of 2-Phenyl-4-anilinothiazole (V). In 20 m*l* of acetyl chloride 0.2 g of V was dissolved, and then the solution was refluxed for one hour. After the removal of the excess acetyl chloride, ether was added to the oily residue. The precipitates were collected and recrystallized from ethanol to give colorless prisms; mp 107—109°C. The yield was 0.2 g. Found: C, 69.51; H, 4.90; N, 10.06%. Calcd for $C_{17}H_{14}N_2OS$: C, 69.39; H, 4.76; N, 9.52%.

Spectrophotometric Determination of the Stability Constants of Mixed Ligand Complexes of Mercury(II)-Ethylenediaminetetraacetate with Thiocyanate and Bromide

Toshiaki NOMURA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received April 25, 1968)

Mercury(II) reacts with ethylenediaminetetraacetate (EDTA or H_2Y^{2-}) to form mercury(II)-ethylenediaminetetraacetate (Hg-EDTA or HgY^{2-}). Thiocyanate,[1] cyanide,[2] iodide and bromide[3] (X^-) react with Hg-EDTA to form a mixed ligand complex $[HgY(X)]^{3-}$. The degrees of the dissociation (α) of the mixed ligand complexes were determined by measuring its absorption. Then, the apparent stability constants of the thiocyanato or bromo mixed ligand complexes of these ions could be calculated by the molar ratio method.[4]

The $[HgY(X)]^{3-}$ mixed ligand complex dissociated to HgY^{2-} and X^-:

$$\underset{C(1-\alpha)}{[HgY(X)]^{3-}} \rightleftharpoons \underset{\alpha C}{HgY^{2-}} + \underset{\alpha C}{X^-} \qquad (1)$$

where C is the molar concentration of the mixed ligand complex assumed to have no dissociation and α, the degree of dissociation for the mixed ligand complex. The apparent stability constant (K) for this reaction may be expressed by:

$$K = \frac{[[HgY(X)]^{3-}]}{[HgY^{2-}][X^-]} = \frac{1-\alpha}{\alpha^2 C} \qquad (2)$$

The degree of dissociation is given by:

$$\alpha = \frac{E_{max} - E_s}{E_{max}} \qquad (3)$$

where E_{max} is the assumed absorbance of the mixed ligand complex, to which all HgY^{2-} should be reacted with X^-, and where E_s is the measured absorbance of the mixed ligand complex, at the equivalent point C. However, HgY^{2-} and X^- had appreciable absorptions in the ultraviolet region. Therefore, if the absorbances of HgY^{2-} and X^- at the equivalent point are given as E_R and E_T respectively, the measured absorbance (E_s') is the sum of the absorbances of the mixed ligand complex (E_s), E_R and E_T:

$$E_s' = E_s + E_R + E_T$$
$$E_s = E_s' - E_R - E_T \qquad (4)$$

Since E_R and E_T are the α times of the absorbances of HgY^{2-} and X^- at the concentration of C (abbreviated as E_r and E_t respectively), Eq. (4) is given as follows:

$$E_s = E_s' - \alpha(E_r + E_t) \qquad (5)$$

When we substitute Eq. (5) into Eq. (3), the expression for the degree of dissociation becomes:

$$\alpha = \frac{E_{max} - E_s'}{E_{max} - E_r - E_t} \qquad (6)$$

Experimental

Reagents. All the analytical-grade reagents employed in this experiment were used without any further purification.

The stock Hg-EDTA solution of 1×10^{-2} M was prepared by dissolving 6.07 g of Doctite Hg-EDTA and diluting it to a volume of exactly 1 *l* with water. The working solution was prepared by diluting this stock solution with water.

The exact concentrations of stock solutions of thiocyanate and bromide prepared by dissolving potassium salts in water were standardized according to Volhard's method. The working thiocyanate solution of 5×10^{-4} M (F=0.977) and bromide solution of 1×10^{-3} M (F=0.998) were prepared by diluting this stock solution with water.

The pH and ionic strength were adjusted to the desired values with 0.1 M potassium perchlorate, 0.1 M disodium hydrogen phosphate, and 0.2 M sodium dihydrogen phosphate solutions.

Apparatus. The absorption measurements were made with a Hitachi Perkin Elmer 139-type spectrophotometer with 10.0 mm quartz cells. A Hitachi-Horiba M-4-type pH meter was used to measure the pH.

Procedure. According to the molar ratio method, the solutions containing 5 m*l* of 5×10^{-4} M (thiocyanate) or 1×10^{-3} M (bromide) Hg-EDTA solutions were adjusted to pH 6.1 and an ionic strength, μ of 0.10; a thiocyanate or bromide solution and then water were added to make the volume exactly 50 m*l*. After these solutions had stood for a few minutes, these absorbances were measured at a fixed wavelength against water.

Results and Discussion

Thiocyanato Mixed Ligand Complex. The thiocyanate ion reacts with Hg-EDTA to form a $[HgY(SCN)]^{3-}$ complex at pH 3—8.3, and the mixed ligand complex has a considerable absorption at 235 mμ.[1] Therefore, the molar ratio method for the thiocyanato mixed ligand complex

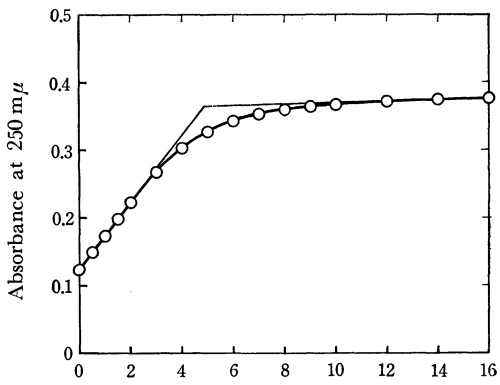
5×10^{-4} M Thiocyanate solution (F=0.977), m*l*

Fig. 1. The apparent stability constant of thiocyanato mixed ligand complex (molar ratio method) 5 m*l* of 5×10^{-4} M Hg-EDTA solution. pH 6.1, μ=0.10

was performed at pH 6.1 and 235 mμ using the previous procedure. The results for this method are shown in Fig. 1. In this figure E_{max}=0.448, E_s'=0.394, E_r=0.059, and E_t=0.033; therefore, the degree of the dissociation of this mixed ligand complex was calculated as α=0.152 using Eq. (6). Further, C, which could be determined as the section point of this method, was 4.64×10^{-5} mol. By putting these results into Eq. (2), the apparent stability constant of the complex was calculated as $K_{SCN}=7.9\times10^5$, or $\log K_{SCN}$=5.9.

Bromo Mixed Ligand Complex. Similarly, the bromide ion also reacts with Hg-EDTA to form the $[HgY(Br)]^{3-}$ complex at pH 3.5—7.7; this complex has a considerable absorption at 250 mμ.[3] Therefore, the molar ratio method was



1×10^{-3} M Bromide solution (F=0.998), m*l*

Fig. 2. The apparent stability constant of bromo mixed ligand complex (molar ratio method). 5 m*l* of 1×10^{-3} M Hg-EDTA solution. pH 6.1, μ=0.10

performed at pH 6.1 and 250 mμ. The results are shown in Fig. 2. The degree of the dissociation of the bromo mixed ligand complex was calculated as was that for the thiocyanate ion. Here, E_{max}=0.366, E_s'=0.326, E_r=0.124, E_t=0.006, and C=9.82×10^{-5} mol. Using these values, the following values were obtained: α=0.169, and $K_{Br}=3.0\times10^5$ or $\log K_{Br}$=5.5.

The apparent stability constants of cyano and iodo mixed ligand complexes can not, however, be calculated with this method, because these mixed ligand complexes dissociate to mercury(II) salts and EDTA by means of the reaction between the complexes and the excess cyanide or iodide ions.[2,3]

The author wishes to thank Professor S. Komatsu for many helpful discussions and suggestions during this work.

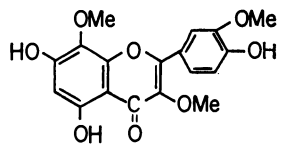
Synthetic Studies of the Flavone Derivatives. VIII.*1 The Synthesis of 5,7,4′-Trihydroxy-3,8,3′-trimethoxyflavone*2

Kenji FUKUI, Takashi MATSUMOTO, Mitsuru NAKAYAMA and Tokunaru HORIE*3

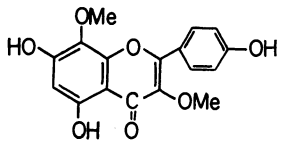
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received May 6, 1968)

Recently, two new pigments were isolated from the leaves and terminal branches of *Cyanostegia angustifolia* Turcz. by Ghisalberti *et al.*[1] On the basis of spectral and chemical studies, they established the structures of these pigments to be 5,7,4′-trihydroxy-3,8,3′-trimethoxyflavone (I) and 5,7,4′-trihydroxy-3,8-dimethoxyflavone (II).



I



II

The present paper will deal with two different syntheses of I and will confirm the proposed structure.

According to Allan-Robinson's flavone synthesis, the condensation of 2,4-dihydroxy-3,6,ω-trimethoxyacetophenone (III)[2] with *O*-benzoylvanillic anhydride, followed by treatment with alcoholic potassium hydroxide, afforded 7,4′-dihydroxy-3,5,8,3′-tetramethoxyflavone (IV), which was then converted to the dibenzyl ether (V) with benzyl chloride. The oxidative demethylation[3] of V with nitric acid gave 7,4′-dibenzyloxy-3,3′-dimethoxyflavone-5,8-quinone (VI) as an intermediate; this was easily reduced to the corresponding 5,8-dihydroxy compound (VII). The partial methylation of VII with diazomethane gave 7,4′-dibenzyloxy-5-hydroxy-3,8,3′-trimethoxyflavone (VIII), which was then debenzylated to I by catalytic hydrogenolysis over palladium-charcoal.

An alternative synthesis of I was carried out as follows. In a previous paper,[4] 2,4,6-trihydroxy-3,ω-dimethoxyacetophenone (IX) was reacted with *O*-benzylvanillic anhydride to give 4′-benzyloxy-5,7-dihydroxy-3,6,3′-trimethoxyflavone (X). Investigating this reaction further, we found that 4′-benzyloxy-5,7-dihydroxy-3,8,3′-trimethoxyflavone (XI), an isomer of X, was produced as a by-product. Each product could be successfully separated by fractional recrystallization from

aqueous alcohol. This suggests that the ring-closure of the ketone IX proceeds in two directions, that is, toward the 2- and 6-hydroxyl group positions with respect to the ketonic group, and that it eventually affords X and XI. The benzyl protective group for the phenolic hydroxyl of XI was eliminated by catalytic hydrogenolysis over palladium-charcoal to yield I, which was identical with the sample described above. The physical properties of synthetic I were in good accordance with those of the natural pigment. Synthetic I was also characterized as triacetate and triethyl ether.

Experimental*4

7,4'-Dihydroxy-3,5,8,3'-tetramethoxyflavone (IV). A mixture of III (2.4 g), *O*-benzoylvanillic anhydride (14.0 g), and potassium *O*-benzoylvanillate (9.0 g) was ground together and heated at 180°C under a vacuum for 5 hr. The reaction mixture was then powdered, refluxed with a solution of aqueous potassium hydroxide (40%: 50 g) and ethanol (170 m*l*) for 20 min, and evaporated under a vacuum to dryness. The residue was dissolved in water, and the alkaline solution, after the removal of a small amount of an insoluble material, was acidified with dilute hydrochloric acid. The precipitate was collected, washed successively with aqueous sodium bicarbonate and water, and then recrystallized from aqueous ethanol to give yellow needles of IV, mp 250—252°C, which gave a green ferric chloride reaction in ethanol; yield, 1.0 g.

Found: C, 61.05; H, 4.73%. Calcd for $C_{19}H_{18}O_8$: C, 60.96; H, 4.85%. UV: λ_{max}^{EtOH} mμ (log ε); 253.5 (4.30), 271.5 (4.30), 353 (4.30).

The Diacetate. Hot acetic anhydride - pyridine method; mp 158—160°C (pale yellow needles from aqueous methanol).

Found: C, 60.03; H, 4.80%. Calcd for $C_{23}H_{22}O_{10}$: C, 60.26; H, 4.84%.

7,4'-Dibenzyloxy-3,5,8,3'-tetramethoxyflavone (V). A mixture of IV (1.2 g), benzyl chloride (980 mg), anhydrous potassium carbonate (2.3 g), and dimethylformamide (2.0 m*l*) was heated at 160—165°C in an oil bath for 1 hr. The reaction mixture was then diluted with water (*ca.* 30 m*l*), and the precipitate was collected, washed with water, and then recrystallized from ethanol to give pale yellow microneedles of V, mp 161—163°C; yield, 1.6 g.

Found: C, 71.47; H, 5.49%. Calcd for $C_{33}H_{30}O_8$: C, 71.47; H, 5.45%. UV: λ_{max}^{EtOH} mμ (log ε); 253.5 (4.38), 272.5 (4.36), 354 (4.32).

7,4'-Dibenzyloxy-5,8-dihydroxy-3,3'-dimethoxyflavone (VII). A suspension of V (1.0 g) in nitric acid (45%: 25 m*l*) was stirred vigorously at 40°C in a water bath for 20 min. After the mixture had cooled, the precipitate was collected, washed with water, and then recrystallized once from acetone to give crude 7,4'-dibenzyloxy-3,3'-dimethoxyflavone-5,8-quinone (VI), mp 194—196°C, as brown microneedles; yield, 0.3 g.

When a solution of crude VI (0.3 g) in hot acetic acid (10 m*l*) was treated with sodium sulfite heptahydrate (1.5 g), the solution turned from deep red to bright yellow.

The reaction mixture was heated on a steam bath for 1 min and then diluted with water. After the mixture had cooled, the yellow precipitate was collected, washed with water, and then recrystallized from ethyl acetate to give yellow microneedles of VII, mp 198—200°C, which gave a green ferric chloride reaction in ethanol; yield, 220 mg.

Found: C, 70.89; H, 5.01%. Calcd for $C_{31}H_{26}O_8$: C, 70.71; H, 4.98%.

7,4'-Dibenzyloxy-5-hydroxy-3,8,3'-trimethoxyflavone (VIII). VII (140 mg) in acetone (30 m*l*) was treated with an excess of diazomethane in ether. After standing at room temperature for 3 hr, the mixture was evaporated under a vacuum to dryness. The residue was recrystallized from an acetone-ethanol mixture to give yellow microneedles of VIII, mp 172—173°C, which gave a green ferric chloride reaction in ethanol; yield, 120 mg.

Found: C, 71.07; H, 5.20%. Calcd for $C_{32}H_{28}O_8$: C, 71.10; H, 5.22%.

4'-Benzyloxy-5,7-dihydroxy-3,8,3'-trimethoxyflavone (XI). The reaction of the ketone (IX) (3.0 g) with *O*-benzylvanillic anhydride (27.0 g) was carried out in a manner previously reported.[4] The crude product was dissolved in hot aqueous ethanol, after which the solution was allowed to stand overnight at room temperature. The precipitate gave 4'-benzyloxy-5,7-dihydroxy-3,6,3'-trimethoxyflavone (X)[4], mp 180—181.5°C; yield, 1.2 g (20%). The solvent of the mother liquor was removed by evaporation to afford a yellowish residue, which was washed with hot acetone and then recrystallized from methyl ethyl ketone to give 4'-benzyloxy-5,7-dihydroxy-3,8,3'-trimethoxyflavone (XI), mp 206—208°C (golden yellow prisms), which gave a green ferric chloride reaction in ethanol; yield, 0.55 g (9%).

Found: C, 66.91; H, 4.70%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%. UV: λ_{max}^{EtOH} mμ (log ε); 257 (4.23), 276 (4.29); 340 (4.18).

5,7,4'-Trihydroxy-3,8,3'-trimethoxyflavone (I). *a) From VIII.* A solution of VIII (60 mg) in ethyl acetate (20 m*l*) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (10%: 100 mg). After the catalyst had been filtered, the

*4 All melting points are uncorrected.

filtrate was evaporated under a vacuum; the residue was then recrystallized from methanol to give yellow plates of I, mp 217—219°C, (lit.[1] mp 215—217°C), which gave a green ferric chloride reaction in ethanol; yield, 25 mg.

Found: C, 59.87; H, 4.56%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%. UV: λ_{max}^{EtOH} mμ (log ε); 260 (4.23), 276.5 (4.29), 340^{sh} (4.17), 365 (4.21).

b) From XI. By a reaction similar to that described above, XI (284 mg), Pd-C (10%: 300 mg), and ethyl acetate (100 m*l*) gave I (mp 213.5—215°C), which was identical with a sample derived by the above described method a); yield, 185 mg.

The Triacetate. Mp 140—141°C, after resolidifying 147—148.5°C (colorless needles from methanol) (lit.[1] mp 146—147°C).

Found: C, 59.25; H, 4.63%. Calcd for $C_{24}H_{22}O_{11}$: C, 59.26; H, 4.56%.

The Triethyl Ether. Mp 104.5—105.5°C (colorless needles from aqueous ethanol) (lit.[1] mp 110—111°C).

Found: C, 62.34; H, 6.49%. Calcd for $C_{24}H_{28}O_8 \cdot H_2O$: C, 62.49; H, 6.22%. Drying at 100°C/0.1 mmHg for 3 hr, mp 121—121.5°C (104.5°C sinter).

Found: C, 64.59; H, 6.18%. Calcd for $C_{24}H_{28}O_8$: C, 64.85; H, 6.35%.

The authors are grateful to Professor P. R. Jefferies, the University of Western Australia, for his gift of the natural pigment. This work was supported by a grant-in-aid from Ministry of Education.

The Studies of 5-Aminosalicylaldehyde Derivatives. III.[1] The Preparation of 5-Aminosalicylaldehyde Hydrazones by Reduction of 5-(*p*-Sulfophenylazo)salicylaldehyde Hydrazone

Mitsunori TANAKA

The Faculty of Education, Kagawa University, Takamatsu, Kagawa

(Received May 9, 1968)

In a previous paper,[1] it was reported that the reduction of the sodium salt of 5-(*p*-sulfophenylazo)-salicylaldehyde (Formula I) with sodium hydrosulfite gave only a resinous product. This fact can be interpreted as follows. Even if the aminosalicylaldehyde is formed in the course of the reduction of I, the formyl and amino groups in aminosalicylaldehyde are so reactive that aminosalicylaldehyde may undergo spontaneous condensation polymerisation. Therefore, in order to obtain the monomeric compound, either the formyl or amino group must be protected from the polymerisation. The purpose of the present investigation is to prepare 5-aminosalicylaldehyde derivatives with the free amino group, which may be formed by the reductive cleavage of the azo linkage in the derivatives of I. According to Weil *et al.*,[2] Oddo *et al.*,[3] and Tanaka,[1] 5-aminosalicylaldehyde phenylhydrazone is one of only a few derivatives

invariably yielded the corresponding hydrazones (Formula IIIA, a—f). The reaction product of I with acid hydrazide differed depending on the solvent used and on the chemical nature of the acid hydrazide. Acetyl-, propionyl-, oxalyl-, malonyl-, succinyl-, or adipoyl-hydrazine and I gave the expected hydrazone (Formula IIIA, g and h. Formula IV, n: 0, 1, 2 and 4) in alcohol or in a pyridine-water mixed solvent. However, in an aqueous solution these hydrazine derivatives all gave the same compound, IIA. This fact was confirmed by the elementary analysis and by a study of the infrared spectrum. Oxalyl-, benzoyl-, hydroxybenzoyl-, aminobenzoyl-, or pyridyl-carbonyl-hydrazine, -semicarbazide, or -thiosemicarbazide and I yielded the expected hydrazones (Formula IV. n : 0. Formula IIIA. i—s) in any solvent (water, alcohol, or a pyridine-water

mixture). The experimental results are listed in Table 1.

The marked difference in the hydrazone formation in an aqueous solution between acylated hydrazine and oxalyl- or aroyl-hydrazine or semicarbazides, appears to be due to the difference between stabilities in the face of the hydrolysis of the acid hydrazides.

These hydrazones and azine were used for the preparation of 5-aminosalicylaldehyde derivatives with a free amino group. In the case of the stable 5-(*p*-sulfophenylazo)salicylaldehyde hydrazones, the reductive cleavage of the azo linkage was accomplished in an aqueous solution without any change in the hydrazone group, and the corresponding 5-aminosalicylaldehyde hydrazones (Formula IIIB, b, i—l and o—s) were obtained. The less stable 5-(*p*-sulfophenylazo)salicylaldehyde

hydrazones derived from acylated hydrazines underwent drastic change in the hydrazone moiety during the reduction; they gave 5-aminosalicylaldehyde azine, which was also obtained by reducing bis [5-(*p*-sulfophenylazo)salicylaldehyde] azine (Formula IIB). These results, confirmed by the results of the elementary analyses and by the infrared spectra, are tabulated in Table 2.

Thus, the above-mentioned experimental results show that the less stable hydrazones are reduced at the hydrazone moiety, whereas the stable hydrazones are reduced to 5-aminosalicylaldehyde hydrazone without any change in the hydrazone moiety.

Experimental

Sodium Salt of 5-(*p*-Sulfophenylazo)salicylaldehyde (I). This salt was prepared by Tummely's method.[4] (Found: C, 42.65; H, 3.52; N, 7.83; Na, 5.98%.)

Sodium Salt of Bis[5-(*p*-sulfophenylazo)salicylaldehyde]azine (IIA). To a hot stirred, solution of 3.64 g of I in 150 m*l* of water, there was added, drop by drop 0.628 g of hydrazine hydrate (80%) in 50 m*l* of water. The precipitate was collected by filtration, washed with water, and recrystallized from a pyridine-water mixture. The yield was almost quantitative.

Sodium Salt of 5-(*p*-Sulfophenylazo)salicylaldehyde methylhydrazone (IIIA, a). To a hot stirred, solution of 3.64 g of I in 150 m*l* of water, there was added 0.46 g of methylhydrazine in 150 m*l* of methanol. The precipitate was treated in a manner similar to that described above.

Sodium Salt of 5-(*p*-Sulfophenylazo)salicylaldehyde Arylhydrazone (IIIA, b, c, d, e and f). A mixture of 0.01 mol arylhydrazine hydrochloride and 0.01 mol of sodium acetate monohydrate (or 0.005 mol of sodium carbonate) in 50 m*l* of ethanol was added to a hot solution of 0.01 mol of the I in 150 m*l* of water. The precipitate was then collected and recrystallized from a pyridine-water mixture.

Sodium Salt of Aliphatic Monocarboxylic Acid Hydrazone and Aliphatic Dicarboxylic Acid Dihydrazone of 5-(*p*-Sulfophenylazo)salicylaldehyde (IIIA, g and h. IV. *n*: 0, 1, 2 and 4). To a hot solution of 0.01 mol of the I in 100 m*l* of a pyridine-water mixture, there was added a solution monohydrazide (0.01 mol) or dihydrazide (0.005 mol) in water or ethyl alcohol. The precipitate was collected and recrystallized from a pyridine-water mixture.

Sodium Salt of Aroylhydrazone, Semicarbazone and Thiosemicarbazone of 5-(*p*-Sulfophenylazo)-salicylaldehyde (IIIA, i—s). To a hot solution of 0.01 mol of the I in 150 m*l* of water, there was added a solution of aroylhydrazine, semicarbazide, or thiosemicarbazide in ethyl alcohol. The precipitate was then treated in a manner similar to that described above.

Bis(5-aminosalicylaldehyde)azine (IIB). To a solution of 4.40 g of IIA and 1.60 g of sodium hydroxide in 300 m*l* of water, 8.40 g of sodium hydrosulfite were added at 60—70°C. The precipitate was then collected by filtration and washed with water. The products were recrystallized from dimethylformamide and washed with ethyl alcohol.

Aryl-, Aroyl-, Pyridylcarbonyl-, Carbamoyl- and Thiocarbamoyl-hydrazones of 5-Aminosalicylaldehyde (IIIB. b and i—s). To a solution of 0.01 mol of IIIA (b and i—s) and 1.60 g of sodium hydroxide in 200 m*l* of water, 4.20 g of sodium hydrosulfite were added at 60—70°C. The precipitate was treated in a manner similar to that described above. The hydrazones, together with the solvents for crystallization, are listed in Table 2.

The author wishes to express his thanks to President Dr. Tokuichi Tsumaki of the Kyushu Institute of Technology and to Professor Dr. Tamotsu Yoshino and Professor Dr. Masaru Yamaguchi of Kyushu University for their exceedingly kind direction of this work.

The Preparation of Some Triorganosiloxy Derivatives of Bis-cyclopentadienyltitanium Dichloride

Toshio TAKIGUCHI and Hideo SUZUKI

Department of Synthetic Chemistry, Kiryu College of Technology, Gunma University, Tenjin-cho, Kiryu

(Received May 13, 1968)

Very little researches have been made on the organosiloxytitanium compounds with cyclopentadienyl groups attached to the titanium atom. The preparation of triphenylsiloxy-bis-cyclopentadienyltitanium chloride[1] and bis-triphenylsiloxy-bis-cyclopentadienyltitanium[1] from the reaction of bis-cyclopentadienyltitanium dichloride with sodium triphenylsilanolate are the only examples reported in the literature.

We wish to report on the preparation of some triorganosiloxy derivatives of bis-cyclopentadienyltitanium dichloride from the reaction of bis-cyclopentadienyltitanium dichloride with the corresponding triorganosilanols in the presence of triethylamine as a hydrogen chloride acceptor

1) J. G. Noltes and G. J. M. Van der Kerk, *Rec. Trav. Chim.*, **81**, 39 (1962).

according to the following schemes:

$$Cp_2TiCl_2 + R_3SiOH + Et_3N \rightarrow R_3SiOTi(Cl)Cp_2 + Et_3N\text{-}HCl \text{ and}$$

$$Cp_2TiCl_2 + 2R_3SiOH + 2Et_3N \rightarrow (R_3SiO)_2TiCp_2 + 2Et_3N\text{-}HCl$$

Most of the products obtained were colored crystalline substances. They are bis-triphenylsiloxy-bis-cyclopentadienyltitanium, bis-diphenylmethylsiloxy-bis-cyclopentadienyltitanium, diphenylmethylsiloxy-bis-cyclopentadienyltitanium chloride, bis - dimethylphenylsiloxy - bis - cyclopentadienyltitanium, dimethylphenylsiloxy-bis-cyclopentadienyltitanium chloride and diphenylbutylsiloxy-bis-cyclopentadienyltitanium chloride, the last five being new compounds. All products were well-defined and characterized by their IR spectra. As for crystalline substances, the X-ray powder patterns were also determined for their rapid identification.

Experimental

Triorganochlorosilanes. Triphenylchlorosilane (mp 98—99°C) was isolated from the high boiling residue[2] of the direct synthesis of phenylchlorosilanes. Diphenylmethylchlorosilane (bp 128—130°C/3 mmHg), dimethylphenylchlorosilane (bp 55—56°C/5 mmHg), diphenylbutylchlorosilane (bp 153—155°C/4 mmHg) were prepared by a Grignard route.[3]

Triorganosilanols. Triphenylsilanol (mp 150—151°C), diphenylmethylsilanol (bp 132—133°C/1.5 mmHg), dimethylphenylsilanol (bp 73.5—74.5°C/5 mmHg) and diphenylbutylsilanol (bp 157—158°C/1.5 mmHg) were prepared by the method[4] reported previously.

Bis-cyclopentadienyltitanium Dichloride. The reaction of cyclopentadienylsodium with titanium tetrachloride in tetrahydrofuran gave bis-cyclopentadienyltitanium dichloride, mp 288—290°C (lit.[5] mp 289—291°C), as bright-red acicular crystals with a yield of 33—35%.

The Preparation of Bis-diphenylmethylsiloxy-bis-cyclopentadienyltitanium and Diphenylmethylsiloxy-bis-cyclopentadienyltitanium Chloride. Typical procedures will be described in detail, using the preparations of mono- and di-diphenylmethylsiloxy derivatives of bis-cyclopentadienyltitanium dichloride as examples. A mixture of bis-cyclopentadienyltitanium dichloride (5 g, 0.02 mol), diphenylmethylsilanol (10.1 g, 0.047 mol) and triethylamine (5 g, 0.05 mol) gave a deep red solution when dissolved in 250 m*l* of tetrahydrofuran. The red solution gradually turned yellowish when refluxed with gentle stirring, and triethylamine hydrochloride precipitates. After it was refluxed for 25 hr, the hydrochloride was filtered off and the filtrate was concentrated under reduced pressure, leaving a brown viscous liquid from which a brown semi-solid separated on addition of cold *n*-hexane.

Extraction of the brown mass with hot *n*-hexane for 30 hr gave a deep yellow solution from which, on cooling in an ice-bath, 1 g (11.7%) of diphenylmethylsiloxy-bis-cyclopentadienyltitanium chloride was obtained as red acicular crystals melting at 160—161.5°C. After filtration of the red crystals, the yellow filtrate was evaporated, giving 5 g (41.3%) of pale yellow platelets.

The extraction residue was a brown solid which proved to be a mixture of unreacted bis-cyclopentadienyltitanium dichloride and its cleavage products.

Further purification of the platelets was effected by recrystallization from *n*-hexane, giving pure bis-diphenylmethylsiloxy-bis-cyclopentadienyltitanium melting at 113.5—114.5°C.

$Ph_2MeSiOTi(Cl)Cp_2$: Found: Si, 6.49; Ti, 11.29; C, 65.00; H, 5.43; Cl, 8.35% (determined by combustion method); mol wt (determined ebullioscopically in benzene), 424. Calcd for $C_{23}H_{23}OSiTiCl$: Si, 6.58; Ti, 11.22; C, 64.71; H, 5.43; Cl, 8.31%; mol wt, 426.9.

$(Ph_2MeSiO)_2TiCp_2$: Found: Si, 9.15; Ti, 8.16; C, 71.85; H, 5.90%; mol wt, 616. Calcd for $C_{36}H_{36}O_2Si_2Ti$; Si, 9.29; Ti, 7.92; C, 71.50; H, 6.00%; mol wt, 604.8.

All of the attempts to modify above procedure, using dioxane, toluene and xylene as reaction media and using pyridine, aniline, *N,N*-dimethylaniline as hydrogenchloride acceptors, proved to be less satisfactory than the combination of tetrahydrofuran and triethylamine because of the complexity of the procedure and the lower yield of the aimed products.

The reaction of bis-cyclopentadienyltitanium dichloride with equimolar diphenylmethylsilanol gave diphenylmethylsiloxy-bis-cyclopentadienyltitanium chloride with reproducible yields of 60—65%, and bis-diphenylmethylsiloxy-bis-cyclopentadienyltitanium was obtained in the yield of less than 5%.

Other Triorganosiloxy Derivatives. Bis-triphenylsiloxy-bis-cyclopentadienyltitanium, white platelets melting at 199—200°C (lit.[1] mp 208—210°C); bis-phenyldimethylsiloxy-bis-cyclopentadienyltitanium, a deep red low melting solid; phenyldimethylsiloxy-bis-cyclopentadienyltitanium chloride, a carmine red solid melting at 56°C; diphenylbutylsiloxy-bis-cyclopentadienyltitanium chloride, an orange yellow crystalline mass melting at 97—99°C. These were all obtained by procedures similar to those used for diphenylmethylsiloxy derivatives.

$(Ph_3SiO)_2TiCp_2$: Found: Si, 7.86; Ti, 6.45; C, 76.3; H, 5.58%; mol wt, 739. Calcd for $C_{46}H_{40}O_2Si_2Ti$: Si, 7.71; Ti, 6.57; C, 75.80; H, 5.53%; mol wt, 728.9.

$Ph_2BuSiOTi(Cl)Cp_2$: Found: Si, 5.76; Ti, 10.09; C, 66.80; H, 6.37; Cl, 7.73%; mol wt, 457. Calcd for $C_{26}H_{29}OSiTiCl$; Si, 5.99; Ti, 10.21; C, 66.59; H, 6.23; Cl, 7.56%; mol wt, 469.0.

$(Me_2PhSiO)_2TiCp_2$: Found: Si, 11.81; Ti, 10.05; C, 65.60; H, 6.75%; mol wt, 461. Calcd for $C_{26}H_{32}O_2Si_2Ti$: Si, 11.69; Ti 9.97; C, 64.98; H, 6.71%; mol wt, 480.6.

$Me_2PhSiOTi(Cl)Cp_2$: Found: Si, 7.81; Ti, 13.30; C, 59.25; H, 5.79; Cl, 9.90% mol wt, 355. Calcd for: $C_{18}H_{21}OSiTiCl$: Si, 7.70; Ti, 13.13; C, 59.26; H, 5.80; Cl, 9.72%; mol wt, 364.8.

All products thus obtained were readily soluble in tetrahydrofuran, toluene, benzene, chloroform and acetone, partly soluble in boiling *n*-hexane and sparingly soluble in cyclohexane, ether and carbon tetrachloride.

IR Absorption Spectra and X-Ray Powder Patterns. As for the IR absorption spectra, the absorption bands due to the Ti-O-Si bonding were observed at 915 cm^{-1} with $(R_3SiO)_2$ $TiCp_2$ type derivatives and at 950 cm^{-1} with $R_3SiOTi(Cl)Cp_2$ type derivatives as a sharp and strong peak in agreement with the previous descriptions[1].

The X-ray powder diffraction was observed for crystalline products by using the Cu$K\alpha$ radiation filtered by Ni as follows.

Nakatani of the National Institute of Science and Technology, Tokyo, for his kind co-operation in the elementary analyses of the products reported herein.

The Catalytic Activity of Sulfate in the Decomposition of Formic Acid

Ken-ichi TANAKA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 4, 1968)

In our previous papers[1] it has been shown that the acidity of the aquo-ion given by the hydrolysis equilibrium constant (pK_a) can be formulated with a generalized electronegativity of the metal ion (X_i) as follows;

$$pK_a = 20\left(1-\frac{X_i}{14}\right)$$

$$X_i = (1+2Z)X_0$$

where X_0 is the electronegativity of the neutral atom ($Z=0$) given by Pauling and where Z is the charge of the ion. This parameter can be successfully applied to solid surfaces; the acid-base properties of the hydrated oxide surface designated by Zero Point of Charge are expressed by the following equation;

$$\text{Zero Point of Charge} = 16.8(1-22/X_i)$$

and the catalytic activity of sulfate in the hydration reaction of propylene and the polymerization of acetaldehyde increase with the acidity parameter, X_i.

It is known that the decomposition of formic acid involves two reactions, dehydration and dehydrogenation, and that the dehydration reaction is commonly promoted by acid. In this experiment, the decomposition of formic acid has been adopted as a test reaction in order to demonstrate a general trend of the catalytic activity of the sulfate.

Experimental

The apparatus employed for this experiment was a flow system with nitrogen as the carrier gas.

The carrier gas was passed through the formic acid evaporator at a constant flow rate of 41 cc/min. The temperature of the evaporator was kept at 22±1°C and the room temperature was about 30—32°C. The carrier gas containing formic acid was allowed to flow through the reactor at the selected temperature. The concentration of formic acid in the carrier gas was determined by the concentration of carbon monoxide in the effluent gas when the formic acid was completely decomposed.

TABLE 1. DETAILS OF THE CATALYST USED

Sulfate	Molecular weight	Amounts doped on 10 g SiO_2 (g)
$ZnSO_4 \cdot 7H_2O$	287.56	0.288
$NiSO_4 \cdot 6H_2O$	262.87	0.263
$MnSO_4 \cdot 4H_2O$	223.07	0.223
$MgSO_4 \cdot 7H_2O$	246.50	0.246
$Fe_2(SO_4)_3 \cdot 9H_2O$	562.04	0.281
$Cr_2(SO_4)_3 \cdot 5H_2O$	482.30	0.241
$Al_2(SO_4)_3 \cdot 16—18H_2O$	630.5—666.5	0.333
$CuSO_4 \cdot 5H_2O$	249.7	0.250

1) K. Tanaka and A. Ozaki, This Bulletin, **40**, 1723 (1967); *J. Catalysis*, **8**, 1 (1967).

The catalyst was prepared as follows: a reagent-grade sulfate of about a 10^{-3} g-cation was supported on 10 g of silica gel (30—50 mesh Wako-gel-G was used) and dried at 100°C. Each experiment was carried out with 3.5 g of a catalyst. The details of the catalysts used are given in Table 1.

The reaction over these catalysts was completely the dehydration; therefore, the reaction was followed by the analysis of the carbon monoxide in the effluent gas by means of gas chromatography.

Results and Discussion

The reaction rate was calculated from the ratio of carbon monoxide to nitrogen in the effluent gas and from the flow rate of the carrier gas, nitrogen.

Figure 1 shows the rate of reaction at various

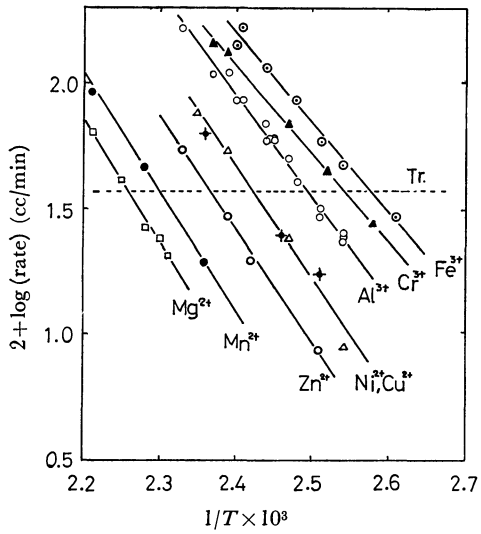

Fig. 1. Reaction rates at various temperatures.

temperatures. From this figure, the relative catalytic activities of the sulfates are in the following sequence:

$$Fe^{3+} > Cr^{3+} > Al^{3+} > Cu^{2+} \simeq Ni^{2+} > Zn^{2+} > Mn^{2+} > Mg^{2+}.$$

This sequence is very similar to that observed in the hydration of propylene.[2]

The catalytic activity of each sulfate, characterized by the temperature at which the concentration of carbon monoxide in the carrier gas reached 1% (approximately an 11% conversion to the formic

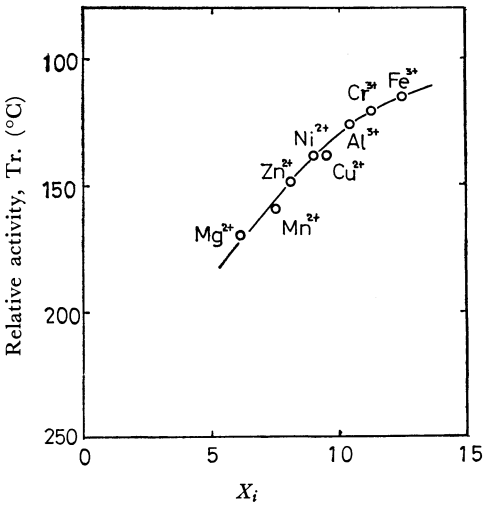

Fig. 2. Relative catalytic activity of sulfates. X_i denotes the electronegativity of metal ion.

acid introduced), is plotted against the acidity parameter of the metal ion (X_i) in Fig. 2.

From this figure, it is obvious that the sulfate containing an acidic metal ion has a high catalytic activity and that the activity sequence is determined by the parameter, X_i.

On the other hand, it has been recognized that the surface acidity of sulfate is strongly affected by the temperature at which the sulfate is dehydrated. Tanabe *et al.*[3] ascribed this phenomena to a specific structure of the sulfate which appeared in the dehydration of sulfate.

In our experiment, however, the surface of the sulfates during the dehydration of formic acid was hydrated with the water produced, so the specific structure such as appearing in the rather rigorous dehydration of sulfate seemingly disappeared from the surface during the reaction. Accordingly, it may be concluded that the dehydration of formic acid is promoted by the acidity of the hydrated cation on the sulfate surface.

The parameter, X_i, is thus seemingly valuable for predicting the acidity and the catalytic activity of the hydrated surfaces.

One of authors is grateful to the Matsunaga Science Foundation for a grant in support of this work.

SHORT COMMUNICATIONS

X-Ray Diffraction Studies on Some Co(III) Complexes

Luigi CAMPANELLA

Institute of Analytical Chemistry, University of Rome, Italian National Researches Council, Rome, Italy

(Received April 27, 1968)

In connection with studies conducted at this Institute on the polarographic behavior of some Co(III) complexes,[1] structural studies on these compounds were undertaken. In this paper the results obtained for *cis*- and *trans*-$[Co\ en_2Cl_2]ClO_4$ and *cis*- and *trans*-$[Co\ en_2(C_6H_{11}COO)_2]ClO_4$ are reported. All the salts were characterised by the X-ray powder patterns taken in a Debye-Scherrer camera of diameter 114,8 mm with monochromatized Cu$K\alpha_1$ and Fe$K\alpha_1$ radiations. The salts were prepared as described by Linhard and Stirn[2] and by Carunchio, Illuminati and Maspero.[3]

Ito's[4] and Hesse-Lipson's[5,6] methods were successful in indexing powder patterns. The use of an IBM computer was helpful in applying the above said methods. X-ray powder studies so far performed lead to the following conclusions:

a) *cis*-$[Co\ en_2Cl_2]ClO_4$: the unit cell is monoclinic with dimensions $a=(7.032\pm0.001)$Å $b=(8.772\pm0.002)$Å $c=(8.000\pm0.002)$Å and $\beta=(107°2'\pm1')$. The measured density is 1.25 g/cm^3; the cell content is 1 formula unit, giving a calculated density of 1.22 g/cm^3.

b) *trans*-$[Co\ en_2Cl_2]ClO_4$: the unit cell is monoclinic with dimensions $a=(6.253\pm0.001)$Å $b=(8.065\pm0.002)$Å $c=(7.587\pm0.001)$Å and $\beta=(100°23'\pm1')$. The measured density is 1.54 g/cm^3; the cell content is 1 formula unit, giving a calculated density of 1.55 g/cm^3.

c) *cis*-$[Co\ en_2(C_6H_{11}COO)_2]ClO_4$: the unit cell is orthorhombic with dimensions $a=(8.696\pm0.002)$ Å $b=(15.625\pm0.006)$Å and $c=(10.870\pm0.003)$Å. The measured density is 1.18 g/cm^3. For 2 formula units in the unit cell the calculated density is 1.20 g/cm^3.

d) *trans*-$[Co\ en_2(C_6H_{11}COO)_2]ClO_4$: the unit cell is orthorhombic with dimensions $a=(7.407\pm0.001)$Å $b=(16.667\pm0.007)$Å and $c=(10.753\pm0.003)$Å. The measured density is 1.35 g/cm^3. For 2 formula units in the unit cell the calculated density is 1.33 g/cm^3.

Financial assistance was given by the Italian National Researches Council.

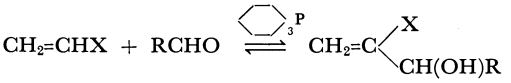
A Tertiary Phosphine-catalyzed Reaction of Acrylic Compounds with Aldehydes

Ken-ichi MORITA, Zennosuke SUZUKI and Hiromitsu HIROSE

The Basic Research Laboratories, Toyo Rayon Company, Ltd., Kamakura

(Received August 14, 1968)

We report here a novel reaction which gives new vinyl monomers. Reaction of acrylonitrile or methyl acrylate with various aldehydes in the presence of tricyclohexylphosphine as a catalyst furnished vinyl compounds 1 to 12 in 70 to 90% yields.[1,2] A typical example is as follows: reaction of 34.4 g (0.4 mol) of methyl acrylate, 26.4 g (0.6 mol) of acetaldehyde and 0.7 g (2.5 mmol) of tricyclohexylphosphine in 12 m*l* of dioxane in an atmosphere of nitrogen at 120—130°C for 2 hr afforded compound 9 in a yield of 85% based on converted methyl acrylate (conversion 23%).



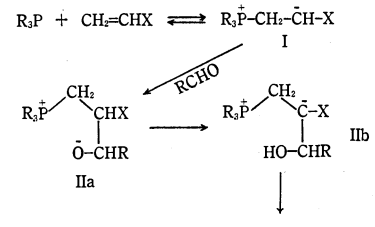
1, X=CN; R=CH_3. 2, CN; CH_2CH_3. 3, CN; $(CH_2)_2CH_3$. 4, CN; $CH(CH_3)_2$. 5, CN; $(CH_2)_6 \cdot CH_3$. 6, CN; C_6H_5. 7, CN; *p*-Cl-C_6H_4. 8, CN; *p*-CH_3-C_6H_4. 9, CO_2CH_3; CH_3. 10, CO_2CH_3, CH_2CH_3. 11, CO_2CH_3; $(CH_2)_2CH_3$. 12, CO_2CH_3; C_6H_5.

Structures for compounds 1 to 12 were assigned on the basis of their elemental analyses, the NMR spectra, the infrared spectra (nitrile band at 2229 cm^{-1} and double bond band at 1623 cm^{-1} for compounds 1 to 8; ester band between 1917 and 1722 cm^{-1} and double bond band between 1631 and 1635 cm^{-1} for compounds 9 to 12), and the ultraviolet absorption spectra (maximum between 202.5 and 206.5 mμ in methanol).

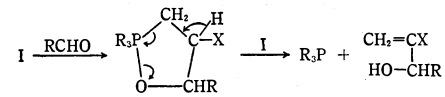
The structures of compound 1 and 9 were further confirmed by conversion of them into 1,4-dicyano-4-vinyl-1-cyclohexene,[4] and 1,4-dicarbomethoxy-4-vinyl-1-cyclohexene,[4] respectively, by treatment with boiling acetic anhydride and pyridine. 2-Cyano-1,3-butadiene and 2-carbomethoxy-1,3-butadiene dimerize readily under these conditions.

The possible mechanisms[5] of the reaction are depicted below.

mechanism I



mechanism II



1) The novel reaction can be called Carbinol. Addition.

2) It has been reported[3] that the reaction of acrylonitrile and triphenylphosphine with benzaldehyde in the presence of alcohol at 140—175°C afforded *trans*-4-phenyl-3-butenenitrile and triphenylphosphine oxide.

3) R. Oda, T. Kawabata and S. Tanimoto, *Tetrahedron Letters*, **1964**, 1653.

4) C. S. Marvel and N. O. Brace, *J. Am. Chem. Soc.*, **71**, 37 (1949).

5) It is conceivable that if triphenylphosphine is used for the reaction the zwitterion I (R=phenyl) can isomerize to an ylid (III) by a proton transfer which then undergoes irreversible reaction with aldehydes to produce triphenylphosphine oxide and an olefin as Oda[3] reported. The absence of the interconversion I $\rightleftarrows$ III when R is alkyl is supported by the absence of 1,4-dicyanobutene in the product when acrylonitrile is dimerized in the presence of catalytic quantities of trialkylphosphines such as tri-*n*-butylphosphine or tricyclohexylphosphine.[6]

Synthesis of an Analogue of Desamino-lysine-vasopressin Containing No Disulfide Bond

Shumpei SAKAKIBARA and Satoe HASE

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received August 19, 1968)

Jošt and Rudinger synthesized two analogues of desamino-oxytocin which have no disulfide bond, and they demonstrated for the first time that the disulfide bond in oxytocin is important as a structural element but is not necessary for biological activity.[1] The present communication will report the synthesis of an analogue of desamino-lysine-vasopressin which has an ethylene linkage in place of the disulfide bond.

The following new compounds were synthesized as starting materials by conventional methods:*1 Z-Lys(Pht)-ONp, mp 99—100°C, $[\alpha]_D^{22}$ −16.0° (*c* 4, DMF); bis-[Z-Asu(OBu^t)-OH] piperazine salt which was derived from Z-Asu-OH,[2] mp 130—131°C, $[\alpha]_D^{28}$ −2.7° (*c* 2, AcOH); Z-Asn-OSu, mp 129—130°C, $[\alpha]_D^{24}$ −27.5° (*c* 2, DMF); Aoc-Phe-OSu, 130—131°C, $[\alpha]_D^{18}$ −52.0° (*c* 2, DMF); Aoc-Tyr(Bu^t)-OSu, mp 112—113°C, $[\alpha]_D^{23}$ −43.4° (*c* 2, DMF).

The synthesis of the protected peptide was started from glycine amide by the step-by-step elongation method using the respective acylamino acid active esters. Carbobenzoxy (Z) groups were removed by catalytic hydrogenation. *t*-Amyloxycarbonyl (Aoc) groups were removed by treatment with trifluoroacetic acid. Thus, the following intermediates were synthesized: Z-Lys(Pht)-Gly-NH_2, mp 215—217°C, $[\alpha]_D^{22}$ −2.2° (*c* 2.1, DMF); Z-Pro-Lys(Pht)-Gly-NH_2, mp 173—175°C, $[\alpha]_D^{22}$ −36.4° (*c* 2.1, DMF); Z-Asu(OBu^t)-Pro-Lys(Pht)-Gly-NH_2, mp 112—115°C, $[\alpha]_D^{18}$ −37.5° (*c* 2, DMF); Z-Asn-Asu-(OBu^t)-Pro-Lys(Pht)-Gly-NH_2, mp 188—190°C, $[\alpha]_D^{19}$ −38.0° (*c* 2, DMF); Z-Gln-Asn-Asu-(OBu^t)-Pro-Lys(Pht)-Gly-NH_2, mp 189—191°C, $[\alpha]_D^{19}$ −36.9° (*c* 1.6, DMF); Aoc-Phe-Gln-Asn-Asu(OBu^t)-Pro-Lys(Pht)-Gly-NH_2, mp 188—190°C (decomp.), $[\alpha]_D^{22}$ −35.4° (*c* 1.5, DMF); Aoc-Tyr(Bu^t)-Phe-Gln-Asn-Asu-Pro-Lys(Pht)-Gly-NH_2 (I), mp 224—226°C (decomp.), $[\alpha]_D^{25}$ −41.9° (*c* 1, AcOH). Found: C, 59.08; H, 6.75; N, 12.76%. Calcd for $C_{66}H_{90}O_{17}N_{12}\cdot H_2O$: C, 59.09; H, 6.91; N, 12.53%. The product, I, was converted to the *p*-nitrophenyl ester at the *ω*-position of the Asu-residue with *p*-nitrophenyl trifluoroacetate;[3] mp 217—220°C (decomp.), $[\alpha]_D^{25}$ −29.2° (*c* 1, DMF). The Aoc and *t*-butyl ether groups were removed with trifluoroacetic acid, and the product was treated in pyridine at 50°C (1 mmol/*l*). Then, the phthalyl group was removed with hydrazine acetate in DMF. The final product was purified by column chromatography on CM-Sephadex C-25, and lyophilized; yield 22% (calcd from I). $[\alpha]_D^{27}$ −80° (*c* 0.44, 1 N AcOH). Found: C, 54.30; H, 6.85; N, 15.89%. Calcd for $C_{48}H_{68}O_{12}N_{12}\cdot 3H_2O$: C, 54.43; H, 7. 04; N, 15.87%. Amino acid analysis: $Tyr_{0.98}$, $Phe_{1.05}$, $Glu_{0.96}$, $Asp_{1.00}$, $Asu_{1.00}$, $Pro_{1.06}$, $Lys_{1.03}$, $Gly_{0.97}$. These analytical data support the following structure for this material:

—Tyr-Phe-Gln-Asn-Asu-Pro-Lys-Gly-$NH_2\cdot 3H_2O$ (II)

Paper chromatography showed that this material was homogeneous: R_f 0.33 (*n*-BuOH : AcOH : H_2O=4 : 1 : 1), R_f 0.57 (Pyridine : AcOH : H_2O= 50 : 35 : 15).

The material II showed distinct pressor and antidiuretic activities, as is shown in Table 1.

TABLE I. BIOLOGICAL ACTIVITY OF COMPOUND II

Compound	Pressor (Rat)	Antidiuretic (Rat)
II	10.4 U/mg	7.8 U/mg
Desamino-Lys-vasopressin[a]	126	301

a) R. D. Kimbrough, Jr., W. D. Cash, L. A. Branda, W. Y. Chan and V. du Vigneaud, *J. Biol. Chem.*, **238**, 1411 (1963).

Thus, it was shown that the disulfide bond in vasopressin was replaceable by a stable ethylene bridge without any essential loss of biological activity.

Ligand Field Activation Energy for Ligand Substitution in Octahedral Complexes

Hideo YAMATERA

Department of Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received August 23, 1968)

Crystal field theory has been successful in interpreting the relative rate of ligand substitution of transition-metal octahedral complexes, especially the relative inertness of the d^3, d^8 and low-spin d^6 complexes.[1] However, there has been disagreement between the crystal field prediction and observation in a few cases.

(1) In the series Mn^{2+}, Fe^{2+} and Co^{2+}, the observed rate of water exchange was $Mn^{2+} > Fe^{2+} > Co^{2+}$ (the activation energy remains nearly unchanged).[2] However, the crystal field activation energy (CFAE) was predicted to become more negative in going along the above series.

(2) Low-spin d^5 complexes, *e. g.*, $[Fe(CN)_6]^{3-}$, are known to be the most inert next to d^6 complexes, and are much more inert than predicted.[3]

In the present communication, the ligand field activation energy (LFAE) is predicted on the basis of molecular orbital theory. The calculation is based on second-order perturbation theory, like that previously reported in connection with the interpretation of the splitting of absorption bands of cobalt(III) complexes.[4] This approach is essentially equivalent to "the angular overlap model" proposed by Schäffer and Jørgensen.[5] Using the latter model, Yatsimirski *et al.*[6] calculated σ- and π-antibonding effects. The present calculation also led to similar results, which were then used to obtain LFAE.

For high-spin d^3, d^5 and d^8 and low-spin d^6 complexes, the present calculation of LFAE gives exactly the same values as the conventional CFAE values, irrespective of the relative contributions of the σ- and π-interactions. This is the case for each model of the transition state: the tetragonal pyramid (C_{4v}), the trigonal bipyramid (D_{3h}) and the pentagonal bipyramid (D_{5h}) models. For other complexes, however, the present LFAE differs appreciably from the conventional CFAE. The results for the C_{4v} model are given in Fig. 1.

Unlike CFAE, LFAE increases in the order $d^5 \leq d^6 \leq d^7 < d^8$ for high-spin and $d^3 \leq d^4 < d^5 < d^6$ for low-spin complexes. This explains the above observations (1) and (2) (crystal field calculations can also explain these observations, if $\rho_2(r)$ is assumed approximately equal to $\rho_4(r)$ instead of $2\rho_4(r)$ as in the conventional calculation).[7]

Additional spin-pairing may occur, in some transition states. Quantitative calculations showed that this is possibly the case for pentagonal bipyramidal transition states of some low-spin d^4 complexes. This gives a molecular orbital version of Adamson's mechanism[8] that $[Mn(CN)_6]^{3-}$—CN^- exchange should proceed through hepta-coordinated, spin-paired $[Mn(CN)_6H_2O]^{3-}$.

Full theoretical results, including those for other models, and detailed discussions on particular cases will be given elsewhere.

Mechanism of Ammonia Synthesis over Molybdenum Nitride

Ken-ichi AIKA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 23, 1968)

The mechanism of ammonia synthesis has been studied extensively with iron catalysts by many workers, but less frequently with other catalysts of different elements. It has been accepted for the iron catalyst that the elementary step of dissociation of nitrogen molecule determines the rate of the reaction.[1] This might be different for the other catalysts. It has been suggested, for those metals which are known to form stable nitrides, that the step of hydrogenation of the dissociated nitrogen determines the rate of the reaction, the step of the dissociation being fast enough.[2] In accordance with this suggestion, Kemball *et al.*[3] have concluded that the rate of ammonia synthesis over molybdenum nitride is determined by the hydrogenation of adsorbed nitrogen. Since the ready formation of nitride is known with molybdenum, this conclusion appears to be reasonable. However if this conclusion is true, a normal isotope effect by deuterium is expected for the rate of ammonia synthesis over the molybdenum nitride, although a reverse isotope effect was observed for the iron catalyst.[4] Thus the deuterium isotope effect in ammonia synthesis over molybdenum nitride was investigated. The catalyst was prepared by reducing molybdenum trioxide (5.09 g) with flowing hydrogen at 492°C followed by nitriding with nitrogen at 502°C. The catalyst thus obtained was identified by X-ray analysis to be Mo_2N. The synthesis runs were carried out in a closed circulating system with a liquid nitrogen trap. The reaction rate was measured by the decrease in total pressure.

It was found that the rate depended on the flow rate and that deuterium reacted faster than hydrogen. A kinetic equation which fits the rate data at 330°C irrespective of the isotopic species of hydrogen is obtained

$$r = 2.5\times10^{-3}\,P/(1+Ky\sqrt{P})^2,\ (l_{NH_3}/\mathrm{hr})$$

where P is the total pressure, y the concentration of ammonia in the effluent gas from the reactor and K a constant, the value of which is different for hydrogen and deuterium, that is, $K_H=1900$, $K_D=600$.

This result is similar to that on the iron catalyst,[4] and a similar interpretation can be applied, that is, the constant K can be interpreted as the equilibrium constant of a dissociative adsorption of ammonia.

$$NH_3 \rightarrow N(a) + 1.5H_2$$

The value of the ratio K_H/K_D ($=1900/600=3.2$) is close to the theoretical one (3.82) which is given as the inverse ratio of the equilibrium constants of ammonia synthesis with hydrogen and deuterium. Thus the rate determining step of the synthesis over molybdenum nitride seems to be the dissociation of nitrogen molecule as was the case for the iron catalyst.

The last conclusion was further examined by the isotopic exchange in nitrogen during the synthesis reaction. The initial isotopic composition of the reactant nitrogen was as follows.

$^{30}N_2$, 28.9%; $^{29}N_2$, 26.6%; $^{28}N_2$, 44.5%

Seventeen samplings were made during 122 hr of the synthesis over the molybdenum nitride at 330°C by which 72.6 m*l* (N.T.P.) of the reactant gas was consumed. During this synthesis the concentration of $^{29}N_2$ remained at 26.6±0.2%. This result clearly shows the absence of isotopic mixing in nitrogen during the synthesis and confirms the non-equilibration of nitrogen dissociation during the synthesis reaction.

It may be concluded that the rate of the ammonia synthesis over molybdenum nitride is not determined by the step of hydrogenation of adsorbed nitrogen atom, but by that of dissociation of nitrogen. The rate equation obtained, the isotope effect observed and the non-equilibration of nitrogen dissociation during the synthesis can be understood only from this view.

Photolysis of Tropone in the Vapor Phase[1]

Toshio MUKAI and Toshiya SATO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

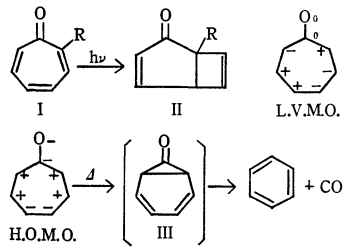
and Makoto TAKAHASI and Hitoshi MIKUNI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received September 4, 1968)

In solution, most tropone derivatives (I), upon irradiation, afford their valence isomer, II[2]. On the other hand, the thermolysis of the troponoids gives benzenoids in a very good yield.[3] The kinetic study of the thermoylsis has suggested that the decarbonylation proceeds *via* norcaradienones.[3] The good contrast between the photochemical behavior and the thermal behavior of the troponoid can be supported by the molecular orbital symmetry theory.[4] The disrotatory process of the lowest vacant molecular orbital can lead to II while the highest occupied molecular orbital leads to III. However, the photoreaction of tropone (I, R=H) is an exceptional case: dimers[5] and benzene[2] were obtained instead of II (R=H). Although the yield was very poor, the photochemical formation of benzene may be assumed to arise from the use of III as an intermediate.[2] However, this assumption is contrary to the molecular orbital symmetry theory described above.

We have studied the photolysis of tropone *in the vapor phase* in order to clarify the mechanism for the decarbonylation of tropone. The photolysis was carried out in a Pyrex vessel (170 ml) at 100±5°, under completely degassed conditions, by external irradiation using Toshiba H 400-P



lamp.[6] The results obtained are shown in the table, although all of them are only preliminary.

The yield of the decarbonylation (runs 1 and 2) increased to about 30% compared with the photolysis in solution, where the yield was 1%. In addition, when an inert gas such as carbon dioxide was added to the reaction system, a decrease in the yield for the decarbonylation was observed (run 3).

These facts suggest that the excited molecule of tropone converts isoenergetically to the vibrationally-excited molecule, which then gives benzene and carbon monoxide through the intermediate III. Although the photo-excited state of tropone cannot be assigned on the basis of the results of the present experiment, it seems unlikely that the triplet state is involved, considering that the estimated triplet energy of tropone (42—53 kcal/mol)[5d] is rather less than the activation energy of the thermal decarbonyl process of tropone (54.1 kcal/mol).[3] The interpretation of the quenching effect of oxygen (run 4) is left for future investigation.

TABLE 1

Run	Tropone μ mol (mmHg)	Gas added (mmHg)	Irr. time hr	CO (μ mol)	Benzene (μ mol)
1	32.1(4.30)	—	1.0	12.2	10.0

New Catalytic Synthesis of Ketones by the Oxidation of Olefins

Yoshihiko MORO-OKA, Shyoji TAN, Yusaku TAKITA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 4, 1968)

It is well known that α-olefins are oxidized to ketones by a palladium chloride catalyst with copper chloride in the presence of hydrogen chloride and water.[1] However, in the heterogeneous oxidation of olefins, allylic oxidation has been mainly reported to occur and no catalyst effective in forming ketones has yet been found. In this communication we wish to report a new catalytic synthesis of ketones by the gas-phase oxidation of olefins in the presence of steam.

The catalyst used in the present synthesis is composed of tin- or cobalt oxide combined with molybdenum trioxide. The atomic ratio of the tin or the cobalt to the molybdenum in the catalyst is usually larger than unity. Sn-90/Mo-10 and Co-90/Mo-10 catalysts were used in this experiment. The catalyst was prepared by the thermal decomposition of a mixture of tin- or cobalt hydroxide and an aqueous solution of ammonium molybdate. It was molded into cylindrical tablets and was fired in air at 550°C for 5 hr before the run. The reactions were carried out in a flow system at an atmospheric pressure. The reaction products were separated by gas chromatography and were identified by mass spectrometry. Typical experimental results are tabulated in Table 1.

Propylene, *n*-butenes, and 1-pentene were converted to acetone, methyl ethyl ketone, and methyl propyl ketone (including diethyl ketone), respectively. When the reactions were carried out at higher temperatures, the per-pass conversion of olefins increased, whereas the selectivity to ketones was decreased by the side reactions forming acetaldehyde, acetic acid, and carbon dioxide.

Ethylene did not react under the same conditions and gave only carbon dioxide at higher temperatures. Isobutene, which has no corresponding ketone, was converted mainly to tertiary butanol and diisobutene under the same conditions, and to α-methylacrolein and carbon dioxide at higher temperatures. On both the tin and cobalt catalysts, primary and secondary alcohols were easily oxidized to the corresponding aldehydes and ketones respectively. These results suggest that ketones, were formed *via* the hydration of olefins to form alcoholic intermediates followed by oxydehydrogenation. Since it has been established that acid catalysts are effective for the hydration of olefins, and since tin-molybdenum and cobalt-molybdenum heteropolyacids are known, it seems that the heteropolyacid is responsible for the first step of the reaction.

Some binary oxides, such as Cr_2O_3-MoO_3, Fe_2O_3-MoO_3, and CuO-MoO_3, were also effective in forming acetone from propylene, however, the selectivities to acetone were far lower than in the cases of SnO_2-MoO_3 and Co_3O_4-MoO_3.

TABLE 1. REACTIONS OF OLEFINS OVER SnO_2-MoO_3 AND Co_3O_4-MoO_3 CATALYSTS

Olefin	Ketone	Catalyst	Reaction temp. (°C)	Conversion of olefin (%)	Selectivity to ketone* (%)

Effect of Laser Irradiation on Infrared Spectrum of Ammonia

Isao SUZUKI* and Shigeko SUZUKI**

* *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo*

** *Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo*

(Received September 10, 1968)

Although a few observations have been reported on the laser-induced fluorescence of vibration-rotation transitions,[1-3] they have been limited to the region where laser frequencies locate, and hardly have they been extended to the region of pure rotational transitions. In this communication, we report on the observation of emission spectrum of ammonia as well as the change in the absorption spectrum in the far-infrared by irradiation of a CO_2 laser. Similar measurements have also been made for the ν_2 band in the 10 μ region, with which the laser frequencies coincide.

The CO_2 laser used consists of a 1.5 m discharge tube with two internal mirrors; one is a concave mirror of radius 3.5 m and the other is a flat germanium plate from which the laser beam is taken out. A leakage transformer (15 kV) was used for ac-excitation. The laser output is distributed among a few vibration-rotation transitions of the 10.6 μ band, of which the P(20) line at 944.25 cm^{-1} is the strongest.

For spectroscopic measurements a cross-cell similar to that described by Ronn[1] was used. The emission perpendicular to the incident laser beam was observed. With this cell we also made absorption measurements with or without laser irradiation. In Fig. 1, we show the emission spectrum of NH_3 (150 mmHg) obtained in the 340—200 cm^{-1} region with a Hitachi EPI-L spectrophotometer, along with the absorption spectra of NH_3 at the same pressure with and without the laser irradiation. The emission is strongest at about 275 cm^{-1} ($J=13\rightarrow14$), where the difference between the normal and irradiated absorption spectra is largest.

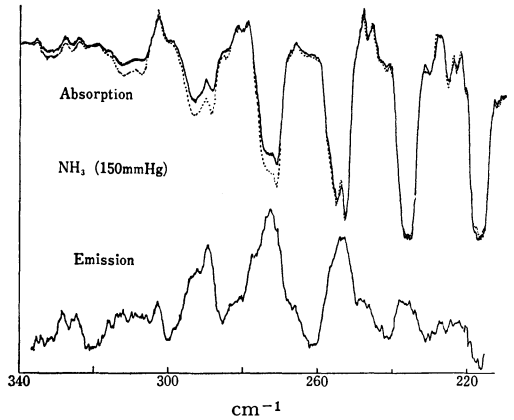

Fig. 1. Infrared spectra of ammonia (150 mmHg) in the 340—200 cm^{-1} region: laser-induced emission (below), and absorption spectra (above). Dotted line indicates the irradiated spectrum.

In the 10 μ region we have also observed rather strong emission. As reported by Ronn,[1] the spectrum is quite complex, probably due to the coincidence of the laser lines with "hot transition" $\nu_2^s\rightarrow2\nu_2^a$ of NH_3. The change in the absorption spectrum is also complex; however, a few remarks can be made: (1) Remarkable change in intensity was observed for the R(12)-R(16) lines of $0^s\rightarrow1^a$ band, and their intensities increased up to twice. (2) The Q-lines with $J=\sim10$ at about 950 cm^{-1} also exhibited intensity increase under the same conditions, whereas the changes were not appreciable for the corresponding P-lines. (3) Every absorption band associated with $1^s\rightarrow2^a$ transitions increases its intensity when irradiated. (4) Some fundamental lines with low J showed intensity decrease.

The above results may be interpreted as follows: since the CO_2 laser serves as a pumping source, the molecules absorb the light of characteristic frequencies and are exicted to the corresponding vibration-rotation levels. The collison relaxation time, however, is sufficiently short to allow the redistributions of the molecules among all the vibration-rotation levels. We may say that a dynamical equilibrium is established, in which the populations of the upper vibrational levels as well as the rotational temperature of each vibration level are higher than those in the thermal equilibrium. Thus, the CO_2 laser irradiation affects not only the vibration rotation transitions around the laser frequencies but also the other vibration-rotation transitions. The observed pure rotational emission and the intensity change in the absorption spectrum can also be explained on the same basis.

No Scrambling in the Decomposition of Labeled Benzoyl Peroxide

Michio KOBAYASHI, Hiroshi MINATO and Yoshikuni OGI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received September 11, 1968)

Taylor and Martin[1] showed that *ca.* 38% of all radical pairs formed in the decomposition of acetyl peroxide recombined in the solvent cage to give acetyl peroxide with scrambling of label. We have investigated a similar reaction with benzoyl peroxide labeled with oxygen-18 in the carbonyl oxygen. We wish to report on a rather surprising finding that the scrambling of the label does not occur during the decomposition of the labeled benzoyl peroxide.

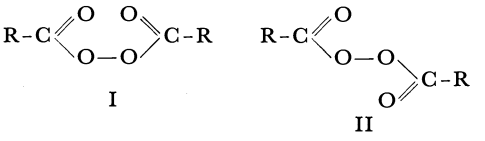
The labeled benzoyl peroxide was prepared from the labeled benzoyl chloride and sodium peroxide. A solution of 120 m*l* of benzene containing 8.00 g of the benzoyl peroxide was refluxed at 78°C for 340 min (a half life of the peroxide). The carbon dioxide evolved was collected in a liquid nitrogen trap. The reaction mixture upon 50% decomposition was cooled and separated into benzoyl peroxide, benzoic acid and an ester fraction, from which phenyl benzoate was isolated by elution chromatography.

These products were converted into carbon dioxide which were assayed for oxygen-18 by mass spectrometry. Several methods were investigated in order to separate the carbonyl oxygen and the peroxidic oxygen in the benzoyl peroxide, and the best method found was converting it into benzhydrazide by the reaction with hydrazine. The hydrazide obtained from the starting peroxide contained all the oxygen-18 that was present in the peroxide. It is interesting to note that hydrazine attacks the carbonyl carbon of benzoyl peroxide, whereas dimethylaniline attacks the peroxidic oxygen.[2] The results are shown in Table 1.

TABLE 1. SPECIFICITY OF ^{18}O-LABELING

Sample	% ^{18}O-excess	% ^{18}O Calcd
Starting BPO	0.696	0.673
Its hydrazide	1.345	(1.345)
Recovered BPO	0.708	0.673
Its hydrazide	1.314	1.345
PhCOOH	0.682	0.673
PhCOOPh	0.628	0.673
CO_2	0.669	0.673

The hydrazide produced from the peroxide recovered after 50% decomposition contained all the oxygen-18 that was present in the starting peroxide (within the experimental error). This finding clearly shows that the scrambling of the label does not occur in the decomposition of the ^{18}O-labeled benzoyl peroxide in contrast to the case of acetyl peroxide.[1] It is difficult to determine the reason for the difference of the behavior of these two peroxides, but following explanation seems to be possible. There are two limiting conformations, I and II, for peroxides. Conformation I is favorable for the scrambling upon decomposition. Because of the resonance with the benzene ring, the carbonyl oxygen of benzoyl peroxide is negatively charged to a greater extent than that of acetyl peroxide. Due to the repulsion of the greater charge on the oxygen, the conformations of the decomposing benzoyl peroxide probably do not contain Conformation I. The majority of the peroxide will be decomposing from the conformations similar to Conformation II.



I II

In order for the radicals produced from Conformation II to scramble, the carboxyl group must rotate. The bond between the methyl carbon and the carboxyl carbon is not restricted, whereas the bond between the benzene ring and the carboxyl carbon is somewhat restricted because of the resonance. The rotation of the benzoyloxy radical as a whole is also expected to be more difficult than the acetoxy radical which is much smaller. However, further investigation is necessary for the clarification of these points.

Effect of Surface Active-Agents and Some Molecules on the Electrical Properties of Lipid Membranes

Masao HASHIMOTO

Department of Physics, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received February 9, 1968)

The electric and mechanical properties of lipid membranes between two electrolyte solutions were observed. The electric resistance was 10^7—10^8 $\Omega \cdot cm^2$; the capacity, 0.2—1 $\mu F/cm^2$, and the surface tension, 2.2—4.9 dyn/cm. The electric conductivity increased with an increase in the surface area of the lipid membranes. Furthermore, the electric resistance and the capacity decreased when an ionic surface-active agent was adsorbed to the lipid membranes. The effect may be caused by the structural change of the lipid membranes due to both the electric and the hydrophobic interactions between the ionic surface-active agent and the lipid membranes.

It has been pointed out experimentally by Overton[1] and Collander[2] that the permeability coefficient of a substance through the membrane of a plant cell is proportional to its oil/water partition coefficient, and that the membrane shows a comparatively high permeability to lipid-soluble substances. On the basis of such experiments, they suggested that lipids might be involved in the membrane structure. On the other hand, the physico-chemical nature of the lipid monolayer has been investigated by many authors, beginning with Gorter and Grendel.[3]

From the fact[4-6] that the surface tension of the urchin egg is larger than that of the lipid monolayer in the range of physiological pH values, Danielli and Davson[7] proposed the lipid bilayer coated with protein as the fundamental element of the biological membranes. Their proposal has been supported by the electron-microscopic observations,[8,9] the X-ray diffraction pattern,[10-12] and so on.

In investigating biological membranes, studies of lipid bilayers will be more useful than those of the monolyaer.

Several years ago, Mueller *et al.*[13-17] and Thompson *et al.*[18-22] succeeded in forming lipid bilayers between two electrolyte solutions, and reported on some physico-chemical properties, *i. e.*, the electric conductivity, the electric capacity, the surface tension, *etc.*, of such systems.

The present author has been especially interested in the work of Mueller *et al.* They found that the electric resistance of a lipid bilayer adsorbing some water-soluble substances is much lower than that of the original, bare lipid bilayer, and showed that the resistance of biological membranes is of an order similar to that of the coated lipid bilayers. Because of the lack of detailed information of the adsorbed molecules, however, we can not really explain the mechanism of such a reduction of the electric resistance.

It is the purpose of this paper to investigate

the effect of the well-defined adsorbed materials on the physico-chemical nature of the lipid bilayers. The author used some surface-active agents, proteins, and polypeptides as the adsorbed materials, and observed such properties as the electric conductivity, the electric capacity, the surface tension, and the relationship between the surface area and the electric conductivity.

Experimental

Apparatus. The block diagrams of the apparatus are given in Figs. 1a and 1b. In Fig. 1a, the glass tube (A) is held vertically, and the end is bent horizontally. The diameter (E) at the end of the tube was 2 mm.

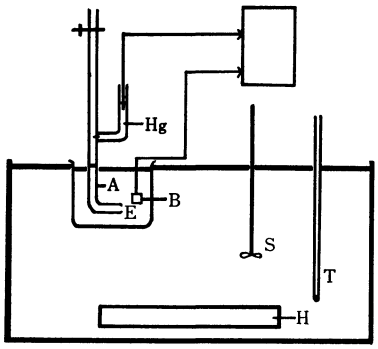

Fig. 1a. The main apparatus used to measure the electrical properties of the membrane.

Both beaker and tube were filled with an electrolyte solution. B, S, T, and H were the platinized platinum plate, stirrer, thermister, and heater respectively. The beaker was immersed in the water both, and the temperature of the electrolyte solution was kept constant within a range of error of ± 0.2°C.

Figure 1b shows the details of the neighborhood of the membrane.

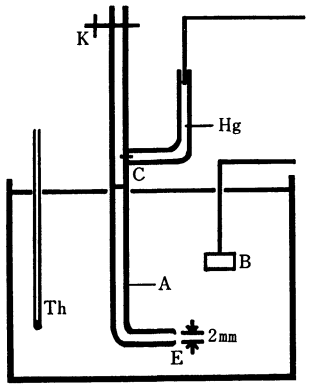

Fig. 1b. The enlargement figure near the membrane.

Th, C, and K are the thermometer, the platinized line, and the glass cock respectively. The membrane was formed by drawing the solution of the lipid with a small brush across the hole at the end of the tube. The surface of the membrane could be seen through a magnifying glass.

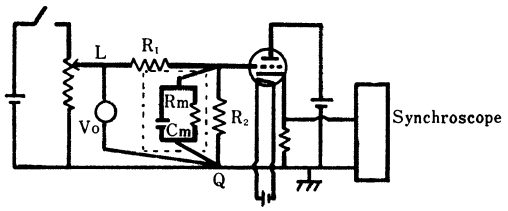

Fig. 2. Outline of the electric circuit.

The outline of the circuit is given in Fig. 2. The equivalent circuit for the membrane is enclosed with a dotted line. It is assumed that the membrane can be represented by an equivalent circuit in which the electric resistance, R_m, and the electric capacity, C_m, are connected in parallel.

A square-wave current was applied across the membrane. The potential difference across the membrane was measured with a synchroscope (Tektro 531 or Iwasaki Synchro Junior 5022). Since the measured potential difference contained the potential difference of the electrolyte solution, the latter was corrected. The resistances, R_1 and R_2, were adjusted to keep the potential difference between L and Q constant. On the basis of the assumption given above, the values of R_m and C_m can be obtained by:

$$V_m = V_0 \frac{\left(\frac{1}{R_m} + \frac{1}{R_2}\right)^{-1}}{\left(\frac{1}{R_m} + \frac{1}{R_2}\right)^{-1} + R_1}$$

$$V = V_m \cdot [1 - \exp(-t/C_m R)]$$

$$R = \left(\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_m}\right)^{-1}$$

where

V_m = Potential difference across the membrane in equilibrium
V = Potential difference across the membrane at time t
V_0 = Potential difference between L and Q measured by a voltage-ampere meter
$C_m R$ = Time constant

Materials. The lipid was extracted from ox brain in the same way as was done by Mueller *et al.* and was preserved in a refrigerator as a chloroform-methanol solution, kept from exposure to light and air.

The experiments were carried out for the *n*-decane solution as well as the chloroform-methanol solution. In the former case, after the evaporation of the solvent of the chloroform-methanol solution, the lipid was again dissolved in *n*-decane.

The salts used for the electrolyte solution were as follows: 1) NaCl, KCl, LiCl, *etc.*, 2) $MgCl_2$ and $CaCl_2$, 3) tetra-methylammonium chloride (TMA) and tetrabutylammonium chloride (TBA). Each of them was dissolved in a 1/500 M phosphoric acid buffer solution (pH 3.5, 7.0, and 10.0, mainly 7.0) after having been boiled in order to remove any oxygen.

Sodium dodecyl sulfate, sodium laurate, dodecyl trimethyl-ammonium chloride, and dodecyl trimethyl-ammonium bromide were used as ionic surface-active agents, while polyoxyethylene sorbitan mono-palmitate

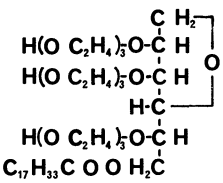
Table 1. The CMC value of ionic agents used in our experiment

Compound	CMC value in water, mM	Temp. °C	CMC value in 0.1 M NaCl soln., mM[1]	Temp. °C
Dodecyl trimethylammonium chloride	16—20	30	2.7—3.3	36
Dodecyl trimethylammonium bromide	15—17	25	2.6—2.9	36
Sodium dodecyl sulfate	8—11	35	1.39	36
Sodium laurate	23—26	25	10—11	36

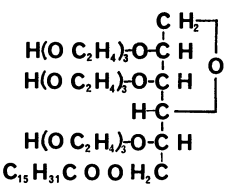
(I) and polyoxethylene sorbitan mono-oleate (II) were used as non-ionic surface-active agents. All these materials were originally commercial products. In order to purify them further, the ionic agents were recrystallized from ethanol.

The values of the critical micelle concentration (CMC) of these detergents were determined from the measurements of the surface tension by using the drop method.[23,24] These values are shown in Table 1.

One criterion of the ionic detergent purity employed in this work was the agreement of the observed CMC values with those reported in the literature.[25-28] Another criterion was that the curve relating the surface tension with the ionic detergent concentration did not show a minimum. The non-ionic agents were used without purification.



(I)



(II)

Polyglutamic acid (PGA) and the lysine-glutamic acid copolymer (L-G copolymer, lysine fraction 6 wt%) were offered by Akiyoshi Wada, while the histone was offered by Koichi Iwai.

Results

Electric Resistance and Electric Capacity of the Membrane. The values of the electric resistance of the lipid membrane at pH 7.0 and 36.0±0.2°C are shown in Table 2. The lipid membrane was formed from the chloroform-methanol solution.

The resistance decreased with an increase in the concentration of the electrolyte solution. Hanai *et al.*[29] reported a similar tendency in the lecithin bilayer. The electric resistance of the membrane in TMA and TBA solutions was larger than that in other electrolyte solutions. The electric capacity was nearly the same for all sorts of electrolyte solutions, the values ranging from 0.2 to 1.0 μF/cm^2.

Table 2. Effect of the concentration of the salt on the electric resistance at 36.0°C and pH 7.0

Salt	Concentration of salt, M	Resistance of the membrane $10^7\ \Omega\cdot cm^2$
NaCl	2.5	2.0
	1.0	2.4
	0.1	3.2
	0.01	3.8
KCl	1.0	1.0
	0.1	8.5
	0.01	15
LiCl	1.0	2.5
	0.1	5.7
	0.01	12
LiF	0.01	4.9
$CaCl_2$	0.1	8.5
	0.01	14
$MgCl_2$	1.0	2.4
	0.1	3.3
	0.01	5.1
TMA	0.1	12
TBA	0.1	18

On the other hand, the pH dependence of the electric resistance and of the capacity of the membrane was very small in each of these electrolyte solutions. For example, the electric resistance in the NaCl solution was $4.1\times10^7\ \Omega\cdot cm^2$ at pH 3.5, $3.2\times10^7\ \Omega\cdot cm^2$ at pH 7.0, and $5.0\times10^7\ \Omega\cdot cm^2$ at pH 10.0.

The membrane broke down upon the application of the electric voltage, 200—250mV.

The Effect of Surface-active Agents. When a cationic active agent, dodecyl trimethylammonium chloride, was added to the electrolyte solution, the resistance of the membrane decreased at the concentration of 0.5m M as is shown in Fig. 3. This concentration is about 1/6 the CMC value.

When the concentration of the surface-active agent was increased to about 2.5m M (about 9/10

○ Dodecyl trimethylammonium chloride
● Dodecyl trimethylammonium bromide

the CMC value), the membrane broke down upon the application of an electric impulse. A further increase in the concentration of the detergent did not allow the membrane to be reformed.

As for dodecyl trimethylammonium bromide, the resistance of the membrane decreased at the concentration of 0.4 mM and the membrane broke down at the concentration of 2.3 mM The anionic agents, sodium dodecyl sulfate and sodium laurate, also reduced the resistance of the membrane (Figs. 4 and 5).

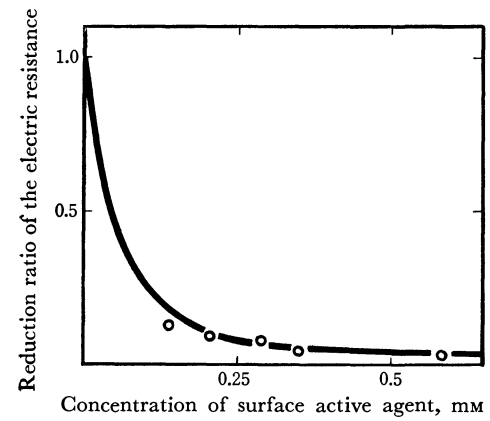

Fig. 4. Effect of the concentration of sodium dodecyl sulfate on the electric resistance of the lipid membrane.

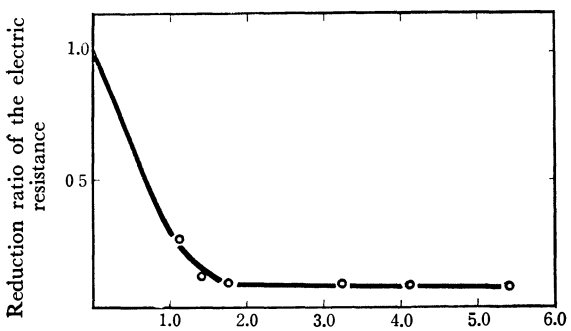

Fig. 5. Effect of the concentration of sodium laurate on the electric resistance of the lipid.

In the concentration range shown in Figs. 3, 4 and 5, the capacities ranged from 0.2 to 0.3μF/cm^2.

On the other hand, the non-ionic agents, polyoxyethylene sorbitan mono-palmitate and polyoxyethylene sorbitan mono-oleate, did not affect either the electric resistance or the capacity of the membrane.

Some Properties of the Membrane. As is well known, PGA is in a helical conformation at pH 4.5 and in a random coil at pH 10.0. In the present experiment, each solution of PGA, at pH 4.5, 7.0 and 10.0 was added to the electrolyte solution on both sides of the membrane.

In order to investigate the ionic effect of the copolymer on the resistance of the lipid membrane, on the other hand, we added the L-G copolymer to the electrolyte solution at pH 3.0, 7.0 and 10.0. In each case, however, no effect was found. Furthermore, the addition of neither histone nor aspartic acid had any effect, either.

In order to measure the surface tension of the membrane, a hydrostatic pressure difference was applied across the membrane in order to observe the radius of the curvature of the curved membrane. The surface tension can then be obtained from the following equation:

$$\gamma = \frac{1}{4} p \cdot r \text{ (dyn/cm)}$$

where p=hydrostatic pressure difference and r= radius of curvature.

The surface tension of the membrane in a NaCl solution was 2.2—4.9 dyn/cm at pH 7.0 and 36.0°C. Hanai *et al.*[30] measured the surface tension of a lecithin membrane formed from an *n*-decane solution by using the same method; they obtained the value of *ca.* 1 dyn/cm. They also reported[29-31]

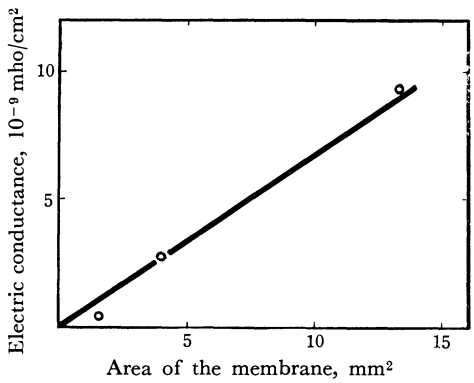

Fig. 6. The relation of the conductivity and the area of the bulged membrane.

30) T. Hanai, *Hyomen*, **4**, 643 (1966). (in Japanese)
31) T. Hanai, D. A. Haydon and J. Taylor, *J. Theoret. Biol.*, **9**, 433 (1965).

that the conductance of the lecithin membrane was nearly proportional to the surface area of the membrane and that the conductance per unit area 1.3×10^{-9} mho/cm in a 0.1 M NaCl solution. We also measured the conductance of the lipid membrane in relation to the surface area. The results are shown in Fig. 6.

The effect of the temperature on the membrane resistance was investigated in the 7—45°C temperature range. The membrane was stable only in the 20—40°C temperature range. The resistance was nearly independent of the temperature within the limits of the experimental error. This finding is not in agreement with that of Thompson.[18] He showed that the resistance changed discontinuously with the temperature. In our experiment described above, a chloroform-methanol mixture was used as the lipid solvent.

In order to investigate the effect of the solvent on the resistance of the membrane, we used *n*-decane as another solvent. The resistance of such a lipid membrane was much larger than that of the lipid membrane formed from a chloroform-methanol solution and was somewhat different from that obtained by Hanai *et al.*[30]

Discussion

As a lipid bilayer is rather simpler than a biological membrane in the sense that it does not contain protein, it is more important to investigate how the lipid bilayer adsorbs substances such as proteins and surface-active agents. Mueller *et al.* have for instance, reported that the resistance of the bilayer decreased when it adsorbed unidentified water-soluble substances extracted from egg white.

We observed that the resistance of the membrane decreased upon the addition of ionic surface-active agents to the electrolyte solution. The resistance did not change upon the addition of non-ionic agents, however.

We interpret the decrease in the electric resistance of the membrane as follows. Since the electric conductivity is due to the ionic current through the membrane, it is reasonable to surmise that the decrease in the electric resistance was caused by the increase in the ionic permeability due to the formation of several kinds of channels for ions with a structural change in the lipid membrane.

It may be considered that the added ionic agents adsorb on the membrane due to the interaction of the ionic agents with ionic sites in the outer region of the phospholipid membrane. Besides, hydrocarbon chains of the ionic agents may interact with the inner region of the lipid membrane. On the other hand, non-ionic agents will interact only with hydrocarbon chains of the lipid membrane.

Our experimental results suggest that the structural change of the membrane may be caused by both electrostatic and hydrophobic interactions of ionic surface-active agents with the membrane, and that the electrostatic interaction is necessary for the change in the membrane structure. That is, no structural change can be effected without ionic interaction in the outer region of the membrane. However, hydrophobic interaction may not be neglected.

The C number of the hydrocarbon chain of the surface active agents in our experiment was 11 or 12; in this case, hydrophobic interaction is plausible. No decrease in the membrane resistance was observed on the addition of substances with a few carbon atoms, for example, tetramethylammonium chloride, tetrabutylammonium chloride, aspartic acid, and caprylic acid. The structural change in the membrane may require the cooperation of electrostatic and hydrophobic interactions.

We shall now discuss the relation between the decrease in the resistance and the CMC values of the ionic agents. The resistance of the membrane decreased abruptly at a concentration of about 1/6 and at 1/10 the CMC value for cationic and anionic agents respectively. The lipid membrane may be sensitive to the solubilizing power of ionic detergents adsorbed due to electrostatic and hydrophobic interactions; the structural change in the membrane may be the consequence.

The CMC value of each ionic detergent may affect the critical concentration at which the abrupt decrease in the membrane resistance occurs. The difference between the decrease in the membrane resistance for cationic and anionic agents may correspond to the difference between the number of cationic and of anionic agents adsorbing on the membrane. As it is considered that the positive ions in the outer region of the

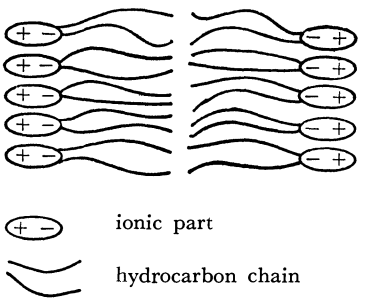

Fig. 7a. Lipid bilayer model.

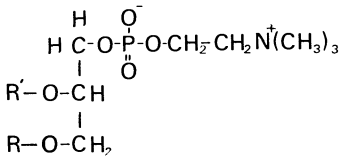

R, R′: Hydrocarbon chain (16 to 22 carbons long)

Fig. 7b. Structural formula of phospholipid.

membrane are nearer to the bulk solution than are the negative ions, the anionic agents will adsorb on the membrane easier than will cationic agents. The details of the lipid bilayer membrane are shown in Figs. 7a and 7b. The proportionality of the conductivity to the surface area of the membrane was not very good, though the conductivity did increase with the increase in the surface area.

In our experiment, the surface tension of the lipid bilayer was larger than that of the biological membrane. This is because the lipid bilayer is not coated with protein.[32-33]

The author wishes to express his deep gratitude to Professor Akiyoshi Wada of the University of Tokyo for his valuable advice and support throughout the course of this work, to Mr. Masaiku Hara for his experimental assistance, and to Professor Koichi Iwai supplying the histone.

Thanks are also due to Professors Syoten Oka and Misazo Yamamoto of Tokyo Metropolitan University for their helfpul suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2828—2832 (1968)

The Structure of an Electrical Double Layer around a Surfactant Micelle

Fumikatsu Tokiwa and Kenji Ohki

Research Laboratories Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received February 13, 1968)

Electrophoretic measurements have been made of the micelles of dimethyldodecylamine oxide (DDAO) and *N*-dodecyl-β-aminopropionic acid (DAPA), while changing the pH values of the solutions in the presence of 0.10 M sodium chloride. A picture of the structure of the electrical double layer around the micelle at different pH's was then constructed, according to Stern's theory, by a combination of the zeta potential, ζ, calculated from the electrophoretic mobility and the surface potential, ψ_0, obtained previously from the potentiometric titration. With the micelle of DDAO, the thickness of the immobile part of the double layer depends slightly on the pH of the solution and is estimated to be about 5 Å. With the micelle of DAPA, the estimated thickness of the immobile part seems rather high, especially on the alkaline side of the solution. The ζ/ψ_0 ratio for the micelles of DDAO and DAPA depends on the pH of the solution; in the case of DDAO the value of ζ/ψ_0 increases with a decrease in the surface potential.

The structure of an electrical double layer around a charged surfactant micelle is governed in general by the potential at the surface of the micelle, ψ_0, and the distribution of counter-ions and co-ions in the locality of the charged surface. The thickness of the immobile part of the double layer, the distance from the surface of the micelle to the plane of shear, is related in particular to the zeta potential of the micelle, the potential at the plane of shear, ζ. Several studies have been reported of the ζ-potentials of micelles of ionic surfactants,[1-4] but there has been a lack of studies of the thickness of the immobile layer of micelles.[5]

In the present paper, the ζ-potentials of the micelles of the surfactants, whose surface-charge density depends on the pH of the solution, have been discussed in connection with the surface potentials of the micelles previously evaluated from potentiometric data[6,7] in order to obtain knowledge of the thickness of the immobile layer. Stern's theory[8] is used to construct a picture of the structure of the electrical double layer around the micelle. The surfactants studied are a nonionic-cationic surfactant, dimethyldodecylamine oxide (abbreviated as DDAO), and an amphoteric surfactant, *N*-dodecyl-β-aminopropionic acid (abbreviated as DAPA). The surface-charge densities of the micelles depend on the pH of the solutions. With DDAO, the nonionic and cationic forms related by the equilibrium[6]:

$$C_{12}H_{25}N(CH_3)_2O \overset{H^+}{\rightleftharpoons} C_{12}H_{25}N^+(CH_3)_2OH$$

With DAPA, the anionic and cationic forms are related by the equilibrium[7]:

$$\begin{array}{ccccc} CH_2CH_2COO^- & & CH_2CH_2COO^- & & \\ | & \overset{H^+}{\rightleftharpoons} & | & \overset{H^+}{\rightleftharpoons} & \\ R\text{-}N\text{-}H & & R\text{-}N^+\text{-}H_2 & & \\ CH_2CH_2COOH & & & & \\ | & & & & \\ R\text{-}N^+\text{-}H_2 & & (R=C_{12}H_{25}) & & \end{array}$$

Experimental

Materials. The dimethyldodecylamine oxide (DDAO) was prepared by the H_2O_2 oxidation of highly-pure dimethyldodecylamine by the method described in a previous paper.[6] The sample was purified by repeated extraction with petroleum ether and by subsequent recrystallization from a mixture of acetone and benzene. The *N*-dodecyl-β-aminopropionic acid (DAPA) was the same as that used elsewhere.[7] The sodium chloride, hydrochloric acid, and sodium hydroxide were of an analytical reagent grade. The water used in this experiment was distilled and subsequently passed through an ion-exchange column.

Electrophoresis. The electrophoretic measurements were carried out in a Tiselius-type cell using a Hitachi Model HTB-2A Tiselius apparatus equipped with a Schlieren optical system. The concentrations of the surfactant in both the upper and lower layers of the cell were taken to be higher than the critical micelle concentration (CMC) in order to avoid the dissociation of the micelle into the monomers at a boundary.[2,4] The concentration of the supporting electrolyte, sodium chloride, was 0.10 M. The pH of solutions was adjusted with hydrochloric acid or sodium hydroxide, and the pH values of all the solutions were rechecked after measurements.

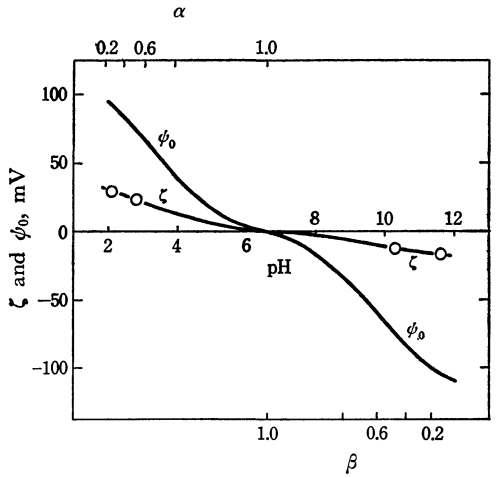

Fig. 2. The values of ζ and ψ_0 for the micelle of DAPA in the presence of 0.10 M NaCl plotted against pH.

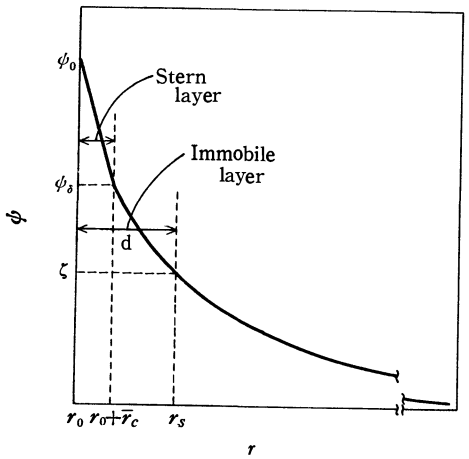

Fig. 3. Schematic representation of the structure of the double layer for the micelle of DDAO at pH 3.0: $\psi_0=117$ mV, $\psi_\delta=73.5$ mV, $\zeta=44.4$ mV, $r_0=29.1$ Å, $\bar{r}_c=1.8$ Å, and $d=5.1$ Å.

Results

In all the systems examined, only one moving boundary was obtained in each of the ascending and descending patterns. The electrophoretic mobility of the micelle, u_M, was calculated from the velocities of the ascending and descending boundaries by applying Dole's theory to the present system.[9,10] The value of u_M was calculated by the equation[2,4]:

$$u_M = X - \frac{Y - X}{(T_M{}^\eta/T_M{}^\alpha) - 1} \qquad (1)$$

Assuming $r_0=25$Å and $n=100$.

The details of Eq. (1) and its derivation are described in the Appendix. Tables 1 and 2 give the values of u_M for DDAO and DAPA respectively, calculated in terms of Eq. (1).

On several simplifying assumptions,[1,5,11] the relation between ζ and u_M may be written in the form[12]:

$$\zeta = 6\pi\eta u_M/D\cdot f(\kappa r_0) \qquad (2)$$

where $f(\kappa r_0)$ is Henry's function;[14] r_0, the radius of the micelle; κ, the inverse Debye radius, and η and D, the viscosity and the dielectric constant of the medium respetively. The ζ-potentials of the micelles of DDAO and DAPA as calculated by Eq. (1) are plotted in Figs. 1 and 2 respectively, together with the surface potentials of the micelles, ψ_0,[6,7] as a function of the pH of the solutions. In calculating Eq. (2), the r_0 values for DDAO were estimated from the potentiometric data reported previously,[15] and the value for DAPA was assumed to be 25 Å.

Discussion

A schematic representation of the structure of a double layer around a micellar particle according to Stern's model is given in Fig. 3 as a simple illustration. The surface potential, ψ_0, is divided into one potential, ψ_δ, over the diffuse part of the double layer and another, $\psi_0-\psi_\delta$, over the molecular condenser, as is shown in Fig. 3, where ψ_δ is a potential at the surface of the Stern layer.[8]

For the Stern layer, the equation for a spherical condenser may be used to obtain the value of ψ_δ from ψ_0. If one assumes that the Stern layer is the adsorbed monolayer of counter-ions,[16,17] and that, hence, the thickness of the layer is equal to the radius of the counter-ions, $\bar{r}_c$, the value of ψ_δ may be estimated by the equation:

$$\psi_\delta = \psi_0 - \frac{Q}{D}\left(\frac{1}{r_0} - \frac{1}{r_0+\bar{r}_c}\right) \qquad (3)$$

where Q is the net charge of the micelle, which is given by $\varepsilon n\beta$ for DDAO and by $\varepsilon n(\beta-\alpha)$ for DAPA, where ε is the elementary charge; n, the number of molecules per micelle; α, the degree of ionization of the carboxyl group, and β, the degree of the protonation of the nitrogen atom. The counter-ion for DDAO is Cl^-, and that for DAPA is Cl^- on the acid side and Na^+ on the alkaline side. A reasonable value of $\bar{r}_c$ is 1.84 Å for Cl^- and 2.17 Å for Na^+.[18] The ψ_δ values for the DDAO micelle at different pH's, as calculated by Eq. (3), are given in Table 1, together with the values of ψ_0, r_0 and n which have previously been obtained from potentiometric titration data in previous works.[6,15] Table 2 also gives the rough ψ_δ values for the DAPA micelle estimated by assuming that $n=100$.

12) Recently Wiersema *et al.*[13] have reported a more strict method of calculating the ζ-potential of a spherical colloidal particle by using an electronic computer. In the present case, however, the difference between the values obtained from Eq. (2) and their calculated values is not significant since the ζ-potentials are relatively low.

18) C. B. Monk, "Electrolytic Dissociation," Academic Press, New York, N. Y. (1961), p. 271.

For the diffuse layer, a potential, ϕ, at a certain distance from the center of a particle, r, may be calculated by Gouy-Chapman's equation for a spherical double layer. With $1/m$ valent electrolyte, Gouy-Chapman's equation is written in the form[19]:

$$r^{-2}\frac{d}{dr}\left(r^2\frac{d\phi}{dr}\right)=\frac{4\pi\varepsilon n_0}{D}\left[\exp\left(\frac{\varepsilon\phi}{kT}\right)-\exp\left(-\frac{\varepsilon\phi}{kT}\right)\right] \quad (4)$$

where n_0 is the concentration (number/cm^3) of positive or negative ions in the bulk of the solution. For the sake of convenience, by introducing a dimensionless "reduced potential" y $(=\varepsilon\phi/kT)$ and a "reduced distance" $q(=\kappa r)$ into Eq. (4), we obtain[19]:

$$q^{-2}\frac{d}{dq}\left(q^2\frac{dy}{dq}\right)=\frac{1}{2}(e^y-e^{-y}) \quad (5)$$

The solutions of Eq. (5) under different boundary conditions, y_0 and q_0, and using an electronic computer have been given by Loeb *et al.*[19] and are tabulated in Ref. 19. In the present case, y_0 and q_0 are written:

$$y_0=\varepsilon\psi_\delta/kT, \quad \text{and} \quad q_0=\kappa(r_0+\bar{r}_c)$$

Thus, we can construct ϕ *vs.* r curves, an example of which for the micelle of DDAO is given in Fig. 3.

The thickness of the immobile part of the double layer, $d(=r_s-r_0)$, may be obtained from the ζ-potential and the ϕ *vs.* r curve. The d values for the DDAO micelle at different pH's are given in Table 1; about 5 Å, they depend slightly on the pH of the solution. The thickness obtained here is comparable to that obtained by Stigter for the micelle of sodium dodecyl sulfate (4—5 Å) from the viscosity and the diffusion data.[5] It is of interest to calculate the ratio of ζ to ϕ_0 from the present data. The ζ/ϕ_0 ratio has been discussed by Davies and Rideal.[20] According to their calculation, the tendency is for ζ/ϕ_0 to increase as the surface potential is lowered. The results obtained here agree in tendency with their calculations.

Table 2 gives the rough values of the thickness of the immobile layer for the DAPA micelle. The thickness is roughly 6—7 Å on the acid side and 9—11 Å on the alkaline side, thicker than that for DDAO. The ζ/ϕ_0 ratios for DAPA are lower than those for DDAO, especially on the alkaline side. The reason for this is not clear; however, the results probably have some relation with the configuration of charged groups[21] at the surface of the micelle. The charged groups would be located relatively inside the surface of the micell.

The authors wish to express their thanks to Dr. H. Kita, Director of the Research Laboratories, for his encouragement and for permission to publish this paper.

Appendix

An initially sharp boundary between two solutions containing n ion species will generally split, upon the passage of an electric current, into $n-1$ separate boundaries, each moving at a different rate. According to Dole,[9,10] the following polynomials can be derived for each moving boundary:

$$\sum_j\frac{T_j^\alpha}{u_j-X_k}=0, \qquad \sum_j\frac{T_j^\eta}{u_j-Y_k}=0 \quad (A1)$$

$$k=1,2,3,\cdots,n-1$$

where:

$$X_1=V^{\alpha\beta}{}_\sigma{}^\beta \qquad Y_1=V^{\alpha\beta}{}_\sigma{}^\alpha$$
$$X_2=V^{\beta\gamma}{}_\sigma{}^\gamma \qquad Y_2=V^{\beta\gamma}{}_\sigma{}^\beta$$
$$\cdots\cdots \qquad \cdots\cdots$$
$$X_{n-1}=V^{\zeta\eta}{}_\sigma{}^\eta \qquad Y_{n-1}=V^{\zeta\eta}{}_\sigma{}^\zeta$$

Here T_j and u_j are the transference number and the mobility of j ion species respectively, σ is the specific conductance of the solution, and V is the boundary velocity. The superscripts α, β,$\cdots$, η refer to the α, β,$\cdots$,η phases, and $\alpha\beta$, $\beta\gamma$,$\cdots$, $\zeta\eta$ refer to $\alpha\beta$,$\beta\gamma$,$\cdots$, $\zeta\eta$ boundaries, respectively. Since the total of each transference number must be unity, *i.e.*, $\sum_j T_j^\alpha=1$, and $\sum_j T_j^\eta=1$, the solutions of Eq. (A1) become:

$$T_j^\alpha=\frac{(u_j-X_1)(u_j-X_2)\cdots(u_j-X_{n-1})}{(u_j-u_1)(u_j-u_2)\cdots(u_j-u_n)} \quad (A2)$$

$$T_j^\eta=\frac{(u_j-Y_1)(u_j-Y_2)\cdots(u_j-Y_{n-1})}{(u_j-u_1)(u_j-u_2)\cdots(u_j-u_n)} \quad (A3)$$

The denominators of Eqs. (A2) and (A3) are identical and may be eliminated to give:

$$\frac{T_j^\alpha}{T_j^\eta}=\frac{(u_j-X_1)(u_j-X_2)\cdots(u_j-X_{n-1})}{(u_j-Y_1)(u_j-Y_2)\cdots(u_j-Y_{n-1})} \quad (A4)$$

In the present system, the ionic species are surfactant monomer (m) and micelle (M) ions, and positive and negative electrolyte ions (Na^+ and Cl^-). However, since the concentrations of m ions can be assumed to be equal in the initial two phases, we can expect two boundaries to appear, one of which is stationary; in fact, we have experimentally obtained only one moving boundary. Thus, the experession of Eq. (A4) for micelles is simplified to:

$$T_M^\alpha/T_M^\eta=(u_M-X)/(u_M-Y) \quad (A5)$$

or:

$$u_M=X-\frac{Y-X}{(T_M^\eta/T_M^\alpha)-1} \quad (A6)$$

The X and Y in Eq. (A6) are written in the following forms when an apparatus of the Tiselius type is used.

20) J. T. Davies and E. K. Rideal, "Interfacial Phenomena," Academic Press, New York (1961), p. 140.

21) K. Durham, Proc. 3rd Intern. Congr. Surface Activity, Cologne, 1960, B/1/3, p. 130.

$$X = V_d\sigma^\eta, \quad \text{and} \quad Y = V_a\sigma^\alpha$$

where V_d and V_a are the velocities of the descending and ascending boundaries respectively. The $T_M{}^\eta/T_M{}^\alpha$ ratio is given by:

$$T_M{}^\eta/T_M{}^\alpha = (C_M{}^\eta/\sigma^\eta)/(C_M{}^\alpha/\sigma^\alpha)$$

where $C_M{}^\alpha$ and $C_M{}^\eta$ are the concentrations of M ions in the upper and lower layers in the cell respectively; they are given by:

$$C_M{}^\alpha = (C - \text{CMC})_\alpha, \text{ and } C_M{}^\eta = (C - \text{CMC})_\eta$$

The values of $C_M{}^\alpha$ and $C_M{}^\eta$ are known, and V_a, V_d, σ^α, and σ^η are all determinable. The u_M values given in Tables 1 and 2 are thus obtained from Eq. (A6).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2832—2834 (1968)

Rate of Electron Exchange between Cuprous and Cupric Ions in Concentrated HCl by Electron Spin Resonance*1

R. Allan STEWART*2 and L. W. REEVES

Department of Chemistry, University of British Columbia, Vancouver, British Columbia

and Shizuo FUJIWARA

Department of Chemistry, The University of Tokyo, Hongo, Tokyo

(Received March 5, 1968)

Contrary to previous reports, the linewidth of the electron spin resonance spectrum of cupric ion as measured in gauss between points of maximum slope is a sensitive function of ionic strength, chloride ion concentration and cuprous ion concentration. Assuming that electron spin relaxation rates do not change greatly on the addition of cuprous ion, it is possible to derive an electron exchange rate for the reaction:

$$Cu^+ + Cu^{2+} \longleftrightarrow Cu^{2+} + Cu^+$$

of $k = 1.53 \times 10^9$ *l*/mol/sec. This value is in good agreement with a previous determination of the same rate constant by McConnell and Weaver using the ^{63}Cu nuclear magnetic resonance (0.5×10^8). The results for the linewidth changes can be rationalized in all cases by assuming that bridge chloride ions between two cupric ions or one cupric and one cuprous ion change drastically in concentration as such factors as ionic strength or chloride ion concentration changes. The *g* value of the electron (free) decreases as chloride ion is added, indicating delocalization of the unpaired electron onto chloride ligands.

While nuclear magnetic resonance (NMR) studies of chemical exchange are widespread, little attention has been paid to the study of electron exchange processes by electron spin resonance (ESR). A recent authoritative review of the subject of exchange studies by magnetic resonance lists only 8 studies[1] carried out by ESR. These 8 investigations are comprised solely of investigations of electron transfer between radical ions and parent molecule. The ESR spectra of these species are composed of many hyperfine transitions, but some attempt has been made to compute lineshapes at various exchange rates, and to compare them with experimental curves.[2] Part of the reason for the absence of more activity in this field is the shortage of suitable systems and the complexity of the ones avaiable. A system which has been studied by an NMR method[3] is the cuprous-cupric electron exchange in aqueous solutions of the chloride. Although this system is complicated, it has the attraction that a single broad ESR line is observed, and the exchange process can be clearly demonstrated to dominate changes in linewidth. The study of linewidths of Cu^{2+} ions in aqueous solutions has already been investigated to some extent.[4]

Solutions of cupric chloride do not obey Beer's law[5,6] due to the formation of chloride complexes.

McConnell and Davidson,[7] by optical methods, established the presence of chlorine bridged complexes containing more than one copper ion, *e. g.*, $Cu_2Cl_5^-$, in aqueous solution. The bridge chloride ion promotes electron exchange between the two copper ions, giving rise to an intense coloration. It is probable that these bridge chloride ions are also responsible, in view of the anomalous spectral coloration, for the electron exchange process $Cu^+ \leftrightarrow Cu^{2+}$ in solutions of mixed oxidation states.

The present study is an attempt to compare directly the same exchange rate obtained by both NMR and ESR methods, and to study related processes which influence the ESR linewidth.

Experimental

Solutions were prepared by standard volumetric methods. The exclusion of air from sample tubes prevented the oxidation of cuprous ion to cupric ion. Samples were measured immediately after preparation of the solutions, but in any case, remained stable in closed tubes for periods in excess of one month. The solubility of $CuCl_2$ decreases in solutions of high HCl concentration, so that measurements were limited to more dilute regions. The cuprous ion is more stable in highly acid solutions. The ESR linewidth varies from 50 to 400 gauss as cupric and chloride ion concentrations are changed. This is in contradiction to a statement of Kozyrev,[8] and the published results of Al'tschuler and Kozyrev,[9] who observed no change from the value of 140 gauss. A JES-118 ESR spectrometer operating in the X-band at room temperature, manufactured by the Japan Electron Optics Company, was used for measurement, and DPPH was the external reference material.

Results and Discussion

It has been pointed out[1,2] that the electron exchange problem in magnetic resonance can be considered as a simple modulation of the electron Larmor frequency by the various nuclear spin states responsible for hyperfine interaction. In this sense, the analogy with the influence of chemical exchange on nuclear magnetic resonance in the interruption of scalar coupling to other nuclei is almost complete. The problem of the natural relaxation processes in electron spin resonance is a complicated one, but it is sufficient that it be considered as a separate relaxation rate process, which is additive to any electron site exchange. This latter effect can be attacked by the time tested methods of chemical kinetics. Precautions must be taken that other relaxation mechanisms do not change greatly over the range of concentrations investigated.

In the present case, the single broad ESR line observed in solution has been interpreted as originating from incomplete averaging of the hyperfine coupling to ^{63}Cu and ^{65}Cu nuclei by relaxation mechanisms which have been previously discussed.[4,10] The gyromagnetic ratios of the two copper isotopes are almost the same, and the spin quantum numbers are identical.

At constant $CuCl_2$ concentration in concentrated HCl, the ESR linewidth (maximum slope to maximum slope in gauss) was measured for a series of solutions of increasing CuCl concentrations. The results are plotted in Fig. 1 for a great excess of chloride ion (concentrated HCl).

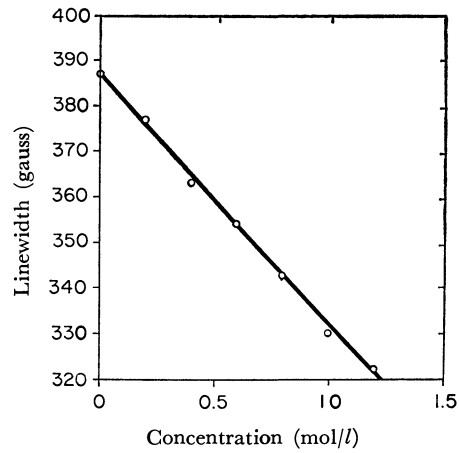

Fig. 1. Linewidth of 1 molar $CuCl_2$ in excess HCl as a function of added CuCl.

The concentration of cupric chloride was maintained at 1 molar. There was a sharp and linear decrease in linewidth of 55 gauss/mol/*l*, indicating that an exchange process, first order in Cu^+ ion is taking place, which results in exchange narrowing. An electron exchange rate can be obtained[1] by converting to appropriate frequency units. A value for the electron exchange rate constant $k = 1.53 \times 10^8$ *l*/mol/sec was obtained for the process

$$Cu^{2+} + Cu^+ \underset{k}{\longleftrightarrow} Cu^+ + Cu^{2+}. \qquad (1)$$

This ESR value is quite close to the value $k = 0.5 \times 10^8$ *l*/mol/sec obtained from ^{63}Cu NMR studies by McConnell and Weaver.[3] The linewidth of the cupric ion resonance is very sensitive to chloride ion concentration in excess of 5 molar, and independent of concentration below this. The results of this study are plotted graphically in Fig. 2 for 1 molar cupric ion (chloride ion added by way of HCl). The pH was found to have little effect on the width or *g* value of the resonance line. The large increase in linewidth in Fig. 2 of the cupric ion resonance is interpreted as being due to

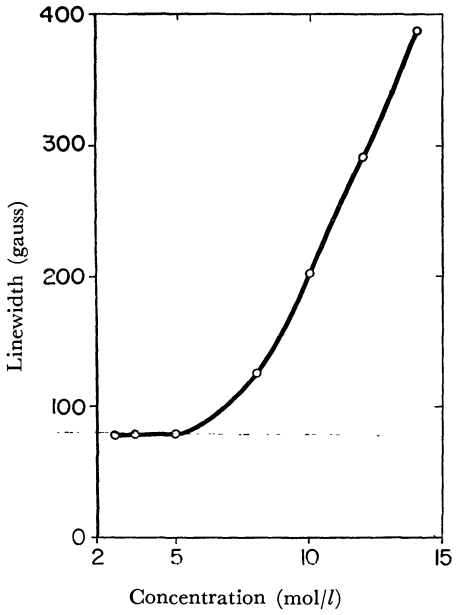

Fig. 2. Linewidth of 1 molar $CuCl_2$ *versus* Cl^- ion (HCl) concentration.

a change in the average species present in solution as Cl^- ion is added.[7] As copper ion becomes more highly complexed by Cl^- ion, the symmetry of the complexes present in solution changes, resulting in a change in the basic ESR relaxation mechanism for copper ion, that of spin-orbit coupling.

In excess HCl, the linewidth of the cupric ion resonance as a function of cupric ion concentration is plotted in Fig. 3, curve (a). The excess chloride was limited to approximately 10 molar by solubility considerations for cupric ion in more concentrated solutions. The linewidth passes through a minimum at approximately 0.55 molar cupric ion. These results are understandable in terms of the two electron exchange mechanism

$$Cu^{2+} + Cu^{2+} \longleftrightarrow Cu^{2+} + Cu^{2+} \qquad (2)$$

if the maximum concentration of bridge chloride ions occurs near that of the minimum linewidth. The rate of electron exchange represented by Eq. (2) is most rapid at this point. Simultaneous electron exchange occurs between two cupric ions, thereby affecting the linewidth of the electron resonance. The rate of this exchange is expected to be slower than that for the process represented by Eq. (1), where only one electron changes site. It is also interesting to note that in Fig. 3, curve (b), where 1 molar cuprous chloride is added to the solutions of curve (a), that the linewidths are always considerably reduced (by 15 to 25 gauss), and the minimum linewidth is displaced by 0.2 mol/*l* to higher cupric ion concentrations. This displacement is thought due to the effect of ionic strength. The ionic strength was kept constant

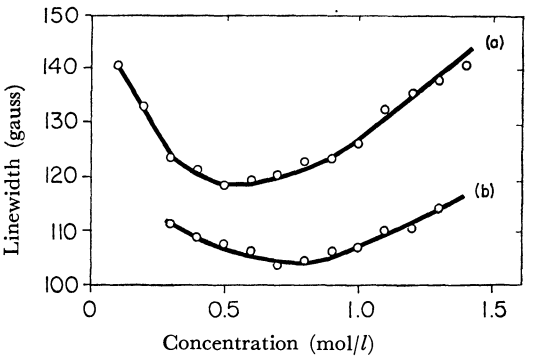

Fig. 3. Curve (a). Linewidth of Cu^{2+} ion resonance *versus* $CuCl_2$ concentration.
Curve (b). Curve (a) with 1 molar CuCl added.

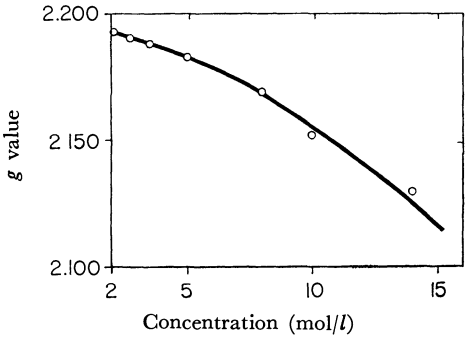

Fig. 4. *g* Value of Cu^{2+} ion resonance *versus* Cl^- ion (HCl) concentration.

in various copper solutions previously investigated[4] through the addition of zinc nitrate (chosen because of its similar ionic properties to copper). The linewidth was found to behave in a similar but more simple fashion with change in other linewidth-influencing factors (such as cupric and chloride ion concentrations) at constant ionic strength.

The *g* value measurements for the cupric ion as a function of concentration are also of some interest. These are plotted as a function of chloride ion (HCl) concentration for a 1 molar cupric ion concentration in Fig. 4. There is a large monotonic decrease in the *g* value of the unpaired electron as the chloride ion concentration increases. This is illustration of the increasing coordination of cupric ion by chloride ion, and the delocalization of electron spin density onto the ligand chloride ions. Stability constants of the various cupric and cuprous chloride complexes are very imperfectly known,[11] but the stable complex in very concentrated chloride solutions is known[5,6] to be $CuCl_4^{2-}$. The hydrated cupric ion has a much more localized unpaired electron spin and the *g* value is higher.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2835—2839 (1968)

ESR Studies of Copper(II) Complexes of Ethylenediamine and Its Analogues

Hiroshi YOKOI and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received March 6, 1968)

The ESR spectra of the copper(II) complexes of ethylenediamine, 1,2-diaminopropane, *meso*-2,3-diaminobutane, 1,3-diaminopropane, and ammonia were measured in methanolic and aqueous solutions at room temperature and in frozen solutions at the temperature of liquid nitrogen. The covalency of the bonding of the copper atom to the ligand atoms in these complexes was evaluated from the g values, the copper hyperfine constants, and the nitrogen super-hyperfine constants. Even in the case of amino groups which were coordinating groups, the π bonding seemed to be as important in determining the properties of the complexes as the σ bonding.

ESR has been proved effective for investigating the bonding in copper(II) complexes.[1-6] However, ESR studies of the copper(II) chelate complexes of ethylenediamine and its analogues have not been carried out in full detail. In these complexes the central copper atom is coordinated to the amino groups, one of best known kinds of coordinating groups; the investigation of the bonding character of copper-amino group bonds is very important in coordination chemistry. The purpose of this work is to obtain the magnetic parameters, neamely, the g values, the copper hyperfine constants, and the nitrogen super-hyperfine constants of the copper(II) complexes of ethylenediamine, 1,2-diaminopropane, *meso*-2,3-diaminobutane, 1,3-diaminopropane, and ammonia in solutions at room temperature and at the temperature of liquid nitrogen, and to discuss the covalency of the bonding of the copper atom to amino groups as evaluated from these magnetic parameters.

Experimental

The copper(II) complexes employed in this study were [I] $[Cu(en)_2](ClO_4)_2$, [II] $[Cu(pn)_2](ClO_4)_2$, [III] $[Cu(m\text{-}bn)_2](ClO_4)_2$, [IV] $[Cu(tn)_2](ClO_4)_2$, and [V] $[Cu(am)_4](ClO_4)_2$, where en, pn, m-bn, tn, and am are ethylenediamine, 1,2-diaminopropane, *meso*-2,3-diaminobutane, 1,3-diaminopropane, and ammonia respectively. All the amines were commercially

ESR spectrometer, model MES-4001, equipped with a 100 kc/s field modulation unit. Furthermore, the second derivative ESR spectra were obtained using 100 kc/s-40 c/s field modulations in order clearly to resolve the nitrogen super-hyperfine structure. The field was calibrated with an NMR probe and then with a benzene solution of vanadyl acetylacetonate or with Mn(II) ions in MgO powder. Some of the ESR spectra observed are shown in Figs. 1—4. The optical absorption spectra of the complexes in solutions were measured with a Cary model 14 spectrometer.

Results and Discussion

Magnetic Parameters. As may be seen in Fig. 1, the copper(II) complexes employed in this work show broad ESR absorption lines. This is due to the poor resolution of the nitrogen super-hyperfine strcture, which is, however, observed on $g_\perp$ components in the high-field part of the spectra of Fig. 1. Figure 4 exibits the second derivative of the super-hyperfine lines, from which the super-hyperfine constants can be obtained with considerable accuracy. The problem of determining the magnetic parameters from the ESR spectra of polycrystalline samples or rigid glass solutions has been studied extensively by several authors.[8]

[V]	Ammonia	M	2.242	2.056	2.055	199	17	2.118	77	12.7

a) M: methanol, MH: 50% water-50% methanol (volume %).
b) $g_\perp$ was calculated using the following equation, $g_0=1/3\ (g_{//}+2g_\perp)$. $A_\perp$ was also calculated in the same way.
c) $g'_\perp$ was directly obtained from the ESR spectrum measured at K-band.
d) Measured at room temperature.

However, it is difficult to analyze completely such ESR spectra as are shown in Fig. 1. The ESR measurements of the copper(II) complexes of ethylenediamine and ammonia in single crystals have revealed that the complexes have axial symmetry (two distinct g values).[9,10] It is now desirable to ascertain whether or not the complexes under discussion have axial symmetry in solutions. Since ESR measurements at both the K-band and X-band are often used to distinguish between two lines of different g values, the ESR spectra were measured at the K-band in this study; some of the ESR spectra are shown in Fig. 3. This figure indicates that, in solutions, axial symmetry is approximately maintained; approximate $g_\perp$ values can be obtained directly from the ESR spectra shown in this figure.

The spin Hamiltonian is expressed as follows:

$$\begin{aligned} H = {} & \beta_0[g_{//}H_zS_z + g_\perp(H_xS_x + H_yS_y)] \\ & + A_{//}S_zI_z + A_\perp(S_xI_x + S_yI_y) \\ & + A_N^{//}S_zI_z^N + A_N^\perp(S_xI_x^N + S_yI_y^N) \end{aligned} \quad (1)$$

The experimental data are listed in Table 1. It is interesting to see in this table that $g_\perp \doteqdot g'_\perp$; therefore, $A_\perp$ was also calculated using the values of $A_{//}$ and A_0 in the same way as in calculating $g_\perp$.

Chemical Bonding. The experimentally determined quantities, $g_{//}$, $g_\perp$, $A_{//}$, $A_\perp$, and $A_N^\perp$ can be used to estimate the character of the chemical bonding of the copper atom to ligand nitrogen atoms by means of the molecular orbital theory. In the complexes of amines, the σ orbitals of ligand nitrogen atoms are the lone-pair electron orbitals formed by sp^3 hydridization. Therefore, these nitrogen atoms do not have pure π orbitals such as the oxygen atoms of acetylacetonate anion have. However, in this study the complexes of amines have been treated on the assumption that amino groups have a kind of π orbital; we used the same procedure as did Maki and McGarvey,[2] and Kivelson and Neiman[3] in treating Cu(II) bisacetylacetonate. The notation of Maki and McGarvey for a square planar complex will be used here. The following antibonding molecular orbitals, in the order of increasing energy, can be formed for the "hole" configuration:

$$\left.\begin{aligned} \Psi_{b_{1g}} &= \alpha d_{x^2-y^2} - \alpha'(-\sigma_x^{(1)} \\ &\quad + \sigma_y^{(2)} + \sigma_x^{(3)} - \sigma_y^{(4)})/2 \\ \Psi_{b_{2g}} &= \beta_1 d_{xy} - \beta_1'\phi_L(xy) \\ \Psi_{a_{1g}} &= \alpha_1 d_{z^2} - \alpha_1'(\sigma_x^{(1)} \\ &\quad + \sigma_y^{(2)} - \sigma_x^{(3)} - \sigma_y^{(4)})/2 \\ \Psi_{e_g} &= \begin{cases} \beta d_{xz} - \beta'\phi_L(xz) \\ \beta d_{yz} - \beta'\phi_L(yz) \end{cases} \end{aligned}\right\} \quad (2)$$

where $\sigma^{(i)}=np^{(i)}\mp(1-n^2)^{1/2}s^{(i)}$, in which $0\leq n\leq 1$, and where $\varphi_L(xy)$, $\varphi_L(xz)$, and $\phi_L(yz)$ are pseudo-π orbitals of amino groups which have been assumed to interact with the d_{xy}, d_{xz} and d_{yz} of copper orbitals respectively. $\Psi_{b_{2g}}$ and Ψ_{e_g} represent the in-plane π bonding and the out-of-plane π bonding respectively. The normalization of the $\Psi_{b_{1g}}$ orbital yields:

$$\alpha^2 + \alpha'^2 - 2\alpha\alpha' S = 1 \quad (3)$$

where S is the overlap integral between the $d_{x^2-y^2}$ of the copper atom and the σ orbitals of ligand nitrogen atoms.

The second-order perturbation calculation results in the following approximate expressions for the spin Hamiltonian parameters in Eq. (1):

9) H. Abe and K. Ono *J. Phys. Soc. Japan*, **11**, 947 (1956).
10) E. H. Carlson and R. D. Spence, *J. Chem. Phys.*, **24**, 471 (1956).

$$\left.\begin{aligned} g_{//} &= 2.002 - \frac{8\lambda}{\Delta E_{xy}}\alpha^2\beta_1^2(1-f_1) \\ g_{\perp} &= 2.002 - \frac{2\lambda}{\Delta E_{xz}}\alpha^2\beta^2(1-f_2) \\ A_{//} &= P\left[-\alpha^2\left(\frac{4}{7}+\kappa_0\right)+(g_{//}-2)+\frac{3}{7}(g_{\perp}-2)+f_3\right] \\ A_{\perp} &= P\left[\alpha^2\left(\frac{2}{7}-\kappa_0\right)+\frac{11}{14}(g_{\perp}-2)+f_4\right] \end{aligned}\right\} \quad (4)$$

Furthermore, $A_N^{\perp}$ is expressible in the form:[2,6]

$$A_N^{\perp} = \left(\frac{\alpha'}{2}\right)^2(2\beta_0\beta_N\gamma_N)\left[\frac{8\pi}{3}(1-n^2)\rho_{2s}(0)+\frac{2}{5}n^2\langle r^{-3}\rangle_{2p}\right] \quad (5)$$

where $P=2\gamma\beta_0\beta_N\langle d_{x^2-y^2}|r^{-3}|d_{x^2-y^2}\rangle$, where κ_0 is the Fermi contact term, where $\Delta E_{xy}=E_{xy}-E_{x^2-y^2}$ and $\Delta E_{xz}=E_{xz}-E_{x^2-y^2}$, where $\rho_{2s}(0)$ is the value of the ligand 2*s* function at the nitrogen nucleus, where r is the radius of the 2*p* ligand orbital, and where f_1, f_2, f_3 and f_4 are small and almost constant values for a variety of copper(II) complexes (f_1, $f_2 \leqq 0.04$, $f_3 \leqq 0.33$, and $f_4 \leqq 0.005$).

Next, the values of ΔE_{xy} and ΔE_{xz} must be determined in order to calculate β_1 and β. The visible absorption spectrum of a square planar copper(II) complex generally consists of three component absorption bands, corresponding to ΔE_{xy}, ΔE_{xz} and ΔE_{z^2}, where $\Delta E_{z^2}=E_{z^2}-E_{x^2-y^2}$. However, the visible absorption spectra of the copper(II) complexes employed in this study show in solutions only a single broad band, the position of the peak of which is tabulated in Table 2, so that it is not easy to determine accurately the values of ΔE_{xy} and ΔE_{xz} for the complexes. The absorption spectral data of the single crystal of bis(ethylenediamine)copper(II) complex are not sufficient to determine the energy values.[11]

The circular dichroism measurements of various metal complexes have been used to estimate the structure of their electronic absorption spectra.[12] 1,2-Diaminopropane contains an optically-active asymmetric carbon. Recently Gillard observed the circular dichroism of $[Cu(-pn)_2]^{2+}$ in an aqueous solution, and showed two bands corresponding to 657 mμ and 510 mμ.[13] The two bands are thought to be due to components of $^2T_2 \leftarrow {}^2E$ from the symmetry arguments of the magnetic dipole transition. Therefore, it may reasonably be considered that the ΔE_{xy} and ΔE_{xz} of $[Cu(pn)_2](ClO_4)_2$ in an aqueous solution correspond approximately to 657 mμ and 510 mμ respectively. The energy values of the ΔE_{xy} and ΔE_{xz} of the other copper(II) complexes under discussion could be estimated roughly on the assumption that there is the same relationship in energy values among ΔE_{xy}, ΔE_{xz} and the maximum absorption peak for these complexes as with the copper(II) complexes of 1,2-diaminopropane. The estimate ligand field energy values of ΔE_{xy} and ΔE_{xz} are listed in Table 2.

Table 2. Ligand field energies

Copper(II) complex	λ_{max}* (mμ)	log ε	Estimated ligand field energies (cm^{-1})	
			ΔE_{xy}	ΔE_{xz}
[I]	547	1.80	15200	19600
[II]	547	1.84	15200	19600
[III]	546	1.85	15200	19600
[IV]	568	2.02	14600	18900
[V]	598	1.70	13900	17900

* Solvents were MH for [I]—[IV] and M for [V]. The description of MH and M is in the footnote of Table 1.

The values of the bonding parameters, namely, α, β_1, β, and κ_0 were calculated using Eq. (4), where $P=0.036\ cm^{-1}$; they are listed in Table 3. Furthermore, the values of α were also calculated from the nitrogen super-hyperfine constants using Eq. (5), where $n=\sqrt{3}/2$ for sp^3 hybrid ligand orbitals, $\rho_{2s}(0)=33.4\times10^{24}\ cm^{-3}$, $\langle r^{-3}\rangle_{2p}=21.1\times10^{24}\ cm^{-3}$, and $S=0.08$.

There are several points of interest in the results shown in Table 3. Values of β_1^2 and β^2 which are indicated to be considerably smaller than unity, namely, $\beta_1^2=0.6$ and $\beta_2=0.7$, are found for all the copper(II) complexes in this work. This implies that remarkably covalent π bonding is

Table 3. Bonding parameters[a]

Copper(II) complex	From Eq. (4)				From Eq. (5)[b]	
	α^2	β_1^2	β^2	κ_0	α'^2	α^2

found in the copper-amino group bonds of the complexes. This finding, to which little attention has yet been paid, is considered to be reliable from the point of ESR. Rajan also suggested the existence of π bonding in $[Cu(en)_2](NO_3)_2$, on reasoning a simple basis.[14] It has generally been believed that the metal-ligand bonding in the metal complexes of amines is almost equivalent to σ bonding, where the ligand orbitals concerned with the bonding are the lone-pair electron orbitals of amines formed by sp^3 hybridization. The values of α^2 in Table 3 indicate that the σ bonding in the copper(II) complexes of amines is also covalent, but the degree of the covalency of the bonding is not very different from that reported for many common copper(II) complexes.[2-6] Accordingly, it is characteristic of the copper(II) complexes of amines that such covalent π bonding as that indicated in Table 3 is present. Now, a very important but difficult problem is that of considering what orbitals of amino groups are used as π orbitals, which are expressed, for convenience, in Eq. (2) as $\varphi_L(xy)$,φ_L (xz), and $\varphi_L(yz)$. One of most probable answers to the problem is that amino groups fulfil such a function of hyperconjugation as does the methyl group of toluene molecule. The fact that the convalent π bonding is present in the metal complexes of amines has much meaning for coordination chemistry and biochemistry, because it suggests that charge transfer, which is thought to be initial step of reactions, may occur easily between the metal atom and ligand molecules through amino groups.

The values of κ_0 in Table 3 are about 0.42 for [I]—[IV], but 0.39 for [V]. The former value is equal to the one reported for some copper(II) complexes,[2,3] and the value of κ_0 has been assumed to be essentially constant for all copper(II) complexes.[15] However, we must bear our mind in cases which the κ_0 value in some copper(II) complexes like [V] in Table 3 deviates from 0.42.[16]

Another point of interest is the values of α^2 calculated from the nitrogen super-hyperfine constants using Eqs. (5) and (3). The super-hyperfine constants listed in Table 1 are almost equal in magnitude to those reported for many nitrogen-bonded copper(II) complexes whose nitrogen valence orbitals are clearly known to be sp^2 hybridized orbitals;[2,3,5,6] therefore, the nitrogen super-hyperfine constants listed in Table 1 seem to be rather too large considering that the nitrogen valence orbitals of amines are nearly sp^3 hybridized orbitals. In Table 3 the values of α^2 calculated from Eq. (5) are compared with those calculated from Eq. (4). The agreement for [I]—[III] in Table 3 is comparatively good considering the various assumptions involved in Eqs. (4) and (5). However, the former is much smaller than the latter for [IV] and [V] in Table 3. This implies that there are slight differences in the characters of copper-amino group bonds between the first three complexes and the last two complexes in Table 3. [IV] in the table is more similar to [V] in chemical and physical properties, for instance, in stability constants,[17] optical absorption spectra and magnetic parameters, than to the first three complexes. This seems to be because the amino groups of 1,3-diaminopropane can be bonded to the copper atom with the same bonding nature as ammonia because of the structural flexibility of the trimethylene group in 1,3-diaminopropane. Since the values of α^2 calculated from Eq. (5) are alway smaller than those calculated from Eq. (4), it seems that the nitrogen orbitals of the copper(II) complexes of amines are not pure sp^3 hybridized orbitals, but, rather, orbitals with a greater degree of s-character. However, further studies of these problems are desirable in order to make the nature of chemical bonding in the complexes clearer.

Spectroscopic Studies of Catalysis by Vanadium Pentoxide

Kimio TARAMA, Satohiro YOSHIDA, Shingo ISHIDA and Hideo KAKIOKA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 18, 1968)

The role of the V=O bond in V_2O_5 in the adsorption of several gases was studied by measuring the electron spin resonance (ESR) and the infrared (IR) spectra. The ESR spectra of V_2O_5 supported on γ-Al_2O_3 were similar to those of $VOSO_4$ on γ-Al_2O_3. When such electron-donating gases as CO, SO_2 and C_2H_4 were adsorbed on this V_2O_5 - γ-Al_2O_3, the signal intensity of ESR increased and the splitting of the h.f.s. became clear. Upon treatment with an electron-accepting gas such as O_2, a reverse change was observed. In the case of V_2O_5 supported on SiO_2, similar ESR spectra were observed by the adsorption of CO after a mild reduction. The IR spectra of V_2O_5 have a sharp absorption peak at 1023 cm^{-1} due to the stretching vibration of the $(V=O)^{3+}$ bond; this peak became broader by adsorption of such gases as CO and SO_2. Simultaneously, the center of the peak shifted to the red region and a weak hump appeared at 980—990 cm^{-1}, probably due to $(V=O)^{2+}$. These results of the ESR and IR measurements reveal that these electron-donating gases are adsorbed on the $(V=O)^{3+}$ bonds on the surface of V_2O_5, and that the increase in electron densities in the adsorption sites results from adsorption of these gases. Furthermore, the role of this $(V=O)^{3+}$ bond in oxidation reaction was also discussed.

Vanadium pentoxide is a well-known oxidation catalyst. There are fairly many works attempting to elucidate the catalytic action of this catalyst by kinetical studies or by studies of its physico-chemical properties.

The present authors[1] themselves previously reported a study of some physico-chemical properties of V_2O_5 and emphasized the importance of the role of the V=O bond, at the 3rd International Congress on Catalysis.

In the present work, the role of this V=O bond in the adsorption of several gases was studied by measuring the electron spin resonance (ESR) and the infrared (IR) spectra.

Recently, van Reijen and Cossee[2] studied the state of V^{4+} ions in V_2O_5 supported on SiO_2 and Al_2O_3 by the ESR method and reported the existence of $(VO_4)^{4-}$ or $(VO)^{2+}$. Ioffe *et al.*[3] studied the change in the IR spectra of V_2O_5 by doping of MoO_3, CoO_2 or P_2O_5 and by treatment with a mixture of benzene and O_2. But these papers were not very helpful for our purpose of elucidating the role of the V=O bond in the gas adsorption.

The present authors' results reveal that the $(V=O)^{3+}$ bond on the surface of V_2O_5 plays an important role as the adsorption site for the electron-donating gas and also as a reaction site for the oxidation reaction.

Experimental

Apparatus and Procedures. The ESR absorption measurements were made on a JES-3BSX-type, X-band spectrometer manufactured by the Japan Electron Optics Co. The cavity input power was 10 mW, and the modulation width was 10 gauss. DPPH was used as the standard for the measurement of the intensity of the ESR signal.

The samples for ESR measurement were evacuated for 3 hr at 350°C and 10^{-6} Torr in a glass reactor which had a quartz tube for ESR measurement as a side arm and which was joined to a vacuum line. After various treatments, the samples were moved to the side tube and the ESR absorptions were measured at room temperature.

The infrared absorption measurements were carried out with an IR-S-type spectrometer manufactured by the Japan Spectroscopic Co. The samples dispersed on a NaCl disk were placed in the center of a specially devised *in situ* cell and the IR absorptions were measured under various atmospheres and temperatures.

The adsorbed amounts of gases were measured by the usual volumetric method.

The catalytic activities for CO oxidation with air were determined by a flow method described previously[1] at 350°C. The gas flow rate was 7.5 cc (NTP)/min for 500 mg of the catalyst, and the ratio of CO to air was kept at 1 : 4.

Materials. Several kinds of V_2O_5 catalysts were used. The unsupported V_2O_5-powders used mainly for the IR measurements were prepared from commercial extra-pure-grade V_2O_5 by grinding it to powder. This sample contained about 0.7 atom% of V^{4+}.

The V_2O_5-samples supported on γ-Al_2O_3 and SiO_2 were prepared by impregnation with an aqueous solution of extra-pure NH_4VO_3, followed by drying at 100°C and calcination at 450°C for 6 hr in a dry-air stream.

The γ-Al_2O_3 was a commercial product of the highest purity from the Sumitomo Chemical Ind. Co. The SiO_2 was prepared from ethyl silicate which had been carefully purified by distillation.

The surface areas of these samples are given in Table 1.

Table 1. The B.E.T. surface areas of the supported catalysts

V_2O_5 Content (wt%)	Surface area (m^2/g)
1 (on γ-Al_2O_3)	170
3 (on γ-Al_2O_3)	180
5 (on γ-Al_2O_3)	180
20 (on γ-Al_2O_3)	170
5 (on SiO_2)	280

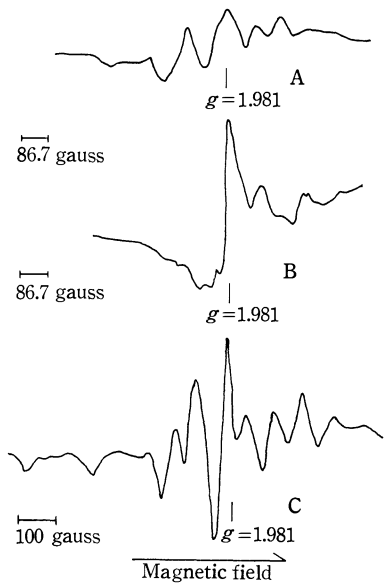

Fig. 1. ESR spectra of V_2O_5 - γ-Al_2O_3 after evacuation for 3 hr at 350°C.
A: V_2O_5(5%) - γ-Al_2O_3
B: V_2O_5(50%) - γ-Al_2O_3
C: $VOSO_4$(0.6%) - γ-Al_2O_3

Results

ESR Spectra of V_2O_5 Dispersed on γ-Al_2O_3. Figures 1-A and B show the ESR absorption spectra of the samples of 5 wt% and 50 wt% V_2O_5 respectively supported on γ-Al_2O_3. These spectra, with the h.f.s., were similar to that of $VOSO_4$ (0.6 wt%) on γ-Al_2O_3 (Fig. 1-C). The average h.f.s. coupling constants are 100 and 85 gauss for 5% V_2O_5-γ-Al_2O_3 and $VOSO_4$-γ-Al_2O_3 respectively. These spectra with h.f.s. were identified as those of $(V{=}O)^{2+}$.

When CO, SO_2 or C_2H_4 was adsorbed on this 5% V_2O_5 - γ-Al_2O_3 at room temperature and at 150°C, the signal intensities of the ESR spectra increased, as is shown in Table 2; the splitting of the h.f.s. also became clear, as Figs. 2-A, B and C show. The adsorbed amounts of CO, SO_2, and C_2H_4 (at room temperature, 200 Torr) were 0.5, 18 and 6 cc/g-cat respectively. The evacuation of gas at room temperature caused a decrease in the signal intensity, but this change was partially irreversible.

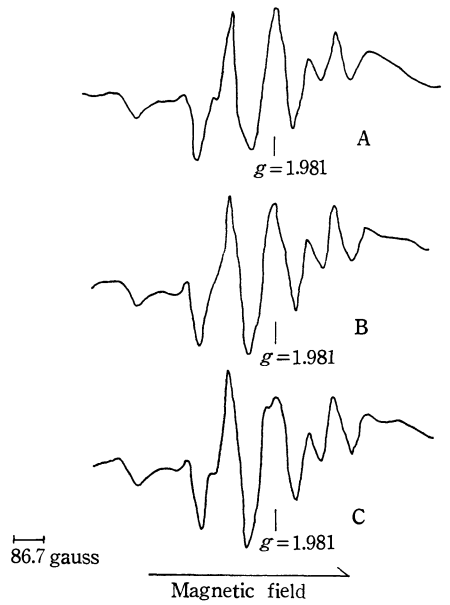

Fig. 2. ESR spectra of V_2O_5(5%) - γ-Al_2O_3.
A: SO_2 was adsorbed for 40 hr at 160 Torr and room temp.
B: C_2H_4 was adsorbed for 150 hr at 260 Torr and room temp.
C: CO was adsorbed for 150 hr at 226 Torr and room temp.

In the case of O_2 adsorption (200 Torr, 150°C, 1 hr), the relative signal intensity decreased to half of that of the starting sample. (The amount of O_2 adsorbed was 0.03 cc/g-cat.)

When O_2 (150 Torr) was introduced at room temperature after the adsorption of CO at 150°C, the relative signal intensity changed from 1.4 to 0.9, as is shown in Table 2 (VC-5, 6).

ESR Spectra of V_2O_5 Supported on SiO_2. In the case of V_2O_5 (5 wt%) supported on SiO_2, no signal of ESR absorption could be observed even after evacuation at 350°C. However, the ESR signal appeared after further reduction with CO at 350°C, as is shown in Fig. 3-A; furthermore, the h.f.s. with a characteristic feature of $(VO)^{2+}$ was observed in the ESR spectrum (Fig. 3-B) of this V_2O_5-SiO_2, which adsorbed CO at room temperature. van Reijen and Cossee[2] have reported

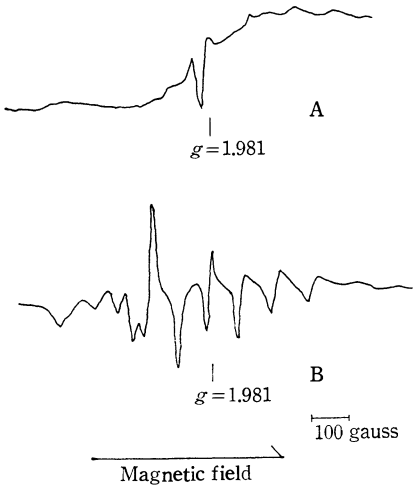

Fig. 3. ESR spectra of V_2O_5(5%)-SiO_2.
A: The sample reduced by CO at 350°C.
B: CO was adsorbed at room temp. on the reduced sample.

a similar ESR spectrum of V_2O_5-SiO_2, one which was evacuated at 500°C and which was subsequently treated with H_2O at 20°C.

When C_2H_4 was adsorbed at room temperature and 150 Torr, a weak signal similar to that in Fig. 1-A appeared.

Infrared Absorption of V_2O_5 Adsorbing Some Gases. V_2O_5 gives infrared spectra composed of a sharp absorption at 1023 cm^{-1} and a broad one at 830 cm^{-1}. This sharp absorption band at 1023 cm^{-1} is assignable to the stretching vibration mode of the $(V=O)^{3+}$ bond by comparison with that of $VOCl_3$.[4,5] It has been reported that this sharp absorption shifts to a longer-wavelength region upon treatment with cyclohexane[4] or after the catalyst has been used for benzene oxidation.[3]

The changes in the absorption spectra by the adsorption of several gases were studied under mild conditions. Figures 4 and 5 show the changes in the spectra by the adsorption of SO_2 and CO respectively.

By the adsorption of SO_2, the absorption band due to the $(V=O)^{3+}$ bond became broader and the center of the absorption peak shifted from 1023 cm^{-1} to 1005 cm,$^{-1}$ and, furthermore, a weak shoulder appeared at 980—990 cm^{-1} as is shown in curves A, B and C of Fig. 4. Almost all these changes in the IR spectra remained even after evacuation for 2 hr at 110°C, but when O_2 was introduced into the cell at 75°C, the center of the absorption band returned from 1005 cm^{-1} to 1013 cm^{-1}, as is shown in curve D of Fig. 4. On the other hand, the broad absorption band at

TABLE 2. THE CHANGES OF ESR SIGNAL INTENSITIES BY TREATMENT WITH SOME GASES

Sample	Condition of treatment with gases				Relative intensity
	Gas	Pressure	Temperature	Duration	
V-O	evacuation for 3 hr at 350°C*				1.0
VC-1	CO	3.9 Torr	room temp.	84 hr	1.3
VC-2	CO	98 Torr	room temp.	55 hr	1.5
VC-3	CO	226 Torr	room temp.	84 hr	2.0
VC-4	VC-3 evacuated for 8 hr at room temp.				1.8
VC-5	CO	17 Torr	150°C	17 hr	1.4
VC-6	VC-5 treated with O_2 (150 Torr) at room temp.				0.9
VC-7	VC-6 kept for 3 hr at 150°C				0.8
VC-8	CO	110 Torr	150°C	17 hr	1.9
VC-9	VC-8 evacuated for 3 hr at room temp.				1.6
VS-1	SO_2	15.2 Torr	room temp.	7 hr	1.2
VS-2	SO_2	163 Torr	room temp.	7 hr	1.6
VS-3	SO_2	300 Torr	room temp.	14 hr	1.4
VS-4	VS-3 evacuated for 8 hr at room temp.				1.2
VE-1	C_2H_4	28.2 Torr	room temp.	192 hr	1.8
VE-2	VE-1 evacuated for 15 hr at room temp.				1.6
VE-3	C_2H_4	260 Torr	room temp.	168 hr	2.1
VE-4	VE-3 evacuated for 15 hr at room temp.				1.6

* The starting samples are V_2O_5(5 wt%) - γ-Alumina evacuated for 3 hr at 350°C in all cases and signal intensity of this sample is adopted as standard.

treated by O_2 at 100°C, no change in the spectra could be observed.

The change induced by the adsorption of CO was the same as that in the case of SO_2, but effect was smaller and a new peak, at 910 cm^{-1}, appeared at 140°C, as is shown in Fig. 5. This peak probably belongs to the absorption band of V_2O_4.[5] Therefore, the appearance of this peak suggests that V_2O_5 was partially reduced to V_2O_4 by CO-treatment at 140°C. In the case of C_2H_4, no change in the IR spectra could be observed upon the treatment at 25°C, but a partial reduction of V_2O_5 to V_2O_4 was observed at 80°C, as in the case of CO.

These results indicate that the reducing power of these gases increases in the order of SO_2, CO and C_2H_4 under these experimental conditions.

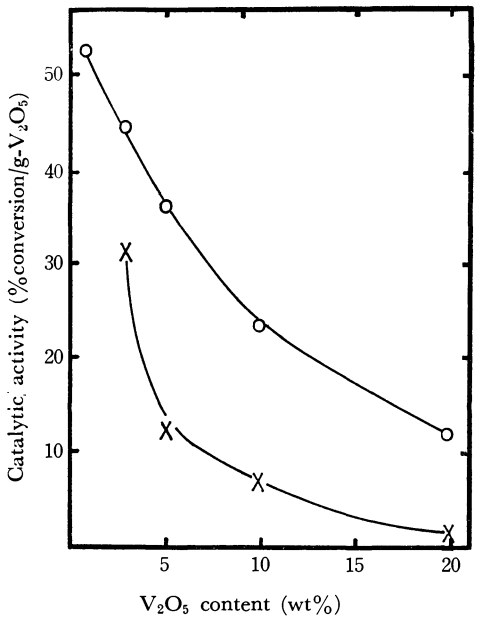

Fig. 6. Catalytic activity for CO-oxidation of supported V_2O_5.
○ and × marks stand for the catalysts supported on γ-Al_2O_3 and SiO_2 respectively.

Oxidation of CO with Air. Because a linear relation between the conversion (α, %) of CO to CO_2 and the contact time was observed up to 30% conversion, the values of α at the same contact time were adopted as the measure of the activity.

The activities of V_2O_5 on γ-Al_2O_3 of various concentrations and V_2O_5 on SiO_2 are shown in Fig. 6. The relative activities per gram of V_2O_5 in the catalysts decreased with the increase in the concentration of V_2O_5. This indicates that the number of effective sites of V_2O_5 is increased by dispersion on carriers.

TABLE 3. REDUCTION OF CATALYST BY CO AT 350°C FOR 1 HR (P_{CO}: 150 Torr)

Catalyst	Produced CO_2 cc(NTP)/g-cat.	Reduction % (V^{4+}/V^{5+} initial)
V_2O_5(5%) on γ-Al_2O_3	4.1	65
V_2O_5(5%) on SiO_2	0.55	9

TABLE 4. THE ADSORPTION SITE ON THE METAL OXIDE OR SULFIDE OF SEMICONDUCTOR

Adsorbent (catalyst)	Adsorbate (gas)	Adsorption site in surface (example)
n-Type semiconductor (example, V_2O_5)	Electron donor	Metal ion at normal lattice point (V^{5+})
	Electron acceptor	Metal ion adjacent to defect of anion (V^{4+})
p-Type semiconductor (example, NiO)	Electron donor	Metal ion adjacent to excess anion (Ni^{3+})
	Electron acceptor	Metal ion at normal lattice point (Ni^{2+})

V_2O_5 - γ-Al_2O_3 catalysts are more active than the V_2O_5-SiO_2 catalyst. These activities are closely correlated with the reducibilities of these catalysts by CO at 350°C, as is shown in Table 3.

Discussion

The State of Vanadium Ions in V_2O_5 Dispersed on Carriers. The unsupported V_2O_5 powder gave a broad single ESR signal, and the line width (ΔH_{msl}) of this absorption signal became larger at a low temperature (ΔH_{msl}; 90 gauss at room temperature and 180 gauss at the temperature of liquid nitrogen), as has previously been reported.[1,6] In the case of V_2O_5 dispersed on γ-Al_2O_3, however, the h.f.s. of the ESR spectrum due to $(V{=}O)^{2+}$ was observed. The appearance of this h.f.s. by the dispersion of V_2O_5 on a carrier seems to result from the decrease in the delocalizability of the electron associated to $(V{=}O)^{2+}$. Therefore, it is clear that V(IV) ions in V_2O_5 on γ-Al_2O_3 are stabilized in the form of $(V{=}O)^{2+}$. However, $(V{=}O)^{2+}$ seems not to be in the isolated state, but to be stabilized as $(V{=}O)^{2+}$ in the thin layer of the micro crystal of V_2O_5 on γ-Al_2O_3 for the following reasons: a) Even the sample of V_2O_5 (50 wt%) on γ-Al_2O_3 gave ESR spectra with fairly well resolved h.f.s. (Fig. 1-B). In this sample, it is quite difficult to believe that $(V{=}O)^{2+}$ ions are isolated on the surfaces of carriers. b) The observed ESR signal for V_2O_5 (5 wt%) on γ-Al_2O_3 is similar to that of $VOSO_4$ in γ-Al_2O_3, but there is some difference in resolutions and in coupling constants between the h.f.s.'s of the two samples. Of course, the resolution of the spectrum depends on the concentration of the paramagentic species. Though the concentration of V(IV) ions is about 1% of the total vanadium in V_2O_5 (5%) on γ-Al_2O_3, and is thus so small that the interaction between paramagnetic species is negligible, the resolution of h.f.s. is not clear.

In the case of V_2O_5 on SiO_2, the state of V(IV) is not clear, either, no signal could be observed as has been reported above; the amount of V(IV) ions in this sample may be too small to be detected by the ESR method.

On the other hand, V(V) ions (the diamagnetic species) can not be detected by ESR measurement, and so their state in V_2O_5 is presumed indirectly from the change in the ESR signal and in the IR specta with gas adsorption or reduction.

The Adsorption Sites on V_2O_5. When electron-donating gases, such as CO, SO_2 and C_2H_4, were adsorbed on V_2O_5 supported on γ-Al_2O_3, the signal intensity of the ESR spectra increased and the splitting of the h.f.s. became clear. Even in the case of the sample supported on SiO_2, which gave no ESR signal after evacuation at 350°C, a weak signal with a h.f.s. identified as $(V{=}O)^{2+}$ appeared by the adsorption of these gases.

The growth of this signal intensity indicates an increase in $(V{=}O)^{2+}$. Therefore, it seems sure that these electron-donating gases are adsorbed on $(V{=}O)^{3+}$ bonds on the surface of a V_2O_5 crystal, and that an electron is transferred from adsorbed gas to an adsorption site, thus leading to the formation of $(V{=}O)^{2+}$.

On the other hand, the signal intensity became weak by O_2 adsorption. As O_2 is an electron-accepting gas, this shows that oxygen is adsorbed on $(V{=}O)^{2+}$ and that this adsorption site is converted to $(V{=}O)^{3+}$ by electron transfer.

The above model for gas adsorption is supported by the IR measurements, too. By the adsorption of CO or SO_2, the IR absorption band due to $(V{=}O)^{3+}$ bond broadened, the center of the peak shifted to the red region, and a weak hump, probably due to the $(V{=}O)^{2+}$ bond,[5] appeared at 980—990 cm^{-1}.

These changes in the IR spectra reflect the increase in the electron density in the V-ion of the $(V{=}O)^{3+}$ bond. The effect of the treatment with O_2 on the IR spectrum was the reverse of that with CO or SO_2.

From the results of these ESR and IR measuremenets, it can be concluded that the adsorption sites on V_2O_5 are $(V{=}O)^{3+}$ for such electron-donating gases as CO, SO_2 and C_2H_4 and $(V{=}O)^{2+}$ for such electron-accepting gases as O_2.

This conclusion is very probable in the light of the general rule previously proposed by one of authors[7] for the adsorption site on the metal oxide or sulfide of a semiconductor, as is shown in Table 4.

The Role of the V=O Bond in Oxidation Reaction. It is generally accepted that the catalysis by V_2O_5 for oxidation reaction is effected by the oxidation-reduction mechanism in which the lattice oxygen of the catalyst is taken away by gas and the catalyst is reoxidized by O_2.

This mechanism seems also to be supported by the finding that the activity of the catalyst in CO-oxidation is closely correlated with its reducibility by CO.

The present authors have presented a hypothesis that the strength of a V=O bond is a controlling factor in the activity of the catalytic oxidation.[1] Recently, Hirota and his collaborators[8] studied the exchange of isotopic oxygen between CO_2 containing ^{18}O and V_2O_5, and showed that this oxygen exchange proceeded through a surface V=O bond of V_2O_5. This finding supports the preceding hypothesis.

Therefore, it can be concluded that the V=O bond on the surface of V_2O_5 performs an important role as the adsorption site and also as the reaction site for the oxidation reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2845—2848 (1968)

Gel Filtration of Mixtures of Surfactants on Sephadex

Fumikatsu TOKIWA, Kenji OHKI and Isao KOKUBO

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama

(Received April 2, 1968)

The gel filtrations of mixtures of sodium dodecyl sulfate (SDS) and sodium tetradecyl sulfate (STS) have been studied for different mole ratios of STS/SDS with varying total concentrations. Above the critical micelle concentration (CMC) of the mixture, two retention volumes V^1_{obs} and V^2_{obs} were obtained from the elution curve, and the difference between V^1_{obs} and V^2_{obs} depends on the total concentrations of the mixture. The initial part of the effluent contains only STS, which means that the separation of STS from the mixture occurs after passing through the column. These results have been discussed by taking into consideration the equilibrium between monomers and micelles for the mixtures of the two surfactants. It is shown that the separation factor is determined by the CMC values of the two surfactants—the greater the ratio CMC_A/CMC_B ($CMC_A > CMC_B$), the greater the degree of separation.

In a previous work[1] an attempt was made to apply gel filtration on Sephadex to micellar solutions of single surfactants. The results have been successfully interpreted by taking into account the existence of both micellized and unmicellized species in solution.

In the present work, the gel filtration study has been extended to the micellar solutions of mixed surfactants. The surfactants studied were sodium dodecyl sulfate (SDS) and sodium tetradecyl sulfate (STS), which were mixed in different ratios. The data obtained were analyzed through equilibrium equations for a two component system containing both monomer and micelle phases.

Experimental

Materials. Sephadex G-50, a cross-linked dextran gel with a particle size of 20—80 microns, and Blue Dextran 2000 with a molecular weight of 2×10^6 were obtained from Pharmacia, Sweden. Sodium dodecyl sulfate (SDS) and sodium tetradecyl sulfate (STS) were the same samples as used in the previous work.[1]

Gel Filtration. Sephadex G-50 was allowed to swell in distilled water for at least 24 hr and then poured into a jacketed column, 1.3 cm in diameter $\times$35.5 cm in height, with a sintered glass plate at the bottom. The column was prepared in the same way as that previously described.[1] The void volume of the column was checked on alternated runs using Blue Dextran 2000. The gel filtrations were carried out at 32$\pm$0.1°C. Fifty milliliters sample solution (SDS-STS mixture) was applied continuously to the top of the column through a siphon connected to the sample reservoir. An automatic fraction-collector was used and fractions of approximately 1 m*l* were collected. The electrical conductivity of each fraction was measured to obtain the elution curve.

Determination of CMC. The critical micelle concentrations (CMC) of the mixtures of SDS and STS for different mixing ratios were determined at 32°C by an electrical conductivity method[2] using a Toa Dempa Model CM-IDB conductance bridge.

2) F. Tokiwa, ibid., **36**, 281 (1963).

Gas Chromatography. The SDS and STS present in the fractions of the effluents were hydrolyzed with hydrochloric acid to obtain dodecyl- and tetradecyl-alcohols, which were extracted with *n*-hexane. The mole fractions of dodecyl- and tetradecyl-alcohols were determined by gas chromatography with a Shimadzu Model 4APT apparatus using a Carbowax 20M column at 230°C.

Results and Discussion

Figure 1 shows typical elution curves for mixed solutions of SDS and STS, whose mixing ratio is 1 to 1 in moles, at various total concentrations, C^t. Below the CMC of the mixture, the elution curve is sigmoidal and the retention volume obtained from the curve is independent of C^t. Above the CMC, on the other hand, the elution curve consists of two sigmoidal plots with a plateau between them, as seen in Fig. 1. The curve is characterized by

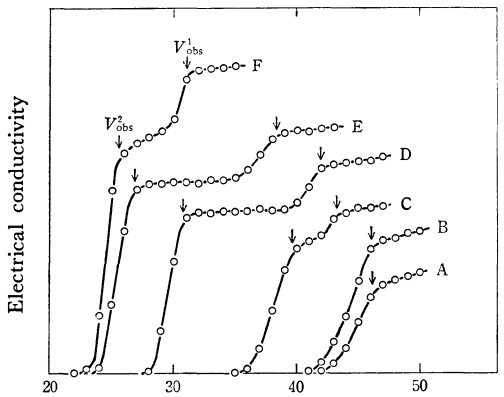

Fig. 1. Elution curves for mixed solutions of SDS and STS at a mixing ratio of 1 to 1 in mole at various total concentrations: A, 0.0020 M; B, 0.0035M; C, 0.0045M; D, 0.0075M; E, 0.011M; F, 0.02 5M. The arrows indicate the retention volumes of the mixture.

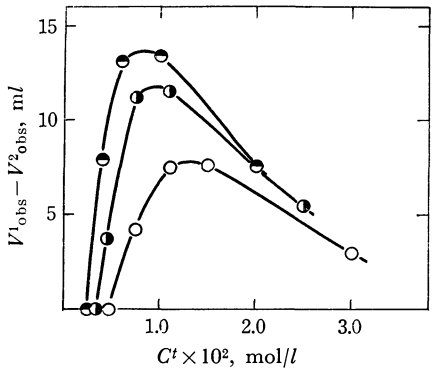

Fig. 2. The values of $(V^1_{obs}-V^2_{obs})$ plotted against C^t at different mixing ratios of STS/SDS: ○, 25/75; ◑, 50/50; ◓, 75/25.

the two retention volumes V^1_{obs} and V^2_{obs} for two shoulders of the curve. The fact that two retention volumes V^1_{obs} and V^2_{obs} are obtained may be explained as due to a continuous change in micelle composition during gel filtration, as will be described later. In Fig. 2, the values of $(V^1_{obs}-V^2_{obs})$ are plotted against C^t for different ratios of STS/SDS. The value of $(V^1_{obs}-V^2_{obs})$ at a given ratio of STS/SDS increases rapidly with C^t and then decreases through a maximum.

It is reasonable to consider that SDS and STS in aqueous solution form mixed micelles rather than the respective micelles of each surfactant. If we now consider a two component system containing both monomer and micelle phases and assume the system to be ideal, we know that for each component the chemical potentials in the two phases are identical at equilibrium. Under such a condition, the equilibrium between monomers and micelles in the mixed solution of SDS(subscript 1) and STS (subscript 2) may be expressed[3]

$$y_1 C^0_{1,2} = x_1 C_1{}^0 \tag{1}$$

and

$$y_2 C^0_{1,2} = x_2 C_2{}^0 \tag{2}$$

or

$$(1-y_1) C^0_{1,2} = (1-x_1) C_2{}^0 \tag{2'}$$

where x or y is the mole fraction of each surfactant in the micelle or monomer phase, respectively, $C^0_{1,2}$ the CMC of the mixture of the two surfactants and C^0 the CMC of the single surfactant. These equations are analogous to Raoult's equation in the form. From Eqs. (1) and (2'), the CMC value of mixed surfactants $C^0_{1,2}$ is written in the following forms as a function of x_1 or y_1.

$$C^0_{1,2} = \frac{C^0_1 - C^0_2}{C^0_1 - (C^0_1 - C^0_2) y_1} \tag{3}$$

and

$$C^0_{1,2} = (C^0_1 - C^0_2) x_1 + C^0_2 \tag{4}$$

The relation between x_1 and y_1 is written

$$y_1 = \frac{C^0_1}{C^0_1 - C^0_2 + (C^0_2/x_1)} \tag{5}$$

The curve of $C^0_{1,2}$ *vs.* x_1 or y_1 is shown in Fig. 3, where the values of CMC for SDS and STS (*i. e.*, C^0_1 and C^0_2) were taken to be 8.1×10^{-3} mol/*l* and 2.2×10^{-3} mol/*l*, respectively. At a given CMC, y_1 is always greater than x_1, that is, the fraction of SDS in the monomer phase is always greater than that in the micelle phase. In Fig. 3 the CMC values of the mixtures of SDS and STS are also shown, determined by electrical conductivity measurement for various total mole fractions of SDS, α_1. The $C^0_{1,2}$ values experimentally obtained lie on the $C^0_{1,2}$ *vs.* y_1 curve. This supports

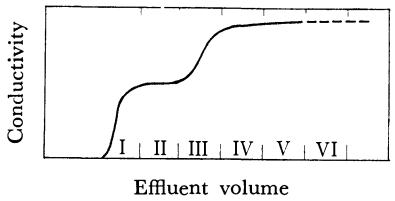
25/75	11.0	0.75	0	0	0.55	0.66	0.76	0.80
50/50	11.0	0.50	0	0	0.38	0.49	0.54	0.52
75/25	10.0	0.25	0	0	0.19	0.23	0.28	0.30



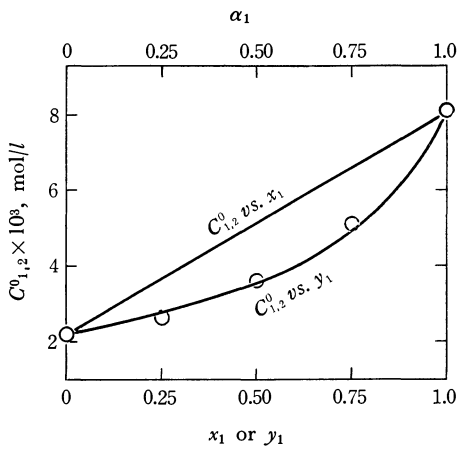


Fig. 3. The relation between $C^0_{1,2}$ and x_1 or y_1, where x_1 and y_1 are the mole fractions of SDS in the micelle and monomer phases respectively. The CMC values determined experimentally are also shown by circles as a function of the total mole fraction of SDS α_1.

the use of Eqs. (1) and (2′) for the equilibria between monomers and micelles.

With gel filtration of a surfactant solution, the micelles flow faster down through the column than the monomers, and dissociate into monomers in the frontal region of the solution since micelles can not exist without monomers. The dissociated monomers will flow more slowly, and the concentration of monomers will be increased by similarly dissociated monomers from other micelles. Then, the monomers will again associate to form new micelles when the concentration reaches the CMC. Thus, the processes of dissociation→association, and association → dissociation will be repeated; in other words, the repeated decomposition and formation of micelles occur continuously during gel filtration. With the gel filtration of a mixture of SDS and STS, the fraction of SDS in the micelle decreases with increasing number of steps of decomposition-formation of micelle and ultimately becomes zero when a long gel column is used, since the fraction of SDS in the micelle is always less than that in the monomer phase at the CMC, as shown in Fig. 3. This explains the fact that two shoulders appear in the elution curve of a mixture of SDS and STS. Table 1 shows the mole fractions of SDS, determined through gas chromatography, in the regions of I, II, III,··· of the effluent which are indicated schematically below the table. As expected from the above discussion, the frontal parts of the effluent, *i. e.*, the regions I and II, contain only STS after passing through the column. Then, the mole fraction of SDS in the effluent increases with increasing elution volume, but would finally become equal to the initial mole fraction through a maximum value.

Now, one has to explain why the difference between V^1_{obs} and V^2_{obs} becomes smaller at higher concentrations of the mixture of SDS and STS, as seen in Fig. 2. The mole fraction of SDS in the micelle phase, x_1, is defined

$$x_1 = \frac{C^M{}_1}{C^M{}_1 + C^M{}_2} = \frac{C^t{}_1 - C^m{}_1}{C^t - C^0{}_{1,2}} \tag{6}$$

that is,

$$x_1 = \frac{\alpha_1 C^t - C^0{}_{1,2} y_1}{C^t - C^0{}_{1,2}} \tag{7}$$

where superscripts m and M refer to monomer and micelle, respectively, and α_1 is the total mole fraction of SDS, *i. e.*, the sum of the mole fractions of SDS in the monomer and micelle phases. Combining Eq. (7) with Eqs. (1) and (4), we have

$$\alpha_1 = \frac{1}{n} \cdot x_1 \{(1+n) - x_1\}, \quad n = C^t/(C^0{}_1 - C^0{}_2) \tag{8}$$

The relations between x_1 and α_1 for different values of n are shown in Fig. 4. The relations between y_1 and α_1 at different values of n are similarly obtained by combination of Eq. (8) and Eq. (5), which

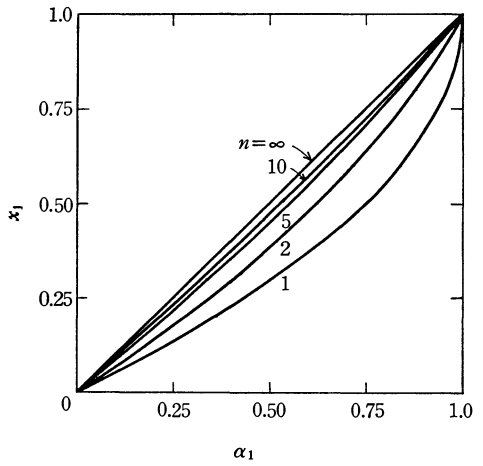

Fig. 4. Curves of x_1 *vs.* α_1 at different values of n, where n is $C^t/(C^0{}_1-C^0{}_2)$.

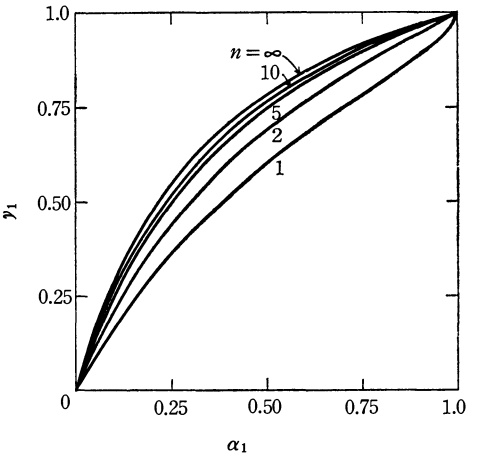

Fig. 5. Curves of y_1 *vs.* α_1 at different values of n, where n is $C^t/(C^0{}_1-C^0{}_2)$.

are also shown in Fig. 5. At very high concentrations where $n \gg 1$, *i.e.*, $C^t \gg (C^0{}_1-C^0{}_2)$, x_1 approaches α_1. This means that the change in the mole fraction of SDS by repeated micelle formation during gel filtration, which has already been described, is small at high concentrations. Thus, the difference between $V^1{}_{obs}$ and $V^2{}_{obs}$ becomes smaller at those concentrations.

The separation factor, β, is generally used as a measure of separation in partition chromatography.[4] In the present case, the β may be defined as K_{STS}/K_{SDS}, where K is the partition coefficient of the surfactant for micelle and monomer phases; that is,

$$\beta = \frac{(C^t-C^0{}_{1,2})x_2/C^0{}_{1,2}y_2}{(C^t-C^0{}_{1,2})x_1/C^0{}_{1,2}y_1} \tag{9}$$

Using Eqs. (1) and (2), Eq. (9) is rewritten

$$\beta = \frac{(C^t-C^0{}_{1,2})x_2/C^0{}_2x_2}{(C^t-C^0{}_{1,2})x_1/C^0{}_1x_1} = \frac{C^0{}_1}{C^0{}_2} \tag{10}$$

Equation (10) indicates that the separation of two surfactants is governed by the CMC values of each surfactant. The greater the ratio of CMC_A/CMC_B where $CMC_A > CMC_B$, the greater is the degree of separation of surfactant B from the mixture of surfactants A and B.

The authors express their thanks to Dr. H. Kita, Director of the Research Laboratories, for his encouragement and permission to publish this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2849—2852 (1968)

A Study on the Electronic Spectra of 1-(*p*-Substituted phenyl)pyrroles*[1]

Taku MATSUO, Hideto SHOSENJI and Reiji MIYAMOTO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received April, 20, 1968)

The longest wavelength electronic absorption band of 1-(*p*-substituted phenyl)pyrrole has been found to show a regular bathochromic shift as the electronegativity of the substituent on the phenyl group increases. The substituent effect is closely related to that for the intramolecular charge-transfer bands of *p*-substituted anilines. Therefore, the longest wavelength absorption band of 1-(*p*-substituted phenyl)pyrroles have been suggested to be originated from an electron transfer from the pyrryl group to the phenyl group. Only one exception is the spectra of 1-(*N,N*-dimethyl-*p*-aminophenyl)pyrrole. In this case, the longest wavelength electronic absorption band is suggested to be due to an electron-transfer from the *N,N*-dimethylamino group to the phenyl group.

A large number of experimental studies have been reported on the electronic spectra of pyrrole derivatives.[1] The present status of the theoretical interpretation, however, is far from satisfactory except for the case of pyrrole itself.[1g,2] The situation may be improved by making a systematic study of the spectra of a series of related pyrrole derivatives. In the present paper, the nature of the longest wavelength absorption bands of 1-(*p*-substituted phenyl)pyrroles are described and the origin of the electronic transitions is discussed.

Results and Discussion

The longest wavelength electronic absorption bands of 1-(*p*-substituted phenyl)pyrroles are invariably strong and appear in the region between 250 mμ and 350 mμ. The wave numbers and the extinction coefficients for the absorption maxima are summarized in Table 1. It is clearly observed there that the absorption band shows a regular bathochromic shift, except for the case of *N,N*-dimethylamino group, as the electronegativity of the *p*-substituent increases. The trend may be taken to indicate that the absorption bands arise from intramolecular charge-transfer as has been suggested in the cases of mono-substituted benzenes.[3,4] Since pyrryl group is a very strong π-electron donor in the formation of charge-transfer complexes,[5] it is very likely that the pyrryl group in 1-phenylpyrrole donates its electrons to the phenyl group. The substituent effect on

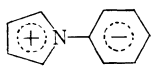
		31.1[c,d]	2.0	31.2[c,d]	2.1

a) The values are given in units of 10^3 cm^{-1}, and the uncertainty is within 100 cm^{-1} unless otherwise specified.
b) The values are given in units of 10^3 $l/mol \cdot cm$, and the uncertainty is within 100 $l/mol \cdot cm$.
c) The position of a shoulder (± 200 cm^{-1}).
d) The absorption band may be mainly due to the locally excited B_{2u} configuration of the phenyl group.
e) No reliable value has been obtained because the solubility of the sample is extremely low.

the charge-transfer band of *N,N*-dimethylaniline*2 was also investigated for the comparison (Table 2). In Fig. 1, the positions of absorption maxima of the 1-phenylpyrrole analogues are plotted against those of the corresponding *N,N*-dimethylanilines. A very close resemblance is observed between the substituent effects in the two series. Analogously to the case of aniline, the absorption spectra of the 1-phenylpyrrole analogues are suggested then to be related to the charge-transter conffgurations of the following type:



In agreement with this suggestion, the absorption band shows both hypsochromic shift and hypochromic effect when the conjugation between the pyrryl and phenyl groups is hindered by the presence of methyl group at either the 2- or the 2′-position*3 (Table 3, Fig. 2). Similar observation was reported also by several investigators.[1b,1g]

When an electronegative group is attached to the *p*-position of the phenyl group, the energy of the charge-transfer configuration should be lowered.

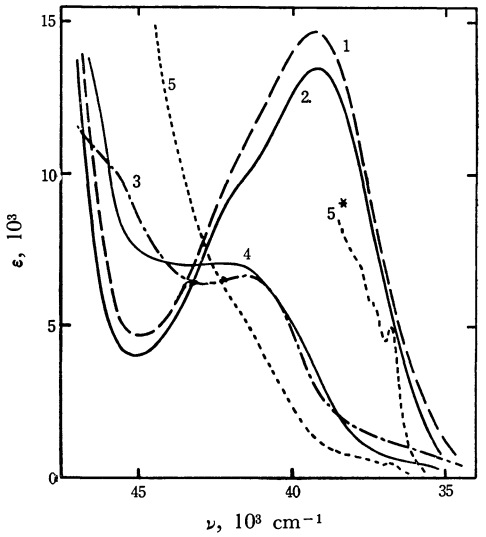


Fig. 2. The ultraviolet spectra of 1-phenylpyrrole and its methyl-substituted analogues in *n*-hexane. The numbers correspond to the numbering of the compounds listed in Table 3. * The real molecular extinction coefficient is one tenth of the value shown in this figure.

*2 The charge-transfer nature of this band has been well established by Nagakura and his associates.[4b]

*3 If one uses Braude and Sondheimers' relationship (Eq. (1))[7] to estimate the angle of twist, θ, between the two groups;

$$\varepsilon/\varepsilon_0 = \cos^2\theta \qquad (1)$$

he gets 50° for 1-(*o*-tolyl)pyrrole. On the basis of a three dimensional molecular model with appropriate van der Waals radii, θ for the same compound is estimated to be approximately 60°.

Table 2. The longest wavelength intramolecular charge-transfer bands of *p*-substituted *N,N*-dimethylanilines[a]

No.[b]	Compound	ν[c]	ε[d]
1	*N,N*-Dimethyl-*p*-nitroaniline[e]	28.7

c) The values are given in units of 10^3 *l*/mol·cm.
d) The position of a shoulder.

The experimental facts are certainly in accordance with this expectation. The only one exception is *N,N*-dimethylamino group. In order to investigate the reason for the bathochromic effect of this group, the spectra were measured in acidic medium. Since the spectra of 1-(*N,N*-dimethyl-*p*-aminophenyl)pyrrole in acidic medium is very close to that of 1-phenylpyrrole in the neutral solution (Fig. 3), the former compound is concluded to be protonated on its *N,N*-dimethylamino group. This conclusion is in agreement with the fact that the basicity of pyrrole (pK_a, -4.4)[1g] is much lower than that of *N,N*-dimethylaniline (pK_a, 5.10).[6] In other words, *N,N*-dimethylamino group is more basic than pyrryl group. Therefore it is very important to take into account the contribution of the charge-transfer configurations where an electron is transferred from the *N,N*-dimethylamino group to the phenyl group. Such electronic configurations are of minor importance in the cases of other substituents in Table 1. Thus the nature of the longest wavelength absorption band of 1-(*N,N*-dimethyl-*p*-aminophenyl)pyrrole may be suggested to be different from those of the other 1-(*p*-substituted phenyl)pyrroles.

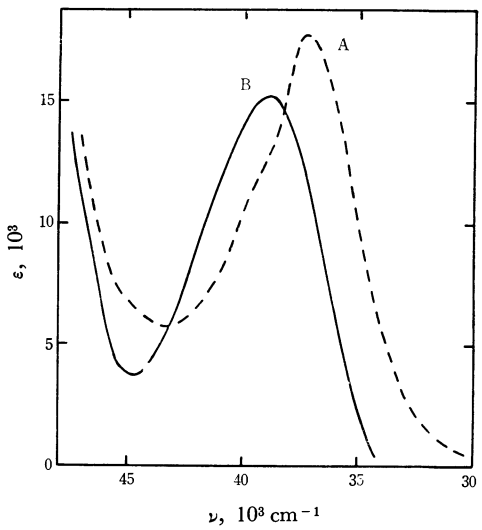

Fig. 3. The ultraviolet spectra of 1-(*N,N*-dimethyl-*p*-aminophenyl)pyrrole in 10% (vol/vol) ethanol-water solution; A, the neutral solution; B, the 10^{-2} N hydrochloric acid solution.

In order to understand the nature of electronic transitions of complex molecules, it is very useful to utilize the method of composite molecules.[3,4] In the present case, the constituent molecules are pyrrole (A) and substituted benzene (B). The presence of an electronegative group in the phenyl group will increase the electron affinity of B. Then the energy of local excitation in either A or B will be above that of the charge-transfer state (A^+B^-) where an electron is transferred from A to B. The situations is entirely different, if the substituent is *N,N*-dimethylamino group which is a highly electron-donating group. Since the electron affinity of B is considerably reduced, in this case, the energy of the charge-transfer state (A^+B^-)

6) N. F. Hall, *J. Am. Chem. Soc.*, **52**, 5115 (1930).

will be raised appreciably. The energy of the lowest excited state in B (*i. e.*, *N,N*-dimethylaniline), on the other hand, is known to be much less than that of unsubstituted benzene.[4b] Then it is quite likely that the local excitation in B may require less energy than an electron-transfer from A to B. If this is the case, the longest wavelength electronic absorption band of 1-(*N,N*-dimethyl-*p*-aminophenyl)pyrrole is considered to be due to an electron transfer from the *N,N*-dimethylamino group (rather than from the pyrryl group) to the phenyl group. The experimental facts are certainly in accordance with this view point. In order to testify the proposed explanation, a quantum mechanical calculation is being carried out to estimate the relative importance of various electronic configurations.

It may be adequate to mention here also that a weak absorption band corresponding to the B_{2u} state of benzene seems to be hidden under the longest wavelength absorption bands discussed above. The band appears only slightly at the tail of the absorption edge of 1-(2′,6′-xylyl)pyrrole (Fig. 2).

Experimental

Chemicals. The preparations of the materials other than described below have been reported elsewhere.[5] The following compounds were prepared according to the literatures as given in the parentheses: 1-*p*-nitrophenylpyrrole (Ref. 8, mp 180.2—181.2°C), 1-*p*-formylphenylpyrrole (Ref. 9,*4 mp 94.5—95.5°C. Found: C, 77.31; H, 5.16; N, 8.12%. Calcd for $C_{11}H_9NO$: C, 77.17; H, 5.29; N, 8.18%), 1-*p*-cyanophenylpyrrole (Ref. 9,*4 mp 104.5—105.5°C. Found: C, 78.58; H, 4.81; N, 16.50%. Calcd for $C_{11}H_8N_2$: C, 78.55; H, 4.80; N, 16.65%), 1-*p*-carbomethoxyphenylpyrrole (Ref. 9,*4 mp 127.7—128.7°C. Found: C, 71.58; H, 5.60; N, 7.17%. Calcd for $C_{12}H_{11}NO_2$: C, 71.68; H, 5.47; N, 6.96%), *N,N*-dimethyl-*p*-aminobenzaldehyde (Ref. 10, mp 74.0—75.0°C) and *N,N*-dimethyl-*p*-aminobenzonitrile (Ref. 11, mp 76.5—77.5°C). The prepared samples were identified by the nuclear magnetic resonance spectra and infrared spectra.

n-Hexane and ethanol were supplied by commercial sources as reagent grade chemicals. They were repeatedly purified by usual methods until they proved to be pure from spectroscopic points of view.

Spectroscopic Measurements. Spectra were measured at 17—19°C by a Baush & Lomb Spectronic Model 505 or Hitachi Model EPS-2 Recording Spectrophotometer. The concentration of the solutions were between 10^{-4} and 10^{-5} mol/*l*.

*4 These compounds were synthesized by modifying the method for the preparations of similar compounds described in the references.

(Received May 6, 1968)

The 4,4'-dinitrobiphenyl complexes with benzidine and tetramethylbenzidine, in which the long axes of the component molecules are known to be perpendicular to each other, were examined for the diffuse reflection spectra. The deep coloration in these complexes was found to be due to the appearance of broad, weak charge-transfer absorptions.

A common feature in the crystal structures of electron donor-acceptor complexes is a plane-to-plane stacking of the molecules.[1] As the structure of a particular complex is a compromise between those molecular orientations most favorable to donor-acceptor interaction and those which give the most efficient molecular packing, the maximum overlap between π-orbitals of the component molecules is not always attained. 4,4'-Dinitrobiphenyl has been known to form complexes with biphenyl and its 4- and 4,4'-derivatives with a structure in which dinitrobiphenyl molecules form a stack with the planar molecules overlying each other, while the other component molecules are in the tubular cavities resulting from the parallel packing of the stacks.[2] The composition is determined by the number of dinitrobiphenyl

molecules in a stack that can be accommodated at right angles to each donor molecule. Thus, the structure of these molecular complexes is exclusively determined by geometrical considerations. Nevertheless, the complexes with benzidine and its tetramethyl derivative are much more deeply colored than the component compounds. This is known to be a general feature in electron donor-acceptor complexes. Therefore, it seemed very interesting to find out whether or not the deep coloration in these dinitrobiphenyl complexes, which are supposed to be in crystal structures unfavorable to π-π interaction, is due to the appearance of new low-energy electronic absorptions, charge-transfer absorptions.

Experimental

The complexes with biphenyl, 4,4'-dihydroxybiphenyl, 4,4'-dimethoxybiphenyl, benzidine, and *N,N,N',N'*-tetramethylbenzidine were prepared as has been described by Rapson *et al.*[2] The pulverized sample was diluted with sodium chloride, mostly in a ratio of 1 : 100 by weight, by grinding it in order to obtain a reasonable reflectance. The spectra were recorded as the difference in reflectance between the mixture and pure sodium chloride by a Beckman DK-2A spectroreflectometer and then plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. The complexes of dimethoxybiphenyl, benzidine, tetramethylbenzidine, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine with various acceptors were examined in a chloroform solution for the charge-transfer absorptions using a Beckman DK-2A spectrophotometer.

Results and Discussion

The compositions of the red benzidine and dark red tetramethylbenzidine complexes are known to be 1 : 4. Tetramethylbenzidine also forms a steel-gray colored complex with a composition of 1 : 1. Their diffuse reflection spectra are presented in Fig. 1, along with the spectrum of dinitrobiphenyl. The absorptions of the other component compounds appear at wave numbers larger than that of dinitrobiphenyl. All these complexes are found to show new low-energy absorptions. Although the appearance of the tetramethylbenzidine 1 : 1 complex is quite different from that of the 1 : 4 complex, their spectra are very much alike. The difference in color arises from a small shift in the low-energy absorption. As these absorptions are weak and broad, and overlap with the strong dinitrobiphenyl absorption, there is some uncertainty in the location of their maxima. The following values may, however, be obtained as rather rough estimates: about 18.5 kK for the tetramethylbenzidine 1 : 1 complex, about 21 kK for the 1 : 4 complex, and about 22.5 kK for the benzidine complex. The complexes with biphenyl, 4,4'-dihydroxybiphenyl, and 4,4'-dimethoxybiphenyl have compositions of 1 : 3, 1 : 3 and 2 : 7 respectively. They have approximately the same colors with dinitrobiphenyl. The only difference observed in the spectra is little tails extending from the small-wave number side of the dinitrobiphenyl absorption.

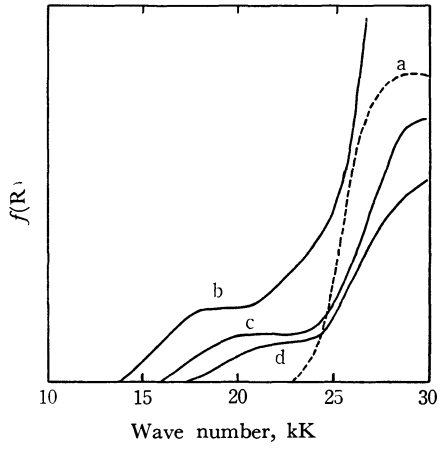

Fig. 1. Diffuse reflection spectra of dinitrobiphenyl (a), the tetramethylbenzidine 1 : 1 (b) and 1 : 4 (c) complexes and the benzidine 1 : 4 complex (d).

Nothing is known of the structure of the tetramethylbenzidine 1 : 1 complex. However, because of its simple composition, the molecules in this complex are presumably in a plane-to-plane stacking. Therefore, the low-energy absorption appearing in this particular complex may be considered to be a charge-transfer absorption arising from electron donor-acceptor interaction between tetramethylbenzidine and dinitrobiphenyl. If so, the weak absorption in the 1 : 4 complex may be of the same nature because of the close similarity in location and shape. As benzidine has a higher ionization potential than its tetramethyl derivative, the charge-transfer absorption in the benzidine complex may be expected to appear at a larger wave number than that of the tetramethylbenzidine complex. This is in accordance with observations. Thus qualitative considerations lead to the tentative conclusion that charge-transfer absorptions are the cause of the deep colors in the dinitrobiphenyl complexes with benzidine and its tetramethyl derivative.

Now we wish to proceed in a more quantitative way. Foster has proposed the empirical relationships that the energies of charge-transfer absorption in a set of complexes of a donor (acceptor) with a series of acceptors (donors) are proportional to those in complexes of the same series of acceptors (donors) with a second donor (acceptor).[3] Such a correlation has been established in a number of

3) R. Foster, *Tetrahedron*, **10**, 96 (1960).

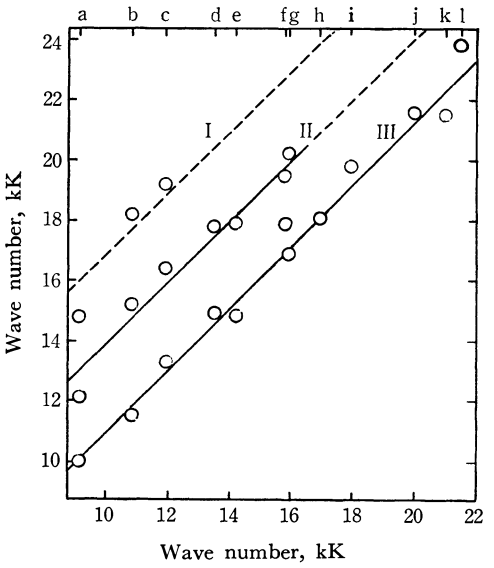

Fig. 2. Plots of wave numbers of maxima of the charge-transfer absorptions in complexes of tetramethyl-*p*-phenylenediamine with the acceptors: tetracyanoethylene (a); *p*-chloranil (b); 2,5-dichloro-*p*-benzoquinone (c); dichloro-*p*-xyloquinone (d); chloro-*p*-benzoquinone (e); *p*-benzoquinone (f); *s*-trinitrobenzene (g); *p*-dinitrobenzene (h); trinitrotoluene (i); *m*-dinitrobenzene (j); dinitrobiphenyl (k); 2,4-dinitrotoluene (l); against wave numbers of the charge-transfer absorptions in the corresponding complexes with the donors: dimethoxybiphenyl (I); benzidine (II); tetramethylbenzidine (III).

the cases by Foster himself and also by Beukers and Szent-Györgyi, and has often been considered as evidence for charge-transfer absorption.[3-5] In Fig. 2 the wave numbers of the absorption maxima in dimethoxybiphenyl, benzidine, and tetramethylbenzidine complexes with each of several acceptors are plotted against those in the corresponding tetramethyl-*p*-phenylenediamine complexes. A large part of the data for the tetramethyl-*p*-phenylenediamine and tetramethylbenzidine complexes was taken from the work by Foster and Thomson.[6] With dinitrobiphenyl as an acceptor (k), the maximum of the low-energy absorption could be located only in the complex of tetramethylbenzidine, the strongest donor among the biphenyl derivatives examined, at about 21.5 kK. This value fits fairly well into the linear relationship shown in Fig. 2, and must be considered to be consistent with the maxima observed in the solid 1 : 1 and 1 : 4 complexes. The appearance of charge-transfer bands in solid complexes at energies a few kK lower than those in a solution is quite common. Furthermore, an examination of Fig. 2 indicates that the charge-transfer interaction between benzidine and dinitrobiphenyl gives an absorption with a maximum around 25 kK. Again, this estimation is in fair agreement with the low-energy absorption in the solid-state spectrum, 22.5 kK. As for the remaining complexes the available data are not enough to enable us to prepare plots like those for benzidine and its tetramethyl derivative. However, if they show charge-transfer absorptions, the maximum in the dimethoxybiphenyl complex may be expected around 28 kK and those in the other two, higher. In accordance with the experimental results, the observation of such absorptions is hardly possible because of the strong absorptions due to the component compounds lying in the same region. Consequently, the thesis that the low-energy absorptions appearing in the solid dinitrobiphenyl complexes arise from charge-transfer interaction, where dinitrobiphenyl acts as an electron acceptor, receives strong support from these considerations.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2855—2858 (1968)

Polarized Absorption Spectra of Single Crystals of Ion Radical Salts. I. Molecular Compounds of 7,7,8,8-Tetracyano-*p*-quinodimethane with *N*,*N*,*N*′,*N*′-Tetramethyl-*p*-phenylenediamine and *N*,*N*-Dimethyl-*p*-phenylenediamine

Haruo KURODA, Shoji HIROMA and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received May 6, 1968)

Polarized absorption spectra in the 10—40 kK region were observed on single crystals of the molecular compounds of tetracyano-*p*-quinodimethane (TCNQ) with tetramethyl-*p*-phenylenediamine (TMPD) and with dimethyl-*p*-phenylenediamine (DMPD). These molecular compounds possess an ionic structure in the ground state. A strong, broad absorption band appears in the near-infrared region of the crystal spectra with a polarization parallel to the crystal axis along which the component ions are alternately stacked making their molecular planes parallel to each other. The absorption maximum of this band is located at 7.7 kK in TMPD·TCNQ and at 8.5 kK in DMPD·TCNQ. These bands are assigned as a one associated with the charge transfer from $TCNQ^-$ ion to the positive ion of the donor. Other absorption bands found in the spectra can be assigned as local excitation bands associated with the intramolecular transitions of the component ions. However, they are found to be considerably broadened and appreciably shifted to higher energy as compared with the solution spectrum of each component ion.

There is a class of solid molecular compounds which possess an ionic structure in the ground state. Such molecular compounds can be formed by the interaction between a strong π-electron donor and a strong π-electron acceptor. The crystal of the 1 : 1 molecular compound involving *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine (TMPD) as the donor and 7,7,8,8,-tetracyano-*p*-quinodimethane (TCNQ) as the acceptor has been suggested to possess a ground state consisting of TMPD monopositive ion and TCNQ mononegative ion.[1,2] This solid molecular compound exhibits a marked electron spin resonance absorption, which has been ascribed to the triplet state arising from the interaction between the radical ions of TMPD and TCNQ.[2] The presence of the visible absorption bands corresponding to the component ions has been reported by Foster and Thomson[1] in the absorption spectrum observed for a Nujol mull of the solid molecular compound. However, no observation has been made on the absorption spectrum of its single crystal, which should provide much informations concerning its electronic structure. In the present investigation, we have studied the polarized absorption spectra of the single crystals of this molecular compound as well as those of the solid molecular compound of *N*,*N*-dimethyl-*p*-phenylenediamine (DMPD) with TCNQ.

Experimental

The polarized absorption spectra in the 10—40 kK region were measured on very small single crystals by using a microspectrophotometer. The details of the apparatus and the experimental procedures were described in a preceding paper.[3]

The solid molecular compound, TMPD·TCNQ, was prepared by mixing an acetonitrile solution of Würster's blue perchlorate (TMPD·ClO_4) and a methanol solution of Li·TCNQ. The black powder of TMPD·TCNQ precipitated as the solution containing equivalent amounts of TMPD·ClO_4 and Li·TCNQ was concentrated by evaporation of the solvent. The solid thus obtained was recrystallized from an acetonitrile solution. The mole ratio of TMPD to TCNQ was confirmed to be 1 : 1 by the elementary analysis. The DMPD·TCNQ was prepared by mixing a chloroform solution of TCNQ with a chloroform solution of an equimolar amount of DMPD.

Minute crystals freshly prepared from an acetonitrile solution were used for the measurement of spectra. The crystals were found to be frequently twinned, so that the selection was needed to find a single crystal which was not twinned, by examinnig by the polarizing microscope. The absorption spectra of the crystalline powders were also observed by the use of liquid paraffin mulls.

Results and Discussion

The polarized absorption spectra observed of a single crystal of TMPD·TCNQ are shown in Fig. 1. According to the crystal structure analysis by Hanson,[4] the crystal is monoclinic with the lattice constants, $a=9.88$ Å, $b=12.71$ Å, $c=7.72$ Å and $\beta=97.34°$, and belongs to the space group $C2/m$. The unit cell contains two molecules of each component. The donor and acceptor molecules are alternately stacked along the c-axis. The absorption spectra shown in Fig. 1, were obtained for a very thin single crystal of a few microns in width, elongated along the c-axis, the developed face of which was assigned to (010) plane. The projection of the crystal structure onto the (010) plane along the b-axis is reproduced schematically in Fig. 2.

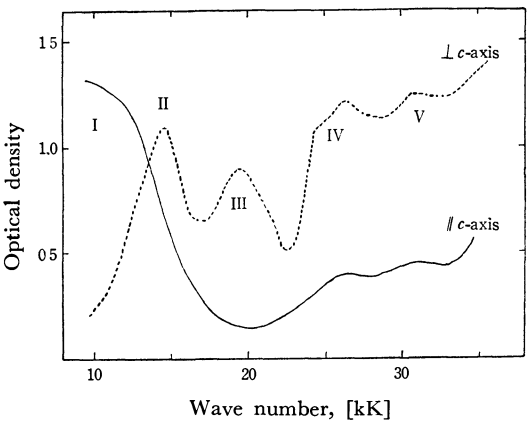

Fig. 1. Polarized absorption spectra of a single crystal of TMPD·TCNQ.

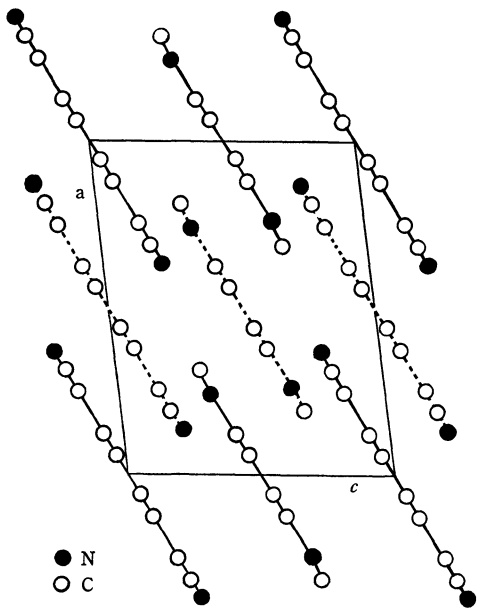

Fig. 2. Crystal structure of TMPD·TCNQ: The short axes of the component ions are parallel to the b-axis; the layer of molecules shown with broken line is $b/2$ above that of the molecules shown with solid line.

Evidently there is a strong band in the near-infrared region, which seems to be exclusively polarized in the c-axis direction. Unfortunately, our microspectrophotometer could not be applied to the region below 9 kK. Thus the absorption in the low energy region was examined by observing the absorption spectrum of the powder sample. The result is shown in Fig. 3, in which one absorption band with a maximum located at about 7.7 kK is found in the near-infrared region. This must correspond to the low energy band found in the $\|c$ spectrum of the single crystal. The intensities of the absorption bands associated with the long-axis polarized transitions of the component ions should be higher in the $\perp c$ spectrum than in the $\|c$ spectrum, since the oriented-gas model predicts the intensity ratio $I_{\perp c}/I_{\|c}$ of 2.5 as shown in Table 1, and the short-axis polarized transitions of the component ions should not appear in the $\|c$ spectrum, nor in the $\perp c$ spectrum. Thus we can assign the 7.7 kK band, which we shall denote as "Band I," to the one associated with the charge-transfer between $TMPD^+$ and $TCNQ^-$ ions stacked on each other. Probably it is associated with a transfer of an electron from a $TCNQ^-$ ion to a $TMPD^+$ ion. A similar charge-transfer band has been found in several other molecular compounds having an ionic structure.[5,6]

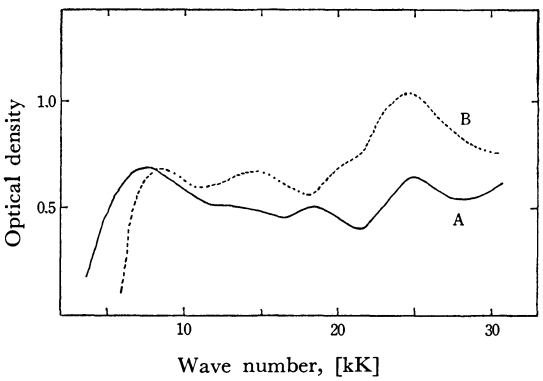

Fig. 3. Absorption spectra of liquid paraffin mulls of the crystalline powders of TMPD·TCNQ (A) and DMPD·TCNQ (B).

In the $\perp c$ spectrum, there are four absorption bands, which are denoted respectively II, III, IV and V in Fig. 1. All these bands are stronger in the $\perp c$ spectrum than in the $\|c$ spectrum.

* Oriented-gas values.

In effect, no absorption maximum corresponding to Band II and Band III can not be found in the $\parallel c$ spectrum. These four bands seem to be mainly associated with the intramolecular transitions of the component ions. The absorption spectra of $TMPD^+$ and $TCNQ^-$ ions in solution are shown in Fig. 4. The open-shell SCF-LCAO-MO calculations have been carried out recently by Lowitz[7] on the electronic transitions of $TCNQ^-$ ion. According to his result, the first strong absorption band located at about 12 kK is due to π–π^* transition polarized along the long-axis of the molecule and the next band is composed of a strong, long-axis polarized transition and a weak, short-axis polarized transition. The polarizations of the transition in $TMPD^+$ ion have been experimentally studied by Albrecht and Simpson,[8] who have concluded that the 18 kK and 30.9 kK transitions are of the long-axis polarization, while the weak 26.2 kK transition is of the short-axis polarization. These are in agreement with theoretical predictions.[9,10]

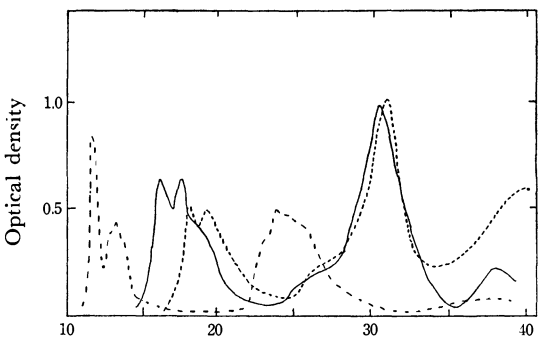

Fig. 4. Absorption spectra of the component ions in acetonitrile: —— $TMPD^+$, - - - $DMPD^+$, —·— $TCNQ^-$.

The probable assignements of the observed bands and the oriented-gas values of the oscillator strength of each intramolecular transition are summarized in Table 1. The observed polarization ratio well agrees with the oriented-gas value in the cases of Band IV and Band V. There seems to be some deviation between the observed and calculated polarization ratios in the cases of Band II and Band III, especially in the last one. From the experiment by Albrecht and Simpson[8] as well as from the reported crystal spectra of the ionic compound formed between TMPD and chloranil,[5,6] there can be no doubt that the 18 kK and 30.9 kK transitions in $TMPD^+$ ion are same as regards the polarization. Thus the difference between their polarization ratios must be associated in someway with the interactions of ions in the crystal lattice. It should be also noticed that the bands II, III and IV in the crystal spectra are shifted to higher energy by about 2 kK compared with the corresponding bands in the solution spectra, and, at the same time, all bands are considerably broadened. A similar effect can be generally found in the crystal spectra of a molecular compound which is composed of positive ions of donor and negative ions of acceptor, when there exists a relatively strong charge-transfer interaction between the component ions.[5]

The polarized absorption spectra of the DMPD·TCNQ are shown in Fig. 5. The crystal structure has not been determined for this molecular compound. The spectra were observed, on a thin single crystal elongated along one direction, for the two polarizations of light parallel and perpendicular to the elongated axis, which we shall denote here as the "*l-axis*" of the crystal.

The observed spectra are quite similar to the

7) D. A. Lowitz, *J. Chem. Phys.*, **46**, 4698 (1967).
8) A. C. Albrecht and W. T. Simpson, *J. Am. Chem. Soc.*, **77**, 4458 (1955).
9) M. Geoppert-Mayer and K. J. McCallum, *Rev. Mod. Phys.*, **14**, 248 (1942).
10) H. J. Monkhorst and J. Kommandeur, *J. Chem. Phys.*, **47**, 391 (1967). They assigned the 13 and 31 kK band to the transitions, polarized along the "*x-axis*", which corresponds to the short-axis according to the notation of molecular axes given in their paper. However, they have recently informed us that this notation is incorrect, and the "*x-axis*" is the long-axis of molecule.

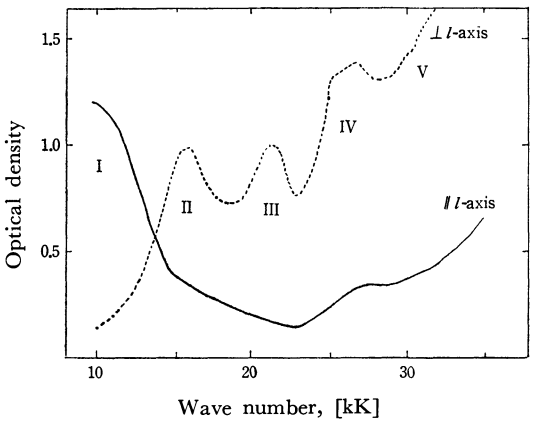

Fig. 5. Polarized absorption spectra of a single crystal of DMPD·TCNQ.

spectra of TMPD·TCNQ: namely, the first absorption band in the near-infrared region is exclusively polarized in the *l-axis* derection while the bands in the 12—35 kK region are stronger in the $\perp l$ spectrum than in the $\parallel l$ spectrum. The absorption maximum of the first band is located at about 8.5 kK according to the absorption spectrum of the liquid paraffin mull of the powder already shown in Fig. 3. We shall assign this low energy band to the charge-transfer from a $TCNQ^-$ ion to the neighboring $DMPD^+$ ion. We can assign the other bands in Fig. 5 to the bands mainly associated with the intramolecular transitions of the component ions: Bands, II and IV, are due to the long-axis polarized transitions of $TCNQ^-$ ions, and Bands, III and V to the long-axis polarized transitions of $DMPD^+$ ion. Band III of DMPD·TCNQ is located at a wave number higher by 1.7 kK than the corresponding band of TMPD·TCNQ. This difference is nearly equal to the difference between the enrgy of the lowest transition of $TMPD^+$ ion and that of $DMPD^+$ ion.

The similarity found between the polarized spectra of TMPD·TCNQ and those of DMPD·TCNQ seems to suggest the resemblance between their crystal structures. Thus we may consider that, in the crystal of DMPD·TCNQ, the ions of the two components are alternately stacked on each other along one crystal axis making their long molecular axes parallel to each other as in the crystal of TMPD·TCNQ.

Finally it should be noted that the intensity of the charge-transfer band is considerably strong in the crystal spectrum of TMPD·TCNQ as well as in that of DMPD·TCNQ. Although we have not carried out the absolute measurement of the intensity of absorption, the fact that the charge-transfer band is observed in the crystal spectra of these molecular compounds with an intensity comparable to or higher than the absorption bands associated with strong intramolecular transitions of the component ions, evidently indicates that the intensity of the charge-transfer band is fairly strong. This phenomenon seems to suggest the presence of a strong charge-transfer interaction between the neighboring ions in the crystal lattice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2858—2860 (1968)

Relative Determination of Soret Coefficients of Alkaline Earth Chlorides

Toshio IKEDA, Hidefusa OHE and Saburo KAWAMURA

Department of Chemistry, Faculty of Science, Shizuoka University, Oiwa, Shizuoka

(Received May 7, 1968)

The Soret coefficients of aqueous solution of alkaline earth chlorides were determined indirectly using combined thermocells. "Combined thermocell" refers to a cell system of a back to back combination of two thermocells made of common electrodes and different electrolytes without liquid junction. The values are -2.79 for $MgCl_2$, -3.43 for $CaCl_2$, -4.09 for $SrCl_2$, and -4.73 for $BaCl_2$, respectively (in the unit of 10^{-3} deg^{-1}) at 0.005 M and 25°C. These agree with reported values found by the direct method.

General Scheme

The Soret coefficients of a series of the alkaline earth chlorides, MCl_2, solution were determined by using combined thermocells of the following system:

$$\underset{T}{\text{Hg-HgCl}},\ \text{LiCl}(m),\ \underset{T+\Delta T}{\text{HgCl-Hg-HgCl}}$$
$$\text{MCl}_2\left(\frac{1}{2}m\right),\ \underset{T}{\text{HgCl-Hg}} \qquad (1)$$

where the concentrations of chloride ion are taken common in both left and right halves of the cell. Lithium chloride was taken as a standard reference because it shows a very slight Soret effect. The initial thermoelectric powers, ε_0^{LiCl} and $\varepsilon_0^{MCl_2}$ for the left and right halves of (1) are expressed respectively as follows:[1]

$$F\varepsilon_0^{LiCl} = S_{Hg} - S_{HgCl} + 2RTt_{Li^+}^{LiCl}B^{LiCl}\sigma^{LiCl} + \overline{\overline{S}}_{Cl^-}^{LiCl} - \overline{\overline{S}}_{el}$$

$$F\varepsilon_0^{MCl_2} = S_{Hg} - S_{HgCl} + \frac{3}{2}RTt_{M^{2+}}^{MCl_2}B^{MCl_2}\sigma^{MCl_2} + \overline{\overline{S}}_{Cl^-}^{MCl_2} - \overline{\overline{S}}_{el}$$

where σ's are the Soret coefficients, t's the ionic transport numbers for ions indicated by the subscripts. Superscripts, LiCl or MCl_2, indicate the solution phases, and so forth. B's are defined by

$$B^{LiCl} = (1 + \mathrm{d}\ln\gamma_{\pm}^{LiCl}/\mathrm{d}\ln m)_{T,P}$$

$$B^{MCl_2} = (1 + \mathrm{d}\ln\gamma_{\pm}^{MCl_2}/\mathrm{d}\ln m)_{T,P}$$

where $\gamma_{\pm}$'s are the mean activity coefficients in the molality scale. $\overline{\overline{S}}_{el}$ is the transported entropy of electrons in the metallic phase, and $\overline{\overline{S}}_{Cl^-}$'s represent the transported entropies of the chloride ions. F, R and T have their usual significances. The temperature coefficient of the resultant thermoelectromotive force, E, of (1) at the initial state, or the initial thermoelectric power, $(\mathrm{d}E/\mathrm{d}T)_0$, of (1) is given by the relation, $(\mathrm{d}E/\mathrm{d}T)_0 = \varepsilon_0^{MCl_2} - \varepsilon_0^{LiCl}$. Then we have

$$\sigma^{MCl_2} = \frac{4t_{Li^+}^{LiCl}B^{LiCl}}{3t_{M^{2+}}^{MCl_2}B^{MCl_2}}\sigma^{LiCl} + \frac{2F(\mathrm{d}E/\mathrm{d}T)_0}{3RTt_{M^{2+}}^{MCl_2}B^{MCl_2}} - \frac{2(\overline{\overline{S}}_{Cl^-}^{MCl_2} - \overline{\overline{S}}_{Cl^-}^{LiCl})}{3RTt_{M^{2+}}^{MCl_2}B^{MCl_2}} \quad (2)$$

Experimental Results and Discussion

All aqueous solutions were prepared from Wakô Guaranteed Reagent grade chemicals (99.8% purity) for a concentration of 0.01 M with respect to the chloride ion. Accuracy of the concentration was within ±0.4%. Experimental equipments are entirely the same as those reported in the previous paper.[2] The measurements were begun after allowing cells to stand at a medium temperature near 25°C for more than 10 days, because, in the early stage, usually during several days after the set up of cell, the stability of electrode system was not sufficient to get reproducible results in measuring such a minute change in emf as the case the present work. Emf of the cell (1) was measured by using a precision Yokogawa potentiometer (New type P-7 for low voltage use) by the aid of Yokogawa sensitive galvanometer, and was accurate within ±0.1 μV. The range of ΔT was about 10° around a mean temperature 25°C, while the temperature on the terminal electrodes was kept constant at 25°C. Measurements were repeated for every possible combination of four or five well-conditioned MCl_2 thermocells with four or five well-conditioned reference LiCl thermocells. Some of the typical results are represented in Fig. 1. The values of $(\mathrm{d}E/\mathrm{d}T)_0$, the initial thermoelectric power of the combined thermocells of type (1), were determined at 25°C with the least squares method, and are listed in Table 1. The data are reproducible, mostly within ±1% of fluctuation.

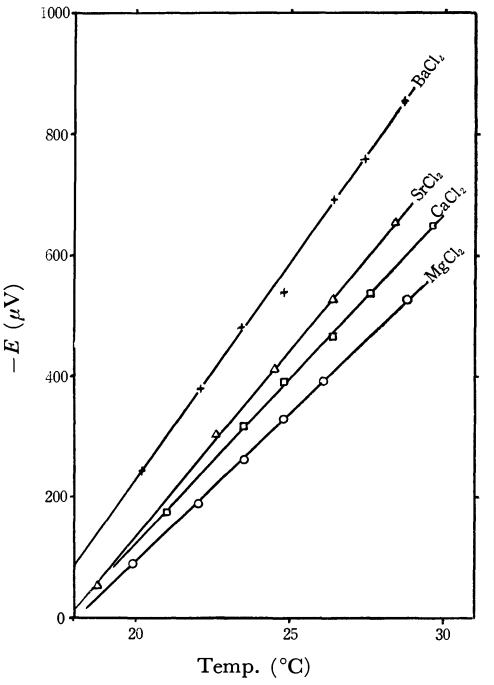

Fig. 1. Emf plots of combined thermocells of the type (1) against the temperature, $(T+\Delta T)$, around the mean temperature 25°C, where the temperature on two terminal electrodes was kept at 25°C constantly. The concentration of solutions was adjusted to 0.01 M with respect to the chloride ions.

According to Snowdon and Turner,[3] the Soret coefficient of LiCl is $0.02\times10^{-3}\,\mathrm{deg}^{-1}$ at 25.3°C and 0.01 M. This value was adjusted to the 25°C

value, $0.01 \times 10^{-3}\ deg^{-1}$, and was used as the standard in the present calculation. B-Values were determined graphically at a concentration $m=$ 0.01 M in the case of LiCl and at 0.005 M in the case of MCl_2, respectively, at 25°C. These values and the present data on $(dE/dT)_0$ were used to get the relative values of the Soret coefficients, σ^{MCl_2}, at 25°C and 0.005 M by the aid of (2). In this treatment $\bar{\bar{S}}^{MCl_2}_{Cl^-} = \bar{\bar{S}}^{LiCl}_{Cl^-}$ was assumed. The results agree very well with those obtained by the direct method by Payton and Turner,[4] except calcium chloride. According to the theory of Helfand and Kirkwood,[5] $\bar{\bar{S}}_{Cl^-}$'s should differ from solution to solution involving different cation species, particularly of high ionic valency, however, the present studies indicate that the difference between $\bar{\bar{S}}_{Cl^-}$'s is practically negligible. This fact seems to indicate that our combined thermocell method is applicable extensively to determine the Soret coefficients of bivalent metal chlorides in water at low concentration by assuming $\bar{\bar{S}}^{MCl_2}_{Cl^-} = \bar{\bar{S}}^{LiCl}_{Cl^-}$.

Radiolysis of Methylcyclohexane. I. Effects of Temperature and Electron Scavengers on Hydrogen Formation

Toyoaki KIMURA, Tetsuo MIYAZAKI, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 15, 1968)

The effects of temperature and electron scavengers on the hydrogen yield in the radiolysis of methylcyclohexane have been investigated by conventional kinetic techniques. The G value for hydrogen formation from pure methylcyclohexane varied from 4.9 to 4.4 in the range from room temperature to liquid nitrogen temperature. In the iodobenzene-methylcyclohexane system, the decrease in hydrogen yield was equal to the yield of benzene produced within experimental error. It is concluded that the benzene is formed through H atom abstraction from the solvent molecules by phenyl radicals which are formed by dissociative electron attachment to iodobenzene and that the benzene yield indicates the scavenged electron yield. Furthermore, a kinetic treatment for electron scavenging in the glassy state was presented. In the N_2O-methylcyclohexane system, it was found that the ratio of the nitrogen yield, $G(N_2)$, to the decrease in hydrogen yield, $\Delta G(H_2)$, is 2 in the temperature range from room temperature to -140°C, 1 at -160°C, and increases from 1 to 4 with increasing N_2O concentration at -196°C, respectively.

The mechanism of radiolysis at -196°C has been investigated mainly by physical methods such as ESR and optical absorption measurements but rarely by chemical methods which involve product analysis. Since it is difficult to apply information obtained by physical methods at -196°C directly to the mechanism of radiolysis at room temperature, it seems useful to get information by chemical methods at -196°C. If both physical and chemical methods are applied to the same system, it can be expected that deeper understanding of the radiolysis mechanism will be obtained. For this purpose we have made a study of the radiolysis of methylcyclohexane at room temperature, -196°C, and several temperatures between room temperature and -196°C. Hitherto, the radiolysis of methylcyclohexane has been studied in the liquid[1-3] and gas phases,[4,5] but not in the glassy state at -196°C.

We studied the effects of temperature on the hydrogen yield in γ-irradiated pure methylcyclohexane, N_2O-methylcyclohexane, and iodobenzene-methylcyclohexane systems. It is well known that organic halides scavenge an electron to yield a halogen anion and a radical.[6,7]

$$RX + e^- \rightarrow R\cdot + X^- \qquad (1)$$

In the case of iodobenzene, the phenyl radical was not detected by ESR[8] in γ-irradiated organic glass at -196°C. This fact indicates that the phenyl radical in hydrocarbon glass abstracts an H atom from the solvent molecule even at -196 °C.[8] Nitrous oxide has extensively been used as an electron scavenger in irradiated gaseous,[5,9-12] liquid,[13-17] and solid[18] hydrocarbons. In this work, an attempt is made to estimate the scavenged electron yield in liquid and glassy methylcyclohexane using iodobenzene and nitrous oxide as electron scavengers and the mechanism of electron scavenging in the glassy state as well as the liquid state is considered.

partly after purification. Being passed through a silica gel column, methylcyclohexane was dried over calcium hydride *in vacuo* until bubbles of hydrogen gas could not be seen. Then the methylcyclohexane was transferred by vacuum distillation to a glass tube coated with a sodium mirror to remove water, passed through soda-lime which had been thoroughly dried and degassed in order to remove carbon dioxide, transferred to another glass tube with a break-seal by vacuum distillation and sealed off. The difference between the results obtained with methylcyclohexane with and without purification was negligible.

Tokyo-Kasei extra pure iodobenzene was passed through a silica gel column, and distilled *in vacuo*. The middle fraction was used. Takachiho-Shoji Co. pure reagent N_2O (99.9%) was used as received.

Sample Preparation. Amounts of methylcyclohexane and iodobenzene were measured volumetrically. Usually 1 m*l* of methylcyclohexane was used. Solutions in irradiation glass cells (equipped with a break-seal and usually 2 m*l*) were degassed by the freeze-pump-thaw technique until bubbles were hardly observed and then sealed off. Nitrous oxide was introduced into a bulb of known volume to the desired pressure and then condensed into the irradiation cell.

Irradiation. A 3000 Ci ^{60}Co source was used for irradiation. The doses used are shown in Table 1.

TABLE 1. DOSES AT VARIOUS IRRADIATION TEMPERATURES

Irradiation temperature	Dose
Room temperature	3.06×10^{20} eV/g
Dry ice - ethanol temperature	3.19×10^{20} eV/g
−123°C	7.99×10^{19} eV/g
−140°C	7.99×10^{19} eV/g
−160°C	2.86×10^{19} eV/g
−196°C	2.75×10^{20} eV/g

The dose rate was determined by Fricke dosimetry with nitrogen saturated ($G(Fe^{3+})=8.07$). Irradiations were performed at room temperature (20°C), dry ice-ethanol temperature, and liquid nitrogen temperature. In addition, the experiments were performed at −123, −140, and −160°C. To keep the sample at −123 and −140°C slushy ethanol and ethanol - *n*-propanol mixture, chilled by mixing with liquid nitrogen, were used respectively. The experiments at −160°C were performed by blowing nitrogen vapor from liquid nitrogen against the samples. Blowing was controlled automatically to keept the temperature within ±2.5°C. These temperatures were measured with a chromel-alumel thermocouple during irradiation to be −123±2.5, −140±5, and −160±2.5°C, respectively.

Analysis. Gaseous products not condensable at liquid nitrogen temperature were collected by a Toepler pump and determined the volume by a gas burette. Then the gas was circulated about 20 cycles through a cupric oxide furnace heated at 220—260°C and a liquid nitrogen trap to convert hydrogen into water. The residual gas was recollected and determined the volume again. Benzene was analyzed by a Hitachi-K53 gas chromatograph with FID using a column of *n*-hexatriacontane (4 mm×2 m).

Results

Pure Methylcyclohexane. The *G* value of hydrogen from pure methylcyclohexane depended little upon the irradiation temperature and amounted to 4.9 at room temperature and 4.4 at −196°C. The *G* value at room temperature agrees with Freeman's value.[1] There are no previous data on the *G* value at −196°C.

Iodobenzene - Methylcyclohexane System. The *G* values for hydrogen and benzene produced from mixtures of methylcyclohexane and iodobenzene irradiated at room temperature and −196°C are shown in Figs. 1 and 2, respectively. At both temperatures, $G(H_2)$ decreased with

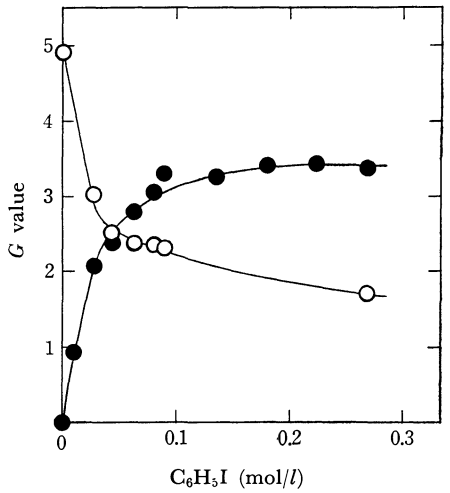

Fig. 1. Yields of hydrogen and benzene from the iodobenzene-methylcyclohexane system irradiated at room temperature.
○, $G(H_2)$; ●, $G(C_6H_6)$

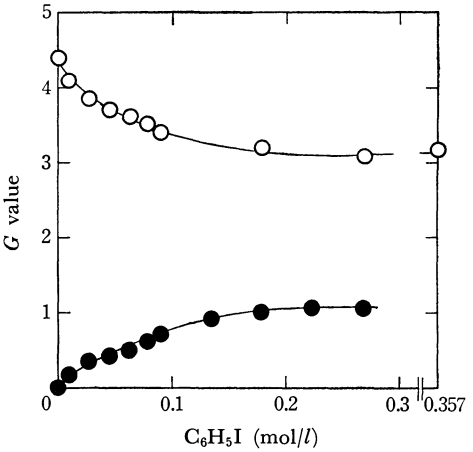

Fig. 2. Yields of hydrogen and benzene from the iodobenzene-methylcyclohexane system irradiated at −196°C.
○, $G(H_2)$; ●, $G(C_6H_6)$

increasing iodobenzene concentration more effectively than in N_2O-methylcyclohexane systems which will be described later on. This seems to indicate that iodobenzene scavenges electrons more effectively than N_2O both in the liquid and glassy states. On the other hand, $G(C_6H_6)$ increases with increasing iodobenzene concentration. Further it should be noted that the decrease in hydrogen yield is equal to the increase in benzene yield at any iodobenzene concentration within experimental error. This result indicates that one molecule of benzene is produced by quenching one precursor of hydrogen.

N_2O-Methylcyclohexane System. The yields of hydrogen and nitrogen produced from mixtures of methylcyclohexane and N_2O irradiated at room temperature, dry ice - ethanol temperature and -196°C are shown in Figs. 3, 4 and 5, respectively. The G values of hydrogen and nitrogen from pure methylcyclohexane and methylcyclohexane containing 0.3 M of N_2O irradiated at various temperatures are shown in Fig. 6. The hydrogen yield from methylcyclohexane containing 0.3 M of N_2O was nearly constant in the range from room temperature to -140°C, changed from 2.5 to 3.8 (G unit) at a temperature between -140 to -160°C, and remained constant in the temperature range from -160 to -196°C. These results seem to indicate that the efficiency of electron scavenging in these systems changes significantly at a temperature between -140 to -160°C.

In the range from room temperature to -140°C, the following relationship holds between the nitrogen yield and the decrease in hydrogen yield at any N_2O concentration,

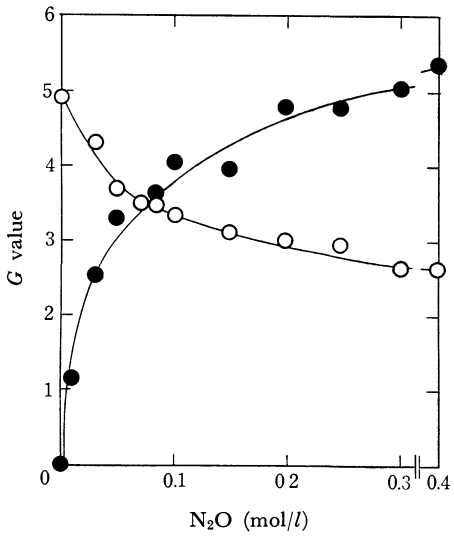

Fig. 3. Yields of hydrogen and nitrogen from the N_2O-methylcyclohexane system irradiated at room temperature.
○, $G(H_2)$; ●, $G(N_2)$

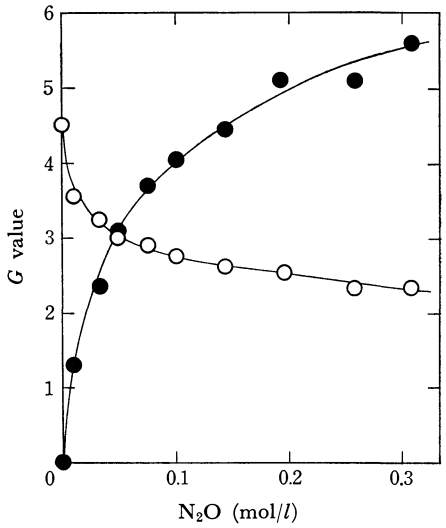

Fig. 4. Yields of hydrogen and nitrogen from the N_2O-methylcyclohexane system irradiated at dry ice-ethanol temperature.
○, $G(H_2)$; ●, $G(N_2)$

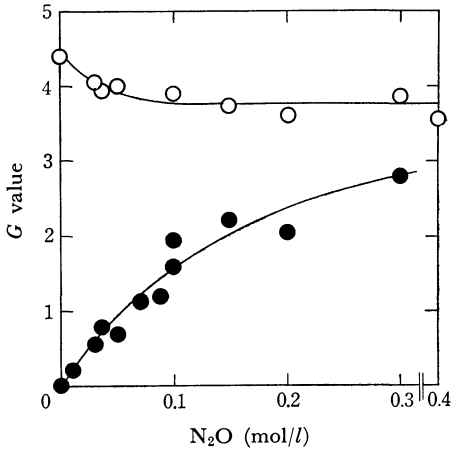

Fig. 5. Yields of hydrogen and nitrogen from the N_2O-methylcyclohexane system irradiated at -196°C.
○, $G(H_2)$; ●, $G(N_2)$

$$G(N_2) = 2\Delta G(H_2) \quad (2)$$

Such a relationship has been reported by other workers for the radiolysis of cyclohexane at room temperature.[15,16] However, at -196°C the ratio of the nitrogen yield to the decrease in hydrogen yield increased from 1 to about 4 with increasing N_2O concentration.

$$G(N_2)/\Delta G(H_2) = 1\text{—}4 \quad (3)$$

The mechanism of nitrogen formation from the mixtures of methylcyclohexane and N_2O in the range from room temperature to -140°C differs apparently from that at -196°C. Furthermore, at -160°C the ratio, $G(N_2)/\Delta G(H_2)$, was 1 at N_2O concentration of 0.3 M.

Discussion

Iodobenzene - Methylcyclohexane System. As is shown in Figs. 1 and 2, the hydrogen yield decreases and the benzene yield increases with increasing iodobenzene concentration. Therefore it is considered that iodobenzene scavenges electrons to produce I^- and the phenyl radical, the latter of which immediately abstracts a hydrogen atom from the solvent molecule (methylcyclohexane) to form benzene.[8,19]

$$MCH \rightsquigarrow MCH^+ + e^- \quad (4)$$

$$MCH^+ + e^- \rightarrow H_2 + \text{residue} \quad (5)$$

$$C_6H_5I + e^- \rightarrow C_6H_5\cdot + I^- \quad (6)$$

$$C_6H_5\cdot + MCH \rightarrow C_6H_6 + MCH\cdot \quad (7)$$

Hydrogen atom abstraction from hydrocarbons by phenyl radicals was previously reported by Bennet *et al.*[19] Our experimental results also support the mechanism described above. If benzene is produced by Reactions (6) and (7), the decrease in hydrogen yield must be equal to the yield of electrons scavenged by iodobenzene and consequently equal to the benzene yield.

$$\Delta G(H_2) = G(C_6H_6) \quad (8)$$

It was found that this relationship holds both in the liquid and glassy states (Figs. 1 and 2). Thus it is concluded that the benzene yield corresponds to the scavenged electron yield. The limiting G value of benzene formation in methylcyclohexane glass at −196°C is about 1.1 which is in good agreement with $G(CH_3\cdot)$ in 3MP and MCH glasses containing CH_3I reported by Shirom and Willard.[20] It should be noted that iodobenzene may be used to measure the scavenged electron yield by the yield of benzene produced.

We now consider the kinetics of electron scavenging. Recently a kinetic treatment of electron scavenging in liquids has been presented by Freeman.[21] In the present treatment the probability of electron scavenging by solute in liquid methylcyclohexane is quoted from that calculated by Freeman. We have calculated the probability of electron scavenging in the glassy state at −196°C by extending Freeman's treatment. In these calculations the following assumptions are made: (i) In the glassy state at −196°C, the mobility of positive ions and the diffusion constant of scavenger (iodobenzene) are negligibly small compared with those of electrons, *i. e.*,

$$u_+ \ll u_- \quad \text{and} \quad D_s \ll D_- \quad (9)$$

where u_+ and u_- are the mobility of positive ion and electron respectively, and D_s and D_- are the diffusion constant of iodobenzene and an electron, respectively. In other words, electrons in the glassy state are treated as "quasifree" electrons,*1 while electrons in the liquid state are treated as "solvated" electrons. (ii) The following equation is used:

$$u/D = \boldsymbol{k}T/e \quad (10)$$

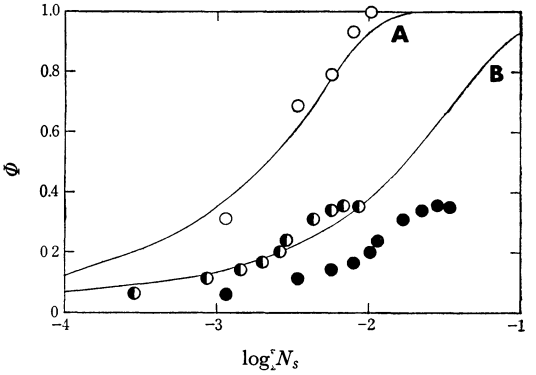

Fig. 7. Probability of electron scavenging in methylcyclohexane.
N_s, mole fraction of iodobenzene; A, calculated curve at room temperature; B, calculated curve at −196°C; ○, observed probability, $G(e^-)_s/G(e^-)_0$, at room temperature, $G(e^-)_0=3$; ●, observed probability at −196°C; ◐, observed probability, assuming aggregation, at −196°C.

20) M. Shirom and J. E. Willard, *J. Chem. Phys.*, **47**, 286 (1967).

21) G. R. Freeman, *ibid.*, **46**, 2822 (1967).

*1 The term quasifree electrons was used as those neither trapped nor solvated in rigid matrices.

where k is Boltzmann constant, T is the absolute temperature, and e is the charge on an electron. (iii) In the glassy state at −196°C, the initial separation distances between positive ions and electrons may be reduced to 70% of those in the liquid state at room temperature, since the density of the medium at −196°C is 1.4 times that at room temperature.

The calculated curve for the probability of electron scavenging in methylcyclohexane at room temperature (quoted from Freeman's results) and that at −196°C calculated here are shown in Fig. 7. The experimental values are also plotted in Fig. 7. In the liquid state at room temperature, the probabilities of electron scavenging obtained by the experiments are in good agreement with the calculated ones, but those in the glassy state at −196°C are a little lower than the calculated results. The reason for this may be explained by assuming aggregation of iodobenzene molecules in nonpolar solvents. Aggregation of organic halides in hydrocarbon glasses has also been suggested by Willard *et al.*[22] and Hamill *et al.*[23] If iodobenzene molecules aggregate in methylcyclohexane glass, the effective concentration of iodobenzene would be lower than the apparent concentration. Assuming the effective concentration to be a quarter of the apparent concentration, the probabilities of electron scavenging were recalculated and plotted in Fig. 7. As is shown in Fig. 7, if it is assumed that three or four iodobenzene molecules aggregate, the probability of electron scavenging obtained by the experiments is in fairly good agreement with the calculated curve. Since the encounter efficiency, f_-, at −196°C is expected to be smaller than 1, the calculated curve probably shows the maximum probability of electron scavenging. Thus it is concluded that electrons in rigid matrices at −196°C may be treated as "quasifree" electrons, while electrons in the liquid state can be treated as "solvated" electrons.[21]

N_2O-Methylcyclohexane System. Nitrous oxide scavenges electrons ejected from γ-irradiated methylcyclohexane to give N_2 and O^- and therefore causes the decrease in hydrogen yield.

$$N_2O + e^- \rightarrow N_2 + O^- \qquad (11)$$

The ratio of the nitrogen yield to the decrease in hydrogen yield indicates that nitrogen is not formed only by single electron attachment process (Reaction (11)) except at −160°C. The other mechanisms of nitrogen formation than the single electron attachment have been proposed by some workers; (i) O atom abstraction from N_2O molecule by O^-,[9] (ii) chain reactions initiated by H atom abstraction from solvent molecules by O^-,[5] (iii) energy transfer from excited solvent molecules to nitrous oxide molecules.[17] However, at −196°C, it is difficult to explain the nitrogen formation by Mechanism (i) or (ii) because $G(N_2)/\Delta G(H_2)$ reaches 4. This ratio will be 2 according to Mechanism (i) and possibly 4 if the chain reactions by (ii) would more easily occur at −196°C than room temperature. The energy transfer (iii) cannot explain the experimental curve shown in Fig. 6. As a possible mechanism at −196°C the following reaction is considered:

$$O^- + N_2O \rightarrow O + N_2O^- \qquad (12)$$

$$N_2O^- \rightarrow N_2 + O^- \qquad (11')$$

The reaction (12) was observed by Paulson in mass spectrometric study.[24] It would be necessary for Reactions (12) and (11') to proceed that nitrous oxide molecules aggregate at −196°C. Such aggregation may be possible because liquid nitrogen temperature is below the glass transition temperature of methylcyclohexane.[25] As is shown in Fig. 8, the increase of $G(N_2)/\Delta G(H_2)$ from 1 to 4 with increasing N_2O concentration seems to indicate this aggregation. However, it is also uncertain if the above reactions occur at −196°C, because Reaction (12) is endothermic in the gas phase.[24] Thus the mechanism for formation of nitrogen from mixtures of nitrous oxide and methylcyclohexane (as well as other hydrocarbons) is not clear at present and remains to be resolved in future.

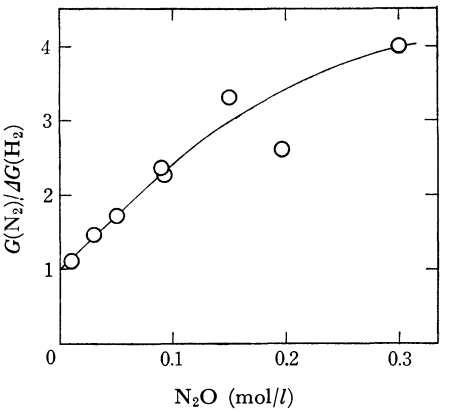

Fig. 8. The ratio of $G(N_2)/\Delta G(H_2)$ *vs.* N_2O concentration.

Mechanism of Hydrogen Formation. The mechanism of hydrogen formation may be written as follows:

22) R. F. C. Claridge and J. E. Willard, *J. Am. Chem. Soc.*, **89**, 510 (1967).
23) E. P. Bertin and W. H. Hamill, *ibid.*, **86**, 1301 (1964).
24) J. F. Paulson, "Ion-Molecule Reactions in the Gase Phase," ed. by F. Gould, American Chemical Society Publications, Washington, D. C. (1966).
25) M. R. Carpenter, D. B. Davies and A. J. Matheson, *J. Chem. Phys.*, **46**, 2451 (1967).

$$C_7H_{14} \xrightarrow{\sim\sim} \begin{cases} C_7H_{14}^* & (13) \\ C_7H_{14}^+ + e^- & (14) \end{cases}$$

$$C_7H_{14}^* \rightarrow H(\text{hot}),\ H(\text{thermal}),\ \text{and/or}\ H_2 \quad (15)$$

$$C_7H_{14}^+ + e^- \rightarrow \begin{cases} H_2 + C_7H_{12} & (16) \\ H(\text{hot}) + C_7H_{13}\cdot & (17) \\ H(\text{thermal}) + C_7H_{13}\cdot & (18) \end{cases}$$

At room temperature both hot and thermal hydrogen atoms can abstract an H atom from the solvent molecule to yield a hydrogen molecule and a solvent radical.

$$H(\text{hot}) + C_7H_{14} \rightarrow H_2 + C_7H_{13}\cdot \quad (19)$$

$$H(\text{thermal}) + C_7H_{14} \rightarrow H_2 + C_7H_{13}\cdot \quad (20)$$

Since thermal H atoms cannot abstract H atoms from solvent molecules at −196°C, they must combine one another or with the solvent radicals. The hydrogen yield from pure methylcyclohexane irradiated at −196°C decreases by 0.5 G unit in comparison with that at room temperature (Fig. 6). If the decrease in hydrogen yield is due to thermal H atoms, the yield of thermal H atoms may be estimated to be lower than 1.0 (G unit).

As has been described already, one molecule of benzene is formed by scavenging an electron and decreasing one hydrogen molecule at −196°C as well as room temperature. Therefore one molecule of hydrogen is formed by neutralization of a positive ion and an electron. A large fraction of hydrogen formed by neutralization will be hot, since its G value is expected to be 4 from W value and that of thermal H atoms is estimated to be about 1.0. Consequently the two solvent radicals produced by Reactions (17) and (19) seem to be very close to each other in the solid state. Then it will be suggested that the amount of trapped radicals does not increase after neutralization, since recombination or disproportionation of these two radicals may immediately occur even at −196°C. Further study on this point is being planned.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2866—2871 (1968)

The Structure of Meisenheimer Complex as Determined by X-ray Crystal Analysis

Hideo UEDA,*1 Noriyoshi SAKABE and Jiro TANAKA*2

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya

and Akio FURUSAKI

Faculty of Science, Kwansei Gakuin University, Nishinomiya, Hyogo

(Received May 16, 1968)

The structure of the Meisenheimer complex has been determined by the X-ray method. The complex is characterized by a symmetrical structure, in which the two methoxyl groups are nearly equivalent to each other. The results showed a peculiar shape of the reaction intermediate, the substituted carbon atom is transformed into a tetrahedral shape, while the planarity of the whole molecule is kept with an increased conjugation between the nitro group and the ring system.

The Meisenheimer complex, a reaction intermediate in a nucleophilic substitution reaction, has been widely investigated from both chemical and structural points of view. The structural formula (I) proposed as an explanation of the chemical behavior has been discussed by many people[1-5]; recent nuclear magnetic resonance results[6,7] indicate that the two methoxyl groups are equivalent in solution.

The crystal of the complex was first isolated by Meisenheimer,[1] while preliminary structure reports have been presented by us[8] and by Destro, Gramaccioli and Simonetta[9] independently. The present paper will describe the full details of the structure of the 1,1'-dimethoxy-2,4,6-trinitrobenzene potassium dihydrate, $(K^+[C_6H_2(NO_2)_3(OCH_3)_2]^- \cdot 2H_2O)$.

Experimental

The material was obtained from the reaction of picryl chloride and potassium methoxide. It was recrystallized from an acetonitrile solution. The crystal includes two molecules of water, which has been confirmed by the elemental analysis (Found: C, 27.36; H, 3.91; N, 11.96%. Calcd for $C_8H_8O_8N_3K \cdot 2H_2O$: C, 27.50; H, 3.45; N, 12.00%.). The unit-cell dimensions and space group were determined by the oscillation and by Weissenberg photographs. The three-dimensional intensity data were collected using Cu$K\alpha$ radiation with a Weissenberg camera by the multiple-film technique for layer lines 0—5 about the b axis and for layer lines 0—5 about the c axis. The intensities were measured visually, and 1897 independent data were obtained. The scaling of the intensity data, including corrections for different films, corrections for Lorentz and polarization factors, and Wilson's statistical-data analysis, were performed on the HITAC 5020 computer at the Computation center of the University of Tokyo. No corrections were made for either absorption or extinction, since the crystal used was sufficiently small in size for these effects to be neglected.

Crystal Data. $K^+[C_6H_2(NO_2)_3(OCH_3)_2]^- \cdot 2H_2O$ MW 348, Triclinic, $P\bar{1}$ $a=9.36\pm0.02$, $b=10.84\pm0.02$, $c=7.40\pm0.02$ Å, $\alpha=87°40'$, $\beta=106°43'$, $\gamma=102°45'\pm 20'$, $Z=2$.

The crystal density, determined by the floatation method in a carbon tetrachloride and methylene iodide mixture, was 1.64 g·cm^{-3}, while the calculated value was 1.65 g·cm^{-3}. No systematic absent spectra have been found.

Structure Analysis. A three-dimensional Patterson synthesis was made using the observed structure factors. The position of the potassium atom was easily found after ascertaining the highest peak. By the aid of the image-seeking method on the Patterson map, we were able to find the location of the benzene ring. At this stage the trial coordinates for all the atoms except the two water molecules were determined, and a least squares refinement with isotropic temperature factors was initiated. After several refinements the R-factor was 26%, at this stage the Fourier synthesis was done, and the locations of two water molecules were established. Including the water molecules, the least-squares refinement was then repeated, the R-factor was 0.16. Using the anisotropic temperature factors for all the atoms the final R-factor was found to be 0.130. The atomic coordinates determined are listed in Table 1, together with the anisotropic temperature factors. The calculated and observed structure factors for all 1897 reflections are kept at the Chemical Society of Japan*[3].

Results and Discussion

The bond distances and angles in the Meisenheimer complex are shown in Figs. 1 and 2. The standard deviations for atomic positions are tabulated in Table 2, the maximum standard deviation for ring carbon atoms is 0.013 Å, while that for substituent methoxyl groups is 0.016 Å. The standard deviation for the bond length in the benzene ring is 0.017 Å, while the values for the substituents are 0.019 Å.

The most important result concerning the structure is that the two methoxyl groups are perfectly equivalent, this confirms the earlier chemical and spectroscopic evidence concerning the symmetrical structure. The lengths of C(1)-O(1) and C(1)-O(2) bonds are 1.42 Å, normal for saturated compound. The C(7), O(1), C(1), O(2) and C(8) atoms are almost on a plane, which can be represented by the equation $0.4951\,X+0.8618\,Y-0.1106\,Z-1.2544=0$ in which the X, Y, and Z coordinates, in Å units, refer to the orthogonal axes a′, b and c′. The orthogonal axes were b, the crystal axis, a′, the projected a axis (a sin γ), and third axis, c′, perpendicular to a′ and b. The deviations from this plane are shown in Table 3. This plane makes an angle of 87°49′ with the

O-2	0.039
C-8	−0.032

benzene-ring plane; this implies that the methoxyl group plane bisects the benzene ring. It also means that the C(1) carbon atom is nearly tetrahedral and is coplanar with the rest of the benzene ring. This conformation is recognized to be the least-hindered structure from the steric repulsion of the nitro group. The substituted benzene ring keeps its planarity; the plane can be represented by the equation $0.8250X-0.3683Y+0.4287Z-2.6464=0$. The deviations from this plane for the ring and nitrogen atoms are tabulated in Table 4. The maximum deviation for ring atoms is 0.03 Å at C(2). The bond angles around the C(1) atom are interesting; the C(2)-C(1)-C(6) angle is 108.8° a nearly exact tetrahedral angle, while the O(1)-C(1)-O(2) angle is 100.1°, appreciably smaller than the tetrahedral. The strain produced by this distrotion is significant; it may be explained in terms of the steric repulsion between the methyl groups and the benzene ring, since the C(2)-C(8) and C(6)-C(8) distances are 2.95 Å, both smaller than the sum of the van der Waals radii of two carbon atoms. The bond lengths of C(2)-C(3) and C(5)-C(6) are shorter than those of C(3)-C(4) and C(4)-C(5); this means that the double bonds are localized, as in the structural formula (I) rather than delocalized, as in the structure (II). Of the three nitro groups, the one at the para-position and that at the C(2) ortho-position are tilted 6°30′ and 5°30′ to the benzene ring respectively; the third one, at the C(6) ortho-position, is twisted as much as 11°19′. The crystal structure of 2,4,6-trinitrophenetole, a related parent compound of the nucleophilic substitution reaction, was recently analyzed by Gramaccioli, Destro and Simonetta[10]; it was found that the nitro group at the para position is tilted 3°, the one at the ortho-position is twisted 33°, and the third, at the other ortho-position, is rotated 62°.

(II)

In the present complex three nitro groups are much plainer with the benzene ring than with the trinitrophenetole; this means that the conjugation between the nitro groups and the benzene ring is increased, presumably because an excess electronic charge delocalizes between the nitro groups and the benzene ring. This explanation is also supported by the recent theoretical calculations of Hosoya, Hosoya and Nagakura[11] on this ion. Although the bond lengths of C(1)-C(2) and C(1)-C(6) are slightly different, the present results are not accurate enough for exact discussion. However, these bond lengths are somewhat shorter than the usual single bond length of 1.54 Å; this may be attributed to the hyperconjugation effect of the pseudo π-orbital, composed of two C-O bonds. If we assume that the shortening of the C(1)-C(2)

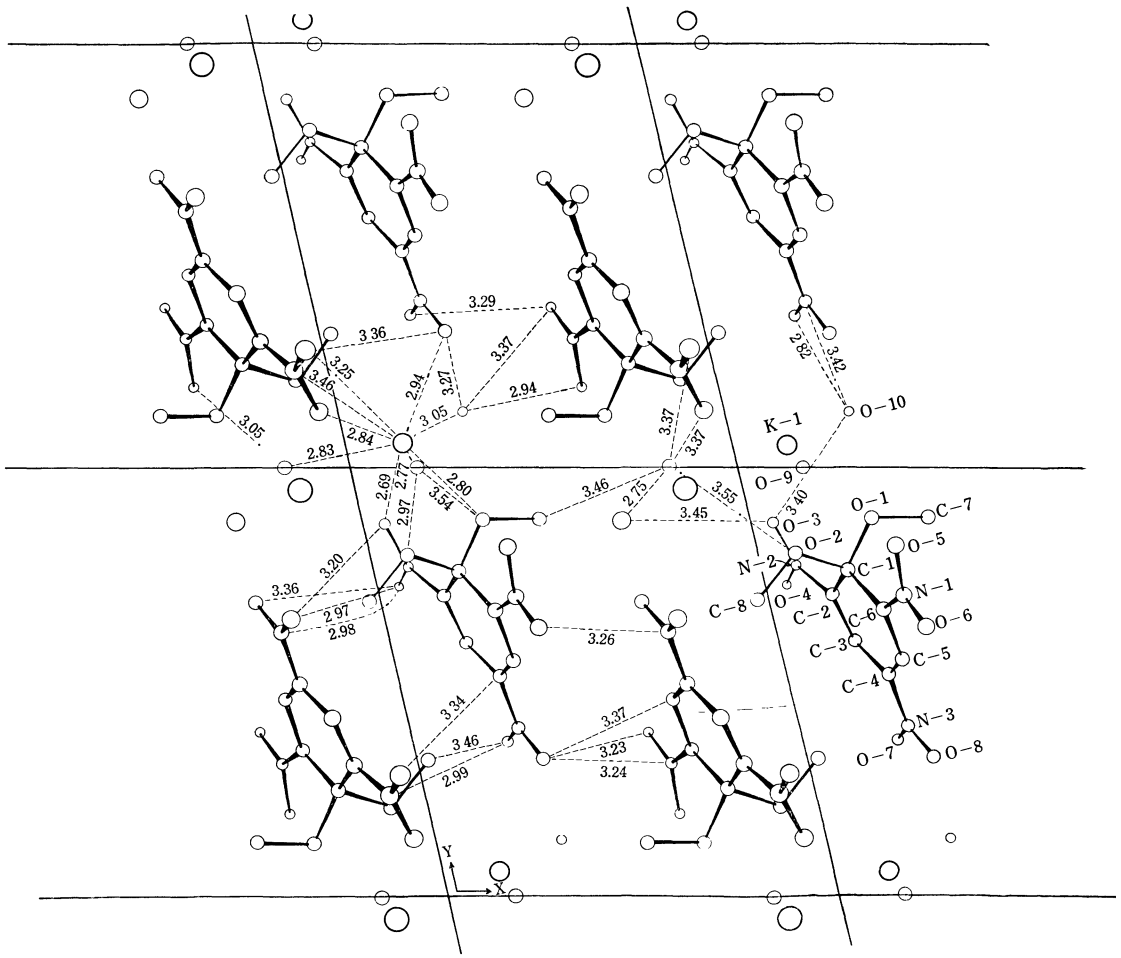

Fig. 3. Interatomic distances between the complex, potassium ion (large and heavy medium circles) and crystalline water (light medium circle and small circles).

or C(1)-C(6) bonds is correlated to the hyperconjugation, it is found that the shorter these bond lengths, the smaller the twisting of the nitro groups at the ortho-positions.

The comparison of the three C-N bond lengths indicates that the shortest one is at the para-position; this is in accord with the structure (I). The distances, C(2)-N(2) and C(6)-N(1), are slightly different from each other, and they are in order on the reverse of that suggested by the magnitude of the conjugation effect. The asymmetry of the Meisenheimer complex with regard to the two ortho nitro groups is unthinkable in a solution. In a crystal, however, the location of the potassium ion is not symmetrical to the three nitro groups. The close distances between the potassium ion and the complex are at two oxygen atoms, (O(3) and 0(8)), of the nitro groups and O(1) and O(2) of the methoxyl groups, as is shown in Fig. 3. The potassium ion in a crystal will attract a negative charge on the neighboring oxygen atoms; as a result, the N-O bond will be lengthened and the nitro group will be more coplanar with the benzene ring. The nitro group at the C(6) ortho position has not potassium ion in the neighborhood; this can explain the largest twisting of this nitro group.

Finally, we should comment on the structure of this complex ion in connection with the mechanism of the nucleophilic substitution reaction. Since Wheland[12] calculated the resonance energy of the activated complex of the substitution reaction, there have been many studies concerning the structure of the reaction intermediate. Two structural formulae, I and II have been proposed, but the structure has not yet been determined accurately. In the present study the complex ion is found to have a quinoid structure of I, and the substituted carbon atom takes a nearly tetrahedral form.

The unusual stability of the reaction intermediate can be explained as resulting from the fact that;

12) G. W. Wheland, *J. Am. Chem. Soc.*, **64**, 900 (1942).

(1) the unsaturated five-membered system is stable in the case of the anion; (2) the possibility of hyperconjugation at the tetrahedral carbon atom, and (3) the coplanarity of nitro groups with the benzene ring, which increases the degree of the delocalization of π-electrons.

One of the author (J. T.) wishes to express his thanks to Professor Saburo Nagakura and Dr. Toshio Sakurai for their kind advice in the early stage of experimentation.

Radiolysis of Hydrogen Cyanide in an Aqueous System.[1] II. Effects of Additives and Reaction Mechanism

Hajime OGURA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 21, 1968)

The ^{60}Co γ-irradiation of dilute aqueous solutions of hydrogen cyanide (6 mM) in the absence of oxygen yielded mainly ammonia with $G=1.9$, formaldehyde with $G=1.1$, and carbon dioxide with $G=0.8$, while $G(-HCN)=5.8$ molecules per 100 eV. Polymeric hydrogen cyanide was also observed with the $G(-HCN(polymer))\simeq 4$, which showed an intense broad absorption band in the UV region upon γ-irradiation. The following material balances were observed with the main products:

$$G(-HCN) \simeq G(NH_3) + G(-HCN(polymer)) \simeq G(CO_2) + G(HCHO) + G(-HCN(polymer))$$

The results can be interpreted in terms of a mechanism involving HCN^-, H_2CN, and $H(OH)CN$ radicals. The ratio of the rate constants for the reactions of e^-_{aq} and H atoms with hydrogen cyanide to those with several scavengers have been determined as $k(e^-_{aq}+HCN)/k(e^-_{aq}+NO_3^-)=0.019$ and $k(H+HCN)/k(H+2\text{-propanol})=1.4$, all at 17°C.

In our previous papers,[1,2] studies have been made of the radiolysis of aqueous solution of hydrogen cyanide with the purpose of elucidating the nature of the reaction, the radiolytic yields of hydrogen cyanide, and the products of the radiolysis, including the HCN tetramer.

The work reported here was undertaken in order to obtain additional information about radiolytic products and a general mechanism of the radiolysis by using several scavengers.

Experimental

The general procedures have already been described,[1] but a review will be given of what was introduced in the present experiment.

Samples. A 5-m*l* portion of an air-free solution, prepared by the conventional vacuum technique with freezing-thawing recycles, was sealed in a 20 m*l* cylindrical glass cell. Nitrous oxide purified by distillation was taken in a calibrated volume until a definite pressure and temperature had been reached and then transfered to the irradiation vessel by using liquid nitrogen. The concentration of the gas in the solution was calculated from the solubility data.[3]

Irradiation. Gamma irradiation was carried out with a ^{60}Co source at a dose rate of 1.68×10^{18} eV·ml^{-1}hr^{-1} based on Fricke dosimetry, taking $G(Fe^{3+})=15.5$.

Analysis. The nitrite ion was determined spectrophotometrically at 520 mμ by using sulfanilic acid and α-naphthylamine.[4] The formaldehyde was determined by means of chromotropic acid when the solution was irradiated in an acidic medium (H_2SO_4 pH=2). However, in the neutral and basic solutions, this method could not be used because of the formation of cyanohydrin[5] from the cyanide ion and formaldehyde produced by γ-irradiation even at low concentrations. Since it has been confirmed that cyanohydrin can also be determined by the use of an acetylacetone reagent which has been generally used for the determination of

formaldehyde in a neutral medium,[6] the concentration of formaldehyde in the presence of hydrogen cyanide in a neutral medium was estimated as follows. A mixture of the irradiated solution and the acetylacetone reagent in equal volumes was kept at 58°C for 90 min; the resulting yellow coloration was determined spectrophotometrically at 412 mμ. The validity of this method under the present experimental conditions, with 6 mM HCN, was established well. The formic acid was determined as was formaldehyde after being reduced by metallic magnesium and hydrochloric acid.[7] The hydrogen peroxide was determined by the ceric sulfate method.

Results and Discussion

Yields of Products. Figure 1 presents typical results of the radiolysis of an air-free 6 mM HCN solution at a natural pH. The initial yields of products expressed as G (molecules per 100 eV) are summarized in Table 1. By improving the analytical procedure, it became possible to observe

formaldehyde as one of major products in addition to those previously observed.[1] Besides the radiolysis products of a low molecular weight listed in Table 1, a polymeric form of hydrogen cyanide was also observed. It has been known that when a small amount of base is added to aqueous solutions of hydrogen cyanide, there appears a very strong broad absorption extending into the UV region; this formation is due to the formation of polymeric hydrogen cyanide.[8,9] In irradiated aqueous solutions of hydrogen cyanide, an absorption of nearly the same type as that chemically prepared was observed in Fig. 2, indicating the polymerization of hydrogen cyanide by γ-irradiation.*1

Figure 3 presents the increase in the absorbance at 230 mμ and 270 mμ against the absorbed dose. The wavelength at which the absorbance was measured was chosen for the sake of convenience in experimentation. The absorbance is seen to increase linearly with the dose, and, from the slope of the line, one can obtain the increase in absorbance per unit dose (−log T/dose), an increase which corresponds to the radiolytic yield of polymeric hydrogen cyanide. One can indicate

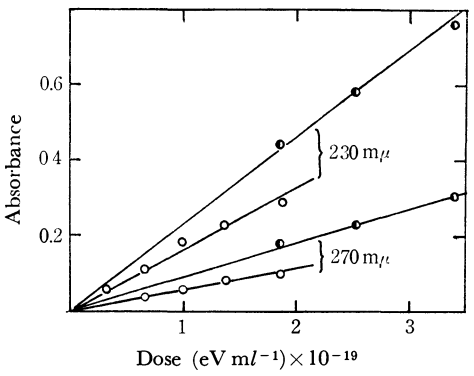

Fig. 3. Increase in absorbance at 230 mμ and 270 mμ with dose in γ-irradiated HCN solutions.
○: 6 mM HCN ◐: 23 mM HCN

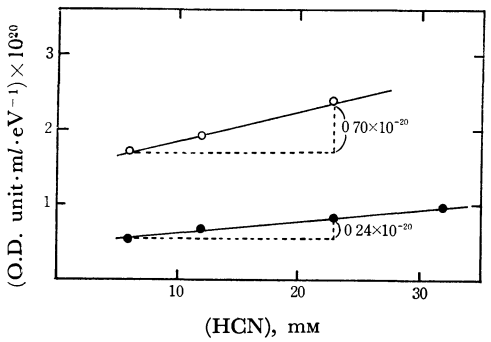

Fig. 4. Dependence of absorbance per unit dose on HCN concentration.
○: at 230 mμ ●: at 270 mμ

as examples of the calculation from Fig. 3, as written, 1.70×10^{-20} (O.D. unit ml eV^{-1}) at 230 mμ and 0.56×10^{-20} (O.D. unit ml eV^{-1}) at 270 mμ with a 6 mM HCN solution.

In Figure 4, the absorbance per unit dose is plotted against the initial concentration of hydrogen cyanide. The increase in this value with the concentration, ranging from 6 mM to 23 mM, is found to be $\Delta(-\log T/\text{dose})=0.70\times10^{-20}$ (O.D. unit ml eV^{-1}) at 230 mμ and 0.24×10^{-20} (O.D. unit ml eV^{-1}) at 270 mμ respectively. In an air-free system, G(-HCN) was determined previously to be 5.8 at 6 mM HCN and 7.5 at 23 mM HCN respectively. Assuming that this increase in the yield, ΔG(-HCN)=1.7, with the concentration is to be attributed to the increasing formation of a polymeric form of hydrogen cyanide*2 which results in an increase in the optical absorption per unit dose, $\Delta(-\log T/\text{dose})$, one can find that the radiolytic yield of hydrogen cyanide leading to the polymeric form is about G(-HCN(polymer))≃ 4 at 6 mM HCN. The difference between the total 100 eV yield of radiolysed hydrogen cyanide and the 100 eV yield of radiolysed hydrogen cyanide leading to the polymeric form is found to be 1.8. This value may correspond to the yields of the major products which give no absorption in the UV region. These products are demonstrated to be ammonia, carbon dioxide, and formaldehyde, the 100 eV yields of which are listed in Table 1. It seems that the following material balances can be established with the major products:

$$G(-\text{HCN}) \simeq G(\text{NH}_3) + G(-\text{HCN(polymer)})$$
$$\simeq G(\text{HCHO}) + G(\text{CO}_2) + G(-\text{HCN(polymer)})$$

Effect of Nitrate Ions. In a previous study,[1] it was shown that dissolved oxygen effectively reduced the radiolytic yields of hydrogen cyanide. This finding indicates the contribution of hydrated electrons to the radiolysis of hydrogen cyanide because of their high reactivity towards oxygen. To confirm this explanation, the nitrate ion, which is known as an effective scavenger[11] for the hydrated electrons, was introduced. Figure 5 illustrates the

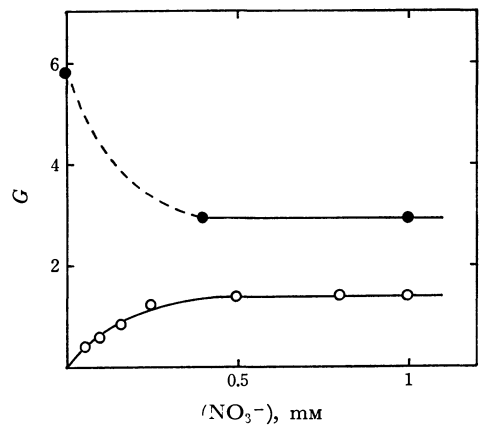

Fig. 5. Effect of nitrate ion on the radiolysis of 6 mM HCN in air-free system.
●: $G(-\text{HCN})$ ○: $G(\text{NO}_2^-)$

effect of these nitrate ions on the radiolysis of an air-free 6 mM HCN solution. The concentration of hydrogen cyanide was chosen at 6 mM, where an almost steady radiolytic yield, G(-HCN) =5.8, was observed;[1] this value is also in close agreement with the total radical yield of water. Nitrate ions are seen to reduced G(-HCN) with an increase in the concentration, leading to a steady value at 0.3 mM. Since the decrease in $G(-\text{HCN})$ at its steady value is found to be 2.9, close to the yield of hydrated electrons, $G_{e^-_{aq}}$, the effect of nitrate ions can readily be explained in terms of the scavenging action of the hydrated

*2 Unlike the increase in the total radiolytic yield of hydrogen cyanide from 6 mM up to 23 mM HCN, the observed increases in the yields of low-molecular products listed in Table 1 are almost negligible in the same concentration region.

11) H. A. Mahlman, *J. Phys. Chem.*, **67**, 1466 (1963).

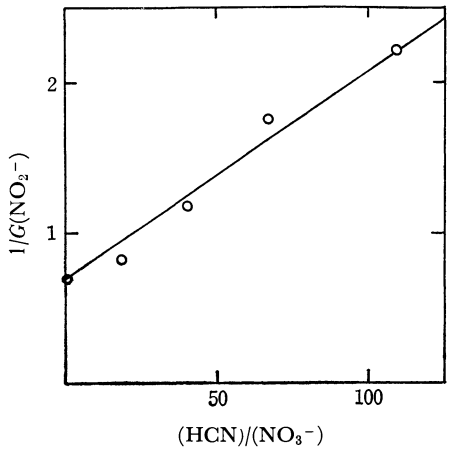

Fig. 6. Competition for hydrated electron between HCN and nitrate ion plotted according to Eq. (I).

electrons. Figure 5 also shows the yield of nitrite ions, $G(NO_2^-)$, which increases with the concentration of nitrate ions, tending to a steady value of 1.4, nearly a half of the $G_{e^-_{aq}}$ value in water radiolysis. These findings may result from the competitive reactions between hydrogen cyanide and nitrate ions for hydrated electrons:

$$e^-_{aq} + HCN \xrightarrow{k_1} P \qquad (1)$$

$$e^-_{aq} + NO_3^- \xrightarrow{k_2} NO_2 + 2OH^- \qquad (2)$$

followed by:

$$2NO_2 + H_2O \rightarrow NO_2^- + NO_3^- + 2H^+ \qquad (3)$$

$G(NO_2^-)$ can thus be expressed as:

$$\frac{1}{G(NO_2^-)} = \frac{2}{G_{e^-_{aq}}}\left\{1 + \frac{k_1(HCN)}{k_2(NO_3^-)}\right\} \qquad (I)$$

The plots of $1/G(NO_2^-)$ *vs.* $(HCN)/(NO_3^-)$ are presented in Fig. 6. The linear plots indicate the adequacy of the proposed mechanism given above. From the slope of the line, k_1/k_2 is obtained as 0.019. Taking the well-established rate constant of k_2 as 1.1×10^{10} M^{-1} sec^{-1},[12] the rate constant for the reaction (1) is found to be 2×10^8 M^{-1} sec^{-1}. As to what becomes of P, only two processes can be postulated. The one is an electron attachment of HCN

$$e^-_{aq} + HCN \rightarrow HCN^- \qquad (1a)$$

The presence of an anionic form of hydrogen cyanide is evidenced by the ESR spectra found in alkaline halide matrices at 77°K by Root *et al.*[13] Hummel *et al.*[14] also indicated its presence as an initiator of the radiation-induced polymerization of pure hydrogen cyanide. The other is possibly a dissociative electron capture process:

$$e^-_{aq} + HCN \rightarrow H + CN^- \qquad (1b)$$

Since the dissociation energy of H-CN is 114.9 kcal/mol,[15] and since the electron affinity of CN is 74 kcal/mol,[16] the reaction (1b) is not likely from a thermochemical point of view.

Effect of Nitrous Oxide. The effect of nitrous oxide[17] on the radiolysis of hydrogen cyanide and the formation of a gaseous product are presented in Fig. 7. The concentrations of nitrous oxide and hydrogen cyanide are about 16 mM and 5.8 mM respectively. It may be seen that nitrous oxide does not affect G(-HCN) and that $G(N_2)$ is very close to $G_{e^-_{aq}}$. Since $G(N_2)$ is quite negligible (<0.1) in the absence of nitrous oxide, as is shown in Fig. 7, the nitrogen observed in this experiment can be taken as almost entirely arising from the reaction (4):

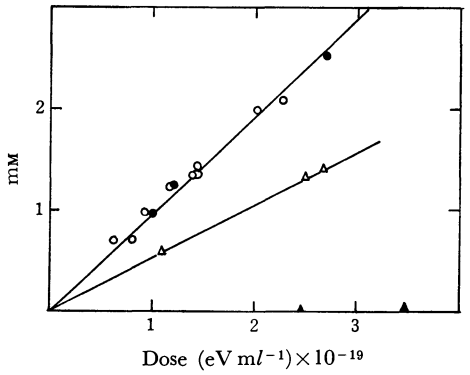

Fig. 7. Effect of nitrous oxide on the radiolysis of 6 mM HCN.
○: HCN consumed, △: N_2 produced in the presence of 16 mM N_2O, ●: HCN consumed, ▲: N_2 produced in the absence of N_2O

$$e^-_{aq} + N_2O \rightarrow N_2 + OH + OH^- \qquad (4)$$

If one assumes that the reactivity of OH radicals towards hydrogen cyanide is nearly equal to that of hydrated electrons, the above finding can be explained well.

As for the reaction of OH radicals with hydrogen cyanide, two reactions, (5a) and (5b), can possibly be expected:

$$OH + HCN \rightarrow H(OH)CN \qquad (5a)$$

$$\searrow H_2O + CN \qquad (5b)$$

The fate of the intermediate in the reaction (5a)

14) D. Hummel and O. Jassen, *Z. Physik. Chem.*, **31**, 111 (1962).
15) C. A. McDowell and J. W. Warren, *Trans. Faraday Soc.*, **48**, 1084 (1952).
16) J. T. Herren and V. H. Dibeler, *J. Am. Chem. Soc.*, **82**, 1555 (1960).
17) F. S. Dainton and D. B. Peterson, *Proc. Roy. Soc., (London)*, **A267**, 443 (1962).

will be described later. The dehydrogenation reaction (5b) is found not to be important on a thermochemical basis. If this occurred, most CN radicals would be expected to react with water, thus regenerating hydrogen cyanide.[18] On this basis, the reaction (5b) can be excluded.

Yield of Hydrogen. The radiolytic yield of hydrogen, $G(H_2)$, is found to be 0.42, which is independent of the concentration of hydrogen cyanide as well as of that of hydrogen ions, as is illustrated in Fig. 8; it is equal to G_{H_2}, the molecular yield of hydrogen from water.[19] One must, therefore, conclude that hydrogen is not formed from

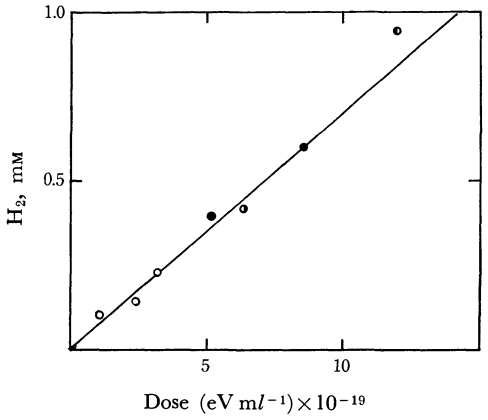

Fig. 8. Formation of hydrogen in γ-irradiated HCN solutions.
6 mM HCN; ◐: pH=1, ◑: pH=2, ○: pH=5.5
30 mM HCN; ●: pH=5.1

the abstraction of hydrogen atom from the HCN molecule:

$$H + HCN \rightarrow H_2 + CN \qquad (6a)$$

As to the fate of the H atom produced primarily from water, an addition to hydrogen cyanide may occur, in which case the adduct will be the methyleneimino radical, H_2CN, according to the reaction (6b):

$$H + HCN \rightarrow H_2CN \qquad (6b)$$

This intermediate has been identified by Cochran *et al.*[19] by means of ESR studies at a low temperature.

Scholes *et al.*[21] have been demontrated a general method of investigating the reactivity of H atoms towards some compound which are not dehydrogenated. This includes the use of 2-propanol and nitrous oxide as scavengers of H atoms and hydrated electrons respectively, and was used in studying the reactivity of H atoms towards hydrogen cyanide in an aqueous solution. In a deaerated N_2O (16 mM)+2-propanol (5—20 mM)+HCN (6 mM) system, the following three processes are involved:

$$e^-_{aq} + N_2O \rightarrow N_2 + OH + OH^- \qquad (4)$$

$$H + HCN \rightarrow H_2CN \qquad (6b)$$

$$H + (CH_3)_2CHOH \rightarrow H_2 + (CH_3)_2COH \qquad (7)$$

In the absence of hydrogen cyanide, the yield of hydrogen, $G(H_2)$, should be equal to $G_H+G_{H_2}$, where G_H denotes the yield of H atoms. In the presence of hydrogen cyanide, $G(H_2)$ is decreased by the simple competition between the reactions (6b) and (7); therefore, the following equation is derived:

$$\frac{1}{G(H_2)-G_{H_2}} = \frac{1}{G_H}\left\{1 + \frac{k_{6b}(HCN)}{k_7(CH_3)_2CHOH}\right\} \qquad (II)$$

where k_{6b} and k_7 represent the rate constants of H atoms with hydrogen cyanide and 2-propanol respectively. The plot of the observed value of $1/[G(H_2)—G_{H_2}]$ against (HCN)/(2-propanol) shown in Fig. 9, indicates the linear relation between the two quantities. From the slope of the line, k_{6b}/k_7 is found to be 1.4; hence, $k_{6b}=3\times 10^7$ M^{-1} sec^{-1}, taking $k_7=2.3\times 10^7$ M^{-1} sec^{-1}.[22]

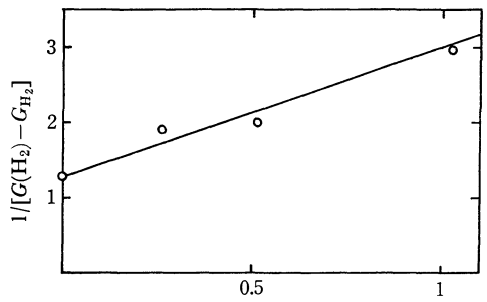

Fig. 9. Competition for H atom between HCN and 2-propanol plotted according to Eq. (II).

Reaction Mechanism. According to the findings described above and the observed yields of products, the following reaction sheme for the present study is proposed:

$$H_2O \text{ -WW-} e^-_{aq}, H, OH, H_2, H_2O_2, H^+_{aq} \qquad (0)$$

As the reactions of the reactive species produced in reaction (0) with hydrogen cyanide, the (1a), (5a), and (6b) reaction have previously been indicated. In addition to these, the reaction (8) can be proposed:

18) R. P. Mitra, D. V. S. Jain, A. K. Bannerjee and K. V. Raghavachari, *Nature*, **200**, 163 (1963).
19) A. O. Allen, "The Radiation Chemistry of Water and Aqueous Solutions," D. Van Norstrand, New York (1961), p. 47.
20) E. L. Cochran, F. J. Adrian and V. A. Bowers, *J. Chem. Phys.*, **36**, 1938 (1962).
21) G. Scholes and M. Simic, *J. Phys. Chem.*, **68**, 1738 (1964).
22) E. Hayon and M. Moreau, *J. Chim. Phys.*, **62**, 301 (1965).

$$HCN^- + H^+ \rightarrow H_2CN \quad (8)$$

Since $G(-HCN)$ is in close agreement with the total radical yield, $G_{e^-_{aq}}+G_H+G_{OH}$, this finding elucidates the fact that reaction intermediates such as HCN^-, H_2CN, and H(OH)CN will not react further with HCN at low concentrations of hydrogen cyanide (6 mM). The fates of these intermediates are supposed to be as follows:

$$H_2CN + H(OH)CN \rightarrow (HCN)_2 + H_2O \quad (9)$$
$$\searrow H_2CNH + HCNO \quad (10)$$

Methyleneimine and cyanic acid are readily hydrolysed to yield ammonia, formaldehyde, and carbon dioxide:

$$H_2CNH + H_2O \rightarrow HCHO + NH_3 \quad (11)$$

$$HCNO + H_2O \rightarrow CO_2 + NH_3 \quad (12)$$

The expected mole ratio of the products, such as $NH_3 : HCHO : CO_2 = 2 : 1 : 1$ from the reactions (11) and (12), is almost equal to that shown in Table 1. The HCN dimer is usually considered to be iminocyanomethane, NH=CH–CN. Serre *et al.*[23] and Matthews *et al.*[24] have pointed out that the HCN dimer would be more stable by 20 kcal/mol in the form of amino cyanomethylene, NH_2–$\dot{C}$=C=$\dot{N}$ (biradical), than in iminocyanomethane. Though neither isomeric form has been isolated, the HCN dimer is likely to grow into a more stable polymeric form, which is considered to be responsible for the broad absorption observed in the UV region. There was observed an increase in the UV absorption with the increase in the HCN concentration resulting from the polymeric products introduced by γ-irradiation, but it was effectively eliminated by the presence of acid or dissolved oxygen, which are effective scavengers of hydrated electrons. These results can most likely be explained in terms of the contribution of the anionic form of HCN as an initiator of the polymerization. as has been indicated by Hummel *et al.*:[14]

$$HCN^- + n HCN \rightarrow \text{polymeric products} \quad (13)$$

The presence of formic acid as a minor product may suggest that formamide is formed by:

$$H(OH)CN + H \searrow$$
$$H_2CN + OH \nearrow H_2NCOH \xrightarrow{H_2O}$$
$$HCOOH + NH_3 \quad (14)$$

Formamide is usually considered to be an intermediate yielding formic acid and ammonia in the course of the hydrolysis of hydrogen cyanide in aqueous solutions.

As is illustrated in Table 1, the observed yield of hydrogen peroxide is fairly low compared with its molecular yield in water;[19] however, its behavior is not clear in detail.

Although more work needs to be done to establish the detail of the system, the mechanism described above appears to be a plausible explanation of the present observation.

The author wishes to express his thanks to Professor M. Kondo of Tokyo Metropolitan University for his interest throughout this work. The author is indebted to Mr. K. Kurita for his assistances in this experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2877—2881 (1968)

γ-Radiolysis of a Binary Mixture of Methanol and Water. The Formation of Formaldehyde in the Radiolysis of Liquid Methanol

Hiroshi SEKI, Reiko NAGAI and Masashi IMAMURA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received May 23, 1968)

The γ radiolysis of a binary mixture of methanol and water over a wide concentration range has been investigated. The observed yields of products are expressed as a linear function of the electron fraction of methanol in the mixture. The yields of molecular hydrogen were also determined. Analyzing the results on reasonable assumptions, one could obtain for neutral water, $G^{w}_{e_S^-}=2.3$—2.5 and $G^{w}_{OH}\geq 2.6$. It was concluded that, in the radiolysis of methanol, formaldehyde may be produced through the decomposition of CH_2OH radicals in the spur region, not by the disproportionation of these radicals.

Liquid methanol and water have been long-term subjects of the most extensive study in radiation chemistry, with plenty of information being accumulated, especially for water.[1,2] The radiolysis of liquid methanol is more complicated than that of water and there remain some unsolved problems.

This work was initiated with the hope of obtaining more detailed information about reactions involving the initial species produced in irradiated methanol using precise data on aqueous systems. Although methanol is frequently used as a radical scavenger in the radiolysis of water, few studies on binary mixtures over a wide concentration range have been reported so far.[3,4]

We obtained some interesting results not only on the radiolysis mechanism of methanol but also on that of water, which will be presented in this paper.

Experimental

Extra-pure grade methanol supplied by the Wako Pure Chemical Co. was purified and dried as described previously.[5] Reagent grade anhydrous ferric chloride was used (as a scavenger) without further purification. Water was triply distilled according to Allen's description.[1]

A definite amount of purified water was pipetted into an irradiation ampoule and degassed thoroughly on a vacuum line before adding degassed methanol by distillation. Methanol-water mixtures containing ferric chloride were prepared beforehand and degassed in a small refluxing apparatus.

Irradiation ampoules were made of hard or Pyrex glass and were cleaned carefully as described previously.[5] Irradiation was carried out at room temperature with ^{60}Co γ rays at a dose rate in the vicinity of 1.5×10^{17} eV/ml·min based on a ferrous sulfate dosimeter taking $G(Fe(III))=15.5$. The dose rate was corrected for the electron density of each mixture.

The radiolysis products, hydrogen, carbon monoxide, methane, ethylene glycol and formaldehyde, were determined by methods previously used.[5] Hydrogen peroxide was determined by the Ghormely method.[6]

Results

Yields of Products. In Fig. 1 the observed yields of the main products, hydrogen, ethylene glycol and formaldehyde, were plotted as a function of the electron fraction of methanol, x, in the mixture. $G(H_2)$, $G(C_2H_6O_2)$ and $G(CH_2O)$ all appear to decrease linearly with increasing concentration of water, the yields for pure methanol being determined as 4.92, 2.95 and 2.15, respectively. (The symbol, G, is the yield as expressed by the number of molecules produced per 100eV of absorbed energy.) It should be noted that the extrapolated $G(CH_2O)$ to $x=0$ is not zero but 0.60. No hydrogen peroxide was detected for all mixtures investigated. Several separate experiments definitely indicated that no hydrogen peroxide was present even immediately after irradiation.[7] The yields of carbon monoxide and methane also show a linear dependence, the extrapolated G values to $x=0$ being zero (not shown in Fig. 1).

The observed yields can be expressed by such

·—·: the line connecting $G^{w}_{H_2}$ and G_{H_2}

linear functions of x as

$$G(H_2) = 1.52x + 3.40 \quad \text{(A)}$$

$$G(C_2H_6O_2) = 0.15x + 2.80 \quad \text{(B)}$$

$$G(CH_2O) = 1.55x + 0.60 \quad \text{(C)}$$

Yields of Molecular Hydrogen. The yield of molecular (unscavengeable) hydrogen, G_{H_2}, from γ-irradiated liquid methanol has been determined as 1.6,[8] 1.8[9] and 1.9.[10] We also determined G_{H_2} to be 1.7, using ferric chloride as a scavenger, in good agreement with published data. The yields of molecular methane and carbon monoxide were determined at the same time. Their sum is about 0.3, in agreement with the result of Choi and Lichtin.[10]

The yield of total gas as well as that of hydrogen was also determined for methanol-water mixtures containing 5×10^{-2}M of ferric chloride. The yields are plotted in Fig. 2 as a function of x. Although the plots are not linear, the extrapolated values are very close to the yield of molecular hydrogen from water, $G^{w}_{H_2}$,[11] at $x=0$, and close to the total yield of the molecular gases from methanol, $G_{H_2}+G_{CO}+G_{CH}$, and G_{H_2} at $x=1$. These results apparently indicate that the formation of molecular hydrogen from methanol or water is not prevented at all by the presence of water or methanol, respectively.

Discussion

As early as 1955, McDonell reported the γ radiolysis of methanol-water mixtures, in which only the yields of ethylene glycol and formaldehyde were determined.[3] The variations in yields are similar to the present ones, but there are some differences.

11) $G^{w}_{H_2}=0.4$ in Ref. 2 and 0.4—0.45 in Proc. 5th Informal Conf. Radiation Chemistry of Water (Univ. Notre Dame 1966), p. 27.

The variation in $G(C_2H_6O_2)$ is linear from 100% methanol ($G=2.9$) down to 30%, the linear portion of the curve to 100% water being extended $G=2.5$. The variation in $G(CH_2O)$ is also linear over the entire range. However, the yield for pure methanol is $G=1.3$ and the extrapolated yield to 100% water is zero.

Recently Schweiner *et al.* observed non-linear variation in $G(H_2)$ for methanol-water mixtures.[4] They assumed that the probability of localization of part of the absorbed energy, leading to hydrogen formation from methanol is higher for a methanol molecule than for a water molecule. No such a deviation from linearity is observed for $G(H_2)$ as well as for other yields in the present study (Fig. 1). The slight deviation observed for G_{H_2} (Fig. 2) might be due, at least in part, to some effect of the relatively high concentration of ferric chloride used, no further discussion being given here.

Equations (A), (B) and (C) could be analyzed on the reasonable assumptions described below.

Hydrogen Yield. Hydrogen is formed by three processes: molecular, ionic and radical processes. Molecular hydrogen is formed separately from methanol and water, the yields of which are represented as G_{H_2} and $G^w_{H_2}$, respectively. As mentioned in Results (Fig. 2). G_{H_2} and $G^w_{H_2}$ are not affected by the presence of water and methanol, respectively. The independent of $G^w_{H_2}$ of the presence of methanol is also supported by results from the radiolysis of aqueous solutions of CD_3OH (0.01—1.0 M).[12] Similar results were obtained in the radiolysis of 2-propanol solutions in D_2O containing nitrous oxide, in which $G(D_2)$ was found constant (0.33) over the concentration range 0.01—1.0 M 2-propanol.[13]

Irradiation of methanol and water produces both solvated electrons and hydrogen atoms. The solvated electrons which arise from methanol and water are assumed to form hydrogen atoms through Reactions (1)—(3).

$$e^-_{solv} + CH_3OH_2^+ \rightarrow H\cdot + CH_3OH \quad (1)$$

$$e^-_{solv} + CH_3OH \rightarrow H\cdot + CH_3O^- \quad (2)$$

$$e^-_{solv} + H_3O^+ \rightarrow H\cdot + H_2O \quad (3)$$

Protonated methanol, $CH_3OH_2^+$, is assumed to form through an ion-molecule reaction similar to that in the gas phase.

$$CH_3OH^+ + CH_3OH \rightarrow CH_3OH_2^+ + CH_3O\cdot, CH_2OH\cdot \quad (4)$$

The hydrogen atoms produced directly both from methanol and water, and indirectly through Reactions (1)—(3) abstract hydrogen atoms from methanol to form hydrogen.

$$CH_3OH + H\cdot \rightarrow H_2 + CH_2OH\cdot \quad (5)$$

Reactions (1) and (2) have been assumed to take place by Baxendale and Mellows,[8] the former being commonly accepted as the principal reaction of the solvated electron in liquid methanol. Reaction (2) has sometimes also been assumed to be the principal reaction.[14] Although the rate constant of Reaction (2) is less than 10^4 M^{-1} sec^{-1},[15] this reaction may become more or less important in the high concentration range of methanol studied.

These assumptions lead to the expression for the yield of hydrogen from the mixtures

$$\begin{aligned} G(H)_2 &= x(G_{H_2} + G_{e^-_s} + G_H) \\ &\quad + (1-x)(G^w_{H_2} + G^w_{e^-_s} + G^w_H) \\ &= x(G_{H_2} + G_{e^-_s} + G_H - G^w_{H_2} - G^w_{e^-_s} - G^w_H) \\ &\quad + (G^w_{H_2} + G^w_{e^-_s} + G^w_H) \end{aligned} \quad (a)$$

Here, the primary yields with superscript w refer to water, those without w to methanol.

Comparison of Eq. (a) with Eq. (A) gives the relations

$$G_{H_2} + G_{e^-_s} + G_H = 4.92 \quad (i)$$

$$G^w_{H_2} + G^w_{e^-_s} + G^w_H = 3.40 \quad (ii)$$

The yield of molecular hydrogen from neutral water seems well-established at 0.4—0.45.[11] The primary yield of hydrogen atoms from neutral water has also been established at 0.55—0.65.[2,16,17] From Eq. (ii), therefore, the yield of hydrated electrons, $G^w_{e^-_s}$, is claculated to be 2.3—2.5.

The yield of hydrated electrons has repeatedly been reported. Czapski and Allen[18] reported 2.85, Allan and Beck[19] 2.80 and Sawai[20] 2.77. Lower values have also been reported: 2.65 by Rabani and Stein,[21] 2.6 by Hochanadel and Casey,[22] 2.45 by Head and Walker,[17] 2.3 by Scholes and Simic,[23] Hayon[24] and Seddon and Allen.[25] A recent study of Russell and Freeman

gave a "free ion" yield $G^{w}_{e^-_s}=2.7$ according to their model.[26] The current value of 2.3—2.5 for the yield of the hydrated electron is in agreement with those of the lower group. In the present study, however, a plausible reaction which lowers the yield can be taken into account,

$$e^-_{solv} + H_2O_2 \rightarrow OH\cdot + OH^- \qquad (6)$$

which might also be responsible for the absence of hydrogen peroxide in the system. Reaction (6) produces OH radicals, which consecutively give CH_2OH radicals through reaction with methanol. However, as will be discussed in a latter section, the majority of CH_2OH radicals do not give formaldehyde but ethylene glycol in the bulk. The excess yield of formaldehyde observed upon extrapolation of the plot of $G(CH_2O)$ to $x=0$ (Fig. 1) is not accounted for by Reaction (6). Thus the possibility of Reaction (6) may be excluded. The excess yield of formaldehyde will be explained in a latter section.

Equation (i) indicates that the total yield of hydrogen from pure methanol is 4.92, which is the experimental value and is less than the "true" value of 5.40 deduced from the methanol-nitrous oxide system.[5] The discrepacny between these two values has been discussed previously;[5] a few experiments show that the values of $G(H_2)+G(N_2)$ obtained from methanol-waterm ixtures containing nitrous oxide fall on the line connecting $G=5.4$ ($x=1$) and 3.4 ($x=0$).

Ethylene Glycol Yield. Ethylene glycol is produced, except for a minor portion by a molecular process, by a combination reaction of CH_2OH radicals

$$2CH_2OH\cdot \rightarrow C_2H_6O_2 \qquad (7)$$

Hydroxymethyl radicals are produced through the reaction of methanol with all radicals, R·, produced in the solution (H· (including H· produced by Reactions (1)—(3)), OH·, CH_3·, CH_3O· and CH_2OH·)

$$CH_3OH + R\cdot \rightarrow CH_2OH\cdot + RH \qquad (8)$$

It is sometimes assumed that some CH_2OH radicals give rise to the formation of formaldehyde through the disproportionation reaction

$$2CH_2OH\cdot \rightarrow CH_2O + CH_3OH \qquad (9)$$

On the basis of the assumptions made above, the yield of ethylene glycol in the present system can be expressed as

$$G(C_2H_6O_2) = x\left(G_{C_2H\ o_2} + \frac{\alpha}{2}G_R\right) + (1-x)\frac{\alpha}{2}(G^{w}_{e^-_s} + G^{w}_{H} + G^{w}_{OH})$$

$$= x\left[G_{C_2H_6O_2} + \frac{\alpha}{2}G_R - \frac{\alpha}{2}(G^{w}_{e^-_s} + G^{w}_{H} + G^{w}_{OH})\right] + \frac{\alpha}{2}\left(G^{w}_{e^-_s} + G^{w}_{H} + G^{w}_{OH}\right) \qquad (b)$$

The molecular yield of ethylene glycol from pure methanol, $G_{C_2H_6O_2}$, has been determined as 0.09[27]—0.1.[10] The factor, α, represents the fraction of CH_2OH radicals which produce ethylene glycol

$$\alpha = k_7/(k_7 + k_9)$$

The superscript w refers to water, as before.

Comparing Eq. (b) with Eq. (B), one obtains the relations

$$\alpha(G^{w}_{e^-_s} + G^{w}_{H} + G^{w}_{OH}) = 5.60 \qquad (iii)$$

$$\alpha G_R = 5.72 \qquad (iv)$$

In the preceding section, we came to the conclusion that $G^{w}_{e^-_s}=2.3-2.5$ depending upon the values of $G^{w}_{H_2}$ and G^{w}_{H}. It is easily found, however, that, from Eqs. (ii) and (iii),

$$G^{w}_{OH} \geq 2.6$$

because α should not exceed unity.

On the other hand, the total yield of radicals from methanol has been determined experimentally as 6.2,[10] which is in agreement with other results.[8] If the value of 6.2 is used for G_R in Eq. (iv), α is calculated to be 0.92. The rate-constant ratio of disproportionation to combination of CH_2OH radicals, k_9/k_7, is then 0.087.[28] Applying $\alpha=0.92$ to Eq. (iii), one obtains $G^{w}_{OH}=3.0$, which is higher than the value quoted by Allen ($G=2.2$).[2]

Daniels and Wigg[29] reported $G^{w}_{OH}=2.53\pm0.10$ for NO_3^- solution, and similar and higher values have also been reported by Hochanadel and Casey[22] (2.59 for $CO+H_2$ solution), by Seddon and Sutton[30] (2.9 for NO solution) and by Sawai[20] (3.0 for 2-propanol+NO_3^- solution). Although it is not possible to give a satisfactory account for the discrepancy at present, it should be emphasized that α is close to unity, *i. e.*, the contribution of the disproportionation reaction of CH_2OH radicals to the formation of formaldehyde is rather small.

Formaldehyde Yield. As described in Results, no hydrogen peroxide was detected in

26) J. C. Russell and G. R. Freeman, *J. Chem. Phys.*, **48**, 90 (1968).

the present system. Similar results have been found for the deaerated neutral ethanol solution,[31] which was ascribed to the efficient secondary decomposition of hydrogen peroxide. In the present study, the extrapolated value of $G(CH_2O)$ to $x=0$ is 0.60 (Fig. 1), which is very close to the value for $G^{w}_{H_2O_2}$.[2] We therefore assume that this excess yield of formaldehyde results from the reaction of the CH_2OH radical with hydrogen peroxide produced molecularly from water.

$$CH_2OH\cdot + H_2O_2 \rightarrow CH_2O + H_2O + OH\cdot \quad (10)$$

A similar reaction has been suggested for C_2H_4OH radicals.[25] The occurrence of Reaction (10) does not reduce $G(C_2H_6O_2)$ because OH radicals will regenerate CH_2OH radicals.

An alternative explanation for the absence of hydrogen peroxide might be given by assuming reaction occurs between the precursor of molecular hydrogen peroxide and methanol. It does not seem that the precursor of molecular hydrogen peroxide in the radiolysis of water has been well-defined, some species other than OH radicals being proposed.[32,33] Such a reaction being assumed to occur, the possibility of OH radical being the precursor of molecular hydrogen peroxide can be excluded also from the fact that an excess yield of aldehyde is close to the value corresponding to $G^{w}_{H_2O}$. If OH radical is the precursor of molecular hydrogen peroxide, scavenging the radical with methanol in the spur region would give rise to the formation of a CH_2OH radical, most of which forms ethylene glycol as discussed in the preceding section. No further discussion on the nature of the precursor is given here.

Several reaction mechanisms for the formation of formaldehyde in the radiolysis of methanol have been discussed. Of possible mechanisms, the disproportionation reaction of CH_2OH radicals (Reaction (9)) has been ruled out as mentioned above. The disproportionation reaction of CH_3O radicals has also been proposed, especially to explain the increasing yield of formaldehyde in the radiolysis of liquid methanol by high LET (linear energy transfer) radiations[34,35]

$$2CH_3O\cdot \rightarrow CH_2O + CH_3OH \quad (11)$$

In fact, the isotopic composition of hydrogen produced by γ radiolysis of CH_3OD shows that $HD > H_2$,[36] indicating the primary yield of the CH_3O radical is greater than that of the CH_2OH radical. If Reaction (11) is responsible for the increasing yield of formaldehyde in the dense ionization tracks of the high LET radiations, the isotopic composition of the hydrogen produced in such systems should also show a tendency similar to that observed for γ radiolysis. This is not the case, but it was found that $H_2 > HD$ for radiolysis with recoiled α, ^{7}Li-particles.[36] Therefore, the second possibility as represented by Reaction (11) may be unimportant.

The remaining possibilities are molecular detachment[37,38]

$$CH_3OH \rightarrow CH_2O + H_2 \quad (12)$$

and thermal decomposition of CH_2OH radicals[37]

$$CH_2OH\cdot \rightarrow CH_2O + H\cdot \quad (13)$$

Both reactions have been proposed for the photolysis of methanol vapor. Phibbs and Darwent found that the activation energy of Reaction (13) is 29 kcal/mol, and pointed out that the reaction is increasingly important above 400°C.[37]

It may be reasonable, from the above discussions, to assume that in the radiolysis of liquid methanol, formaldehyde may be produced molecularly (in the spur region) by Reaction (13) and/or Reaction (12). The increasing yield of formaldehyde in radiolysis with high LET radiations may therefore be explained by assuming thermal spikes in these radiation tracks, which will promote Reaction (13) to produce formaldehyde in a higher yield. Similar processes have also been proposed by McDonell and Gordon.[39]

Now, the observed yield of formaldehyde can be expressed as

$$\begin{aligned} G(CH_2O) &= xG_{CH_2O} + (1-x)G^{w}_{X} \\ &= x(G_{CH_2O} - G^{w}_{X}) + G^{w}_{X} \end{aligned} \quad (c)$$

Here, G^{w}_{X} corresponds to $G^{w}_{H_2O_2}$, as mentioned above. From Eq. (C) and Eq. (c), the molecular yield of formaldehyde from pure methanol is 2.15.

ESR and Optical Studies of the Reaction Intermediates Produced from Phenyl Halides by Dissociative Electron Attachment in γ-Irradiated Organic Glasses at 77°K

Syozi NODA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 29, 1968)

ESR and optical studies have been made of dissociative electron attachment by phenyl halides and reaction intermediates produced in γ-irradiated glassy solid matrices at 77°K. Dissociative electron attachment by phenyl halides is an efficient process and the ratio of cross sections $C_6H_5I/C_6H_5Br/C_6H_5Cl$ for this process in MTHF glass is 1.5/1.0/1.0. The phenyl radical produced abstracts a hydrogen atom from solvents (MTHF, 3MP) at 77°K and is stable in aqueous alkali-metal hydroxide glass. A part of 3MP radicals in a γ-irradiated solution of phenyl bromide in 3MP at 77°K disappear by a first-order process for which $k=4.3\times10^{-2}$ min^{-1}. γ-Irradiated 3MP glasses containing phenyl halides exhibit the optical absorption spectra having characteristic absorption bands in the visible and UV region which are assigned to solute cations and hydrogen-adducts respectively.

Dissociative electron attachment by organic halides ($RX+e^-\rightarrow R+X^-$) has been shown by ESR[1,2] and optical[3] measurements to be an efficient process in glassy solid matrices whenever the electron affinity of X exceeds the bond dissociation energy of R-X. Consequently, low concentrations of organic halides may serve as electron scavengers in radiolytic systems. It is also expected that dissociative electron attachment could selectively yield the radical R from organic halides RX. Most of the previous studies are concerned with alkyl halides as solutes.

In the present work, a study was made of dissociative electron attachment by phenyl halides in γ-irradiated organic glasses and reaction intermediates produced in these systems at 77°K. ESR and optical absorption techniques were applied to detect the reaction intermediates.

Experimental

Materials. MTHF was purified by passing through an activated alumina column. 3MP and *n*-butyl chloride were purified by passing through a silica-gel column. Solvents were dried with calcium hydride. Commercially available purest phenyl halides were used with purification by vacuum distillation.

Sample Preparation. Phenyl halide was stored in vacuum and was distilled from the storage bulb, pipetted into an ESR tube or an optical absorption cell containing a known amount of solvent, then returned to the vacuum line and degassed by conventional vacuum techniques before sealing the tube or the cell.

Irradiations, ESR and Optical Measurements. Samples were prepared, γ-irradiated and measured in quartz ESR tubes (i. d. 5 mm) or optical absorption cells (1 cm × 1 cm), sealed in vacuum and immersed in liquid nitrogen prior to irradiation and subsequent measurements. They were examined using a JES-3BX ESR spectrometer and a Hitachi-Perkin-Elmer-139 UV-VS spectrophotometer. Doses were 2.3×10^5 rad and 8.0×10^4 rad for ESR and optical experiments, respectively. Photobleaching of γ-irradiated samples was performed with visible light from a tungsten lamp and using glass filters as needed.

Results

Phenyl Halides in MTHF. γ-Irradiated MTHF glasses containing phenyl halides displayed the ESR spectrum of trapped electron superimposed on that of MTHF radical, the intensity of their signals depending on solute concentration. Figure 1 shows the dependence of trapped electron or MTHF radical concentration on the concentration of phenyl iodide. It can be seen from Fig. 1 that the concentration of trapped electrons decreases and that of MTHF radicals increases with increasing phenyl iodide concentration. The concentration of MTHF radicals approaches to a limiting value of twice that of the radicals in pure MTHF at *ca.* 2 mol% solute concentration, while the concentration of trapped electrons is nearly zero at the same solution concentration.

A γ-irradiated MTHF glass containing 1.0 mol% phenyl iodide did not exhibit any absorption bands in the wavelength region $\lambda > 300$ mμ in

the optical absorption spectrum. Figure 2 shows a plot of $1/G_{C_{12}H_{10}^-}$ *vs.* the concentration of phenyl halides (iodide, bromide, and chloride) in MTHF solutions containing 0.15 mol% biphenyl. $G_{C_{12}H_{10}^-}$ is the *G*-value for biphenyl anions formed. There are linear relationships between these quantities for all the solutes. Optical measurements were made for determination of the yield of biphenyl anion, in which the extinction coefficient for biphenyl anion was taken to be 3.7×10^4 $l\,mol^{-1}\cdot cm^{-1}$ at 410 mμ.[4] As shown in Fig. 2, straight lines drawn through the experimental points can be extrapolated to the same point on the ordinate.

Phenyl Halides in 3MP. The ESR spectrum of γ-irradiated 3MP glass containing 0.2 mol% phenyl iodide was similar in shape to that of pure 3MP glass, indicating only the solvent radical (Fig. 3). However, the amount of solvent radicals produced in 3MP containing phenyl iodide was larger than that in pure 3MP under the same irradiation condition.

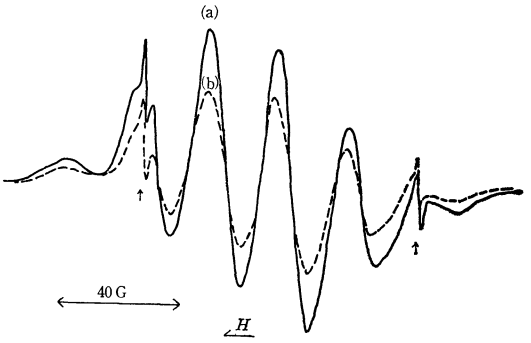

Fig. 3. ESR spectra of γ-irradiated 3MP solutions with and without phenyl iodide at 77°K. (a) 3MP containing 0.2 mol% phenyl iodide; (b) pure 3MP. Arrows indicate the signal of Mn.

4) M. R. Ronayne, J. P. Guarino and W. H. Hamill, *J. Am. Chem. Soc.*, **84**, 4230 (1962).

In γ-irradiated 3MP glasses containing phenyl halides, a part of solvent radicals disappeared much rapidly than those in pure 3MP glass. A first-order plot for the decay of such 3MP radicals at 77°K is shown in Fig. 4. The decay rate for these radicals is obtained to be $k=4.3\times10^{-2}$ min^{-1}. After the rapidly decaying 3MP radicals had disappeared, residual 3MP radicals disappeared very slowly as those in pure 3MP.

3MP glasses containing phenyl iodide or bromide, after γ-irradiation, exhibited the optical absorption spectra as shown in Fig. 5 or 6. In a 3MP glass containing 0.2 mol% phenyl iodide, the absorption bands having $\lambda_{max}=300$, 560 and 710 mμ were observed in the spectrum obtained 0.5 hr after termination of the γ-irradiation. Although the 300 mμ band did not change with time, the 710 mμ band decreased in intensity and new absorption bands having $\lambda_{max}=410$ and 520 mμ appeared in the spectrum obtained 2 hr after termination of the γ-irradiation. In a 3MP glass containing 0.2 mol% phenyl bromide, the absorption bands having $\lambda_{max}=290$ and 620 mμ and a shoulder at 330 mμ were observed in the spectrum obtained 0.5 hr after termination of the γ-irradiation. The 620 mμ band decreased in intensity and the 330 mμ band increased in the spectrum obtained 1.5 hr after termination of the γ-irradiation, while the 290 mμ band did not change with time. In a 3MP glass containing phenyl chloride, the absorption band having $\lambda_{max}=580$ mμ was observed and other bands were too broad for their maxima to be discernible in the spectrum.

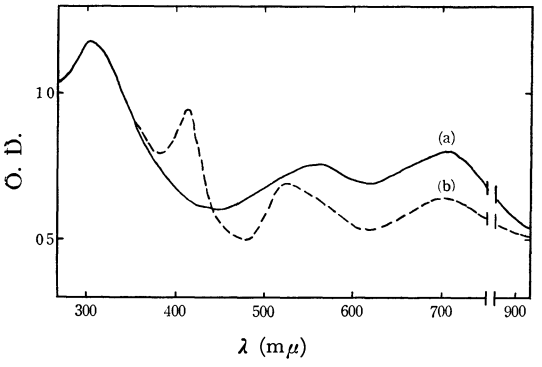

Fig. 5. Absorption spectra of a γ-irradiated solution of 0.2 mol% phenyl iodide in 3MP at 77°K. (a) 0.5 hr, (b) 2 hr after termination of the γ-irradiation.

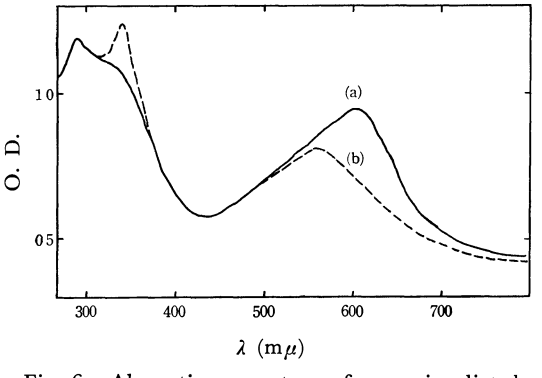

Fig. 6. Absorption spectra of a γ-irradiated solution of 0.2 mol% phenyl bromide in 3MP at 77°K. (a) 0.5 hr, (b) 1.5 hr after termination of the γ-irradiation.

Phenyl Halides in *n*-BuCl. It was found by ESR measurements that the yield of solvent radicals produced in γ-irradiated *n*-BuCl glass containing 1.0 mol% phenyl iodide was nearly equal to that in pure *n*-BuCl glass under the same irradiation condition.

γ-Irradiated *n*-BuCl glasses containing 0.5 mol% phenyl iodide or bromide displayed the optical absorption spectra having an absorption band with $\lambda_{max}=710$ or 620 mμ, respectively, in addition to the bands attributable to the intermediates from *n*-BuCl.

Phenyl Halides in Aqueous Alkali-metal Hydroxide Glass. γ-Irradiated glassy aqueous solutions of 10 mol% NaOH containing a saturated concentration of phenyl iodide exhibited a narrow

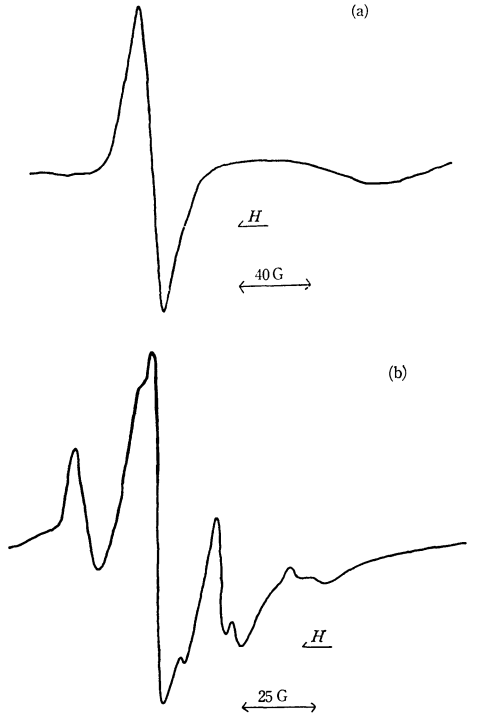

Fig. 7. ESR spectra of a γ-irradiated 10 mol% NaOH aqueous solution containing a saturated concentration of phenyl iodide at 77°K. (a) before photobleaching, (b) after photobleaching with visible light. The spectrum (b) was obtained using a 50 times greater sensitivity than the spectrum (a).

ESR singlet at $g=2.001$ and a broad singlet in the lower magnetic field (Fig. 7(a)). Photobleaching of the same sample as the preceding with visible light yielded the spectrum with the hyperfine structure as shown in Fig. 7(b).

Discussion

It is well known that trapped electrons are produced in γ-irradiated MTHF glass at 77°K.[4,5] The results that the yield of trapped electrons decreases in the presence of phenyl halides indicate that phenyl halides compete with the solvent for capturing electrons. Electrons are captured almost completely by phenyl iodide at *ca.* 2 mol% concentration in MTHF. On the other hand, the yield of MTHF radicals increases with phenyl iodide concentration, approaching to a limiting value of twice that of the radicals in pure MTHF. It is generally accepted that the MTHF radical is formed by the ion-molecule reaction $C_5H_{10}O^+ + C_5H_{10}O \rightarrow C_5H_{10}OH^+ + C_5H_9O$ in γ-irradiated pure MTHF.[6,7] The increase in the yield of MTHF radicals observed in MTHF solutions containing phenyl iodide is interpreted in terms of H-abstraction by phenyl radicals from the solvent. When electrons are captured completely by phenyl halides, the yield of phenyl radicals formed should be equal to that of MTHF cations. Therefore, at sufficiently high concentrations of phenyl iodide, the yield of MTHF radicals reaches twice that in pure MTHF.

The relative cross section for electron attachment is obtained by making use of competitive reactions for electrons between a reference solute and other solutes in MTHF. A simple kinetic treatment leads to the relation[8]:

$$\frac{1}{G_{Y^-}} = \frac{1}{G^\circ_{Y^-}} + \frac{1}{G^\circ_{Y^-}} \frac{\sigma_X[X]}{\sigma_Y[Y]} \qquad (1)$$

where Y is a reference solute of known anion spectrum, X any second solute, and σ_Y and σ_X are the respective electron attachment cross sections. G_{Y^-} and $G^\circ_{Y^-}$ are the G-values for formation of anion Y^- in solutions with and without the second solute respectively. A plot of $1/G_{Y^-}$ *vs.* $[X]$ with a fixed concentration of Y yields the relative cross section σ_X/σ_Y and extrapolation of this plot to $[X]=0$ gives $G^\circ_{Y^-}$ in Eq. (1). In the present study, in which biphenyl is used as the reference solute, $G^\circ_{Y^-}$ is obtained as 2.9 which is in agreement with the literature value.[4] The ratio of cross sections $C_6H_5I/C_6H_5Br/C_6H_5Cl$ for dissociative electron attachment in MTHF is 1.5/1.0/1.0.

The increase in the yield of 3MP radicals observed in 3MP glasses containing phenyl halides is also interpreted in terms of H-abstraction by phenyl radicals from the solvent.*1 Such an interpretation is supported by the fact that the yield of benzene formed is equal to the decrease in hydrogen yield in the radiolysis of methylcyclohexane glass at 77°K.[9]

A part of 3MP radicals produced in a 3MP solution containing phenyl bromide at 77°K disappear rapidly by a first order process unitl the concentration of 3MP radicals in this solution becomes equal to that produced in pure 3MP under the same irradiation condition, and the residual 3MP radicals disappear very slowly as those in pure 3 MP. The 3MP radicals which disappear rapidly may combine with some intermediates formed in close proximity to those 3MP radicals. Aggregation of phenyl halides in 3MP glass may be responsible for this phenomenon, because such a rapid decay of solvent radicals as that in 3MP glass is not observed in MTHF glass. Aggregation of alkyl iodides in 3MP glass at 77°K has previously been suggested by Claridge and Willard[10] and Mittal and Hamill.[11] The detailed mechanism for the rapid decay of 3MP radicals has not yet been established.

The narrow ESR singlet and the broad singlet observed in a γ-irradiated aqueous alkali-metal hydroxide glass containing phenyl iodide are apparently the same as those in an aqueous alkali-metal hydroxide glass without the solute. These singlets are attributed to trapped electrons and the O^- radical ions respectively.[12-18] The ESR spectrum obtained after photobleaching of the tra ed electron si nal is identified with that of the phenyl radical.[19] The low yield of phenyl radicals observed is probably due to the low solubility of phenyl iodide in aqueous solution at 77°K.

It is understandable in view of the difference in bond dissociation energy between C-H and O-H that the phenyl radical can abstract an H-atom from the solvents in MTHF and 3MP glasses, but not in aqueous alkali-metal hydroxide glass at 77°K.

The 300 or 290 mμ band in the optical absorption spectrum of γ-irradiated 3MP glass containing phenyl iodide or bromide is attributed to H-atom addition to the benzene ring.[20] The 710, 620 and 580 mμ bands observed in 3MP containing phenyl iodide, bromide and chloride are attributed to the respective halide cations, because the same absorption bands are observed in *n*-BuCl glass, in which positive holes migrate to the solutes and electrons are trapped in the matrix.[7] Recently, Baker *et al.* have measured various ionization potentials of phenyl halides by photoelectron spectroscopy.[21] According to their results, the difference in energy between the lowest and second ionization energy bands is $\sim$2 eV, which is in general agreement with the transition energies of the cation bands observed in the present study. The lowest ionization energy bands are attributed to the removal of an electron from the orbitals corresponding to the highest occupied π orbitals in benzene and the second ionization energy bands to the removal of an electron from halogen lone pairs. Thus the observed cation bands are attributed to the $n\rightarrow\pi$ transition of an electron in the phenyl halide cations. The assignment of the 560 mμ band observed in γ-irradiated phenyl iodide in 3MP glass is not established at present.

Since the 410 and 520 mμ bands observed in γ-irradiated 3MP glass containing phenyl iodide increase in intensity with time after termination of the γ-irradiation, these bands must be attributed to secondary intermediates produced by the reaction between primary intermediates. These bands are tentatively assigned to a complex, $C_6H_5I\cdot I$, which may be produced by ion recombination between $C_6H_5I^+$ and I^-. Such an assignment is consistent with the result that the cation band decreases in intensity with time. The 390 and 480 mμ bands produced by γ-irradiation of alkyl iodides (RI) in alkane matrices at 77°K have previously been assigned to $RI\cdot I$.[11] However, the possibility of I_2^- [10] for the 410 mμ band cannot be excluded at present. The 330 mμ band observed in 3MP containing phenyl bromide may be attributed to $C_6H_5Br\cdot Br$, although the possibility of Br_2^- cannot be excluded. Further study is required to establish the assignment of the secondary reaction intermediates.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2886—2894 (1968)

On the Isomerization of Dimers of Perchloro-(3,4-dimethylenecyclobutene) as Revealed by X-ray Methods

Akio FURUSAKI

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received June 6, 1968)

The isomerization of several dimers of perchloro-(3,4-dimethylenecyclobutene) (I) has recently been reported by Fujino *et al.* Of these dimers, one (II) is transformed to other isomers (IIIa) and (IIIb) by means of pyrolysis at *ca.* 200°C. When heated to *ca.* 250°C, IIIa and IIIb are further converted into a fourth isomer (IV). The present X-ray study has revealed that II corresponds to perchloro-(3,4,7,8-tetramethylene-tricyclo[4.2.0.$0^{2,5}$]octane), as supposed from the chemical evidence, and IV, to perchloro-(4,8-dimethylene-tricyclo[3.3.2.$0^{1,5}$]deca-2,6-diene). It has been further established, from the results of the X-ray analysis of the dichloride of IIIa with the help of the chemical information, that IIIa and IIIb have the same two-dimensional chemical structure, perchloro-(3,4,7,8-tetramethylene-cycloocta-1,5-diene), rather than perchloro-(2,3,7,8-tetramethylene-bicyclo[4.2.0]octa-4-ene) which was speculated by Fujino *et al.*, and that IIIa and IIIb are different from each other in the conformation of the cyclooctadiene ring. These structures for II, IIIa, IIIb, and IV give a reasonable explanation of the mechanism of the successive isomerization reactions mentioned above.

It has been reported by Fujino *et al.* that the pyrolysis of perchloro-(3,4-dimethylenecyclobutene) (I) affords, depending on the heating temperature applied, at least four different isomeric

compounds, $C_{12}Cl_{12}$.[1] Of these isomers, one (II), mp 166°C, is obtained from I in a 30% yield by means of pyrolysis at *ca.* 160°C, as is shown in Fig. 1. When heated to *ca.* 200°C, either as it is

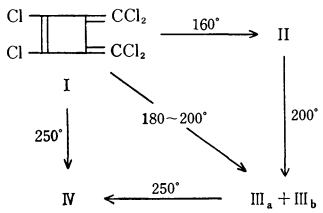

Fig. 1. The relationship among the four isomers of the formula $C_{12}Cl_{12}$.

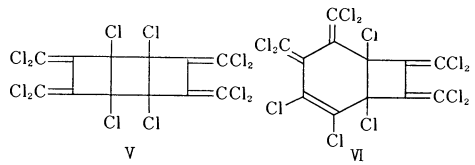
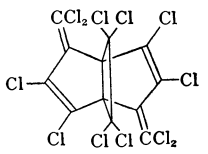
or in the medium of nitrobenzene, II is further transformed to a mixture of other isomers, (IIIa) and (IIIb), in which IIIa with a mp of 215°C dominates IIIb, mp 262°C. These two isomers show very similar IR absorption spectra in spite of fairly different chemical behavior. With the exception of its melting point, which is close, IIIb is different from II in all respects. Lastly, the application of pyrolysis at *ca.* 250°C to III results in a low-yield formation of the fourth isomer (IV), mp 273°C. III and IV are also derived directly from I through pyrolysis at 180—200°C and 250°C respectively. The yields are, however, much lower than those in the step-by-step conversion, since the direct transformation is always accompanied by the production of perchlorobenzene (ordinarily the major product), perchlorofulvene, perchloro-4-methylenecyclopent-1-ene, and an uncharacterized glassy material with the composition of $(CCl)_x$, which is the major product, particularly in higher-temperature pyrolyses in a solution.

Of the four isomers produced in the course of the pyrolytic transformation described above, II has been supposed, on the basis of the chemical analysis, to be perchloro-(3,4,7,8-tetramethylene-tricyclo[4.2.0.0^{2,5}]octane) (V).[1] Further, it has been tentatively proposed, on the basis of the chemical and IR data, that the two-dimensional chemical structure of IIIa and that of IIIb are both perchloro-(2,3,7,8-tetramethylene-bicyclo-[4.2.0]octa-4-ene) (VI).[1] On the other hand, the structure determination of IV by means of the chemical analysis did not seem feasible because of the poor yield of the compound in the pyrolytic reaction.

It is the purpose of the present study to confirm, or to determine by means of X-ray analysis, the molecular structures of II, III, and IV, and to elucidate the mechanism of the successive isomerization reactions. Of these substances, the molecular structures of II[2] and IV[3] have already been determined by such methods and found to correspond to V and VII respectively. Since, unfortunately, the sample supplied as IIIb was not such, but the dichloride of IIIa, the X-ray analysis has been carried out with this compound. However, the structure determination of the dichloride has enabled us to conclude unequivocally the structures of IIIa and IIIb.





VII

All the samples used in the present experiment were kindly supplied by Professor Akira Fujino, Research Institute for Atomic Energy, Osaka City University. The calculations necessary for the present study were carried out on a Bendix G-20 computer at the C. Itoh Electronic Computing Service Co., Ltd., and on a HITAC 5020 computer at the University of Tokyo, using programs devised at this laboratory.

Structure Determination of th Dichloride of IIIa

Experimental. The crystals of the dichloride of the isomer IIIa were colorless and in the shape of thick rhombic plates. The samples used were cut out from thse crystals into adequate rod-shapes with a razor. The crystal data have been derived from Weissenberg photographs around the *a* and *b* axes, taken with Cu$K\alpha$ radiation; the results are summarized in Table 1. From the systematic absences, the space group was found to be either

$C2/c$ or Cc. As a final result of the present analysis, the former has been concluded to be the corresponding group.

In order to collect three-dimensional intensity data, equi-inclination Weissenberg photographs were taken with Ni-filtered Cu$K\alpha$ radiation for the zeroth to the twelfth layer around the a axis and for the zeroth to the sixth layer around the b axis. The intensities were measured visually using a calibrated scale. Due to the rule of absences corresponding to $C2/c$, the intensities of (hkl) reflections with h and k even and those with h and k odd cannot be compared directly with each other only using the intensity data from the a and b axes. Therefore, the (hkk) photographs were taken around the [011] axis in order to obtain an approximate intensity ratio between two such types of reflections. This intensity ratio was then revalued by a comparison of the observed and calculated structure factors in the course of analysis. Thus, the structure factors of 1683 reflections were uniquely derived; they were then converted into an absolute scale by Wilson's method. Though the samples used were not very small, no correction was applied with regard to the absorption effect.

Structure Determination. The crystal structure was successfully elucidated by using the same method as was applied to the structure determination of IV.[3] The three vectors used for the minimum function method were (3/60, 11/30, 7/60), (33/60, 12/30, 37/60), and (30/60, 23/30, 30/60). The minimum function diagram thus obtained contained twenty-four significant peaks per quarter of the unit cell. As it was believed at this stage that the compound presently being studied had the molecular formula $C_{12}Cl_{12}$, the twelve peaks were chosen as the chlorine atoms out of the twenty-four peaks solely on condition of satisfying the Patterson map. The arrangement of these twelve peaks showed the presence of two-fold rotation axes. Therefore, the space group was concluded to be $C2/c$, as has already been mentioned.

The coordinates of the chlorine atoms were refined by the use of the diagonal-matrix least-squares method. However, five cycles of the refinement lowered the R factor from its initial value of 0.46 by only 0.05. In order to ascertain the correctness of the structure obtained from the minimum function, a three-dimensional electron density distribution was calculated using Sim's method.[4] From the electron density diagram, the positions of the six independent chlorine atoms already obtained were found to be essentially correct. Besides, the diagram revealed not only the positions of the six independent carbon atoms, but also the presence of an additional chlorine atom per asymmetric unit. Consequently, the molecular formula of the compound presently being studied might not be $C_{12}Cl_{12}$, but $C_{12}Cl_{14}$. This was also supported by the fact that, for the $C_{12}Cl_{12}$ formula, the calculated density is 1.73 g/cm^3; this value seems too small compared with those of II and IV, 2.07 and 2.17 g/cm^3 respectively, the crystal structures of which have already been determined.

The atomic parameters of the seven chlorine and six carbon atoms were refined by the use of the diagonal-matrix least-squares method with individual isotropic temperature factors using 1319 data around the b axis. After five cycles, the R factor dropped only to 0.207. This large value may be due to the weakness of the reflection intensities recorded on the Weissenberg photographs, or it may be attributed to the absorption effect, since the samples used were not small enough, as has been mentioned already. The electron density distribution, calculated at this stage using all the observed data, is given in Fig. 2. Further, the atomic coordinates were refined by the block-diagonal-matrix least-squares method assuming anisotropic thermal motions of all the atoms using 827 data around the b axis except for very weak reflections. After three cycles of the refinement, R was lowered to 0.100. The final atomic parameters thus obtained are listed in Table 2.

Description of the Structure of the Dichloride of IIIa

The molecular framework thus obtained and the bond lengths and angles calculated with the final atomic coordinates are shown in Figs. 3 and 4 respectively. The standard deviations of the coordinates are 0.008 Å for chlorine atoms and 0.021 Å for carbon atoms; therefore, those of the distances between mutually-independent atoms are

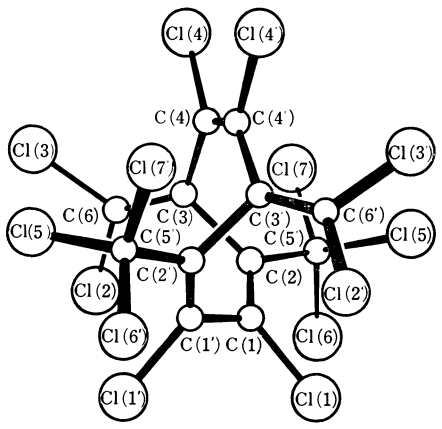

Fig. 3. The molecular framework of the dichloride of IIIa.

0.022 Å for C–Cl and 0.030 Å for C–C. Judging from the present results, it may be concluded that the dichloride of the isomer IIIa corresponds to perchloro-(1,4-dimethyl-5,8-dimethylene-cycloocta-1,3,6-triene).

The molecule has a symmetry of C_2, the diad of which coincides with a crystallographic one and runs parallel to the mean plane of the cyclooctatriene ring. The ring has a somewhat distorted tub-form compared with that of cyclooctatetraene.

The mean plane through the six atoms, Cl(1), C(1), C(2), C(3), C(5), and C(1'), is determined by means of the least-squares method as the following equation:

$$0.5904X + 0.5489Y - 0.5916Z - 3.374 = 0 \quad (1)$$

where X, Y, and Z are the rectangular coordinates in Å unit, where $X = x + z\cos\beta$, $Y = y$, and $Z = z\sin\beta$. As is shown in Fig. 5, four of the six atoms, Cl(1), C(1), C(2), and C(3), are nearly coplanar, but the C(5)–C(2)–C(1)–C(1') segment is somewhat concave toward the center of the molecule. Such a deviation from planarity may be due to the close approaches between Cl(1) and the trichloromethyl group (Cl(5), Cl(6), Cl(7), or C(5)) and between Cl(1) and Cl(1'); Cl(1) is located at distances of 3.19 Å from C(5), 3.26 Å from Cl(6), 3.39 Å from Cl(5), and 3.37 Å from Cl(1'). As is shown in Fig. 6, the trichloromethyl group takes such a conformation around the C(2)–C(5) bond that one

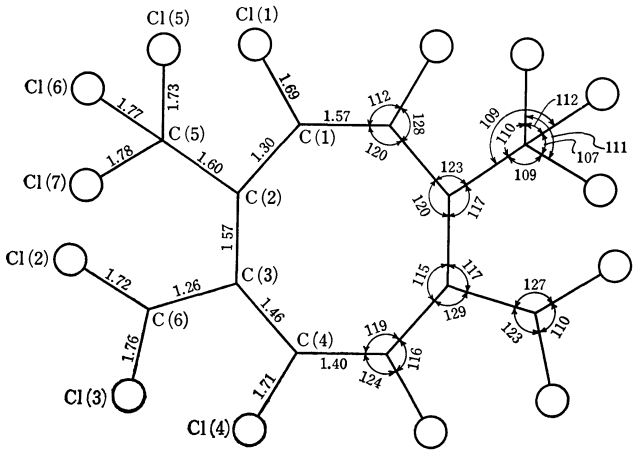

Fig. 4. The bond lengths (Å) and angles (°) of the dichloride of IIIa.

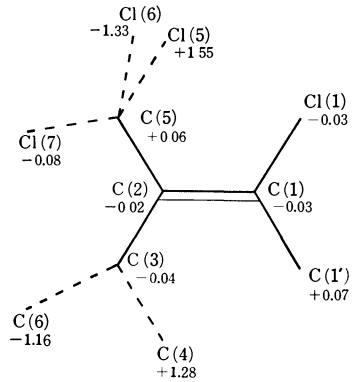

Fig. 5. The deviations of the atoms from the mean plane (1).

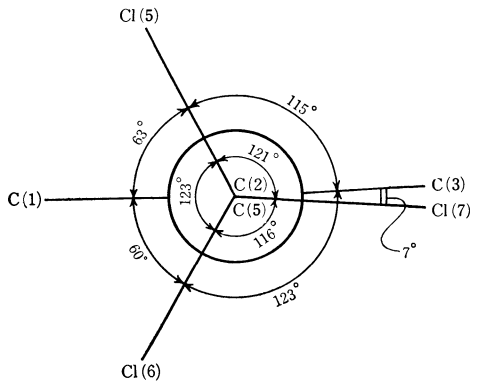

Fig. 6. The conformation of the trichloromethyl group around the bond C(2)-C(5).

of the three planes of the trichloromethyl group, through Cl(7), C(2), and C(5), is approximately coplanar with the plane (1) given above, Cl(7) being most remote from Cl(1). The adjacent endo-cyclic double bonds, C(1)-C(2) and C(1')-C(2'), deviate by 62° from the virtual cis-conformation around C(1)-C(1'). Since, besides, the bond distance C(1)-C(1') is about 1.57 Å, the conjugation between these two double bonds seems to be very weak.

The best plane, determined to run through Cl(2), Cl(3), C(2), C(3), C(4) and C(6), is described by the equation:

$$0.8305\,X-0.4715\,Y+0.2966\,Z-5.772=0$$

Figure 7 shows the deviations of the atoms from this plane. The double bond C(3)-C(6) is shown to be twisted to a considerable degree. Since, of these six atoms, two sets, Cl(2), Cl(3), C(3), and C(6), and C(2), C(3), C(4), and C(6), are almost coplanar, the angle of twisting around C(3)-C(6) is represented by the angle between the mean planes of these two sets of atoms; the twisting angle is estimated at about 8°. The sense of this twisting is just such that the chlorine atoms, Cl(3) and Cl(4), separate from each other, giving rise to an interatomic distance still with a value of 3.24 Å.

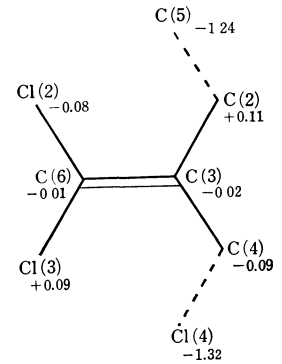

Fig. 7. The deviations of the atoms from the mean plane,
$0.8305X - 0.4715Y + 0.2966Z - 5.772 = 0$.

Since the double bond C(3)-C(6) makes an azimuthal angle of about 96° with C(1)-C(2), these two double bonds seem hardly to be conjugated at all. This idea is supported by the fact that the bond, C(2)-C(3), between the two double bonds is about 1.57 Å long. As a result of the large azimuthal angle (about 81°) of the bonds, C(2)-C(5) and C(3)-C(6), around C(2)-C(3), the trichloromethyl group and the dichloromethylene group adjoining to it are sufficiently apart from each other; the nearest approach between their chlorine atoms occurs between Cl(2) and Cl(7), when the distance is 3.92 Å.

The six atoms, Cl(4), C(3), C(4), Cl(4') C(3'), and C(4') (the double bond of which is C(4)-C(4')), are nearly coplanar in spite of the close approach between Cl(4) and Cl(4') at a distance of 3.07 Å, their mean plane being described by the equation:

$$0.4020X + 0.9156Z - 6.546 = 0$$

The deviations of the atoms from this plane are shown in Fig. 8. The double bond C(4)-C(4') makes an azimuthal angle of about 125° with C(3)-C(6) and C(3')-C(3'). These three double bonds are closest to planarity among all the pairs

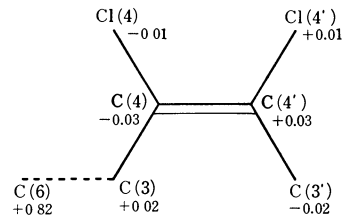

Fig. 8. The deviations of the atoms from the mean plane.
$0.4020X + 0.9156Z - 6.546 = 0.$

of double bonds adjacent to each central single bond. The length of the C(3)-C(4) bond is 1.46 Å, and that of C(4)-C(4'), 1.40 Å. Thus, it may be concluded that the three double bonds are conjugated with one another to a certain extent.

The projection of the crystal sturcture along the *a* and *b* axes are shown in Figs. 9 and 10 respectively, where all the intermolecular distances smaller than 4.0 Å are also given. It is of interest to note that the center of a molecule is located at $x=1/2$, $y\approx 1/4$, and $z=1/4$; therefore, those of the three remaining molecules in the unit cell are situated at approximately (0, 3/4, 1/4), (0, 1/4, 3/4),

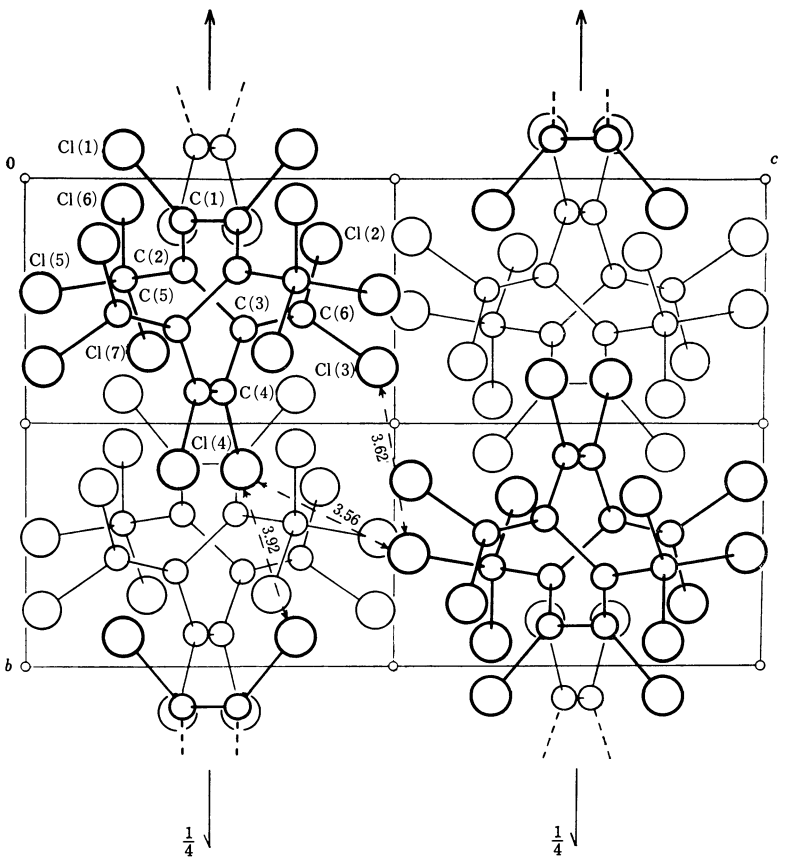

Fig. 9. The crystal structure of the dichloride of IIIa viewed along the *a* axis.

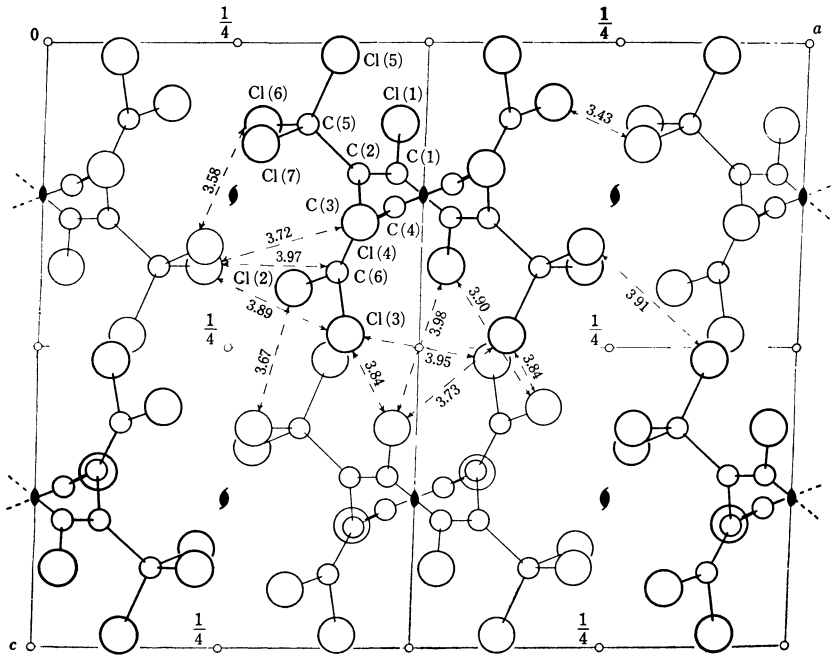

Fig. 10. The crystal structure of the dichloride of IIIa viewed along the *b* axis.

and (1/2, 3/4, 3/4); these four sets of coordinates correspond to those of lattice points in the face-centered cubic lattice. If adjacent molecules with intermolecular contacts of less than 4.0 Å are taken as nearest neighbors, each molecule is found to have twelve nearest neighbors. The central molecule at the height of $y \approx 1/4$ has two neighbors at the same height, four at the $y \approx -1/4$ height, four at $y=3/4$, and two just above and below. Due to the deviation of the molecular form from an ideal sphere, the three principal axes, *a*, *b*, and *c*, are not equal in length, but are in the ratio 1.84 : 1.00 : 1.47, the β angle deviating from a right angle by 1.8°.

As in II and IV, in the present crystal also close intermolecular Cl···Cl contacts are found: 3.43, 3.56, and 3.58 Å. Of these three close contacts, the former two occur between the chlorine atoms, one of the chloroethylene type and the other of the chloromethane type. The last one is that between the chlorine atoms, both of the chloromethane type. The difference between this observed distance and twice the standard van der Waals radius, 3.60 Å, may not be significant considering the accuracy of the present determination. Thus, the closer approaches found in the present crystal may be looked upon as due to the chlorine atoms of the chloroethylene type.

Discussion

All the molecular sturctures of II, IV, and the dichloride of IIIa have now been elucidated by means of X-ray analysis. Judging from the facts that IIIa reacts with liquid chlorine to form its dichloride, while the dichloride loses two chlorine atoms in the presence of Raney nickel to form IIIa, IIIa should have a structure closely similar to that of its dichloride. Thus, it may be concluded that the two-dimensional chemical structure of IIIa is perchloro-(3,4,7,8-tetramethylene-cycloocta-1,5-diene) (VIII) rather than perchloro-(2,3,7,8-tetramethylene - bicyclo[4.2.0]octa - 4 - ene) (VI), which, as has already been mentioned, was proposed from the chemical analysis. For the former, the formation of the dichloride can be simply explained through the 1,6-addition of chlorine to IIIa, as is shown in Fig. 11, whereas, for the latter, any explanation has to assume a complicated structural change.

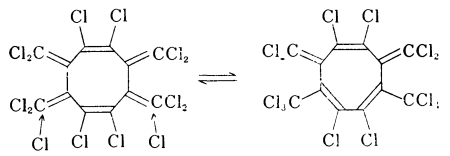

Fig. 11. The 1,6-addition of Cl_2 to IIIa.

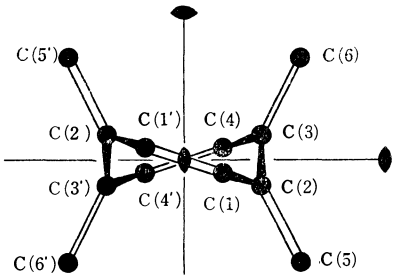
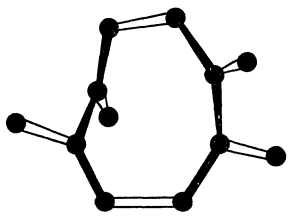
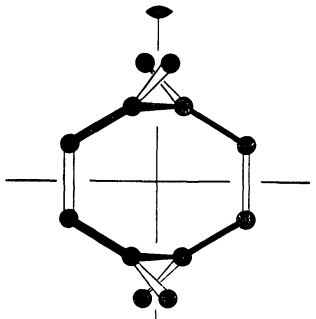
As for the structure VIII, the conceivable molecular forms can be divided into two groups. Of these two, the one (VIIIa) with a twisted ring has a symmetry of D_2, but this molecular form can be easily changed into another with a lower symmetry C_2 by a conformational change around the single

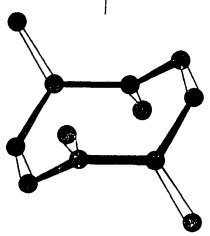
bonds. On the other hand, the other group (VIIIb) has a symmetry of C_{2h}, and the cyclooctadiene ring takes the very rigid frame of a chair-like form.





VIIIa





VIIIb

The molecular structure VIIIa makes possible a lucid explanation of the isomerization reaction of III into IV. In VIIIa, the two exo-cyclic double bonds, C(2)–C(5) and C(3)'–C(6'), or C(3)–C(6) and C(2')–C(5'), which are to form a four-membered ring, stand out to the same side of the mean plane of the ring: moreover, because of the ring's flexibility, these bonds can approach each other without much bond distortion. Thus, the addition reaction of such two double bonds results in the formation of a four-membered ring, giving rise to IV,

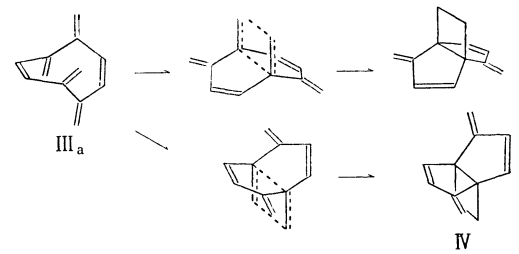


Fig. 12. The process of the isomerization of IIIa into IV.

as is shown in Fig. 12. On the other side, neither VI nor VIIIb can give so adequate an explanation of the isomerization of III as VIIIa can. Thus, it is reasonable to consider that VIIIa is the molecular structure of either IIIa or IIIb.

From the similarity of the IR data, it has been proposed by Fujino *et al.* that two isomers, IIIa and IIIb, have the same two-dimensional chemical structure. According to them, it seems that either the molecular structure of IIIa corresponds to VIIIa and IIIb to VIIIb, or *vice versa*. The former possibility seems to be more probable judging from the following points. In the first place, the fact that IIIb resists the oxydization of nitric acid and the addition of chlorine, while IIIa does not, seems to favor the present conclusion that IIIb has an inflexible and rigid structure, VIIIb, while IIIa has a labile and deformable structure, VIIIa, which is more likely to be attacked by reagents. Further, the change in the π-bond location seems to be effected by the attack of chlorine more smoothly in VIIIa than in VIIIb, because the part which is concerned with the 1,6-addition of chlorine is closer to planarity in the

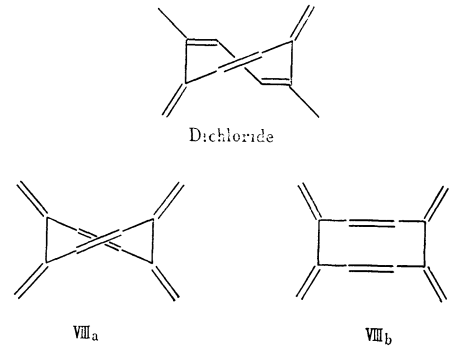

Fig. 13. The conformational resemblance of VIIIa to the dichloride.

former. The unchanged part of the 1,6-addition product found in the present analysis is more similar in conformation to the corresponding part of VIIIa than to that of VIIIb, as is shown in Fig. 13. Therefore, it may be concluded that the molecular structure of IIIa, the precursor of the 1,6-addition

product, corresponds to VIIIa rather than to VIIIb.

The transformation of IIIa into IV has already been explained. Thus, the only remaining problem is to elucidate how II is transformed into IIIa and IIIb. As has been mentioned above, the molecular structure of II has been found to be perchloro-(3,4,7,8-tetramethylene-tricyclo-[4.2.0.0^{2,5}]octane) (V) by the X-ray method. The three adjoining four-membered rings take a chair-like form, and the two pairs of alternating double bonds are both nearly planar. Thus, the whole molecule has a symmetry of C_{2h}. It seems reasonable to suppose that the transformation of II begins with the cleavage of the two single bonds which partition the eight-membered ring into three four-membered rings. As this cleavage proceeds, two dichloromethylene groups in the same conjugated system come to be unable to keep their planarity because these groups move on toward each other due to the relaxation of the considerable bond distortions in the three adjoining four-membered rings. Thus, two exo-cyclic double bonds, C(2)-C(5) and C(3)-C(6), or C(2')-C(5') and C(3')-C(6'), are rotated around the single bond, C(2)-C(3) or C(2')-C(3'), so as to avoid close approaches between the dichloromethylene groups. In this case, there are two different ways conceivable as to how the two pairs of the adjoining double bonds deviate from their planar conformation. One is that out of the molecular symmetry, C_{2h}, of II, a center of symmetry is preserved, as is shown in Fig. 14; the other is that a two-fold rotation symmetry is kept, as is shown in Fig. 15. Of course, such rotations around the single bonds, C(2)-C(3) and C(2')-C(3'), are accompanied by a change in the

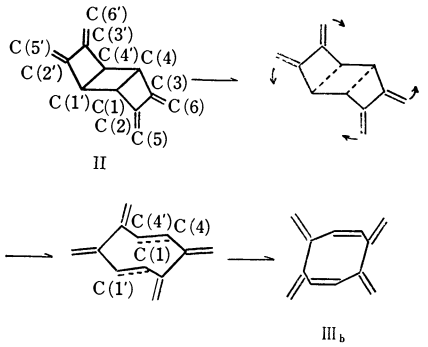

Fig. 14. The process of the isomerization of II into IIIb.

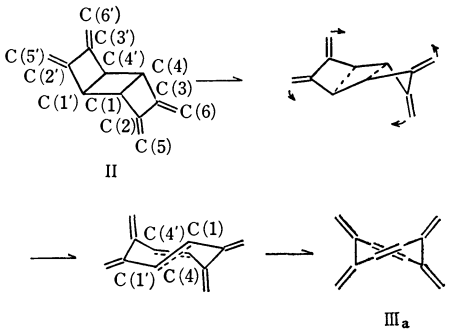

Fig. 15. The process of the isomerization of II into IIIa.

conformation around the bonds, C(1)-C(1') and C(4)-C(4'). Then new π-bonds begin to be formed, as the conformation around the latter bonds becomes favorable for the overlapping of the 2pπ-orbitals of these two pairs of atoms. Thus, one may assume two possible processes of the isomerization reaction; in the former, the isomer IIIb, with a molecular symmetry of C_{2h}, is formed, while in the latter the other isomer, IIIa, with C_2 or D_2 is formed.

After all, the problems regarding the mechanism of the successive isomerization reactions posed in the introduction to the present paper may be looked upon as solved through the series of X-ray structure analyses made on the compounds II, the dichloride of IIIa, and IV.

Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.*1

The author is very grateful to Professor Akira Fujino and his co-workers, Research Institute for Atomic Energy, Osaka City University, for providing him with the samples and for their valuable discussions. The author also wishes to acknowledge with deep gratitude his debt to Professor Isamu Nitta and the late Professor Yujiro Tomiie for their kind guidance and helpful discussions during this work. Thanks are also due to the staff of the C. Itoh Electronic Computing Service Co., Ltd., for allowing the use of the Bendix G-20 computer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2895—2899 (1968)

Phase Changes in the ZrO_2-TiO_2 System

Tetsuo NOGUCHI and Masao MIZUNO

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya

(Received March 28, 1968)

The liquidus curve in the ZrO_2-TiO_2 system previously reported by the present authors was again examined with a heliostat-type solar furnace in order to determine the peritectic point in the ZrO_2-rich side region. Quenched specimens from the melt of the ZrO_2-rich side region were analysed by the X-ray technique. The cooling curves from the melt suggested the existence of a new phase stable at higher temperatures, and a tentative phase diagram at high temperatures is presented.

The phase diagram in the ZrO_2-TiO_2 system has been studied by many investigators. Since the liquidus curve in the system was first published by von Wartenberg[1] in 1931, Sowman and Andrew[2] have demonstrated the results of high-temperature X-ray diffractometry on the ZrO_2-TiO_2 system, while Coughanour *et al.*[3] and later Brown and Duwez[4] proposed the phase diagrams which have been generally accepted up to the present. Recently, however, the subliquidus phase in the diagram was revised by Cocco and Torriano.[5]

Phase changes in the ZrO_2-TiO_2 system were also studied with a heliostat-type solar furnace; the results of the freezing point measurement and of the X-ray analysis of quenched specimens from the melt have been reported by the present authors previously.[6] The subliquidus phase study in the system and the freezing-point data on the specimens between 2.5 and 20 mol% TiO_2 compositions will be supplemented in the present work, and a revised diagram at higher temperatures will be presented.

Apparatus and Materials

In the freezing-point measurements undertaken to obtain additional data, a heliostat-type solar furnace equipped with a brightness pyrometer was used, and the specular reflection method[7,8] reported previously was used. The accuracy of the pyrometer was within $\pm 20°$ at 3000°K and $\pm 15°$ at 2000°K, including the reading error for oscillograms.

ZrO_2 99.8% pure (including about 1.8% HfO_2) from the Yokozawa Chemicals Co., Tokyo, and TiO_2 99.7% pure from the Kanto Chemicals Co., Tokyo, both used in the previous work, were carefully mixed in an agate mortar and then heated in an electric resistance furnace at 1500°C for 3 hr. After two grinding and heating cycles, the specimen was pressed into a $6 \times 6 \times 30$ mm bar under 4000 kg/cm^2 pressure without any lubricant or binder for the freezing-point measurements. No repeated fusion was made for the sample preparation in order to avoid any deviation from the stoichiometry of the composition at higher temperatures and also any contamination by impurities resulting from the grinding process and pressing.

X-Ray diffraction measurements of the quenched specimen were made using a diffractometer on a Shimadzu diffraction unit GX-3 and by nickel-filtered Cu$K\alpha$ radiation. High-temperature X-ray diffraction data were obtained with a Shimadzu HX-II model, the hot stage of which consists of a platinum-rhodium-wound heating element encased in an alumina refractory sleeve. Temperature measurements were made with platinum *versus* platinum-10% rhodium thermocouple.

Results and Discussions

Freezing-point Measurements. On the basis of the results of Cocco and Torriano, who claimed to have found a solid solution boundary between tetragonal zirconia and the two phase region (tetragonal zirconia plus $ZrTiO_4$) of 15mol% TiO_2 at elevated temperatures, the former anomaly in the liquidus curve reported by the authors was again examined in the compositions containing between 2.5 and 17.5 mol% TiO_2.

The seven specimens, in 2.5 mol% TiO_2 increments, were fused by means of the solar furnace, and their freezing temperatures were obtained from the cooling curves and spectral emissivity measurements. The cooling curves for each specimen were measured, using a dual-beam cathode ray oscilloscope, at several points across the sun's image under various heating temperatures after the thermal equilibrium had been attained. The thermal equilibrium was attained wihtin several seconds[9] from the attenuater opening. The measurements were repeated on different parts of the specimen surface more than thirty times in order to confirm the homogeneity of the composition in the specimen; the data agreed within the limits of error of the pyrometer reading. The cooling curves for each composition are shown schematically in Fig 1. The spectral reflectivity was also measured in order to obtain the spectral emissivity at 0.65μ near and at the respective freezing-point.

Table 1. Freezing point data of the compositions containing TiO_2 up to 20 mol percent

TiO_2 content (mol%)	Freezing point (±20°C)	Spectral emissivity at 0.65 μ	Temperature of* exothermic peaks in solid state (°C)	
0**	2706	0.81	—	—
2.5	2701	0.83	2487	—
5.0	2655	0.87	2498	2338
7.5	2618	0.84	2484	2332
10.0**	2580	0.95	2468	—
12.5	2495	0.94	—	—
15.0	2395	0.92	—	—
17.5	2343	0.96	—	—
20.0**	2316	0.92	—	—

* These values were calculated from their brightness temperatures and the emissivity data at the respective freezing point.

** Quoted from the previous work by the authors.

The average values of the freezing temperature for each composition are listed in Table 1, along with the spectral emissivity data. The results show that the anomaly in the liquidus curve is shifted from 20 mol% to 17.5 mol% TiO_2.

Chemical Analysis of Quenched Specimens. In order to examine the stoichiometry of the composition in specimens fused with the solar furnace in air, chemical analysis was made on specimens containing 10, 20, 30, 50 and 70 mol% TiO_2. The specimens were kept about 100°C higher than the respective melting temperatures for 3 min.*1 Because of the difficulty in separating TiO_2 from ZrO_2, the ZrO_2 content in the specimen was determined by the following method.

A weighed specimen of about 50 mg in a platinum crucible was fused with the addition of ten times as much sodium pyrosulfate and then dissolved with nitric acid into a sample solution. After the addition of an excess amount of an EDTA standard solution (0.009594 M), a 10% solution of ammonium tartarate was added; the pH of the sample solution was then adjusted to between 1—2 with nitric acid or ammonia water. The sample solution was heated for five minutes and then back-titrated with a bismuth nitrate standard solution (0.017669M) using the XO indicator. The end point was shown by the color change from yellow to red purple; the results are shown in Table 2.

The ZrO_2 content was determined by the spectrochemical analysis to contain about 1.8% HfO_2, which was calculated as ZrO_2. Therefore, a correction was made in examining the stoichiometry,

Table 2. Results of chemical analysis on quenched specimens from the melt

Sample	ZrO_2 content % (theoretical)	ZrO_2 content % (determined)	Corrected values		Deviation from theoretical value
			wt%	mol%	mol%

9) T. Noguchi and T. Kozuka, *Solar Energy.*, **10**, 203 (1966).

*1 Several seconds were necessary for the fusion of a specimen with the solar furnace, and several additional seconds were required to attain the thermal equilibrium. Therefore, the time for the cooling curve measurements was about 10 sec.

and the deviation from the theoretical values was found to be less than 0.4 mol%. The titanium content in the fused TiO_2 specimen was determined by the gravimetric method. The composition was found to be $TiO_{1,997}$ and to agree with the results of Bauer and Littke.[10]

X-Ray Diffraction Data

X-Ray diffraction measurements were made on quenched specimens from the melt and on those heated at 1700°C for 6 hr in an electric-resistance furnace. The molten specimens were prepared with the solar furnace by heating them to about 100°C higher than the respective melting points for 20 sec before quenching. The diffraction data are listed in Table 3, along with the data on the ZrO_2-TiO_2 system obtained in a previous paper.

The single phase of the $ZrTiO_4$ compound was observed on the specimen (1:1) heated at 1700°C, while the quenched specimen from the melt showed three components, $ZrTiO_4$, monoclinic ZrO_2, and tetragonal TiO_2 as an incongruently melting material. The lattice parameters of the $ZrTiO_4$ solid solution with compositions containing 35 to 60 mol% TiO_2 were obtained using the diffraction lines from (032), (014) and (400) with the scanning speed of 2θ 1/8° min for the specimens fired at 1700 °C. Both a and c axes contracted from 41 mol% composition, and the unit cell volume increased from a 50 mol to a 53 mol% composition. Moreover, the boundaries of the $ZrTiO_4$ solid solution for ZrO_2 and TiO_2 sides at 1700°C were located at 41 mol% and 53 mol% TiO_2 respectively, as is shown in Fig. 2.

Table 3. X-ray diffraction data on the quenched specimens in ZrO_2-TiO_2 system

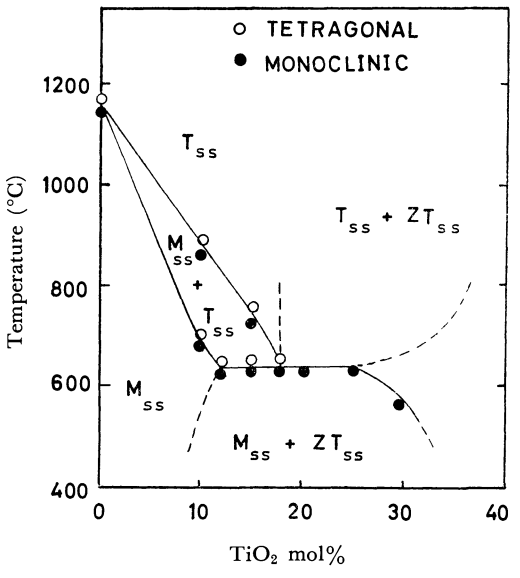

Fig. 3. High temperature X-ray diffraction data in ZrO_2 rich side region.

10) G. Bauer and W. Littke, *J. Inorg. Nucl. Chem.*, **16**, 67 (1960).

The specimens containing up to 30 mol% of TiO_2 were fired at 1700°C for 3 hr and then examined by high-temperature X-ray diffractometry in order to determine the solid solution boundaries at lower temperatures. The diffraction data were obtained from 2θ 27° through 33° and by the heating and cooling rates of 2°C/min. The average values obtained by five heating and cooling cycles are shown in Fig. 3; the data agreed with Cocco's results, which differ from those of Duwez, who estimated the solid solution boundary on the basis of the thermal expansion measurement. However, the boundary between tetragonal and monoclinic ZrO_2 solid solutions in the present work seems to be about 140°C higher than that obtained by Cocco. Moreover, this boundary was not straight with the increase in the TiO_2 content, the transformation temperature decreasing, as was claimed by Duwez.

The lattice parameters of the monoclinic solid solution in the specimens quenched from the melt and at 1700°C are shown in Fig. 4. The quenching rate from the melt was about 2300°C/sec. The data were obtained with the diffraction lines from (111), (11$\bar{1}$), (011), and (002).

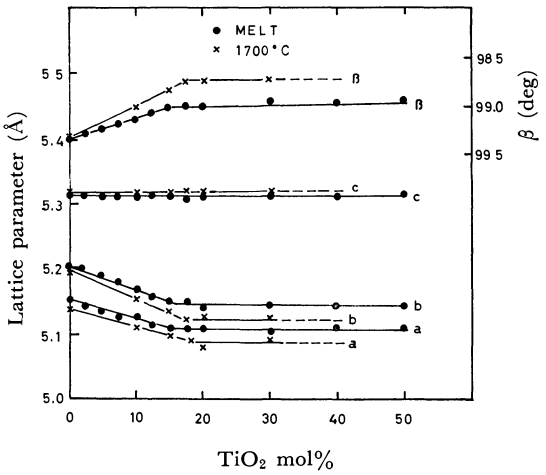

Fig. 4. Lattice parameters of monoclinic ZrO_2 solid solution.

While the solubility limit of TiO_2 in a $ZrTiO_4$ solid solution in the specimens quenched from the melt was previously found at 80 mol% TiO_2, the quenched specimen from 1700°C showed a solid solution boundary at 83.5 mol% TiO_2.

Phase Diagram

Tentative additions to the phase diagram in the ZrO_2-TiO_2 system were made to the revised diagram by Cocco and Torriano, using the liquidus curve in the system shown in Fig. 5.

Pure zirconia has shown the exothermic peaks[7] at 2494° and 2325°C respectively, while the latter

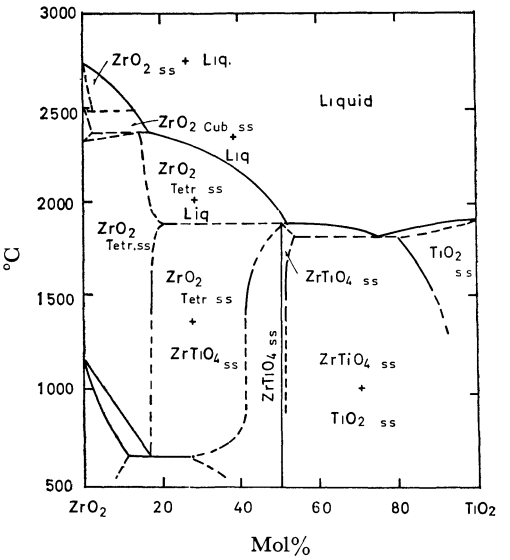

Fig. 5. Tentative phase diagram of ZrO_2-TiO_2 system at high temperature.

was estimated to be the transformation from a cubic to a tetragonal modification of ZrO_2. The very weak exothermic peaks which appeared in the cooling curves of the compositions containing 2.5, 5, 7.5 and 10 mol% TiO_2 in the solid state*2 were observed at temperatures slightly lower than 2500 °C. Although the high accuracy in the temperature measurement upon a transformation in the solid state can not usually be expected by such a dynamic method, the ZrO_2 modification in this region was not frozen by the quenching rate in the present work and was considered to show a diffusionless phase change.[11] Therefore, the accuracy of these values were estimated to be close to that obtained in the freezing-point measurements. A complete interpretation of these phenomena was not possible in the present work; however, a transformation from a stable form at above 2500°C to a cubic form might be suggested on the basis of the experimental evidence in establishing the phase relation on the ZrO_2-rich side region at very high temperatures. The existence of a very narrow two-phase region was assumed without actual experimental proof below 2500°C in order to satisfy the phase rule. The highly speculative hypothesis developed by Sense[12] that ZrO_2 may have the monoclinic crystal structure and be quenchable might not be acceptable in the present work, though the crystal structure of zirconia above 2500°C is not yet known. The lattice parameters of zirconia specimens of both the green and those quenched

*2 The freezing point was confirmed by visual observation through the ocular lens of the brightness pyrometer and with both oscillograms and data from the automatic voltage-recording meter.

11) G. M. Wolten, *J. Am. Ceram. Soc.*, **46**, 418 (1963).
12) K. A. Sense, *ibid.*, **44**, 465 (1961).

from the melt showed no remarkable difference within the limits of accuracy of the measurements. An electron micrograph of the quenched zirconia from the melt showed a crack on the thermally-etched surface as in the previous paper.

The second exothermic peaks appearing in the solid state were slightly higher than the transition point from the cubic to the tetragonal form of ZrO_2; the temperatures of these points, almost identical to the freezing temperature of the 17.5 mol% TiO_2 composition, accounted for the solidus line.

The solid solution boundary between tetragonal ZrO_2 and the two-phase region of tetragonal ZrO_2 plus $ZrTiO_4$ under the solidus line was located at 15 mol% TiO_2, while that at 1700°C was located at 17.5 mol% TiO_2 (*cf.* Fig. 4).

The other parts of the diagram were based on the following experimental results:

1) The solid solution boundaries between tetragonal and monoclinic forms of zirconia, and other two-phase regions at lower temperatures, as is shown in Fig. 3.

2) The solid solution boundaries of $ZrTiO_4$ for both ZrO_2 and TiO_2 sides.

3) The solid solution field of TiO_2.

Conclusions

The anomaly in the liquidus curve in the ZrO_2-TiO_2 system has been found at 17.5 mol% TiO_2. A tentative phase diagram for the ZrO_2-TiO_2 system at higher temperatures has been presented, and the existence of a new high-temperature modification of ZrO_2 above 2500°C has been suggested. Further, the phases of ZrO_2 at very high temperatures should be examined by a dynamic method such as high temperature X-ray diffractometry with imaging furnaces.

The authors wish to express their appreciation to Dr. Hiroshi Hayashi for his cooperation in the chemical analysis of the specimens and to Drs. Hiroshi Okuda and Toshiyasu Horibe for their valuable suggestions regarding the experimental results.

Alkali Fusion - Gas Chromatography of Alkyl Sulfates

Terumichi NAKAGAWA, Koichiro MIYAJIMA and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received April 1, 1968)

The alkali fusion of alkyl sulfates was investigated by pyrolyzing a mixture of alkyl sulfates and alkali metal hydroxide between 200—500°C. The pyrolyzates were isolated and identified to be 1-olefins, internal olefins, alcohols, and dialkyl ethers by gas chromatography and IR spectroscopy. The mechanism of this reaction was proposed from these results and an attempt was carried out to estimate the alkyl chain carbon number distribution of the commercially available sodium alkyl sulfates.

The analysis of the lipophylic groups of alkyl sulfates has been carried out by means of acid hydrolysis followed by gas chromatographic identification of the resulting alkyl alcohols.

Knight and Hous[1] reported the decomposition of alkyl sulfates in hot phosphoric acid to result the corresponding olefins, which was comfirmed by several other workers.[2,3] Lew[4] described that the pyrolysis of alkyl sulfates with P_2O_5 gave a mixture of 1-olefin and internal olefin isomers with the same carbon numbers as the alkyl group of the original sulfate, but gave neither alcohols nor dialkyl ethers. The direct pyrolysis of alkyl sulfates without any reagent also yielded the corresponding olefins,[4,5] and alcohols.[5] Moreover, Nishi[6] presented a simple identification method of anionic surfactants by alkali fusion. He reported that the alkyl sulfates were decomposed only to alcohols, but he did not give any detailed discussion. The present paper deals with the mechanism of alkali fusion of alkyl sulfates as compared with that of alkyl sulfonates, which has been reported in the previous paper.[7]

Experimental

Preparation of Sodium *n*-Alkyl Sulfates. One tenth mole of *n*-alkyl alcohol (alkyl carbon numbers: 5, 6, 7, 8, 9, 10, 12, 14 and 16) was placed in a 500 m*l* flask fitted with a mechanical stirrer, a dropping funnel, a thermometer, and a reflux condenser, from the top of which HCl gas was removed. The flask was cooled in an ice bath at 0—5°C and 0.1 mol of chlorosulfonic acid was added dropwise with a thorough agitation. After addition, stirring was continued for two hours at room temperature, then the reaction mixture was allowed to stand overnight, neutralized with sodium hydroxide solution, and evaporated to almost dryness. Alkyl sulfate was extracted from the dried residue with absolute ethyl alcohol for 6 hr by using a Soxhlet extractor to remove the inorganic impurity, *i. e.*, NaCl. After removing ethyl alcohol from the extract, the crude sulfate which still contained a minor amount of unchanged original alcohol was recrystallized twice from absolute ethyl alcohol, rinsed by acetone and dried in the desiccator. The raw materials, *n*-alkyl alcohols, had been purified by distillation and checked cautiously by gas chromatography. The IR spectra of the sulfates, obtained above, did not indicate contamination with the original alcohols.

Preparation of Di-*n*-alkyl Ethers. Di-*n*-alkyl ethers were prepared by Williamson's reaction. One tenth gram atom of sodium metal was dissolved in 0.2 mol of *n*-alkyl alcohol at 100°C with stirring. Then 0.1 mol of *n*-alkyl bromide with the same carbon numbers as the alcohol was added dropwise into the solution. The stirring was continued at 100°C until the pH of the reaction mixture became nearly neutral. After reaction, 100 m*l* of ethyl ether was poured into the reaction mixture and sodium bromide was removed by extracting the ethereal layer with 50 m*l* of water. The ethereal layer was dried over anhydrous sodium sulfate and the ether was removed. The residue was distilled under reduced pressure. Purity of these dialkyl ethers was checked by gas chromatography. The boiling points and the results of elemental analysis are listed in Table 1.

Other Reagents. Reagent grade LiOH, NaOH, KOH, RbOH, CsOH, were used. *cis*-*n*-2-Octene (K & K Laboratories Inc.), and *trans*-*n*-3-octene, *trans*-*n*-4-octene (Aldrich Chemical Co., Inc.), and other olefins (Tokyo Kasei Kogyo Co., Ltd.) were used without further purification. All the olefins were pure enough to use for the standard of gas chromatography.

Pyrolysis Apparatus. A Shimadzu Pyrolyzer Model PYR-1A was used. The apparatus was equipped with 170 mm length and 6 mm i. d. quartz pipe which was heated externally by nichrome wire. Its temperature was measured by thermocouple and heating was controlled by a voltage regulator. The pyrolyzer and the gas chromatography were connected in series. The alkali fusion was carried out in a platinum boat in the quartz pipe in an atomosphere of nitrogen.

Gas Chromatographic Conditions.

Apparatus: Shimadzu Gas Chromatograph Model GC-1C

Packing: 20 wt% Apiezon L, 20 wt% squalane, 10 wt% DEGS and 20 wt% PEG 20 M coated on 60/80 mesh Chromosorb W pretreated with HCl and DMCS-methanol.

Column: Stainless steel U tube, 3 mm i. d.

Carrier gas: Nitrogen

Detector: FID

The column temperature, column length, and nitrogen flow rate were appropriately adjusted in each case.

Isolation of the Pyrolyzates. Two grams of a sodium *n*-alkyl sulfate prepared was ground quickly and mixed uniformly with 10 g of alkali metal hydroxide in a mortar and put in a stainless steel reactor, which

was heated at 400°C for one hour. After reaction, the products were cooled and extracted with ethyl ether, and the extract was filtered, dried, and condensed carefully. Distillation of the residue gave *n*-alkyl alcohol, di-*n*-alkyl ether and a mixture of 1-olefin and internal olefin isomers with the same number of carbon atoms as the alkyl group of the original sulfates. Pentenes and hexenes were, however, so volatile that they could not be isolated. The products were identified employing authentic samples by gas chromatography and IR spectroscopy. The IR spectra of *n*-octyl alcohol, di-*n*-octyl ether, and a mixture of *n*-1-octene and internal octenes, which were the alkali fusion products of sodium *n*-octyl sulfate, and the corresponding gas chromatograms are shown in Figs. 1 and 2, respectively. Discussion on the identification of the alkali fusion products is given below.

4. *n*-2-Octene

Results and Discussion

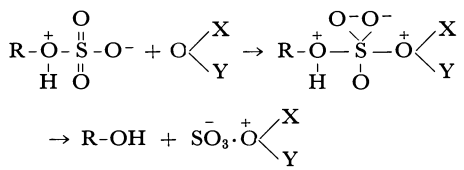
Identification of Alkali Fusion Products. The identification of the alkali fusion products of alkyl sulfates to be *n*-1-olefins, a mixture of internal olefins, higher alcohols, and dialkyl ethers are based on a comparison of their retention times and IR spectra with those of authentic samples.

The absorption bands of IR spectrum (Fig. 1 (1)) at 990 cm^{-1} and at 910 cm^{-1} indicate the formation of monosubstituted ethylene group and the bands at 965 cm^{-1} and 680 cm^{-1} suggest the existence of *trans*- and *cis*-disubstituted ethylene group, respectively.

On the other hand, the formation of 2,2-disubstituted and trisubstituted ethylene group is ruled out because of the absence of the absorption bands near 890 cm^{-1} and between 800 cm^{-1} and 840 cm^{-1}, respectively. According to these observations, it is concluded that the olefinic compounds obtained from the alkali fusion reaction of sodium *n*-octyl sulfate are *n*-1-octene and a mixture of *trans* and *cis* internal octene isomers, and that the branching of the alkyl group does not take place during the reaction. The IR spectra of alkali fusion products of sodium *n*-octyl sulfate shown in Figs. 1(2) and 1(3) agreed with those of authentic *n*-octyl alcohol and di-*n*-octyl ether, respectively.

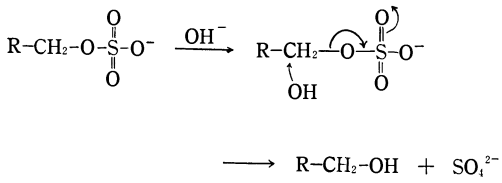
Figure 2 shows the gas chromatograms of alkali fusion products of sodium *n*-octyl sulfate. The peak 1 in Fig. 2(1) is the overlapping peak of *n*-1-octene and internal octene isomers that can not be separated under the conditions (20 wt% Apiezon L, 75 cm, 220°C, 40m*l*). Peak 2 and peak 3 are assigned to *n*-octyl alcohol and di-*n*-octyl ether by comparing the retention times with those of authentic samples. Further separation of the olefinic products was carried out under the conditions (20 wt% squalane, 3 m, 100°C, 30 m*l*). In Fig. 2(2), the peak assignments to *n*-1-octene, *n*-2-octene, *n*-3-octene, and *n*-4-octene are based on a comparison of their retention times with those of standard *n*-1-octene, *cis*-*n*-2-octene, *trans*-*n*-3-octene, and *trans*-*n*-4-octene, respectively. The peak 1 is identified to be *n*-1-octene. Because a mixture of *trans*- and *cis*-*n*-2-octene gave only a single peak whose retention time agreed with that of standard *cis*-*n*-2-octene, it is assumed to be impossible to separate the mixture of *trans*- and *cis*-octene isomers from each other under the above conditions. Thus the peaks 2, peak 3, and peak 4 may be identified to be a mixture of *trans*- and *cis*-*n*-4-octenes, *n*-3-octenes, and *n*-2-octenes, respectively.

Reaction Mechanism. The mechanism of acid hydrolysis of an alkyl sulfate is represented as follows:[8]



On the other hand, although alkyl sulfates are stable in the alkaline medium,[9] they are hydrolyzed to the corresponding alcohols in the fused alkali metal hydroxide. The mechanism of this reaction may be considered to be

8) V. A. Motsavage and H. B. Kostenbauder, *J. Colloid Sci.*, **18**, 603 (1960).
9) R. Aoki and E. Iwayama, *J. Pharm. Soc. Japan*, **80**, 1749 (1960).



In order to elucidate the mechanism of formation of dialkyl ether, *n*-alkyl alcohol was heated with an excess amount of KOH at 400°C in a sealed glass tube. In the reaction products obtained, an appreciable amount of di-*n*-alkyl ether and a mixture of *n*-1-olefin and internal olefin isomers were detected by gas chromatography and IR spectroscopy. From these facts the mechanism of formation of di-*n*-alkyl ether and olefins may be considered to be the dehydration of one molecule of water from two molecules of *n*-alkyl alcohol, and one molecule of water from one molecule of *n*-alkyl alcohol, respectively. The formation route of internal olefins from 1-olefin was discussed in the previous paper.[7]

Effect of Alkali Metal Hydroxide and Reaction Temperature. The variation of the reaction temperature between 200°C and 500°C did not affect the kinds of the reaction products obtained. The pyrolysis without any reagent also gave the same products, but the temperature at which the reaction occured was higher than that of the pyrolysis with alkali metal hydroxide.

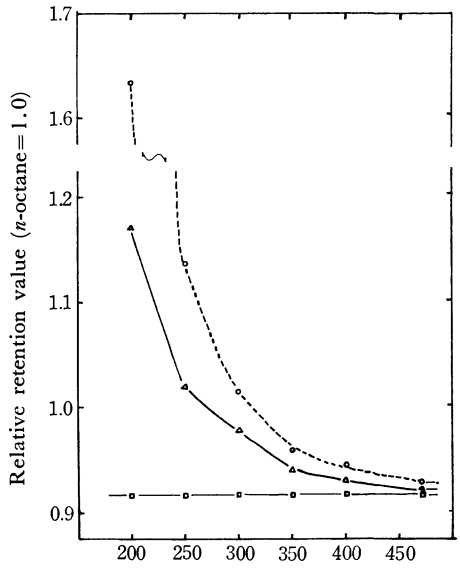


Fig. 3. Relation between alkali fusion temperature and relative retention value of *n*-1-octene from sodium *n*-octyl sulfate.

○···○ with KOH
□—□ standard *n*-1-octene
△—△ without KOH

The relation between the reaction temperature and the relative retention value against *n*-octane (the internal standard) of *n*-octenes produced by alkali fusion of sodium *n*-octyl sulfate with KOH is shown in Fig. 3. Such relation suggests that the addition of KOH accelerates the reaction. These effects, however, are not so remarkable as in the case of alkyl sulfonates.

Practical Application

The present method was applied to determine the alkyl chain carbon number distribution of the commercially available sodium alkyl sulfates (SDS). Three to five milligrams of a mixture of the same amount of SDS and KOH was put in a platinum boat in the pyrolyzer which had been heated at 400°C and the volatile reaction products were swept into a column by the continuous nitrogen stream which flowed in series from the pyrolyzer to gas chromatograph. The chromatogram of the sample B in Table 2 obtained by this method is shown in Fig. 4 (1). The chromatographic conditions were 20 wt% PEG 20M, 1.5 m, 120—240°C, temperature programming rate 10°C/min, 40 m*l*.

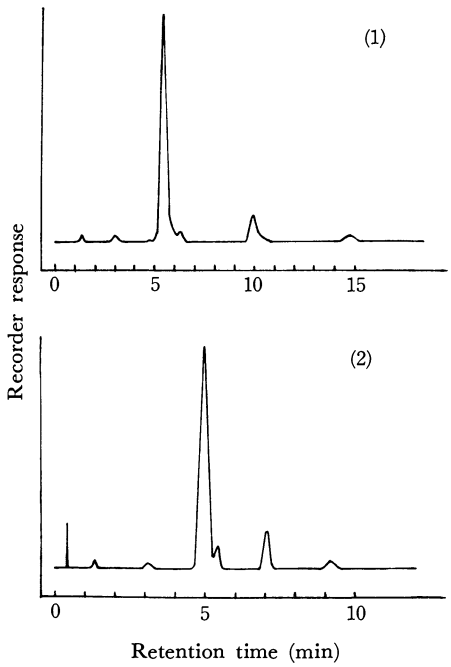

Fig. 4. Gas chromatogram of SDS.

(1) Olefinic products of alkali fusion of SDS
(2) Acetates from the same SDS

Under these conditions, the peaks of the alcohols did not interfere the separation of the olefinic products by which the alkyl carbon number distribution of the SDS was determined. On the other hand, the alcohols obtained by the acid

* Acetate from acetylation of alcohol obtained by acid hydrolysis of SDS was analyzed in Shimadzu Gas Chromatograph Model GC-1C with 75 cm × 3 mm, 10 wt% DEGS on Chromosorb W (AW, HMDS); column temp., 150—210°C, temp. programming rate, 10°C/min, nitrogen, 40 ml/min.

hydrolysis of the same SDS were acetylated by acetic anhydride in pyridine and the alkyl carbon number distribution was measured by the peaks of the acetates (Fig. 4 (2)) in order to confirm the reliability of this method. The distribution values are listed in Table 2 together with the average molecular weight and the average alkyl carbon number calculated from them. The agreement between these two methods is satisfactory. The qualitative and quantitative analysis of the lipophylic groups of *n*-alkyl sulfates can be successfully carried out by this method rapidly and briefly.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2903—2908 (1968)

Polarography of Lead-Arginine Hydrochloride Complexes

Tsai-Teh LAI and Mon-Chao CHEN

Chemical Engineering Department, Cheng Kung University, Tainan, Taiwan, China

(Received April 11, 1968)

The complexation of lead ion with arginine hydrochloride has been studied polarographically at 30°C. Four kinds of complex species, $PbCl^+$, $Pb(H_2Arg)Cl^{2+}$, $Pb(H_2Arg)(OH)^{2+}$ and $Pb(H_2Arg)_2(OH)^{3+}$ (where H_2Arg denotes the arginine univalent cation) were confirmed in various pH range, respectively. The logarithmic dissociation constant of $Pb(H_2Arg)_2(OH)^{3+}$ was found to be 10.33 ± 0.03 at ionic strength 0.9.

The complexes of arginine with copper and zinc have been studied by polarographic and other methods and the metal-ligand ratios have been shown to be 1 : 1 and 1 : 2.[1-3] The effect of amino acid structure on the stability of the complexes formed with metals of Hg, Be, Zn and Cd has been reported by Perkins.[4,5] The stability constant of calcium-arginine chelate was determined by pH titration method.[6] The effect of temperature on the dissociation constants of arginine and its different metal complexes was investigated by Pelletier.[7]

This paper presents the results of the polarographic behavior of lead-arginine hydrochloride system.

Experimental

Apparatus. All polarograms were recorded manually using a Sargent Model XII Polarograph, equipped with a Leeds and Northrup Student Potentiometer. A modified H-cell, containing an external saturated calomel reference electrode (SCE) and a potassium chloride - agar plug was used. All experiments were carried out at 30 ± 0.1°C.

The mercury flow rate and the dropping time of the capillary used were 2.067 mg/sec and 3.56 sec respectively at an applied potential −0.5 V *vs.* SCE with the mercury column height 73.2 cm, measured in a solution which contained 1.0 mM lead nitrate, 0.4 M arginine hydrochloride, 0.5 M sodium nitrate, and 0.003% Triton X-100 at pH 6.85.

Chemicals. The stock solution of 0.01 M lead nitrate was prepared and analyzed as described previously.[8] The arginine hydrochloride (Aldrich Chemical Co.) was research grade and the solutions were freshly prepared before use. Triton X-100 was used as a maximum suppressor. Sodium nitrate was used as supporting electrolyte with which the ionic strength of the polarographic solutions were adjusted to 0.9. The pH values of the polarographic solutions were adjusted with nitric acid or sodium hydroxide and no buffer was used.

Results and Discussion

The polarographic characteristics of the lead-arginine hydrochloride complex were studied with the solutions which contained 1.0 mM lead nitrate and varying concentration of arginine hydrochloride from 0.1 M to 0.6 M over the pH range 0.80—9.05. At higher pH value precipitation occurred when the arginine hydrochloride concentration was lower than 0.2 M.

at pH lower than 9.05 for the ligand concentration 0.6 M.

At pH>8.30 and ligand concentrations between 0.1 M and 0.4 M the electrode process was regarded as a quasi-reversible reduction as can be evidenced from the slopes of $\log i/(i_d-i)$ *vs.* $E_{d.e.}$, 0.038—0.039 (Table 2), and the asymmetrical waves (Fig. 1). The distortion of the polarograms was attributed to the adsorption effect of the maximum suppressor.[9,10] In confirm this assertion solutions containing higher concentration of maximum suppressor were polarographed. As can be observed from the curve 1 in Fig. 1, the addition of 0.006% Triton X-100, was enough to cause the wave become asymmetric when the polarographic solution contained no chelating agent.

The temperature coefficient of the half-wave potential was -0.2 mV/°C at pH<8.30 and in the conditions of the asymmetrical waves it was -0.7 mV/°C, which is still in the limiting value for a reversible reduction.

The constant value of $i_d/\sqrt{h}$, 0.766±0.014, for h=71.6—32.2 cm and ligand concentration 0.1 M at pH 6.18, revealed that the limiting current was entirely diffusion-controlled.

The temperature coefficient of the diffusion current was 1.4%/°C in the whole pH range investigated in this work. This also proves the diffusion-controlled system.

Effect of pH on Half-wave Potential and Diffusion Current. The dependences of half-wave potential and diffusion current on the pH value are shown in Figs. 2 and 3 respectively. In the two figures the curves all break into four sections at the same pH values. This fact reveals the existence of four kinds of complex species at each section of pH<2.0, pH 2.0—5.0, pH 5.0—7.0 and pH 7.0—9.1.

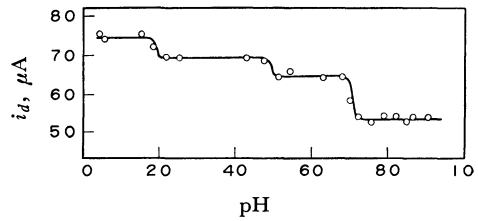

Fig. 3. Effect of pH on the diffusion current.
1.0 mM $Pb(NO_3)_2$, 0.003% Triton X-100, $NaNO_3$ at μ 0.9 $[Cl^-]=C_{Arg}=0.2$ M

The horizontal lines at pH<2.0 for varying concentrations of complexing agent in Fig. 2 were ascribed to the formation of the lead chloro complex rather than the lead-arginine complex, as can be confirmed by the half-wave potential data of the lead-sodium chloride system in Table 3.

In the pH range 2.0—5.0, the half-wave potentials shifted a little to negative side, and the diffusion current decreased (Fig. 3). These changes indicate the participation of arginine ligand to the lead-chloro complex.

In the pH range 5.0—7.0 in Fig. 2, the slope of the curve is 0.010 V. This minute slope demonstrates the partial substitution of the chloride ligand in the lead complex with the hydroxyl ligand and the releasing of the hydroxyl ion in the cathodic reduction. The higher the ligand concentration, the greater the shifting of the breaking point to lower pH value. This fact indicates that the higher arginine concentration is in favor of the substitution of the chloride ligand with the hydroxyl ligand.

When the pH value is greater than 7.0, the $E_{1/2}$ *vs.* pH curves show a third inflection with a slope of 0.034 V, showing that one hydroxyl ion was involved in the reduction.

It is obvious from Fig. 3, that each change in complex species resulted in a separate diffusion current drop.

Effect of Ligand Concentration on Half-wave Potential. To determine the metal-ligand ratio of the lead-arginine hydrochloride complexes, the half-wave potentials were plotted against the logarithm of the concentration of arginine hydrochloride (Fig. 4).

As shown in Fig. 4, lead does not form complexes with arginine hydrochloride below pH 5.0 when the ligand concentration is lower than 0.22 M. At pH<2.0 and C_{Arg}>0.22 M, the reciprocal slope is 0.030 V. In referring to the Fig. 2 and Table 3, the formation of the complex species, $PbCl^+$, was

	3.81	0.423	7.70	0.029

The competition between arginine and chloride ion for electron pair donation to the lead ion was demonstrated in Fig. 5, in which the polarographic solutions contained sodium chloride besides arginine hydrochloride to maintain the chloride ion concentration at 0.60 M.

It is evident from Fig. 5, when $C_{Arg}<0.22$ M and $[Cl^-]=0.60$ M, the chloride ion predominate arginine in the competition for electron pair donation in the pH range 2.0—9.1. Even under the condition, $C_{Arg}>0.22$ M at pH<5.0, the arginine ligand predominates scarcely the chloride ligand, and the arginine coordinates with lead ion rather weakly, as can be confirmed from the minute reciprocal slope 0.016 V in Fig. 5. When $C_{Arg}>0.22$ M, the reciprocal solopes are 0.030 V and 0.052 V for the pH ranges 5.0—7.0 and 7.0—9.1, respectively, indicating the formation of 1 : 1 and 1 : 2 lead-arginine complexes in these pH ranges.

Complex Species and Dissociation Constant. The pK_1 and pK_2 values of arginine are 2.17 and 9.04[11] and the isoelectric point is 10.76,[12] so that the predominant ligand species in the pH region studied in this work must be arginine univalent cation (H_2Arg^+) rather than the dipolar molecule (HArg).

If a complex $Pb(H_2Arg)_m(OH)_nCl_r^{2+m-n-r}$ was formed in the solution, the cathodic reduction at the dropping mercury electrode must be

$$Pb(H_2Arg)_m(OH)_nCl_r^{2+m-n-r} + 2e + Hg = Pb(Hg) + mH_2Arg^+ + nOH^- + rCl^- \quad (1)$$

The shift of the half-wave potential by complexation and reduction in Eq. (1) must obey:

Table 4. Ligand number and complex species

pH range	Ligand concn. $C_{Arg}=[Cl^-]$	Total ligand No. $(m+r)$	Arginine ligand No. (m)	Cl^- ligand No. (r)	OH^- ligand No. (n)	Complex species
0.8—2.0	0—0.22	0	0	0	0	Pb^{2+}
	0.22—0.6	1.0	0	1.0	0	$PbCl^+$
2.0—5.0	0—0.22	0	0	0	0	Pb^{2+}
	0.22—0.6	1.5	0.5	1.0	0	$Pb(H_2Arg)Cl^{2+}$
5.0—7.0	0.22—0.6	1.0	1.0	0	0.3	$Pb(H_2Arg)(OH)^{2+}$
7.0—9.1	0.22—0.6	1.7	1.7	0	1.1	$Pb(H_2Arg)_2(OH)^{3+}$

$$(E_{1/2})_c = (E_{1/2})_s + 0.030\log K_c - 0.030\log(D_c/D_s) - 0.030m\log[H_2Arg^+] - 0.030n\log[OH^-] - 0.030r\log[Cl^-] \quad (2)$$

where $K_c = \dfrac{[H_2Arg^+]^m[OH^-]^n[Cl^-]^r[Pb^{2+}]}{[Pb(H_2Arg)_m(OH)_nCl_r^{2+m-n-r}]}$

D_c and D_s are diffusion coefficients of complex and simple lead ion, respectively.

For $pK_1 < pH < pK_2$

$$C_{Arg} \simeq [H_2Arg^+] = [Cl^-]$$

and $$-\log[OH^-] = 14 - pH$$

where C_{Arg} is the nominal concentration of arginine hydrochloride solution, then, the values of m, n and r can be determined as follows:

$$m + r = -\Delta(E_{1/2})_c/0.030(\Delta\log C_{Arg})$$

(when pH keeps constant)

$$m = -\Delta(E_{1/2})_c/0.030(\Delta\log C_{Arg})$$

(when both pH and $[Cl^-]$ keeps constant)

$$n = -\Delta(E_{1/2})_c/0.030(\Delta pH)$$

(when C_{Arg} keeps constant)

and $r = (m + r) - m$

Results based on the foregoing polarographic data and discussion were summarized in Table 4. Thus, the predominant complex species formed in various pH range were proved to be $PbCl^+$, $Pb(H_2Arg)Cl^{2+}$, $Pb(H_2Arg)(OH)^{2+}$ and $Pb(H_2Arg)_2(OH)^{3+}$ for pH <2.0, pH 2.0—5.0, pH 5.0—7.0 and pH 7.0—9.1, respectively. These change in complex species and the increment in the size for each complex may cause the stepwise decrease in diffusion current. This reduction was in good agreement with the results in Fig. 3 and was supported by Fig. 2.

Although from the data in Figs. 2, 4 and 5 the assignment of other formula $Pb(H_2Arg)(Harg)^{3+}$ in pH 7.0—9.1 is possible, the calculated dissociation constant ($pK_c=4.87\pm0.03$) (Table 5) shows that it is much less stable than $Pb(H_2Arg)_2(OH)^{3+}$ ($pK_c=10.33+0.03$) (Table 6), so that the latter formula was adopted as a predominant species.

In these complex species mentioned above only the complex species $Pb(H_2Arg)_2(OH)^{3+}$ in pH 7.0—9.1 can be regarded as a steady form and the others are in transition.

Table 5. Dissociation constants of $Pb(H_2Arg)(HArg)^{3+}$

	0.6	0.096	0.64	10.34
				ave. 10.33 ± 0.03

When a complex species $Pb(H_2Arg)_m(OH)_n^{2+m-n}$ is reduced reversibly, the half-wave potential obeys the Eq. (2) except losing the last term, $-0.030\,r\log[Cl^-]$.

In pH range, $pK_1 \ll pH < pK_2$

$$[H_2Arg^+] = \frac{C_{Arg}\cdot[H^+]}{[H^+]+K_2}$$

and $$D_c/D_s = (i_d)_c/(i_d)_s$$

then, $$pK_c = \frac{(E_{1/2})_s-(E_{1/2})_c}{0.030} - \frac{1}{2}\log(i_d)_c/(i_d)_s - m\log C_{Arg} + (m-n)pH + m\log([H^+]+K_2) + 14n$$

It has been shown above that at pH 7.0—9.1, $m=1.7$ (Fig. 4) and $n=1.1$ (Fig. 2). Then, the dissociation constant of the comlpex $Pb(H_2Arg)_2(OH)^{3+}$ was calculated to be $pK_c=10.33+0.03$ (Table 6).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2908—2913 (1968)

The Thermal Decomposition of Hexamminenickel(II) Complexes

Nobuyuki TANAKA, Masahiro KAGAWA and Minoru KAMADA*1

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received May 9, 1968)

From the thermogravimetric analysis, hexamminenickel(II) complexes were confirmed to decompose in two or three steps through lower ammine intermediates $NiX_m \cdot nNH_3$: $n=2$, 1 and $m=2$ for X=Cl; $n=2$ and $m=2$ for X=I, Br; $n=4$ and $m=2$ for $X=NO_3$ and $n=2$, 1/2 and $m=1$ for $X=SO_4$. The diffuse reflectance spectra of these intermediates have been measured in a range between 5000 to 27000 cm^{-1}, and they suggested that these intermediates may be polymers in which nickel ions were octahedrally coordinated with ammonia molecules and bridging halogen atoms. The infrared absorption spectra of these intermediates obtained in a range between 5000 and 60 cm^{-1} are also reported.

There have been several papers on the relative thermal stability, the stoichiometry of the decomposition process and other thermal properties of hexamminenickel(II) complexes.[1-4] In addition, the kinetics of the decomposition process and the structures of the intermediates have been reported recently.[5-10] Nevertheless, the effects of the heating rate on the processes and the structures of the intermediates in the thermal decomposition of hexamminenickel(II) complexes do not seem to be satisfactorily clear yet.

In the present study, the decomposition processes of various salts of hexamminenickel(II) have been reexamined by the methods of thermogravimetric analysis under the condition of smaller heating rates and by the chemical analysis of the intermediates. The structures of the intermediates have also been investigated by the measurements of the diffuse reflectance spectra and the infrared absorption spectra.

Experimental

Preparation of Complexes. Chloride, bromide, iodide, sulfate and nitrate of hexamminenickel(II) were precipitated from the strongly ammoniacal solution of nickel sulfate with appropriate ammonium salts. Only the sulfate was precipitated with ethanol because of its greater solubility in water. These compounds were recrystallized from concentrated ammonia, washed with ethanol and ether, and dried in air. They were identified by the measurements of their infrared absorption spectra.

Apparatus and Procedure. Thermogravimetric curves were recorded with a recording thermobalance, Shimadzu Thermano Balance RT-2, with 400 mg of sample at about 3°C/min of heating rate in nitrogen atmosphere of the flow rate of about 300 ml/min.

Hitachi infrared spectrometers EPI-2G and FIS-1 were used for the measurement of the infrared absorption spectra in the regions from 5000 to 400 cm^{-1} and from 500 to 60 cm^{-1}, respectively. Nujol mull method was adopted; in potassium bromide disk an absorption band due to ammonium ions was observed at 1400 cm^{-1}, which were considered to be formed by the reaction between ammonia of a complex or an intermediate and a trace of water contained in potassium bromide.

The diffuse reflectance spectra were recorded for magnesium oxide as a reference with a standard integrating sphere attached to a Hitachi spectrophotometer Type EPU-2 and a recording EPS-3T.

The chemical analysis was carried out as follows: Nickel and sulfate contents were determined by the gravimetric method by precipitating nickel ions with dimethylglyoxime and sulfate ions with barium chloride. The determination of halogens was followed by Fajans' method after removing nickel ions with a cation exchanger Dowex-50W-X8 in Na-form. Ammonia was analyzed in the following way. After a sample was dissolved into a known amount of excess standard hydrochloric acid, the unreacted acid was determined by the back titration with a standard sodium hydroxide solution. The mixed indicator, *i. e.*, the alcoholic solution of bromocresol green and methyl red, was used to detect the end-point (pH 5.5). Its color is gray or colorless at the end-point, pink in an acid and green in an alkaline region. It was found from the preliminary experiments carried out with synthetic samples that the color of nickel ions did not interfere with the detection of the end-point and the result was not affected by the amount of ammonium ions present in the solution. After removing nickel ions by using a cation exchanger in the potassium form, the nitrate content was determined with spectrophotometric method using absorption band at 200 mμ which is due to the charge transfer between a nitrate ion and a water molecule.

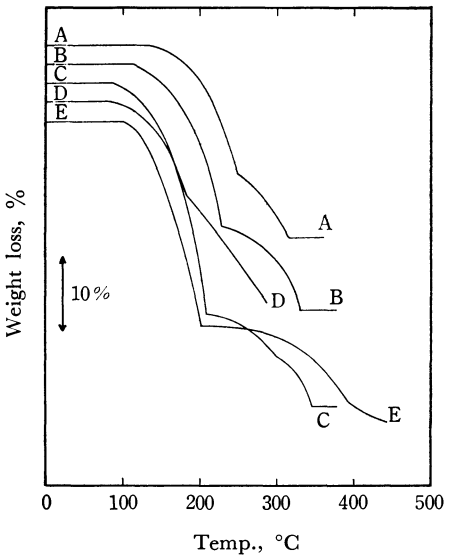

Fig. 1. Thermogravimetric curves of (A) $[Ni(NH_3)_6]I_2$, (B) $[Ni(NH_3)_6]Br_2$, (C) $[Ni(NH_3)_6]Cl_2$, (D) $[Ni(NH_3)_6](NO_3)_2$ and (E) $[Ni(NH_3)_6]SO_4$.

Results and Discussion

Thermogravimetric and Chemical Analyses. Figure 1 shows the thermogravimetric curves of hexamminenickel(II) complexes. The values of weight loss determined by the measurement of the thermogravimetric curves were well agreed with the calculated values, when the weight loss was assumed to be due to only the loss of ammonia. The analytical data of the intermediates are given in Table 1.

Hexamminenickel(II) chloride decomposed in three steps. On the thermogravimetric curves, the first one corresponding to the reaction

$$[Ni(NH_3)_6]Cl_2 \rightarrow NiCl_2 \cdot 2NH_3 + 4NH_3$$

proceeded in a temperature range from 85 to 211°C, the second one corresponding to the reaction

$$NiCl_2 \cdot 2NH_3 \rightarrow NiCl_2 \cdot NH_3 + NH_3,$$

from 211 to 303°C and the third one corresponding to the reaction

$$NiCl_2 \cdot NH_3 \rightarrow NiCl_2 + NH_3,$$

from 303 to 350°C. Since a small amount of NH_4Cl was formed above 300°C, the results of chemical analyses of $NiCl_2 \cdot NH_3$ and $NiCl_2$ somewhat deviated from the calculated values. However, the diffuse reflectance spectra and the infrared absorption spectra of these two intermediates

Table 1. Analytical data of intermediates

	Ni, %		NH_3, %		Anion, %	
	Found	Calcd	Found	Calcd	Found	Calcd
$[Ni(NH_3)_6]Cl_2$	25.4	25.3	43.8	44.1	30.6	30.6

$Ni(NO_3)_2 \cdot 4NH_3$	23.4	23.4	27.1	27.2	48.2	45.4

indicated that the greater parts of these intermediates were $NiCl_2 \cdot NH_3$ and $NiCl_2$, respectively.

The formation of $NiCl_2 \cdot NH_3$ is considered to depend greatly on the experimental condition, especially on the heating rate. For example, according to George and Wendlandt,[3] $NiCl_2 \cdot NH_3$ was not found in the process of decomposition at the larger heating rate, 7°C/min.

Hexamminenickel(II) iodide and bromide decomposed to NiX_2 (X=Br, I), obviously in two steps through $NiX_2 \cdot 2NH_3$. The first step,

$$[Ni(NH_3)_6]X_2 \rightarrow NiX_2 \cdot 2NH_3 + 4NH_3$$

proceeded at 109 to 231°C for X=Br and at 131 to 252°C for X=I. The second step,

$$NiX_2 \cdot 2NH_3 \rightarrow NiX_2 + 2NH_3$$

took place at 231 to 335°C for X=Br and at 252 to 318°C for X=I. Although the formation of $NiBr_2 \cdot NH_3$ had been reported,[1,5] it was not observed in this experiment.

Hexamminenickel(II) sulfate also decomposed to anhydrous $NiSO_4$ in three steps through $NiSO_4 \cdot 2NH_3$ and $NiSO_4 \cdot \frac{1}{2}NH_3$. The reaction,

$$[Ni(NH_3)_6]SO_4 \rightarrow NiSO_4 \cdot 2NH_3 + 4NH_3$$

proceeded at 100 to 205°C, the reaction,

$$NiSO_4 \cdot 2NH_3 \rightarrow NiSO_4 \cdot \tfrac{1}{2}NH_3 + \tfrac{3}{2}NH_3$$

at 205 to 397°C, and the reaction,

$$NiSO_4 \cdot \tfrac{1}{2}NH_3 \rightarrow NiSO_4 + \tfrac{1}{2}NH_3$$

at 397 to 455°C. $NiSO_4 \cdot \frac{1}{2}NH_3$ was not found at the heating rate 7°C/min,[3] whereas it was found at the heating rate 5°C/min.[4]

Hexamminenickel(II) nitrate was changed to $Ni(NO_3)_2 \cdot 4NH_3$ in a temperature range from 78 to 181°C by the reaction,

$$[Ni(NH_3)_6](NO_3)_2 \rightarrow Ni(NO_3)_2 \cdot 4NH_3 + 2NH_3 \cdot$$

Upon further heating, it decomposed violently leaving a black residue. The ratio of ammonia to nickel contents in this intermediate was confirmed to be exactly 4 : 1 by the chemical analysis. George and Wendlandt,[3] and Viltange[4] have reported that the intermediate which was formed at the first step had ammonia less than 4 mol. This disagreement is considered mainly due to the difference in heating rate. The smaller heating rate employed in this experiment may be the main cause of the formation of the tetrammine intermediate, similarly to the fact that $NiCl_2 \cdot \frac{1}{2}NH_3$ has been demonstrated by Murgulescu *et al.*[6] at the smaller heating rate, 2°C/min.

The thermal stability or the decomposition temperature of hexamminenickel(II) complexes at which a complex begins to decompose increased in order of the nitrate<the chloride<the sulfate<the bormide<the idodide. Especially, the order of the halides is the same as the increasing order of the size of halide ions, *i. e.*, $Cl^- < Br^- < I^-$. This may indicate a possibility that the dissociation of ammonia of hexamminenickel(II) complexes occurs after an outer-sphere ion enters into the coordination sphere (S_N2 mechanism), because, if the bond breaking between ammonia and nickel takes place before the bond formation between nickel and outer-sphere ion, the decomposition temperature is expected to be independent of the kind of outer-sphere ion.

Diffuse Reflectance Spectra. The wave numbers of the band maxima of diffuse reflectance spectra of hexamminenickel(II) complex and the intermediates are given in Table 2. The measurement of NiI_2 was not successful.

The diffuse reflectance spectra of nickel(II) chloride and nickel(II) bromide have been analyzed in the field of octahedral symmetry,[11] and these halides are reported to have a polymeric structure similar to cadmium chloride.[11] The reflectance spectra of $NiCl_2 \cdot 2NH_3$, $NiBr_2 \cdot 2NH_3$ and $NiI_2 \cdot 2NH_3$ obtained in the region above 10000 cm^{-1} have also been reported.[9,10] These compounds

are considered to have polymeric pseudo-octahedral symmetry; the absorption band, $^3A_{2g} \rightarrow {}^3T_{2g}$ (F), was confirmed in this experiment. Their configurational structure is assumed to be not similar to $CdCl_2$ but similar to $NiCl_2 \cdot 2py$ (py= pyridine). In $NiX_2 \cdot 2NH_3$ (X=halogens), each nickel ion is considered to be surrounded by four bridging halogens arranged in a square planar configuration and two ammonia molecules located in trans position. Some spin-forbidden bands were observed because the symmetry of their ligand field was lower than the octahedral one.

It may be concluded from these results that the nickel ion keeps the coordination number 6 in whole thermal decomposition process when ammonia molecules are replaced stepwise by halogen ions. The fact that ammonia molecules and halogens are coordinated to a nickel ion is important for the band assignment of the infrared absorption spectra of these intermediates.

Although a nickel(II) ion of monoammine compound, $NiCl_2 \cdot NH_3$, is considered to be also six-coordinated because its spectrum has a great resemblance to that of $NiCl_2$ or $NiCl_2 \cdot 2NH_3$, its configurational structure has not been known yet.

Nelson and Shepherd[9] were successful in explaining the well-known fact that $NiX_2 \cdot 4py$ could be prepared whereas $NiX_2 \cdot 4NH_3$ has not been found yet. According to their discussion, in the case of $NiX_2 \cdot 4py$, the excess negative charge on nickel caused by the electron transfer from coordinated halogen could be reduced with the presence of a π-electron acceptor capacity of coordinated pyridine molecule; the "electroneutrality principle" holds. This seems to be the most probable cause of the stabilization of $NiX_2 \cdot 4py$. This consideration explains the instability of $NiX_2 \cdot 4NH_3$, because an NH_3 molecule does not have such a π-electron acceptor capacity and, consequently, if the compound were formed, negative charges must be localized on nikel. Since bridging halogens have a smaller capacity of electron transfer, $NiX_2 \cdot 2NH_3$ may exist in stable form though it has four halogens coordinated to nickel ion. The discussion cited above may be one of the important examples in which the process of the thermal decomposition is attempted to be explained from the considerations of the electronic structure.

Infrared Absorption Spectra. Figure 2 shows the infrared absorption spectra of the chloride, and Table 3 gives the wave numbers and the assignment of the absorption bands of the hexamminenickel(II) halides and their thermal decomposition products.

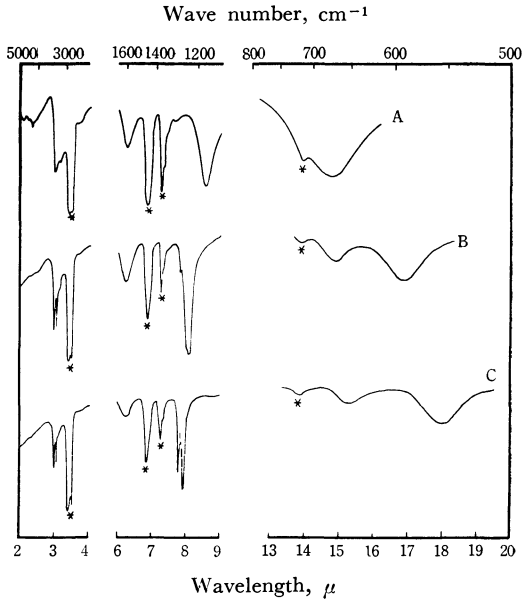

Fig. 2. The infrared absorption spectra of (A) $[Ni(NH_3)_6]Cl_2$, (B) $NiCl_2 \cdot 2NH_3$ and (C) $NiCl_2 \cdot NH_3$ in the range from 5000 cm^{-1} to 500 cm^{-1}. Optical density scale displaced arbitrarily.

The assignment of the absorption bands of hexamminenickel(II) halides has been reported previously.[4,12] It is interesting to know how the absorption bands due to ammonia are affected by the structure change which occurs when the monomeric structure in the hexammine complex is changed to the polymeric one bridged with halogen ions in the lower ammine intermediates.

In the case of the diamminenickel(II) chloride, for example, the ν(NH) split into two peaks, whereas $\delta_{deg}(NH_3)$ neither split nor shifted, compared with those of hexamminenickel(II) chloride. The $\delta_s(NH_3)$, being affected by the structure change, shifted to higher wave numbers. Ammonia is considered to coordinate to nickel ion from the diffuse reflectance spectra, which suggests that the absorption band due to the $\rho_r(NH_3)$ must appear. A weak absorption band, however, was observed in the usual rocking region, while a strong absorption band appeared at 590.3 cm^{-1} and a new band at 435 cm^{-1}. This phenomenon has been recently reported on various kinds of diammine complexes by Clark and Williams,[10] who assigned the former two bands to $\rho_r(NH_3)$ and the latter to the ν(NiN). Although $\delta_s(NH_3)$, $\rho_r(NH_3)$ and ν(NiN) are generally expected from their modes of vibration to shift to the same direction, the experimental results did not agree with this expectation. However, since ammonia and halogen must be coordinated to nickel ion, this assignment is considered as reasonable. Especially, the $\rho_r(NH_3)$ of the diammine complexes shifted to higher wave numbers in order of the iodide > the bromide > the chloride, which was the reverse of the order in the hexammine compounds. This change may be explained by considering that the effect of outer-sphere ions[12] disappears as the halogen ion is coordinated to nickel. The ν(NiN) of the diammine complexes was observed at higher wave numbers by 100 cm^{-1} than that of hexamminenickel(II). The reason why, in the case of the diammine complexes, the $\delta_s(NH_3)$ and ν(NiN) shift to higher wave numbers in the opposite direction of the $\rho_r(NH_3)$ has not been understood yet. The strong absorption band observed at 216 cm^{-1} may be assigned to ν(NiCl). However, other absorption bands observed at 189 cm^{-1} and 150 cm^{-1} were not assigned yet. The same was also observed with the bromides and the iodides.

Nickel chloride, bromide and iodide gave the same type of absorption bands. The absorption bands at 292 cm^{-1} for nickl chloride, at 229 cm^{-1} for nickel bromide and at 183 cm^{-1} for nickel iodide may be assigned to ν(NiCl), ν(NiBr) and ν(NiI), respectively. Other absorption bands were not assigned.

As to monoamminenickel(II) chloride, $NiCl_2 \cdot NH_3$, the $\delta_s(NH_3)$ split and shifted to higher wave numbers than that of diamminenickel(II), whereas the $\rho_r(NH_3)$ shifted to lower wave numbers, 555.6 cm^{-1}. It is interesting that the $\rho_r(NH_3)$ was observed in a region of such lower wave numbers.

The infrared absorption spectra of $[Ni(NH_3)_6]SO_4$ and its diammine intermediate are given in Table 4. In the diammine compound, the ν(NH), the $\delta_{deg}(NH_3)$ and the $\delta_s(NH_3)$ due to ammonia showed the same behavior as the diamminenickel(II) chloride. The SO_4^{2-} absorption band may be explained with C_{2v} symmetry, though it is not clear whether the SO_4^{2-} ion behaves as a simple bidentate or a bridging bidentate. As for the hemiammine compound, it was difficult to deduce whether the SO_4^{2-} ion is coordinated to a nickel(II) ion or not, because the band at 1130 cm^{-1} did not split and that at 977 cm^{-1} was strong; the former is characteristic of a free SO_4^{2-} ion and the latter is characteristic of a coordinated one. These may be attributed to the distortion of the SO_4^{2-} ion which was caused by heating.

12) J. Fujita, K. Nakamoto and M. Kobayashi, *J. Am. Chem. Soc.*, **78**, 3295 (1956).

The wave numbers of the absorption bands of hexamminenickel(II) nitrate and its intermediate are also given in Table 4. The measurement was made by both nujol and HCB mull methods. The NO_3^- ion was considered to be coordinated to nickel ion in the tetrammine compound from its spectral change from a D_{3h} symmetry in the hexammine complex to a C_{2v} symmetry in the dinitratotetrammine complex. The structure of the tetramminenickel(II) nitrate may be monomeric because the shift of the $\rho_r(NH_3)$ to lower wave numbers was not observed.

The measurement of infrared absorption spectra was carried out by Mr. Mitsuo Sato and the members of the late Professor Kinumaki's Labolatory at the Chemical Research Institute of Non-aqueous Solutions, Tohoku University. The authors wish to thank the Ministry of Education for the financial support granted for this research.

Polarography of Halides in Dimethylformamide. I. Bromide Ion and Its Mercuric Compounds

Yoshihisa MATSUI, Ryuji KAWAKADO and Yoshio DATE

Department of Agricultural Chemistry, Faculty of Agriculture, Shimane University, Nishikawazu-cho, Matsue

(Received May 14, 1968)

The complex formation between tetraethylammonium bromide (TEB) and mercuric bromide in dimethylformamide was observed conductometrically, and a complex, tetraethylammonium tribromomercurate (TETM), was isolated. Voltammetric studies of TEB, TETM, and mercuric bromide were made, using the dropping mercury electrode in dimethylformamide containing 0.1 M tetraethylammonium perchlorate. It was found that TEB gives two reversible anodic waves, of which the more negative one is due to the oxidation of mercury to TETM, and the more positive, to the oxidation of mercury to mercuric bromide. The electrode reaction mechanism was also investigated by means of large-scale electrolysis with a controlled potential.

At the dropping mercury electrode the halide ion gives a reversible anodic wave due to the oxidation of mercury to halogenated mercury species. For example, it is well known that the halide ion in water depolarizes the dropping mercury electrode upon the formation of insoluble mercurous halide.[1]

However, the polarographic behavior of halide ions in dimethylformamide (DMF) has been shown to differ from that in water.[2,3] Given and Peover[2] observed that the iodide ion in DMF gives two anodic waves, of which the more negative may be attributed to the oxidation of mercury to the tetraiodomercurate ion on the basis of the analysis of the wave. The more positive wave was suggested to arise from the oxidation of mercury to the triiodomercurate ion, but it was not proved experimentally. They also reported that the chloride ion in DMF showed virtually the same polarographic behavior as the iodide ion except for some departures of the more negative wave from that to be expected on the basis of the equation of the wave, probably as a result of the partial dissociation of the tetrachloromercurate ion to the trichloromercurate ion and the chloride ion. The behavior of the bromide ion in DMF was studied by Breant and Kiet,[3] who reported the formation of the tetrabromomercurate ion by the oxidation of mercury. However, the behavior of these halide ions on the electrode surface has still remained obscure, especially the electrode reaction mechanism at the potential of the more positive wave.

In the present paper, the polarographic behavior of the bromide ion and its mercuric compounds in DMF will be examined in detail in order to make clearer the mechanism of the electrooxidation of mercury; we will use the methods of d. c. polarography, large-scale electrolysis with a controlled potential, and conductometry.

Experimental

Materials. DMF obtained commercially was purified by the method of Wawzonek *et al.*[4] (bp 51.0—52.3°C/18 mmHg). Tetraethylammonium perchlorate

1) I. M. Kolthoff and C. S. Miller, *J. Am. Chem. Soc.*, **63**, 1405 (1941).
2) P. H. Given and M. E. Peover, *J. Chem. Soc.*, **1959**, 1602.
3) M. Breant and N. V. Kiet, *Compt. Rend.*, **262**, 955 (1966).
4) S. Wawzonek, E. W. Blaha, R. Berkey and M. E. Runner, *J. Electrochem. Soc.*, **102**, 235 (1955).

(TEP) was prepared from tetraethylammonium hydroxide and perchloric acid according to the directions of Geske and Maki.[5] The crude product was recrystallized twice from water and dried in a vacuum oven at 65°C. The 0.10 M solution of TEP in DMF showed virtually no polarographic wave within the range from +0.4 to −2.7 V *vs.* SCE. Tetraethylammonium bromide (TEB) was prepared according to the directions of Fleischer and Nachod.[6]

Found: Br, 37.77%. Calcd for $C_8H_{20}NBr$: Br, 38.02%.

Mercuric bromide obtained commercially was purified by recrystallizing it from ethanol-water. A reagent-grade sample of mercurous bromide was used without further purification.

Tetraethylammonium Tribromomercurate (TETM). This was prepared by a method similar to that described by Cruse, Goertz, and Petermöller.[7] Mercuric bromide (3.60 g) and TEB (2.10 g) were added to 30 m*l* of DMF and stirred until they were in solution. The solution was then poured into 150 m*l* of water; the precipitate was collected by filtration, washed with water, and recrystallized from DMF-ethanol. There was thus obtained 2.2 g (39%) of TETM, which had the following characteristics: mp 138.0—139.5°C (lit.[7] mp 124°C), IR (KBr disk): 1456 and 1402 cm^{-1} (δ C-H), 1183 and 1030 cm^{-1} (ν C-N).

Found: C, 16.83; N, 2.63%. Calcd for $C_8H_{20}NHgBr_3$: C, 16.84; N, 2.46%.

Conductivity Measurements. A Yanagimoto conductivity outfit (model MY-7) was used for these measurements. A conductivity cell was fitted with circular, blacked platinum electrodes separated by 10 mm. The cell constant was 0.4455. All the measurements were made at 25±0.1°C.

Polarographic Measurements. Anhydrous DMF was used as a solvent, with 0.10 M TEP as the supporting electrolyte. An H-type cell was used for the polarography. The current-potential curves were recorded with a Shimadzu polarograph, model RP-50. The bridged saturated calomel electrode proposed by Takaoka[8] was used throughout as a reference electrode. All the potentials were corrected for the bridge potentials measured in the way described in the literature. The potential drifting during one polarographic measurement was less than ±5 mV. All the potentials were corrected automatically for the IR-drop across the electrolysis cell with a Shimadzu automatic potential corrector, model AIC-50. The dropping mercury electrode had the following characteristics in a 0.10 M solution of TEP in DMF (open circuit): m=1.165 mg/sec and t=5.6 sec for h=66.0 cm. All the measurements were made at 25±0.1°C.

Large-Scale Electrolysis with Controlled Potential. Electrolysis was carried out in a cell similar in construction to that used by Fujinaga *et al.*[9] The mercury pool and the platinum electrode used had areas of approximately 75 and 60 cm^2 respectively. The bridged saturated calomel electrode mentioned above was used as a reference electrode. The potential of the mercury pool was controlled with an improved Yanagimoto VE-3 controlled potential electrolyser.

A solution of 300 m*l* of DMF with 6.89 g of TEP, and 3.60 g of mercuric bromide or 1.26 g of TEB was degassed for 2 hr with pure nitrogen, and then electrolyzed at a controlled potential with stirring and with cooling in an ice bath (3—5°C). The quantity of electricity required for the electrolysis was estimated graphically from the current-time curve. After the electrolysis, the electrolyte was concentrated by vacuum distillation to about 20 m*l*. The products were isolated by fractional crystallization from water. All the products were identified by their melting points, IR spectra, elementary analyses, and/or polarograms.

Results and Discussion

Solubility Relations. TEB and mercuric bromide are easily soluble in DMF, while mercurous bromide is insoluble. If a concentrated solution of mercuric bromide in DMF is shaken with mercury, mercurous bromide precipitates at once, but if the solution is dilute enough (below 0.025 M at 25°C), no precipitation occurs. If a trace amount of mercurous bromide is shaken with DMF, it dissolves with the separation of mercury. These observations indicate that the equilibrium between mercuric and mercurous bromide (Eq. (1)) is established rapidly, and that the solubility of mercuric bromide in the presence of mercury is about 0.025 M at 25°C.

$$HgBr_2 + Hg \rightleftharpoons Hg_2Br_2 \qquad (1)$$

Accordingly, when a dilute solution of mercuric bromide (below 0.005 M) is polarographically studied in DMF, it is not necessary to consider the reaction between mercuric bromide and mercury.

There is no separation of mercurous bromide when a concentrated solution of mercuric bromide in DMF is shaken with mercury in the presence of TEB. This suggests that the complex formation between mercuric bromide and TEB occurs in solution, as has been reported by Cruse et al. in the case of acetonitrile.[7]

Conductometric Measurements. If the complex formation between mercuric bromide and TEB occurs in DMF and if the value of the conductivity of the complex is different from those of the constituents, the mole-ratio between the constituents can be determined by the method of conductometric titration. The results of conductometric titration are given in Fig. 1. The addition of mercuric bromide to the solution of TEB in DMF lowered the specific conductivity, which reached the minimum value when the concentration of mercuric bromide added became equal to that of TEB. This obviously suggests that complex formation occurs in solution and that

the mole-ratio between the constituents is equal to one. The equivalent conductivity of the mixture of mercuric bromide and TEB with the mole ratio of 1 : 1 is plotted in Fig. 2, together with those of the constituents.

The complex, TETM, was isolated as has been described in the Experimental section. The polarographic and conductometric behavior of this complex in DMF coincided with those of the mixture of the constituents with the mole ratio of 1 : 1. Irrespective of the presence or absence of mercury, TETM is easily soluble in DMF (about 50% by weight), while it is insoluble in water.

Polarographic Measurements. Using anhydrous DMF as a solvent with 0.10 M TEP as a supporting electrolyte, the polarographic behavior of TEB, TETM, and mercuric bromide was investigated (Fig. 3). TEB gives two anodic waves and no maximum over the potential range of +0.4——2.7 V *vs.* SCE in the concentrations studied. TETM gives two waves, anodic and cathodic; on the latter a maximum appears at concentrations above 0.25 mM. Mercuric bromide gives two cathodic waves, on the more negative wave of which a maximum arises in the concentrations above 0.50 mM. Since both of these maxima arise at a more negative potential of the more negative waves, they do not prevent us from estimating the half-wave potentials and the limiting currents of the more negative waves.

The half-wave potentials ($E_{1/2}$) and the diffusion current constants (I_d) in various concentrations of these depolarizers are given in Table 1. All the I_d's were effectively constant over the concentration range studied. The limiting currents for 0.50 mM TEB were found to be proportional to the square root of the effective pressure of the mercury applied to the dropping mercury electrode (Table 2). Similar results were obtained for both TETM and mercuric bromide, indicating that the limiting currents of all these waves are diffusion-controlled.

The ratios of the I_d's of the more positive waves to those of the more negative waves caused by these depolarizers were approximately 1 : 2, suggesting that the ratios of the numbers of electrons transferred at the more positive wave to those transferred at the more negative wave may be 1 : 2. Assuming that the overall electroreduction of three molecules of mercuric bromide is due to the reversible transfer of six electrons from the dropping mercury electrode, yielding mercury and bromide ions, it follows that two electrons should be assigned to the more positive reduction process and four electrons to the more negative reduction process. A similar deduction may be made with regard to the electrooxidation of mercury in the presence of bromide ions. Thus, the mechanism of the electrode reactions may be given by:

$$3HgBr_2 + 2e \rightleftarrows Hg + 2HgBr_3^- \quad (2)$$

$$2HgBr_3^- + 4e \rightleftarrows 2Hg + 6Br^- \quad (3)$$

This mechanism can make clear the polarographic characteristics of TETM. Namely, it indicates that the more positive wave should be anodic, the more negative wave, cathodic, and the ratio between the I_d's, 1 : 2.

This hypothetical mechanism was substantiated by analyzing the waves of complex mercury ions studied by Kolthoff and Miller.[1] By applying their method to this mechanism, the potential of the dropping mercury electrode is given for the more positive wave by:

$$E_p = C_p + (\boldsymbol{RT}/2\boldsymbol{F}) \ln ([HgBr_2]_0^3/[HgBr_3^-]_0^2) \quad (4)$$

and for the more negative wave by:

$$E_n = C_n + (\boldsymbol{RT}/2\boldsymbol{F}) \ln ([HgBr_3^-]_0/[Br^-]_0^3) \quad (5)$$

where the subscript zero denotes the concentration at the surface of the dropping mercury electrode, and where C_p and C_n are constant. It can easily be shown that the equations of the waves of bromide ion are:

$$E_p = C_p' + (\boldsymbol{RT}/2\boldsymbol{F}) \ln [i^3/(i_d - i)^2] \quad (6)$$

$$E_n = C_n' + (\boldsymbol{RT}/2\boldsymbol{F}) \ln [i/(i_d - i)^3] \quad (7)$$

These equations show that the half-wave potentials should change with i_d or with the concentrations of bromide ion according to:

$$E_{p,1/2} = C_p'' + (\boldsymbol{RT}/2\boldsymbol{F}) \ln [Br^-] \quad (8)$$

$$E_{n,1/2} = C_n'' - (\boldsymbol{RT}/\boldsymbol{F}) \ln [Br^-] \quad (9)$$

The results of the analyses of the waves are given in Fig. 4. The plotting of $\log[i^3/(i_d-i)^2]$ against the potential for the more positive wave gave a fairly good straight line, with a slope equal to 0.032 V (calculated for Eq. (6); 0.030 V), indicating that Eq. (2) is valid. The plot of $\log [i/(i_d-i)^3]$ against the potential for the more

negative wave was also linear, with a slope equal to 0.034 V, over the greater part of the potential range, but it became curved at the more negative potentials (above −0.2 V *vs.* SCE), indicating a behavior different, probably due to the adsorption of bromide ions on the surface of the dropping mercury electrode, as has been shown by Biegler in an aqueous solution.[10]

The relation between the half-wave potentials and the concentrations of the bromide ion is plotted in Fig. 5. A straight line relation was obtained for the more positive wave with a slope equal to 0.035 V (calculated for Eq. (8); 0.030 V) and one for the more negative wave with a slope equal to −0.062 V (calculated for Eq. (9); −0.059 V), though the plot for the latter became somewhat curved at low concentrations. Similar studies were carried out concerning TETM and mercuric bromide; all the results agreed well with the equations derived from the mechanism postulated above.

Large-Scale Electrolysis with a Controlled Potential. In order to make sure of the electrode reaction mechanism, a large-scale electrolysis of mercuric bromide and TEB was carried out with a controlled potential in DMF. The results are given in Table 3.

The electroreduction of mercuric bromide with the Hg cathode at the potential of the plateau of the more positive wave yielded TETM (26%); the quantity of electricity transferred per mole of the depolarizer (n) was 0.66 F (calculated for Eq. (2); 0.67 F), indicating that Eq. (2) is valid. TEB was obtained (41%) by the electroreduction of mercuric bromide at the potential of the plateau of the more negative wave, and the value of n was equal to 2.12 F (calculated for Eq. (2) and (3); 2.00 F), indicating that Eq. (3) is also valid. The polarograms of the catholytes after electrolysis, in both cases, agreed closely with those of the products.

The electrooxidation of TEB with the Hg anode at the potential of the plateau of the more negative wave yielded TETM (40%), as expected, whereas the value of n (1.01 F) was much greater than that expected on the basis of Eq. (3) (0.67 F). The polarogram of the anolyte showed that there was considerable increase in the anoidc wave as well as in the wave of TETM, caused probably by the formation of oxidizable species at the cathode, but the details have not been studied. The electrooxidation of TEB at the potential of the plateau of the more positive wave yielded mercuric bromide (27%), as expected, while the value of n (2.45 F) was also much greater than that expected on the basis of Eqs. (2) and (3) (1.00 F).

The Mechanism of the Anodic Dissolution of Mercury in the Presence of the Bromide Ion in DMF. On the basis of the observations presented above, it is reasonable to conclude that the two anodic waves given by the bromide ions in DMF are due to oxidation of mercury to tribromomercurate ions (Eq. (3)) and to mercuric bromide (Eq. (2)). On the other hand, it has already been reported by Given and Peover[2] that halide ions in DMF depolarize the dropping mercury electrode, mainly forming tetrahalogenomercurate ions (HgX_4^{2-}). However, they also observed that the ratios between the I_d's of the two waves of these depolarizers are approximately 1 : 2, indicating the formation of trihalogenomercurate ions. We have also observed, by means of conductometric titration, that complex formation occurs between mercuric iodide and tetraethylammonium iodide in the mole ratio of 1 : 1. Accordingly, it may be necessary to reinvestigate the polarographic behavior of halide ions other than the bromide ion.

The mechanism proposed in the present paper is similar to that at such inert electrodes as platinum[11,12] and graphite[13] in DMF or acetonitrile, where halide ions also give two anodic

10) T. Biegler, *J. Electroanal. Chem.*, **6**, 365 (1963).

waves, one of which corresponds to that of the oxidation of halide ions (X^-) to trihalide ions (X_3^-), and the other, to that of trihalide ions to halogen molecules (X_2). Considering that both trihalide ions and halogen molecules react rapidly with mercury, it might be possible to divide the anodic dissolution processes of mercury into the oxidation stpes of halide ions and the reaction steps between the oxidized species and mercury as follows:

$$\begin{array}{ccccc} 6X^- & \rightleftharpoons & 2X_3^- + 4e & \rightleftharpoons & 3X_2 + 6e \\ & & \downarrow{\scriptstyle 2Hg} & & \downarrow{\scriptstyle 3Hg} \\ & & 3HgX_3^- & & 3HgX_2 \end{array} \qquad (10)$$

With this mechanism, however, it is difficult to explain that the anodic waves are reversible, because the reactions between mecury and trihalide ions and between mercury and halogen molecules are both certainly irreversible. According to this mechanism, it is also difficult to explain the polarographic behavior of TETM and mercuric bromide, indicating that this mechanism is implausible.

The polarographic behavior of the bromide ion in DMF is obviously different from that in water. This difference can be related to the difference in the stability of the mercury species in these solvents. It is well known that mercuric halides in water react with mercury even in a very dilute solution, forming insoluble mercurous halides.[14] On the other hand, we have observed that mercuric bromide in DMF remains inert to mercury even in a comparatively concentrated solution, as has been described above. TETM is reported to possess great stability in acetonitrile, but less stability in water.[7] We have also observed that it is very stable in DMF. Thus, in an aqueous solution the bromide ion depolarizes the dropping mercury electrode, thus forming mercurous bromide, which is the most stable species in water. In DMF, however, mercurous bromide is less stable than either the tribromomercurate ion or mercuric bromide, so the bromide ion gives two anodic waves in DMF which correspond to the formation of the latter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2918—2921 (1968)

Preparation and Properties of Metal Complexes in Non-aqueous Solutions. I. Preparation of the *trans*-Dicyano-bis(ethylenediamine)cobalt(III) Complex by the Use of Dimethylsulfoxide as Solvent[1]

Masayuki MUTO, Tetsuo BABA[2] and Hayami YONEDA

Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received May 14, 1968)

An isomeric form of the hitherto known *cis*-$[Co(CN)_2\ en_2]^+$ was prepared from *cis*- or *trans*-$[CoCl_2\ en_2]^+$ and potassium cyanide in dimethylsulfoxide solution. The new complex was characterized by UV, IR and NMR spectra, and its trans configuration was established.

Two peculiarities may be noticed about the preparation of $[Co(CN)_2en_2]^+$. One is the fact that only the cis form is known. The other is the way of its preparation. Usually, diacido-bis-ethylenediamine complexes, $[CoX_2en_2]^+$ can be prepared from *trans*-$[CoCl_2en_2]^+$ by substitution of X for Cl. However, the cyano mixed complex is obtained only via *trans*-$[Co(S_2O_3)_2en_2]^-$. When the dichloro complex is treated with potassium cyanide in an aqueous solution, disproportionation occurs to produce $[Co\ en_3]^{3+}$ and $[Co(CN)_6]^{3-}$. This fact indicates that the incoming cyano groups expel the other kind of ligands from the coordination sphere. On the other hand, it is generally known that cobalt(III) ammines were quite labile in an alkaline solution. In the preparation of the cyano mixed complex, the reaction mixture is fairly alkaline due to hydrolysis of the added cyanide. This alkalinity of the solution might make

1) Presented at the 17th Symposium of Coordination Chemistry held at the Hiroshima University, Hiroshima, December 11, 1967.

2) On leave from the Minoshima High School, Arita-shi, Wakayama.

3) H. Yoneda, This Bulletin, **31**, 74 (1958).

the complex labile and lead it to disproportionation.

In our previous report[3] on the decomposition of cobalt(III) ammines, the proton dissociation mechanism was proposed. In that mechanism, it was assumed that, in the decomposition process, proton dissociation from the coordinated NH_3 takes place first, and that then the NH_2^- thus produced came out of the coordination sphere. A similar proton dissociation may be considered in the present case. Therefore, it was felt necessary to work under conditions where proton dissociation can not occur. To fulfill these conditions, we tried to use dimethylsulfoxide as a solvent and succeeded in obtaining the cyano diamine mixed complex which proved to be isomeric to the hitherto known *cis*-$[Co(CN)_2en_2]^+$ complex, directly from the dichloro complex.[4,5]

Experimental

Method of Preparation. One gram (0.016 mol) of powdered potassium cyanide was dissolved in 150 m*l* of dimethylsulfoxide heated at 60°C. To this solution was added in small portions 1.5 g (0.05 mol) of *trans*-$[CoCl_2en_2]NO_3$ under constant stirring. The added complex reacted gradually with the cyanide and, after a while, yellow precipitate of greenish tint was formed. At about 60°C, the reaction was complete in 15—20 min. When *cis*-$[CoCl_2en_2]Cl$ was used as a starting material, the reaction proceeded much more smoothly to form an orange yellow precipitate in one or two minutes. (Both reactions gave the same final product). The greenish tint probably originated from unreacted green *trans*-$[CoCl_2en_2]NO_3$. The precipitate thus formed was filtered and washed with warm dimethylsulfoxide and then with acetone. Through this procedure the precipitate became light yellow. This product was supposed to be $[Co(CN)_2en_2]Cl$ with some contamination. This was not soluble in dimethylsulfoxide nor in ethanol. In water it was too much soluble to obtain good crystals. Therefore, purification was attempted by converting it to the perchlorate salt. The crude product was dissolved in a small volume of water and, after filtration, was added with the saturated solution of sodium perchlorate. An orange yellow crystalline powder came out. This was washed with small amount of water and ethanol, and dried in air.

Found: C, 21.79; H, 5.06; N, 24.88%. Calcd for $[Co(CN)_2en_2]ClO_4$: C, 21.80; H, 4.88; N, 25.42%.

Spectral Measurements. The UV spectra were measured with a Shimadzu QR 50 spectrophotometer. The IR spectra were recorded with a Hitachi EPI S2 spectrophotometer equipped with NaCl optics. The KBr disc method was adopted in the IR measurement. The NMR spectra were run on a Varian A60 NMR spectrometer. Deuterium oxide was used as solven., and the sodium salt of trimethylsilylpropane sulfonic acid was used as an internal reference.

Results and Disucssion

The Ligand Field Absorption Bands. The UV absorption curve of the new $[Co(CN)_2en_2]ClO_4$ is shown in Fig. 1 with that of the known *cis*-$[Co(CN)_2en_2]ClO_4$. The absorption data are summarized in Table 1. The main difference

	24.0	1.69		

between the absorption curves of both isomers appears in their first absorption bands: While the first band of the cis isomer shows no clear split, that of the new one seems to split into two components. A similar kind of difference is observed in the first bands of *cis*- and *trans*-$[CoCl_2en_2]^+$ too.[6] In this case also, the cis isomer has no

4) Two works concerning the preparation of $[Co(CN)_2en_2]^+$ in an aqueous solution were reported at the 21st Annual Meeting of the Chemical Society of Japan (April, 1968): K. Kuroda prepared *cis*-$[Co(CN)_2en_2]^+$ by treating $[CoCO_3en_2]^+$ with CN^- in an aqueous solution. M. Shibata *et al.* prepared *cis* and *trans*-$[Co(CN_2)en_2]^+$ from $[Co\ en_3]^{3+}$ and CN^- in an aqueous solution.

5) Previously we reported the preparation of *cis*-$[Co(CN)_2en_2]Cl$ by the use of dimethylsulfoxide as solvent. H. Yoneda, T. Baba and M. Muto. This Bulletin, **40**, 1736 (1967). However, no attempts were successful to reproduce the result. The interconversion between the cis and trans forms is now being studied.

6) M. Linhard and M. Weigel, *Z. anorg. Chem.*, **271**, 101 (1952).

split band, and the trans isomer has a markedly split first band. Therefore, if we assume the trans configuration for the new $[Co(CN)_2en_2]^+$, the present situation can reasonably be understood. However, this can not be a decisive proof for the trans configuration, because we know that the first band of *trans*-$[CoCl(CN)en_2]^+$ shows no split, while that of the cis isomer split markedly into two components.[7] In addition, there are several possible structures which are isomeric to the known *cis*-$[Co(CN)_2en_2]^+$.

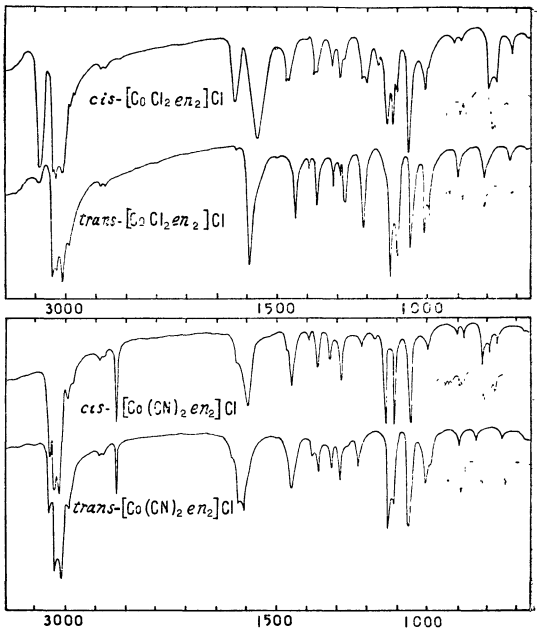
Corey and Bailar[8] classified two possible conformations of the ethylenediamine molecules in $[Co\ en_3]^{3+}$ into the "lel" and "ob" forms. The "lel" form represents the conformation in which the C-C axis is nearly parallel to the threefold axis of $[Co\ en_3]^{3+}$, and the "ob" form to the conformation in which the C-C axis is almost perpendicular to the threefold axis of the complex (In the actual $[Co\ en_3]^{3+}$, all three ethylenediamine molecules take the "lel" form). Such kinds of conformation can be considered in the *cis* bisethylenediamine complex too. In this case, there are three possible combinations of two ethylenediamine molecules, lel-lel, lel-ob and ob-ob form. The active chloride[9] of *cis*-$[(Co(CN)_2en_2]^+$ proved to have an ob-ob conformation, while the racemic chloride[10] of *cis*-$[CoCl_2en_2]^+$ a lel-ob conformation. Thus our new complex can be considered to have the following several possible structures.

1) The two cyano groups are linked to the metal ion with the nitrogen atom.[11]

2) The two ethylenediamine molecules take a lel-lel or lel-ob conformation.

3) The two cyano groups are coordinated to the metal ion in trans positions.

IR Spectra. In order to obtain informations concerning the structure of the new complex, the IR spectra of the new and the *cis*-$[Co(CN)_2en_2]^+$ were measured.[12] For comparison, the spectra of *cis*- and *trans*-$[CoCl_2en_2]^+$ were also measured. The results are shown in Fig. 2. Usually CN^- is linked to the metal ion with the C atom. In the case of *cis*-$[Co(CN)_2en_2]^+$, this was confirmed by



Wave number (cm^{-1})

X-ray analysis.[9] If CN^- were linked to the metal ion through the N atom in the new complex, the CN bond nature in the new isomer should be different from that of the *cis* isomer. While in the C coordination, CN^- should have a triple bond character ($Co^{3+}\leftarrow{}^-C{\equiv}N$), in the N coordination it should have a triple bond character ($Co^{3+}\leftarrow{}^-N{=}C$). Therefore, the absorption band due to the CN stretching in the new isomer should appear in longer wavelength region than that in the cis

11) K. Kuroda and P. S. Gentile, Proceedings of 10th ICCC, p. 280 (1967).
12) The pure chloride of the new $[Co(CN)_2en_2]^+$ for IR measurement was obtained as follows. The crude chloride was dissolved in a small volume of water, and, after filtration, ethanol was added in small portions until a slight turbidity appeared. The solution was filtered and the filtrate was evaporated to dryness under reduced pressure without heating. The dried residue was dissolved in water, and the procedure was repeated.
13) Baldwin also reported that the spectrum pattern in these regions is more complicated in the *cis*-$[CoX_2en_2]^+$ than in the trans isomer. M. E. Baldwin, *J. Chem. Soc.*, **1960**, 4369.

isomer. However, this is not the case. The CN stretching absorption band appears just at the same wave number (2130 cm^{-1}). Therefore, the N coordination can not be considered. If the new complex had the lel-ob conformation, the spectrum pattern of the new complex should be similar to that of *cis*-$[CoCl_2en_2]^+$. This is not the case. The IR spectra of the new $[Co(CN)_2\ en_2]^+$ and the *cis*-$[CoCl_2en_2]^+$ are fairly different in appearance. Rather, the spectrum pattern of the new complex shows a similarity to that of *trans*-$[CoCl_2en_2]^+$, especially in the CH_2 twisting and NH_2 rocking regions (see Fig. 2, 900—700 cm^{-1}). On the other hand, *cis*-$[CoCl_2en_2]^+$ and *cis*-$[Co(CN)_2en_2]$ show quite a unique splitting of bands in the CH_2 twisting and the NH_2 rocking region.[13] This fact makes a marked contrast to the trans isomer. This situation holds not only in the chlorides but also in the perchlorates. These findings seem to support the trans configuration of the new isomer, although they can not exclude the possibility of the lel-lel conformation.

NMR Spectra. To obtain the decisive conclusion concerning the structure of the new complex, the NMR spectra of the new and the known *cis*-$[Co(CN)_2en_2]^+$ dissolved in deuterium oxide were recorded. Figure 3 shows the CH_2 signals of both isomers (The NH_2 signals disappeared soon after dissolution due to deuteration). As expected, the CH_2 signal of the cis isomer shows a complicated pattern. On the contrary, the new isomer shows a sharp singlet which corresponds to the single species of the CH_2 protons. Thus the trans configuration of the new isomer was established.

The authors wish to thank the Ministry of Education of Japan for the financial support granted for this study.

The Selective Reduction of Aromatic Compounds by Electrolysis. I. Reduction of Naphthalene by Electrolysis[1)]

Akira MISONO, Tetsuo OSA and Takamichi YAMAGISHI

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo

(Received May 15, 1967)

The direct electro-reduction of naphthalene was investigated in various solvents, mainly in an acetonitrile-water solution using supporting electrolytes containing tetraethylammonium and tetra-*n*-butylammonium cations. The main reduction product was 1,4-dihydronaphthalene, though small amounts of 1,2-dihydronaphthalene and tetralin were also detected. Under optimum conditions, the selectivity and the current efficiency of the formation of 1,4-dihydronaphthalene were 98% and 86.4% respectively. It was found that the water concentration and the solvent had a significant influence on the reduction products and the current efficiency. 1,4-Dihydronaphthalene is mainly formed through the step-by-step addition of two electrons and protons. In addition, 1,4-dihydronaphthalene may be formed by the protonation of the dianion formed by the disproportionation of the anion radical. Further, it was proposed that the formation of the tetraethylammonium radical might partly occur by means of the electron transfer from the anion radical of naphthalene to the tetraethylammonium cation, besides the direct electron transfer to the cation from the electrode.

The reduction of aromatic hydrocarbons by an alkali metal in liquid ammonia or in low-molecular-weight amine, especially in a mixture of liquid ammonia and alcohol (Birch reduction), has been studied by many investigators and a mechanism for the reduction has been proposed.[2)] In the electrolytic reduction, many polarographic studies of condensed aromatic hydrocarbons in aprotic solvents in the presence or in the absence of a proton-donor have been reported,[3)] but the reduction products and the effect of reaction conditions have scarcely been investigated at all. In regard to the macro-scale electro-reduction of naphthalene, which

indicates the most negative value in the polarographic half-wave potential among all polycondensed unsubstituted aromatic hydrocarbons, only a few studies have been reported.[4,5] In the reduction of naphthalene by an alkali metal in liquid ammonia or amine, a considerable isomerization of unconjugated products to conjugated compounds occurs, whereas there hardly exists such possibility in the electro-reduction.

The present paper will deal with the macro-scale electro-reduction of naphthalene in organic solvents, such as acetonitrile, *N,N*-dimethylformamide (DMF), 1,4-dioxane (DIOX), tetrahydrofuran (THF), 1,2-dimethoxyethane (DME), or diglyme (DGL), in the presence of a proton-donor; the investigation was undertaken in order to clarify the reaction mechanism of the above reaction, to obtain 1,4-dihydro-product selectively, and also to examine the influence of the reaction conditions on the reaction products.

Experimental

Reaction Apparatus. Two different types of cells, H-type and cylindrical cells, with a glass-fritted disk of medium porosity (No. 3 and 4) and of different radii (from 5 to 12 mm) in order to separate the catholyte and anolyte were used. Mercury and platinum were used as the cathode and the anode respectively.

Materials. Naphthalene was purified by recrystallization from methanol - water (mp 79.9—80.0°C). Acetonitrile was purified by distillation from phosphorus pentoxide[6] (bp 81.4°C). DMF was distilled *in vacuo* from calcium oxide (bp 64—65°C/25 mmHg). DIOX and THF were distilled from sodium wire after having been treated with potassium hydroxide[7] (bp 66°C and 101—102°C respectively). DME and DGL were prepared by a variation of the directions in the literature[8] and were purified by distillation from sodium wire[7] (bp 82.5—83.0°C and 162.5—163.0°C respectively). Tetraethylammonium *p*-toluenesulfonate (McKee's salt) was prepared and purified according to the literature.[9] Tetra-*n*-butylammonium bromide was purified by recrystallization from acetone.

Procedure. The base electrolyte was prepared by dissolving a supporting electrolyte in a 100 m*l* solution of a solvent and a proton-donor. This base electrolyte was named, for the sake of convenience, solution A. The catholyte consisted of a substrate to be reduced and 70 m*l* of solution A, while the anolyte was a 30 m*l* portion of solution A. The reaction cell was cooled by a water bath in order to maintain the temperature near room temperature during electrolysis. The cathode potential was set up and controlled by using the saturated calomel electrode (SCE) as a reference electrode and a controlled potential electrolyzer from the Yanagimoto Co., Ltd. (type VE-3). Electrolysis was carried out for about 8 hr with a constant stirring of the catholyte by the use of a magnetic stirrer. The current passed through was measured by a copper coulometer. The variations in the reaction conditions were as follows: water concentration, 0—30 vol%; concentration of the supporting electrolyte, 3—30 g/100 m*l* CH_3CN-H_2O; naphthalene concentration, 6—14 g/100m*l* solution A; cathode potential, from −2.3V to −2.4V *vs.* SCE; current density, 0.05—0.40 A/dm^2; reaction temperature, 2—50°C. The cathode area was about 50 cm^2 in all the experiments.

Identification and Analysis of the Reduction Products. The reduction products were 1,4-dihydronaphthalene (1,4-DHN), 1,2-dihydronaphthalene (1,2-DHN), and tetralin. No further reduction products of naphthalene could be identified.

After the reaction, water was added to the reaction mixture, and the oily upper layer was separated. The oily products were distilled *in vacuo* after having been dried with anhydrous sodium carbonate. The fraction boiling at 71.8—72.6°C/5 mmHg (uncorrected) gave a white crystal (I) (mp 24.8°C) by recrystallization from methanol - water. The reduction products in a THF solution were similarly treated and fractionated to give a fraction boiling at 93.0—93.2°C/19 mmHg. This fraction contained I, another compound, II, which was supposed to be a dihydro-product, and small amounts of naphthalene and tetralin. From the NMR and IR spectra of I, I was identified as 1,4-DHN. By comparing the NMR and IR spectra of the fraction containing II with those of 1,2-DHN prepared from 1,4-DHN by isomerization with sodium isopropoxide in DMF, II was identified as 1,2-DHN. The retention time of II accorded with that of 1,2-DHN in gas chromatography. In NMR spectra, I had absorptions at τ=6.65, 4.11, and 2.94 (intensity ratio 4 : 2 : 4), whereas II had them at τ=7.75, 7.30, 4.15, 3.67, and 3.09 (intensity ratio 2 : 2 : 1 : 1 : 4). In the 1700—1400 cm^{-1} region of the IR spectra, I had absorptions at 1665, 1597, 1590, 1500, 1455, and 1425 cm^{-1}, while II had them at 1600, 1490, 1480, 1450, 1431, and 1420 cm^{-1}. Tetralin was confirmed by the retention time in the gas chromatogram.

The quantitative analysis of the reduction products was performed by the gas chromatographic method (Column, Carbowax 1500 (10%) on Diasolid M (60—80 mesh) 2 m; Column temperature, 180°C; Carrier gas, H_2, 30 cc/min; Detector, Thermal conductivity cell. The calibration of 1,2-DHN was performed with a hydrogen-flame ionizing detector, assuming that the relative molar sensitivities of 1,2- and 1,4-DHN were equal when the hydrogen-flame ionizing detector was used.

The NMR spectra were measured with a JES model LAB-2160 spectrometer (60 Mc), and the IR spectra, with a Hitachi Infrared Spectrophotometer, Model EPI-S2.

Results

Effect of the Reaction Conditions. The electrolytic reduction was mainly carried out in

a medium of acetonitrile-water containing McKee's salt as a supporting electrolyte. In the examination of the reaction conditions, the current efficiencies for the formation of dihydro- and tetrahydro-products were defined as follows:

$$\eta_{DH} = \frac{\text{Amount of the dihydro-product (mole)} \times 2}{\text{Current passage (Faraday)}} \times 100\ (\%)$$

$$\eta_{TH} = \frac{\text{Amount of the tetrahydro-product (mole)} \times 4}{\text{Current passage (Faraday)}} \times 100\ (\%)$$

In the above equations, the 2 and 4 factors correspond to the numbers of electrons required for the formation of dihydro- and tetrahydro-products respectively.

Effect of the Water Concentration. In the electro-reduction of naphthalene, the concentration of a proton-donor was supposed to be an important factor affecting the reduction products and the current efficiency. The effect of the addition of water as a proton-donor to a solution of tetraethylammonium *p*-toluenesulfonate in acetonitrile was investigated. As is indicated in Fig. 1, the current efficiency was very dependent on the water concentration. As the water concentration increased, the current efficiency for 1,4-DHN ($\eta_{1,4DH}$) also increased, reaching a maximum value of 74.8% at a 25% water concentration; on the other hand, the current efficiency for 1,2-DHN ($\eta_{1,2DH}$) decreased with an increase in the addition of water and became almost zero when the water concentration reached 20%. η_{TH} was nearly constant and small except in very low water concentrations. In the electrolysis without water, the catholyte turned dark green and tetralin was formed preferentially, but upon the addition of 5% water no coloration was observed. This color may be due to the anion radical of naphthalene solvated by acetonitrile.

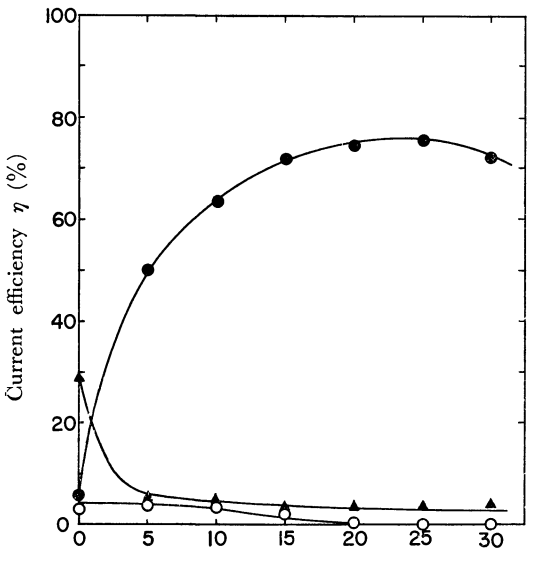

Fig. 1. Effect of the water concentration.
Cathode potential: −2.4 V *vs.* SCE;
McKee's salt concentration: 30 g/100 m*l* CH_3CN-H_2O
Naphthalene Concentration: 14.29 g/100 m*l* solution A
Current density: about 0.35 A/dm²
—●— $\eta_{1.4DH}$ —○— $\eta_{1.2DH}$ —▲— η_{TH}

Effect of the McKee's Salt Concentration. This effect was examined in a 25% water-acetonitrile solution. $\eta_{1,4DH}$ increased with an increase in the McKee's salt concentration in the low concentration range, but it decreased inversely in the high concentration range. Under the reaction conditions examined, 1,2-DHN was not detected, while η_{TH} remained constant and low (Fig. 2).

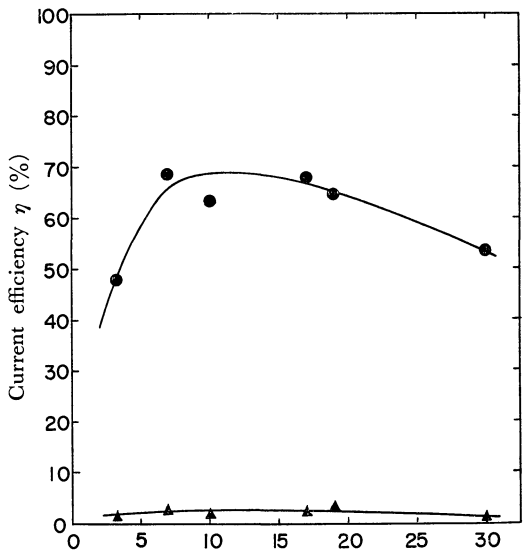

Fig. 2. Effect of the McKee's salt concentration.
Cathode potential: −2.4 V *vs.* SCE;
Water concentration: 25 vol%;
Naphthalene concentration: 11.43 g/100 m*l* solution A;
Current density: about 0.3 A/dm².
—●— $\eta_{1.4DH}$ —▲— η_{TH}

Effect of the Naphthalene Concentration. The effect of the naphthalene concentration is shown in Fig. 3. $\eta_{1,4DH}$ reached the maximum value of 83% at an optimum naphthalene concentration, but it did not vary much under the conditions examined. η_{TH} remained low and nearly constant. 1,2-DHN was not observed.

Temperature Effect. The reaction temperature was changed over the range from 2 to 50°C. Within this temperature range, $\eta_{1,4DH}$ increased as the reaction temperature rose (Table 1).

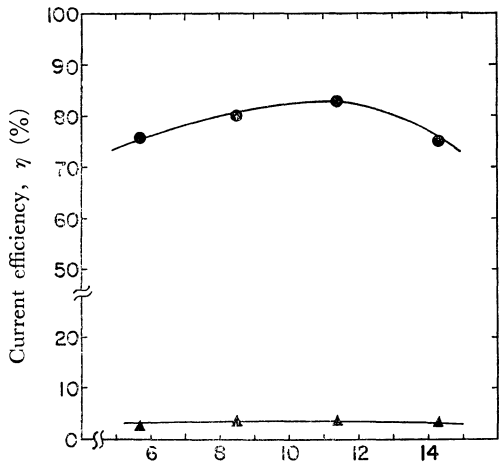

Fig. 3. Effect of the naphthalene concentration.
Cathode potential: −2.4 V *vs.* SCE;
Water concentration: 25 vol%;
Current density: about 0.3 A/dm².

Table 1. Temperature effect in the reduction of naphthalene

Temperature (°C)	Reaction time (min)	Current passage (Faraday)	Current density (A/dm²)	$\eta_{1.4DH}$ (%)
2	540	0.0082	0.049	21.4
11	480	0.0119	0.081	37.3
13	460	0.0110	0.078	40.7
30	500	0.0150	0.097	44.2
53	440	0.0266	0.195	55.0

Cathode potential: −2.4 V *vs.* SCE;
Naphthalene concentration: 8.57 g/100 ml solution A;
McKee's salt concentration: 20 g/100 ml acetonitrile-water;
Water concentration: 20 vol%.

As is shown in Table 1, $\eta_{1,4DH}$ at 30°C was about 1.1 times larger than that at 10°C (both were of approximately same current densities.).

Electrolysis in Various Solvents. The electrolytic reduction of naphthalene was investigated in the following solvents: acetonitrile, DIOX, THF, DME, and DGL. In these experiments, tetra-*n*-butylammonium bromide was used as the supporting electrolyte in place of tetraethylammonium *p*-toluenesulfonate. In an acetonitrile-water medium, $\eta_{1,2DH}$ was low, though it was larger than in an acetonitrile-water-tetraethylammonium *p*-toluenesulfonate system. However, reduction in other solvents (ethers) gave fairly large values of $\eta_{1,2DH}$. η_{TH} was low in all solvents. The ratio of $\eta_{1,2DH}+1/2\eta_{TH}$ to $\eta_{1,4DH}$ was in the following order:

$$DGL > DME \approx THF > DIOX > Acetonitrile$$

This order seems to be independent of the dielectric constant of the solvents (Table 2).

Effect of Proton-donors. In the electrolysis, water, methanol, ethanol, phenol, and *p*-hydroxybenzoic acid were used as the proton-donors. The effects of the proton-donors are shown in Table 3. Water, methanol, and ethanol all served as effective proton-donors, though the current efficiency ($\eta_{DH}+\eta_{TH}$) using methanol was a little higher than that using water or ethanol. This result partly depends on the difference in the current density. In the reduction using phenol or *p*-hydroxybenzoic acid as the proton-donor, the main reaction was hydrogen evolution and no formation of dihydro- or tetrahydro-products was observed.

Effect of the Current Density. As shown in Table 3, a large difference was observed in the current efficiencies when methanol was used as the proton-donor. This difference was supposed to be caused mainly by the difference in the current densities. Therefore, we examined the effect of

the current density by altering the porosity and radius of the glass-fritted disk*1 (Table 4). It was observed that $\eta_{1,4DH}$ increased with an increase in the current density, while η_{TH} did not vary much. Therefore, the ratio of $\eta_{1,4DH}$ to η_{TH} increased with an increase in the current density.

Discussion

Among the reaction factors examined, the water concentration and the solvent showed the most considerable influence on the reduction of naphthalene.

The measurement of the polarogram of naphthalene has shown that the first reduction wave involves only one one-electron addition, while the next one-electron addition occurs at a more negative potential in an aprotic system.[10] In the presence of a proton-donor, the anion radical is immediately protonated to become a monohydro radical. As the reduction potential of this monohydro radical is more positive than that of the original molecule,[11] the one-electron addition that follows occurs easily, without any change in the reduction potential, and a two-electrons transfer wave is observed. Therefore, in a reduction with an unsufficient amount of a proton-donor, the current efficiency of 1,4-DHN will be low. The tendency shown in Fig. 1 was consistent with this prediction, though the behavior of η_{TH} was in contrast with that of $\eta_{1,4DH}$. In the presence of a large amount of water, the solubility of naphthalene lowered and a considerable evolution of hydrogen occurred; thus $\eta_{1,4DH}$ had a maximum value under optimum conditions when the addition of water increased.

As has been mentioned previously, during the reduction of naphthalene in the medium of anhydrous acetonitrile, the catholyte turned dark green and the overall current efficiency was low. A considerable amount of the anion radical may take the following possible courses prior to protonation in the absence of water, for acetonitrile is not such an effective proton-donor as water, ethanol, or methanol:

1. Dimerization of anion radicals.
2. Electron transfer to a tetraethylammonium cation.
3. Electron exchange with an electrode.

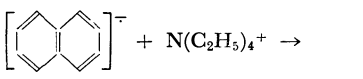
If the dimerization of the anion radicals occurs, 1,4,1',4'-tetrahydro-1,1'-binaphthalene will be formed. The naphthalene consumed was, however, almost entirely converted to the monomeric reduction products and no dimeric products could be detected. Therefore, the dimerization of the anion radicals is regarded as negligible.

*1 The current density was changed fairly much by this means, but the cathode potential could not be maintained at the set potential for long (for a few hours in the extreme case) after the reaction started in electolyses with low current densities.

10) P. H. Given and M. E. Peover, *J. Chem. Soc.*, **1960**, 385.

11) G. J. Hoijtink, J. van Schooten, E. de Boer and W. Ij. Aalbersberg, *Rec. Trav. Chim.*, **73**, 355 (1954).

If the electron transfer to a tetraethylammonium cation takes place, the tetraethylammonium radical will be formed. This radical, being unstable, decomposes into triethylamine and ethyl radical.[12] The gas-chromatographic analysis of the gaseous products of the electrolysis of naphthalene in anhydrous acetonitrile containing tetraethylammonium *p*-toluenesulfonate indicated that the gaseous products contained a considerable amount of C_2H_4 and a small amount of C_2H_6 (the ratio of C_2H_4 to C_2H_6 was about 30 : 1, and the current efficiency for $C_2H_4+C_2H_6$, about 30%). The tetraethylammonium radical is also formed by the direct electron transfer to the tetraethylammonium cation from the electrode.[13] The polarographic analysis of naphthalene in anhydrous acetonitrile-tetraethylammonium *p*-toluenesulfonate showed that naphthalene was reduced at about 0.25 V more anodic potential than the cation of the supporting salt. Accordingly, the following process may be included in the reaction scheme besides the direct electron transfer to the tetraethylammonium cation:



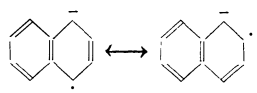
$$+ \cdot N(C_2H_5)_4$$

$$\cdot N(C_2H_5)_4 \rightarrow N(C_2H_5)_3 + \cdot C_2H_5$$

In Table 2, the ratios of $\eta_{1,2DH}+\frac{1}{2}\eta_{TH}$ to $\eta_{1,4DH}$ for the solvent used increase in the following order:

DGL > DME ≈ THF > DIOX > Acetonitrile

The order of the ethers was consistent with the basicity of the ethers as Lewis bases. The above order may be supposed to represent the solvation effect on the anion radical or the monohydro radical of naphthalene by the solvents used. The anion radical of naphthalene may be tentatively shown as below:



As the basicity of the solvent increases, the electronic configuration of the naphthalene anion radical solvated will be changed and the electron density of the 2 position may increase. A similar change will occur with the monohydro radical of naphthalene. Therefore, the formation of 1,2-DHN will increase as the basicity of the solvent increases in the cases of ether solvents.

In Fig. 1, the behavior of η_{TH} is remarkable. η_{TH} has a value of 29.3% when the water concentration is 0%. This predominant formation of tetralin in anhydrous acetonitrile can be similarly ascribed to the change in the electronic configuration of the naphthalene radical, brought about by the solvation by acetonitrile. This change results in the preferential formation of 1,2-DHN, which is then easily reduced to tetralin as the polarographic half-wave potential of 1,2-DHN is nearly the same as that of naphthalene (though it is slightly more negative than that of naphthalene).[14] The addition of water will change the solvation by acetonitrile and will cause 1,4-DHN to be preferentially formed.

The solvation state cannot be simply interpreted by the apparent physical properties of the solvent, such as its basicity as a Lewis base, its dielectric constant, and so on. We intend, therefore, to clarify the solvent effect by utilizing the ESR technique.

The effect of the concentration of McKee's salt can be interpreted as the coexistence of the stabilization of the naphthalene anion radical by the tetraethylammonium cation and the electron transfer to the cation from the anion radical. At a low concentration of McKee's salt, the stabilization effect is predominant, but with an increase in the concentration the electron transfer may increase. Furthermore, the approach of the water molecule may be hindered by the bulky tetraethylammonium cation.

The rise of the reaction temperature seems to accelerate the protonation of the anion radical by water and relatively suppress the side reactions of the anion radical within the temperature range examined.

As may be seen in Table 3, the values of $\eta_{DH}+\eta_{TH}$ were not very different when water or methanol was used as a proton-donor with fairly high current densities over about 0.3 A/dm^2. The dissociation constants of water and methanol are, however, different. In the case of ethanol, $\eta_{DH}+\eta_{TH}$ had a fairly large value (52%). Furthermore, in the medium of acetonitrile without water, the sum of the current efficiencies was about 38%, not much less than what we had expected from the dissociation constant of acetonitrile if the protonation was mainly the addition of a free proton to the anion radical or to the monoanion. In the reduction using phenol or *p*-hydroxybenzoic acid as a proton-donor, 1,4-DHN was not formed and the evolution of hydrogen occurred predominantly. Therefore, the protonation of the naphthalene anion radical and monoanion occurred mainly by the abstraction of the proton from the proton-donor, as has been proposed on the basis of the results of

12) H. H. Schlubach, *Ber.*, **53B**, 1689 (1920).
13) M. Finkelstein, R. C. Petersen and S. D. Ross, *J. Am. Chem. Soc.*, **81**, 2361 (1959); S. D. Ross, M. Finkelstein and R. C. Petersen, *ibid.*, **82**, 1582 (1960); M. Finkelstein, *J. Org. Chem.*, **27**, 4076 (1962).

the polarographic studies,[10,15] though a part of the protonation may occur by the addition of a free proton to the anion. The fact that phenol or *p*-hydroxybenzoic acid did not serve as the proton-donor indicates that the hydrogen atom scarcely contributed at all to the reduction of naphthalene.

It is obvious that the reaction proceeds in accordance with the following reaction scheme:

$$R + e \rightleftarrows R^{\cdot-}$$
$$R^{\cdot-} + HX \rightarrow \cdot RH + X^-$$
$$\cdot RH + e \rightarrow RH^-$$
$$RH^- + HX \rightarrow RH_2 + X^-$$

15) S. Wawzonek and J. W. Fan, *ibid.*, **68**, 2541 (1946).

where HX is the proton-donor. Further, as shown in Table 4, a tendency for $\eta_{1,4DH}$ to increase with an increase in the current density was observed. Therefore, it may be supposed that this equilibrium may exist:

$$2R^{\cdot-} \rightleftarrows R^{2-} + R$$

The increase in the current density may result in an increase in R^{2-}, thus suppressing the side reactions of $R^{\cdot-}$ (as the proton affinity of a dianion is larger than that of an anion radical) and increasing the current efficiency for 1,4-DHN formation. As has been described before, the naphthalene consumed was exclusively converted to the monomeric hydrogenated products, and the proportion of the dimerization of anion radicals was small.

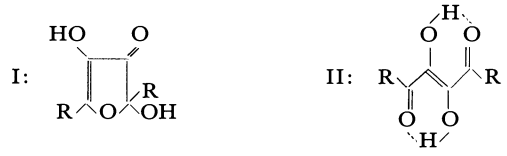
Syntheses and Structures of Acetylformoin and Related Compounds. VI. Substituent Effects

Yo MIYAGI, Sadao KIMURA and Ryozo GOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received October 19, 1967)

In the presence of cyanide ions, an α-ketoaldehyde dimerizes to give an acylformoin. The tautomerism of this compound was studied. It was found that the tautomerism between I and II is affected by the solvents and by the substituents. In proton-accepting solvents (EtOH, THF), I predominates. In ethanol-free chloroform, II is dominant for almost all substituents. In ethanol-containing chloroform, some acylformoins exist as I, while the others exist as II. The former case is observed when R=*t*-Bu and *p*-X-C_6H_4 (X=H, *t*-Bu, Cl, and Br); the latter case, when R=Me, *i*-Pr, and *p*-Me-C_6H_4. In the former case, ethanol reacts slowly with I to give an *O*-ethyl derivative (III). When R=2,4,6-Me_3-C_6H_2, II predominates in all states. When R=*p*-Cl-C_6H_4 and *p*-Br-C_6H_4, I and II were isolated as crylstals. The solvent effects are interpreted in terms of the hydrogen-bonding interactions of I with basic and hydroxylic solvents.



By a self-condensation similar to the benzoin condensation, an α-ketoaldehyde (an alkyl- or aryl-glyoxal) gives an acylformoin (Eq. (1)). Although five tautomers are possible for such compounds, only two tautomers, 2,5-dialkyl (or diaryl)-2,4-dihydroxyfuranone-3 (I) and *trans*-1,2-diacyl (or diaroyl)-1,2-dihydroxyethylene (II), have been found to exist for various acylformoins.[1] I and II have quite different spectral properties; these properties are summarized in Table 1. This paper will be concerned with the tautomerism of some homologues of benzoylformoins. Some detailed studies of chloroform solutions of acylformaoins will also be reported. Table 2 summarizes the spectral results.

$$2RCOCHO \xrightarrow{CN^-} RCOCH(OH)COCOR \quad (1)$$

I 
II 
p-Chloro- and p-Bromo-benzoylformoin. *p*-Chloro- and *p*-bromo-benzoylformoins (R=*p*-Cl-C_6H_4 and *p*-Br-C_6H_4 respectively, in Eq. (1)), were first reported by Karrer and his co-workers.[2] They carried out the condensation in an aqueous alcoholic solution containing potassium cyanide and obtained red crystals by recrystallizing the reaction products from hot benzene in both cases. Following their method, the present authors found that the addition of water to a reaction solution precipitates yellow crystals, which can then be recrystallized from ethanol. When a hot benzene solution of yellow crystals is allowed to stand, at first red crystals and then yellow crystals precipitate. After a prolonged heating of the benzene solution, only the red crystals precipitate. The red crystals of both acylformoins do not change their color on heating and melt sharply at their melting points. On the other hand, the yellow crystals of both acylformoins gradually turn red on heating and melt at a temperatures slightly lower than the melting point of the corresponding red crystals. Thus, the melting points proper to the yellow crystals can not be observed. The yellow crystals have IR spectral characteristics of I, while the red crystals have those of II, in both cases.

p-Anisoylformoin and Mesitoylformoin. The syntheses of *p*-anisoylformoin[3] and mesitoylformoin[4] (R=*p*-MeO-C_6H_4 and 2,4,6-Me_3-C_6H_2 in Eq. (1) respectively) have been reported in the literature. In these cases, the present authors could not isolate the two tautomers as crystals. Both acylformoins are red crystals and show IR

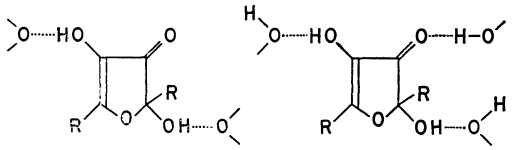
spectra characteristic of II.

Tautomers in Tetrahydrofuran and Ethanol. Solutions of the three acylformoins other than mesitoylformoin in tetrahydrofuran or ethanol show the IR and UV spectra characteristic of I. It has been reported that I arises also in these solutions of other acylformoins, and it has been suggested that proton-accepting solvents might stabilize I by a solvation such as that depicted in Fig. 1, so that I can be predominant in these solvents.[1d]

Unlike the others, however, mesitoylformoin does not show any tautomerism and exists as II in chloroform and also in tetrahydrofuran.

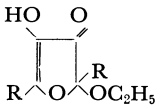


(A) (B)

Fig. 1. Solvation by ethers (A) and alcohols (B).

Tautomers in Chloroform. Since benzoyl-, *t*-butylbenzoyl-, and neopentoyl-formoins are easily oxidized in chloroform, the UV spectra of the solutions were measured in vacuum-sealed cells. Solutions of these acylformoins in ethanol-containing chloroform[5] show the UV spectra characteristic of I.

However, Eistert isolated an *O*-ethyl derivative (III, $R=C_6H_5$) by refluxing an ethanol-chloroform solution of benzoylformoin.[6] III ($R=C_6H_5$) shows the same UV spectra as that of II ($R=C_6H_5$).



III

He suggested that benzoylformoin reacts with ethanol to give III ($R=C_6H_5$) in ethanol-containing chloroform. The spectrum observed in our experiments could, therefore, be due to III and not to I.

The following facts suggest, however, that the absorption of the ethanol-containing chloroform solution is not always caused by III. In a vacuum-sealed cell, a solution of neopentoylformoin in ethanol-containing chloroform shows an absorption at 310 mμ characteristic of I or III. After the solution has stood overnight, the intensity of this absorption does not change. When the cell is then opened to the atmosphere, the intensity decreases gradually, as has been reported previously[1d] (Fig. 2). However, when the cell is opened immediately after sealing, the 310 mμ band decreases rapidly and disappears after two hours. Since I may be more easily oxidized than III, these facts suggest the predominance of I immediately after dissolution and the subsequent predominance of III after the solution has been allowed to stand overnight. This means that I reacts slowly with ethanol to give III.[7]

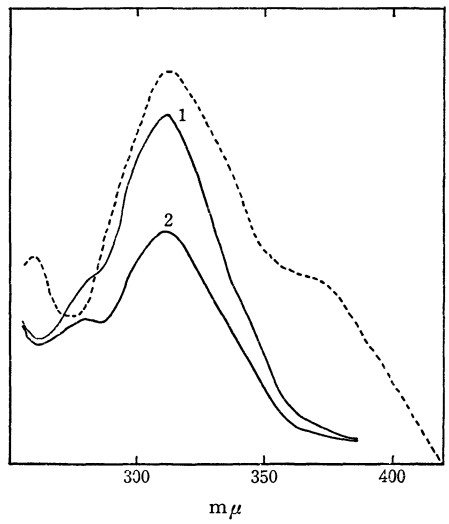


Fig. 2. Ultraviolet spectra of neopentoylformoin in vacuum-sealed cells: ——1, in ethanol-containing chloroform, ——2, 2 hr after breaking seal of a cell after standing overnight an ethanol-containing chloroform solution; ---- in ethanol-free chloroform.

The spectrum of neopentoylformoin in ethanol-free chloroform[8] (Fig. 2) shows its main absorption at 311 mμ, with a shoulder at about 370 mμ, indicating a mixture of I (the major component) and II (the minor component). It may be concluded that, in the case of neopentoylformoin, I predominates even in this solvent where stabilization by solvation by ethanol is absent. An ethanol-containing chloroform solution of acetylformoin shows an absorption band characteristic of II at 355 mμ; this band gradually decreases in an open cell. When measured in a vacuum-sealed cell, however, the spectrum did not change on standing. This means that acetylformoin does not react with ethanol in chloroform, since, if this were the case, an absorption would arise at about 310 mμ on standing.

5) As the ethanol-containing chloroform, we used spectro-grad chloroform (Dotite) containing ethanol as a stabilizer (the ethanol content was about 0.5%).

6) B. Eistert, private communication. We are indebted to him for informing us of his observations prior to publication.

7) There is a possibility that this etherification is catalyzed by a trace amount of hydrogen chloride present as an impurity.

8) Ethanol-free chloroform was prepared by shaking spectro-grade chloroform with sulfuric acid, washing it with water, drying, and distilling.

As has been briefly mentioned in a previous paper[1e], *p*-*t*-butylbenzoylformoin behaves interestingly. In a vacuum-sealed cell, the λ_{max} value of its ethanol-containing chloroform solution is 371 mμ. However, an ethanol-free chloroform solution shows an absorption at about 380 mμ immediately after dissolution; this absorption maximum shifts to 405 mμ in about five minutes (Fig. 3). These facts mean that this acylformoin exists as I immediately after dissolution, but is rapidly converted to II in this solvent. The fact that I exists in ethanol-containing chloroform, while II exists in ethanol-free chloroform, can be explained in terms of the solvation of I by ethanol, as is shown in Fig. 1.

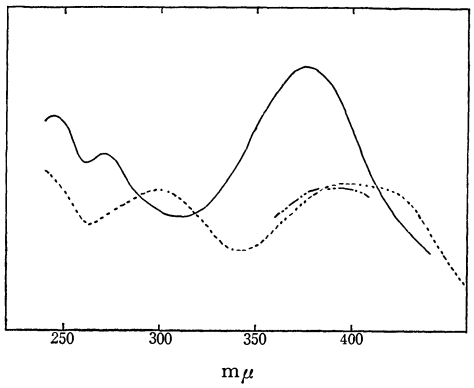

Fig. 3. UV spectra of *p*-*t*-butylbenzoylformoin in vacuum-sealed cells: ——— immediately after dissolving in ethanol-free chloroform; ---- about five minutes after dissolving in ethanol-free chloroform; —— in ethanol-containing chloroform.

p-Toluylformoin shows an absorption at 380 mμ, with a should around 410 mμ in ethanol-containing chloroform (Fig. 4). On the other hand, in ethanol-free chloroform the only absorption maximum is at 405 mμ. Thus, II seems to exist in ethanol-free chloroform and an equilibrium

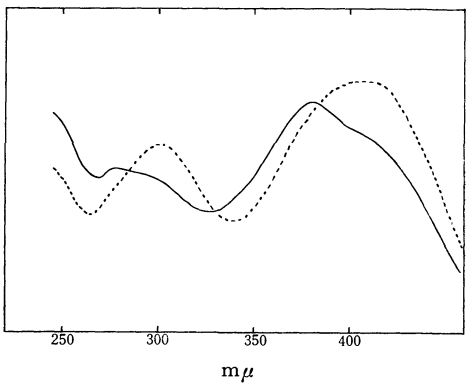

Fig. 4. UV spectra of *p*-toluylformoin in vacuum-sealed cells: —— in ethanol-containing chloroform; ---- in ethanol-free chloroform.

mixture of I (the major component) and II (the minor component) in ethanol-containing chloroform.

p-Chloro- and *p*-bromo-benzoylformoins are not easily oxidized in chloroform. Their UV sepctra can be measured in open cells. These acylformoins show absorption bands at 370 mμ in ethanol-containing chloroform and at 410 mμ in ethanol-free chloroform and in carbon tetrachloride.

p-Anisoylformoin shows an absorption at 410 mμ in carbon tetrachloride, but a broad band around 350—400 mμ in chloroform. Nothing conclusive has been obtained regarding the latter solution.

Discussion

The tautomeric behavior of the acylformoin is summarized in Table 3.

In tetrahydrofuran and ethanol, all the acylformoins studied except mesitoylformoin exist as I, presumably solvated as depicted in Fig. 1. Although some acylformoins are easily oxidized

Table 3. Tautomers of acylformoins

Formoin	Ref.	R in Eq. (1)	Solid state	Solution in		
				THF, C_2H_5OH	$CHCl_3$-C_2H_5OH	$CHCl_3, CCl_4$
Acetyl-	1a	Me	II	I	II	II
Isobutyryl-	1c	Me_2CH-	I	I	II	II
Neopentoyl-	1b	Me_3C-	I	I	I	I+II (I>II)
p-*t*-Butylbenzoyl	1e	*p*-Me_3C-C_6H_4	I	I	I	II
Benzoyl-	1a,d	C_6H_5	I	I	I	II
p-Chlorobenzoyl-	2	*p*-Cl-C_6H_4	I,II	I	I	II
p-Bromobenzoyl-	2	*p*-Br-C_6H_4	I,II	I	I	II
p-Anisoyl-	3	*p*-Me O-C_6H_4	II	I	I	II
p-Toluyl-	1e	*p*-Me-C_6H_4	I	I	I+II (I>II)	II
Mesitoyl-	4	2,4,6-Me_3-C_6H_2	II	II	II	II

in chloroform, they are rather stable to oxidation in these solvents.

In most cases, I predominates in ethanol-containing chloroform, while II is dominant in ethanol-free chloroform or carbon tetrachloride. Since I is solvated by ethanol in the former solvent, it may be considered that II is more stable than I in the absence of solvation by ethanol. However, as for neopentoylformoin, I is more stable than II, even in the absence of ethanol and its accompanying solvation.

It may be feasible to consider that the stability of II is affected by the substituent, R. For acetyl-, isobutyryl- and *p*-toluyl-formoins, II may be considered to be more stable than for the other acylformoins. For the first two, II exists as a sole component, even in ethanol-containing chloroform. For the third, II is observed as one component of an equilibrium mixture. Consequently, for the above three acylformoins II is present in ethanol-containing chloroform, while other acylformoins exist as I in this solvent. In the case of neopentoylformoin, in which the R is *t*-butyl, II is unstable, as has been mentioned above.

Mesitoylformoin exists as II in all states.

In the case of *p*-chloro- and *p*-bromo-benzoylformoins, the stability of II presumably becomes comparable with that of I and the isolation of both tautomers is possible.

From the above considerations, it may be suggested that hyperconjugation is effective in stabilizing II. However, nothing confirmative has yet been obtained.

Experimental

Acylformoins. The following four acylformoins were prepared in the same way. A solution of sodium cyanide (0.2 g) in 20 m*l* of 50% aqueous ethanol was added to a solution of a glyoxal hydrate (5 g) in 50 m*l* of ethanol. After standing for 3 hr in an ice-cold bath, the solution was poured into cold water. The precipitated crystals were collected by filtration.

p-Bromobenzoylformoin. Yellow crystals, recrystallized from ethanol; on heating began to turn red at around 80°C and melted at 178—184°C. Red crystals, recrystallized from benzene; mp 195°C.

p-Chlorobenzoylformoin. Yellow crystals, recrystallized from ethanol; on heating, began to tunr red at around 145°C and melted at 181—182°C. Red crystals, recrystallized from benzene; mp 181—182°C.

p-Anisoylformoin. Red crystals, recrystallized from ethanol; mp 145—146°C (lit.,[3] 151°C).

Mesitoylformoin. Red crystals, recrystallized from ethanol; mp 188—189°C.

Technique of Vacuum-sealed Cell; explained in experimental part of Reference 1d; the absorption intensities in Figs. 2—4 are arbitrary.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2931—2935 (1968)

Metal-Containing Initiator Systems. III.*[1] Polymerization of Styrene by Some Activated Metals in the Presence of Organic Halides

Takayuki OTSU and Masami YAMAGUCHI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimotocho, Sumiyoshi-ku, Osaka

(Received December 27, 1967)

The polymerization of styrene with systems of various metals and organic halides was investigated at 60°C. It was found that the metals which could be used as hydrogenation catalysts were effective as initiators and that the organic halides with a weak carbon-halogen bond showed a high initiating activity for styrene polymerization. From the kinetic studies of the polymerization of styrene by reduced nickel and chloroform, the rate of polymerization was shown to be proportional to the monomer concentration and to the square-root concentration of both nickel and chloroform in the lower concentration range of chloroform. Some radical inhibitors were also found to inhibit this polymerization. These results indicated that this initiator system could induce the radical polymerization. The apparent overall activation energy for the polymerization by this system was estimated as 11 kcal/mol. The resulting polystyrene was found to be a relatively-low-molecular-weight atactic polymer.

In previous papers,[1,2] it has been reported that some activated metals can serve as radical initiators of vinyl monomers in the presence of some organic

*1 Parts I and II of this series are Refs. 1 and 2 respectively.

halides. Recently, similar investigations have been published independently by Olivé and Olivé[3] and by Iwatsuki *et al.*[4]

The present paper will describe our detailed findings on the polymerization of styrene by systems of various metals and organic halides at 60°C, and on our kinetic studies of the polymerization by a system of reduced nickel and chloroform.

Experimental

Materials. Raney metals were prepared from their commercial aluminum alloys according to the Adkins W-5 method,[5] followed by successive washings with water, methanol, and benzene.

The Urushibara metals were obtained by adding zinc dust to a metal chloride aqueous solution by the method of Taira[6]; they were used after having been washed with water, methanol, and benzene.

The reduced nickel used was a commercially-obtainable stabilized hydrogenation catalyst (Nikki Chemical Co.) composed of a 50% Ni atom on kieselguhr. Before use, this catalyst was activated by heating it at about 200°C in a stream of hydrogen for an hour. The other hydrogenation catalyst, formate nickel (Nikko Rikagaku Co.), prepared by the thermal decomposition of nickel formate, was a commercial product (50% Ni atom on kieselguhr). The commercial metal powders were also used without further purification.

The organic halides used in this study were purified by distillation or recrystallization. The styrene was purified by the ordinary method and distilled under reduced pressure before use. The other reagents were purified by ordinary methods.

Polymerization Procedure. Into a hard glass tube containing a given amount of the metal, the required amounts of organic halide and monomer were placed. After degassing the contents of this tube by a successive freezing and thawing technique, the tube was sealed off under a vacuum.

Polymerizations were carried out in the dark with shaking in a thermostat maintained at 60°C. After polymerization, the contents of the tube were poured into a large amount of methanol containing concentrated hydrochloric acid in order to precipitate the polymer and dissolve the residual metal initiator. The resulting polymer was then purified by reprecipitating it two or three times using a system of benzene and methanol. The conversion was calculated from the weight of the dried polymer thus obtained.

Analysis of the Polymers. The number-average molecular weight ($\overline{M}_n$) of the polymers was calculated from their intrinsic viscosities, [η], determined in benzene at 30°C according to the following equation[7]:

$$[\eta] = 1.74\times10^{-4}\,\overline{M}_n^{0.71}$$

Results and Discussion

Effect of Metals. The effects of various kinds of metals on the polymerization of styrene in the presence of carbon tetrachloride at 60°C in benzene were investigated. The results are shown in Table 1.

Table 1. Polymerization of styrene with the systems of some metals and carbon tetrachloride at 60°C for 18 hr
[M]=4.14 mol/l, [CCl_4]=0.49 mol/l
[Metal]=0.81 g-atom/l in benzene

Metal	Polymer yield, %	Metal	Polymer yield, %
Raney Ni	68.3	Raney Cu	60.7
Urushibara Ni	78.6	Urushibara Cu	70.7
Formate Ni	17.7	Commercial Cu	1.8
Reduced Ni	90.2	Raney Fe	51.2
Commercial Ni	0.5	Urushibara Fe	46.1
Raney Co	76.8	Commercial Fe	1.9
Urushibara Co	76.2	Commercial Zn	0.3
Commercial Co	1.1	None	0.5

As can be seen from Table 1, the systems of Raney and Urushibara metals with carbon tetrachloride were effective as initiators of the styrene polymerization. However, the systems consisting of commericial metal powders were completely inactive with regard to initiation, indicating it is necessary that the metals have a fresh surface.

No definite relationship between the initiating activities and the kinds of metals can be observed from Table 1, because the polymerization system was heterogeneous. However, it might be considered that both the oxidation potential of the metals, as was suggested by Olivé *et al.*,[3] and their preparation and activation methods, which determined their surface area and purity, were the controlling factors in the initiating activity of these systems.

The resulting polymers were soluble in methyl ethyl ketone at room temperature, indicating that no isotactic polystyrene was obtained and that these systems could not induce the stereospecific polymerization of styrene.

Effect of Organic Halides. Table 2 shows the results of the polymerization of styrene with reduced nickel in the presence of various kinds of organic halides at 60°C.

In Table 2 the initiating activity can be seen to increase as the substitution by halogen atom increases and also as the labile halogen atom is involved. These results suggest that the effectiveness of organic halides in initiation increases with a decrease in the bond-dissociation energy of the carbon-halogen bonds involved in organic halides. The reactivity of the initiating radical

Table 2. Effect of organic halides on the polymerization of styrene at 60°C for 8 hr
[M]=4.14 mol/*l*, [Halide]=0.2 mol/*l*
[Ni]=0.4 g-atom/*l* in benzene

Organic halide	Polymer yield, %	Degree of polymerization
CH_2Cl_2	6.9	2300
$CHCl_3$	21.7	160
CCl_4	26.5	80
$CHBr_3$	48.6	50
CHI_3	36.0	20

n-C_4H_9Cl	1.4	—
t-C_4H_9Cl	7.7	1500
C_6H_5Cl	1.0	—
$C_6H_5CH_2Cl$	46.8	120
CH_2=$CHCH_2Cl$	11.3	700
None	0.6	—

produced from organic halides toward the styrene monomer might also be important.

In Table 2 the degree of polymerization of the resulting polymers can also be observed to decrease in proportion to the increase in the initiating activity of the systems. Since the chain-transfer reactivity of these organic halides has been known to be correlated also with the bond-dissociation energy of their carbon-halogen bonds, such a change in the degree of polymerization might be expected from the reactivities of organic halides in both the initiation and the chain-transfer reaction.

Kinetic Studies of the Polymerization by the System of Reduced Nickel and Chloroform. Figure 1 shows the relationship between the conversion and the polymerization time at 30, 45, 60, and 80°C. In this figure, straight-line relationships can be observed between them at every temperature.

The rates of polymerization (R_p), which were determined from the slopes of the straight lines in Fig. 1, are plotted against the reciprocal polymerization temperatures in Fig. 2. From the slope of the resulting straight line, the apparent activation energy for the overall polymerization by this initiator system was calculated to be 11.1 kcal/mol. Accordingly, the activation energy for initiation was obtained as 9.2 kcal/mol by using the reported rate constants[8] for propagation and termination. This value is quite small compared with that of benzoyl peroxide (29.6 kcal/mol).[9]

Figure 3 shows the relationship between the rate of polymerization and the concentration of reduced nickel at constant concentrations of both

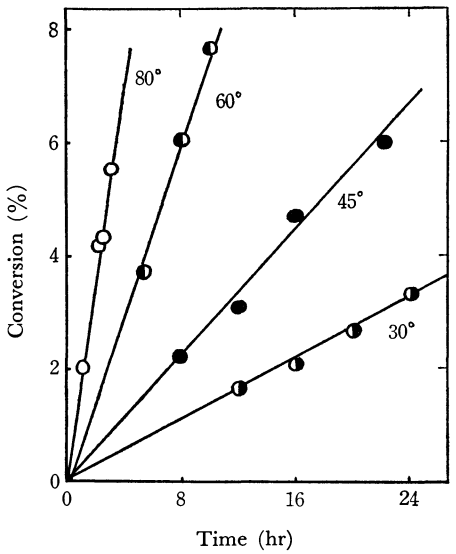

Fig. 1. Time-conversion relations on the polymerization of styrene by the system of reduced nickel and chloroform at 30—80°C: [Ni]=2.5 $\times 10^{-2}$ g-atom/*l*, [$CHCl_3$]=2.5$\times 10^{-2}$ mol/*l*, [M] =4.35 mol/*l* in benzene.

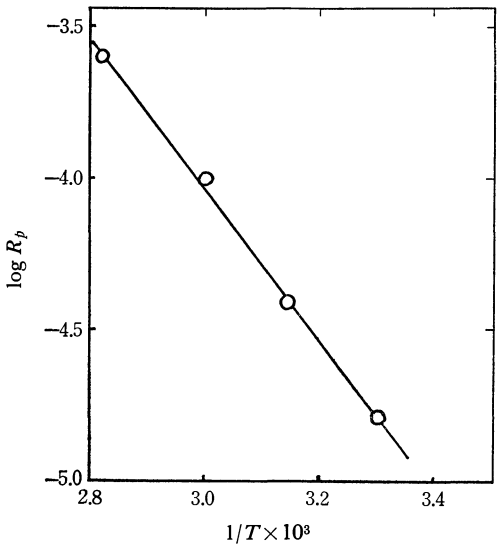

Fig. 2. Arrehnius plot between R_p and $1/T$.

the styrene monomer and chloroform. From this figure, the rate can be seen to be proportional to the square-root concentration of reduced nickel, indicating that the radical polymerization occurred.

The relationship between the rate of polymerization and the concentration of chloroform is shown in Fig. 4, from which the square-root dependence of the concentration of chloroform on the rate was observed only in the concentration range lower than 5×10^{-3} mol/*l*. In the concentration range above this, the rate was constant independently of the concentration of chloroform. This result

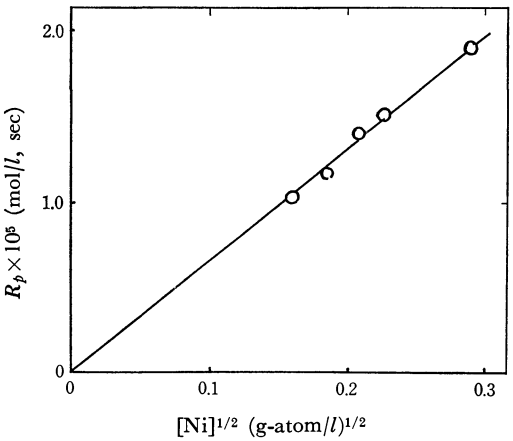

Fig. 3. Relationship between R_p and the concentration of reduced nickel: $[CHCl_3]=2.5\times10^{-2}$ mol/l, $[M]=4.35$ mol/l in benzene at 60°C.

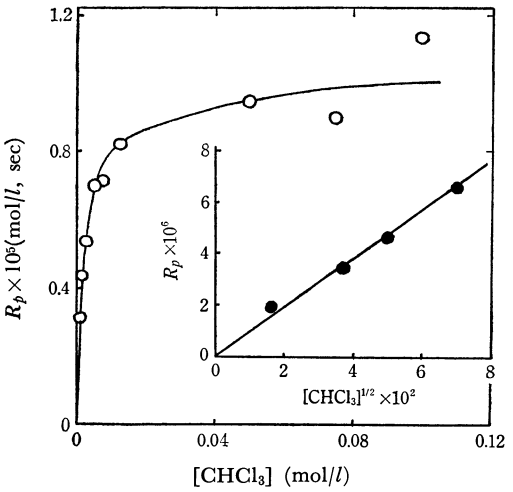

Fig. 4. Relationship between R_p and the concentration of chloroform: $[Ni]=2.5\times10^{-2}$ g-atom/l, $[M]=4.35$ mol/l in benzene at 60°C.

suggests that the initiating radical is produced *via* a complex formation between reduced nickel and chloroform, as was pointed out by Olivé and Olivé[3] and by Iwatsuki *et al.*[4]

Figure 5 shows the plot of the polymerization rate against the concentration of the styrene monomer. It was clear that the rate was directly proportional to the monomer concentration. This result also indicates that the monomer did not participate in intiating radical production.

Effect of Radical Inhibitor. The effect of some radical inhibitors on the polymerization by a system of reduced nickel and carbon tetrachloride was also investigated. The results are shown in Table 3.

In Table 3, *p*-benzoquinone, diphenylpicrylhydrazyl (DPPH), and oxygen can be seen to inhibit this polymerization. Accordingly, it is

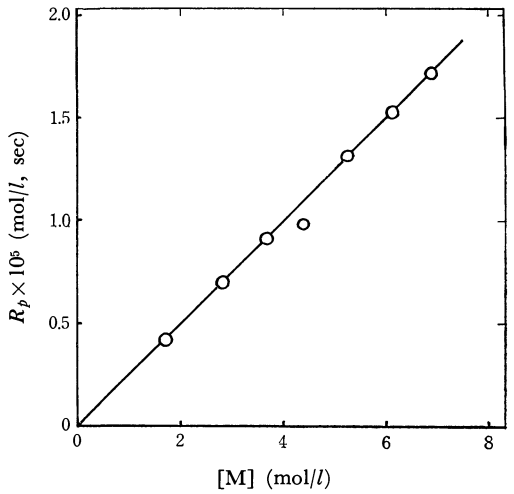

Fig. 5. Relationship between R_p and monomer concentration: $[Ni]=2.5\times10^{-2}$ g-am/l, $[CHCl_3]=2.5\times10^{-2}$ mol/l in benzene at 60°C.

DPPH (0.05)	0.4

obvious that this initiator system induced the radical polymerization of styrene. However, the hydroquinone does not act as a radical inhibitor.

Mechanism of Styrene Polymerization by These Systems. From the results of the polymerization kinetics and of the radical inhibitor, it is clear that the polymerization of styrene by these systems proceeds via a radical mechanism. This conclusion is also supported by the results of copolymerization with methyl methacrylate by a system of reduced nickel and carbon tetrachloride at 60°C.[10]

As was pointed out Olivé and Olivé[3] and by Iwatsuki *et al.*,[4] the initiation by these systems may be considered to occur in the following way: a complex between the metal (Me) and the organic halide (RX) is formed, and then a one-electron transfer from the metal to the carbon-halogen bond in the halide to give the initiating radical occurs:

$$R\text{-}X + Me \rightleftarrows [complex] \rightarrow R\cdot + Me^+ + X^-$$

This mechanism is also confirmed by the fact

10) T. Otsu and M. Yamaguchi, *J. Polymer Sci.*, **A1**, **6**, 3075 (1968).

that hexachloroethane and nickel chloride were found in a reaction mixture of reduced nickel and carbon tetrachloride.[10]

If the step of the one-electron transfer is rate-determining, the ease of the initiating radical production may be dependent on both the oxidation potential of the metal and the bond-dissociation energy of the carbon-halogen bond in the halide. However, no definite correlation was obtained between the initiator activity and the kind of metal, as may be seen in Table 1. This result is understandable if it is assumed that the surface area and the purity of the metal are more significant than its oxidation potential in the formation of the complex with the halide rather.

The probable structure of the complex in the transition state may be written as follows:

$$\underset{\text{I}}{[R:X\ Me} \rightarrow \underset{\text{II}}{R\cdot X^{-}:Me^{+}]}$$

in which the I structure is the structure near the reactant system and the II structure is that after the one-electron transfer has occurred. The importance of a similar transition-state structure has been discussed by Kochi *et al.*[11] for the reduction of alkyl halides with the chromium(II) ion.

From Table 2, the degrees of polymerization of some polystyrenes can be seen to be lower than that to be expected from the chain-transfer constant and the concentration of the organic halides used. In connection with this observation, we found recently that the systems of reduced nickel and methylchlorosilanes could induce the cationic polymerization of styrene.[12] This point will be clarified in a later paper.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 41 2935—2941 (1968)

Tropylation of Azulene, 1-Oxaazulan-2-one, and Their Derivatives, and Electrophilic Reactions of the Tropylazulene Derivatives*[1]

Tetsuo NOZOE, Takashi TODA, Toyonobu ASAO and Akira YAMANOUCHI*[2]

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received January 29, 1968)

The tropylation of azulene, oxaazulan-2-one, and their derivatives was investigated, and various 1 and/or 3-tropylazulenes and 3-tropyloxaazulan-2-ones were obtained. The NMR, UV, and visible spectra of these tropylazulenes were then discussed. Some electrophilic reactions, such as azo-coupling and the acid treatment of four kinds of tropylazulenes, were studied, and it was found that exchanges of the tropyl group and the attacking electrophilies occurred.

The tropylium ion, one of the most stable carbonium ions, is known to react with various bases (anionoid reagents) resulting in the tropylation of nucleophiles, and in hydride abstraction in some cases.[1,2] The reaction can also be carried out conveniently using tropyl ethers,[2] sometimes with the addition of catalytic amounts of the tropylium ion or acids, in place of tropylium salts because of the facile ionization of the former to the latter under these conditions. In our laboratory, a continuous effeort has been made to tropylate various phenols[3,4] and tropolone[5] with these reagents, as well as to abstract the hydride ion from the tropylated products by means of the tropylium ion or other oxidizing reagents.[3,4]

Since sodium salts of cyclopentadiene[1,6] and indene[6] are also known to undergo tropylation by

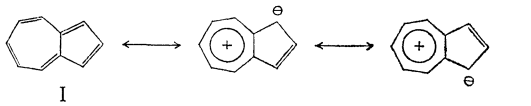
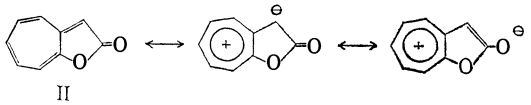
the tropylium ion, the 1 and 3 positions of azulene, being of the highest electron density in the ring system and having properties similar to those of these carbanions,[7a] may have sufficient anionic property to undergo tropylation. This anticipation led us to investigate the reaction of tropyl ethers with azulene (I) as well as 1-oxaazulan-2-one (II), the 3-position of which was also expected to be capable of electrophilic substitution.[7b] However, apart from our studies, Hafner *et al.*[8] and Anderson and Replogle[9] have reported the synthesis of some tropylazulenes by the reaction of of azulenes with tropylium perchlorate or tropylium fluoroborate.

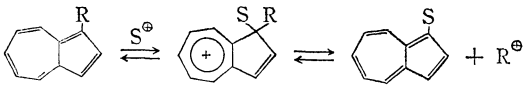


I



II

The intermediate of the electrophilic substitution reactions of azulenes may be represented as Formula A; it gives a final procuct such as B.[7b]



A B

It is a well-known phenomenon that when azulenes are dissolved in concentrated acids, the color of the azulenes disappears,[7a,10] while when R and S are hydrogen atoms, it has actually been proved by NMR[11] and UV[12] spectral techniques that azulenes exist in Formula A. When R is a group or atom can be eliminated easily, R will be replaced by other reagents, S. In fact, when R is acetyl, carboxyl, or sulfonyl, those groups are replaced by arylazo or halogens.[13,14] Since the tropyl groups readily forms the tropylium ion, the 1-tropylazulenes obtained above may be expected to cause an exchange reaction with other electrophilic reagents.

No reaction took place in benzene or cyclohexane between azulene and tropyl ethyl ether or ditropyl ether, even when the mixture was heated. However, the addition of a catalytic amount of tropylium bromide or mineral acids to the above mixture caused a smooth reaction, one which gave 1,3-ditropylazulene (III). In a similar manner, 5-isopropylazulene and 2-acetamidoazulene yielded the corresponding 1,3-ditropyl derivatives, (IV) and (V) respectively. Although it was difficult to control the reaction at the stage of monotropylation in the above reactions, this was achieved with 2-chloroazulene (VI); 2-chloro-1-tropylazulene (VIII) and 2-chloro-1,3-ditropylazulene (VII) were obtained using a half-molar equivalent of the reagent.

1-Methylazulene and guaiazulene (IX) which are substituted at the 1-position, gave monotropyl derivatives, (X) and (XI) respectively; diethyl azulene-1,3-dicarboxylate did not undergo tropylation, even when the reaction mixture was heated. Hence, it may be considered that the tropyl groups in the tropylazulenes are located at the 1 and/or 3-positions of azulene nuclei; this is clear from the studies of their NMR spectra and visible absorption spectra, which will be described later.

A formyl or ethoxycarbonyl group at the C 1-position diminishes the reactivity of azulene to tropylation; however, 1-formylazulene, ethyl azulene-1-carboxylate (XII), and their 2-chloro derivatives gave, in the reaction with ditropyl ether in the presence of tropylium bromide or hydrochloric acid, the corresponding monotropyl derivatives (XIII-XVI) in high yields at an elevated temperature. Ethyl 2-aminoazulene-1-carboxylate also gave the 3-tropyl derivative (XVII). XV was also obtained by the formylation of 2-chloro-1-tropylazulene (VIII) by Vilsmeyer's method.

1-Tropylazulene (XVIII) was obtained from ethyl 1-tropyl-azulene-3-carboxylate (XIV) by alkaline hydrolysis and subsequent decarboxylation. The heating of the oxime of XV with acetic anhydride furnished 2-chloro-1-cyano-3-tropylazulene (XIX).

It has been known[15] that the thermal isomerization of double bonds in a tropyl group occurs readily. Therefore, the tropyl group in XVIII or XIX obtained through thermal process might undergo isomerization.*3

Fig. 1

Since it has been found[16] that diethyl 2-amino- or 2-hydroxy-azulene-1,3-dicarboxylate was brominated on its 6-position, the tropylation of diethyl 2-amino or 2-hydroxyazulene-1,3-dicarboxylate was attempted. However, even at an elevated temperature, the azulenes failed to undergo tropylation, and the starting azulenes were recovered.

As in the case of azulene, the tropylation of 1-oxaazulan-2-one (II) with tropyl ethyl ether in the presence of tropylium bromide or hydrochloric acid yielded the 3-tropyl derivative (XX). In a similar manner, the 4-methyl and 5-isopropyl derivatives of II gave the corresponding 3-tropyl derivatives, (XXI) and (XXII).

In order to determine the position of the extra hydrogen in the tropyl group attached to azulene, the NMR spectra were studied. The peaks due to the extra hydrogen (C_7-H) in the tropyl group appear as a triplet at τ 6.68 (J=5.3 cps) in III, 6.42 (J=5.3 cps) in VII, and 7.38 (J=5.4 cps) in XX, and the peaks due to olefinic protons of the 1- and 6-positions in the tropyl group appear as a double doublet (d, d) at τ 4.46 (J=5.3 and 9.0 cps) in III, 4.48 (J=5.3 and 9.4 cps) in VII, and 4.59 (J=5.4 and 9.6 cps) in XX. The ratio of the areas of above two kinds of proton signals is about 1 : 2, showing clearly that the bonds are formed between the 7-position of tropilidene and the azulene nuclei.

The facts that the signal of the C_2-H of the azulene nucleus of III appears at τ 1.90 as a singlet, and that no signals of C_1-H and C_3-H are observed in the spectra of III and VII, clearly show tropyl groups are located at the and 3-positions of azulenes. The large down-field shifts of the C_7-H of the tropyl groups in these compounds compared with that of tropilidene[17] (7.806 τ) may be ascribed to the paramagnetic deshielding effects of the azulene or oxaazulanone nucleus.

The absorption maxima in the visible spectra of tropylazulenes are recorded in Table 1. From this table, it is clear that the introduction of one tropyl group causes a bathochromic shift of 16—24 mμ in the maxima of the highest intensity, this effect being almost equal to that of alkyl groups.[7a,18]

In order to clarify the electronic and steric effects of the electrophilic substitution reactions of substituted tropylazulenes, 2-chloro-1-tropylazulene (VIII), 3-tropylguaiazulene (XI), ethyl 3-tropylazulene-1-carboxylate (XVII) were submitted to electrophilic substitution reactions.

The treatment of XI and XVII with *p*-toluenediazonium chloride (XXIII) under mild conditions readily afforded the corresponding azo compounds, 3-(*p*-tolylazo)guaiazulene (XXIV) and ethyl 2-amino-3-(*p*-tolylazo)azulene-1-carboxylate

Table 2. The results of the acid treatment of tropylazulene derivatives

Tropylazulene / Condition	VIII	XI	XIV	XVII
Conc. H_2SO_4	VI and VIII	IX (74%)	Recovery (94%)	Recovery (61%)
Dil. H_2SO_4	VI and VIII	IX (90%)	Recovery (100%)	Recovery (90%)

(XXV).[19] However, VIII and XIV were recovered when treated under the same reaction conditions. Also, ethyl azulene-1-carboxylate was recovered by the same treatment. Although the azo-coupling reaction of VIII was carried out at an elevated temperature, 80% of the starting material was recovered, plus a small amount of a black resinous substance, which has so far not been identified.

The Friedel-Crafts reaction of XI with an equimole of benzoyl chloride afforded 32% of guaizulene and 23% of 3-benzoylguaiazulene (XXVI).[20] The yield of XXVI from guaiazulene (IX) under the same reaction conditions was also not good, 16%. The treatment of XVII under the same reaction conditions resulted in an entire recovery of the starting material. This may be explained as follows: the formation of the complex of the 2-amino-group of XVII with aluminum chloride decreases the electron density of the azulene nucleus, and, at the same time the bulkiness of the complex causes serious steric hindrance. On the other hand, the reaction of VIII and XIV with 2 equimoles of benzoyl chloride afforded 1,3-dibenzoyl-2-chloro-azulene (XXVII), together with a small amount of the recovered starting substances, and ethyl 3-benzoylazulene-1-carboxylate (XXVIII), respectively. Although the C-3 position of VIII is not substituted, 3-benzoyl-2-chloro-1-tropylazulene could not be isolated even when an equimole of benzoyl chloride was used. It was also found that the reaction of 2-chloroazulene and one mole of benzoyl chloride resulted in the formation of XXVII and the recovery of 2-chloroazulene.

It is expected that the reaction of tropylazulene with acids regenerates azulenes and the tropylium ion. The results of the treatment of tropylazulenes with concentrated and diluted sulfuric acid are shown in Table 2.

Although a small amount of VI was separated from the reaction mixture of VIII and acid, the complete separation of VI and VIII was unsuccessful. The mixture was identified with a mixture of authentic samples of VI and VIII by means of their IR spectra. However, the exact ratio of VI and VIII was not clear.

The recovery of XIV can be explained as follows: the protonation of XIV took place not only at C-3, as has been shown before, to form a D intermediate, but also at the carbonyl group to form a C intermediate. In fact, the NMR spectrum of XIV shows at τ 8.3 and the methylene quartet at τ 5.6 in carbon tetrachloride, but the signal is changed to a complex multipet in a trifluoroacetic acid solution. It can resonably be understood that XIV is protonated to form and equilibrium mixture of substances such as C, D, and XIV in the acidic solution, and presumably the equilibrium

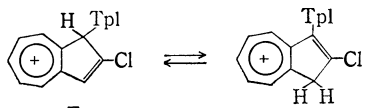
XIV C D

tends to the C form; because XIV was recovered quantitatively. An analogous phenomenon was observed when 1-nitroazulene was dissolved in strong acid and protonation was favorable at the oxygen atoms of the nitro group, but not at the C-3 position.[21] In the case of XVII, the protonation takes place not only at the carbonyl group, but also at the amino group, this makes protonation at C-3 harder and no proton-tropylium cation exchange reaction occurs. In the case of VIII, E- and F-type intermediates may form, 2-chloroazulene should be obtained from the E-type intermediate. Therefore, the prolonged treatment of VIII with acid would give VI in a good yield.



E F

However, because of the unstability of the tropyl group in relation to acid, the prolonged treatment of VIII increases the amount of intractable resinous products and does not give any clear-cut results.

The treatment of XVII with isoamyl nitrite and sulfuric acid afforded brown micro needles (XXIX) which were identical with ethyl 2-amino-3-nitrosoazulene-1-carboxylate.[22] As has been mentioned above, XVII did not eliminate the tropylium cation to form ethyl 2-aminoazulene-1-carboxylate upon acid treatment. Therefore, the nitrosation of XVII must happen by the direct exchange reaction of the tropylium cation and the nitrosonium ion. It is interesting and noteworthy that even though the C-1 and C-3 positions of azulene nuclei of XVII are substituted, the diazotization of amino group does not take place and an exchange reaction occurs.

Experimental*4

General Procedure for the Tropylation of Azulenes and 1-Oxaazulanones. To a stirred solution of azulenes (or 1-oxaazulanones) in cyclohexane (or benzene), ditropyl ether (or tropyl ethyl ether) and a catalytic amount of tropylium bromide (or concentrated hydrochloric acid) were added at room temperature. After the solution has been stirred at room temperature for 2 hr—one day, it was washed with water and dried over anhydrous sodium sulfate, and the products purified by passing them through an alumina column and then recrystallizing them.

1,3-Ditropylazulene (III). The reaction of azulene and 2 molar equivalents of tropyl ether afforded III as blue needles (62%), mp 137—138°C (from cyclohexane).

Found: C, 93.23; H, 6.46%. Calcd for $C_{24}H_{20}$: C, 93.46; H, 6.54%.

1,3-Ditropyl-5-isopropylazulene (IV). The reaction of 5-isopropylazulene and 2-molar equivalents of tropyl ether gave IV as a blue oil (90%). IV did not give a trinitrobenzene complex and changed to a dark yellow substance upon standing in air.

Found: C, 92.30; H, 7.79%. Calcd for $C_{27}H_{26}$: C, 92.52; H, 7.48%.

2-Acetamido-1,3-ditropylazulene (V). The reaction of 2-acetamidoazulene and 2 molar equivalents of tropyl ether gave V as blue crystals (45%), mp 206.5—207°C (from benzene-cyclohexane).

Found: C, 85.58; H, 6.65; N, 3.42%. Calcd for $C_{26}H_{23}ON$:C, 85.45; H, 6.34; N, 3.83%.

2-Chloro-1,3-ditropylazulene (VII). The reaction of 2-chloroazulene and 2-molar equivalents of tropyl ether afforded VII as blue needles (85%), mp 164—165°C (from cyclohexane).

Found: C, 83.79; H, 6.01%. Calcd for $C_{24}H_{19}Cl$: C, 84.08; H, 5.59%.

2-Chloro-1-tropylazulene (VIII). The reaction of 2-chloroazulen with one molar equivalent of tropyl ether afforded VII (27%) and VIII (62%) as violet needles, mp 87—88°C (from petroleum ether), besides the recovered 2-chloroazulene.

Found: C, 80.60; H, 5.56%. Calcd for $C_{17}H_{13}Cl$: C, 80.60; H, 5.17%.

1-Methyl-3-tropylazulene (X). X was obtained from 1-methylazulene as a blue oil (75%).

Trinitrobenzene complex: mp 155.5—156°C.

Found: C, 64.98; H, 4.19; N, 9.07%. Calcd for $C_{21}H_{19}O_6N_3$: C, 64.71; H, 4.30; N, 9.43%.

3-Tropylguaiazulene (XI). XI was obtained from guaiazulene as blue crystals (86%), mp 74—75°C.

Found: C, 91.56; H, 8.50%. Calcd for $C_{22}H_{24}$: C, 91.61; H, 8.39%.

Trinitrobenzene complex: black needles, mp 96—97°C.

Found: C, 67.12; H, 5.24; N, 8.23%. Calcd for $C_{28}H_{27}O_6N_3$: C, 67.05; H, 5.43; N, 8.38%.

1-Formyl-3-tropylazulene (XIII). XIII was obtained from 1-formylazulene as a reddish-violet oil.

Trinitrobenzene complex: brown needles, mp 108—109°C.

Found: C, 63.02; H, 3.92; N, 8.60%. Calcd for $C_{24}H_{17}O_6N_3$: C, 62.74; H, 3.73; N, 9.15%.

Ethyl 3-Tropylazulene-1-carboxylate (XIV). XIV was obtained from ethyl azulene-1-carboxylate as a reddish-violet oil (98%).

Trinitrobenzene complex: brown needles, mp 80°C.

Found: C, 61.97; H. 4.18; N, 8.11%. Calcd for $C_{26}H_{21}O_8N_3$: C, 62.02; H, 4.20; N, 8.35%.

2-Chloro-1-formyl-3-tropylazulene (XV). a) A solution of 65 mg of VIII, 3 m*l* of dimethylformamide, and 50 mg of phosphoryl chloride was allowed to stand overnight. Water (30 m*l*) was then added, and the mixture was neutralized with sodium hydrogen carbonate and extracted with benzene. The extract was

*4 All melting points are uncorrected.

dried and passed through an alumina column. VIII (52 mg) was recovered from the first eluate, and 14 mg of XV, from the next eluate. Recrystallization from benzene-petrolum ether afforded XV as reddish-violet needles, mp 192.5—193.5°C.

Found: C, 77.13; H, 4.91%. Calcd for $C_{18}H_{13}OCl$: C, 77.01; H, 4.67%. b) The tropylation of 2-chloro-1-formylazulene afforded XV (68%), mp 191—192°C, which showed no depression of melting point on admixture with the sample obtained by Procedure a).

Ethyl 2-Chloro-3-tropylazulene-1-carboxylate (XVI). The tropylation of ethyl 2-chloroazulene-1-carboxylate afforded XVI as reddish-violet crystals (quantitative yield), mp 115°C.

Found: C, 74.30; H, 5.23%. Calcd for $C_{20}H_{17}O_2Cl$: C, 73.95; H, 5.28%.

Ethyl 2-Amino-3-tropylazulene-2-carboxylate (XVII). The tropylation of ethyl 2-aminoazulene-1-carboxylate afforded XVII as a reddish-brown oil (quantitative yield).

Picrate, mp 133—134°C.

Found: C, 58.45; H, 3.89; N, 10.03%. Calcd for $C_{26}H_{22}O_9N_4$: C, 58.42; H, 4.15; N, 10.43%.

1-Tropylazulene (XVIII). A solution of 390 mg of XIV and 230 mg of potassium hydroxide in 20 m*l* of ethanol and 6 m*l* of water was refluxed for 4.5 hr. After the ethanol had then been removed, the solution was acidified with hydrochloric acid. A reddish-violet precipitate was collected, dried, and heated in a sublimation apparatus under reduced pressure to give a blue oil. This oil was purified by chromatography to afford 1-tropylazulene as a greenish-blue oil.

Found: C, 93.30; H, 6.39%. Calcd for $C_{17}H_{14}$: C, 93.53; H, 6.47%.

Trinitrobenzene complex: mp 97.5°C.

Found: C, 64.50; H, 4.02; N, 9.83%. Calcd for $C_{23}H_{17}O_6N_3$: C, 64.03; H, 3.97; N, 9.74%.

2-Chloro-1-cyano-3-tropylazulene (XIX). A solution of 130 mg of XV, 200 mg of hydroxylamine hydrochloride, and 2 m*l* of a 0.5 N sodium hydroxide solution in 3 m*l* of ethanol was refluxed for 20 min. The ethanol was removed, water was added and then extracted with chloroform, and the extract was evaporated to leave a green solid. When a solution of the solid in 2 m*l* of acetic anhydride was refluxed for 30 min, 20 mg of reddish-violet crystals (XIX) were obtained, mp 155°C.

Found: C, 64.57; H, 3.80; N, 5.35%. Calcd for $C_{14}H_{10}O_2NCl$: C, 64.77; H, 3.88; N, 5.40%.

3-Tropyl-1-oxaazulan-2-one (XX). The tropylation of 1-oxaazulan-2-one afforded XX (85%), as yellowish-orange plates, mp 108-110°C (from ethanol).

Found: C, 81.65; H, 5.48%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%.

4-Methyl-3-tropyl-1-oxaazulan-2-one (XXI). The tropylation of 4-methyl-1-oxaazulan-2-one gave XXI (80%), as orange prisms, mp 170—171°C (from acetone).

Found: C, 81.44; H, 5.63%. Calcd for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

5-Isopropyl-3-tropyl-1-oxaazulan-3-one (XXII). The tropylation of 5-isopropyl-1-oxaazulan-2-one gave XXII (73%), as orange needles, mp 87—89°C (from ethanol).

Found: C, 82.08; H, 6.74%. Calcd for $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%.

3-(*p*-Tolylazo)guaiazulene (XXIV). a) Into a solution of 100 mg of IX in 1 m*l* of pyridine cooled in an ice bath, aqueous *p*-toluidine diazonium chloride (XXIII) prepared from 54 mg of *p*-toluidine, 50 mg of sodium nitrite, 0.5 m*l* of 6 N hydrochloric acid, and 0.3 m*l* of water, was stirred, drop by drop. The solution turned from blue to a brownish yellow. After the solution had been stirred for one hour at room temperature, 2 m*l* of water were added and then extracted with chloroform. The combined chloroform layers were dried over sodium sulfate, filtered off, and concentrated to give a dark green, crystalline substance. Recrystallization from ethanol afforded 144 mg of XXIV, mp 138°C.

Found: C, 83.46; H, 7.50; N, 8.45%. Calcd for $C_{22}H_{24}N_2$: C, 83.50; H, 7.64; N, 8.85%.

b) To a solution of 100 mg of XI in 1 m*l* of pyridine cooled in an ice bath, a solution of XXIII prepared from 75 mg of *p*-toluidine was added, drop by drop. The reaction was carried out for 4 hr at room temperature, and then the results were treated as above to give 50 mg of XXIV, mp 136°C, which was identical with the XXIV obtained above.

Ethyl 2-Amino-3-(*p*-tolylazo)azulene-1-carboxylate (XXV). From 100 mg of XVII in 1 m*l* of pyridine and XXIII prepared from 53 mg of *p*-toluidine, 160 mg of an oily substance was obtained. The oil was chromatographed on alumina; the cyclohexane eluate afforded 107 mg of reddish-brown micro-needles whose melting point was 119.5°C after having been recrystallized from ethanol and which was identical with authentic XXV.[15]

Azo-coupling Reaction of VIII. Into a solution of 100 mg of VIII in 1.5 m*l* of pyridine in an ice bath, aqueous XXIII (from 43 mg of *p*-toluidine) was stirred. A precipitate formed immediately, but the reaction was continued for 2 hr. The precipitate was then filtered off and dried in a desiccator. The mother layer was extracted with chloroform, and the combined extracts were washed with water, dried over sodium sulfate, and concentrated to give a residue. The residue and the precipitate were dissolved in petroleum ether and chromatographed on alumina to give 86 mg of recovered VIII.

Ethyl 3-Benzoylazulene-1-carboxylate (XXVIII). a) To 30 m*l* of dry carbon disulfide, 200 mg of XIV, 195 mg of benzoyl chloride, and 183 mg of anhydrous aluminum chloride were added, and the resulting solution was refluxed for 15 hr. The organic layer was separated, washed with water and N sodium hydroxide, dried over sodium sulfate, and then concentrated to give a residue. The residue was dissolved in petroleum chromatographed on alumina. The petroleum ether eluate afforded 125 mg of XIV while the benzene-petroleum ether eluate gave 70 mg of a dark red residue, which in turn afforded 64 mg of dark red prisms of XXVIII, mp 107°C, after recrystallization from ethanol.

Found: C, 79.26; H, 5.39%. Calcd for $C_{20}H_{16}O_3$: C, 78.93; H, 5.30%.

b) A solution of 200 mg of ethyl azulene-1-carboxylate, 282 mg of benzoyl chloride, and 266 mg of aluminum chloride in 30 m*l* of carbon disulfide was heated to reflux for 13 hr and then worked up as above to give 170 mg of XXVII, mp 108°C, after recrystallization from ethanol.

3-Benzoylguaiazulene (XXVI). A solution of 400 mg of XI, 215 mg of aluminum chloride, and 202 mg of benzoyl chloride in 20 m*l* of carbon disulfide was heated to reflux for 14 hr. After the reaction had been

completed, the mixture was worked up as above and chromatographed on alumina. The first benzene effluent afforded 87 mg of a blue oil which was identical with guaiazulene (31.6%), while the second effluent gave 41 mg of a dark green semisolid which in turn afforded 10 mg of XXVI, mp 119°C, after recrystallization from ethanol and which was identical with the 3-benzoylguaiazulene prepared by the reported method.[20]

2-Chloro-1,3-dibenzoylazulene (XXVII). a) solution of 150 mg of VIII, 168 mg of benzoyl chloride, and 160 mg of aluminum chloride in 25 m*l* of carbon disulfide was refluxed for 14 hr, and then worked up in the usual manner. The first petroleum ether effluent gave 22 mg of VI, while the second gave 124 mg of a dark red oil. The latter was rechromatographed, and the benzene effluent gave 25 mg of red prisms of XXVII, mp 179—180°C; recrystallization from benzene raised its melting point to 185°C.

Found: C, 77.85; H, 4.28%. Calcd for $C_{24}H_{15}O_2Cl$: C, 77.73; H, 4.35%.

b) A solution of 200 mg of VI, 260 mg of benzoyl chloride, and 245 mg of aluminum chloride in 30 m*l* of carbon disulfide was refluxed for 13 hr; a subsequent work-up in the usual manner afforded 32 mg of VI and 143 mg of XXVII.

Ethyl 2-Amino-3-nitrosoazulene-1-carboxylate (XXIX). a) To a solution of 450 mg of XVII in 20 m*l* of ethanol in an ice bath, 1 m*l* of concentrated sulfuric acid was added, and then 342 mg of isoamyl nitrite were added. After the mixture had been allowed to stand overnight at room temperature, the precipitate thus formed was filtered off, washed with aqueous sodium hydrogen carbonate and water, and dried in a desiccator. Recrystallization from chloroform afforded 190 mg of dark brown scales of XXIX, mp 174—174.5°C.

Found: C, 63.61; H, 4.73; N, 11.25%. Calcd for $C_{13}H_{12}O_3N_2$: C, 63.92; H, 4.95; N, 11.47%.

b) A solution of 300 mg of XVII in 12 m*l* of ethanol cooled in an ice bath was saturated with dry hydrogen chloride, and then 230 mg of isoamyl nitrite were added, drop by drop. After 4 hr, the solution was poured into 50 m*l* of water, and the separated water layer was neutralized with sodium hydrogen carbonate to form a precipitate. The precipitate was washed with water, dried in a desiccator, and recrystallized from chloroform to afford 90 mg of XXIX, mp 174°C.

The Exchange Reactions of the Tropyl Group with the Proton on the Tropylazulenes. *i) 3-Tropylguaiazulene.* a) A solution of XI in 4 m*l* of concentrated sulfuric acid was allowed to stand at room temperature for 1 hr; then it was poured into 20 m*l* of ice water and extracted with benzene. The combined extract was washed with aqueous sodium hydrogen carbonate and water, dried over sodium sulfate, and chromatographed on alumina to afford 50 mg of a blue oil. The IR, UV, and visible spectra of the oil were identical with those of guaiazulene.

b) To a solution of 100 mg of XI in 4 m*l* of dioxane, 2 m*l* of 1 N sulfuric acid were added, after which the mixture was heated on a water bath for 30 min. After cooling, the solution was neutralized with aqueous sodium hydrogen carbonate, and extracted with benzene. The combined extracts were washed with water, dried over sodium sulfate, and chromatographed on alumina to give 60 mg of IX.

ii) Ethyl 2-Amino-3-tropylazulene-1-carboxylate. a) A solution of 100 mg of XVII in 5 m*l* of concentrated sulfuric acid was treated as above; the ethyl acetate effluent yielded 61 mg of the starting material.

b) To a solution of 100 mg of XVII in 4 m*l* of dioxane, 2 m*l* of 1 N sulfuric acid were added, after which the mixture was heated on a water bath for 2 hr. A subsequent work-up in the usual method gave 92 mg of the unchanged, recovered substance.

iii) Ethyl 3-Tropylazulene-1-carboxylate. a) To a solution of 100 mg of XIV in 4 m*l* of dioxane, 1 m*l* of dioxane, 1 m*l* of concentrated sulfuric acid was added, after which the solution was allowed to stand for 1 hr at room temperature. The reaction mixture was then worked up in the usual manner: the benzene effluent of the chromatography of the crude substance gave 94 mg of the starting substance.

b) A mixture of 100 mg of XIV, 4 m*l* of dioxane, and 2 m*l* of 1 N sulfuric acid was heated on a water bath for 2 hr; then it was worked up as above to give 100 mg of the recovered starting substance.

iv) 2-Chloro-1-tropylazulene. a) To a solution of VIII in 3 m*l* of dioxane, 1 m*l* of concentrated sulfuric acid was added, after which the solution was allowed to stand at room temperature for 30 min and then worked up as above. The petroleum ether effluent of the chromatography afforded 76 mg of a blue oil substance whose IR spectrum showed that the oil was a mixture of VIII and 2-chloroazulene.

b) A mixture of 100 mg of VIII, 4 m*l* of dioxane, and 2 m*l* of 1 N sulfuric acid was heated on a water bath for 2 hr, and then worked up as above. The first petroleum ether effluent gave 10 mg of 2-chloroazulene, mp 91°C, while the second effluent afforded 70 mg of a blue oil which was a mixture of VI and VIII.

The authors wish to express their gratitude to the Sankyo Co. for its donation of a research fund which covered a part of the expenses for this work. The infrared and ultraviolet spectrophotometers used in this study were purchased with a Grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., Ltd., to which the authors are also grateful.

3,4-Benzotropolone and Related Compounds. V.[1] Bromo- and Hydroxy-2,3-benzotropones

Seiji EBINE, Masamatsu HOSHINO and Kazuko TAKAHASHI*1

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama-ken

(Received February 8, 1968)

Isomeric 5,7- and 4,7-dibromo-2,3-benzotropones were prepared, not *via* 2,3-benzotropone, but by the bromination and subsequent dehydrobromination of 2,3-benzocycloheptenone. The tropone structure of these compounds was based on spectral data and hydrogenation to 2,3-benzocycloheptenone. The dibromo-2,3-benzotropones, when treated with hydroxylamine, underwent cine-reaction to 5- and 4-bromo-6-hydroxylamino-2,3-benzotropone oximes, which were then hydrolyzed and debrominated to the same 6-hydroxy-2,3-benzotropone. 5,7,5'-Tribromo-2,3-benzotropone was obtained by the drastic bromination, followed by the dehydrobromination, of 2,3-benzocycloheptenone. The position of a hydroxyl group in 6-hydroxy-2,3-benzotropone was confirmed by oxidation to *o*-carboxycinnamic acid, while that of the 5'-bromo substituent in 5,7,5'-tribromo-2,3-benzotropone was confirmed by hydrogenation to 5'-bromo-2,3-benzocycloheptenone.

It has previously been found that the treatment of 2-cycloheptenone[2] or cycloheptanone[3] with bromine brings about bromination, followed by spontaneous dehydrobromination, to afford 2,4,7-tribromotropone. According to this reaction, an attempt was made to prepare a bromo-substituted benzotropone by treating 2,3-benzocycloheptenone (I) with bromine. The reaction of I with excess bromine, however, did not give a brominated benzotropone, but instead produced two isomeric tetrabromo-2,3-benzocycloheptenones (IIa, mp 142°C and IIb, mp 146.5°C). The application of less bromine to I gave tribromo-2,3-benzocycloheptenone, and the reaction of I with bromine in the presence of sodium acetate produced dibromoacetoxy-2,3-benzocycloheptenone.*2

The dehydrobromination of IIa was then attempted. IIa remained unchanged when heated with sodium acetate in an ethanolic or acetic acid solution, and resinified when treated with diethylamine or potassium hydroxide in an ethanolic solution at room temperature. IIa was effectively dehydrobrominated when its pyridine solution was allowed to stand at room temperature for a week it yielded two isomeric dibromo-2,3-benzotropones (IIIa and IIIb), with a predominance of the former. Under the same conditions, IIb produced only IIIa. The tropone structure of IIIa and IIIb is assumed on the basis of the catalytic reduction to 2,3-benzotropone (in a low yield) and I (in a fair yield), the ultraviolet absorption spectra having peaks in the 220—270 and 300—350 mμ

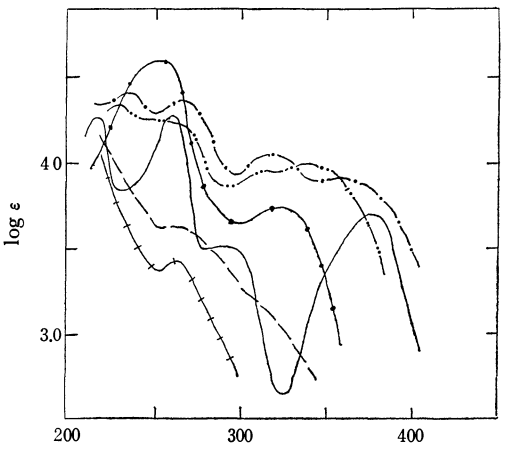

Fig. 1. Ultraviolet absorption spectra of isomeric tetrabromo-2,3-benzocycloheptenones (IIa, — — and IIb, +—+), isomeric dibromo-2,3-benzotropones (5,7-dibromo-, IIIa, —·— and 4,7-dibromo-, IIIb, —··—), uncharacterized compound (VII, ——) and 6-hydroxy-2,3-benzotropone (VIII, —•—•—) in methanol.

*2 These brominated benzocycloheptenones, when oxidized with permanganate, gave phthalic acid, indicating that they possess all the bromo substituents in the cycloheptenone ring.

regions (Fig. 1), and the infrared absorption spectra having carbonyl bands at frequencies below 1650 cm^{-1} (Experimental), characteristics which are in accord with the spectral features of troponoid compounds.[4] IIIa and IIIb, like other troponoid compounds, dissolve in concentrated sulfuric acid and precipitate unchanged upon dilution with water. IIIa was not affected when heated with sodium acetate in a methanolic or an acetic acid solution at 120°C for 10 hr, with cupric acetate in a pyridine solution at 110°C for 12 hr, and with concentrated hydrochloric acid in an acetic acid solution at 150°C for 50 hr. It has been found that the out-of-plane deformation vibration of troponoid CH in halogenated benzotropolones is correlated with the position of the halogen substituents,[5] but the infrared absorption spectra of IIIa and IIIb made possible no definite conclusion regarding the position of substituents. IIIa showed an infrared absorption band at 898 cm^{-1}, hardly suggesting the presence of isolated hydrogen atoms.

In order to elucidate the position of the bromo substituents, IIIa and IIIb were subjected to Diels-Alder reaction with maleic anhydride, and the NMR spectra of the adducts were examined. The spectrum of the IIIb - maleic anhydride adduct contained AB-type absorption bands at 7.05 and 6.30 ppm (J=9.5 cps) ascribable to adjacent two ethylenic hydrogens, indicating that the adduct carries the bromo substituents at the positions given in Formula XVIIIb. It follows, therefore, that IIIb is the 4,7-dibromo compound. The spectrum of the IIIa - maleic anhydride adduct contained a doublet at 6.61 ppm with a long-range coupling constant (J=1.8 cps) ascribable to an ethylenic hydrogen which couples with a distant hydrogen, suggesting that the adduct carries the bromo substituents as given in formula XVIIIa or XVIIIa'. Accordingly, IIIa is either the 5,7- or 4,6-dibromo compound. As will be described below, IIIa and IIIb gave isomeric bromo-hydroxy-benzotropones (VIa and VIb, respectively) when treated with hydroxylamine and then with sulfuric acid, and these two isomers gave the same hydroxy-benzotropone (VIII) upon debromination. This fact leads to the conclusion that IIIa is the 5,7-dibromo compound. The position of bromo substituents was further proved to be 5,7- in IIIa and 4,7- in IIIb from an NMR spectral study of IIIa, IIIb, and related compounds, the details of which will be published elsewhere.[6] IIIa is presumably identical with Buchanan's dibromo-2,3-benzotropone obtained by the bromination of 2,3-benzotropone or 2,3-benzo-2,4-cycloheptadienone.[7]

IIIa was allowed to react with methanolic potassium hydroxide at room temperature to yield 5-bromo-6-methoxy-2,3-benzotropone (V), 5-bromo-6-hydroxy-2,3-benzotropone (VIa), and an uncharacterized compound (VII),*3 along with a considerable amount of tar. The ultraviolet absorption spectrum of V (Fig. 1) is essentially superimposable upon that of isomeric 7-bromo-3,4-benzotropolone methyl ether.[8]

IIIa and IIIb were treated with hydroxylamine in a pyridine solution to give 5-bromo-6-hydroxylamino-2,3-benzotropone oxime (Xa) and the corresponding 4-bromo isomer (Xb), which were then hydrolyzed with sulfuric acid to 5-bromo-6-hydroxy-2,3-benzotropone (VIa) and the corresponding 4-bromo isomer (VIb) respectively. These, in turn, were debrominated with hydrogen over a palladium-charcoal catalyst to the same 5-hydroxy-2,3-benzotropone (VIII). VIII was also produced from Xa or Xb *via* 6-hydroxylamino-2,3-benzotropone oxime (XI). VIII is soluble in dilute alkali or in concentrated sulfuric acid, and can be precipitated unchanged upon the neutralization of its alkaline solution or on the dilution of its concentrated sulfuric acid solution with water. VIII gives no ferric chloride coloration. The tropone structure of VIII is based on its ultraviolet absorption spectrum, which shows two peaks at 255 and 335 mμ (Fig. 1), and its infrared absorption spectrum, which shows a carbonyl band below 1650 cm^{-1}.[4] The position of a hydroxyl group of VIII was confirmed by oxidation with alkaline hydrogen peroxide to *o*-carboxycinnamic acid (XII), and by hydrogenation with excess hydrogen over a platinum oxide catalyst to 4,5-benzocycloheptene-1,3-diol (IX), followed by oxidation with potassium permanganate to *o*-carboxyhydrocinnamic acid (XIII).

4) For a reference on the ultraviolet spectra of troponoid compounds, see M. Tsuboi, This Bulletin, **25**, 369 (1952). For references on the infrared spectra of troponoid compounds, see S. Kinumaki, K. Aida and Y. Ikegami, *Sci. Repts. Res. Inst. Tohoku Univ.*, **A-8**, 263 (1956), and E. Kloster-Jensen, N. Tarkoy, A. Eschenmoser and E. Heilbronner, *Helv. Chim. Acta*, **39**, 780 (1956).

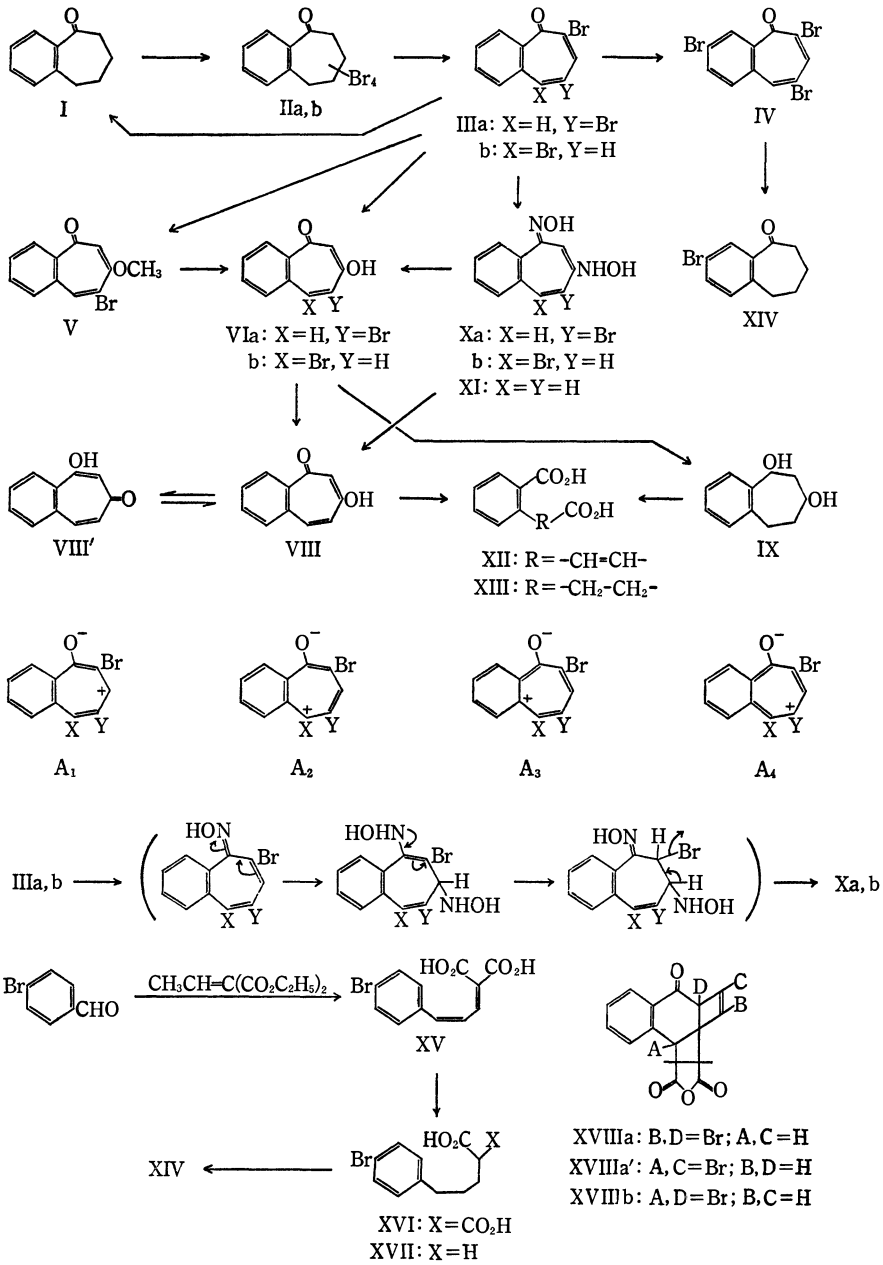
*3 The uncharacterized compound (VII) dissolves in alkali, shows a weak silver-mirror reaction, and produces a monoacetate. Its ultraviolet absorption spectrum (Fig. 1) deviates from those of general troponoid compounds and rather resembles those of hydroxynaphthaldehydes (N. C. Melchior, *J. Am. Chem. Soc.*, **71**, 3647 (1949).). The infrared absorption band at 1670 cm^{-1} (KBr) corresponds to carbonyl bands of hydroxynaphthaldehydes (I. M. Hunsberger, *ibid.*, **72**, 5626 (1950).). From these facts and by analogy with the transformation of 2-bromo-7-chlorotropone with alkali to 3-chlorosalicylaldehyde (T. Nozoe, S. Seto and S. Matsumura, *Proc. Japan Acad.*, **28**, 483 (1952); S. Seto, *Sci. Repts. Tohoku Univ., Ser. I*, **37**, 377 (1953).), VII is assumed to be hydroxy-methoxy-naphthaldehyde; however, it was not further investigated because we lacked a sample.

8) S. Ebine, This Bulletin, **35**, 115 (1962).



VIII is a novel isomer of previously-reported 4-hydroxy-2,3-benzotropone,[9] 3,4-benzotropolone,[10] and 4,5-benzotropolone.[11] VIII is capable of existing as a tautomeric mixture with 3-hydroxy-4,5-benzotropone (VIII'), but this compound gives a single methyl ether, acetate, and 2,4-dinitrophenylhydrazone. Although it is not clear which form predominates in the tautomeric mixture, the VIII formula is tentatively employed in this paper. VI and X would also hold under the same circumstances as VIII.

The halogenated troponoids tend to undergo abnormal "cine-reaction" on being treated with basic reagents.[12] The formation of V, VI and

X from III falls in the same category. The reason why III brings about such a type of reaction is as follows: the resonance structure of III is much contributed to by the A_1 and A_2 formulas, but little by the A_3 and A_4 formulas, because the condensed benzene ring of the former is aromatic, while that of latter is quinonoid[5,8,13]; moreover, a substitution reaction at the 4-position encounters a slight steric hindrance caused by the *peri* position of the benzene ring.[5] The mechanism of the formation of X from III is illustrated in the chart.

5,7,5'-Tribromo-2,3-benzotropone (IV) was prepared by the further bromination of IIIa, or by the bromination of I under drastic conditions and by subsequent treatment with pyridine. The position of the 5'-bromo substituent was determined by its oxidation to 4-bromophthalic acid and by its hydrogenation to 5'-bromo-2,3-benzocycloheptenone (XIV), which was identified by a synthesis consisting of the successive reactions shown in the chart: the condensation of *p*-bromobenzaldehyde with diethyl ethylidenemalonate to *p*-bromocinnamylidenemalonic acid, hydrogenation, followed by decarboxylation to δ-(*p*-bromophenyl-)valeric acid, and ring-closure with polyphosphoric acid to XIV.

It is noteworthy that, upon being treated with anionoid reagents, a 7-bromo substituent of 2,3-benzotropone derivatives undergoes an abnormal "cine substitution" exclusively.

Experimental*4

Bromination of 2,3-Benzocycloheptenone (I). *Dibromo-acetoxy-2,3-benzocycloheptenone.* A solution of 4 g of bromine in an equal amount of acetic acid was added to a solution of 1 g of 2,3-benzocycloheptenone (I) in 20 m*l* of acetic acid containing 6.6 g of sodium acetate, and the mixture was heated on a water bath for 5 hr. The evaporation of the acetic acid, and the crystallization of the residue from petroleum ether gave 470 mg (20%) of colorless needles; mp 104—105°C, infrared spectrum (Nujol): 1748 cm^{-1} for an acetyl carbonyl and 1720 cm^{-1} for a cycloheptenone carbonyl.

Found: C, 41.63; H, 3.42%. Calcd for $C_{13}H_{12}O_3Br_2$: C, 41.51; H, 3.22%.

Tribromo-2,3-benzocycloheptenone. A solution of 1 g of I and 4.0 g of bromine in 6 m*l* of acetic acid was heated on a water bath for 15 hr. The subsequent recrystallization of the product from dilute ethanol afforded 0.57 g (23%) of a colorless crystalline powder; mp 133—134°C.

Found: C, 33.45; H, 2.30%. Calcd for $C_{11}H_9OBr_3$: C, 33.28; H, 2.29%.

Isomeric Tetrabromo-2,3-benzocycloheptenones (IIa and IIb). A solution of 10 g of I and 40 g of bromine in 50 m*l* of acetic acid was heated on a water bath for 7 hr. To this there was again added 40 g of bromine, and heating was continued for a further 7 hr. The fractional recrystallization of the product from ethanol gave 12.6 g (43%) of IIa and 0.8 g (2.8%) of IIb.

IIa, colorless granular crystals, mp 141.5—142°C, infrared spectrum (Nujol): 1712 cm^{-1} for carbonyl, ultraviolet spectrum (MeOH): 265 mμ (log ε 3.65).

Found: C, 27.82; H, 2.03%. Calcd for $C_{11}H_8OBr_4$: C, 27.76; H, 1.70%.

IIb, colorless plates, mp 145.5—146.5°C, infrared spectrum ($CHCl_3$): 1717 cm^{-1} for carbonyl, ultraviolet spectrum (MeOH): 263 mμ (log ε 3.47).

Found: C, 27.79; H, 1.75%. Calcd for $C_{11}H_8OBr_4$: C, 27.76; H, 1.70%.

The admixture of IIa and IIb showed a depression in the melting point to *ca.* 112°C. Crude IIa and IIb produce severe vesication on the skin, but purified samples are harmless and can be handled safely.

Oxidation of IIa and IIb. IIa or IIb (0.5 g) dissolved in 180 m*l* of acetone was oxidized with 5 g of potassium permanganate by heating it under reflux for 2 hr; this afforded phthalic acid in 60—65% yields; mp and mixed mp 192—194°C. (It was further identified by conversion to phthalanil; mp and mixed mp 201—202°C.)

Isomeric 5,7-Dibromo-2,3-benzotropone (IIIa) and 4,7-Dibromo-2,3-benzotropone (IIIb). A solution of 8 g of IIa in 24 m*l* of pyridine was set aside at room temperature for a week. The crystalline product which thus separated was filtered and recrystallized from ethanol (100 m*l*) to yield 3.30 g (63%) of IIa as pale yellow fibrous needles; mp 165°C, infrared spectrum, (KBr) in carbonyl region: 1620, 1595, 1535 cm^{-1}, ultraviolet spectrum (MeOH): mμ (log ε), 242 (4.37), 277 (4.33), 325 (4.03), 370 (3.87).

Found: C, 41.97; H, 1.78%. Calcd for $C_{11}H_6OBr_2$: C, 42.07; H, 1.93%.

After the IIIa had been removed, the pyridine filtrate was diluted with water (50 m*l*) to give a precipitate of a second product. Recrystallization from petroleum ether gave 1.00 g (19%) of IIIb as pale yellow fibrous needles melting at 65.5°C; infrared spectrum (KBr) in carbonyl region: 1627, 1607, 1592, 1561, 1532 cm^{-1}, ultraviolet spectrum (MeOH): mμ (log ε), 235 (4.33), 270 (4.22), 320 (3.97), 340 (3.95).

Found: C, 42.29; H, 2.17%. Calcd for $C_{11}H_6OBr_2$: C, 42.07; H, 1.93%.

Hydrogenation of IIIa. a) A solution of 500 mg of IIIa in 250 m*l* of acetic acid was hydrogenated in the presence of 250 mg of 5% palladium-on-charcoal and 500 mg of anhydrous sodium acetate at an ordinary temperature and pressure. The uptake of hydrogen amounted to 4 mol equiv. After a usual work-up, crude I was obtained in good yield and identified by conversion to its 2,4-dinitrophenylhydrazone; red crystals, mp 204—205°C, undepressed on admixture with an authentic specimen of 2,3-benzocycloheptenone 2,4-dinitrophenylhydrazone. (Found: C, 59.74; H, 4.48; N, 16.53%. Calcd for $C_{17}H_{16}O_4N_4$: C, 59.99; H, 4.74; N, 16.46%).

b) A solution of 500 mg of IIIa in 100 m*l* of ethanol was hydrogenated as above until 2 mol equivalent of hydrogen had been taken up. The oily product was treated with 2,4-dinitrophenylhydrazine, giving 75 mg of 2,3-benzotropone 2,4-dinitrophenylhydrazone, mp 227—228°C. (Found: C, 61.07; H, 3.51; N, 16.06%. Calcd for $C_{17}H_{12}O_4N_4$: C, 60.71; H, 3.61; N, 16.66%).

13) S. Ebine, This Bulletin, **34**, 887 (1961).

*4 Thanks are due to the Department of Chemistry, Faculty of Science, Tohoku University, for the microanalyses.

Reaction of IIIa with Methanolic Potassium Hydroxide. A solution of 3.2 g of IIIa and 8 g of potassium hydroxide in 800 m*l* of methanol was allowed to stand at room temperature for 24 hr. The solution was acidified with 2 N hydrochloric acid and then concentrated to a semi-solid mass. The fractional recrystallization of the product from ethanol afforded 205 mg (6.4% recovery) of an unchanged material (IIIa), 360 mg (13%) of 5-bromo-6-methoxy-2,3-benzotropone (V), 50 mg (2.0%) of 5-bromo-6-hydroxy-2,3-benzotropone (VIa), and 50 mg of an uncharacterized product (VII).

5-Bromo-6-methoxy-2,3-benzotropone (V), colorless prisms, mp 140.5°C, infrared spectrum (KBr) in carbonyl region: 1617, 1578, 1565 cm^{-1}, ultraviolet spectrum (MeOH): mμ (log ε), 260 (4.58), 337 (3.76). V was also obtained in an excellent yield by the methylation of VIa with diazomethane.

Found: C, 54.43; H, 3.55%. Calcd for $C_{12}H_9O_2Br$: C, 54.36; H, 3.42%.

5-Bromo-6-hydroxy-2,3-benzotropone (VIa), described below.

An Uncharacterized Compound (VII), assumed to be hydroxy-methoxy-naphthaldehyde, pale yellow needles, mp 186°C, infrared spectrum (KBr) above 1500 cm^{-1}: 3447, 1670, 1621, 1601 cm^{-1}, ultraviolet spectrum (MeOH): mμ (log ε), 220 (4.32), 265 (4.26), 290 (3.52), 380 (3.64).

Found: C, 70.70; H, 4.74%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

Acetate of VII, colorless needles, mp 60—61°C.

Found: C, 68.78; H, 4.98%. Calcd for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95%.

Isomeric 5-Bromo-6-hydroxylamino-2,3-benzotropone Oxime (Xa) and 4-Bromo-6-hydroxylamino-2,3-benzotropone Oxime (Xb). A solution of 5 g of IIIa (or IIIb) and 3.5 g of hydroxylamine hydrochloride in 160 m*l* of pyridine was allowed to stand at room temperature for 24 hr. The pyridine was then distilled below 30°C under reduced pressure, and the residue was recrystallized from ethanol; this yielded 2.40 g (71%) of Xa (or 2.47 g, 73%, of Xb).

Xa, colorless needles, mp 228°C (dec.).

Found: C, 46.92; H, 3.30; N, 9.66%. Calcd for $C_{11}H_9O_2N_2Br$: C, 47.00; H, 3.23; N, 9.97%.

Diacetate, colorless needles, mp 148—149°C.

Found: C, 49.61; H, 3.33; N, 7.49%. Calcd for $C_{15}H_{13}O_4N_2Br$: C, 49.82; H, 3.59; N, 7.67%.

Xb, colorless needles, mp 185—186°C (dec.).

Found: C, 47.16; H, 3.18; N, 9.59%. Calcd for $C_{11}H_9O_2N_2Br$: C, 47.00; H, 3.23; N, 9.97%.

Isomeric 5-Bromo-6-hydroxy-2,3-benzotropone (VIa) and 4-Bromo-6-hydroxy-2,3-benzotropone (VIb). a) Xa or Xb (2 g) dissolved in 75 m*l* of 80% sulfuric acid was heated at 160—165°C for 2.5 hr. After dilution with 1 *l* of water, the solution was extracted with ethyl acetate and the extract was shaken with 1 N sodium hydroxide. The acidification of the alkaline layer gave a crude product, which was then recrystallized from dilute ethanol or acetic acid to yield 1.52 g (85%) of VIa or 1.61 g (90%) of VIb.

VIa, pale yellow needles, mp 234°C (dec.).

Found: C, 52.67; H, 2.97%. Calcd for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%.

Acetate of VIa, colorless scales, mp 164.5°C.

Found: C, 53.00; H, 3.06%. Calcd for $C_{13}H_9O_3Br$: C, 53.27; H, 3.10%.

Methyl ether of VIa, described above as V.

VIb, pale yellow needles, mp 201—202°C (dec.).

Found: C, 52.59; H, 3.04%. Calcd for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%.

b) V (500 mg) was heated with 100 m*l* of concentrated hydrochloric acid on a water bath for 3.5 hr, this afforded VIa in a quantitative yield. The action of methanolic potassium hydroxide on IIIa also gave VIa, as has been described above.

Oxidation of VIa and VIb. VIa or VIb (350 mg) dissolved in 50 m*l* of 0.5 N sodium hydroxide was oxidized with 4 m*l* of 35% hydrogen peroxide in the same way as will be described below for the oxidation of VIII; this afforded phthalic acid in 40—45% yields.

6-Hydroxylamino-2,3-benzotropone Oxime (XI). a) The catalytic debromination of Xa or Xb (1 g) in ethanolic solution, using 5% palladium-on-charcoal (400 mg) and anhydrous sodium acetate (400 mg), was allowed to proceed until the hydrogen uptake amounted to 1 mol equivalent. The product was then recrystallized from ethanol, giving XI (590 mg, 82%), colorless needles, mp 205°C (dec.).

Found: C, 65.19; H, 4.72; N, 13.33%. Calcd for $C_{11}H_{10}O_2N_2$: C, 65.53; H, 4.98; N, 13.86%.

b) XI (130 mg, 74%) was also obtained by the reaction of VIII (150 mg) with hydroxylamine hydrochloride (150 mg) in a pyridine solution at 100°C for 2 hr in the same way as has been described for the formation of Xa and Xb.

6-Hydroxy-2,3-benzotropone (VIII). A solution of 1 g of VIa or VIb in 100 m*l* of ethanol, containing 200 mg of 5% palladium-on-charcoal and 660 mg of anhydrous sodium acetate, was shaken under a hydrogen atmosphere and at an ordinary temperature and pressure until 1 mol equivalent of hydrogen had been taken up. The product was recrystallized from ethanol to yield 540 mg (79%) of VIII, pale yellow needles, mp 208.5°C (dec.), infrared spectrum (KBr) above 1500 cm^{-1}: 3400, 3040, 2640, 2550, 1640, 1582, 1557, 1535 cm^{-1}, ultraviolet spectrum (MeOH): mμ (log ε), 255 (4.57), 335 (3.72).

VIII (70 mg, 21%) was also obtained by the hydrolysis of XI (400 mg) with 80% sulfuric acid (30 m*l*) at 160—165°C.

Found: C, 76.50; H, 4.46%. Calcd for $C_{11}H_8O_2$: C, 76.73; H, 4.68%.

Methyl Ether, colorless needles, mp 73—74°C.

Found: C, 77.71; H, 5.09%. Calcd for $C_{12}H_{10}O_2$: C, 77.40; H, 5.41%.

Acetate, colorless needles, mp 97—98°C.

Found: C, 72.72; H, 4.78%. Calcd for $C_{13}H_{10}O_3$: C, 72.89; H, 4.71%.

VIII reacted with 2,4-dinitrophenylhydrazine to give 6-(2,4-dinitrophenylhydrazino-)2,3-benzotropone 2,4-dinitrophenylhydrazone, reddish-brown granular crystals, mp 273—275°C.

Found: C, 51.70; H, 2.81; N, 20.94%. Calcd for $C_{23}H_{16}O_8N_8$: C, 51.88; H, 3.03; N, 21.05%.

VIII reacted with hydroxylamine in pyridine at 100°C to give XI, mp and mixed mp 205°C.

Oxidation of VIII. To a solution of 200 mg of VIII in 20 m*l* of 0.5 N sodium hydroxide, 10 m*l* of 35% hydrogen peroxide were added; the resulting solution

14) F. Ramirez and A. F. Kirby, *J. Am. Chem. Soc.*, **75**, 6226 (1953).

was allowed to stand at room temperature (25°C) for 10 days. The product that separated on acidification was recrystallized from ethanol to give 130 mg (58%) of *o*-carboxycinnamic acid, mp 196—197°C (Found: C, 62.61; H, 4.19%. Calcd for $C_{10}H_8O_4$: C, 62.50; H, 4.20%). The mp was not depressed on admixture with an authentic sample,[15] and the infrared spectra of the two samples were superimposable in all respects.

4,5-Benzocycloheptene-1,3-diol] (IX). VIa (1 g), dissolved in 100 m*l* of ethanol, was hydrogenated over 200 mg of platinum oxide and 660 mg of anhydrous sodium acetate until the hydrogen uptake ceased. The semisolid product was then dissolved in benzene and chromatographed on silica gel, yielding 600 mg (85%) of colorless needles of IX, mp 98.5°C.

Found: C, 73.94; H, 7.73%. Calcd for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92%.

Oxidation of IX. To a solution of 570 mg of IX in 50 m*l* of acetone, 990 mg of powdered potassium permanganate were added in small portions over a period of an hour, after which the reaction mixture was heated at 30°C for 5 hr. After the manganese dioxide had been removed by filtration, the filtrate was acidified, evaporated, and extracted with ether. The extract was evaporated to a syrup, which was then allowed to crystallize in an ice-chest. The recrystallization of the product from benzene gave 75 mg (12%) of *o*-carboxyhydrocinnamic acid, colorless needles, mp 165°C[16] (Found: C, 61.84; H, 4.98%. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%).

5,7,5'-Tribromo-2,3-benzotropone (IV). a) Bromine (25 g) was dropped into 5 g of 2,3-benzocycloheptenone (I) under ice-cooling; the resulting solution was allowed to stand at room temperature for 2 days and was then heated on a water bath for 15 hr. After the evaporation of the excess bromine, a dark brown, syrupy residue was dissolved in 10 m*l* of pyridine and set aside overnight to give a crystalline mass. The recrystallization of the product from acetic acid gave 2.7 g (24%) of IV, yellow needles, mp 205°C, and 1.0 g (11%) of IIIa.

Found: C, 33.89; H, 1.40%. Calcd for $C_{11}H_5OBr_3$: C, 33.62; H, 1.28%.

b) A solution of 300 mg of 5,7-dibromo-2,3-benzotropone (IIIa) in 1.5 g of bromine was refluxed for 3 hr. The excess bromine was evaporated, and the residual solid was crystallized from acetic acid to give 110 mg (29%) of IV, mp 205°C, (Found: C, 33.77; H, 1.38%).

Hydrogenation to 5'-Bromo-3,2-benzocycloheptenone (XIV). A solution of 400 mg of IV in 350 m*l* of acetic acid was shaken with hydrogen in the presence of 200 mg of 5% palladium-on-charcoal and 330 mg of fused sodium acetate at an ordinary temperature and pressure. After 4 mol equivalents (97 m*l*) of hydrogen had been taken up, the catalyst and the solvent were removed, the residue was extracted with ether, and the extract was evaporated. The crude XIV thus obtained was identified by converting it to its 2,4-dinitrophenylhydrazone, yellowish-orange needles, mp 243°C, (Found: C, 48.35; H, 3.45; N, 13.06%. Calcd for $C_{17}H_{15}N_4O_4Br$: C, 48.70; H, 3.61; N, 13.37%.), not depressed on admixture with a synthetic sample to be described below.

Oxidation to 4-Bromophthalic Acid. To a boiling solution of 500 mg of IV in 100 m*l* of acetone was added, portion by portion, 7.0 g of potassium permanganate; the solution was then refluxed for 3 hr. The excess potassium permanganate was decomposed by the addition of a little methanol, and the manganese dioxide that precipitated was collected and washed with 1 N potassium hydroxide. The acetone filtrate and alkaline washings were combined, acidified with hydrochloric acid, concentrated to a small volume, and extracted with ether. The ether extract was evaporated and the residual 4-bromophthalic acid was sublimed to give 245 mg (85%) of 4-bromophthalic anhydride, colorless granular crystals, mp and mixed mp 108—109.5°C.[17]

5,5'-Dibromo-6-hydroxylamino-2,3-benzotropone Oxime. A solution of 1 g of 5,7,5'-tribromo-2,3-benzotropone (IV) and 0.4 g of hydroxylamine hydrochloride in 80 m*l* of pyridine was treated in the same way as in the case of Xa. The product was recrystallized from ethanol to give 0.6 g (67%) of colorless crystals, mp 225°C.

Found: C, 37.01; H, 2.30; N, 7.39%. Calcd for $C_{11}H_8O_2N_2Br_2$: C, 36.69; H, 2.24; N, 7.68%.

5,5'-Dibromo-6-hydroxy-2,3-benzotropone. A solution of 500 mg of the above 5,5'-dibromo-6-hydroxylamino-2,3-benzotropone oxime in 22 m*l* of 66% sulfuric acid was heated at 160°C for 2 hr and then treated as has been described for VIa, b. The recrystallization of the product from ethanol gave 350 mg (76%) of pale yellow prisms melting at 243°C (dec.).

Found: C, 40.10; H, 1.57%. Calcd for $C_{11}H_6O_2Br_2$: C, 40.03; H, 1.83%.

Acetate: colorless needles (recrystallized from ethanol), mp 193—193.5°C.

Found: C, 41.93; H, 1.87%. Calcd for $C_{13}H_8O_3Br_2$: C, 41.97; H, 2.17%.

Synthesis of 5'-Bromo-3,2-benzocycloheptenone (XIV). The synthesis was carried out according to the reported method for the preparation of 2,3-benzocycloheptenone derivatives.[18]

p-Bromocinnamylidenemalonic Acid (XV). To a solution of 34.6 g of diethyl ethylidenemalonate and 11.3 g of *p*-bromobenzaldehyde in 113 m*l* of absolute ethanol, there was added, in small portions, 24.5 g of powdered potassium hydroxide; the resulting solution was allowed to stand at room temperature (18°C) for 2 days. The solution was then acidified with dilute hydrochloric acid, and the precipitate that separated was recrystallized from dilute acetone to yield 11.73 g (65%) of XV, yellow prisms, mp 199°C.

Found: C, 48.31; H, 3.37%. Calcd for $C_{12}H_9O_4Br$: C, 48.51; H, 3.02%.

δ-(p-Bromophenyl-)valeric Acid (XVII). A solution of 12 g of XV in 1200 m*l* of methanol was hydrogenated in the presence of 400 mg of platinum oxide. The hydrogenation was stopped after the uptake of 2 mol equivalents of hydrogen, the catalyst and the solvent were removed, and the residual γ-(*p*-bromophenyl)-propylmalonic acid (XVI) was decarboxylated by

heating it at 145—150°C under 10 mmHg. The recrystallization of the product from benzene - petroleum ether (1 : 1) gave 3.5 g (34%, based on XV) of XVII, colorless granular crystals, mp 91—92°C, along with a considerable amount of δ-phenylvaleric acid.

Found: C, 51.47; H, 4.91%. Calcd for $C_{11}H_{13}O_2Br$: C, 51.38; H, 5.10%.

5'-Bromo-2,3-benzocycloheptenone (XIV). XVII (3 g) was added, portion by portion, to hot (90°C) and stirred polyphosphoric acid prepared from 107 g of phosphoric acid and 95 g of phosphorus pentoxide. After heating at 100°C for 5 hr, the solution was poured onto crushed ice and extracted with ether. The extract was washed with dilute alkali. The acidification of the alkaline washings gave 2.0 g (66.7% recovery) of unreacted XVII, and the evaporation of the ether extract gave 0.8 g (28.6%) of crude XIV. 2,4-Dinitrophenylhydrazone of XIV: yellowish orange needles (from acetic acid), mp 243°C.

Found: C, 48.40; H, 3.51; N, 13.11%. Calcd for $C_{17}H_{15}N_4O_4Br$: C, 48.70; H, 3.61; N, 13.37%.

Diels-Alder Reaction of IIIa and IIIb. *Adduct of IIIa with Maleic Anhydride.* A mixture of 500 mg of IIIa and 500 mg of maleic anhydride was heated at 165°C for 30 min. After cooling, ether was added to the reaction mixture and an insoluble product was collected by filtration. The product was recrystallized from ether to give 400 mg (68%) of XVIIIa, colorless granular crystals, mp 216—217°C. The NMR spectrum in deuteriochloroform: 8.33—7.37 ppm (4H, multiplet, aromatic hydrogens), 6.61 ppm (doublet, J=1.8 cps, an ethylenic hydrogen), 4.40 ppm (multiplet, a benzylic hydrogen), 3.97 ppm (1H, a doublet, J=9 cps, of doublets, J=2.5 cps) and 3.70 ppm (1H, doublet, J=9 cps) (the latter two bands are attributable to two α-hydrogens of maleic anhydride part).

Found: C, 43.78; H, 2.33%. Calcd for $C_{15}H_8O_4Br_2$: C, 43.72; H, 1.96%.

Adduct of IIIb with Maleic Anhydride (XVIIIb). This was obtained in a similar manner by heating a mixture of 500 mg of IIIb and 500 mg of maleic anhydride at 165°C for 5 hr. Colorless needles, mp 255—256°C (dec.). Yield, 320 mg (55%). The NMR spectrum in acetonitrile; 8.20—7.25 ppm (4H, multiplet, aromatic hydrogens), 7.05 and 6.30 ppm (2H, AB-type doublets, J=9.5 cps, adjacent two ethylenic hydrogens), 4.65 and 4.20 ppm (2H, AB-type doublets, J=10.8 cps, adjacent two α-hydrogens of the maleic anhydride part).

Found: C, 44.22; H, 2.27%. Calcd for $C_{15}H_8O_4Br_2$: C, 43.72; H, 1.96%.

3,4-Benzotropolone and Related Compounds. VI.[1] Brominated 6-Hydroxy-2,3-benzotropone (or Brominated 3-Hyroxy-4,5-benzotropone). Formation and Reaction

Masamatsu HOSHINO and Seiji EBINE

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama-ken

(Received March 7, 1968)

6-Hydroxy-2,3-benzotropone (or 3-hydroxy-4,5-benzotropone) (I) was brominated under various conditions, and the bromination products were subjected to debromination, substitution, and some other reactions. I reacted with a molar equivalent of bromine at 25°C to give 7-bromo-6-hydroxy-2,3-benzotropone (II), and with two molar equivalents of bromine at 25°C to give an adduct of II with bromine (V), which, on heating, was dehydrobrominated to 5,7-dibromo-6-hydroxy-2,3-benzotropone (IV). On the other hand, I reacted with bromine at 100°C to give 5-bromo-6-hydroxy-2,3-benzotropone (III), IV, and 2,2,7-tribromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (VI), depending on the amount of bromine employed. All these bromination products could be debrominated with ease with hydrogen in the presence of catalyst to yield I. When II was heated with hydrobromic acid, the 7-bromo substituent was in part eliminated to give I and migrated in part to give III. When IV and 4,7-dibromo-6-hydroxy-2,3-benzotropone (X) were heated with hydrobromic acid, the 7-bromo substituents were eliminated and the 4- or 5-bromo substituent remained unreacted, producing III and 4-bromo-6-hydroxy-2,3-benzotropone (IX) respectively. When II and IV were heated with hydrochloric acid, the 7-bromo substituents were not eliminated but, rather, substituted with chlorine atoms to give 7-chloro-6-hydroxy-2,3-benzotropone (VII) and 5-bromo-7-chloro-6-hydroxy-2,3-benzotropone (VIII) respectively. These facts suggest that I and its bromo derivative sometimes behave as unsaturated β-diketones (I').

In a previous paper[1] the present authors reported the formation of 6-hydroxy-2,3-benzotropone (I). Attention has now been directed toward the chemical properties of I and toward comparing those properties with those of three well-known isomers, 3,4-benzotropolone,[2,3] 4,5-benzotropolone,[4] and 4-hydroxy-2,3-benzotropone.[5] The present paper will deal with the formation and reaction of bromo derivatives of I. I is tautomeric with 4,5-benzocyclohepta-4,6-diene-1,3-dione (I') and with 3-hydroxy-4,5-benzotropone (I''). In this paper the (I) formula is tentatively employed as representative of these tautomers because it is at present unknown which of these is predominant.

An acetic acid solution of I was brominated under various conditions. The reaction of I with a molar equivalent of bromine at 25°C gave 7-bromo-6-hydroxy-2,3-benzotropone (II), the position of the bromo substitutent of which was established by its oxidation with alkaline hydrogen peroxide to *o*-carboxycinnamic acid, and by a study of its NMR absorption spectrum which contained AB-type double doublets at 7.55 and 6.98 ppm, doublets ascribable to two hydrogen atoms at the 4 and 5 positions. The same reaction of I with bromine, but at 100°C instead of 25°C, gave 5-bromo-6-hydroxy-2,3-benzotropone (III), which was identified by a mixed-melting-point determination and by a comparison of its infrared spectrum with that of a sample obtained previously[1] by another method. On being heated at 100°C with a molar equivalent of bromine, both II and III produced dibromo-2,3-benzotropone (IV). This fact indicates that the dibromo substituents of IV are situated at the 5- and 7-positions. IV was oxidized to phthalic acid under the same conditions as in the oxidation of II to *o*-carboxycinnamic acid. II, III, and IV were debrominated with ease to I when treated with hydrogen in the presence of a palladium-charcoal catalyst. These bromo derivatives exhibit two peaks in the 265—285 mμ and 355—365 mμ ranges in the ultraviolet absorption spectra (Fig. 1) and a carbonyl band below 1650 cm^{-1} in the infrared spectra (see

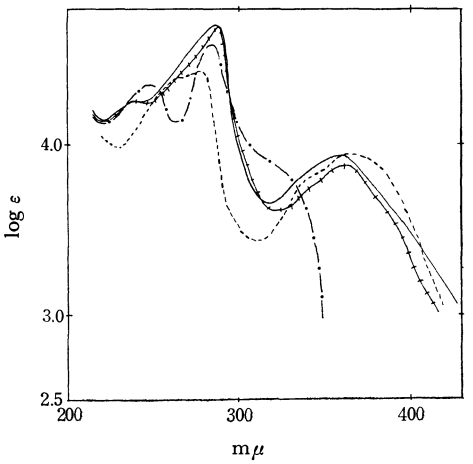

Fig. 1. Ultraviolet absorption spectra of 7-bromo-6-hydroxy-2,3-benzotropone (II, ----), 5,7-dibromo-6-hydroxy-2,3-benzotropone (IV, —+), 7-chloro-6-hydroxy-2,3-benzotropone (VII, —·) and 5-bromo-7-chloro-6-hydroxy-2,3-benzotropone (VIII, ——).

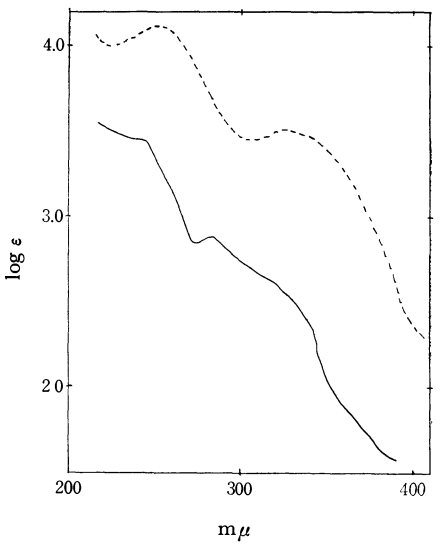

Fig. 2. Ultraviolet absorption spectra of adduct of II with Bromine (V, ----), and 2,2,7-tribromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (VI, ——).

Experimental section), in agreement with the spectral features of troponoids.[6] It has been reported that the methylation of 3-bromotropolone gives two isomeric methyl ethers, 3-bromo-2-methoxy- and 7-bromo-2-methoxy-tropones.[7] However, II, III, and IV gave a single methyl ether and acetate, suggesting that one form predominates in their tautomerism. IV was further brominated at 100°C to 2,2,7-tribromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (VI), which had carbonyl bands at 1710 and 1692 cm^{-1} in the infrared absorption spectrum. VI was also produced directly from I, II, and III when they were heated at 100°C with excess bromine. VI was debrominated to IV when its methanolic solution was left to stand with alkali and to I when treated with hydrogen in the presence of a palladium-charcoal catalyst. II reacted with bromine at 20°C to give an adduct (V), which was debrominated with ease to IV when its ethanolic or acetic acid solution was heated. I, with two molar equivalents of bromine at 20°C, gave the same adduct. Under the same conditions, III did not add bromine, but gave IV. V and VI showed ultraviolet absorption spectra entirely different from those of troponoids, as is shown in Fig. 2. From the above results, it is evident that the bromination of I proceeds in the sequence of II and V at 20°C, and in that of III, IV, and VI at 100°C.

When II was heated at 100°C with hydrobromic acid in an acetic acid solution, its 7-bromo substituent migrated in part to the 5-position, giving III, and was in part eliminated, giving I. II reacted with hydrochloric acid in a similar way to give 7-chloro-6-hydroxy-2,3-benzotropone (VII) and I. However, III remained unreacted when heated with hydrobromic or hydrochloric acid. IV as well as VI reacted with hydrobromic acid to give III, and with hydrochloric acid to give 5-bromo-7-chloro-6-hydroxy-2,3-benzotropone (VIII). To make sure of the positions of the substituents, VII and VIII were oxidized with alkaline hydrogen peroxide to give *o*-carboxycinnamic acid and phthalic acid respectively, and VIII was treated with one molar equivalent of hydrogen in the presence of a palladium-charcoal catalyst to give III and VII. Both VII and VIII were dehalogenated to I with the calculated amount of hydrogen in the presence of the catalyst. The formation of free bromine was verified during the reaction of II, IV, and VI with hydrobromic acid. These debromination reactions, therefore, may be illustrated as in the scheme. The bromo migration may consist of two reactions: the debromination of II with hydrobromic acid to I, with the liberation of bromine, and the subsequent bromination of I to give III. It has been described above that the bromination of I at 100°C takes place at the 5-position to give III. In a similar manner, 4-bromo-6-hydroxy-2,3-benzotropone (IX), reported on in the preceding paper,[1] was brominated to 4,7-dibromo-6-hydroxy-2,3-benzotropone (X), while the latter was debrominated to the former when heated with hydrobromic acid.

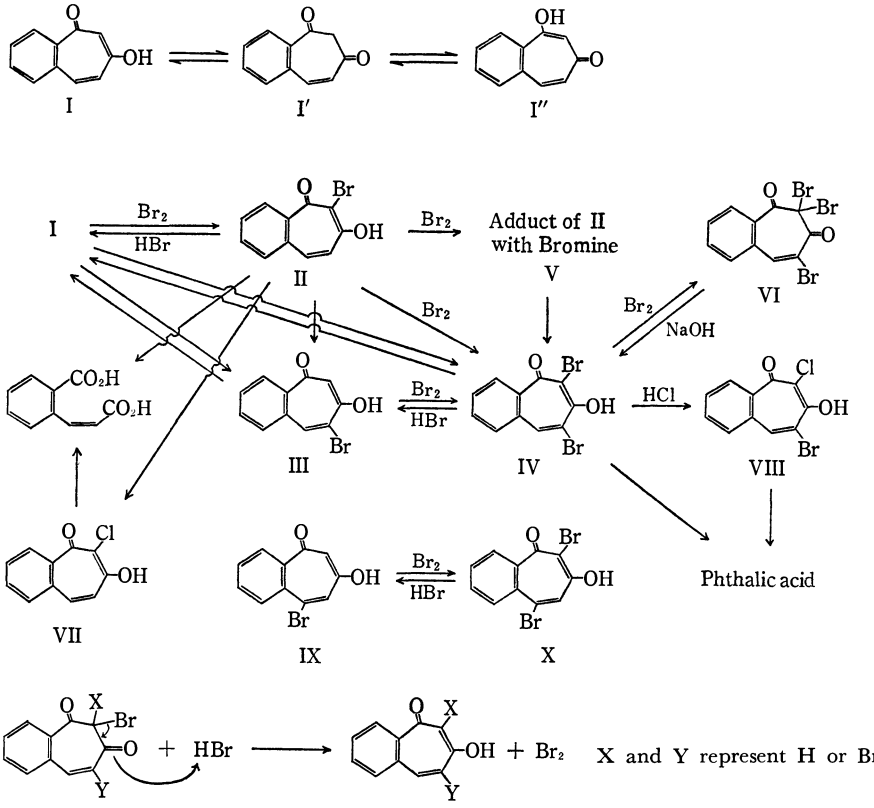
7) T. Nozoe, Y. Kitahara and S. Masamune, *Proc. Japan Acad.*, **27**, 649 (1951); T. Sato, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **80**, 1340 (1959).



From the above results it has become evident that, although I and its bromo derivatives exhibit ultraviolet and infrared spectra characteristic of troponoids, they sometimes behave like unsaturated β-diketones represented by the (I') formula; for example, the bromination of I, III, and IX takes place at the 7-position (or the 2-position as a β-diketone) to give II, IV, and X respectively, IV is further brominated to VI, and II adds bromine to give V. Furthermore, it has proved that the 7-bromo substituents of brominated 6-hydroxy-2,3-benzotropones is especially reactive; for example, upon heating with hydrobromic acid, the 7-bromo substituents of II, IV, and X were eliminated to give I, III, and IX respectively, while simultaneously the substituent of II migrated in part to give III. No such type of reaction has ever been described in connection with the bromo derivatives of isomeric 3,4-benzotropolone, 4,5-benzotropolone, and 4-hydroxy-2,3-benzotropone. It is of peculiar interest to compare the enhanced reactivity of the 7-bromo substituent described above with the reported[8] inertness of 7-chloro-2,3-benzotropone.

Experimental

7-Bromo-6-hydroxy-2,3-benzotropone (II). To a solution of 300 mg (1.74 mmol) of I in 30 m*l* of acetic acid, there was dropped, at 15°C, a solution of 280 mg (1.75 mmol) of bromine in 1 m*l* of acetic acid. After the mixture had stood for an hour at room temperature (17°C), the acetic acid was removed below 25°C under reduced pressure and the crystalline residue was fractionally recrystallized from ethanol to give 215 mg (55%) of II (pale yellow granular crystals melting at 173—173.5°C (dec.); also, 30 mg of unreacted I were recovered. The same bromination in the presence of 215 mg of anhydrous sodium acetate gave 421 mg (96%) of II. Ultraviolet spectrum (methanol): mμ (log ε), 269 (4.40), 365 (3.93), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3026, 1645, 1569, 1511 cm^{-1}.

Found: C, 52.92; H, 2.87%. Calcd for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%.

The NMR spectrum in deuterated dimethyl sulfoxide (d_6-DMSO): 8.47—7.85 ppm (4H, multiplet, aromatic hydrogens), 7.55 and 6.98 ppm (2H, AB-type doublets, J=12.8 cps, two hydrogens at the 4 and 5 positions).

5-Bromo-6-hydroxy-2,3-benzotropone (III). Bromine (110 mg, 0.69 mmol), diluted with 1 m*l* of acetic acid, was dropped into a warm solution of 100 mg (0.58 mmol) of I in 5 m*l* of acetic acid, and the resulting solution was heated at 100°C for 3 hr. When the mixture stood overnight at room temperature, a crystalline product separated out; this product was collected by filtration. The filtrate was concentrated to give a further crop of the product. The combined products (90 mg, 62%) were recrystallized from ethanol to give pale yellow needles of III melting at 234°C (dec.),

8) W. E. Parham, D. A. Bolon and E. E. Schweizer, *J. Am. Chem. Soc.*, **83**, 603 (1961).

ultraviolet spectrum (methanol): 275 mμ, (log ε 4.64), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3050, 2970, 2730, 2580, 1615, 1584, 1552, 1512 cm^{-1}.

Found: C, 52.38; H, 2.88%. Calcd for $C_{11}H_7O_2Br$: C, 52.61; H, 2.81%.

Adduct of II with Bromine (V). *a) From I.* To a solution of 300 mg (1.74 mmol) of I in 45 m*l* of acetic acid, there was added, drop by drop at 20°C, a solution of 560 mg (3.5 mmol) of bromine in 5 m*l* of acetic acid. After it has stood at this same temperature for 2.5 hr, the reaction mixture was concentrated below 25°C under diminished pressure; the product which separated was collected and recrystallized from benzene or dilute ethanol to give 460 mg (64%) of V in the form of colorless, granular crystals with a double melting point of 135—136°C and 179—180°C (dec.).

b) From II. A solution of 100 mg (0.63 mmol) of bromine in 1 m*l* of acetic acid was added to a solution of 150 mg (0.60 mmol) of II in 14 m*l* of acetic acid, and the resulting solution was worked up as above to give 105 mg (43%) of III.

The above two samples showed the same ultraviolet and infrared spectra. Ultraviolet spectrum (methanol): 330—336 mμ (log ε 3.82), infrared spectrum (KBr): 3340, 1635, 1617, 1595, 1552, 1540, 1525 cm^{-1}.

Found: C, 32.50; H, 1.77%. Calcd for $C_{11}H_7O_2Br_3$: C, 32.15; H, 1.72%.

5,7-Dibromo-6-hydroxy-2,3-benzotropone (IV). *a) From I.* A solution of 100 mg (0.58 mmol) of I and 200 mg (1.25 mmol) of bromine in 6 m*l* of acetic acid was heated at 100°C for 3 hr and then worked up in the same way as has been described for the bromination of I to III; this gave 180 mg (94%) of pale yellow needles of IV melting at 181—182°C (dec.).

b) From II. A similar work-up of a solution of 150 mg (0.60 mmol) of II and 100 mg (0.63 mmol) of bromine in 14 m*l* of acetic acid gave 170 mg (86%) of IV.

c) From III. III (1 g, 3.98 mmol) and 770 mg (4.82 mmol) of bromine, dissolved in 100 m*l* of acetic acid, were heated at 100°C for 3 hr to give 1.2 g (91%) of IV. The same reaction, but at 20°C, gave an 80% yield of IV.

d) From V. A solution of 100 mg of V in 3.5 m*l* of acetic acid was heated at 100°C for 2.5 hr. A crystalline product which separated on cooling was filtered, and the filtrate was concentrated to give an additional crop of the product. The recrystallization of the combined products from ethanol afforded 68 mg (84%) of IV. When dissolved in 1 N sodium hydroxide and allowed to stand for 1.5 hr at room temperature, V decomposed to produce IV in a fair yield.

e) From VI. A solution of 100 mg of VI in 3 m*l* of methanol containing 0.15 m*l* of 2 N sodium hydroxide was allowed to stand for 3 hr, and then the precipitate which had separated on acidification was collected and recrystallized. Yield, 30 mg (37%).

The identities of the samples obtained above have been confirmed by mixed-melting-point determinations and by infrared-spectrum comparisons. Ultraviolet spectrum (methanol): mμ (log ε), 285 (4.71), 355 (3.82), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3330, 1593, 1568, 1513 cm^{-1}.

Found: C, 40.30; H, 1.81%. Calcd for $C_{11}H_6O_2Br_2$: C, 40.03; H, 1.83%.

Acetate of IV, colorless granular crystals (recrystallized from methanol), mp 172—173°C.

Found: C, 41.90; H, 2.27%. Calcd for $C_{13}H_8O_3Br_2$: C, 41.97; H, 2.17%.

Methyl ether of IV, colorless needles (recrystallized from methanol), mp 160—161°C.

Found: C, 42.22; H, 2.21%. Calcd for $C_{12}H_8O_2Br_2$: C, 41.89; H, 2.34%.

2,2,7-Tribromo-4,5-benzocyclohepta-4,6-diene-1,3-dione (VI). *a) From IV.* A mixture of 100 mg (0.30 mmol) of IV and 2 g (12.5 mmol) of bromine was refluxed for 4 hr, the excess bromine was distilled, and then the residue was recrystallized from ethanol to afford 90 mg (73%) of yellow needles of VI melting at 132—133°C.

b) From I and III. A similar treatment of 100 mg (0.58 mmol) of I with 2 g (12.5 mmol) of bromine gave 50 mg (21%) of VI and 20 mg (10%) of IV, while the treatment of 100 mg (0.40 mmol) of III with 2 g (12.5 mmol) of bromine gave 110 mg (68%) of VI. Ultraviolet spectrum (methanol): 288 mμ, (log ε 3.77), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 1710, 1692, 1591, 1569 cm^{-1}.

Found: C, 32.32; H, 1.64%. Calcd for $C_{11}H_5O_2Br_3$: C, 32.31; H, 1.23%.

Debromination of II, IV, and VI to I. The reaction was carried out in the same way as has already been described for the debromination of III to I. A solution of 300 mg (0.91 mmol) of IV in 100 m*l* of ethanol was shaken with hydrogen in the presence of 100 mg of 5% palladium chloride-charcoal and 100 mg of anhydrous sodium acetate. After 43.6 m*l* (1.84 mmol) of hydrogen had been taken up at 16°C, the catalyst was filtered, the filtrate was evaporated, and the residue was recrystallized from ethanol, giving 130 mg (83%) of I, mp and mixed mp 208.5°C (dec.). A similar treatment of II and VI with hydrogen gave I in 80% and 48% yields respectively.

Reaction of II with Hydrobromic or Hydrochloric Acid. a) II (200 mg), dissolved in 25 m*l* of acetic acid and 15 m*l* of 47% hydrobromic acid, was heated under reflux for 2.5 hr. The solution gave a positive patassium iodide - starch paper test, indicating the presence of free bromine. The solution was then concentrated, and the product was fractionally recrystallized from ethanol to give 58 mg (29%) of III and 5 mg (4%) of I.

b) The heating of 120 mg of II, dissolved in a mixture of 15 m*l* of acetic acid and 12 m*l* of 6 N hydrochloric acid for 2 hr, and the recrystallization of the product from dilute ethanol gave 70 mg (71%) of 7-chloro-6-hydroxy-2,3-benzotropone (VII) as pale yellow needles melting at 172—173°C (dec.), along with 10 mg (12%) of I. VII, ultraviolet spectrum (methanol): mμ (log ε), 245 (4.34), 283 (4.60), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3006, 1646, 1570, 1518, 1507 cm^{-1}.

Found: C, 63.77; H, 3.53%. Calcd for $C_{11}H_7O_2Cl$: C, 63.94; H, 3.41%.

Reaction of IV with Hydrochloric or Hydrobromic Acid. The reaction was carried out in the same way as above. The reaction of 200 mg of IV with 20 m*l* of 47% hydrobromic acid in 15 m*l* of acetic acid gave 130 mg (85%) of III, mp and mixed mp 243°C (dec.), while the reaction of 300 mg of IV with 15 m*l* of 6 N hydrochloric acid in 30 m*l* of acetic acid gave

5-bromo-7-chloro-6-hydroxy-2,3-benzotropone (VIII) as yellow needles (from ethanol), mp 213—214°C (dec.), yield 215 mg (83%). VIII, ultraviolet spectrum (methanol): mμ (log ε), 287 (4.73), 357 (3.93), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3306, 1590, 1566, 1514 cm^{-1}.

Found: C, 46.22; H, 2.25%. Calcd for $C_{11}H_6O_2ClBr$: C, 46.27; H, 2.12%.

During the former reaction a considerable amount of bromine was liberated; it was identified by a potassium iodide - starch paper test.

Acetate of VIII, colorless, granular crystals, mp 183—184°C.

Found: C, 48.03; H, 2.57%. Calcd for $C_{13}H_8O_3ClBr$: C, 47.66; H, 2.46%.

Reaction of VI with Hydrobromic or Hydrochloric Acid. A similar treatment of VI (400 mg) with 47% hydrobromic acid (30 m*l*) in acetic acid (50 m*l*) gave III (173 mg, 71%), while that of VI (400 mg) with 6 N hydrochloric acid (30 m*l*) in acetic acid (50 m*l*) gave VIII (100 mg, 36%).

Dehalogenation of VIII. The dehalogenation was carried out in the same manner as has been described for the debromination of II, IV, and VI. a) A solution of 300 mg of VIII in 100 m*l* of ethanol was treated with hydrogen in the presence of 150 mg of 5% palladium chloride - charcoal and 130 mg of anhydrous sodium acetate. The reaction was stopped when a molar equivalent of hydrogen had been taken up. The recrystallization of the product from ethanol gave 81 mg (31%) of III and 101 mg (47%) of VII. b) When stopped after the uptake of two molar equivalents of hydrogen, the same reaction, using 300 mg of VIII, 150 mg of 5% palladium chloride-charcoal, 260 mg of anhydrous sodium acetate, and 100 m*l* of ethanol, produced 121 mg (67%) of I. The products obtained in a) and b) were identified by a mixed-melting-point determination and by a comparison of the infrared spectra.

Oxidation of II, IV, VII and VIII. A 200-mg sample was dissolved in 20 m*l* of 0.5 N sodium hydroxide, and to this 5 m*l* of 35% hydrogen peroxide were added. After standing at 50°C for 5 hr, the solution was acidified by dilute hydrochloric acid to precipitate unreacted material (30—50% recovery), which was removed by filtration. The filtrate was extracted with ether, and the extract was evaporated to give the product. The oxidation of II and VII gave *o*-carboxycinnamic acid (mp and mixed mp 185—186°C) in 47 and 33% yields respectively, while that of IV and VIII gave phthalic acid, mp and mixed mp 200°C, in 40 and 35% yields respectively.

Bromination of 4-Bromo-6-hydroxy-2,3-benzotropone (IX) to 4,7-Dibromo-6-hydroxy-2,3-benzotropone (X) and Debromination of X to IX. These reactions were carried out exactly as has been described above for the bromination of III and for the reaction of IV with hydrobromic acid. The reaction of IX (400 mg) and bromine (300 mg) in acetic acid at 100°C for 1 hr gave X (410 mg, 78%) as pale yellow prisms (from dilute ethanol) melting at 156—157°C. X, ultraviolet spectrum (methanol): mμ (log ε), 265 (4.39), 349 (3.79), infrared spectrum (KBr) in the region above 1500 cm^{-1}: 3186, 1616, 1599, 1581, 1555, 1543, 1528 cm^{-1}.

Found: C, 39.99; H, 2.05%. Calcd for $C_{11}H_6O_2Br_2$: C, 40.03; H, 1.83%.

The reaction of X (150 mg) and 47% hydrobromic acid (20 m*l*) in acetic acid (15 m*l*) at 100°C for 2 hr produced IX (60 mg, 53%).

Part of the expenses of this work has been defrayed by a Scientific Research Grant from the Ministry of Education.

1,3-Dipolar Cycloaddition Reaction of Thiophenecarbonitrile *N*-Oxides with Various Dipolarophiles

Yoshio IWAKURA, Keikichi UNO, Shinsaku SHIRAISHI and Tatsuhiko HONGU

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received February 29, 1968)

Thiophene-2-carbonitrile *N*-oxide (I) and 5-chlorothiophene-2-carbonitrile *N*-oxide (II) were synthesized by the chlorination of corresponding aldoxime with nitrosyl chloride. These compounds gave Δ^2-isoxazolines and isoxazoles through 1,3-dipolar cycloaddition reaction with compounds having double or triple bond as dipolarophiles. In the cycloaddition reaction, II was less reactive than I. This would be explained by stability of II owing to electron-withdrawing ability of chlorine atom at 5-position in the thiophene ring. Furoxans, the dimers of the nitrile *N*-oxide, were formed from these 1,3-dipoles in the absence of dipolarophile.

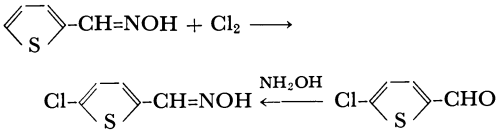
Many kinds of aromatic and aliphatic carbonitrile *N*-oxides and their reactions have been known.[1-7] We have also reported the 1,3-dipolar cycloaddition reaction as an elementary reaction of polymer formation.[8] However, neither synthesis of thiophenecarbonitrile *N*-oxides nor 1,3-dipolar cycloaddition reaction with them have ever been reported up to date. In the present study, synthesis of thiophene- and 5-chlorothiophene-2-carbonitrile *N*-oxides and their reactions with dipolarophile have been studied. Although thiophene-2-carbonitrile *N*-oxide and 5-chlorothiophene-2-carbonitrile *N*-oxide themselves could not be isolated, thiophene- and 5-chlorothiophene-2-carbohydroxamoyl chlorides reacted with dipolarophiles in the presence of triethylamine to give the products which would be expected from the corresponding carbonitrile *N*-oxides and dipolarophiles. The details will be described below.

Results and Discussion

I. Synthesis of Thiophene- and 5-Chlorothiophene-2-carbohydroxamoyl Chlorides. For a synthesis of hydroxamoyl chloride, the reaction of aldoxime with chlorine has generally been utilized.[5-8]

$$\mathrm{R\text{-}CH{=}NOH + Cl_2 \rightarrow R\text{-}\overset{\displaystyle Cl}{\overset{|}{C}}{=}NOH + HCl}$$

When thiophenecarboxaldoxime was subjected to such a chlorination procedure, the product obtained was not hydroxamoyl chloride but 5-chlorothiophene-2-carboxaldoxime resulted through chlorination of thiophene nuclei. The product was identical with the one prepared from 5-chlorothiophene-2-carboxaldehyde and hydroxylamine.



Accordingly, this reaction is inadequate to the preparation of thiophenecarbohydroxamoyl chloride.

The reaction of aldoxime with nitrosyl chloride has been reported by Rheinbolt[9] as an another method of preparing hydroxamoyl chloride.

When the cooled ether solution of nitrosyl chloride was added to the cooled ether solution of thiophene-2-carboxaldoxime, precipitates were formed immediately and then disappeared slowly with evolution of gas on standing the reaction mixture at a low temperature. After the precipitates were dissolved completely and the evolution of gas stopped, hydroxamoyl chloride was obtained from the reaction mixture. If the precipitate was kept in chloroform-benzene at room temperature for a long period, thiophene-2-carbonamide was obtained. On contact with air, the precipitate decomposed slowly to give thiophene-2-carboxaldehyde and thiophene-2-carbonitrile. The results of the reaction of thiophenecarboxaldoxime with nitrosyl chloride are summarized in Table 1.

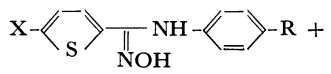
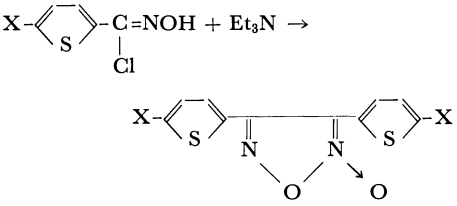
X=H (III) R=H, CH_3
X=Cl (IV) R=H



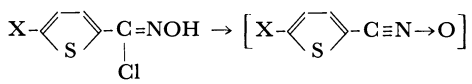
the presence of chlorine on 5-position in thiophene ring gave profound effect on the reaction of thiophenecarbohydroxamoyl chloride with amines. Thiophene-2-carbohydroxamoyl chloride reacted explosively with amines in the absence of solvent, but 5-chlorothiophene-2-carbohydroxamoyl chloride did not react unless it was heated. The influence of chlorine on 5-position to the reactivity was also observed in an aldoxime. When 5-chlorothiophene-2-carboxaldoxime was heated in an aqueous alkaline solution, it rearranged readily to 5-chlorothiophene-2-carbonamide, but thiophene-2-carboxaldoxime gave only alkali salt, and could be was recovered by treating the salt with acid.

Thiophenecarbohydroxamoyl chlorides gave furoxan in a quantitative yield in the presence of triethylamine.

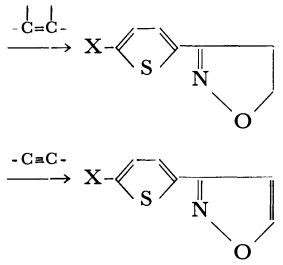


The furoxan derived from 5-chlorothiophenecarbohydroxamoyl chloride was hardly soluble in usual organic solvents and was decomposed slowly above 100°C, whereas the furoxan derived from thiophenecarbohydroxamoyl chloride was more stable. Results are summarized in Table 2.

II-2. 1,3-Cycloaddition Reaction. When hydroxamoyl chloride was treated with triethylamine in the presence of alkenes or alkynes, it reacted with them preferentially. For example, 3-(2-thienyl)-4,6-dioxo-3a,4,5,6a-tetrahydro-6*H*-pyrrolo-[3,4-d]-isoxazole was obtained from thiophene-2-carbohydroxamoyl chloride and *N*-phenylmaleimide. It would be reasonable to consider that thiophenecarbohydroxamoyl chloride reacts with double bond or triple bond through nitrile *N*-oxide as an intermediate.



X=H (III) X=H (I)
X=Cl (IV) X=Cl (II)



Results of 1,3-cycloaddition reaction are shown in Tables 3 and 4.

Allyl alcohol was less reactive upon hydroxamoyl chloride than maleimide. Such a result would be interpreted by following consideration accepted generally. 1,3-Dipolar cycloaddition reaction was enhanced by electron-withdrawing group in dipolarophile.[1] Further, a difference in the reactivity was observed between thiophene and 5-chlorothiophene derivative. Furoxan was obtained as a by-product in every reaction of 5-chlorothiophene derivative. Therefore, the reactivity of 5-chlorothiophenecarbohydroxamoyl chloride seems to be reduced by chlorine atom at 5-position. This might be explained by resonance effect of chlorine substituent.

Experimental

5-Chlorothiophene-2-carboxaldehyde. 5-Chlorothiophene-2-carboxaldehyde was prepared by Vilsmeier reaction[10] from 2-chlorothiophene, bp 105—107°C/19 mmHg (lit.[11] 100—105°C/18 mmHg).

Thiophene-2-carboxaldoximes. The oxime was prepared by treating 1 mol of thiophenecarboxaldehyde with 1.1 mol of hydroxylamine hydrochloride and 1.1 mol of sodium hydroxide in aqueous ethanol solution. Thiophene-2-carboxaldoxime was recrystallized from benzene, mp 136°C (lit.[12] 135—136°C). 5-Chlorothiophene-2-carboxaldoxime; mp 140°C (from EtOH) (lit.[11] 140°C).

Thiophenecarbohydroxamoyl chlorides. A solution of 19.7 g (0.155 mol) of the thiophene-2-carboxaldoxime in 250 m*l* of anhydrous ether was cooled below −10°C. Into the stirred solution was added a solution of 35 g (0.54 mol) of nitrosyl chloride in 180 m*l* of anhydrous ether in 30 min under dry nitrogen atmosphere. After the reaction mixture was allowed to stand at a temperature below −10°C for 5 hr, another 200 m*l* of anhydrous ether was added. Stirring and introducing nitrogen gas were continued until the evolution of hydrogen chloride stopped. It took about

evolution of hydrogen chloride stopped. It took about 25 hr.

After filtration of oxime hydrochloride, the solvent was removed under reduced pressure without heating, and light brown solid and small amount of oil were obtained. The solid was recrystallized from ligroin to give colorless crystals of thiophene-2-carbohydroxamoyl chloride (III), 11 g (44%), mp 102°C.

Found: C, 37.54; H, 2.81; N, 8.49%. Calcd for C_5H_4ClNOS: C, 37.17; H, 2.50; N, 8.67%.

The oily product was identified as thiophene-2-carboxaldehyde by IR.

In a similar way 5-chlorothiophene-2-carbohydroxamoyl chloride (IV) was prepared, mp 127—128°C (ligroin).

Found: C, 30.48; H, 1.75; N, 7.12%. Calcd for $C_5H_3Cl_2NOS$: C, 30.64; H, 1.54; N, 7.15%.

5-Chlorothiophene-2-carboxaldehyde was also detected by IR.

5-Chlorothiophene-2-carbonamide. In 20 m*l* of 0.1 N aqueous sodium hydroxide solution was dissolved 0.1 g of 5-chlorothiophene-2-carboxaldoxime, refluxed for 30 min and was allowed to stand overnight. The reaction mixture was evaporated under reduced pressure to give a solid mass. Extraction and recrystallization of this solid with benzene gave white needles, 5-chlorothiophene-2-carbonamide, mp 178°C (lit.[13] 179°C, 181°C). IR(KBr): -NH(3400, 3200 cm^{-1}), amide I (1685 cm^{-1}) and amide II (1600 cm^{-1}).

Reaction of III and IV with Aniline and *p*-Toluidine. To a solution of 0.5 g of III in 20 m*l* of anhydrous THF, 0.56 g of aniline (0.006 mol) was added dropwise, and white needles formed within a few minutes. The reaction mixture was refluxed for 2 hr and allowed to stand overnight. The needles deposited were filtered and the filtrate was evaporated *in vacuo* to give a solid mass, which was recrystallized from benzene - *n*-hexane to yield crystals, mp 90—93°C. The reaction of III with *p*-toluidine and of IV with aniline were conducted similarly.

Reaction of III and IV with Triethylamine. To a mixture of 20 m*l* of anhydrous THF and 0.5 g (0.003 mol) of III was added 0.4 g (0.004 mol; 30 mol% excess) of triethylamine at room temperature with stirring. The reaction mixture was allowed to stand for 2 days. The precipitate was filtered off and washed with anhydrous THF. Combined THF solution was evaporated *in vacuo* to afford white mass. Recrystallization from THF - benzene gave white powder of 2,2'-dithienylfuroxan, mp 112—114°C (dec.). This furoxan was soluble in THF, but hardly soluble in benzene, toluene, carbon tetrachloride, chloroform, methanol, ethanol, and water. The reaction of IV with triethylamine was conducted by the similar procedure as described above.

Reaction of III and IV with Various Dipolarophiles (1,3-Dipolar Cycloaddition Reaction). All of the reaction were conducted in anhydrous THF using triethylamine as a hydrogen chloride acceptor. In each reaction, 30 mol% excess amount of a dipolarophile was used. A typical example of the reaction is as follows. To a mixture of 10 m*l* of anhydrous THF, 0.5 g (0.003 mol) of III and 0.7 g (0.004 mol) of *N*-phenylmaleimide was added dropwise 0.5 g (0.0031 mol) of triethylamine at −5°C with stirring. Triethylamine hydrochloride formed immediately. The reaction mixture was allowed to stand overnight at room temperature. The triethylamine hydrochloride was filtered and washed with a large amount of anhydrous THF. The solid product was obtained by removing the solvent from the filtrate. Recrystallization three times from benzene gave 0.8 g (87%) of colorless needles, mp 170—171°C.

Studies on Heteroaromaticity. XXI.[1] 1,3-Dipolar Cycloaddition of *N*-Phenyl-*C*-(6-uracilyl)nitrone

Tadashi SASAKI and Moriyasu ANDO

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 1, 1968)

N-Phenyl-*C*-(6-uracilyl)nitrone (II) was prepared in 80% yield from orotaldehyde (I) and phenylhydroxylamine. II underwent 1,3-dipolar cycloaddition reactions with several ethylenic and acetylenic compounds to afford the corresponding isoxazolidines (IIIa—f) and isoxazolines (IVg—i). Similar reactions of II with phenyl isocyanate, carbon disulfide and with enamine were carried out successfully. The structural elucidation of these products was done on the basis of their NMR spectra.

The 1,3-dipolar cycloaddition reactions of nitrones with olefins are known to supply a general synthetic method of isoxazolidines.[2] Many papers have been published on this line, but little has been documented on the nitrones of nitrogen heteroaromatic systems except on ring nitrogen *N*-oxide.[3] A recent publication of the most convenient preparative method for orotaldehyde (I) among hitherto reported ones[4] opened a new synthetic route for preparing new chemical species involving an uracil moiety. This paper is concerned with the 1,3-dipolar cycloaddition of *N*-phenyl-*C*-(6-uracilyl)nitrone (II), a nitrone readily prepared from orotaldehyde (I).

Results and Discussion

Orotaldehyde (I) was treated with phenylhydroxylamine in ethanol according to the general procedure for preparing nitrones[5] to give a nitrone II in 80% yield; II was stable in the air but reactive enough to undergo the 1,3-dipolar cycloaddition reactions with several ethylenic and acetylenic compounds to afford the corresponding isoxazolidines (IIIa—f) and isoxazolines (IVg—i) respectively, as shown in Tables 1 and 2.

As is obvious from Table 1, the 1,3-dipolar cycloaddition of II to α,β-unsaturated carbonyl compounds such as b, c and f, aryl-conjugated alkenes such as d and e, and non-conjugated alkene such as a proceeded similarly with high yields, but it was necessary for a to be heated for a longer time than when b was used. In each case, the reaction time was seemingly parallel to the reactivity of the used dipolarophile. In fact, the reaction with maleic anhydride, which is regarded as one of the strongest dipolarophiles,[6] resulted in the formation of intractable tars even on cooling, and the reaction with *trans*-stilbene, which is a weak dipolarophile, resulted in recovering the starting materials even on heating the reaction mixture for 1 day. With acetylenic compounds, the reactions were carried out in dioxane instead of dimethylformamide (DMF) for avoiding the reaction of DMF with such acetylenic compounds.[7] As illustrated in Table 2, the yields were generally lower than those with ethylenic compounds, presumably because of their lower reactivity as dipolarophiles and higher tendency to the thermal polymerization. In fact, the thermal polymerization was clearly observed in the reactions of II with dimethyl acetylenedicarboxylate, propargyl bromide, ethyl phenylpropiolate and chlorocyanoacetylene,[8] all resulted in the thermal polymerization of used alkynes and in recovering II, except those with propargyl alcohol (g), cyanoacetylene (h)[9] and phenylacetylene (i), which afforded the corresponding isoxazolines (IVg—i) as indicated in Table 2.

Conversion of II to III is clearly observed in the

comparison of their ultraviolet and infrared spectra; in the ultraviolet spectra as indicated in Fig. 1 and Table 1, which IIIa—e show the similar patterns of absorptions except IIIf, all indicating hypsochromic shifts compared with that of II. This suggests interruption of the conjugation between the pyrimidine ring and a substituent at the 6-position in II by the conversion. In the infrared spectra, disappearance of a $\nu_{N\to O}$ absorption[10] after the conversion also supports the occurrence of the 1,3-dipolar cycloaddition. In the ultraviolet spectral comparison of III and IV, slightly bathochromic shifts of IV indicate the increase in unsaturation of IV, but other general patterns resemble each other as shown in Tables 1 and 2.

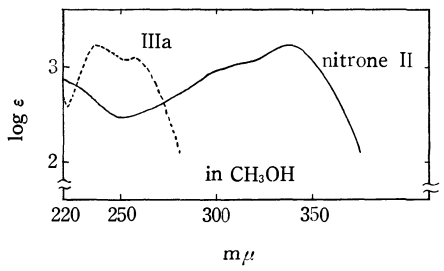

Fig. 1. UV absorption spectra of II and IIIa.

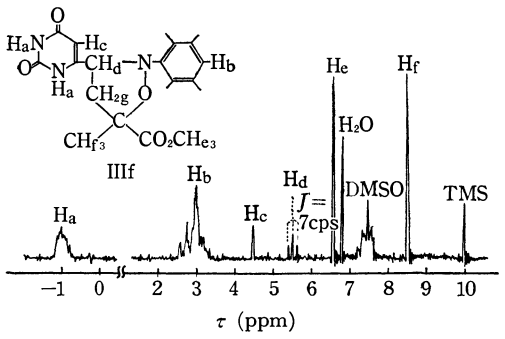

Fig. 2. NMR spectrum of IIIf (DMSO-d_6).

For III, there are two possible structures, III and III', depending on two different directions of addition. In the NMR spectrum in DMSO-d_6, a signal due to H_d was observed at 5.37τ as a triplet, (J=7.0 cps), as shown in Fig. 2, and consequently IIIf was concluded to be a correct structure.*1 Similarly, appearance of a H_d signal at 5.25 τ as a quartet supports IIId structure. The fact that no reaction had occurred between II and ethyl cinnamate even on heating for a longer time may be explained by the steric hindrance of a

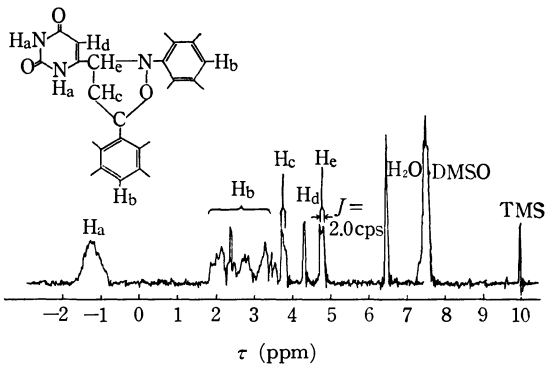

Fig. 3. NMR spectrum of IVi.

bulky phenyl group attached to the vinyl carbon of the cinnamate.

The structural elucidation of IV was carried out on the basis of their NMR spectra. For example, IVi was confirmed to be a 5-substituted isoxazoline from its NMR spectrum as shown in Fig. 3.

For further investigation of the reactivity of this nitrone, II was treated with heterocumulenes like phenyl isocyanate, carbon disulfide, phenyl isothiocyanate, benzoyl isocyanate and benzoyl isothiocyanate, and with enamines. Among these dipolarophiles, the first two and the last one were successfully subjected to the 1,3-dipolar cycloaddition; in the reaction with phenyl isocyanate, a catalytic amount of triethylamine was added to the reaction mixture, since without triethylamine, no reaction had occurred. In the reaction with carbon disulfide, the yield of the product was below 10%. A recent publication of the formation of isoxazolidines by the reactions of enamines with diphenylnitrone[11] prompted us to report our results. The reaction of II with 1-morpholino-1-cyclohexene was carried out in a sealed tube under nitrogen, because the same reaction in the air resulted in the formation of intractable tars.

For the reaction product of II with the enamine, there are two possible structures, VII and VII', assumable, depending on two directions of addition. Appearance of a signal due to H_a at 4.56 τ in the NMR spectrum in DMSO-d_6 indicates that VII is preferable to VII'. The coupling constant J_{ab} was 3.8 cps, which is different from the value reported by Nomura and his coworkers.[11]

Experimental

All the melting points are uncorrected. Infrared spectra were determined on a Nippon Bunko IR-S type spectrometer and electronic spectra were obtained with a Nippon Bunko optical rotary dispersion recorder,

10) L. G. Bellamy, "The Infrared Spectra of Complex Molecules," 2nd Ed., John Wiley and Sons, Inc., New York, N. Y. (1958), pp. 115, 305.

*1 For IIIf, a signal due to H_d should be a triplet or a quartet by the presence of vicinal protons. H_g, on the contrary, for IIIf', it should be a singlet because of the absence of a vicinal proton.

12) W. Schulze and Wullitzer, *J. prakt. Chem.*, **33**, 50 (1966).

Model ORD/UV-5. NMR spectra were determined on a Varian A-60 spectrometer, with tetramethylsilane as an internal standard and the peak positions are expressed by τ-values.

***N*-Phenyl-*C*-(6-uracilyl)nitrone (II).** Orotaldehyde (I)[4] (1 g) was suspended in 30 m*l* of ethanol and 0.8 g of phenylhydroxylamine was added to this suspension. The reaction mixture was refluxed for 2 hr until the suspension of I went into solution. After cooling, the precipitates were filtered and recrystallized from ethanol to give II as yellow needles, mp 280—285°C. IR (KBr) cm^{-1}: 1060 ($\nu_{N\to O}$). NMR (DMSO-d_6)τ: −1.20 (2H, broad, NH), 1.49 (1H, singlet, –CH–N–), 2.0—2.5 (5H, multiplet, phenyl protons), 3.35 (1H, singlet, 5-C–H).

Found: C, 57.39; H, 3.63; N, 17.98%. Calcd for $C_{11}H_9O_3N_3$: C, 57.14; H, 3.92; N, 18.18%.

All attempts for preparing II from 6-methyluracil by the reported procedures[12] were unsuccessful.

2-Phenyl-3-(6-uracily)-5-hydroxymethylisoxazolidine (IIIa). To a suspension of 0.2 g of II in 20 m*l* of dry DMF was added 0.5 m*l* of allyl alcohol with stirring. The mixture was heated at 85°C for 12 hr with occasional stirring until the suspension went into solution. After cooling, excess allyl alcohol and DMF were removed under reduced pressure to afford 0.23 g of IIIa as colorless crystals. The mps, yields, elemental analyses and ultraviolet spectra of the reaction products with several ethylenic compounds are summarized in Table 1.

2-Phenyl-3-(6-uracilyl)-5-hydroxymethylisoxazoline (IVg). To a suspension of 0.2 g of II in 20 m*l* of dry dioxane was added 0.5 m*l* of propargyl alcohol. The mixture was fused in a glass tube and heated at 100°C for 1 hr until a clear solution was obtained. After removing an excess amount of propargyl alcohol and dioxane under reduced pressure, the oily residue was dissolved in methanol and a crystalline material precipitated upon addition of ether was recrystallized from tetrahydrofuran to yield IVg as colorless crystals. The yields, mps, elemental analyses and ultraviolet spectral data of the reaction products with several acetylenic compounds are summarized in Table 2.

2-Phenyl-3-(6-uracilyl)-4-phenyl-1,2,4-oxadiazole-5-one (V). Three drops of triethylamine was added to a suspension of 0.3 g of II in 15 m*l* of dioxane and 0.12 m*l* of phenyl isocyanate. The mixture was fused in a glass tube and heated at 85°C for 2 days until a clear solution was obtained. After removing the distillable parts from the reaction mixture under reduced pressure on a water bath, the residue was extracted with 1 m*l* of ethyl acetate - acetone (1 : 1). Solvents were removed from the extract and the residue was recrystallized from benzene-ethyl acetate to afford 0.28 g (62%) of a 1 : 1 adduct (V) as pale yellow crystals, mp 254°C. IR (KBr): 1825 cm^{-1} (ν_{CO}). UV λ_{max}^{MeOH} mμ (log ε): 366 (3.00), 256 (3.84), 222 (4.18).

Found: C, 61.31; H, 3.79; N, 16.00%. Calcd for $C_{18}H_{14}O_4N_4$: C, 61.71; H, 4.03; N, 15.99%.

4-(6-Uracilyl)-5-phenyl-1,3,5-oxathiazole-2-thione (VI). To a suspension of 0.3 g of II in a mixture of 2 m*l* of carbon disulfide and 15 m*l* of dry dioxane was added 3 drops of triethylamine. The mixture was fused in a glass tube filled up with nitrogen and heated at 85°C for 3 days. Work-up as above afforded a 1 : 1 adduct (VI) in 10% yield. Mp 218°C after recrystallization from ethyl acetate. IR (KBr): 1300 cm^{-1} (ν_{CS}). UV λ_{max}^{MeOH} mμ (log ε): 308 (3.75, shoulder), 253 (3.88, shoulder), 253 (3.88, shoulder).

Found: C, 46.16; H, 3.42; N, 12.99%. Calcd for $C_{12}H_9O_3N_3S_2$: C, 46.89; H, 2.95; N, 13.67%.

Reaction of II with 1-Morpholino-1-cyclohexene. A mixture of 0.3 g of II and 0.5 g of 1-morpholino-1-cyclohexene was added to 15 m*l* of dioxane. The resulting mixture was fused in a glass tube filled up with nitrogen and heated at 85°C for 3 days. After removing the distillable parts from the reaction mixture under reduced pressure on a water bath, the residue was dissolved in 5 m*l* of benzene. Upon addition of ether, 0.36 g (72%) of a 1 : 1 adduct (VII) precipitated as brown crystals, mp 203°C. UV λ_{max}^{MeOH} mμ (log ε): 265 (4.09, shoulder), 245 (4.26). NMR (DMSO-d_6)τ: 2.49—3.24 (multiplet, phenyl protons), 4.17 (singlet, 5-C–H), 4.56 (doublet, J=3.8 cps, 3-C–H), 7.0—7.7 (multiplet, morpholine ring protons), 8.0—9.0 (multiplet, cyclohexane ring protons).

Found: C, 63.70; H, 6.90; N, 13.82%. Calcd for $C_{21}H_{26}O_4N_4$: C, 63.30; H, 6.58; N, 14.06%.

The authors are much indebted to Mr. Akiho Ishihara for elemental analyses and to be Dainippon Pharmaceutical Co. for the NMR measurement.

Studies of Heteroaromaticity. XXIV. 1,3-Dipolar Cycloaddition of *C*-(5-Nitro-2-furyl)-*N*-phenylnitrone[1]

Tadashi SASAKI, Toshiyuki YOSHIOKA and Iwao IZURE

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

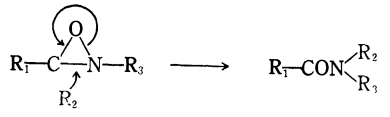
(Received April 15, 1968)

C-(5-Nitro-2-furyl)-*N*-phenylnitrone (I) was prepared from 5-nitro-2-furfural and phenylhydroxylamine in an 80% yield. The 1,3-dipolar cycloaddition reactions of I with various olefins were carried out, and the corresponding 5-substituted isoxazolidine derivatives were obtained. The structual elucidation of these products was made on the basis of the nmr spectral data. Several observations support the theory that these reactions proceed *via* a concerted one-step process.

In a previous paper[2] we reported the 1,3-dipolar cycloaddition reactions of a nitrone derived from orotaldehyde. This paper will deal with its preparation and with its 1,3-dipolar cycloaddition reactions with several olefins of a nitrone containing a nitrofuran ring as a heaterocyclic side chain. Furthermore, the structural elucidation of the products will be discussed, mainly on the basis of the nmr spectral data.

Results and Discussion

C-(5-Nitro-2-furyl)-*N*-phenylnitrone (I) was prepared from 5-nitro-2-furfural and phenylhydroxylamine in an 80% yield by the usual procedure.[3] All attempts to synthesize I by the thermal isomerization of the corresponding oxaziridine derivative (III), which might be produced as an intermediate in the direct peracetic acid-oxidation of *N*-(5-nitro-2-furfurylidene)aniline (II), were unsuccessful, though this is regarded as a general procedure for preparing nitrones,[4] and from the tar-like products, 5-nitro-2-furanilide (IV) was isolated as a crystalline product in a 20% yield. Various alkyloxaziranes are known to be converted to amides under pyrolytic conditions through such a concerted rearrangement mechanism as:[5]



This amide (IV) is, therefore, assumed to be produced *via* the oxazirane (III) by a mechanism similar to that are described above; in fact, IV could not be isolated from the reaction of I with acetic anhydride when heated as low as 80°C.

The nitrone structure of I was confirmed by the elemental analysis and by the presence in the infrared spectrum of a 1096 cm^{-1} absorption due to $\nu_{N\rightarrow O}$. A bathochromic shift of the ultraviolet absorption maximum of I compared with that of II (*cf.* Fig. 1) indicates some contribution to a conjugation of an azomethine linkage with a nitrofuran ring by the formation of N→O bonding.

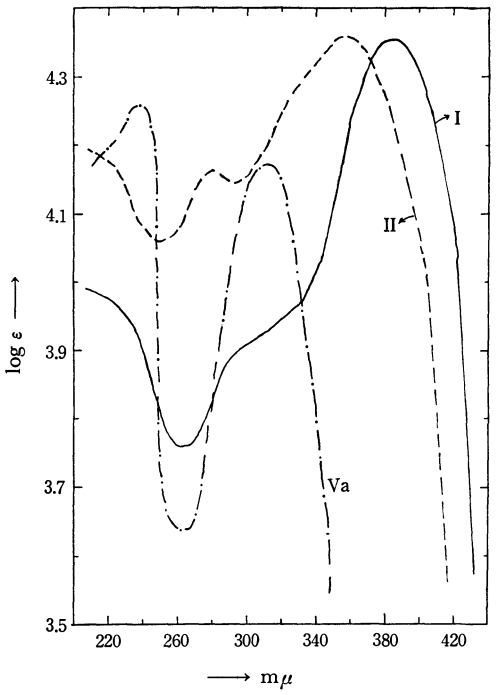


Fig. 1. UV comparison of I, II and Va (in EtOH).

I was sensitive to the light and gradually decomposed to a black tar; therefore, it must be stored in a dark and cool place.

The 1,3-dipolar cycloaddition of I was carried out both in ethanol and in toluene at each refluxing temperature by using several olefins. The results are summarized in Table 1.

As is obvious from this table, the yields of Va, for instance, were 41% after 5 hrs' refluxing in ethanol and 98% after 2 hrs' refluxing in toluene,

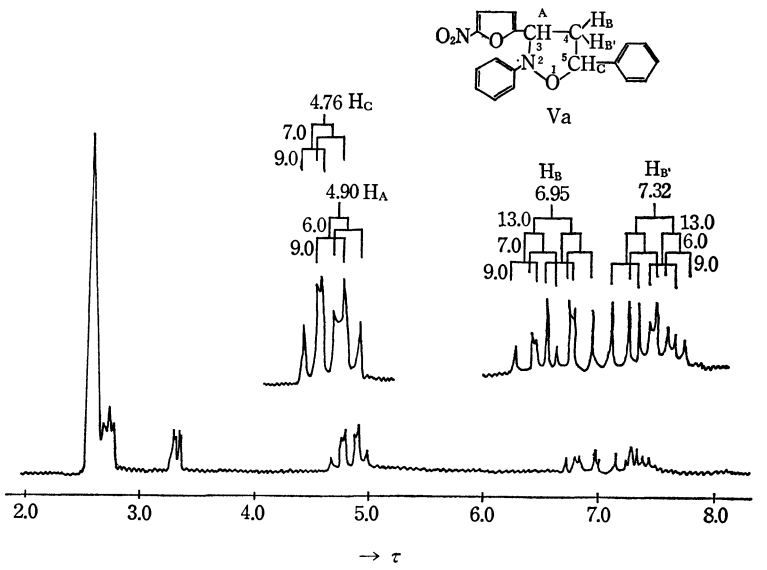

Fig. 2. NMR spectrum of Va (in $CDCl_3$ by τ-values).

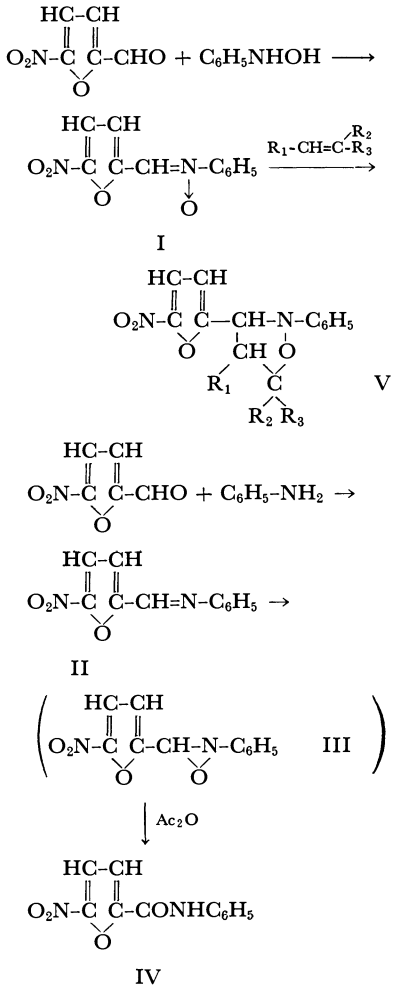
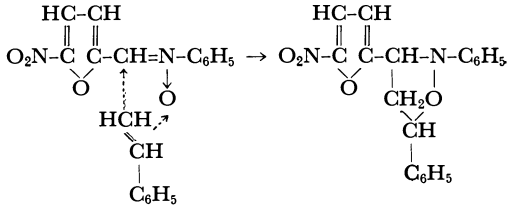
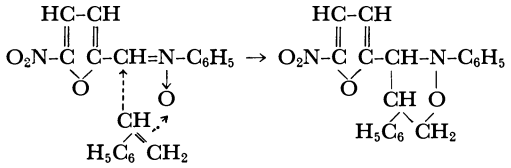
indicating these reactions proceeded by the general principle of the larger temperature dependence rather than the polarity dependence of the solvent used.[6] This trend can be observed in other cases in Table 1. It can be concluded that the yields of the 1,3-dipolar cycloaddition products are much more influenced by the reaction temperature and by the steric factor of the dipolarophilic olefins than by the polarity of the solvent and by the electronic character of the olefins. All these features seem to support the theory that the 1,3-dipolar cycloaddition of I proceeds *via* the concerted one-step mechanism suggested by Huisgen.[8]



The occurrence of the cycloaddition of I at the N→O linkage is established by the disappearance of an N→O absorption in the infrared spectrum of Va; it is further supported by a hypsochromic shift of Va compared with that of I in their ultraviolet spectra, as is indicated in Fig. 1. For Va, there are two possible structures, Va and Va', depending on which of two different directions of addition holds. Figure 2 shows the nmr spectrum of Va, in which the signals at 2.5—3.5 τ (12 H) are readily assignable to benzene and nitrofuran ring protons, while those at 4.90 τ (1 H, quartet) and at 4.76 τ (1 H, quartet) should be assigned to two methine protons at the C-3 and C-5 respectively of an isoxazolidine ring.[7] These results support a 5-substituted structure for Va rather than the corresponding 4-substituted structure Va'.



Va: 5-substituted structure



Va': 4-substituted structure

The nmr spectra of other products, which are summarized in Table 2, were similarly considered; all the products seem to have 5-substituted structures.

In the reaction with dicyclopentadiene, two products, Vh and Vh', with the same elemental analyses and only slightly different ultraviolet spectra, but with different nmr spectra could be isolated. (*Cf.* Tables 1 and 2). Alder and Stein[9] have distinguished *endo-* and *exo*-dicyclopentadiene by their chemical conversion to their adducts with phenyl azide and Bruson and others[10] have repotred that *endo*-dicyclopentadiene reacts under acidic conditions with proton donors to give products possessing the *exo*-configuration. At the same time, the possibility of the *endo-* and *exo*-attack of I on dicyclopentadiene should be considered, since a similar type of attack has been observed in the 1,3-dipolar cycloaddition of diphenylnitrilimine to

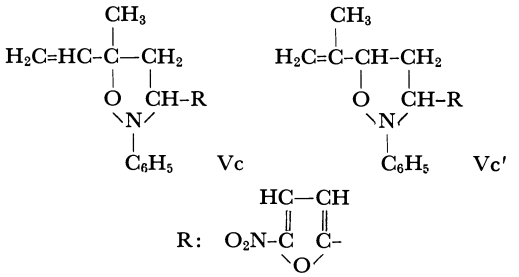
norbornene.[11] As is shown in Table 2, the shift of a C-3-H signal for Vh' to a higher magnetic field than that for Vh, which is located in the normal region of 4.95 τ, may be explained by postulating for Vh' the structure of an adduct produced by the *endo*-attack of I on *endo*-dicyclopentadiene,[12] in which the anisotropy effect of a neighboring ethylenic linkage of the cyclopropene ring caused a shift of C-3-H to a higher magnetic field.

The conversion of the 1,3-dipolar cycloaddition reaction of I with isoprene was as high as 95% after their purification by column chromatography; it was found on TLC[13] to be a mixture of two products, which were separated by fractional crystallization to Vc as a high-melting-point fraction and Vc' as a low one. The presence of a vinyl absorption in the infrared spectrum of Vc at 990 and 910 cm^{-1} [14] and that of a terminal methylene in Vc' at 890 cm^{-1} [14] suggest that their structures are as follows:



The validity of Vc structure was further confirmed by the nmr spectrum, as is illustrated in Table 2.

So far the 1,3-dipolar cycloaddition of nitrones has been reported mainly with olefins,[15] and only a few times with acetylenic compounds.[2] I was treated with phenylacetylene, propargyl bromide, and propargyl alcohol, but instead of the expected isoxazolines, an anil, II, and amide, IV, were isolated, as is shown in Table 3: the main product was a black polymer with a mp of over 300°C.

Similarly, the reactions of I with heterocumulenes such as carbon disulfide, dicyclohexylcarbodiimide, and phenyl isocyanate gave only II as an isolated crystalline product; the main product was a black polymer, as is indicated in Table 3. It is noteworthy that in the latter reactions, no amide (IV) formation could be observed. The similar treatment of I in the absence of any dipolarophile resulted only in the formation of black tars. The

12) The commerical dicyclopentadiene is known to possess the *endo*-configuration mainly. Therefore, two possible structures can most reasonably assigned to the products depending on the *endo*- and *exo*-attack of I on *endo*-dicyclopentadiene. About their absolute configuration, a more detailed investigation is necessary.

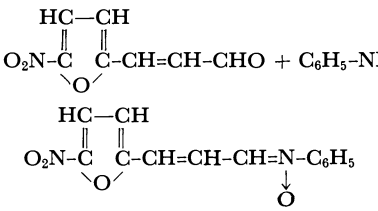
mechanism of the formation of II and IV from I in the above reactions is uncertain at present. However, I was treated with deoxygenator like triphenylphosphine to afford II, as expected.

Similarly, *C*-2-(5-nitro-2-furyl)vinyl-*N*-phenylnitrone (VI) was prepared from β-(5-nitro-2-furyl)acrolein[19] and phenylhydroxylamine; VI was very stable and did not react at all with triphenylphosphine under refluxing in toluene; furthermore, all attempts at the intermolecular cyclization of VI were unsuccessful.



VI

Experimental

All the melting points were determined on a Yanagimoto micromelting-point apparatus and are uncorrected. The microanalyses were carried out on a Yanagimoto C. H. N. Corder, Model MT-1. The infrared spectra were recorded on a JASCO Model IR-S infrared spectrometer, while the nmr spectra were obtained with a Hitachi high resolution NMR spectrometer, Model H-6031, at 60 Mc, and the chemical shifts are reported in τ-values relative to tetramethylsilane as the internal standard. The ultraviolet spectra were measured with a JASCO Model ORD/UV-5 optical rotatry dispersion recorder.

***C*-(5-Nitro-2-furyl)-*N*-phenylnitrone (I).** A solution of 2.8 g (20 mmol) of 5-nitro-2-furfural and 2.2 g (20 mmol) of phenylhydroxylamine in 50 m*l* of ethanol was refluxed at 80°C for 5 min. After cooling, the precipitated yellow crystals were collected and recrystallized from ethanol to give 3.8 g (80%) of I as yellow crystals, mp 184°C (decomp). IR (KBr) cm^{-1}: 1603 ($\nu_{C=N}$), 1096 ($\nu_{N\to O}$).

Found: C, 57.19; H, 3.49; N, 12.18%. Calcd for $C_{11}H_8O_4N_2$: C, 56.90; H, 3.47; N, 12.07%.

Attempts at Synthesizing I. *N*-(5-Nitro-2-furfurylidene)aniline,[16] (II) (0.5 g (2.3 mmol)) was dissolved in 15 m*l* of dichloromethane, and to this solution there was added a solution of peracetic acid, prepared from 0.5 m*l* of 60% hydrogen peroxide and 2.5 g of acetic acid. After the addition of a catalytic amount of 98% sulfuric acid, the reaction mixture was kept standing at room temperature for 12 hr. The mixture was then poured into 250 m*l* of water and extracted with chloroform. The chloroform layer was washed with 5% aqueous ammonia, and then with 10% sulfuric acid, and dried over magnesium sulfate. The removal of the chloroform at room temperature under reduced pressure afforded an oil, whichw as purified by chromatography (silica-gel, chloroform). Yellow needles with a mp of 177°C were separateed from the second fraction, which was characterized as 5-nitro-2-furanilide (II) by a comparison of its IR spectrum with a specimen prepared by a known method.[17]

1,3-Dipolar Cycloaddition of I with Styrene. A mixture of 0.5 g (2 mmol) of I, 1 m*l* of styrene, and 30 m*l* of toluene was refluxed for 2 hr after the addition of five drops of triethylamine as a catalyst. After the distillable parts had been removed under reduced pressure, the residue was dissolved in chloroform and purified on a silica-gel column. Va was obtained as yellow crystals from the first fraction. Similarly, Vb—j were obtained; their yields, UV spectra, and microanalyses are summarized in Table 1.

Reaction of I with Triphenylphosphine. A solution of 0.4 g (1.2 mmol) of I and 0.45 g (1.2 mmol) of triphenylphosphine in 16 m*l* of dry benzene was heated at 90°C in a sealed tube for 2 hr. After the solvent had then been removed under reduced pressure, the residue was purified on a silica-gel column, using chloroform as the eluent. From the first fraction there was obtained a small amount of an oil, which was discarded. 0.15 g (40%) of yellow crystals (mp 124—128°C) was obtained from the second fraction; this substance was identified as II by a comparison of its IR spectrum with that of a specimen[16] and by a mixed-melting-point determination. From the third fraction, 40 mg (10%) of I were recovered, while from the fourth fraction, 0.25 g (60%) of triphenylphosphine oxide, mp 156°C,[18] was obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2969—2974 (1968)

The Reaction Products of the Hydroformylation of Acrolein Acetals and Acetates*1

Itsutoshi MAEDA and Ryonosuke YOSHIDA

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received March 4, 1968)

The hydroformylation reactions of acrolein acetals and acetates were carried out in order to discuss the side reactions and any subsequent reactions. Acrolein cyclic acetals reacted with carbon monoxide and hydrogen in the presence of a dicobalt octacarbonyl catalyst to give *n*- and iso-aldehydes in a 2 : 1 ratio; they gave no further reaction products. Acrolein diethylacetal underwent hydroformylation using a rhodium catalyst to give *n*- and iso-aldehydes in a 1 : 2 ratio. In the presence of a cobalt catalyst, however, various products were obtained. As a result of the acidity of cobalt hydrocarbonyl and a high reaction temperature, *n*-aldehyde, first formed in benzene, underwent change to 2,5-diethoxytetrahydrofuran and 1,1,4-triethoxybutane. In ethanol, *n*- and iso-aldehydes gave the corresponding acetals. In the hydroformylation of acrolein acetate, only *n*-aldehyde was obtained. Iso-aldehyde seemed to be converted into 2-methyl-3-acetoxyacrolein by deacetylation. In ethanol, besides *n*-acetal, iso-acetal and propionaldehyde acetate, 2,5-diethoxytetrahydrofuran and 2-methyl-3-ethoxyacrolein were recognized. The former seemed to be formed from *n*-aldehyde by ring closure and ethanolysis. The latter seemed to be formed by the ethanolysis of 2-methyl-3-acetoxyacrolein. In ethyl orthoformate, no side reaction was observed and the yield of the main product, 1,1-diacetoxy-4,4-diethoxybutane, amounted to 80%.

Customarily hydroformylation is carried out using a cobalt carbonyl as the catalyst. The cobalt carbonyl shows an acidity under the reaction conditions.

In this case the aldehydes formed first undergo subsequent reactions to give various reaction products. It has been reported[1] that acrolein diethylacetal absorbed 50—70% of the amount of hydrogen and carbon monoxide required for complete hydroformylation, but no aldehyde could be isolated from the reaction mixture. The present investigation of the hydroformylation of acrolein acetals and acrolein acetates was undertaken in order to confirm the by-products and propose a scheme for the subsequent reaction.

Results and Discussion

The Hydroformylation of Acrolein Cyclic Acetals. The treatment of acrolein cyclic acetals with hydrogen and carbon monoxide at 110°C and 200 atm in the presence of a cobalt carbonyl catalyst gave the usual hydroformylation products, *n*- and iso-aldehydes, in a 2 : 1 ratio. The results are summarized in Table 1. The hydroformylation products of acrolein cyclic acetals did not

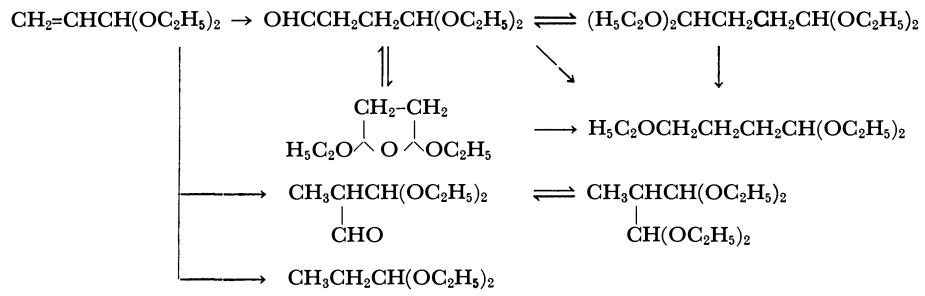
undergo any further, subsequent reaction because of their stability.

The Hydroformylation of Acrolein Diethylacetal. With a rhodium carbonyl catalyst, the hydroformylation of acrolein diethylacetal resulted in a mixture of aldehydes, *n*- and iso-aldehydes, in a 1 : 2 ratio. On the other hand, with a cobalt carbonyl catalyst various products were obtained.



Scheme I

Gas-chromatographic analysis showed 11 peaks. Eight of them were identified by mixed chromatography with authentic samples and by preparative chromatography. The results of gas chromatographs for various products obtained from acrolein diethylacetal by reactions at 130°C and 150°C with a cobalt carbonyl catalyst are given in Table 2. The yields of the products were calculated on the basis of the area of each peak in a gas chromatograph after a usual calibration using authentic samples.

In order to evolve a scheme consistent with all these observations, the present authors considered the possibility that 1,1-diethoxy-3-formylpropane and 1,1-diethoxy-2-formylpropane underwent subsequent reactions. To test this hypothesis, 1,1-diethoxy-3-formylpropane, 1,1,4,4-tetraethoxybutane, and 2,4-diethoxy-tetrahydrofuran were synthesized and then treated under the hydroformylation reaction conditions respectively. They were thus converted into several compounds, which were listed in Table 3.

These compounds were almost identical with the hydroformylation products of acrolein diethylacetal.

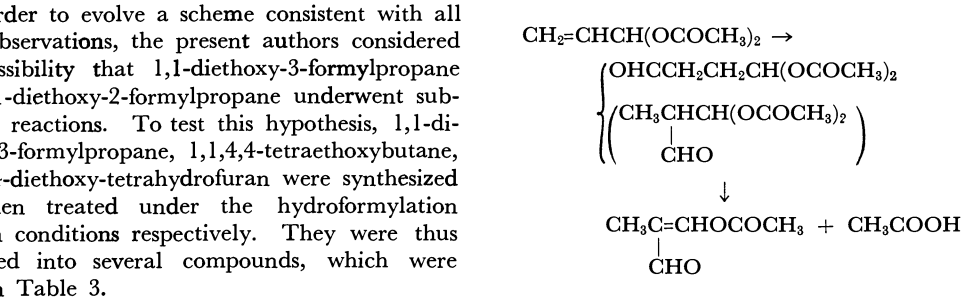
On the basis of these data, it seemed reasonable to assume that the hydroformylation products of acrolein diethylacetal were formed according to the scheme shown below (scheme I).

The Hydroformylation of Acrolein Acetates. It has previously been reported by Adkins[1] that acrolein acetate (1,1-diacetoxypropene) was converted to *n*-aldehyde (1,1-diacetoxy-3-formylpropane) alone by hydroformylation in benzene using a cobalt carbonyl catalyst. The present authors carried out the hydroformylation of acrolein acetate with a rhodium carbonyl catalyst in benzene. As the products, 2-methyl-3-acetoxyacrolein and acetic acid were obtained; iso-aldehyde with a branched chain structure could not be obtained. The NMR-spectrum analysis of the mixture of 2-methyl-3-acetoxyacrolein and acetic acid is shown in Table 4.

TABLE 4. NMR SPECTRUM OF THE MIXTURE OF 2-METHYL-3-ACETOXYACROLEIN AND ACETIC ACID

(TMS)	No. of H	Assignment
1.76	3.0	Methyl
2.04	1.5	Methyl of acetic acid
2.32	3.0	Methyl of ester
8.06	1.0	CH
8.54	0.5	H of acetic acid
9.50	1.0	H of aldehyde

The evidence thus obtained suggests that the isoaldehyde formed by the hydroformylation decomposed to 2-methyl-3-acetoxyacrolein and acetic acid.



In alcohol the yield of the *n*-aldehyde acetal did not exceed 50%.

The hydroformylations of various kinds of acrolein acetates were carried out in an alcohol solution with cobalt catalysts. The results are listed in Table 5. According to the reaction of acrolein acetates, the yields of the major products, 1,1-diacyloxy-4,4-dialkoxybutane, were 30—50%; the side reaction products were identified by gas-chromatographic and NMR spectra analyses. The results are given in Table 6.

On the basis of these data, it seemed reasonable to assume that the hydroformylation products of acrolein acetate formed first were *n*-aldehyde (1,1-diacetoxy-3-formylpropane, about 60%), iso-aldehyde (1,1-diacetoxy-2-formylpropane, about 5—10%), and propionaldehyde acetate (1,1-diacetoxypropane, about 5%). Then these aldehydes were converted to their acetals, and a part of the *n*-aldehyde was converted to 2,5-diethoxytetrahydrofuran (10%)[2] by the acidity of the cobalt catalyst, while the iso-aldehyde was decomposed to 2-methyl-3-acetoxyacrolein and acetic acid.

1,1-Diacetoxy-2-methyl-3,3-diethoxy-propane	0.8
2-Methyl-3-ethoxyacrolein	5—10
1,1-Diacetoxypropane	4.9

The overall reaction scheme may be illustrated as follows (Scheme II).

To prevent these side reactions and to promote the formation of 1,1-diacetoxy-4,4-diethoxybutane (I), the hydroformylation was carried out in the presence of ethyl orthoformate instead of ethanol. In these cases the formation of 1,1-diacetoxy-3-formylpropane, 2,5-diethoxytetrahydrofuran, 2-methyl-3-ethoxyacrolein and acetic acid were not seen, while 1,1-diacetoxy-2-methyl-2,3-diethoxy-propane (II) and 1,1-diacetoxypropane were found as by-products. The presence of ethyl orthoformate

was useful for the formation of I and II and reduced the formation of acetic acid. When ethyl orthoformate was used in excess to acrolein acetate, as shown in Table 7, the yield of main product, 1,1-diacetoxy-4,4-diethoxybutane, amounted to 80%.

Experimental*2

Materials. These acrolein cyclic acetals (2-vinyl-4, 4,6-trimethyl-1,3-dioxane, 2-vinyl-4-methyl-1,3-dioxane and 2-vinyl-1,3-dioxane) were prepared from acrolein and glycols according to the directions of Fischer and Smith.[3] The acrolein diethylacetal was prepared according to the procedures described in a previous paper.[4] These acrolein acetates (1,1-diacetoxypropene, 1,1-dipropoxypropene, and 1,1-dibutyroxypropene) were prepared from acrolein and acid anhydrides.[5] All of the above materials were shown by gas chromatographic analysis to have no impurity affecting the results.

Reaction Procedures. *(1) The Hydroformylation of Acrolein Cyclic Acetals.* Acrolein acetal (0.1 mol) and 9 m*l* of a dicobalt octacarbonyl solution in benzene (containing 17.8 g/*l* as cobalt) were put into an autoclave with a 100 m*l* capacity and equipped with a magnetic stirrer. Benzene was added until it filled half of the vessel. Hydrogen and carbon monoxide mixture (1 : 1) were then introduced to 200 kg/cm^2, using a compressor, after the air in the alutoclave had been replaced with their gases. The autoclave was kept at 110°C by electrical heating for about one hour, and then after the gauge pressure ceased to decline, it was chilled. The gas mixture was purged, and the carbonyl catalyst was decomposed by triphenylphosphine. The filtrate of the reaction mixture was distilled under reduced pressure. The analyses of the ratio of *n*- and iso-aldehydes were carried out on the reaction mixture by gas chromatography and NMR spectra.

(2) The Hydroformylation of Acrolein Diethylacetal. (a) With a rhodium carbonyl catalyst in benzene. Acrolein diethylacetal (39.0 g, 0.3 mol), rhodium oxide (129.6 mg, 0.5 g/*l* as Rh) and benzene (104 m*l*) were charged in a 300 m*l*, stainless-steel pressure reactor. The mixture was then treated in a manner similar to that used in the experiment described for (1) except that the reaction was carried out at 110°C for 30 min. After the solvent had been removed under reduced pressure, the mixture (29.9 g), consisting of 1,1-diethoxy-2-formylpropane (I) and 1,1-diethoxy-3-formylpropane (II), was distilled at 61—64°C/5 mmHg. Found: C, 60.00; H, 10.17%. Calcd for $C_8H_{16}O_3$: C, 59.98; H, 10.07%. The ratio of I and II was determined to be 1.82 : 1 by using the integral of the NMR spectra ($CHCl_3$); CHO, 0.40 τ. I and II were separated by preparative gas chromatography. I; n_D^{25} 1.4178, II; n_D^{25} 1.4167.

(b) With a cobalt carbonyl catalyst in benzene or ethanol. The method used here was virtually identical with that described for (a), but acrolein diethylacetal (13.0 g, 0.1 mol) and dicobalt octacarbonyl (4 g/*l* as cobalt) in benzene (or ethanol) were charged in a 100 m*l* autoclave. The benzene (or ethanol) was added until it filled half of the vessel. The reaction was carried out at 130°C (or 150°C) for one hour (or two hours).

(3) The Hydroformylation of Acrolein Acetates. (a) With a rhodium carbonyl catalyst in benzene or ethanol. Rhodium oxide (260 mg, 1 g/*l* as Rh), 1,1-diacetoxypropene (47.4 g, 0.3 mol), and 105.6 m*l* of benzene (or ethanol) were put into a 300 m*l*, stainless-steel autoclave. The reaction was similar to that described for (1), but the reaction temperature was kept at 100°C. The reaction mixture was filtered and diluted with benzene (or ethanol) to 200 m*l*, then the aldehydes were distilled

Table 8. The hydroformylation products of 1,1-diacetoxypropene with cobalt carbonyl in ethanol

Fraction of the distillate	Weight	Substance	Weight calcd by gas chro. anal.

and analysis of the reaction products will be described in analytical procedures.

(b) With a cobalt carbonyl catalyst in ehtanol. A dicobalt octacarbonyl solution in ethanol (2—4 g/*l* as cobalt) and 1,1-diacyloxypropene (0.1 mol) were put into a 100 m*l* autoclave. The reaction was carried out according to the procedure described for (1), except that the reactor was kept at 110°C for 15 min after the gauge pressure ceased to decline. The contents of the autoclave were then filtered and diluted with ethanol to 100 m*l*. The distillation and analysis of aldehyde acetals and other reaction products will be described below.

(c) With a cobalt carbonyl catalyst in ethyl orthoformate. The method used here was identical with that described for (b), but ethyl orthoformate was added (0.5, 1, 1.1, 1.2, 1.4 and 1.5 mol per mol of 1,1-diacetoxypropene).

Analytical Procedures. *(1) The Hydroformylation of Acrolein Acetals.* (a) Authentic-sample preparation. The 2,5-diethoxy-tetrahydrofuran was prepared by the bromination of furan and its reduction.[6] (Found: C, 60.05; H, 10.24%). By the Grignard reaction of acetylene and ethyl orthoformate,[7] 1,1,4,4-tetraethoxybutyne-2 was prepared; it was then reduced to 1,1,4,4-tetraethoxybutane.[8] (Found: C, 61.51; H, 11.00%). Propionaldehyde diethylacetal was prepared using the technique for acrolein acetal. 1,1-Diethoxy-2-formylpropane and 1,1-diethoxy-3-formylpropane were separated by preparative gas chromatography (the column packed with 10% Carbowax 20M coated on Diasolid M at 100°C) from their mixture prepared by the hydroformylation of acrolein diethylacetal with a rhodium carbonyl catalyst. From 1,1-diethoxy-2-formylpropane and ethyl orthoformate, 1,1,3,3-tetraethoxy-2-methylpropane was prepared. Found: C, 61.44; H, 11.19%. Calcd for $C_{12}H_{26}O_4$: C, 61.50; H, 11.18%. By preparative gas chromatography, 1,1,4-triethoxybutane was separated from the hydroformylation solution of acrolein diethylacetal with a cobalt carbonyl catalyst. The structure of 1,1,4-triethoxybutane was established by its IR and NMR spectra. Found: C, 63.08; H, 11.23%. Calcd for $C_{10}H_{22}O_3$: C, 63.01; H, 11.58%. n_D^{25} 1.4124.

(b) Gas chromatography was carried out with 5% carbowax 6000 on Diasolid M (4 mmϕ×3 m; column temperature, 95°C; flow rate of He, 80 m*l*/min; internal standard, acetophenone). The individual peaks were identified by a comparison of their retention times with those of authentic samples. The low-boiling substances, propionaldehyde diethylacetal and acrolein diethylacetal, were analyzed with 20% β,β'-oxydipropionitrile on chromosorb W (4 mmϕ×2 m; column temperature, 70°C; flow rate of He, 80 m*l*/min; internal standard, *n*-butanol).

(2) The Hydroformylation of Acrolein Acetates. The separation and identification of reaction products were performed by distillation and by gas chromatographic and NMR spectra analyses. The gas chromatography was carried out with 5% polyethylene glycol 4000 on chromosorb T (4 mmϕ×2 m; column temperature, 150°C; flow rate of He, 75 m*l*/min; internal standard, diethyl adipate).

(a) With a rhodium carbonyl catalyst in benzene. After the benzene had been removed, the reaction mixture was distilled under reduced pressure. By fractionating low-boiling fractions collected from several runs (bp 33—61°C/5 mmHg), the following compounds were isolated and identified. Gas chromatography showed two kinds of compounds; their NMR spectra showed that they were acetic acid and 2-methyl-3-acetoxyacrolein, is shown in Table 4. The next boiling fractions (bp 61—113°C/5 mmHg) were mixtures of acetic acid, 2-methyl-3-acetoxyacrolein and 1,1-diacetoxy-3-formylpropane. The only high-boiling fraction (bp 113—114°C/5 mmHg) was 1,1-diacetoxy-3-formylpropane. In gas chromatographic analysis, 1,1-diacetoxy-2-formylpropane was not found.

(b) With a rhodium carbonyl catalyst in ethanol. Five compounds were found in the distillate by gas-chromatographic analysis. In the fractions of the distillate, the following compounds were identified: Bp 54—117°C/7 mmHg, a mixture of acetic acid, 2-methyl-2-acetoxyacrolein, an unknown substance, 1,1-diacetoxy-2-formylpropane, and 1,1-diacetoxy-3- formylpropane; bp 118—124°C/7 mmHg, a mixture of 1,1-diacetoxy-2-formylpropane and 1,1-diacetoxy-3- formylpropane. Found: C, 50.67; H, 6.54%. Calcd for $C_8H_{12}O_5$: C, 51.06; H, 6.43%.

(c) With a cobalt carbonyl catalyst in ethanol. After the hydroformylation of 1,1-diacetoxypropene (0.4 mol), the reaction mixture was distilled. In the fractions of the distillate, the compounds as shown in Table 8 were identified and quantified by gas-chromatographic and NMR spectra analyses.

(d) With a cobalt carbonyl catalyst in ethyl orthoformate. After the hydroformylation of 1,1-diacetoxypropene (0.1 mol), the 1,1-diacetoxy-4,4-diethoxybutane and 1,1-diacetoxy-2-methyl-3,3-diethoxypropane were analyzed by gas chromatography. Gas chromatography was carried out with 5% carbowax 20 M on chromosorb T (4 mmϕ×2 m; column temperature, 165°C; flow rate of He, 75 m*l*/min; internal standard, dimethyl terephthalate).

The authors wish to thank Mr. Masahiko Takesada and Dr. Hachiro Wakamatsu for many helpful discussions and suggestions during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2975—2978 (1968)

A Synthesis of DL-Tryptophan from Acrolein*[1]

Itsutoshi MAEDA and Ryonosuke YOSHIDA

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received March 4, 1968)

DL-Tryptophan hydrantoin was obtained from phenylhydrazone of β-(hydanto-5-yl)-propionaldehyde acetal (5-(γ,γ-dialkoxypropyl)hydantoin) by Fischer's indole synthesis. β-(Hydanto-5-yl)propionaldehyde acetal was prepared by Bucherer's reaction from 1,1-diacetoxy-4,4-dialkoxybutane obtained by the hydroformylation of acrolein acetate. Attempts to crystallize β-(hydanto-5-yl)-propionaldehyde acetal from Bucherer's reaction solution were unsuccessful, but 5-alkoxy-1,3-dioxoperhydropyrro[1,2-*c*]imidazole was obtained by treating the solution with ion exchange resins in alcohol. It could be also converted to tryptophan hydantoin.

Tryptophan, an essential amino acid for human and animals, has been prepared by various synthetic routes since the first successful synthesis, by Ellinger, in 1907. The method using acrolein as the starting material was employed by Warner and Moe[1] and developed by Chibata and Yamada.[2] Namely, DL-tryptophan was obtained by the hydrolysis and decarboxylation of the indole derivative prepared from phenylhydrazone of γ-acetamido-γ,γ-dicarbethoxybutyraldehyde by Fischer's indole synthesis. The aldehyde was obtained by a Michael-type condensation between acrolein and ethyl acetamidomalonate. Of the hitherto reported methods, the synthetic route employed by Komachiya *et al.*[3] appears to be one of the most suitable routes for industrial synthesis. Tryptophan was obtained by the hydrolysis of β-(hydanto-5-ylmethyl)indole prepared from phenylhydrazone of β-(hydanto-5-yl)propionaldehyde by Fischer's indole synthesis. The aldehyde was formed by the catalytic hydrogenation of the 5-(β-cyanoethyl)-hydantoin obtained by Bucherer's reaction of β-cyanopropionaldehyde in aqueous acetic acid in the presence of a Raney nickel catalyst poisoned with lead. Considering these facts, it seemed possible to prepare DL-tryptophan from the 1,1-diacetoxy-4,4-dialkoxybutane obtained by the hydroformylation of acrolein acetate described in a previous paper.[4] The object of this paper is to describe this method.

The acetals of 4,4-diacyloxybutyraldehyde have two reactive groups. The diacetoxy group may be converted to the hydantoin group by Bucherer's reaction, while the acetal group may remain unchanged under these conditions, thus the acetals of 4,4-diacyloxybutyraldehyde can be converted to 5-(γ,γ-dialkoxypropyl)hydantoin. Therefore, the phenylhydrazone of this hydantoin derivative can be employed advantageously in the synthesis of DL-tryptophan.

Results and Discussion

In a previous paper,[4] it was reported that 1,1-diacetoxy-4,4-dialkoxybutane (I) was obtained by the hydroformylation of acrolein acetate. In the usual manner, 5-(γ,γ-dialkoxypropyl)hydantoin (II) was obtained from I by Bucherer's reaction. The reaction mixture in Bucherer's reaction was dried up, and attempts to crystallize II from the resultant syrup were unsuccessful. The alcohol solution of the syrup was then added to cation exchange resins and the mixture boiled for several hours. When the reaction solution was dried up, the residual oil crystallized spontaneously to colorless needles upon cooling. It has been shown by elementary analysis that this substance was not in agreement with II, but it was identified with the structure lost by one mole of alcohol from the formula of II. The infrared spectra of the substance showed that there was evidently a hydantoin ring, while the NMR spectra showed that one of the two NH functional groups of hydantoin ring has no hydrogen atom. Either the 1- or 3-position of hydantoin appeared to be substituted. Stucky[5] has shown that hydantoin in an aqueous or alcoholic alkaline solution underwent amido-imidol tautomerism involving the hydrogen of the 3-position; therefore, substitution in the 3-position was easily detected by the change in the ultraviolet absorption

spectra. The substance not substituted in the 3-position of hydantoin indicates the absorption at wavelengths from 2000 to 2300 Å, while the 3-substituted substance does not show the absorption. The UV spectrum of the substance obtained from II is shown in Fig. 1.

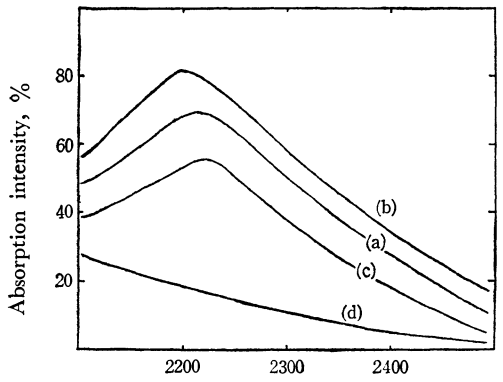

Fig. 1. The UV spectrum in 0.01 N aqueous sodium hydroxide solution.
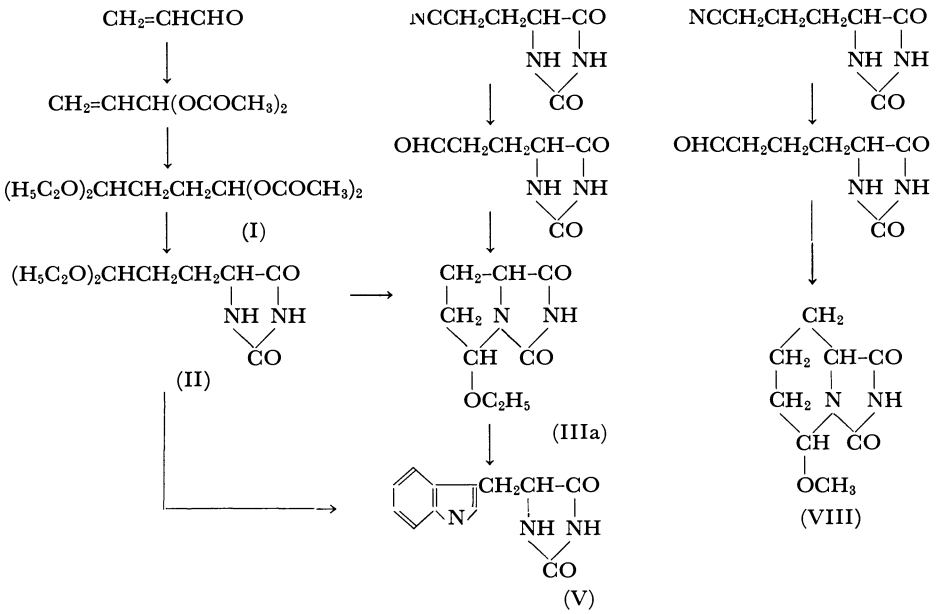
(a) III λ_{max} 2205 Å $\varepsilon_{max}=9060$
(b) Tryptophan hydantoin λ_{max} 2195 Å $\varepsilon_{max}=38650$
(c) 5-Methylhydantoin λ_{max} 2210 Å $\varepsilon_{max}=6375$
(d) 3-Cyanoethylhydantoin

It seemed likely that this substance was a hydantoin derivative which was substaituted not in the 3-position, but in the 1-position. In view of the above facts, the most reasonable structure of this substance was 5-alkoxy-1,3-dioxoperhydropyrro[1,2-*c*]imidazole (III). III could also be obtained by another route. Namely, 5-(β-cyanoethyl)-hydantoin was reduced to 5-(β-formylethyl)hydantoin according to the directions of Komachiya *et al.*[3]; this latter substance could be isolated as a crystalline semicarbazone derivative from the reaction mixture. When treated with ion exchange resins in alcohol as has been described above, this semicarbazone was converted to III. Similarly, the semicarbazone of 5-(γ-formylpropyl)-hydantoin obtained from 5-(γ-cyanopropyl) hydantoin was converted to 5-alkoxy-1,3-dioxoperhydropyrido[1,2-*c*]imidazole (VIII).

The phenylhydrazone of III was unstable to heat and light. It was converted to tryptophan hydantoin using the technique of Fischer's indole synthesis. This reaction could also be carried out without the isolation of the unstable phenylhydrazone. The procedure was simple, and satisfactory results were obtained. Instead of crystalline III, the syrup obtained from I by Bucherer's reaction could be employed for the Fischer's indole synthesis. Although the yield based on the starting material was low, the procedure has the advantage of simplicity. The results of these experiments are summarized in Scheme I.

Experimental*2

5-Alkoxy-1,3-dioxoperhydropyrro[1,2-*c*]imidazole (III) from β-(Hydanto-5-yl)propionaldehyde Semicarbazone (VI). *(1) 5-Ethoxy-1,3-dioxoperhydropyrro[1,2-c]imidazole (IIIa).* A mixture of 21.3 g



Scheme I

*2 All melting points are uncorrected.

(0.1 mol) of β-(hydanto-5-yl)propionaldehyde semicarbazone (VI)[8] and 250 ml of dried cation exchange (H^+) resins (Diaion SK #1) in 400 ml of ethanol was heated with stirring for 3 hr at from 50 to 60°C. The resins were then filtered off and washed with ethanol. The removal of the ethanol by evaporation from the filtrate yielded 13.4 g (72.5%) of crude crystals; mp 102—104°C. Recrystallization from ethanol gave white needles; mp 119—120°C.

Found: C, 52.20; H, 6.63; N, 15.18%. Calcd for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%. Mol wt (Rast), 185.9, Calcd 184.2. The 2,4-dinitrophenylhydrazone prepared by the usual procedure decomposed at 216.5—217.5°C.

Found: C, 42.53; H, 3.75; N, 24.01%. Calcd for $C_{12}H_{12}O_6N_6$: C, 42.86; H, 3.60; N, 24.99%.

(2) 5-Methoxy-1,3-dioxoperhydropyrro[1,2-c]imidazole (IIIb). The method was identical with that described for (1), except that the ethanol was replaced with 500 ml of methanol. The crude product obtained weighed 13.8 g (81%). It was recrystallized from methanol to afford white crystals; mp 118—119°C.

Found: C, 49.42; H, 6.26; N, 16.42%. Calcd for $C_7H_{10}O_3N_2$: C, 49.40; H, 5.92; N, 16.46%.

γ-(Hydanto-5-yl)butyraldehyde Semicarbazone (VII) from 5-(γ-Cyanopropyl)hydantoin. To a mixture of 40 ml of water and 10 ml of methanol was added 4.2 g (0.025 mol) of 5-(γ-cyanopropyl)hydantoin, which had been obtained by Bucherer's reaction of γ-cyanobutyraldehyde. After the hydantoin had dissolved upon slight warming, these were added to the solution at room temperature 7.45 ml of glacial acetic acid, 0.058 g of lead acetate, and 1.05 g of Raney nickel which had been treated with sodium hydroxide in the usual manner. The reaction was run at room temperature under a hydrogen atmosphere in a shaking vessel. The hydrogen uptake was almost complete in about two hours. After the removal of the catalyst, 2.8 g (0.025 mol) of semicarbazide hydrochloride was added to the reaction mixture and it was stirred for half a day. The semicarbazone which crystallized when the mixture stood in an ice box overnight was filtered, washed with water, dried, and weighed; 3.7 g (65.8%), mp 198.5—199.5°C.

Found: C, 42.23; H, 6.20; N, 29.96%. Calcd for $C_8H_{13}O_3N_5$: C, 42.29; H, 5.77; N, 30.82%.

5-Methoxy-1,3-dioxoperhydropyrido[1,2-c]-imidazole (VIII) from γ-(Hydanto-5-yl)butyraldehyde Semicarbazone (VII). A mixture of 2.8 g (0.012 mol) of VII and 200 ml of dried cation exchange (H^+) resins in 300 ml of methanol was heated at from 50°C to 60°C for 3 hr with stirring. The resins were then filtered off and washed with methanol. After the methanol had been removed under reduced pressure, 1.8 g (79.2%) of a crude, powder-like product were obtained. Recrystallization from methanol gave white needles (mp 156—158°C).

Found: C, 52.46; H, 6.74; N, 15.05%. Calcd for $C_8H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%. Mol wt (Rast), 183.4, Calcd 184.2. The NMR spectrum of this substance was measured in a $CDCl_3$ solution, with tetramethylsilane as the standard; these measurement showed that the ratio of the NH functional group to the CH functional group was 1 : 1. The UV spectrum indicated a maximum absorption at 2275 Å (ε_{max} = 6,840).

β-(Hydanto-5-yl)propionaldehydediethylacetal (II) from 1,1-diacetoxy-4,4-diethoxybutane (I). Into a mixture of 14.3 g (0.125 mol) of ammonium carbonate and 73.6 ml (0.11 mol as CN^- ion) of ammonium cyanide in an ammonia solution (1.5 mol per l as CN^- ion and 11 mol per l as NH_4^+ ion), 26.2 g (0.1 mol) of I were stirred at room temperature. The mixture was heated with stirring at from 50°C to 60°C for 3 hr, and then at from 60°C to 70°C for an additional hr. After the mixture had been dried up *in vacuo*, attempts to crystallize the resultant syrup were unsuccessful. The 2,4-dinitrophenylhydrazone was prepared by the usual procedure, which yielded red needles (74.5%). It decomposed at 217—218°C.

Found: C, 42.89; H, 3.87; N, 25.01%. Calcd for $C_{12}H_{12}O_6N_6$: C, 42.86; H, 3.60; N, 24.99%.

5-Ethoxy-1,3-dioxoperhydropyrro[1,2-c]imidazole (III) from II. By treating 0.05 mol of I by the method described above, II was obtained in a syrupy state. The syrup was added to 50 ml of cation exchange (H^+) resins in ethanol. The mixture was then heated at from 60°C to 70°C with stirring for 4 hr. After the resins had been removed and the ethanol evaporated, a white, crystalline substance was separated, dried, and weighed; 7.2 g (78.5% based on I, mp 116—117°C). Recrystallization from ethanol gave white needles; mp 119—120°C.

Found: C, 52.20; H, 6.66; N, 15.20%. Calcd for $C_6H_{12}O_3N_2$: C, 52.16; H, 6.57; N, 15.21%.

β-(Hydanto-5-yl)propionaldehyde Phenylhydrazone (IV). *(1) From 5-Ethoxy-1,3-dioxoperhydropyrro-[1,2-c]imidazole (IIIa).* A solution of 9.2 g (0.05 mol) of IIIa in 50 ml of water was refluxed for 1.5 hr. The solution was then cooled and added to a solution of 7.2 g (0.05 mol) of phenylhydrazine hydrochloride in 50 ml of water. The product which crystallized from the reaction mixture upon standing overnight in an ice box was filtered, washed, dried *in vacuo* at room temperature in a dark desiccator, and weighed; 10.5 g (82%).

Found: C, 58.16; H, 5.89; N, 22.23%. Calcd for $C_{12}H_{14}O_2N_4$: C, 58.52; H, 5.73; N, 22.75%.

(2) From II. The syrup of II was obtained by treating 0.025 mol of I by the method described above. Ethanol was added to the syrup, and it was evaporated again to remove the ammonia. A mixture of the syrup and diluted hydrochloric acid was refluxed for 1.5 hr. After cooling, the reaction mixture was poured into a solution of 3.6 g of phenylhydrazine hydrochloride in 40 ml of water; the crystals obtained on standing overnight in an ice box were filtered, washed, dried and weighed; 2.2 g (34.1% based on I). The infrared spectrum of the crystals was identical with that of the product described in the case of (1).

Tryptophan Hydantoin (V) from II. This method is a modification of the directions of Komachiya *et al.*[8] A syrup of II was afforded by treating 0.1 mol of I as above. To the syrup these were then added 2.5 ml of conc. hydrochloric acid, after which the mixture was diluted to 200 ml with water. A mixture of 1.25 ml of conc. hydrochloric acid and 13.9 g (0.096 mol) of phenylhydrazine hydrochloride was diluted to 200 ml with water. In a 1 l, four-necked, round-bottomed flask equipped with a reflux condenser, a sealed stirrer, a dropping funnel, and a thermometer, the solution of phenylhydrazine was placed. To the boiled solution in the flask, the solution of II was added, drop by drop,

through the dropping funnel. After the addition, the mixture was refluxed while being stirred for 30 min. The flask was chilled to 80°C and then cooled with water to 20°C. After being allowed to stand at 20°C for 30 min, the crystals were filtered, washed, and dried. The yield was 10.3 g (45% based on I); mp 215°C.

Found: C, 63.03; H, 5.16; N, 18.37%. Calcd for $C_{12}H_{11}O_2N_3$: C, 62.87; H, 4.84; N, 18.33%.

In this case, a deposit of polymer was observed on the bottom of the flask. When the volume of conc. hydrochloric acid added to the syrup of II was increased to 7.5 m*l*, the yield of V was 14.2 g (62.1%), mp 212—213°C.

Found: C, 62.91; H, 5.25; N, 18.45%.

Tryptophan Hydantoin (V) from III. The reaction of 13.6 g (0.08 mol) of III in 200 m*l* of 0.1 N hydrochloric acid with 14.5 g (0.1 mol) of phenylhydrazine hydrochloride in 200 m*l* of 0.1 N hydrochloric acid was carried out in a manner similar to that used in the experiment described above. The first crop of crystals of tryptophan hydantoin (melting at 212—213°C) weighed 15.8 g (86.2%).

Found: C, 62.48; H, 5.36; N, 18.7%.

The second crop (1.3 g, melting at 207—208°C) was obtained by allowing the mother liquor to stand at room temperature. The total yield of tryptophan hydantoin was 93.2% based on III.

Our thanks are due to Dr. Yoshioki Komachiya for helpful discussions and technical advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2978—2984 (1968)

The Electrophilic Substitution Reactions of 2-Aminotropone and Its *N*-Alkyl Derivatives[1]

Tetsuo Nozoe, Shoji Ryu[2] and Takashi Toda

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 15, 1968)

The electrophilic substitution reactions of 2-aminotropone (I), 2-methylaminotropone (II), and 2-dimethylaminotropone (III) were investigated. The structure of the products was proved by hydrolysis to lead to known tropolone derivatives. By the nitrosation of II, *N*-nitroso-2-methylaminotropone was obtained in a good yield; this compound is a new type of active troponoid compound. The substitution reactions of III gave tropolone derivatives, accompanied by the hydrolysis of the dimethylamino group. The mechanism of the hydrolysis is then discussed.

The relation of tropolone and 2-aminotropone (I) corresponds to the relation of phenol and aniline, and to investigate the chemical properties of I is both important and interesting. Althougth the reactivities of tropolones have been investigated in detail,[3] the chemical properties of I have been known for only a few examples of such cationoid substitution reactions as bromination and the azo-coupling reaction[4] and of reactions with active methylene compounds to synthesize 1-azaazulan-2-one and its derivatives.[5] No report has appeared about the chemical properties of 2-methylaminotropone (II)[4] and 2-dimethylaminotropone (III),[4] even though these compounds are an important family of I, corresponding to *N*-methylaniline and *N*-dimethylaniline. From this point of view, the electrophilic substitution reactions of 2-aminotropone and its *N*-alkyl derivatives, II and III, were undertaken. The authors wish to report here the results obtained.

Halogenations of 2-Aminotropone, 2-Methylaminotropone, 2-Dimethylaminotropone, and the Copper Complex of 2-Aminotropone. The bromination of I in acetic acid or chloroform was investigated in detail.[4] It was proved that substitution took place in the following order; at C-7 first, then at C-5, and finally at the C-3 position of I.[4] The halogenations of I, II, and III under a variety of conditions were then reinvestigated by comparison with the results previously obtained. The results of the reinvestigation

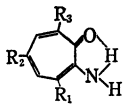
*** Pyridine perbromide.

are shown in Table 1, which shows that the halogenation of these compounds occurs at the C-7 position first, and then at the C-5 and C-3 positions. The reactivities of I and II are almost the same. On the other hand, III shows different properties and the hydrolysis of the dimethylamino group occurs during halogenation, giving tropolone derivatives.

The bromination of the copper complex (IV)[4] of I was also investigated by comparison with the properties of the copper complex of tropolone.[6] In chloroform, IV with equimolar bromine gave



I: $R_1=R_2=R_3=H$
V: $R_1=R_2=R_3=Cl$

5,7-dibromo-2-aminotropone[4] in a 50% yield; the rest of the starting substance was recovered. This result is parallel with the properties[6] of the copper complex of tropolone.

3,5,7-Trichloro-2-aminotropone (V), 7-iodo-2-aminotropone (VII), 3,5,7-tribromo-2-methylaminotropone (VIII), 5,7-dibromo-2-methylaminotropone (IX), and 7-iodo-2-methylaminotropone (X) are new compounds. The hydrolyses of these compounds gave known tropolone derivatives: 3,5,7-trichlorotropolone[7] from V, 3-iodotropolone (XIII)[8] from VII and X, 3,5,7-tribromotropolone (XII)[9] from VIII, and 3,5-dibromotropolone[9a] from IX. Thus, the structures of these compounds are proved. VII and X were also obtained from the methyl ether of XIII by treating it with ammonia and monomethylamine respectively.

Nitration, Azo-coupling Reaction and Sulfonation of 2-Methylaminotropone. As has been shown above, in properties I and II are very similar to each other. Because it is easy to handle, the nitration, azo-coupling reaction, and sulfonation of II were undertaken.

The nitration of II with an equimole of nitric acid in acetic acid afforded 5-nitro-2-methylaminotropone (XIV) in an 85% yield. Generally,

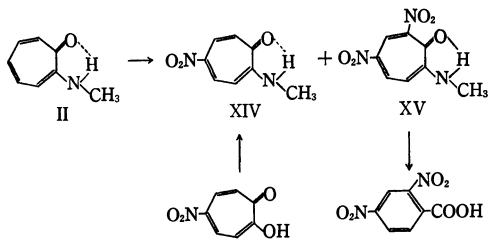
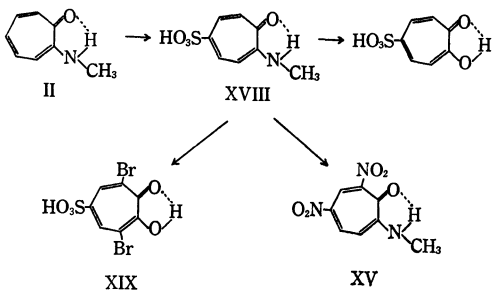
nitrotropolones give nitro-2-aminotropone derivatives when treated with amines.[3b,10] By the application of this method, the treatment of 5-nitrotropolone[10b,11] with methylamine afforded XIV. Thus, the structure of XIV is proved. In the same manner, the reaction of II with excess nitric acid gave a yellow, crystalline substance (XV) in a 60% yield besides 35% of XIV. XV was obtained when 3,5-dinitrotropolone[10b] was treated with methylamine; hence, XV is 5,7-dinitro-2-methylaminotropone. The treatment of XV with alcoholic alkali gave 2,4-dinitrobenzoic acid in a good yield, just as with nitrotropolones.[3b,10]



On the other hand, the treatment of I and III with excess nitric acid under the same reaction conditions as above resulted in the recovery of the starting substances.

The azo-coupling reaction of 2-aminotropones has been known to give 5-arylazo derivatives.[4,12] The treatment of II with phenyldiazonium salt and *p*-nitrophenyldiazonium salt gave the corresponding 5-phenylazo-2-methylaminotropone (XVI) and 5-(*p*-nitrophenyl)azo-2-methylaminotropone (XVII) in 45% and 95% yields respectively. XVI and XVII were also obtained from the corresponding methyl ethers[13] of 5-arylazotropolones by treatment with methylamine.

The reaction of 1.5 mol of sulfamic acid at 150—160°C gave a high-melting-point substance (XVIII) in a 50% yield, while II was also recovered (40%). The elemental analysis of XVIII is agreeable with the sulfonic acid derivative of II, and the hydrolysis of XVIII formed tropolone-5-sulfonic acid.[14] Hence, XVIII is 2-methylaminotropone-5-sulfonic acid. The nitration of XVIII with excess nitric acid resulted in XV in a 70% yield; there was also an exchange of the sulfonic acid group with the nitro group. The same type of exchange reaction was observed when tropolone-5-sulfonic acid was treated with nitric acid.[10b] On the other hand, the bromination of XVIII in an aqueous solution gave 3,7-dibromotropolone-5-sulfonic acid (XIX) in a 65% yield, while the 2-methylamino group was hydrolyzed.



Nitrosation of 2-Methylaminotropone. Although 2-aminotropone gave an unidentified powder when treated with nitrous acid,[4] it is expected that 2-methyaminotropone, as a secondary amine, would form an *N*-nitroso derivative. When II was treated with nitrous acid, white needles (XX) and yellow scales (XXI) were obtained in 80% and 10% yields respectively. The elemental analyses of them agree with those of the nitroso derivatives of II. The IR spectrum of XX does not show any NH stretching vibrations, while that of XXI possesses a broad NH stretching band at 3250 cm^{-1} (KBr pellet). Therefore, XX is assumed to be the *N*-nitroso derivative of II, and XXI, the 5-nitroso compound of II. It is known that 5-nitrosotropolones[11a,15] give 5-nitroso-2-aminotropones when treated with ammonia.[16] Since the treatment of 5-nitrosotropolone with methylamine afforded XXI, the structure of XXI is established to be 5-nitroso-2-methylaminotropone. On the other hand, the reaction of XX with alcoholic potassium hydroxide gave benzoic acid; hence, the structure of XX is 2-*N*-nitroso-2-methylaminotropone, as has been predicted. This is the first *N*-nitroso-2-methylaminotropone derivative obtained. XX is a new type

of active troponoid compound[17] and has interesting properties.

Azo-coupling Reaction, Nitrosation and Sulfonation of 2-Dimethylaminotropone. Substitution reactions do not occur when tropolone methyl ethers are treated with cationoid reagents, but addition reactions do take place.[18] However, the halogenation of III shows that the substitution reactions occur with the hydrolysis of the dimethylamino group, as has been mentioned before. Therefore, the reactions of III with cationoid reagents other than halogens were undertaken.

Although the nitration of III resulted in the recovery of the starting substance, as has been mentioned before, the nitrosation of III in ordinary ways gave 5-nitrosotropolone[11a,15] in a 95% yield. Also, 5-(*p*-nitrophenyl)azotropolone[19] was obtained quantitatively when III was treated with *p*-nitrophenyl diazonium salt. The reaction of III with 1.5 mol of sulfamic acid afforded tropolone-5-sulfonic acid[14] in a 35% yield; there was also a 50% recovery of III.

The electrophilic substitution reactions of III always resulted in the hydrolysis of the 2-dimethylamino group, thus forming tropolone derivatives as in the case of halogenations. It is possible that III is hydrolized to form tropolone first, and that then the attack of a cationoid reagent takes place. However, the treatment of III under the same conditions as in the substitution reactions, but without reagents, resulted in the recovery of III unchanged. Moreover, in the case of nitration, III was recovered quantitatively even if reagents were present. It is also known that if a reaction is carried out under anhydrous conditions, III and its derivatives give substituted derivatives of III without any hydrolysis of the 2-dimethylamino group.[20] Therefore, the mechanism of the reactions can be explained as follows: the nucleophilic attack of water on the C-2 position of the intermediate A to give tropolone derivatives *via* a B-type intermediate, because the steric interference of the dimethylamino group of A makes it difficult for A to keep the dimethylamino group in the same plane of the seven-membered ring.

On the other hand, II can form a C-type intermediate which possesses a hydrogen bond that contributes to the stability of C; the hydrogen is even able to leave to form D and other types of intermediates under some conditions. These entities do not have serious steric interference like that of A. This is the reason why only III gives hydrolized products during the electrophilic substitution reactions.

It is very interesting that, unlike tropolone methyl ethers,[18] not addition reactions but substitution reactions take place in the case of electrophilic reactions of III.

By cationoid substitution reactions under acidic conditions as in nitration, I and III were recovered unchanged, but only II afforded substitution products. This relation is parallel with the order of basicity of primary-, secondary-, and tertiary-amines.

Experimental[21]

3,5,7-Trichloro-2-aminotropone (V). To a solution of 0.60 g of I in 5 m*l* of chloroform cooled in an ice bath, 0.35 g of chlorine in 5 m*l* of chloroform was added drop by drop, and then the mixture was allowed to stand overnight at room temperature. The precipitate formed was separated by filtration; then the chloroform layer was washed with aqueous sodium bicarbonate and water and dried over sodium sulfate, and the chloroform was removed. The residue was recrystallized from benzene-methanol to give 0.35 g of V; yellow needles, mp 183—185°C.

Found: C, 37.85; H, 2.00; N, 6.62%. Calcd for $C_7H_3ONCl_3$: C, 37.45; H, 1.79; N, 6.24%.

The former precipitate was treated with aqueous sodium bicarbonate and extracted with chloroform. The chloroform layer was washed with water and dried

21) All melting points are uncorrected.

over sodium sulfate; the chloroform was then removed under reduced pressure to give 0.40 g of I.

Hydrolysis of V; 3,5,7-Trichlorotropolone. A mixture of 0.10 g of V and 5 m*l* of 1.6 N potassium hydroxide was heated on a water bath for 4 hr. The V was then gradually dissolved, whereupon ammonia gas evolved. The solution was acidified with N hydrochloric acid and extracted with chloroform. The chloroform layer was washed with water and dried over sodium sulfate, and then the chloroform was removed under reduced pressure to give 70 mg of pale yellow needles, the melting point of which failed to show any depression on admixture with authentic 3,5,7-trichlorotropolone.[7]

Bromination of 2-Aminotropone Copper Complex (IV). To a solution of 1.21 g of IV in 100 m*l* of chloroform, 1.09 g of sodium acetate was added, and then 30 m*l* of chloroform containing 1.28 g of bromine was added, drop by drop. A dark green precipitate was formed immediately, and then the mixture was allowed to stand overnight. The precipitate formed was separated by filtration and recrystailized from chloroform to give greenish scales of the complex of VI, mp 253—255°C. The complex was dissolved in 100 m*l* of methanol containing a few drops of 1 N hydrochloric acid, and the mixture was treated with hydrogen sulfide. The solvent was removed, and the residue obtained was recrystallized from cyclohexane - acetone to give 1.00 g of yellow needles, mp 203—205°C, which was undepressed on admixture with an authentic sample of 5,7-dibromo-2-aminotropone.[4]

The chloroform layer was treated as above to give 0.38 g of recovered I.

Bromination of I with Pyridine Perbromide (PPB); 3,5,7-Tribromo-2-aminotropone (VI). *a) With 1 mol of PPB.* A solution of 0.37 g of I in 5 m*l* of chloroform cooled in an ice bath was treated with 0.72 g of PPB prepared by McElvain's method.[22] The precipitate thus formed was recrystallized from ethanol to give 0.32 g of yellow needles, mp 196—198°C, which were found to be identical with the 3,5,7-tribromo-2-aminotropolone[4] by a comparison of their mixed mp and IR spectra.

The chloroform layer was neutralized and concentrated to give 0.20 g of recovered I.

b) With 2 mol of PPB. From 0.37 g of I and 1.44 g of PPB, 0.60 g of VI and 0.10 g of recovered I were obtained.

Bromination of II by PPB; 3,5,7-Tribromo-2-*N*-methylaminotropone (VIII). *a) With 1 mol of PPB.* From 0.34 g of II and 0.60 g of PPB, 0.25 g of yellow needles of VIII was obtained; mp 197—199°C after recrystallization from cyclohexane - acetone.

Found: C, 26.26; H, 2.09; N, 4.03%. Calcd for $C_8H_6ONBr_3$: C, 25.84; H, 1.63; N, 3.78%.

From the chloroform layer, 0.20 g of II was recovered.

b) With 2 mol of PPB. From 0.34 g of II and 1.20 g of PPB, 0.51 g of VIII and 0.20 g of a mixture of mono- and dibromo-derivatives of II were obtained.

Bromination of II in Acid. *a) With 1 mol of Bromine.* Into a solution of 0.34 g of II in 5 m*l* of acetic acid cooled in an ice bath, 0.40 g of bromine in 2 m*l* of acetic acid was stirred, drop by drop: then the mixture was allowed to stand overnight at room temperature. The yellow precipitate thus formed was separated by filtration and washed with aqueous sodium bicarbonate and water. Recrystallization from cyclohexane - acetone gave 0.26 g of yellow needles of VIII. The acetic acid layer was diluted with water, and extracted with chloroform, and the chloroform layer was washed with water, and dried over sodium sulfate. After the chloroform had then been removed, the residue was recrystallized from cyclohexane to give 0.20 g of recovered II, mp 75—76°C.

b) With 3 mol of Bromine. From 0.34 g of II, 3 equivalent moles of sodium acetate, and 1.2 g of bromine, 0.82 g of VIII was obtained under the same reaction conditions.

Hydrolysis of VIII; 3,5,7-Tribromotropolone. A solution of 100 mg of VIII in 4 m*l* of 1.6 N methanolic potassium hydroxide was refluxed on a water bath for 4 hr. After cooling, the solution was acidified with 1 N hydrochloric acid and extracted with benzene. The benzene layer was washed with water, dried over sodium sulfate, and concentrated. The residue thus obtained was recrystallized from cyclohexane - benzene to give 60 mg of pale yellow needles, mp 125—127°C, which failed to show any depression upon admixture with 3,5,7-tribromotropolone.

Bromination of II in Methanol: 5,7-Dibromo-2-methylaminotropone (IX). *a) With 1 mol of Bromine.* Into a solution of 0.34 g of II in 5 m*l* of methanol cooled in an ice bath, 0.40 g of bromine in 10 m*l* of methanol was stirred drop by drop, and then the mixture was allowed to stand at room temperature overnight. The precipitate thus formed was separated by filtration, washed with aqueous sodium bicarbonate and water, and dried in a desiccator. Recrystallization from cyclohexane - acetone afforded 0.20 g of yellow needles of IX, mp 204—205°C.

Found: C, 32.77; H. 2.36; N, 4.73%. Calcd for $C_8H_7ONBr_2$: C, 32.80; H, 2.41; N, 4.75%.

From the methanol layer, 0.15 g of II was recovered.

b) With 3 mol of Bromine. From 0.34 g of II and 1.2 g of bromine, 0.62 g of IX was obtained.

Bromination of III in Methanol. *a) With 1 mol of Bromine.* A methanol solution (5 m*l*) of 0.15 g of III was cooled in an ice bath, and then into this solution 0.16 g of bromine in 1 m*l* of methanol was stirred, drop by drop. The color of the bromine disappeared gradually. The solution was allowed to stand at room temperature for 1 hr and then the methanol was removed under reduced pressure. The addition of water caused the precipitation of a crystalline substance, 62 mg, the melting point of which was 156—158°C after recrystallization from methanol. This substance was found to be identical with 3,5-dibromotropolone by a comparison of their IR spectra and by a mixed-melting-point determination.

To the filtrated mother layer, 5 m*l* of 1 N sodium hydroxide was added, and then the mixture was extracted with chloroform. From the water layer, 37 mg of pale yellow crystals were obtained, mp 126—127°C, which were found to be identical with 3,5,7-tribromotropolone by comparison of thir IR spectra and by a mixed-melting-point determination.

From the chloroform layer 0.10 g of a yellow oil was obtained; this oil was found to be identical with be original substance by a comparison of their IR spectra.

22) S. M. McElvain and L. R. Morris, *J. Am. Chem. Soc.*, **73**, 206 (1951).

and the mixed mp of the picrate, mp 155°C.

b) With 3 mol of Bromine. From 0.15 g of III and 3 equivalent moles of bromine, 0.38 g of 3,5,7-tribromotropolone was obtained by the treatment described above.

7-Iodo-2-aminotropone (VII). I (0.60 g) and potassium carbonate (1.5 g) were dissolved in 6 m*l* of water and methanol (1 : 1) cooled in an ice bath, and into this, a solution of 1.4 g of iodine and 1.0 g of potassium iodide in 10 m*l* of cold water was stirred, drop by drop. The mixture was then allowed to stand at room temperature overnight. The mixture was slightly acidified by the addition of 1 N hydrochloric acid; the precipitate thus formed was then recrystallized from cyclohexane to give 0.28 g of pale green needles of VII, mp 202—203°C.

Found: C, 35.72; H, 2.50; N, 5.76%. Calcd for C_7H_6ONI: C, 35.45; H, 2.55; N, 5.92%.

The mother layer was extracted with chloroform, after which the chloroform layer was treated as before to give 0.35 g of recovered I.

7-Iodo-2-methylaminotropone (X). From 0.67 g of II, 1.5 g of potassium carbonate, and a solution of 1.4 g of iodine and 1.0 g of potassium iodide, 1.22 g of X, mp 179—180°C, was obtained by the treatment described above.

Found: C, 36.35; H, 3.46; N, 5.03%. Calcd for C_8H_8ONI: C, 36.81; H, 3.09; N, 5.37%.

Hydrolysis of VII and X; 3-Iodo-tropolone (XIII). A solution of 0.10 g of VII in 5 m*l* of 1.6 N methanolic potassium hydroxide was heated under reflux for 4 hr; then it was concentrated, and water was added. The water layer was neutralized with 1 N hydrochloric acid and extracted with benzene. After the benzene had been removed, the residue was sublimated under reduced pressure. The recrystallization of the sublimated from cyclohexane - benzene afforded 60 mg of a pale yellow, crystalline substance, mp 101—102°C, which was identical with authentic 3-iodotropolone. By the same procedure, 0.10 g of X gave 70 mg of XIII.

Iodination of III. A solution of 0.75 g of III and 1.5 g of potassium carbonate in 4 m*l* of methanol and water (1 : 4), and a solution of 1.4 g of iodine and 1.0 g of potassium iodide in 10 m*l* of water were treated in the same way as I and II. After recrystallization from cyclohexane, 1.02 g of XIII were obtained.

Nitration of II. *a) With 1 mol of Nitric Acid, 5-Nitro-2-methylaminotropone (XIV).* A solution of 0.40 g of II in 3 m*l* of acetic acid was cooled in an ice bath, and into this, 0.33 g of 60% nitric acid in 2 m*l* of acetic acid was added stirred, drop by drop. The reaction mixture was then poured into crushed ice, and the prepipitate thus formed was separated by filtration and dried in a desiccator overnight. Recrystallization from cyclohexane - benzene afforded 0.45 g of green-yellow, micro needles of XIV, mp 214—216°C.

Found: C, 54.85; H, 4.32; N, 15.30%. Calcd for $C_8H_9O_3N_2$: C, 55.33; H, 4.48; N, 15.55%.

b) With Excess Nitric Acid. XIV and 5,7-Dinitro-2-methylaminotropone (XV). From 0.40 g of II and 1.0 m*l* of 60% nitric acid, 0.70 g of a crude substance was obtained by the same treatment as above. Recrystallization from ethanol gave 0.19 g of pale green needles, mp 214—216°C, which were identical with XIV. Ethanol-layer condensation afforded 0.41 g of a residue the recrystallization of which from cyclohexane-benzene gave orange-yellow needles of XV, mp 195—196°C.

Found: C, 43.04; H, 3.39; N, 18.26%. Calcd for $C_8H_7O_5N_3$: C, 42.70; H, 3.14; N, 18.64%.

Treatment of Nitrotropolones with Monomethylamine. *a) XIV.* A solution of 0.20 g of 5-nitrotropolone in 20 m*l* of benzene cooled in an ice bath, was saturated with dry monomethylamine, then the mixture was allowed to stand overnight. After the benzene and monomethylamine had been removed under reduced pressure, the residue was recrystallized from cyclohexane - benzene to give 0.16 g of yellow needles, mp 210—213°C, which did not show any depression on admixture with XIV.

b) XV. 3,5-Dinitrotropolone (0.20 g) was treated as above to give 0.14 g of XV.

Nitration of I. Nitric acid (60%, 1 m*l*) was stirred into a solution of 0.60 g of I in 2 m*l* of acetic acid cooled in an ice bath, and then the mixture was allowed to stand overnight. The reaction mixture was poured into crushed ice, the precipitate thus formed was separated by filtration, dried in a desiccator, and recrystallized from cyclohexane to give 0.55 g of the starting material.

Nitration of III. III (0.45 g) was treated with 1 m*l* of 60% nitric acid as above. An oily substance was obtained; this was found to be identical with III by a comparison of their IR spectra. This oil afforded 0.75 g of the picrate of III, mp 143—145°C.

5-Phenylazo-2-methylaminotropone (XVI). a) Into a solution of 0.135 g of II in 0.4 m*l* of 4 N of hydrochloric acid cooled in an ice bath, a phenyldiazonium chloride solution, prepared from 0.10 g of aniline in the ordinary way, was stirred. After 2 hr, the pH of the solution was adjusted to about 7.5 with aqueous sodium bicarbonate and extracted with benzene. The benzene layer was washed with water, dried over sodium salfate and chromatographed on alumina. From the cyclohexane-benzene elution part, 0.10 g of red needles of XVI was obtained; mp 145—146°C from the same mixed solvent.

Found: C, 70.65; H, 5.34; N, 17.26%. Calcd for $C_{14}H_{13}ON_3$: C, 70.27; H, 5.48; N, 17.56%.

From the benzene-acetone elution part, 40 mg of II were recovered.

b) 5-Phenylazotropolone methyl ether (0.20 g) was treated with excess methylamine in a sealed tube at room temperature for 4 days. After the methylamine had then been removed, the residue was recrystallized from cyclohexane-benzene to give 0.20 g of red needles of XVI, mp 140—141°C.

5-(*p*-Nitrophenylazo)-2-methylaminotropone (XVII). a) From 0.28 g of II and 1.5 equimoles of *p*-nitroaniline, 0.54 g of dark red scales of XVII, mp 254—256°C from cyclohexane - benzene was obtained by the same treatment as above.

Found: C, 59.87; H, 4.70; N, 20.52%. Calcd for $C_{14}H_{12}O_3N_4$: C, 59.15; H, 4.26; N, 19.71%.

b) 5-*p*-(Nitrophenylazo)tropolone methyl ether (50 mg) was treated with excess methylamine as above; 40 mg of XVII, mp 214—216°C from cyclohexane-benzene were thus obtained. The azo compounds obtained by the a and b method were found to be identical with each other by a comparison of their IR spectra and by a mixed-melting-point determination.

Azo-coupling Reaction of 2-Dimethylaminotropone (III); 5-(*p*-Nitrophenylazo)tropolone. *p*-Nitrophenyl diazonium chloride prepared from 0.60 g

of *p*-nitroaniline was added, drop by drop, to a solution of 0.45 g of III in 5 m*l* of dioxane, and then the mixture was allowed to stand for 2 hr while being stirred. The reaction mixture was neutralized with aqueous sodium bicarbonate.

The precipitate thus formed was separated by filtration, dried in a desiccator, and recrystallized from benzene to give 0.78 g of orange scales, mp 233—235°C, which were found to be identical with 5-(*p*-nitrophenylazo)tropolone by a comparison of their IR spectra and by a mixed-melting-point determination.

Sulfonation of II; 2-Methylaminotropone-5-sulfonic acid (XVIII). A well-ground mixture of 2.70 g of II and 2.90 g of sulfamic acid was heated in fusion at 160°C for 6 hr under a nitrogen atmosphere. After the reaction, the reaction mixture was extracted with chloroform and hot water. The concentration of the chloroform afforded 1.07 g of recovered II. The water layer was concentrated under reduced pressure to give pale yellow needles which, when recrystallized from methanol, afforded 2.01 g of pale yellow needles of XVIII, mp>350°C. This was treated with an equimole of benzylthiourea in diluted methanol; the recrystallization of the benzylthioronium salt thus obtained afforded pale yellow needles, mp 172—174°C.

Found: C, 50.37; H, 4.81; N, 10.77%. Calcd for $C_{16}H_{19}O_4N_3S_2$: C, 50.31; H, 5.02; N, 11.01%.

Sulfonation of III; Tropolone-5-sulfonic Acid. III (0.40 g) and sulfamic acid (0.39 g) were treated at 180°C for 10 hr in the way described above. From the chloroform extract, 0.51 g of III was recovered as its picrate, mp 145°C. The water layer showed a positive ferric chloride test and the addition of *p*-toluidine afforded colorless needles, mp 236—238°C. The melting point did not show any depression on admixture with *p*-toluidinium salt of tropolone-5-sulfonic acid, and their IR spectra were identical.

Hydrolysis of XVIII. On a water bath, 0.10 g of XVIII was heated for reflux in 2 m*l* of 1.6 N ethanolic potassium hydroxide for 4 hr. The pH of the solution was then adjusted about 3 with 1 N hydrochloric acid and 0.10 g of *p*-toluidine was added. The needles thus formed, mp 237—239°C, were identical with the *p*-toluidinium salt of tropolone-5-sulfonic acid.

Nitration of XVIII; 5,7-Dinitro-2-methylaminotropone (XV). Into a solution of 0.20 g of XVIII in 20 m*l* of acetic acid cooled in an ice bath, 1.0 m*l* of 60% nitric acid was stirred. After it had been allowed to stand for a couple of hours, the reaction mixmixture was poured onto ice; the precipitate thus formed was then separated by filtration and dried in a desiccator. Recrystallization from cyclohexane - benzene gave 0.15 g of orange yellow scales, mp 197—199°C, which were identical with 5,7-dinitro-2-methylaminotropone.

Bromination of XVII; 3,5-Dibromotropolone-5-sulfonic Acid (XIX). XVIII (0.20 g) was dissolved in 10 m of water and methanol (1 : 1), and then the mixture was cooled in an ice bath. Into this, 0.60 g of bromine was stirred, drop by drop, and then the reaction was continued for 30 min. The concentration of the solution caused the precipitation of a crystalline substance, the recrystallization of which from ethanol afforded 0.22 g of white rhombo prisms, mp 217—220°C.

Found: C, 23.50; H, 1.52%. Calcd for $C_7H_4O_5SBr_2$: C, 23.35; H, 1.12%.

Nitrosation of II; 2*N*-Nitrosomethylaminotropone (XX) and 5-Nitroso-2-methylaminotropone (XXI). Into a cold solution of 0.68 g of II in 5 m*l* of 10% hydrochloric acid, 0.43 g of sodium nitrite dissolved in 10 m*l* of water was stirred; the mixture was then allowed to stand for a couple of hours. The reaction mixture was then poured onto crushed ice, and the precipitate thus formed was separated by filtration and dried in a desiccator. Recrystallization form cyclohexane afforded 0.70 g of white needles of XX, mp 98—99°C.

Found: C, 58.74; H, 4.78; N, 16.78%. Calcd for $C_8H_8O_2N_2$: C, 58.53; H, 4.91; N, 17.07%.

The water layer was neutralized with aqueous sodium bicarbonate and extracted with benzene. The benzene layer was dried over sodium sulfate, and then filtered off, and the residue was recrystallized from cyclohexane - benzene to give 80 mg of brown-yellow scales of XXI, mp 128—130°C.

Found: C, 58.98; H, 5.18; N, 16.84%. Calcd for $C_8H_8O_2N_2$: C, 58.53; H, 4.91; N, 17.07%.

5-Nitrosotropolone (0.30 g) was dissolved in 20 m*l* of benzene, and the mixture was cooled in an ice bath. This was then saturated with dry methylamine. The precipitate thus formed was then separated by filtration and recrystallized from cyclohexane - benzene to give 0.15 g of brown-yellow scales, mp 123—125°C, which were identical with the XXI obtained above.

Rearrangement of XX. XX (0.16 g) was refluxed in 3 m*l* of 1.6 N ethanolic potassium hydroxide for 4 hr. After cooling, the solution was acidified with N hydrochloric acid and extracted with ether. The ether layer was washed with water and dried over sodium sulfate, and the ether was removed. White needles, mp 120—121°C, were obtained; the melting point did not show any depression on admixture with benzoic acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 2985—2989 (1968)

Electrolytic Reduction of Naphthalene in Various Alcohol-Hexamethylphosphoramide Systems

Teruzo ASAHARA, Manabu SENŌ and Hideaki KANEKO

The Institute of Industrial Science, The University of Tokyo, Roppongi, Minatoku, Tokyo

(Received April 26, 1968)

The electrolytic reduction of naphthalene was carried out in various alcohol-hexamethylphosphoramide (HMPA) systems in the presence of lithium chloride. The reduction of naphthalene proceeds effectively at relatively low cathode potentials in the presence of HMPA; the composition of the products varies with the changes in the reduction potential, the kind of alcohols, and the concentration of HMPA. The dark blue color is observed at the cathode during the electrolysis in HMPA solutions in either the presence or the absence of ethanol. It is suggested that the color reflects the generation of solvated electrons, and that reduction of naphthalene is caused not through a direct electron-transfer from the cathode, but through a reaction with solvated electrons as the reductive agent.

In this series of investigations, the reduction of various organic compounds by solvated electrons will be discussed. It has been considered that the solvated electrons are generated especially in polar solvents by high-energy radiation and exist in amine or ether solutions of alkali metals, especially in a dilute metal-ammonia solutions.[1] Extensive investigations have been carried out into their properties and reactions with various compounds in metal-ammonia solutions; however, there have been few investigations of reactions in other systems.[2,3] The existence and the properties of solvated electrons have been suggested and examined by the methods of electric conductivities, absorption spectra, and electron-spin resonances, but a complete understanding has not yet been obtained. Recently, Sternberg *et al.* reported a series of investigations of the electrolytic reduction of aromatic compounds in the ethylenediamine-lithium chloride systems and suggested that the reduction was caused by an indirect electron-transfer mechanism.[4,5] In these systems, it might be considered that the solvated electrons act as a reductive agent. In the present paper, the electrolytic selective reduction of naphthalene in mixed solvent systems of various alcohols and hexamethylphosphoramide in the presence of lithium chloride will be reported. The generation of solvated electrons has been suggested in this system.[6]

Experimental

Reagents. The hexamethylphosphoramide (HMPA, Japan Oil Seal Co.) was purified by reflux over calcium hydride and by subsequent distillation under reduced pressures. The alcohols (methanol, ethanol, 1-propanol, and 2-propanol) were purified by reflux over calcium oxide and by distillation. Lithium chloride of a reagent grade was used without further purification, while the naphthalene was purified by recrystallization and sublimation.

Apparatus and Procedure. The electrolysis vessel used is an H-cell with a total capacity of 40 m*l*. It is separated by a filter paper, Toyo Roshi No. 2, into two compartments. A platinum anode and cathode were used through the present experiments. The area of each electrode is 3 cm^2. The electrode potential was measured against an Ag wire used as a reference electrode. The electrolysis vessel was set in a water bath maintained at nearly constant temperatures, 18—20°C. All electrolyses were carried out at constant voltages or constant currents by a manually-controlled device.

The concentrations of naphthalene and lithium chloride are 0.2 and 0.5 M respectively, except when otherwise stated; the total volume of the reaction mixture is 20 m*l*, and the HMPA content varies from 0 to 50 vol%. The reduction products were analyzed by gas chromatography (column, polyethylene glycol 6000, 2.5 m; column temperature, 150°C; helium flow rate, 40 m*l*/min) and by mass-spectrometry. The identification was made through a comparison of the retention time with those of the authentic samples, while the yield was estimated by the measurement of the peak heights.

Results

Ethanol-HMPA System. The results for the electrolysis of naphthalene in a mixed ethanol-HMPA system containing lithium chloride are

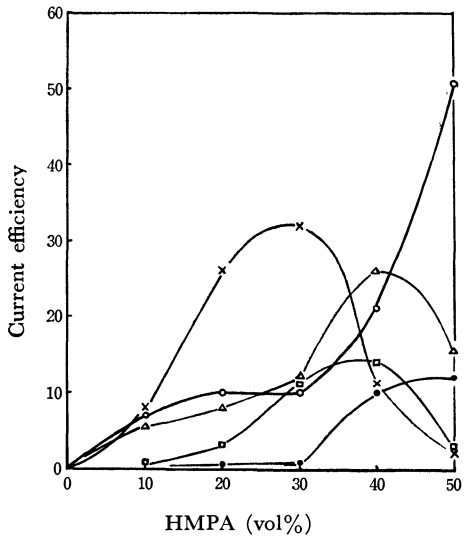

Fig. 1. Ethanol-HMPA system at −3.10 V *vs.* Ag wire.
○—○ Dihydronaphthalene ●—● Tetralin
△—△ Hexaline □—□ Octalin
×—× Decalin

given in Fig. 1. The concentrations of naphthalene and lithium chloride were 0.4 and 0.5M, respectively, and the cathode potential was maintained at nearly −3.10 V *vs.* Ag wire. This potential is more negative by about 1 volt than the reduction potential of naphthalene. As is shown in Fig. 1, no reduction products were detected in the absence of HMPA. When HMPA is added, the reduction of naphthalene occurs effectively, and the total current efficiency for the production of hydronaphthalenes increases with an increase in the HMPA content. The selectivity of reduction depends remarkably on the HMPA content. The current efficiencies for dihydronaphthalenes and tetralin increase monotonously with an increase in the content of HMPA, ranging from 0 to 50 vol%; on the other hand, the maximum current efficiencies of hexalin, octalin, and decalin are found at 40, 35, and 30 vol% of HMPA, respectively.

The electrolytic reduction at various reduction potentials was carried out under similar conditions.

Table 1. Electrolytic reduction of naphthalene in ethanol-HMPA system at −1.70±0.05 V *vs.* Ag wire

HMPA (vol%) Product (mole ratio, %)	40	30	20	10
1,2-Dihydronaphthalene	12	—	34	33
1,4-Dihydronaphthalene	88	100	66	67
Curr. eff. (%)	61.3	50.4	44.0	25.2

Table 1 shows the results of electrolytic reduction at −1.7±0.05 V *vs.* Ag wire. The reduction products are 1,2- and 1,4-dihydronaphthalene, with the latter the main product. The electrolyses carried out at −2.0±0.05 V and −2.5±0.05 V *vs.* Ag wire also afford only 1,2- and 1,4-dihydronaphthalene.

Methanol-HMPA System. In order to get some insights into the effect of alcohols on the reduction of naphthalene, the electrolytic reduction was carried out in the methanol-HMPA system under conditions similar to those in the ethanol-HMPA system. The results are shown in Tables 2 and 3.

Table 2. Electrolytic reduction of naphthalene in methanol-HMPA system at −1.20—−1.30 V *vs.* Ag wire

Hexalin	6	—	1	—	—
Curr. eff. (%)	85.3	38.8	40.8	27.1	20.1

In the absence of HMPA, the reduction of naphthalene does not occur. When HMPA is added, the main products are dihydronaphthalenes and tetralin, but the yield of tetralin decreases with an increase in the HMPA content. The selective reduction into dihydronaphthalenes becomes almost complete at higher HMPA contents, especially when the electrode potential is low. The total current efficiency increases with an increase in the content of HMPA, except for the case of a lower electrode potential (−1.20—−1.30 V *vs.* Ag wire). Table 4 shows the effect of the cathode potential in the range from −1.20 to −1.75 V *vs.* Ag wire at the HMPA content of 30 vol%. The increase in reduction potentials results in an increase in the total current efficiency, but a decrease in the selectivity for the formation of dihydronaphthalenes.

It must be noticed that the electrolytic reduction of naphthalene takes place steadily at the cathode potential of −1.20—−1.30 V *vs.* Ag wire. The polarographic half-wave potential of naphthalene

has been reported to be −1.98 V *vs.* SCE in an ethylene glycol monomethyl ether solution using 0.1 M tetrabutylammonium iodide as a supporting electrolyte,[7] and −2.53 V *vs.* SCE in a 75% dioxane solution.[8] Even if the reduction potential in the macro-electrolysis differs somewhat from that in micro-electrolysis, this finding shows that the electrolytic reduction of naphthalene does occur in a system containing HMPA at lower cathode potentials than the half-wave potential, which is required for the direct electron-transfer from the cathode to naphthalene molecules. This fact may be interpreted on the assumption of some indirect electron-transfer machamism, which is probably closely connected with the existence of HMPA, as will be discussed in detail later.

Propanol-HMPA System. In order to examine the effect of alcohols further investigations were carried out by using 2-propanol and 1-propanol. The electrolysis was done under a constant current of 20 mA, because these systems are very resistive and a sufficiently high current is not obtained when a similar cathode potential as employed in the methanol and ethanol system is used. The results in the 2-propanol-HMPA system are shown in Table 5, where the cathode potentials are also given. Upon an increase in the HMPA content, the cathode potential decreases remarkably. In the absence of HMPA, the cathode potential is irreproducible but very high, and naphthalene is reduced electrolytically into hydronaphthalenes; this is in contrast to the case of a pure methanol or ethanol system, where a high-electrode potential sufficiency for direct electron-transfer is not retained.

7) E. M. Elofson, *Anal. Chem.*, **21**, 916 (1949).
8) G. J. Hojitink and J. V. Schooten, *Rec. Trav. Chim.*, **71**, 1089 (1952).

The results of electrolyses in the mixed solvents of 1-propanol-HMPA are shown in Table 6. In the absence of HMPA, the cathode potential is very high and naphthalene is reduced into dihydronaphthalenes electrolytically, but the current efficiency is very low. Upon an increase in the HMPA content, the cathode potential necessary for the passage of a constant current, 20 mA, decreases, but the total current efficiency for the reduction of naphthalene is nearly quantitative and the main product is decalin.

Effect of the Addition of Water. In order to examine the effect of the addition of water as a proton donor, the electrolysis of naphthalene in the ethanol-HMPA-water system (volume ratio, 10 : 10 : 4) was carried out. The conditions of electrolysis were as follows: the concentration of naphthalene and LiCl are 0.32 M and 0.4 M, respectively, and the cathode potential is 3.0 V *vs.* Ag wire. During the electrolysis the evolution of gas is violent at the cathode, probably because of the electrolytic decomposition of water, but naphthalene is not reduced on the passage of 4.68×10^2 coulomb.

Current-Voltage Relation. In Fig. 2 the current-voltage relationships in systems of water, methanol, ethanol, 1-propanol, 2-propanol, and respective alcohol-HMPA mixed solvents containing 0.5 M lithium chloride are shown. The cell temperature was maintained at 18—20°C in a water bath.

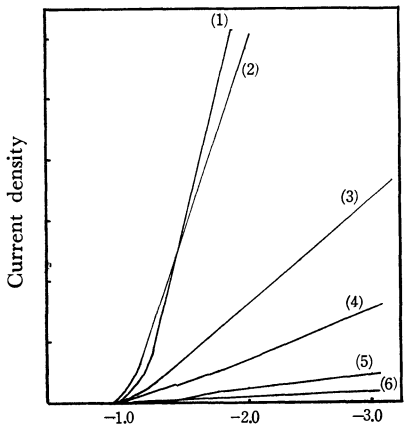

Fig. 2. Current-voltage relation.
(1) H_2O, (2) Methanol, (3) Methanol+HMPA (vol. ratio 1 : 1), (4) Ethanol, (5) 1-Propanol, (6) 2-Propanol; containing 0.5 M lithium chloride in all cases.

In these systems the addition of naphthalene (0.5 M) has little effect on the current-voltage curve. The decomposition voltages are nearly the same, about −1.0 V *vs.* Ag wire, in all these systems. In the methanol system, the current density is very high compared to that in the other alcohol systems. The current density at the same electrode potential decreases in the order: $H_2O \sim$ methanol > ethanol > 1-propanol > 2-propanol, an order which agrees with the order of the decreasing dielectric constant or acidity. In the methanol system, the addition of HMPA depresses the current density by about half compared to the case of its absence; on the contrary, the addition of HMPA has little effect on the current density in the other alcohol systems.

Discussion

As has been described in the preceding section, the reduction of naphthalene does not take place in the absence of HMPA if the cathode potential is not extremely high, while naphthalene is effectively reduced even at cathode potentials lower than the polarographic half-wave potential if HMPA is added. These results suggest that the reduction of naphthalene is not caused through a direct electron-transfer mechanism in the present systems. The reduction mechanism is characteristic of an alcohol-HMPA system containing lithium chloride, as has been suggested by Sternberg *et al.*[6] They observed a dark blue color at the cathode during the electrolysis of lithium chroride in an HMPA-ethanol system, and suggested the generation of solvated electrons. These observations were confirmed in the present investigation, as will be described below.

When the electrolysis of lithium chloride in a pure HMPA system was carried out in an open H-cell with a diaphragm, the generation of dark blue globules was observed at the cathode after the evolution of gases. The globules disappear during the diffusion into the bulk solution and the liquid surface. When the electrolysis was carried out in a vacuum system, dark blue globules generate at the cathode, diffuse into the bulk, and disperse thoroughly in the cathode compartment. The coloration remains for several hours after the electrolysis.

When the vacuum electrolysis is carried out in the HMPA-ethanol system (volume ratio 1 : 1), a dark blue color is observed at the cathode surface, but it disappears during diffusion into the bulk. When naphthalene is added to this system, only a faint color is observed.

This coloration is the same as that observed in the system where alkali metals are dissolved in HMPA and shows a strong absorption band around 650 mμ. This absorption band is the same as that ascribed to the solvated electrons.[9] Moreover, it may be pointed out that the decomposition potentials in various HMPA-alcohol systems

9) M. Ottolenghi, K. Bar-Eli, H. Linschitz and T. R. Tuttle, *J. Chem. Phys.*, **40**, 3729 (1964).

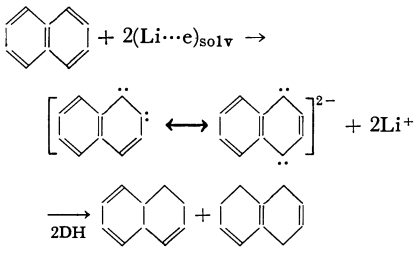
are nearly all the same, around -1.0 V *vs.* Ag wire. At the electrode potentials over this value, naphthalene is reduced effectively. This value is lower than that ascribed to the reduction of naphthalene.

These results show that the reduction of naphthalene proceeds according to a mechanism similar to that proposed by Krapcho *et al.*[10] for the reduction of aromatic hydrocarbons by alkali metals in liquid ammonia and by Sternberg *et al.*[4] for the electrolytic reduction of the benzene ring in ethylenediamine saturated with lithium chloride. The general reaction scheme is as follows:

$$\mathrm{Li^+ + e \rightarrow (Li\cdots e)_{solv}}$$
$$\mathrm{(Li\cdots e)_{solv} + R \rightarrow Li^+ + R^{\mp}}$$
$$\begin{cases} \mathrm{R^{\mp} + DH \rightarrow RH + D^{\mp}} \\ \mathrm{R^{\mp} + (Li\cdots e)_{solv} \rightarrow R^{2-} + Li^+} \\ \mathrm{R^{2-} + 2DH \rightarrow RH_2 + 2D^-} \end{cases}$$

where R is an unsaturated compound to be reduced, DH is a proton donor, and $\mathrm{(Li\cdots e)_{solv}}$ is the solvated lithium and electron.

It is proposed that naphthalene is reduced into dihydronaphthalene according to the following scheme:



It may be supposed from the polarographic results of the one-step two-electron reduction that the two-electron transfer occurs successively from solvated lithium to naphthalene in the first step of reduction. In the present systems, alcohols probably act as proton donors.

The selectivity of the reaction is affected by various factors: the kind of alcohols, the alcohol content, and the reduction potentials. In the ethanol-HMPA system, the hydrogenation proceeds more intensively with an increase in the ethanol content, as is shown in Fig. 1. This is reasonable when ethanol is considered to act as a proton donor. Dihydronaphthalenes are the main product when the HMPA content is high. In the methanol-HMPA and the 2-propanol-HMPA systems, the main products are dihydronaphthalene and tetralin; the yield of the former increases with an increase in the HMPA content.

It may be considered that the hydrogenation proceeds more extensively with an increasing acidity of alcohols and that, on the other hand, more strongly acidic alcohols react more intensively with solvated lithium and electrons, resulting in the hydrogen evolution. This is the reason why water does not act as a proton donor for the reduction of naphthalene and why extensively hydrogenated products are obtained only in a system consisting of ethanol, a moderately strong proton donor.

The increase in reduction potentials extensively encourages the hydrogenation as shown in Table 4 in the methanol-HMPA system. This result can also be understood in view of the fact that the solvated electrons increase in quantity with an increase in the potential.

In the 1-propanol-HMPA system, the main product is decalin. This result can not be interpreted from the standpoint described above; it is now being investigated further.

A detailed discussion of the selectivity of this reaction system will be reported in the near future, together with the results of the polarographic examination and of the reduction of benzene in similar systems.

Studies of the Organic Reactions of Metal Carbonyls. XIV.*1 The Reaction of Potassium Iron Carbonylates with Isoprene

Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Isao KANAYA, Takeaki MITSUDO, Toshiharu OKAJIMA, Yoshihiko MORISHITA and Hiromitsu MASADA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 8, 1968)

The reaction between potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$) and isoprene has been studied. Isoprene is reduced at room temperature to give three olefins (3-methyl-1-butene (I), 2-methyl-1-butene (II), and 2-methyl-2-butene (III)). The reaction conditions (solvents, atmospheres, additives such as water) have a great effect on the yield and distribution of the olefins. Under carbon monoxide in the presence of water, the reduction is highly promoted, giving 2 mol/mol-$Fe(CO)_4^{2-}$ of the olefins. The percentage of II is almost constant (about 15%) in any case, but the percentages of I and III, very dependent on the conditions, change in the 3—40 and 50—80% ranges respectively. The reaction is suggested to proceed *via* some kinds of σ- and π-allyl iron carbonyl complexes. Under carbon monoxide the carbonylation of isoprene also occurs.

Previous work in this laboratory has shown that potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$) react with styrene oxide under carbon monoxide to give styrene and carbon dioxide.[1] Several workers have also shown that $H_2Fe(CO)_4$ and $KHFe(CO)_4$ have a large activity in the reduction of organic compounds, such as acetone, nitrobenzene, quinone, and acetylene.[2]

The present study will deal with the reaction of the iron carbonylate, mainly $KHFe(CO)_4$, with isoprene. The results obtained indicate that isoprene is reduced to give three different monoolefins, and that the yield and distribution of the olefins are remarkably affected by the reaction conditions.

Experimental

The Preparation of Potassium Iron Carbonylates, $KHFe(CO)_4$, $K_2Fe(CO)_4$. The alcoholic solutions of these salts were prepared according to the method described in a previous paper.[1] An 80 m*l* portion of 0.14 M $KHFe(CO)_4$ or $K_2Fe(CO)_4$ solution was used in each run.

When $KHFe(CO)_4$ is prepared, an equivalent mole of water is formed:[3]

$$Fe(CO)_5 + 3KOH \xrightarrow{\text{in alcohol}} KHFe(CO)_4 + K_2CO_3 + H_2O$$

Therefore, when a dry solution of $KHFe(CO)_4$ was required, the solvent of $KHFe(CO)_4$ solution was once distilled under a vacuum, and then 80 m*l* of a new dry solvent was added.

Materials. The isoprene, iron pentacarbonyl, methyl ethyl ketone, tetrahydrofuran, isopropyl ether, and other compounds employed in this study were all commercial products.

Reaction Procedures. Under Atmospheric Pressure. To the solution of the potassium iron carbonylate described above, 5 m*l* (50 mmol) of isoprene and 0.4 m*l* of cyclopentane, as an internal standard for analysis, were added. The mixture was then agitated for a certain reaction time at 30°C under an atmosphere of carbon monoxide, nitrogen, or hydrogen. After a certain reaction time, a 0.5 m*l* sample of the solution was removed and then diluted with 1.5 m*l* of cyclohexane. This cyclohexane solution was immediately submitted to analysis.

Under Hydrogen Pressure. An autoclave (100 m*l*) equipped with a magnetic stirrer was used. 1.5 m*l* of $Fe(CO)_5$, 33 m*l* of a 1 N KOH solution in ethyl alcohol, and 5 m*l* of isoprene were placed into the autoclave at −80°C. After the air in the autoclave had been replaced with nitrogen, hydrogen were introduced at 60 kg/cm^2. The autoclave was then kept at a certain temperature for 5 hr.

Analysis of the Products. The reaction products (three different olefins) were identified by gas chromatography using a PEG-Golay column. Further, the monoolefins produced were confirmed by being converted to isopentane; after hydrogenation with Raney

butene (I), 2-methyl-1-butene (II), and 2-methyl-2-butene (III) are obtained. Isopentane is not obtained, indicating that $KHFe(CO)_4$ is not active in the reduction of monoolefins under the conditions employed. As Figs. 1 and 2 show, the yield and distribution of the monoolefins obtained are remarkably affected by the reaction conditions.

The Yield of Monoolefins. In dry ethyl alcohol under nitrogen, the yield of the monoolefins is 1.0 mol/mol-$Fe(CO)_4^{2-}$ at its maximum (Exp. 1).

When there is 1 or 10 mol*2 of water present in the system (Exps. 2 and 3), the yield increases to about 1.5 mol. Under carbon monoxide, the reduction is highly promoted and the maximum yield of the olefins amounts to 2.0 mol (Exp. 4). Under hydrogen the maximum yield is also 2 mol (Exp. 5). In dry ethyl alcohol, $K_2Fe(CO)_4$ also reduces isoprene, but more slowly, and the maximum yield of the olefins is less than 0.5 mol (Exp. 6).

The Distribution of the Olefins. As Fig. 2 shows, the amount of water and the atmosphere have a great effect on the distribution of the olefins (I and III). The percentage of the olefin II, however, is almost constant (about 15%) in any case. In dry ethyl alcohol under nitrogen, the percentage of I increases with an increase of the reaction time, finally amounting to 40% (Exp. 1). In the presence of 1 or 10 mol of water, the percentage of I decreases to about 32 or 18%, respectively (Exps. 2 and 3). Under carbon monoxide or hydrogen, the percentage of I also decreases to about 21 or 28%, respectively (compare Exps. 4 and 5 with Exp. 2). In the case of $K_2Fe(CO)_4$,

even in dry ethyl alcohol under nitrogen, the percentage of I is less than 30% (Exp. 6).

Carbonylated Products. Under carbon monoxide, more than 1 mol of the gas is absorbed for about 20 hr (Exp. 4). The infrared spectrum of the reaction mixture has strong bands at 2005, 1982, and 1971 cm^{-1} characteristic of some iron carbonyls, and one at 1700 cm^{-1}. The band at 1700 cm^{-1} seems to be attributable to some acyliron carbonyl complex.

The reaction mixture treated with an iodine and hydrogen chloride solution in alcohol shows a band at 1735 characteristic of an ester and one at 1720 cm^{-1}.

On the basis of these facts, it may reasonably be concluded that isoprene is carbonylated to give some acyliron carbonyl complex, which seems to be converted to a corresponding ester by the treatment with iodine. The yield of the ester is about 0.1 mol. The structures of the complex and the ester, however, are not yet clear in this study.

The Reaction of $KHFe(CO)_4$ with Isoprene in Other Solvents. The solvent effects on this reaction were examined; the results are summarized in Tables 2 and 3. In *n*- and isopropyl alcohol, the monoolefins are also produced (Table 2). The water added and atmosphere have effects on the yield and distribution of the olefins (I and III) similar to those in ethyl alcohol; the presence of a water and carbon monoxide atmosphere promotes the reduction, but is less favorable for the production of I. The distribution of the olefins (I and III) depends remarkably on the kind of alcohols. The percentage of I is greatest in ethyl alcohol, followed by *n*-propyl alcohol and isopropyl alcohol in that order; in isopropyl alcohol even in a dry system, the percentage of I is only 13% (Exp. 7 *cf.* Exp. 1). As Table 3 shows, in methyl ethyl ketone, tetrahydrofuran, and isopropyl ether the reduction occurs much more slowly and the maximum yield of the olefins is less than 0.5 mol.

The Reaction of Isoprene under Hydrogen Pressure. The results are summarized in Table 4. Under 60 kg/cm^2 of hydrogen at 35°C, the reduction occurs more rapidly to give 2.5 mol of the olefins (compare Exp. 16 with Exp. 5). Even at 100°C, the yield of the olefins is 2.5 mol at most (Exp. 17), indicating that the iron carbonylate ($KHFe(CO)_4$) does not catalyze the hydrogenation of isoprene under the conditions used and that the carbonylate acts as a reducing reagent in the

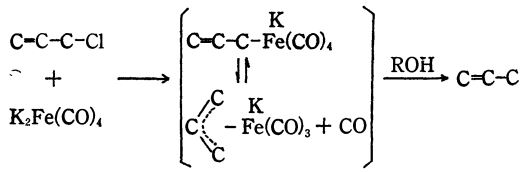
reaction. This explanation is consistent with the fact that the amount of olefins decreases proportionally with a decrease in the amount of the carbonylate used (Exp. 18).

The Reaction of $K_2Fe_2(CO)_8$ with Isoprene. The results are summarized in Table 5. All of the reactions were carried out in ethyl alcohol at 30°C.

As Table 5 shows, $K_2Fe_2(CO)_8$ also reacts with isoprene. In dry ethyl alcohol under nitrogen, the reduction occurs slowly to give about 0.5 mol of the olefins, and the percentage of I amounts to 31% (Exp. 19). When 1 mol of water is present, the yield increases to about 0.9 mol, but the percentage of I decreases to only 3% (Exp. 20). Under a carbon monoxide atmosphere the reduction is promoted to give more than 1 mol of the olefins (Exp. 21).

Discussion

Recently we have found that allyl halide reacts rapidly with $K_2Fe(CO)_4$ in ethyl alcohol, accompanied by an evolution of carbon monoxide and propylene.*3 This reaction is considered to proceed *via* the σ- and π-allyl iron carbonyl complexes.



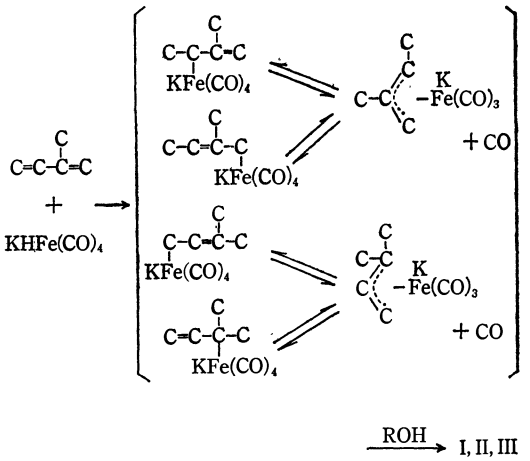
These complex may be unstable in an alcoholic solution, giving propylene in a good yield.

In the light of this reaction, the reaction of isoprene with $KHFe(CO)_4$ is considered to follow the following reaction scheme.

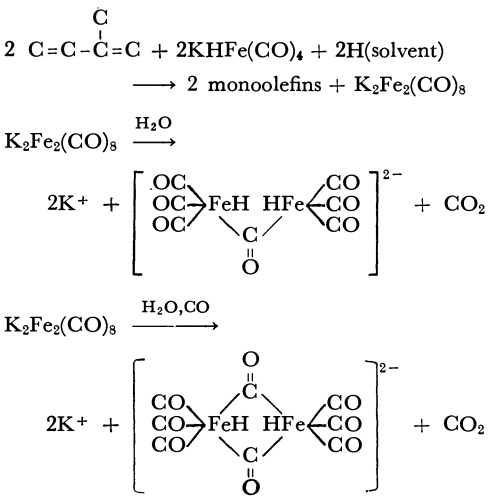
At first the four isomeric σ- allyl iron carbonylates are possible; then from these the two π- allyl iron carbonylates may be derived. In protic solvents these complexes decompose to give three different olefins and $K_2Fe_2(CO)_8$.

In aprotic solvents such as methyl ethyl ketone, $KHFe(CO)_4$ seems to give less than 0.5 mol of the olefins and $K_2Fe_2(CO)_8$. In these reactions $KHFe(CO)_4$ seems to be the only hydrogen source.

The formation of $K_2Fe_2(CO)_8$ may be supported by the fact that the reaction mixture turns from



light brown to deep ruby red. In the presence of water and under carbon monoxide, the $K_2Fe_2(CO)_8$ thus formed has been proposed to give new iron hydride complexes:[4]



Thus, the promoting effect of water and carbon monoxide on the reduction may be attributed to the formation of the new hydrides, which react further with isoprene.

A detailed mechanism, especially concerning the effect of water, solvents, and carbon monoxide on the distribution of the olefins, is not yet clear.

This work was supported in part by the Kawakami Foundation, to which our thanks are due.

*3 A more detailed study will be presented later.

Copolymerization of Vinyl Chloride with Ethylene by the $VO(OEt)_3$-Alkylaluminum Catalyst Systems

Akira MISONO*, Yasuzo UCHIDA*, Kunikazu YAMADA** and Tadashi SAEKI*

* *Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo*
** *Research Laboratory, Sekisui Chemical Co., Shimamoto-cho, Mishima-gun, Osaka*

(Received May 14, 1968)

The copolymerization of vinyl chloride with ethylene was carried out in *n*-heptane by using the catalyst systems consisting of $VO(OEt)_3$ and $AlEt_3$, $AlEt_2Cl$, or $AlEtCl_2$ at 50°C. It was found that each of the above catalyst systems produces a random copolymer at Al/V molar ratios below 1.5; however, polyethylene is mainly obtained above the ratio of 1.5. With the $VO(OEt)_3$/$AlEt_3$ catalyst system, its good catalyst activity being in contrast with the inactivity of the $Ti(O\text{-}n\text{-}Bu)_4$/$AlEt_3$ catalyst system, the maximum catalyst activity was observed at the Al/V molar ratio of 0.5. The copolymerization rate decreased with an increase in the ethylene fraction in the monomer mixture, reaching a minimum value at a 80 mol% ethylene feed; however, the rate increased above this feed ratio with a further increase in the ethylene feed. The contamination of a copolymer with polyethylene which has been observed in the copolymerization by the $Ti(O\text{-}n\text{-}Bu)_4$/$AlEt_2Cl$ or $AlEtCl_2$ catalyst system was not observed in the present case. The monomer reactivity ratios for the copolymerization by the $VO(OEt)_3$/$AlEt_3$ catalyst system were found to be r_1(vinyl chloride)=2.48 and r_2(ethylene)=0.02. The reaction between $VO(OEt)_3$ and $AlEt_3$ was investigated by means of infrared spectroscopy and gasometry, and it was found that the average valency states of the V of the catalyst system is higher than four at the Al/V molar ratio range where a random copolymer is exclusively obtained.

The copolymerization of vinyl chloride with ethylene has been drawing attention from the fundamental as well as from the industrial point of view. In previous papers[1-4] the present authors have already reported the copolymerization of vinyl chloride with ethylene by the trialkylboron/peroxide as well as by the $Ti(O\text{-}n\text{-}Bu)_4$/alkylaluminum catalyst systems. The copolymerization by Ziegler-Natta catalysts seems especially interesting in view of the expectation that ethylene is more susceptible to coordination polymerization than to free-radical polymerization; a copolymer richer in ethylene than that obtained from radical copolymerization could be obtained.

The present authors have found that the catalyst systems consisting of alkyl orthovanadate and alkylaluminum can copolymerize vinyl chloride with ethylene; it seems interesting to compare these results with the copolymerization results obtained by using the $Ti(O\text{-}n\text{-}Bu)_4$/alkylaluminum catalyst systems. In this paper, the authors wish to report the general features of the copolymerization of vinyl chloride with ethylene by the $VO(OEt)_3$/alkylaluminum catalyst systems, and also discuss briefly the reaction of the catalyst component in order to elucidate the nature of the active site-formation reaction.

Experimental

Materials. Vinyl chloride supplied by the Chisso Co. was purified by passing it through a column containing calcium chloride and then one containing phosphorous pentoxide. Ethylene supplied by the Nihon Petrochemical Co. was used without further purification. Each alkylaluminum was purified by distillation under reduced pressure and was stored as a normal solution in *n*-heptane. Ethyl orthovanadate was prepared from vanadium pentoxide and absolute ethanol according to the method of Prandtl *et al.*,[5] and was stored much like an alkylaluminum, bp 80°C/5 mmHg. The solvent was purified by shaking it with concentrated sulfuric acid and by distillation over sodium wire.

Polymerization. The reaction vessel was a 100 m*l* stainless-steel autoclave equipped with an electromagnetic agitating device. The catalyst system was

prepared by mixing $VO(OEt)_3$ and an alkylaluminum as a *n*-heptane solution in *n*-heptane at room temperature in the absence of the monomers under a pure nitrogen atmosphere; it was then aged for about one hour prior to use in the polymerization. After the autoclave had been cooled below −40°C, the inner nitrogen was evacuated. Vinyl chloride and then ethylene were introduced into the autoclave according to the method described in a previous paper.[1] Then the autoclave was set in an electric heater and maintained at 50°C for three hours. The resultant products were treated and purified as has been reported in a previous paper.[4] The composition of the product was calculated from the results of elemental C and Cl analyses. The reduced specific viscosity of the polymer was measured in a 0.5 g/100 m*l* cyclohexanone solution at 30.0°C. The infrared spectrum of the polymer was measured with a Hitachi model EPI-S2 infrared spectrometer (KBr disk method). The NMR spectrum of the polymer was measured with a Nihon Denshi model C-60 high-resolution NMR spectrometer at 60 Mc and 110°C in a 10 wt/vol% monochlorobenzene solution, using tetramethylsilane as the internal standard.

Gasometric Measurements. The reaction of $VO(OEt)_3$ and $AlEt_3$ was carried out in an apparatus fitted with a side arm. A *n*-heptane solution of $AlEt_3$, stored in the side arm of the Schlenk apparatus, was added to a *n*-heptane solution of $VO(OEt)_3$ placed in the bottom of the apparatus. During the operation, the catalyst solution was kept at 20°C with stirring under a pure nitrogen atmosphere. The gaseous products were analyzed by means of gas chromatography using a column packed with silica gel at 70°C.

Results and Discussion

The Influence of the Structure of Alkylaluminum. Table 1 summarizes the results of the copolymerization of vinyl chloride with ethylene by the $VO(OEt)_3/AlEt_mCl_{3-m}$ catalyst systems at various Al/V molar ratios. Figure 1 shows the infrared spectra of the copolymerization products obtained by some of the catalyst systems shown in Table 1. As has been reported in a previous paper,[6] a random copolymer of vinyl chloride with ethylene shows a characteristic absorption at 745 cm^{-1}, an absorption which has been assigned to the methylene rocking mode of a boundary structure in the copolymer chain as follows:

$$-CHCl-CH_2-CH_2-CH_2-CHCl-$$

On the basis of the arguments presented in a previous paper,[4] it follows, from the results shown

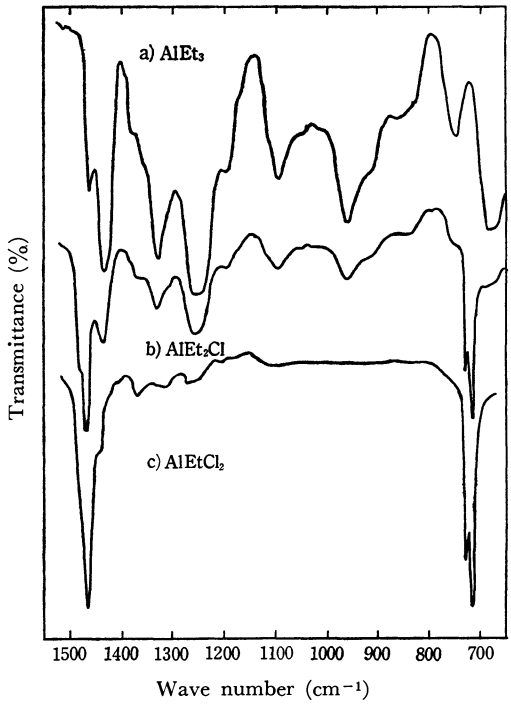

Fig. 1. Infrared spectra of copolymerization products.
a) Al/V=1.5, VCl mol%=82.3
b) Al/V=3.0, VCl mol%=14.1
c) Al/V=5.0, VCl mol%=1.0

Table 1. Copolymerization results by the $VO(OEt)_3/AlEt_mCl_{3-m}$ catalyst systems

Alkylaluminum	Al/V molar ratio	Yield(%)	VCl mol% in product	Main product	η_{sp}/c (dl/g)
$AlEt_3$	1.5	11.3	82.3	Copolymer	0.346
$AlEt_3$	3.0	3.2	6.4	PE	—
$AlEt_3$	5.0	0.3	18.3	PE+Copolymer	—
$AlEt_2Cl$	1.5	5.8	86.6	Copolymer	0.367
$AlEt_2Cl$	3.0	13.1	14.1	PE+Copolymer	—
$AlEt_2Cl$	5.0	25.2	2.5	PE	—
$AlEtCl_2$	1.5	2.6	82.5	Copolymer	0.283

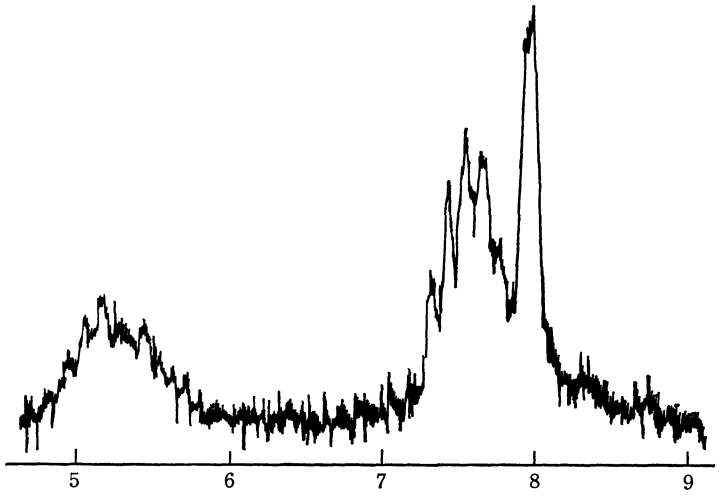

Fig. 2. NMR spectrum of a copolymer (VCl mol% = 82.3)

in Table 1 and Fig. 1, that the catalyst systems consisting of $VO(OEt)_3$ and each alkylaluminum produce random copolymers at the Al/V molar ratio of 1.5. Figure 2 shows the NMR spectrum of the copolymerization product obtained by the $VO(OEt)_3/AlEt_3$ catalyst system at the Al/V molar ratio of 1.5. The resonance peak observed at 8.35 τ has been assigned to the protons of a methylene group having a methine and a methylene group in the nearest neighbors in the copolymer chain presented above,[7] also indicating that the product consists of a random copolymer.

At the Al/V molar ratio of 3 and 5, the resultant products are composed mainly of polyethylene. However, a considerable amount of vinyl chloride was found in the products obtained by the $VO(OEt)_3/AlEt_2Cl$ catalyst system at the Al/V molar ratio of 3. The results of successive solvent extractions using tetrahydrofuran and monochlorobenzene indicate that the products consist of a random copolymer (26.0wt%) and polyethylene (74.0wt%).

The Influence of the Al/V Molar Ratio. With the $VO(OEt)_3/AlEt_2Cl$ or $AlEtCl_2$ catalyst system, the copolymer yield increases remarkably with an increase in the Al/V molar ratio at higher molar ratio, where polyethylene is the main product. These tendencies are analogous to what has been observed in the copolymerization by the $Ti(O\text{-}n\text{-}Bu)_4/AlEt_2Cl$ or $AlEtCl_2$ catalyst system. On the other hand, the copolymer yield decreases with an increase in the Al/V molar ratio when the $VO(OEt)_3/AlEt_3$ catalyst system is adopted. At Al/V molar ratio below 1.5 in the copolymerization by this catalyst system, the products consists exclusively of random copolymers with essentially the same compositions as that obtained at the ratio of 1.5.

In the copolymerization by the $VO(OEt)_3/AlEt_3$ catalyst system, the copolymer yield increases with an increase in Al/V molar ratio, reaching the maximum at the ratio of 0.5, and then it decreases continuously at ratios higher than this, as is shown in Fig. 3. It is interesting to note that $AlEt_3$, in combination with $VO(OEt)_3$, shows such a good catalyst activity in the copolymerization of vinyl chloride with ethylene in spite of the fact it is inactive in the copolymerization when combined with $Ti(O\text{-}n\text{-}Bu)_4$.

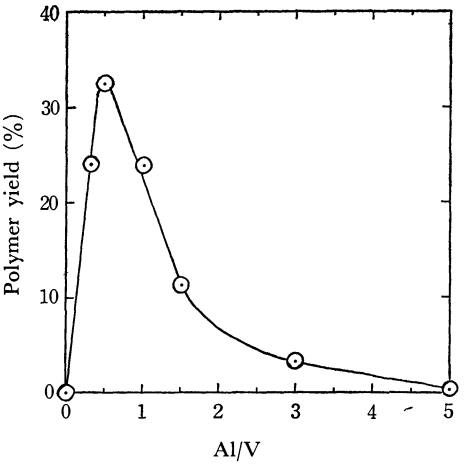

Fig. 3. Influence of the Al/V molar ratio.
Experimental conditions: vinyl chloride, 0.3 mol; ethylene, 0.2 mol; $VO(OEt)_3$, 2.0 mmol; $AlEt_3$, varied; solvent, *n*-heptane; volume of catalyst solution, 50 m*l*; polymerization temperature, 50°C; polymerization time, 3 hr.

7) A. Misono, Y. Uchida and K. Yamada, Preprints for the 21st Annual Meeting of Chemical Society of Japan (Osaka, 1968), No. 17313.

The Influence of the Monomer Feed Ratio. The copolymerization products obtained by using the $VO(OEt)_3/AlEt_3$ catalyst system at Al/V molar ratios lower than 1.5 at various monomer feed ratios consist exclusively of random copolymers, and there occurs no such contamination of the copolymer with polyethylene as has been observed in the copolymerization by the $Ti(O\text{-}n\text{-}Bu)_4$/alkylaluminum catalyst systems at higher ethylene feed ratios.[4] Therefore, it may be considered that only one kind of active site producing random copolymers exclusively operates in the copolymerization by the $VO(OEt)_3/AlEt_3$ catalyst system at relatively low Al/V molar ratios. The rate of copolymerization and the reduced specific viscosity of the copolymer decrease with an increase in the ethylene feed ratio, reaching a minimum value at 80 mol% ethylene feed ratio, as is shown in Fig. 4. The facts that the copolymerization rate again increases above this ethylene feed ratio, and that ethylene homopolymerizes in the presence of the catalyst systems active in the vinyl chloride-ethylene copolymerization, are in contrast with what has been observed in the copolymerization by the $Ti(O\text{-}n\text{-}Bu)_4$/alkylaluminum catalyst systems.

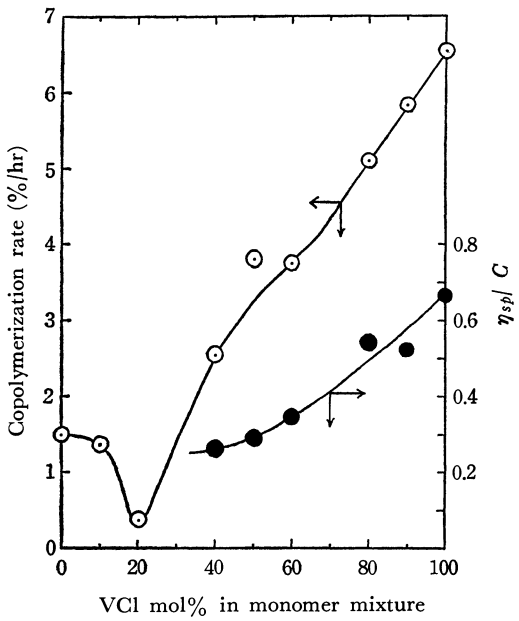

Fig. 4. Influence of monomer feed ratio. Experimental conditions: vinyl chloride + ethylene, 0.5 mol; $VO(OEt)_3$, 2.0 mmol; Al/V, 1.5; volume of catalyst solution, 50 ml; polymerization temperature, 50°C; polymerization time, 3 hr.

The Copolymer Composition. The copolymer composition curve for the copolymerization by the $VO(OEt)_3/AlEt_3$ catalyst system is shown in Fig. 5. The compositions of the copolymers obtained by the $VO(OEt)_3/AlEt_2Cl$ or $AlEtCl_2$ were 86.6 and 85.5 mol% vinyl chloride respectively; these values are comparable to that of 82.3 mol% vinyl chloride obtained for the $VO(OEt)_3/AlEt_3$ catalyst system. Using the Fineman-Ross plot shown in Fig. 6, the monomer reactivity ratios were determined; in Table 2 they are compared with those found in the copolymerization by the $Ti(O\text{-}n\text{-}Bu)_4$/alkylaluminum as well as those obtained by the use of the trialkylboron/peroxide catalyst systems. The monomer reactivity ratios found in the copolymerization catalyzed by the $VO(OEt)_3/AlEt_3$ catalyst system are of values

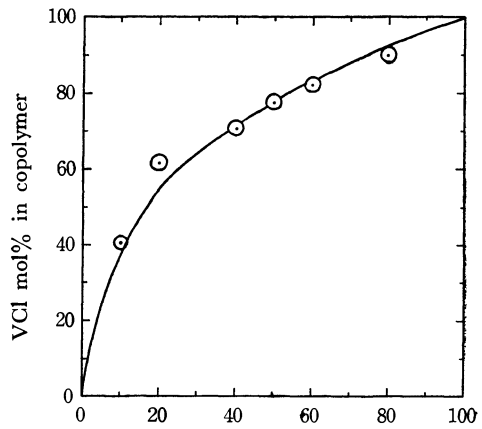

Fig. 5. Copolymer composition curve obtained by the $VO(OEt)_3$-$AlEt_3$ catalyst system at the Al/V molar ratio of 1.5.

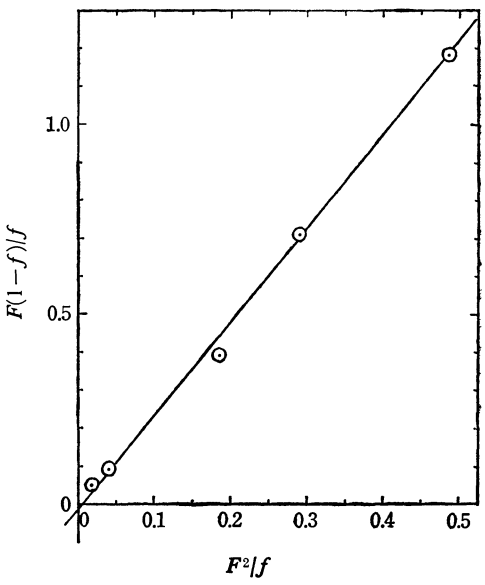

Fig. 6. Determination of r_1 and r_2 by Fineman-Ross method.

intermediate between those found for the $Ti(O-n-Bu)_4$/alkylaluminum-catalyzed and the trialkylboron-catalyzed copolymerizations. The copolymerization catalyzed by the alkyl orthovanadate catalyst system seems to be of a more radical nature than that catalyzed with the alkyl titanate catalyst systems, judging from the monomer reactivity ratios. The copolymerization by the $VO(OEt)_3/AlEt_3$ catalyst system was completely inhibited upon the addition of diphenylpycrylhydrazyl in an amount equimolar to $VO(OEt)_3$. However, it seems unclear whether or not this fact directly supports a radical polymerization mechanism for a reason presented in a previous paper.[4]

Table 2. Comparison of monomer reactivity ratios

$VO(OEt)_3/AlEt_3$	2.48	0.02	this work

t-BHP: *t*-butyl hydroperoxide, THF: tetrahydrofuran

Observation of the Catalyst System. $VO(OEt)_3$ reacts with $AlEt_3$, with gas evolution, to form a colored solution in *n*-heptane; this indicates the occurence of a chemical reaction between the two components. At Al/V molar ratios higher than unity, the dark brown color of the catalyst solution grows deeper as the molar ratio increases. At Al/V molar ratios lower than unity, however, the brown color of the catalyst solution observed soon after it is prepared gradually fades and a green color appears; the solution is essentially green when it has been aged for about one hour. Each color change suggests the presence of a new chemical species and illustrates the complexity of the catalyst-forming reaction. In order to obtained further information concerning the active site-forming reaction, the $VO(OEt)_3/AlEt_3$ catalyst system was investigated by means of infrared spectroscopy and gasometry.

Figure 7 shows the infrared spectra of both the catalyst components, together with that of diethylaluminum ethoxide, each sample having been prepared as a *n*-heptane solution. Sekiguchi *et al.*[8] have studied the infrared spectrum of alkyl orthovanadates in their crude phase. They have considered the strong absorption at 970 cm^{-1} of $VO(O-i-Pr)_3$, which shifted to a somewhat lower

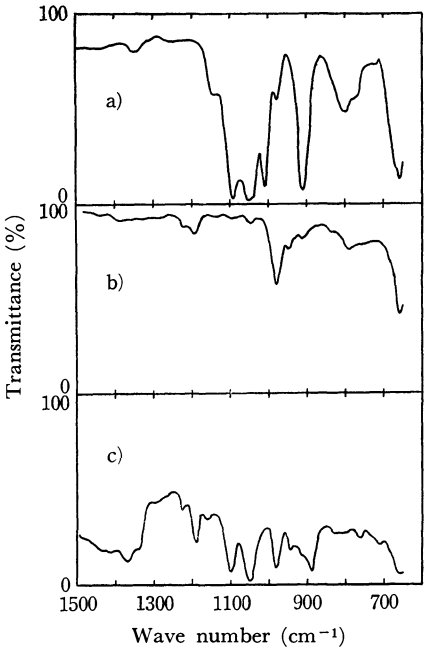

Fig. 7. Infrared spectra of catalyst components.
a) $VO(OEt)_3$ in *n*-heptane, 40 mmol/*l*
b) $AlEt_3$ in *n*-heptane, 40 mmol/*l*
c) $AlEt_2(OEt)$ in *n*-heptane, *ca.* 100 mmol/*l*.

frequency in the case of $VO(OEt)_3$, to be due to the V–O–C structure in the orthovanadates. No such a strong absorption is observed in the spectrum of $VO(OEt)_3$ There are no other available data concerning the infrared spectra of $VO(OEt)_3$ and other alkyl orthovanadates; hence, not even tentative assignments of the absorptions observed in the spectrum under consideration have yet been made.

Figure 8 shows the infrared spectra of the catalyst solutions in *n*-heptane at various Al/V molar ratios, the concentration of $VO(OEt)_3$ in each solution being adjusted to 40 mmol/*l*. It is obvious from the spectra shown in Figs. 7 and 8 that, in addition to the absorptions of both $VO(OEt)_3$ and $AlEt_3$, some new absorptions appear in the spectrum of the catalyst solution. For example, a strong and sharp band appears at 890 cm^{-1}. However, it is not clear whether this band arises from the V–O–C structure, which would shift to a lower frequency on complex-formation with $AlEt_3$, or from the Al–O–C structure, which would be formed in the ligand exchange reaction between $VO(OEt)_3$ and $AlEt_3$. A weak absorption at 1155 cm^{-1}, which is not observed in the spectrum of each component, slightly shifts to 1160 cm^{-1} as the Al/V molar ratio of the catalyst system increases. The original strong bands of $VO(OEt)_3$ at 1010, 910, and 800 cm^{-1} quickly disappear as the Al/V molar ratio increases from 0.25 to 1.0, whereas those at 1090 and 1050 cm^{-1} keep their original intensities

8) S. Sekiguchi and A. Kurihara, *Kogyo Kagaku Zasshi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **69**, 2002 (1966).

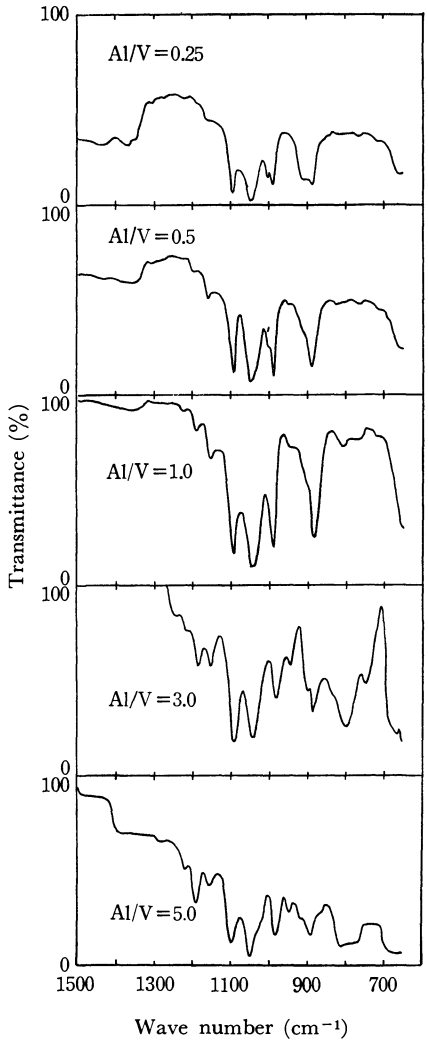

Fig. 8. Infrared spectra of catalyst solutions.

almost independent of the Al/V molar ratio. The absorption at 1090 cm^{-1}, however, shifts to 1100 cm^{-1} as the Al/V molar ratio increases. Other absorptions are observed in the spectrum of the catalyst solution which may be due to $AlEt_3$ present in the solution absorptions at 1225 (weak), 1190(weak), 985(strong), and 800(weak when Al/V<1.0, but strong when Al/V>3.0) cm^{-1}.

It is obvious that the spectrum of the catalyst solution becomes similar to that of $AlEt_2(OEt)$ as the Al/V molar ratio increases, and that the spectrum at the ratio of 5 is essentially identical with that of $AlEt_2(OEt)$ over the frequency range from 850 to 1300 cm^{-1}. The absorptions at 1160, 1100, and 890 cm^{-1} in the spectrum of $AlEt_2$-(OEt) may be related to the Al–O–C structure in the catalyst solution, judging from the results of a comparison of it with the spectrum of $AlEt_3$. Such absorptions are also observed in the spectrum of the catalyst solution, as has been mentioned previously. In the spectrum of $Al(O\text{-}n\text{-}Bu)_3$ the Al–O–C stretching mode appears at 1080 cm^{-1}. Therefore, one or both of the strong absorptions at 1050 and 1090 cm^{-1}, and the resulting overlapping of the absorptions arising from the two different chemical species, make it impossible to measure quantitatively the concentration of the Al–O–C structure in the catalyst system.

From the results mentioned above, it is, at any rate, obvious that the catalyst system is not a mere mixture of the two components, but that some ligand exchange reaction proceeds, leading to the formation of the Al–O–Et and the V–Et structure in the catalyst system:

$$VO(OEt)_3 + AlEt_3 \rightarrow EtVO(OEt)_2 + AlEt_2(OEt)$$

followed by the reductive dealkylation of the unstable organovanadium compound:

$$EtVO(OEt)_2 \rightarrow VO(OEt)_2 + Et\cdot$$

At higher Al/V molar ratios, ligand exchange and reductive dealkylation may be considered to proceed successively.

Figure 9 shows the amount of gaseous products liberated from the catalyst solution plotted *versus* the reaction time for the reaction of $VO(OEt)_3$ with $AlEt_3$ at 20°C. The gaseous products from the reactions of these two components at the Al/V molar ratio of 1.0 were analyzed after a reaction period of 72 hr; they were found to be composed of ethane and ethylene (1.00 : 0.64), only a small amount of C_4 fractions, and a considerable amount of an unidentified product the peak of which in the gas chromatogram appeared behind the position of that of *n*-heptane. Assuming the unidentified product to be a C_9 fraction resulting from the

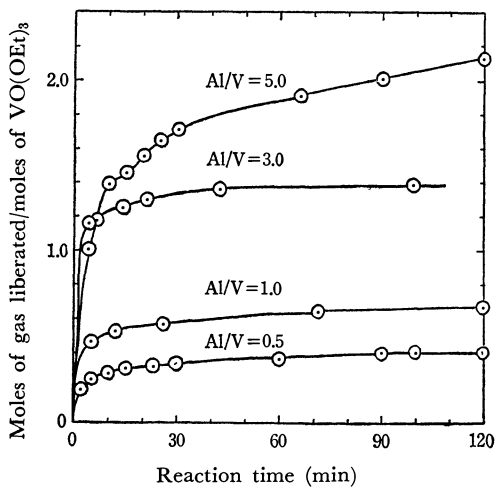

Fig. 9. Reaction of $VO(OEt)_3$ with $AlEt_3$. Experimental conditions: $VO(OEt)_3$, 1.0 mmol, 0.5 mmol for Al/V=3.0); solvent, *n*-heptane; volume of catalyst solution, 10 m*l*; reaction temperature, 20°C.

reaction of the ethyl radical with the solvent, its amount could be estimated to be about 20 mol%.

As the reduction of one mole of each organovanadium compound by one valency state leads to the liberation of one mole of gaseous products, it is possible to estimate the average valency state of vanadium in the catalyst system from the results shown in Fig. 9. Figure 10 shows the average valency state of vanadium after the reaction period of one hour plotted against the Al/V molar ratio of the catalyst system. It is obvious that, at the lower Al/V molar ratios, where random copolymers are obtained, the vanadium in the catalyst system is in the valency states higher than four; however, the valency state of vanadium is lower than four at the higher Al/V molar ratios, where polyethylene is mainly obtained in the copolymerization of vinyl chloride with ethylene. This is analogous to what has been considered to hold in the copolymerization of vinyl chloride with ethylene by the $Ti(O\text{-}n\text{-}Bu)_4/AlEtCl_2$ catalyst system[3,9]; the active site producing a random copolymer in this catalyst system may be a titanium complex in a higher valency state, probably a tetravalent one.

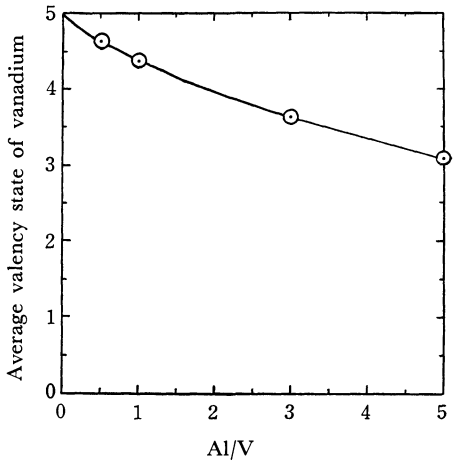

Fig. 10. Average valency state of vanadium *vs.* Al/V molar ratio.

At this stage of invesigation, it can tentatively be considered that the active site in the copolymerization of vinyl chloride with ethylene by the $VO(OEt)_3$/alkylaluminum catalyst systems is an unstable carbon-vanadium bond resulting from the ligand exchange reaction between the two components, as has usually been assumed in polymerizations by Ziegler-Natta catalysts.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 3001—3007 (1968)

The Reductive Coupling Reactions of Benzyl Chloride by Copper(I) Complexes*1

Keisuke WADA and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 21, 1968)

The reactions between benzyl chloride and cuprous chloride were studied. It was found that good yields of bibenzyl were obtained by the addition of ethylenediamine, diethylenetriamine, triethylenetetramine, acetylacetone and EDTA. Nothing of bibenzyl was observed in the cases of ethanolamine, pyridine, dipyridyl, phenanthroline and triphenylphosphine. These facts, together with the spectral studies of copper complexes can reasonably be explained by the formation of reactive species of the type $Cu^{I}(en)_nCl$. The course of the reaction was discussed on the basis of the substituent and medium effects. Radical but not free type mechanisms which include the transient organocopper species were considered. Some additional comments were also made.

It may safely be pointed out that in many of the copper-catalyzed organic reactions the redox ligand transfer processes key roles. In other words, the reaction of organic substrate XY and cuprous complex $Cu^{I}Z$, for example, can be delineated in the following way. (M=Cu).

$$XY + M^{(n-1)+}Z \rightarrow X\cdot + M^{n+}YZ \quad (1)$$

$$X\cdot + M^{(n-1)+}Z \rightarrow XM^{(n-1)+}Z \quad (2)$$

$$X\cdot + X\cdot \rightarrow XX \quad (3)$$

*1 Oxidation-Reduction Reactions by Transition Metal Complexes. III.

$$X\cdot + M^{n+}YZ \rightarrow XZ + M^{(n-1)+}Y$$
$$\text{or } XY + M^{(n-1)+}Z \quad (4)$$
$$X\cdot + SH \rightarrow XH + S\cdot \quad (5)$$
$$S\cdot + M^{n+}YZ \rightarrow SZ + M^{(n-1)+}Y$$
$$\text{or } SY + M^{(n-1)+}Z \quad (4')$$
$$X\cdot + C{=}C \rightarrow X{-}C{-}C\cdot \quad (6)$$
$$X{-}C{-}C\cdot + M^{n+}YZ \rightarrow X{-}C{-}C{-}Z + M^{(n-1)+}Y$$
$$\text{or } X{-}C{-}C{-}Y + M^{(n-1)+}Z \quad (4'')$$

The well-known copper-catalyzed peroxide reactions are typical of these processes.[1,2] Similar argument may possibly be made to the Sandmeyer-Meerwein reactions,[3] to the copper-catalyzed halogen transfer reactions[4-13] and, to some extent, to the copper-catalyzed halogen exchange reactions of aryl halides.[14-16]

The reaction (4) is commonly called "ligand transfer oxidation." This process, though not sufficiently, is relatively well studied and some discussion was already made by us in the previous studies of this series.[17] Little is known, however, about the reaction (1) which we tentatively named "ligand transfer reduction." Much is to be learned about the nature of the interaction of low valent copper complexes with organic structures in somewhat simplified reaction environments.

In this paper, the reactions of cuprous complexes and organic halides will be discussed.

Experimental

Materials. Cuprous perchlorate $CuClO_4 \cdot CH_3CN$ was prepared according to the method of Kubota and Johnston.[18] Cuprous chloride, bromide, iodide and cyanide were commercial reagent grade and purified as usual manner. Authentic samples of dichloro-bis-ethylene-diamine copper(II) and dichloro-monoethylenediamine copper(II) were prepared by the method of Olszewski and Martin.[19]

Benzyl chloride and benzyl bromide were reagent grade and distilled twice. Benzyl iodide was prepared according to the method of Coleman and Hanser.[20] *p*-Methoxybenzyl chloride was synthesized from *p*-methoxybenzyl alcohol.[21] *p*-Methylbenzyl chloride, *p*-chlorobenzyl chloride and *p*-nitrobenzyl chloride were commercially first grade. All of these benzyl chlorides were checked by NMR spectra.

Reagent grade ethanolamine, ethylenediamine, diethylenetriamine, triethylenetetramine, pyridine, bipyridyl, phenanthroline, EDTA, triphenylphosphine and acetylacetone were used. Some of these were recrystallized or distilled if necessary. Sodium acetylacetonate was prepared from acetylacetone and sodium metal.

Acetonitrile was purified by the method of O'Donnell *et al.*[22] Dimethyl sulfoxide and Dimethylformamide were purified according to the method of Gutmann *et al.*[23] and Thomas *et al.*[24]

Typical Reaction Procedure. Benzyl chloride (0.633 g, 0.500×10^{-2} mol) and cuprous chloride (0.990 g, 1.00×10^{-2} mol) were dissolved in 40 m*l* of acetonitrile in a four-necked, 100 m*l*, round-bottomed flask equipped with a 30 cm Dimroth condenser, a nitrogen inlet, a thermometer, a dropping funnel and a magnetic stirrer. The solution was then swept with oxygen-free nitrogen and heated with stirring to the refluxing temperature. At that time, a solution of ethylenediamine (0.601 g, 1.00×10^{-2} mol) in 10 m*l* of acetonitrile was added through the dropping funnel. The reaction was continued for an hour under nitrogen stream.

Product Analyses. Two types of the standard methods were employed for the product analysis. In the first method the reaction mixture was treated with water, extracted with heptane, dried on sodium sulfate, concentrated to *ca.* 5 m*l* volume and analyzed by g.l.c. In the second, the solvent was removed by distillation from the reaction mixture. In this procedure the temperature of oil bath was maintained at 90°C. The remaining solid was treated with benzene and filtered. The filtrate was again concentrated to *ca.* 5 m*l* and analyzed by g.l.c. employing a 2 m silicone DC 550 column at 80 and 160°C. Bromobenzene and *p*-nitrotoluene were used as markers. The qualitative analyses by NMR and IR spectra were also made in some cases. The analytical values of the products but toluene did not markedly differ from one another

in these two methods. Hence, almost all analyses were conducted according to the latter. The violet crystals remaining in the filter were dried *in vacuo* for several days and checked by elemental analyses, powdered X-ray diffraction patterns, electronic, vibrational and paramagnetic resonance spectra.

In the cases of competitive reactions of *p*-substituted benzyl chlorides, quantitative analyses were undertaken by nuclear magnetic resonance spectra. The chemical shifts used to identify the materials were tabulated in Table 1. Diphenylmethane was used as marker.

Results and Discussion

The Effect of Ethylenediamine. The results of reactions in acetonitrile are summarized in Tables 2, 3, 4 and 5. It should be noted that complexing of the cuprous ion with ligands such as ethylenediamine greatly enhance its ability to reduce benzyl chloride to toluene and bibenzyl. It was also found that even the less reactive iodobenzene is successfully reduced by these cuprous complexes. These results are somewhat interesting since only the reactive substrates such as organic peroxides and polyhalohydrocarbons have shown to be sensitive to the normal cuprous ion at moderately low temperature.[1-13]

The yield of bibenzyl increases monotonously with cuprous ion concentration. In contrast, a small but definite retarding effect is observed when a large excess of ethylenediamine exists in the system. This may possibly be due to the

inaccessibility of benzyl chloride to the coordinative site of copper ion by the intervention of ethylenediamine which occupy the coordination sphere preferentially. This view of the reaction is supported by the results of supplementary experiments C and D in Table 6. To some extent, the retarding effect is also ascribed to the side-reaction of benzyl chloride with ethylenediamine. The NMR studies of the reaction products, however, have shown that the effect is not interpreted by the latter mechanism only.

Furthermore, the experiments C and D in Table 6 support the idea that the intrinsic reagent in the system is cuprous complexes of the type $Cu^I(en)_nCl$. Though the details of the complexes are not yet clear, the species is found to be sensitive to the molecular oxygen and oxidized easily to the stable copper(II) state. This is cofirmed by the reaction E in Table 6. The yield of bibenzyl is considerably decreased by the preliminary contact with oxygen. The marked difference between the reactions B and E may be understood if we assume that the rates of the reactions between the complexes and benzyl chloride are faster than that of air oxidation.

As is seen in Table 3, in addition to ethylenediamine, several other ligands such as diethylenetriamine, triethylenetetramine, EDTA and acetylacetone are effectively used to promote the reaction. Monoethanolamine, however, and pyridine, dipyridyl, *o*-phenanthroline and triphenylphosphine are ineffective. These facts remind us of the change in the oxidation-reduction potential of copper(II)-copper(I) couple by complexing. The data of the potentials from references are listed in Table 7. There seems to be a certain relationship between the ligand effect and the potentials.[25-30] Thus, we conclude with some hesitation that the accelerating effects of the ligands exist in the formation of the reactive copper(I) complexes.

Studies of Copper(I) and Copper(II) Complexes. From the discussion given above the general feature of the reaction is profiled as follows.

$$Cu^ICl + n(en) \rightarrow Cu^I(en)_nCl \quad (7)$$

$$2C_6H_5CH_2Cl + 2Cu^I(en)_nCl \rightarrow (C_6H_5CH_2)_2 + 2Cu^{II}(en)_nCl_2 \quad (8)$$

As is shown in Fig. 1, a remarkable spectral change is observed when ethylenediamine is added to the solution of cuprous chloride in acetonitrile, assuring the formation of cuprous complexes. Further

change is also observed if an amount of benzyl chloride is introduced to this solution. This last spectrum, together with the studies about isolated cupric complexes from typical runs, strongly suggests the production of cupric complexes of the type $Cu^{II}(en)_nCl_2$. These are illustrated in Table 8. It has been shown that the complexes produced are $Cu^{II}(en)Cl_2$ and $Cu^{II}(en)_2Cl_2$ in the reactions of ratios halide: Cu^{I} : en = 1 : 2 : 2 and 1 : 2 : 4, respectively.

The Mechanisms of the Reaction. As in the case of ligand transfer oxidation, the reverse process is explainable by the following scheme.

$$C_6H_5CH_2Cl + Cu^{I}Cl \rightarrow C_6H_5CH_2Cl\cdot Cu^{I}Cl \quad (9)$$

$$C_6H_5CH_2Cl\cdot Cu^{I}Cl \rightarrow [C_6H_5CH_2\overset{\circ}{\underset{\circ}{}}Cl\circ Cu^{II}Cl \longleftrightarrow \text{(J)}$$

$$C_6H_5CH_2^{-}\overset{\circ}{\underset{\circ}{}}Cl + Cu^{II}Cl \longleftrightarrow \text{(K)}$$

$$C_6H_5CH_2^{+}\circ Cl^{-}\overset{\circ}{\underset{\circ}{}}Cu^{II}Cl] \rightarrow \text{(L)}$$

$$C_6H_5CH_2^{\circ}\cdot ClCu^{II}Cl \quad (10)^{31}$$

This scheme certainly reflects the close similarity to the chlorine atom abstraction reactions by organic radicals. The contribution of step (9) is fairly plausible since our recent work have revealed that a stable cuprous complex $Cu^ICl(C_6H_5CH_2I)$-$(TPP)_2$ is quantitatively obtained in the reaction of cuprous chloride, benzyl iodide and triphenylphosphine in acetonitrile.[33]

Concerning the reaction step (10), the substituent effect on benzyl chloride was examined. The results are in Table 9. Though the effect observed is very feasible, its electrophilic character may probably refer to the contribution of the structure (K).[31] The extraordinary large effect of nitro group, reminiscent of its effect in Ullmann coupling reaction,[34] can be ascribed to the considerable resonance term. *p*-Methoxybenzyl chloride is so unstable that certain side reactions must be present in its competitive reaction, and hence the datum is that for only reference.

Although the radical feature of the reaction is backed up by the formation of coupling product and the data in Table 3, there remains some uncertainty. To assure this, several additional experiments were achieved. Tables 10 and 11 illustrate the effects of solvents and hydrogen donors. No appreciable change, however, is observed in the yield of toluene despite rather large

33) K. Wada and H. Hashimoto, to be published.

34) P. E. Fanta, *Chem. Revs.*, **64**, 613 (1964).

changes in environment. Therefore, the existence of benzyl radical in its free state is hardly accepted. Hence, it appears plausible to presume the mechanisms depicted below.

$$2C_6H_5CH_2\cdot ClCu^{II}Cl \rightarrow (C_6H_5CH_2)_2 + 2Cu^{II}Cl_2 \quad (11)$$

$$C_6H_5CH_2\cdot ClCu^{II}Cl + C_6H_5CH_2Cl + Cu^{I}Cl \rightarrow (C_6H_5CH_2)_2 + 2Cu^{II}Cl_2 \quad (12)$$

$$C_6H_5CH_2\cdot ClCu^{II}Cl + Cu^{I}Cl \rightarrow C_6H_5CH_2\cdot Cu^{I}Cl + Cu^{II}Cl_2 \quad (13)$$

$$C_6H_5CH_2\cdot Cu^{I}Cl + C_6H_5CH_2Cl \rightarrow (C_6H_5CH_2)_2 + Cu^{II}Cl_2 \quad (14)$$

$$2C_6H_5CH_2\cdot Cu^{I}Cl \rightarrow (C_6H_5CH_2)_2 + 2Cu^{I}Cl \quad (15)$$

At the present stage, however, we are not able to decide which of these processes prevails.

Finally, some comments must be made about the reactions of chromous species. Recent works by several groups of laboratories have shown that the relatively longlived organochromium species are effectively formed in the reactions of alkyl halides and chromous ion.[35-39] The hydrolysis and dimerization reactions of these species were also studied and various mechanisms have been discussed for these reactions. For example, Kochi and his coworkers have suggested the following scheme.[29,30,35-38]

$$C_6H_5CH_2Br + Cr^{II}_{aq} \rightarrow C_6H_5CH_2\cdot + Cr^{III}Br_{aq} \quad (16)$$

$$C_6H_5CH_2\cdot + Cr^{II}_{aq} \rightarrow C_6H_5CH_2\cdot Cr^{II}_{aq} \quad (17)$$

$$C_6H_5CH_2Cr^{II}_{aq} + C_6H_5CH_2Br \rightarrow (C_6H_5CH_2)_2 + Cr^{III}Br_{aq} \quad (18)$$

In contrast to our results mentioned above, free benzyl radical is included in their scheme.

Further works must be necessary for the discussion of this discrepancy.

$$R\cdot + S\text{-}T \rightarrow [R\cdot S:T \longleftrightarrow R^-:S\cdot{}^+T \longleftrightarrow R:S\cdot T] \rightarrow R\text{-}S + \cdot T \quad (19)$$

The mechanism (19), however we think, is erroneous or not sufficient for its unreasonably estimated resonance terms.

Here, we are rather inclined to suggest a more reasonable reformation. The Eq. (20) is a schematical description of transition state in our idea.

$$\underset{(O)}{R\cdot S:T} \longleftrightarrow \underset{(P)}{R^-:S^+\cdot} \longleftrightarrow \underset{(Q)}{R^+S^-\!\!:\!\!\cdot T} \quad (20)$$

The structure (O) represents the system in which one electron stays in the half-occupied orbital of group R and two electron in the S–T bonding orbital. The structure (P) is a picture of a charge transfer from S–T bonding orbital to originally half-occupied orbital of group R. A charge transfer from half-occupied orbital to S–T antibonding orbital is drawn out by the structure (Q). It may be considered that the position of group S and the charge distribution in the transition state and hence the degree of the contribution of (O), (P) and (Q) are changed variously from reaction to reaction.

In most of the organic reactions, the contribution of the structure (P) prevails. In the reactions of copper complexes, however, the larger contribution may be expected from the structure (Q).

In the case of ligand transfer oxidation of phenyl radical,[17] the groups R, S and T, correspond to phenyl group, chlorine atom and cupric ion, respectively. In this system the structure (P) needs the unstable $(3d)^8$ configuration of copper moiety. In the ligand transfer reduction of benzyl chloride, cuprous ion, chlorine atom and benzyl group are expressed by R, S and T respectively. In this case, the structure (P) demands the configuration of $(3d)^{10}$ (4s) character. This configuration is also rather difficult to be achieved at the condition employed. Thus, it may be concluded that the substituent effects in both of the reactions are well explained by the contribution of relatively favourable structure (Q).

It may safely be pointed out also that the nucleophilic character of attacking radical which is overlooked by Russell's mechanism can successfully be introduced by this consideration.

The comments mentioned above is not at all a qualitative one. Thus, a more elaborated refinement must be made for the discussion of the detail aspects of the group transfer reactions.

NOTES

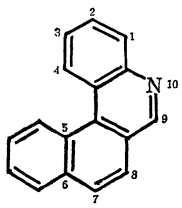
Synthesis of 5 : 6-Benzphenanthridines

V. KESAVAN, V. C. DEVANATHAN and N. ARUMUGAM

Department of Chemistry, Madurai University, Madurai-2, South India

(Received January 11, 1968)

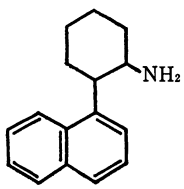
5:6-Benzphenanthridine (A) is one of the six benzphenanthridines possible depending upon the manner of fusion of a benzene ring to the phenanthridine nucleus.



A

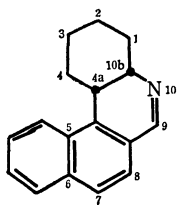
The synthesis of this benzphenanthridine nucleus has not received much attention. Mills and Schofield[1] reported the syntheses of a few 5 : 6-benzphenanthridines by cyclisation of 1-*O*-acylaminophenylnaphthalenes. But the handicap in this method, according to the above authors was the low yields of 1-(*o*-nitroaryl)naphthalenes from the Ullmann reaction of the relevant halo compounds. Brown and co-workers[2] recorded the synthesis of *N*-methyl-5:6-benzphenanthridone from 1-amino-*N*-methyl-2-naphthalide and the difficulty in this approach is stated to be the preparation of 1-amino-2-naphthoic acid. Keene and Schofield[3] had employed Schmidt reaction of benzofluorenone which resulted in the difficultly separable mixture of 3:4- and 5:6-benzphenanthridones. We report here the syntheses of a few 5:6-benzphenanthridines through the well known Bruckner method.[4]

Addition of dinitrogen trioxide to 1-(α-naphthyl)-cyclohexene yields according to the conditions 1-(α-naphthyl)-2-nitrocyclohexene and an alkali soluble compound (X), mp 210°C. This behaviour of 1-(α-naphthyl)-cyclohexene is similar to 1-phenyl- or 1-substituted phenylcyclohexenes.[5,6] The reduction of 1-(α-naphthyl)-2-nitrocyclohexene by lithium aluminum hydride gave the *cis*-2-(α-naphthyl)-cyclohexylamine (B) in good yields. The amino group in this amine is shown to be axial on the basis of the IR spectrum and comparison with the trans isomer.[7]



B

The formyl, acetyl and the benzoyl derivatives of this amine when cyclised with 4:5 phosphorus pentoxide-phosphoric acid mixture yielded the corresponding *cis*-1,2,3,4,4a,10b-hexahydro-5:6-benzphenanthridines (C).



C

The above hexahydrobenzphenanthridines on dehydrogenation over palladised charcoal in decalin yielded the fully aromatised 5:6-benzphenanthridines.

The 1-(4-methyl-1-naphthyl)-cyclohex-1-ene, 1-(4-methoxy-1-naphthyl)-cyclohex-1-ene and 1-(9'-phenanthryl)-cyclohexene when carried through a

	Benzoyl	200 (alcohol)	$C_{27}H_{25}NO$	C, 85.6 H, 6.6	C, 85.5 H, 6.8	

similar series of reactions yielded (i) *cis*-7,9-dimethyl-1,2,3,4,4a,10b-hexahydro-5:6-benzphenanthridine, (ii) *cis*-7-methyl-9-phenyl-1,2,3,4,4*a*,10*b*-hexahydro-5:6-benzphenanthridine, (iii) *cis*-9-methyl-7-methoxy-1,2,3,4,4a,10b-hexahydro-5:6-benzphenanthridine, (iv) *cis*-9-methyl-1,2,3,4,4a,10b-hexahydro-5:6,7:8-dibenzphenanthridine and (v) *cis*-9-phenyl-1,2,3,4,4a,10b-hexahydro-5:6,7:8-dibenzphenanthridine. Compounds (i) and (iv) were aromatised to 7,9-dimethyl-5:6-benzphenanthridine and 9-methyl-5:6,7:8-dibenzphenanthridine. The ultraviolet spectra of 9-methyl- and 7,9-dimethyl-5:6-benzphenanthridines are recorded (Fig. 1).

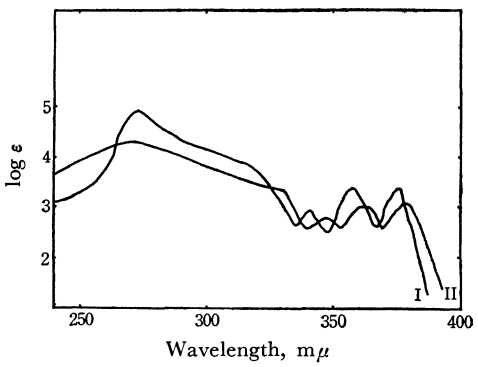

Fig. 1. Ultraviolet spectra of
i: 9-methyl-5:6-benzphenanthridine,
ii: 7,9-dimethyl-5:6-benzphenanthridine.

The compound (X), mp 210°C, mentioned earlier is regarded as 3-nitro-2-(α-naphthyl)-cyclohex-2-en-1-one oxime on the basis of the IR spectrum, and in analogy with the work of Govindachari *et al.*[6] This compound on hydrolysis gives a ketone which can be reconverted to the original compound (X) through hydroxylamine hydrochloride. It is inferred that the similar alkali soluble compcunds obtained from the addition of dinitrogen trioxide to 1-(4-methyl-1-naphthyl)-cyclohex-1-ene and 1-(4-methoxy-1-naphthyl)-cyclohex-1-ene possess structures similar to the compound (X).

Experimental

All melting points are uncorrected. Ultraviolet spectra were taken in Hilger and Watts model 700. Infrared spectra were recorded in Perkin-Elmer model 421. Detailed experimental procedures are presented only for one representative sequence of reactions. All other sequences were conducted in a similar manner using appropriate quantities of reactants. The relevant data are given in tables.

1-(α-Naphthyl)-2-nitrocyclohexene. A mixture of saturated solution of sodium nitrite (50 m*l*) and 1-(α-naphthyl)-cyclohexene (3 g) in ether (50 m*l*) was cooled in ice water and treated with 4 N sulfuric acid in drops till the green colour changed to yellow. The ether layer was immediately separated, washed with water and dried. The combined ether extracts from ten such experiments were treated with sodium (10 g) in methanol (100 m*l*) with vigorous shaking, diluted with water and the basic aqueous layer was separated. The ether layer was washed with 10% sodium hydroxide till free from alkali soluble material, washed with water, dried (sodium sulfate) and evaporated to yield 1-(α-naphthyl)-2-nitrocyclohexene (20 g), mp 95°C (from ether). ν_{max} (KBr) 1640 (-C=C-), 1550 and 1350 cm^{-1} ($-NO_2$).

The alkaline extracts were cooled and acidified with concentrated hydrochloric acid to give 3-nitro-2-(α-naphthyl)-cyclohex-2-en-1-one oxime (8 g) mp 210°C (from ethanol).

Found: C, 67.8; H, 5.2%. Calcd for $C_{16}H_{14}N_2O_3$: C, 68.08; H, 5.0%.

ν_{max} (KBr) 3247 (-OH), 1640 (-C=N) and 1515 and 1337 cm^{-1} ($-NO_2$).

A suspension of the above oxime (3 g) in 4 N sulfuric acid (50 m*l*) and dioxane (30 m*l*) was refluxed for three hours. The mixture was poured onto ice, extracted with ether, dried (sodium sulfate) and evaporated to yield 3-nitro-2-(α-naphthyl)-cyclohex-2-en-1-one (1.5 g), mp 130—131°C (from methanol). This ketone (1 g) and hydroxylamine hydrochloride (1 g) in alcohol (5 m*l*) and pyridine (5 m*l*) refluxed for three hours gave the oxime, mp 210°C (from ethanol). Mixed mp with the 3-nitro-2-(α-naphthyl)-cyclohex-2-en-1-one oxime showed no depression.

***cis*-2-(α-Naphthyl)-cyclohexylamine.** To a stirred solution of lithium aluminum hydride (2 g) in ether was added gradually a solution of 1-(α-naphthyl)-2-nitrocyclohexene (5 g). The mixture was left at 30°C for twenty four hours, then decomposed with water. The ether layer was decanted and extracted repeatedly with 2 N hydrochloric acid. The combined acid extracts were cooled, made alkaline and extracted with ether. The extract on evaporation left *cis*-2-(α-naphthyl)-cyclohexylamine as an oil (3.5 g).

Formyl derivative, mp 160—162°C (from ethanol).

Found: C, 80.4; H, 7.5%. Calcd for $C_{17}H_{19}NO$: C, 80.61; H, 7.5%.

Acetyl derivative, mp 186°C (from benzene - light petroleum).

Found: C, 81.1; H, 7.6%. Calcd for $C_{18}H_{21}NO$: C, 80.9; H, 7.9%.

Benzoyl derivative, mp 165—166°C (from dilute ethanol).

Found: C, 83.9; H, 7.1%. Calcd for $C_{23}H_{23}NO$: C, 83.9; H, 7.0%.

ν_{max} (KBr) 3340 and 3060 cm^{-1} (NH association band for axial -NH).[8]

***cis*-1,2,3,4,4a,10b-Hexahydro-5:6-benzphenanthridine.** A mixture of *cis*-1-formamido-2-(α-naphthyl)-cyclohexane (1 g) and 4:5 phosphorus pentoxide-phosphoric acid (20 g) was heated on an oil bath for two hours at 160°C. The mixture was cooled, decomposed with ice, the aqueous layer made alkaline and extracted with ether. The base in the etheral layer after purification by one more passage through acid gave *cis*-1,2,3,4,4a,10b-hexahydro-5:6-benzphenanthridine as an oil (0.6 g). The picrate prepared in the usual manner was crystallised from alcohol as yellow needles. Mp 239°C (decomp.).

Found: C, 59.8; H, 4.5%. Calcd for $C_{23}H_{20}N_4O_7$: C, 59.5; H, 4.3%.

5:6-Benzphenanthridine. *cis*-1,2,3,4,4a,10b-Hexahydro-5:6-benzphenanthridine (1 g) was dehydrogenated over 30% palladised charcoal (0.5 g) in refluxing decalin (25 m*l*) during eight hours, in a current of nitrogen. The 5:6-benzphenanthridine crystallising from acetone had mp 108°C.

Found: C, 89.2, H, 5.0%. Calcd for $C_{17}H_{11}N$: C, 89.1; H, 4.9%.

λ_{max} 272, 341 and 376 mμ. (log ε 4.5, 3.0 and 3.2 respectively).

The picrate was crystallised from alcohol as yellow needles, mp 253°C (decomp).

Found: C, 60.2; H, 2.9%. Calcd for $C_{23}H_{14}N_4O_7$: C, 60.3; H, 3.1%.

Summary

Syntheses of 5:6-benzphenanthridine, 9-methyl- and 7,9-dimethyl-5:6-benzphenanthridine, 9-methyl-5:6,7:8-dibenzphenanthridine, *cis*-9-phenyl-, *cis*-7-methyl-9-phenyl- and *cis*-7-methoxy-9-phenyl-1,2,3,4,4a,10b-hexahydro-5:6-benz-phenanthridine and *cis*-9-phenyl-1,2,3,4,4a,10b-hexahydro-5:6,7:8-dibenzphenanthridine are reported.

We thank R. Balasubramanian, Department of Chemistry, University of Madras, and CIBA Research Centre, Bombay, for analyses and IR spectra. Our thanks are also due to Government of India and U. G. C. for a scholarship and a Fellowship to V. K. and V. C. D. respectively.

Studies on Heteroaromaticity. XXV.[1] 1,3-Dipolar Cycloaddition of *C*-(2-Benzimidazolyl)-*N*-phenylnitrone

Tadashi SASAKI and Toshio OHISHI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 2, 1968)

In continuation from the previous papers concerning the heterocyclic nitrones involving nitrofuran-[1] and pyrimidine-ring,[2] this paper deals with a nitrone having a benzimidazole ring and its 1,3-dipolar cycloaddition reactivity with dipolarophilic olefins such as styrene and methyl acrylate. *C*-(2-Benzimidazolyl)-*N*-phenylnitrone (I) was readily prepared from benzimidazole-2-carboxaldehyde[3] and phenylhydroxylamine in a 55% yield by the routine procedure.[4] I was relatively stable and could be stored in a brown desiccator but readily decomposed to colored tars in the light.

As typical examples of its 1,3-dipolar cycloaddition reactions, styrene and methyl acrylate were treated in dioxane with I affording the corresponding adducts, II and III, in 40 and 50% yields, respectively. Each structure of both compounds, II and III, was determined by the NMR spectrum. Figure 1 shows the NMR spectrum of

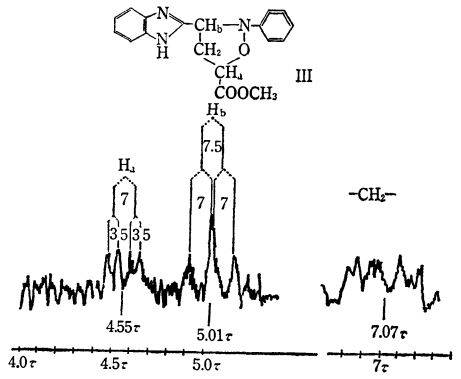

Fig. 1. NMR spectrum of III (DMSO-d_6).

III as an example. The existence of two quartets around 4.55 and 5.01 τ for two methine protons of an isoxazolidine ring in the NMR spectrum supports structure III, which is 5- instead of 4-carbomethoxy structure.[1] Similarly, II is concluded to have 5-phenylisoxazolidine ring. Such a constant direction of the addtion irrespective of the electronic character of a substituent of the olefin demonstrates that this reaction proceeds in the manner similar to that in the case of *C*-(5-nitro-2-furyl)-*N*-phenylnitrone,[1] both followed by the general principle suggested by Huisgen.[5]

Experimental[6]

Preparation of *C*-(2-Benzimidazolyl)-*N*-phenylnitrone (I). A solution of 6 g (41 mmol) of benzimidazole-2-carboxaldehyde[3] and 8 g (40 mmol) of phenylhydroxylamine[7] in 400 m*l* of ethanol was refluxed for two days. The precipitates were collected after cooling, washed with acetone and recrystallized from ethanol to give 5.3 g (55%) of I as yellow needles, mp 245—248°C (decomp). IR (KBr) cm^{-1}: 1565, 1580 ($\nu_{C=N}$), 1065 ($\nu_{N\to O}$). UV λ_{max}^{EtOH} mμ (log ε): 355 (4.45).

Found: C, 71.21; H, 4.56; N, 17.90%. Calcd for $C_{14}H_{11}ON_3$: C, 70.87; H, 4.67; N, 17.71%.

Reaction of I with Styrene. A solution of 0.3 g (1.3 mmol) of I and 0.2 g (1.9 mmol) of styrene in 30 m*l* of dioxane was heated at 90°C on a water bath for 27 hr. After dioxane was removed under reduced pressure, the residual oil was dissolved in a small amount of chloroform and made turbid by addition of petroleum ether. A separated oil solidified gradually in an ice box. The separated crystals were collected and recrystallized from chloroform-ether to give 0.11 g (40%) of II as colorless powders, mp 178—180°C. In the infrared spectrum, a $\nu_{N\to O}$ absorption disappeared and a new one appeared at 1620 cm^{-1} due to $\nu_{C=N}$. UV λ_{max}^{EtOH} mμ (log ε): 238 (4.27), 274 (4.01), 280 (4.02).

Found: C, 77.35; H, 5.38; N, 11.84%. Calcd for $C_{22}H_{19}ON_3$: C, 77.39; H, 5.61; N, 12.31%.

Reaction of I with Methyl Acrylate. A solution of 0.3 g (1.3 mmol) of I and 0.2 g (2.3 mmol) of methyl acrylate in 26 m*l* of dioxane was heated at 90°C on a water bath for 25 hr. Work-up as above afforded 0.17 g (50%) of III as colorless crystals, mp 172—174°C. IR (KBr) cm^{-1}: 1740 (ν_{CO}), 1620 ($\nu_{C=N}$), UV λ_{max}^{EtOH} mμ (log ε): 238 (3.60), 275 (3.57), 280 (2.57).

Found: C, 66.71; H, 5.08; N, 12.73%. Calcd for $C_{18}H_{17}O_3N_3$: C, 66.86; H, 5.30; N, 13.00%.

Studies of the Alkaline Earth Complexes in Various Solutions. IV. Solvent Extraction Study of Radium(II) Complexes with Some Aminocarboxylic Acids in Perchlorate Media

Tatsuya SEKINE, Yoshimitsu KAWASHIMA, Takaaki UNNAI and Mitsuo SAKAIRI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 11, 1968)

Few investigations have been conducted on complex formation of radium(II) in aqueous solutions. This may be due to the fact that only tracer studies are possible in practice because of the high level radioacitivity of radium isotopes.

In the present paper, the complex formation of radium(II) with six very common aminocarboxylic acids has been studied by a liquid-liquid distribution method. Radium(II) was extracted with a mixture of thenoyltrifluoroacetone (TTA) and tributylphosphate (TBP) in carbon tetrachloride. Stability constants were determined by a graphic method from the distribution data.

Experimental

Radium-228 was imported from Radiochemical Center, Amersham, England. It was purified by a solvent extraction cycle which was reported previously.[1] The organic phases were always carbon tetrachloride containing 0.1 M TTA and 0.1 M TBP. The aqueous phase was sodium perchlorate media at ionic strength 0.1 M. No special buffer was added to the aqueous phase, but the hydrogen ion concentration was adjusted by the substitution of 0.1 M sodium hydroxide for 0.1 M sodium perchlorate. This hydroxide carried an equivalent amount of TTA from the organic phase into the aqueous phase and this dissociated TTA anion, together with a small amount of undissociated TTA,*1 buffered the aqueous phase. The addition of a complex forming ligand was made by way of various amounts of disodium salt solution of the aminocarboxylic acid. The aqueous and organic phases were placed in stoppered glass tubes (volume 20 m*l*) and agitated mechanically for one hour. The initial volume of the two phases was 5.0 m*l*. The two phases were then centrifuged and a 2 m*l* portion was pipetted from each phase and the samples thus separated let stand for 3 days. The γ-radioactivity of the samples in which radium-228 (half-life 6.7 yr.) was in transient radioactive equilibrium with γ-radioactive actinium-228 (half-life 6.13 hr) was measured with a well-type (NaI) scintillation counter. A small portion was also taken from the aqueous phase and the hydrogen ion concentration measured potentiometrically using an aqueous solution containing 0.0100 M perchloric acid and 0.09 M sodium perchlorate as the standard of $-\log[H^+]=2.00$.

TABLE 1. DISSOCIATION CONSTANTS OF THE AMINOCARBOXYLIC ACIDS AND THE STABILITY CONSTANTS OF THE ALKALINE EARTH METAL COMPLEXES WITH THESE LIGANDS IN 0.1 M SODIUM PERCHLORATE MEDIA AT 25°C

$K = [RaL^{2-l}]/[Ra^{2+}][L^{l-}]$

Ligand*	pK_a**					log K***

2) Y. Hasegawa and T. Sekine, unpublished data.
3) J. Stary, "The Solvent Extraction of Metal Chelates," Pergamon Press, Oxford (1964).

Results

The distribution ratio of radium(II) was calculated as follows:

$$D = \frac{[\mathrm{Ra(II)}]_{\mathrm{org,total}}}{[\mathrm{Ra(II)}]_{\mathrm{total}}} = \frac{\gamma\text{-count-rate per ml org. phase}}{\gamma\text{-count-rate per ml aq. phase}}$$

Figure 1 gives the $\log D$ *vs.* $-\log[\mathrm{H^+}]$ plot when the aqueous phase was 0.1 M sodium perchlorate

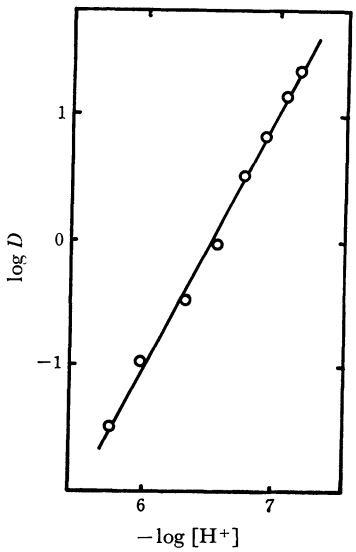

Fig. 1. $-\log[\mathrm{H^+}]$ dependence of radium(II) extraction from 0.1 M $NaClO_4$ at 25°C.
Organic phase: carbon tetrachloride containing 0.1 M TTA and 0.1 M TBP.
The solid line is $\log D = -2\log[\mathrm{H^+}] - 12.94$

containing no ligand. The following extraction constant was obtained from these data;

$$K_{ex_0} = D_0[\mathrm{H^+}]^2[\mathrm{HA}]_{\mathrm{org}}^{-2} = 10^{-10.92} \quad ([\mathrm{TBP}]_{\mathrm{org}} = 0.1\ \mathrm{M}) \qquad (1)$$

here D_0 denotes $[\mathrm{RaA_2}]_{\mathrm{org}}/[\mathrm{Ra^{2+}}]$ and HA denotes TTA.

The stability constant of the first complex is defined as;

$$K = [\mathrm{RaL^{2-}}^{l}]/[\mathrm{Ra^{2+}}][\mathrm{L}^{l-}] \qquad (2)$$

When the aqueous phase contains only the first metal complex, the following equation may be written;

$$D = [\mathrm{RaA_2}]_{\mathrm{org}}/([\mathrm{Ra^{2+}}] + [\mathrm{RaL^{2-}}^{l}]) \qquad (3)$$

From Eqs. (2) and (3), the following extraction constant may be obtained;

$$K_{ex} = D[\mathrm{H^+}]^2[\mathrm{HA}]_{\mathrm{org}}^{-2} = \frac{D_0[\mathrm{H^+}]^2[\mathrm{HA}]_{\mathrm{org}}^{-2}}{1 + K[\mathrm{L}^{l-}]} \qquad (4)$$

Then from Eqs. (1) and (4), the following equation is obtained;

$$K_{ex}/K_{ex_0} = (1 + K[\mathrm{L}^{l-}])^{-1} \qquad (5)$$

Further details on the statistical treatment have already been given in Paper I of this series.[4]

The ligand concentration was calculated using

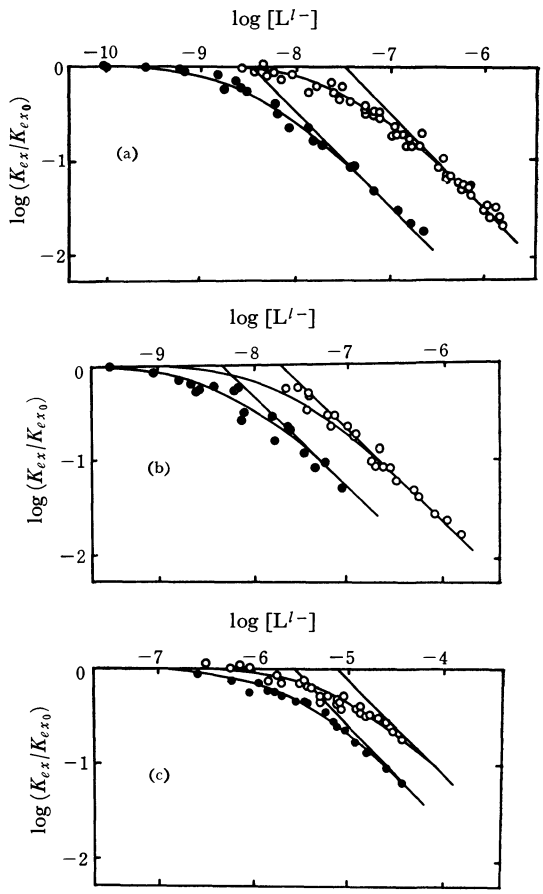

Fig. 2. $\log(K_{ex}/K_{ex_0})$ *vs.* $\log[\mathrm{L}^{l-}]$ plot.
Organic phase: carbon tetrachloride containing 0.1 M TTA and 0.1 M TBP.
Aqueous phase: 0.1 M $Na(ClO_4)$
The ligand and the curves drawn in the figures are as follows:

4) T. Sekine, M. Sakairi and Y. Hasegawa, This Bulletin, **39**, 2141 (1966).

the acid dissociation constants[5] given in Table 1. These acid dissociation constants previously reported were calculated from pH measurements. On the other hand, in the present work, the stoichiometric hydrogen ion concentration was always measured and thus the activity coefficient of hydrogen ion, 0.86,[6] was used to convert $-\log[H^+]$ into pH.

Figures 2a to 2c show the log (K_{ex}/K_{ex0}) *vs.* $\log[L^{l-}]$ plot. The stability constants were determined by a curve-fitting method.[4] Data analysis was carried out assuming no formation of complexes containing protons. This assumption seems reasonable because no remarkable deviation of the points, which might be caused by the formation of such complexes, is observed in the figures containing experimental data obtained at various different hydrogen ion concentrations ($6<-\log[H^+]<7$).

The present measurement for the EDTA complex ($\log K=7.5$) is very close to a previous measurement ($\log K=7.4$).[7] No data seems to have been reported on radium(II) complexes with other ligands.

Part of this work was carried out at the Laboratory of Nuclear Chemistry, the Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, Head of the laboratory.

Oxygen-18 Tracer Study on the Reduction of Arylsulfonyl Chloride with Zinc

Norio KUNIEDA, Kazuo SAKAI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshiku. Osaka

(Received April 12, 1968)

Optically active, ^{18}O-labeled sulfoxides are very convenient for studying the nature of substitution reactions on the trivalent sulfur atom, while ^{18}O-labeled arylsulfinic acids are essential starting materials for the preparation of optically active and ^{18}O-labeled sulfoxides.[1] Meanwhile sulfonyl chlorides are known to be reduced by treating with metallic zinc to the corresponding sulfinic acids.[2] In this note, we wish to report a tracer study on this reduction and a convenient procedure for the preparation of the arylsulfinic acid-^{18}O. ^{18}O-Labeled arylsulfonyl chloride can be prepared readily by treating aryl mercaptan with chlorine in a media containing $H_2{}^{18}O$. If there is no oxygen exchange between the reactants and water during the reduction of the ^{18}O-labeled sulfonyl chlorides, this zinc reduction of sulfonyl chlorides will be definitely simpler and better than the conventional procedure in which the ^{18}O-labeled sulfinic acids are usually obtained by the hydrolysis of the corresponding unlabeled sulfinyl chlorides with ^{18}O-enriched water,[3] thereby the sulfinic acids obtained contain only a half the concentration of ^{18}O of that of ^{18}O-enriched water used. An ^{18}O-labeled arylsulfonyl chloride was treated with zinc dust in hot water, and the sodium arylsulfinate was obtained by the successive treatments with sodium hydroxide and sodium carbonate according to the method described by Whitmore and Hamilton.[2] Sodium arylsulfinate thus obtained was converted to the corresponding sulfinic acid by neutralization and also to sulfinyl chloride by the treatment with thionyl chloride, respectively. The results of ^{18}O-analyses of these products are listed in Table 1. As shown in Table 1, the ^{18}O-concentrations of all the products obtained were found to be identical to that of the arylsulfonyl chloride started.

Table 1. Results of ^{18}O-analyses

R	(Atom%-^{18}O)

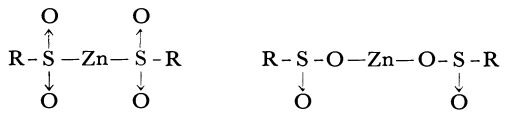
This reduction has been known to proceed stoichiometrically according to the following manner.

At first the chlorine atom of the sulfonyl chloride is considered to be replaced by zinc to form a complex (I), the intermediary product, by the same fashion as in the preparation of zinc dialkyls from alkyl halides and metallic zinc.[4] This complex (I) would be stabilized by the coordination of several water molecules around zinc atom of (I). When the complex (I) is decomposed by the treatment with alkali, sodium arylsulfinate is formed. In fact, Haszeldine and Kidd have successfully isolated zinc trifluoromethanesulfinate, $(CF_3SO_2)_2Zn\cdot 4H_2O$, as an intermediate in this zinc reduction.[5,6] The complex (I) would assume either one of the following form, A or B, however, in view of the fact that the oxygen atom of the sulfinate ion is more basic than the sulfur atom, the form B seems to be more plausible.[7]



A B

Since there was no oxygen exchange in the next step, *i. e.*, the reaction between the complex (I) and alkali hydroxide, the process involving the ligand exchange with hydroxide ion is the only conceivable path for the formation of sodium aryl sulfinate.

5) R. N. Haszeldine and J. M. Kidd, *J. Chem. Soc.*, **1955**, 2901.
6) The structure of the product of dimethylzinc and sulfur dioxide has been also proposed to be $(CH_3SO\cdot O)_2\cdot Zn$ based on IR spectra; N. A. D Carey and H C. Clark, *Can. J. Chem.*, **46**, 649 (1968).
7) We do not intend to specify the bonding of this complex which would assume either ionic or covalent bonding. Presumably, however, Zn-O bond of I is near covalent. See also the related observation that *p*-tolylsulfinyl copper complex has O-Cu bond with considerable covalent character; D. A. Langs and C. R. Hare, *Chem. Commun.* (London), **1967**, 853.

Experimental

^{18}O-Labeled Arylsulfonyl Chloride. A mixture of aryl mercaptan (0.1 mol) and ^{18}O-enriched water (0.22 mol, 1.60 atom%-^{18}O) was cooled in an ice bath, and chlorine gas was passed till the color of the mixture became pale yellow. Then the mixture was poured into ice water and extracted with chloroform. The extract was washed with 10% aqueous sodium carbonate, 10% aqueous sodium thiosulfate and water succesively. The ^{18}O-labeled arylsulfonyl chloride was distilled or recrystallized from n-hexane several times. RSO_2Cl; [R, mp or bp(°C)(lit.), yield(%), atom%-^{18}O]. C_6H_5, 77—78/2 mmHg (147/45 mmHg),[8] 90, 1.14. *p*-CH_3-C_6H_4, 69(69),[9] 93, 1.53, 1.59. *p*-Br-C_6H_4, 73—74 (74—75),[10] 91, 1.43.

The Reduction of Arylsulfonyl Chloride with Zinc was carried out following the procedure described by Whitmore and Hamilton,[2] using ^{18}O-labeled arylsulfonyl chloride (0.06 mol). The sodium arylsulfinate dihydrate was obtained in a good yield, 75—90%. The dihydrate was dehydrated *in vacuo* for 5 hr at 120—130°C for the mass analysis.

^{18}O-Labeled Arylsulfinic Acid was prepared by the careful neutralization of the ^{18}O-labeled sodium arylsulfinate with hydrochloric acid. It was recrystallized from *n*-hexane - ether. RSO_2H; [R, mp(°C)(lit)]. C_6H_5, 83(83).[11] *p*-CH_3-C_6H_4, 85(85).[12] *p*-Br-C_6H_4, 113 (114).[11]

^{18}O-Labeled Benzenesulfinyl Chloride was prepared from anhydrous sodium benzenesulfinate(1.8 g) and thionyl chloride (4.0 g),[13] bp 81—82°C/2 mmHg (lit[14] 96—98°C/4 mmHg), yield 1.1 g.

The Mass-spectrometric Analysis was carried out in the form of carbon dioxide gas and the atom%-^{18}O was calculated from the mass peak heights 44 and 46.

The Base-induced Pyrolysis of Tosylhydrazones of Mesityl Oxide and Dypnone*1

Tadashi SATO and Sotaro WATANABE

Department of Applied Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo

(Received May 13, 1968)

Closs, Closs, and Böll[1] carried out the base-induced pyrolysis of tosylhydrazones of α,β-unsaturated aldehydes and ketones and found that the decomposition gave mainly cyclopropenes when the β-carbon atom was replaced by two alkyl groups, while it gave mainly pyrazoles when the β-carbon atom was monosubstituted or not replaced by an alkyl group. They proposed that this difference arose bacause the steric hindrance and inductive effect resulting from increasing methyl substitution at the β-position retarded the rate of cyclization of the diazo intermediates and accelerated the rate of nitrogen elimination of the diazo intermediates.

As an extension of the study concerned with the effect of substituents on the reaction routes, the base-induced pyrolysis of tosylhydrazones of mesityl oxide (I) and dypnone (V) was compared under several conditions.

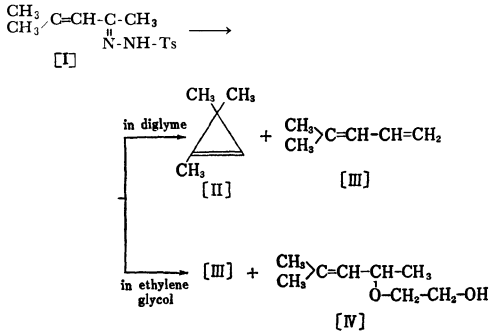

Chart 1

Mesityl oxide tosylhydrazone (I) has been known[1] to give 1,3,3-trimethylcyclopropene (II) as the major product, and 4-methylpenta-1,3-diene (III) as the minor product, when added to a suspension of sodium methoxide in an aprotic solvent (diglyme) at 160°C. The pyrolysis of I with sodium alkoxides in a protic solvent (ethylene glycol) was carried out; 4-methylpenta-1,3-diene (III) and β-hydroxyethyl ether IV were obtained in ratios of 5 : 1, indicating that under these conditions nitrogen elimination was predominant.

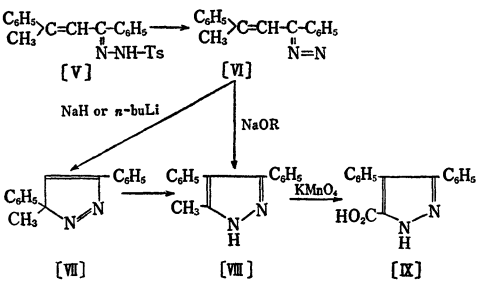

Chart 2

When dypnone tosylhydrazone (V) was added to a solution or suspension of sodium methoxide in a protic solvent (ethylene glycol) or in an aprotic solvent (diglyme), a red color developed which was attributable to the diazo intermediate VI. The red color disappeared when the solution was heated, and 5-methyl-3,4-diphenylpyrazole (VIII) was obtained quantitatively. Obviously phenyl migration occurred during the VI—VIII reaction; this migration seemed to be effected by the action of the proton from ethylene glycol or from methanol, which was formed *in situ* from the tosylhydrazone and sodium methoxide in diglyme. In support of this, the pyrolysis of V with *n*-butyllithium or sodium hydride in refluxing *n*-hexane afforded 3-methyl-3,5-diphenyl-3*H*-pyrazole (VII) in an excellent yield, and VII was rearranged into VIII when refluxed in ethanol.

The structure of VIII was established by its oxidation to the known 3,4-diphenylpyrazole-5-carboxylic acid (IX).[2] This pyrazolecarboxylic acid was identical with the authentic sample prepared according to the method reported by Borsche and Hahn.[3]

Shapiro and Heath[4] and Kaufman, Cook, and Shechter[5] have reported olefin synthesis by treating tosylhydrazones with *n*-butyllithium. It should be noted that the reactions of both sodium alkoxides and *n*-butyllithium with tosylhydrazone of dypnone afforded the cyclization products

(VII and VIII) of the diazo intermediate VI, without any accompanying nitrogen elimination. It was concluded that, unlike the case of tosylhydrazone of mesityl oxide, the diazo intermediate VI formed by the decomposition of tosylhydrazone of dypnone was so stabilized by aromatic groups that no reaction accompanying the nitrogen elimination could be observed, even though the cyclization leading to the 3*H*-pyrazole or pyrazole might be considered to be unfavorable because of the two bulky groups on the β-carbon atom.

Experimental

The NMR spectra were measured on a Hitachi R-20 spectrometer in a deuterochloroform solution. The chemical shifts are described in ppm downfield from an internal tetramethylsilane reference.

Pyrolysis of Mesityl Oxide Tosylhydrazone (I). A suspension of mesityl oxide tosylhydrazone (20 g, 0.075 mol) in ethylene glycol (50 m*l*) was added, over a period of 30 to 60 min, to a solution of sodium ethylene glycolate (0.15 mol) in ethylene glycol (100 m*l*) heated to 160—190°C. The volatile matter which distilled during the addition separated into two layers. The lower layer was found by gas chromatographic analysis to be composed mainly of ethylene glycol. The upper layer (0.8—1 g) was fractionated into two components in the ratio of 5 : 1 by preparative gas chromatography on a Silicone SE 30 column at 120°C. The major component was shown to be 4-methylpenta-1,3-diene (III) from its IR and NMR spectra.[1]

NMR: δ 1.8 (m, 6H), δ 4.8 (m, 2H), δ 6.0—6.5 (m, 2H). IR: 1650, 1605, 885, 874 cm^{-1}.

The minor component was shown to be β-hydroxyethyl ether (IV) from its IR and NMR spectra.

NMR: δ 1.15 (d, 3H), for $C\underline{H}_3$-CH-, δ 1.70 (d, 6H) for $(C\underline{H}_3)_2C$=, δ 2.80 (s, 1H) for -O<u>H</u>, δ 3.2—3.7 (m, 4H) for -$C\underline{H}_2$-$C\underline{H}_2$-, δ 3.8—4.4 (m, 1H) for -C<u>H</u>-CH_3, δ 4.6—5.6 (m, 1H) for -C<u>H</u>=. IR: 3600—3200 cm^{-1} for O-H, 1670 cm^{-1} for C=C, 1105 cm^{-1} for -O-, 1050 cm^{-1} for C-OH.

Dypnone Tosylhydrazone (V). A mixture of dypnone (1 g, 0.0045 mol), tosylhydrazide (0.84 g, 0.0045 mol), and concentrated hydrochloric acid (0.1 m*l*) in methanol (10 m*l*) was refluxed for 30 min. The solution was then cooled to room temperature, and the product was allowed to crystallize, filtered, and recrystallized from methanol, mp 149—150°C. Yield: 84%.

Found: C, 70.51; H, 5.99; N, 7.22%. Calcd for $C_{23}H_{22}N_2SO_2$: C, 70.77; H, 5.65; N, 7.18%.

Pyrolysis of Dypnone Tosylhydrazone (V). *a) With Sodium Methoxide in Ethylene Glycol or Diglyme.* Dypnone tosylhydrazone (1 g, 0.0025 mol) was added all at once to a solution or suspension of sodium methoxide (0.0050 mol) in ethylene glycol or diglyme (25 m*l*) heated to 160—190°C, and then the solution was refluxed for 1 hr. After the solvent had been evaporated *in vacuo*, water was added and the reaction product was extracted with ether. The ether extract was dried over anhydrous sodium sulfate, and the ether was evaporated. The product was recrystallized from benzene - *n*-hexane to give white needles of 5-methyl-3,4-diphenylpyrazole (VIII) in a 92% yield; mp 179—180°C, lit.[2] mp 185—186°C, (IR: 3400—2400 cm^{-1} for N-H, Found: C, 82.01; H, 6.15; N, 12.01%).

N-Acetyl derivative; mp 66°C.

Found: C, 78.13; H, 5.79; N, 9.94%. Calcd for $C_{18}H_{16}N_2O$: C, 78.26; H, 5.79; N, 10.15%.

b) With n-Butyllithium or Sodium Hydride in n-Hexane. Dypnone tosylhydrazone (1 g, 0.0025 mol) was added all at once to a solution or suspension of *n*-butyllithium (0.0050 mol) or sodium hydride (0.0050 mol) in *n*-hexane (15 m*l*). When the solution was heated to a boiling point, a red color indicating the formation of a diazo intermediate developed; the solution was then refluxed for 2—5 hr, during which period the red color disappeared. The solution, after being washed with water, was left to stand overnight. The crystals were filtered and recrystallized from *n*-hexane. White needles of 3-methyl-3,5-diphenyl-3*H*-pyrazole(VII) melting at 83—84°C were obtained in a yield of 90—92%.

Found: C, 81.82; H, 6.15; N, 12.17%. Calcd for $C_{16}H_{14}N_2$: C, 82.05; H, 5.99; N, 11.96%.

Oxidation of 5-Methyl-3,4-diphenylpyrazole (VIII) to 3,4-Diphenylpyrazole-5-carboxylic Acid (IX). 5-Methyl-3,4-diphenylpyrazole (0.37 g, 0.016 mol) was oxidized with potassium permanganate (0.50 g, 0.038 mol) in a mixture of water (5 m*l*) and *t*-butyl alcohol (6 m*l*) according to the method reported by Parham and Hasek[2]. A crude acid (0.07 g) melting at 254—255°C was obtained; it was identical with an authentic sample of 5-methyl-3,4-diphenylpyrazole, mp 261°C[3] (IR spectra and mixed mp).

Conversion of 3-Methyl-3,5-diphenyl-3*H*-pyrazole (VII) to 5-Methyl-3,4-diphenylpyrazole (VIII). A solution of 3-methyl-3,5-diphenyl-3*H*-pyrazole (0.5 g) in ethanol (15 m*l*) was refluxed for 1 hr. The solvent was then evaporated, and the product was recrystallized to give a 95—100% yield of 5-methyl-3,4-diphenylpyrazole.

Force Constants and Mean Amplitudes of Glyoxal

Tsutomu FUKUYAMA, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 22, 1968)

In a recent investigation of the gas-phase structures of butadiene, acrolein and glyoxal,[1] a least-squares analysis was carried out on the electron diffraction intensities and rotational constants as joint observables. The method is based on the conversion of electron-diffraction r_a distances into r_α^0 distances, and that of ground-state rotational constants into average rotational constants. For the conversions, one must know the quadratic force field. The force constants for butadiene were determined by Abe and Shimanouchi,[2] but no data were available on the force fields for glyoxal and acrolein except for the out-of-plane force constants for glyoxal reported by Brand.[3] Thus, a set of force constants have been estimated for the latter molecules from the reported vibrational frequencies of normal and certain deuterated species, at least with sufficient accuracy for calculating small correction terms ($r_\alpha^0-r_a$, A_z-A_0, *etc.*).

Observed Vibrational Frequencies. Glyoxal is a molecule with C_{2h} symmetry and has twelve fundamental frequencies: $5A_g+4B_u+2A_u+B_g$. In accordance with the rule of mutual exclusion, the B_u and A_u species are infrared active and the A_g and B_g species Raman active. Because of the experimental difficulty, the Raman spectra of glyoxal have never been observed successfully. Harris assigned all infrared-active fundamentals and some combination frequencies, from which he estimated the frequencies of the Raman active fundamentals.[4] The present note on the force constants for glyoxal is mainly based on the frequencies reported by him. The fundamental frequencies of $C_2D_2O_2$ reported by Brand and Minkoff[5] were also taken into account, in addition to the frequencies of the normal species by Harris.

In-plane Vibrations. A modified Urey-Bradley force field was assumed for the description of the in-plane vibrations: The potential

energy was expressed in terms of the three sets of force constants (force constants for the bond stretching K, for the valence angle deformation H and for the non-bonded interaction F) and two interaction constants f. The latter constants were introduced between the two coordinates corresponding to the C=O stretching and between the two C–C=O bending coordinates. An apparent difference between the bond-stretching force constant for C–H and that for C–D was taken into account through the relation $K_{C-D}/K_{C-H}=1.026$.[6]

The force constants transferred from formaldehyde, acetaldehyde and acetone[7] were used as initial values, and then adjusted by trial-and-error calculations. In the final stage, a least-squares fit was made by taking K_{C-C}, H_{HCO}, H_{CCO}, f(CO, CO), and f(CCO, CCO) as variable parameters. The result is shown in Table 1 and the frequencies calculated using those force constants are compared with the observed values in Table 2.

The two interaction constants f(CO, CO) and f(CCO, CCO) were essential for reproducing the symmetric and antisymmetric frequencies of the C=O stretching and the CCO bending vibrations. The situation is essentially the same as that for butadiene, as indicated in Table 11 of Ref. 2, where the corresponding force constants, f_{dd} and f_{gg}, are relatively large negative and positive elements, respectively.

Out-of-plane Vibrations. Glyoxal has three out-of-plane vibrations: two in the A_u species and one in the B_g species. The number of elements in the F_s matrix are therefore three and one for respective symmetry blocks. The use of the frequencies of $C_2H_2O_2$ and $C_2D_2O_2$ made it possible to determine the F_s matrices uniquely. The result is shown in Table 3 in an internal coordinate system (F_R matrix). Brand determined the out-of-plane force constants by assuming that $(GF)_{76}$ was zero.[3] The F_R elements for each isotopic species (also given in Table 3) calculated by his method with the molecular geometry determined recently[1] are close to the present estimates.

Mean Amplitudes. Mean square amplitudes for several atom pairs of glyoxal were calculated from the derived force constants. The results shown in Table 4 account for the observed values reasonably except for the C–H amplitudes. The small discrepancy in the C–H amplitude may be ascribed to a systematic error included in the diffraction experiment.

Force Constants and Mean Amplitudes of Acrolein

Tsutomu FUKUYAMA, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 22, 1968)

As mentioned in the preceding note for glyoxal,[1] the force constants were estimated for acrolein in order to obtain the correction terms necessary for correlating the structural data observed by electron diffraction and spectroscopy.

Observed Vibrational Frequencies. Acrolein is a planar molecule (C_s symmetry) with eighteen fundamental frequencies: 13A'+5A''. All but one of them were assigned by Brand and Williamson[2] on the basis of the observation of near-ultraviolet spectra. They assigned most of the fundamental frequencies of CH_2=CHCDO as well. On the other hand, Harris observed infrared and Raman spectra and assigned the fundamentals of the normal species.[3] His assignment differs from that of Brand in that the schematic descriptions of the 1158 cm^{-1} (ν_{10}) and 912 cm^{-1} (ν_{11}) modes are interchanged. We accepted the assignment of Harris since it is consistent with a

recent assignment of the fundamentals of butadiene reported by Abe and Shimanouchi.[4]

In-plane Vibrations. The potential energy was expressed in terms of K, H, F and three additional force constants. One interaction constant was introduced between the two C–H stretching coordinates of the methylene group. The other constants were introduced between the C=C and the C=O stretching coordinates and between the CCC and the CCO bending coordinates. Initial values of the force constants were taken from those for butadiene and glyoxal. After several trials, they were adjusted by a least-squares method with K_{C-C}, H_{HCH} and f(CCC, CCO) as variable parameters. The result is shown in Table 1, and the calculated frequencies are compared with observed values in Table 2.

The force constants for the vinyl group, including p(CH, CH), are close to the corresponding constants for butadiene, except for the C=C stretching force constant $K_{C=C}$ (7.1 mdyn/Å), which is larger than that for butadiene (6.6 mdyn/Å).[4] The force constants for the aldehyde group are roughly equal to those for glyoxal. A systematic decrease in the C–C stretching force constant observed for butadiene (3.82 mdyn/Å), acrolein (3.46 mdyn/Å) and glyoxal (3.25 mdyn/Å) correspond to a systematic increase in the bond distance r_g(C–C) (1.465, 1.480, and 1.526 Å, respectively)[5] and a systematic decrease in the π-bond order (0.224, 0.200, and 0.132).

Out-of-plane Vibrations. Abe and Shimanouchi introduced an F_a matrix of nearly general form in the analysis of the out-of-plane vibrations of butadiene.[4] For acrolein the F_R matrix, which is here equivalent to F_a, was set up in an analogous manner. Initial values of the elements were transferred from butadiene and glyoxal and then adjusted by trial and error. The final matrix is shown in Table 3. In order to facilitate comparison, notations for the elements are taken from Table 10 of Ref. 4. Effective two-fold torsional barriers around the central C–C bonds are found to be 8.1, 6.3 and 3.7 kcal/mol, respectively, for butadiene, acrolein and glyoxal. They are in essential agreement with the pure torsional transitions observed by Fateley *et al.* in the far infrared;[6] according to their one-dimensional analysis, V_1 and V_3 being ignored, their V_2 values are 7.0, 5.3 and 3.4 kcal/mol, respectively. It is interesting to note that a roughly linear relation exists between the torsional barriers and the lengths of the C–C bonds.

A Comment on the Structure of Glassy Carbon

Tokiti NODA,* Michio INAGAKI** and Shigehiko YAMADA***

* *Mie University, Tsu, Mie-Ken*
** *Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya*
*** *Nagoya Plant, Tokai Electrode Mfg. Co., Showa-ku, Nagoya*
Department of Applied Chemistry, Aichi Institute of Technology, Chikusa-ku, Nagoya

(Received June 4, 1968)

Glassy carbon is an apparently isotropic, continuous and non-porous material, showing conchoidal surface of fracture. It has a similar spectral dependence of reflectance to that of graphite.[1] Its electrical resistivity is of the same order as that of regular carbon materials and its thermal conductivity is relatively high compared with that of common ceramic materials.[2] The changes in Hall coefficient and magnetoresistance of glassy carbon with heat treatment temperature (HTT) resemble those of very hard carbon.[3] Its high strength, high Young's modulus, high hardness and also high impermeability to gases[2] suggest that glassy carbon must have a unique structure different from those of regular carbons.

The first proposal concerning the structure of glassy carbon was made with the aid of radial distribution function by two of the present authors.[4] Two other models of the structure of glassy carbon have been proposed since then.[5,6] Noda and Inagaki[4] proposed the contribution of tetrahedral bond together with trigonal bond as the principal bonds to the construction of glassy carbon. The extension of region consisting of only trigonally-bound carbon atoms or only tetrahedrally-bound carbon atoms can not be known by the radial distribution analysis. From the observation that the X-ray diffraction pattern of glassy carbon is very similar to that of turbostratic carbons,[4] it was deduced for the structure of glassy carbon that trigonal carbon atoms make small domains of two-dimensional graphite-like arrangement and that these domains are linked by tetrahedral bonds, while tetrahedral carbon atoms themselves make no domain of regular arrangement.

Furukawa[5] composed a model of three-dimensional irregular network configuration which contains all kinds of C-C bonds, *i. e.*, tetrahedral, planar double, linear triple and also conjugated C-C bonds. This model has no repetition of hexagonal rings of trigonal carbon atoms more than three. Insofar as glassy carbon heat-treated at such a low temperature as 800°C is concerned, the above two models are similar to each other, because the model of Noda and Inagaki consists of a large amount of tetrahedral carbon atoms and a number of small domains of trigonal carbon atoms, and Furukawa's model mainly consists of carbon atoms bound by tetrahedral and planar double bonds. According to Noda and Inagaki,[4] the content of trigonal carbon atoms increases and so the content of tetrahedral carbon atoms decreases with rise of HTT, and the X-ray diffraction band of (00*l*) becomes narrower with rise of HTT. These changes may be attributed to the increase in the size of the domains of trigonal carbon atoms. Takahashi and Westrum[7] measured the specific heat of glassy carbon, which was heat-treated at 3000°C, by adiabatic calorimetry from 6 to 350°K and found its T^2-dependence. This result suggests that glassy carbon mainly consists of two-dimensional layer lattice. Furukawa's model is not in harmony with this suggestion.

Kakinoki[6] proposed a model which consists of two kinds of domains, which are respectively composed of tetrahedral and trigonal carbon atoms and linked to neighboring domains by oxygen bridges. In his model, the oxygen bridges are responsible for the low density of glassy carbon and for the fact that the carbon is hardly graphitized at temperatures as high as 3000°C.[2,4] The oxygen content of glassy carbon directly determined by chemical analysis[8] was found to be about 1.2 per cent for 900°C-treated and about 0.3 per cent for 1200°C-treated glassy carbons, and 0.1—0.2 per cent for glassy carbon heat-treated at 1300—3000°C, respectively, the last value was determined by activation analysis.[9] The porosity of glassy carbon changes with HTT. Glassy carbon heat-treated at 600—700°C has the maximum apparent porosity (10—11%) and absorbs moisture of about 10 per cent by weight.[10] The oxygen

content as high as about 5—6 per cent, which was mentioned by one of the present authors (S. Y.) at an informal meeting of the Symposium on Carbon in Tokyo (1964) and was used by Kakinoki for construction of his model, was found later by Yamada to be mainly due to the moisture absorbed in glassy carbon. Fitzer, Schäfer and Yamada also obtained similar results on moisture absorption[11] and oxygen content[12] in the cases of glass-like carbons obtained from phenolic and furan resins. Therefore, Kakinoki's model seems to be inappropriate, because it has been derived from the presumption that glassy carbon contains several per cent of oxygen.

Ergun and Tiensuu[13] pointed out that X-ray diffraction study is not sufficient to ascertain the presence of diamond-like structures in amorphous carbons, but other properties of carbons such as hardness, density, electronic properties, graphitizability, *etc.*, must be considered. From the above discussions and also by considering the properties of glassy carbon,[2,3] the structural model of Noda and Inagaki, *viz.*, trigonal carbon atoms make small domains of two-dimensional graphite-like arrangement and these domains are linked by tetrahedral bonds, may be considered to be the most probable for the structure of glassy carbon. The possibility, that some kinds of bonds other than the tetrahedral one contribute to the linking of graphite-like layers, may not be ruled out.

Small graphite-like layers linked by C–C bonds three-dimensionally without any ordering make a continuous and low-density glassy carbon body which is isotropic and homogeneous in the long range ordering. In low-temperature-treated glassy carbons, the size of graphite-like layers is small and the percentage of linking carbon atoms is relatively high, but the size of layers increases and the percentage of linking carbon atoms decreases with rise of HTT. Insofar as to the structure that graphite-like layers are linked by so-called criss-cross linkages, glassy carbon is basically similar to regular carbons. The characteristics of glassy carbon, such as high strength, high hardness, impermeability, *etc.*, are mostly due to the high content of carbon atoms linking graphite-like layers successively in the three-dimensional way without any ordering. The high content of linking carbon atoms is also the main reason for non-graphitizability of glassy carbon.

SHORT COMMUNICATIONS

Photolysis of Sugar Tosylate. A New Procedure for the De-*O*-tosylation

Shonosuke ZEN, Seiko TASHIMA and Shinkichi KOTŌ

College of Pharmaceutical Sciences, Kitasato University, Shirokane-sankocho, Shiba, Minato-ku, Tokyo

(Received October 1, 1968)

The authors wish here to report a new method for the photolytic de-*O*-tosylation of sugar tosylate.[1]

Sugar tosylates are extensively used as important intermediates in the synthesis of carbohydrate derivatives. De-*O*-tosylations have usually been performed by catalytic hydrogenolysis,[1] but the application of this reaction is somewhat limited by the fact that a side reaction of a considerable extent might occur simultaneously.

Very recently it has been found in our laboratory that a tosyl group of sugar derivatives can be readily removed by a photolysis without any side reaction.

When a sugar tosylate in methanol is irradiated by UV in the presence of an equimolecular amount of sodium methoxide at room temperature, a parent sugar derivative is regenerated in an excellent yield. Without any UV irradiation, the de-*O*-tosylation does not occur under the same reaction conditions. A typical method is as follows: a methanolic solution (250 ml) of methyl 6-*O*-tosyl-α-D-glucopyranoside[2] (1.0 g) containing sodium methoxide was irradiated with a 100-W high-pressure mercury lamp in a water-cooled quartz immersion well (*Ushio Denki Co.*) at 25—27°C for 5 hr, with a gentle bubbling-in of nitrogen. The progress of the reaction was examined by thin-layer chromatography (TLC). The irradiated mixture was filtered and evaporated *in vacuo* to afford a brown syrup, which was then purified by silica-gel column chromatography. Methyl α-D-glucopyranoside was recovered in a 90% yield; it was identified with an authentic sample by a mixed-melting-point determination and by a comparison of their infrared spectra.

Without any UV irradiation, the starting material was recovered quantitatively under the same conditions. By cutting off wavelengths under 3100 A in an UV irradiation with a Pyrex tube,*1 the reaction was also retarded completely.

A similar procedure for 1,2:3,4-di-*O*-isopropylidene-6-*O*-tosyl-α-D-galactopyranose,[3] which has a primary tosyloxy group, gave quantitatively the syrupy 1,2 : 3,4-di-*O*-isopropylidene-α-D-galactopyranose, which could be identified with an authentic specimen[3] by a comparison of their IR spectra and by TLC, and which could also be converted into the tosylate again. This tosylate was identified with the starting material by a comparison of their melting point and IR spectra.

The method described above has been successfully applied to a secondary tosyloxy group: from methyl 3-*O*-tosyl-β-D-glucopyranoside, which had been prepared by the selective de-*O*-acetylation of methyl 2,4,6-tri-*O*-acetyl-3-*O*-tosyl-β-D-glucopyranoside,[4] methyl α-D-glucopyranoside was obtained in a 80% yield, while from 1,2 : 5,6-di-*O*-isopropylidene-3-*O*-tosyl-α-D-glucopyranose[5] 1,2 : 5,6-di-*O*-isopropylidene-α-D-glucopyranose was regenerated in a quantitative yield.

The details of this work will be reported later.

Reaction of Bromine Activated by Bromine-82m Isomeric Transition in Liquid and Solid Benzene*[1]

Chiro SHINOMIYA and Toshiaki KISHIKAWA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-cho, Kumamoto

(Received May 31, 1968)

The discovery of the ^{82m}Br(I.T.)^{82}Br nuclear reaction[1,2] has made it possible to study isomeric transition-induced reactions free from any possible influence of the gamma-radiation from a reactor. The chemical effects of the subjecting transformation in liquid organic media have been investigated by Iyer and Willard[3] and by Stamouli and Katsanos.[4] To determine whether a similar chemical effect occurs (1) in the solid state, we mixed neutron-irradiated molecular bromine with benzene, and allowed it to stand at the temperature of dry ice for 60 min, by which time almost all the ^{82m}Br had decayed to ^{82}Br. The inorganic radiobromine was then separated by means of extraction.

A separate run was performed (2) in the liquid state. After mixing irradiated bromine with benzene at room temperature, the inorganic radiobromine in a portion of the mixture was separated by extraction at different time intervals. To analyze the rate of growth of the organic yield in the run (2), $OY^{\infty}_{obs}-OY^{\Delta t}_{obs}$ were plotted against Δt, where OY^{∞}_{obs} represents the ^{82}Br organic yield reached in the system (1) or system (2) after all the ^{82m}Br had decayed to the ^{82}Br ground state, and where $OY^{\Delta t}_{obs}$ represents it at any time before the ^{82m}Br has completely decayed. The plot gave a straight line. The half-time of the reaction so obtained was 6.27 min.

Correcting for the contributions of the activities of the ground-state ^{82}Br produced directly from radiative neutron capture and for those of the activities decayed from ^{82m}Br before mixing, one can obtain the net organic yields (OY^{∞}_{net}).

TABLE 1. ORGANIC YIELD OF ^{82}Br PRODUCED IN SOLID AND LIQUID BENZENE AS A RESULT OF THE DECAY OF ^{82m}Br(Br_2) BY ISOMERIC TRANSITION

Phase	Mole fraction of $Br_2\cdot10^3$	Total organic yield, OY^{∞}_{net} %	Ref.
Solid	4.23	113.1±15.6	
Liquid	4.23	34.0± 3.1	
Liquid	8.11	26.1± 0.6	4a

Bromine-82m decays by a highly converted transition[2] of 46 keV (internal conversion coefficient $\alpha_k=268$). This means that a large fraction of the ^{82}Br is produced with a positive charge. If the observed increases in the ^{82}Br organic yield result from chemical excitation by the isomeric transition, the rate of growth should depend only on the decay of ^{82m}Br (the half-lives in Refs. 1—3 are 6.05, 6.20, and 6.20 min, respectively). The closed value of the rate data may be attributed to the ^{82m}Br-decay-depending reaction. Because it is well known that aromatic bromination with molecular bromine proceeds quite gently in a nonpolar organic medium unless an electrophilic reagent such as ferric bromide is added. Stamouli *et al.*[4a] have reported the organic yield value of 26.1% where the bromine concentration was 8.11×10^{-3} mol fraction. Though the value in the present work is a little higher, it may be considered to be reasonable[4a] if the difference in the bromine concentration is taken into consideration.

In the solid system at the temperature of dry ice, a valid amount of activities in the system was found only in the benzene layer. Bromine forms a 1 : 1 molecular compound with benzene[5] (mp −14.0°C). Though the phase diagram of the system has not yet been completed, no evidence of the bromine clumping which is formed in certain hydrocarbon systems[6,7] is found in the present system. Electron capture during partial neutralization from the immediate environment (*i. e.*, a molecular compound or molecular compound-benzene) will cause further excitation and damage within a highly-localized region. The high solid-state organic yield must be the result of recombination reactions with damaged organic fragments or benzene. A more detailed report will be published later.

The investigation was performed at the Research Reactor Institute, Kyoto University.

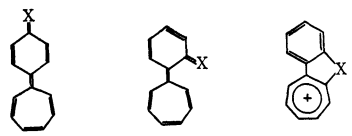
A Convenient Synthesis of Benzo[*b*]-1-azaazulene Derivatives

Kahei TAKASE, Toyonobu ASAO and Naonori HIRATA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 1, 1968)

It has been reported that the hydride abstraction of *p*-tropylphenol, followed by the base treatment, furnished a deep-colored dye named *p*-benzoquinonetropide (Ia).[1] The hydride abstraction of *p*-tropylanilines also afforded immonium ions (Ib).[1b,2]



Ia X=O
Ib X=$\overset{+}{N}R_2$

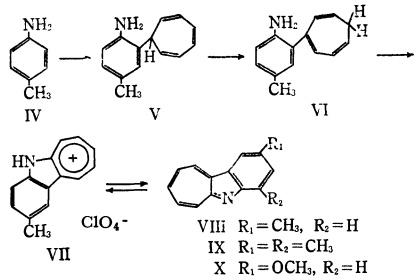
IIa X=O
IIb X=NH

IIIa X=O
IIIb X=NH

On the other hand, the similar treatment of *o*-tropylphenol did not yield *o*-benzoquinonetropide (IIa), but the tricyclic tropylium cation (IIIa).[1d,3] These results led us to investigate the hydride abstraction of *o*-tropylanilines to see if the reaction would give either *o*-benzoquinonetropidimine (IIb) or the tricyclic compound (IIIb). The results will be reported in this communication.

The tropylation of *p*-toluidine (IV) with ethoxytropilidene in ethanol in the presence of hydrochloric acid afforded oily 2-(7-tropyl)-*p*-toluidine (V).*1

The distillation of V under reduced pressure easily triggered the thermal isomerization of the tropyl group[4] to give mainly 2-(3-tropyl)-*p*-toluidine (VI), bp 143°C/1.8 mmHg; *N*-acetyl derivative, mp 113—114°C. The treatment of VI with 2.3 molar equivalents of triphenylmethyl perchlorate in methylene chloride yielded a tropylium perchlorate (VII), mp 260°C (decomp.), in a 62.6% yield. The use of a smaller amount of the reagent in the above reaction diminished the yield of the compound VII. The basification of VII with sodium hydrogencarbonate yielded violet crystals (VIII), mp 120—120.5°C, in a quantitative yield; these crystals were readily reversed to VII with perchloric acid.



IV V VI

VII ClO_4^-

VIII $R_1=CH_3$, $R_2=H$
IX $R_1=R_2=CH_3$
X $R_1=OCH_3$, $R_2=H$

The spectroscopic properties of the compound (VIII) as well as the results of the elemental analyses support the idea that the compound is not a *o*-benzoquinonetropidimine derivative, but 2-methylbenzo[*b*]-1-azaazulene: UV (Table 1); similar to that of benzo[*b*]-1-azaazulene, NMR (in $CDCl_3$); methyl protons at 2.58 ppm and aromatic protons (8H) between 7.5—8.7 ppm, mass spectrum; parent ion peak (base peak) at 193.

Although benzo[*b*]-1-azaazulenes have already been synthesized by several methods, the present method is the simplest and most convenient.

2,4-Dimethylbenzo[*b*]-1-azaazulene (IX), deep violet crystals, mp 100—101°C, and 2-methoxybenzo[*b*]-1-azaazulene (X), deep violet plates, mp 132.5—133°C, were synthesized by a similar method starting from 2,4-dimethylaniline and *p*-anisidine respectively. The ultraviolet and visible absorption maxima of these azaazulenes are shown in Table 1.

TABLE 1. ABSORPTION MAXIMA OF THREE BENZO[*b*]-1-AZAAZULENES

Compound	λ_{max}^{MeOH} mμ (log ε)
VIII	230^{sh}(4.50), 290^{sh}(4.57), 313(4.70), 360^{sh}(4.10), 490(2.64)
IX	238(4.27), 291.5(4.39), 318.5(4.48), 360^{sh}(3.76), 520(2.60)
X	228(4.40), 314(4.65), 324(4.64), 363(3.89), 550(2.66)

The Formation of Peptide Bonds at the Coordination Sites around Copper(II)

Tadayoshi HIGASHIYAMA, Hideo UEDA and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received August 30, 1968)

In a previous paper[1] we reported the metal ion promoted hydrolysis of some oligopeptides. The structure of the intermediate complexes postulated then has recently led us to undertake the formation reaction of peptide bonds, without being confined to the cleavage reaction of them. This was because of the successful experiments of Buckingham[2] and Collman[3]; they reported that treatment of β_2-[Co(trien)Cl(glyOEt)]$(ClO_4)_2$ with glycine ethyl ester in nonaqueous solution results in the rapid condensation of two glycinester residues and the formation of the β_2-[Co(trien)glyglyOEt] ion.

Now we have also succeeded in finding out another type of formation reaction of peptide bonds by using copper(II) complex of the Schiff base derived from salicylaldehyde and glycinamide. The outline of the reactions can be represented by the schemes (1) and (2):

$$\text{Cu(Salal=Glyam)}^{*1} + \text{GlyOEt} \xrightarrow[\text{5 min, in DMFA}]{\text{KOH, 25°C}} \text{Cu(Salal=Glyglyam}^{*1}\text{)}, \quad (1)$$

$$\text{Cu(Salal=Glyam)} + \alpha\text{-AlaOEt} \xrightarrow[\text{5 min, in DMFA}]{\text{KOH, 25°C}} \text{Cu(Salal=}\alpha\text{-Alaglyam)}. \quad (2)$$

The isolation of resulting chelates shown in the schemes (1) and (2) has been carried out by using a Sephadex column and the techniques of vacuum condensation. The confirmation of peptide bond formation has been attained on the basis of three experimental results. Firstly, the infrared spectrum of the resulting chelate in the scheme (1) has shown good agreement with that of the standard samples, whose structure was already established as the copper(II) chelate of the Schiff base derived from salicylaldehyde and glycylglycinamide.[4] Secondly, the results of amino acid analyses*2 of the reaction products have clearly shown the presence of glycylglycine or its amide in the solution for the scheme (1), and α-alanylglycine or its amide in the solution for the scheme (2), respectively. Thirdly, the one- and two-dimensional paperchromatographic tests have unambiguously shown that the reaction product for the schemes (1) or (2) is not the complex with glycylglycine or α-alanylglycine but that with glycylglycinamide or α-alanylglycinamide, respectively.

Comparison between the reactions of Buckingham or Collman and of the present authors is of interest. In the reaction of Buckingham or Collman, the condensation reaction occurs between the terminal carbethoxy group of the glycinester in coordination and the amino group of free glycinester. On the other hand, in the present authors' reaction, condensation occurs between the imino-nitrogen of the glycinamide moiety in coordination and the carbethoxy group of free glycinester. Accordingly, the reaction of glycine residue in coordination with free α-alanine is expected to give glycyl-α-alanine in the Buckingham-Collman reaction, and reversely α-alanylglycine in the present authors' reaction, as has already been described. The present reaction can be interpreted to proceed as depicted in Fig. 1, though it still awaits further pursuit.

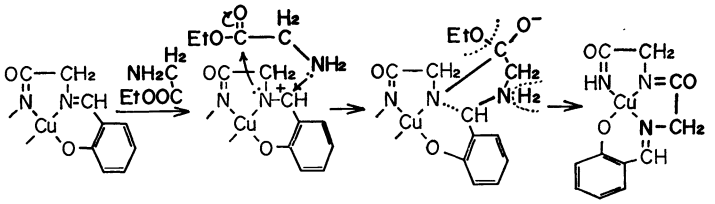

Fig. 1. A possible mechanism of the peptide formation reaction.

Electronic Spectra of Copper(II) Acetylacetonates and Their Activity as Initiators of the Polymerization of Styrene

Kaku UEHARA, Makoto TANAKA and Niro MURATA

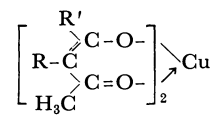
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received September 2, 1968)

In a preceding communication,[1] we reported that copper(II) chelates A showed a high activity as initiators of the radical polymerization of styrene and methyl methacrylate. The polymerization proceeds *via* the reduction of Cu(II), and the ligand is incorporated into the polymer chain.

As is shown in Table 1, the order of the activity in initiation of the polymerization of styrene is as follows:

$$A>B>C>D>E>F>G$$



A_1: R=

A_2: R=$CH_3CH=CH-$

A_3: R=$CH_3CH_2CH=CH-$

C_1: R=$CH_3CH_2CH_2-$

C_2: R=$CH_3CH_2CH_2CH_2-$

D_1: R=$CH_2=CHCH_2-$

D_2: R= 
B_1: R=

B_2: R=

E: R′=$(CH_3)_3C-$

F: R′=CH_3-

G: R′=CF_3-

(A—D, R′=CH_3; E—G, R=H)

TABLE 1. RATE OF BULK POLYMERIZATION OF STYRENE INITIATED BY COPPER(II) CHELATES AT 80°C AND THE ULTRAVIOLET ABSORPTION BAND(III) OF THE CHELATES IN CHLOROFORM

Cu(II)	Chelate (mol/l)[a]	Rate of Polymerization (wt%/hr)	λ_{max} (mμ)	ε_{max}
A_1	0.0137	11.90	312	20300
A_2	0.0135	6.20	312	23400

None	—	0.60	—	—

a) Concentration of chelate added in the polymerization.

Figure 1 presents the visible spectra of these chelates in chloroform. The marked color changes from G to A upon the substitution of the hydrogen of F, $Cu(acac)_2$, are associated with the ultraviolet tail of the first allowed electronic absorption band (Band III in terms of the notation of a recent paper[2]; it occurs at ~300 mμ). Table 1 lists the wave lengths and intensities observed for Band III in chloroform.

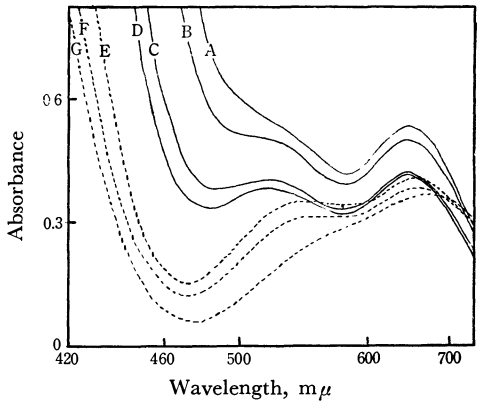

Fig. 1. Visible spectra of copper(II) chelates in chloroform.
[Cu(II) chelate]=0.01 mol/l

It is observed that the Band III of the chelate A is most remarkably broadened and that the tail extends considerably into the visible region of the spectrum. The order of the magnitude of the broadening of Band III upon substitution and the extending of the ultraviolet tail into the visible region seem to be as follows:

$$A>B>C>D>E(>F)>G$$

This order is essentially the same as the order of the activity in the polymerization. A similar broadening is also observed in the visible spectra of the chelate F with a rise in the temperature, this compound being known as a thermochromic substance.[3,4]

A Base Induced Oxidation-Reduction Reaction of Bis(salicylaldimine)copper(II)

Akira MISONO and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 5, 1968)

It seems interesting to determine what kind of effects an external base has on the internal oxidation-reduction reactions of complexes. We studied this in connection with our study of the role of an existing base in an oxidation reaction by a metal ion. We investigated the oxidation reactions of imines,[1] and so, naturally, have been interested in the internal oxidation-reduction reaction of bis(salicylaldimine)copper(II). This complex decomposes through an internal oxidation-reduction reaction at a higher temperature (for thermal-induced oxidation-reduction reactions, *cf.* Ref. 2); at the same time, the central copper(II) ion is reduced to metallic copper and some of the ligands are oxidized to the corresponding nitrile.[3] At room temperature, however, this complex is very stable in the solid state and also in a pyridine solution. Oxygen oxidizes this complex in a pyridine solution at relatively high temperatures, thus yielding coordinated salicylonitrile, according to Shinra *et al.*[4]

The present authors found that this complex decomposed easily in a pyridine solution when treated with a strong base such as sodium amide, sodium hydroxide, and sodium methoxide.

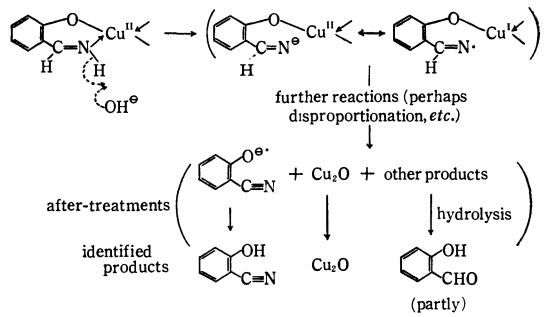
When this complex and a base was stirred in pyridine under a nitrogen atmosphere at room temperature, the color of the mixture changed from green to a final yellow-brown in several steps. After the resulting mixture had been treated by adequate methods, copper(I) oxide, salicylonitrile, and salicylaldehyde were found. These products and their relative amounts (the starting complex: Cu_2O : salicylonitrile $\fallingdotseq$ 2 : 1 : 1) suggest the following stoichiometric reaction:

$$2\ Cu(HN{=}CH\text{-}C_6H_4\text{-}O)_2 + 4\ NaOH \xrightarrow[\text{after-treatments}]{\text{reaction and}} Cu_2O + 3H_2O + \text{salicylonitrile}$$

+ other products such as salicylaldehyde (products obtained through no electron transfer)

When the copper complex was not stirred with a strong base in pyridine, no salicylonitrile was detected.

The existing base may abstract the imine hydrogen of the complex dissolved in pyridine, and then an oxidation-reduction reaction may occur between the deprotonated ligand and the central ion. The deprotonated ligand may be more easily oxidized than the undeprotonated one. This supposition may also be supported by the fact that a similar mechanism has been suggested for other oxidation reactions by the copper(II) ion.[5]



This reaction should also be compared to the deprotonation reaction of cobalt(III) complexes with amines by an amide ion in liquid ammonia, which is followed by no internal electron transfer from the deprotonated ligand to the central ion.[6] The redox potential of the central ion of the resulting complex after the deprotonation reaction may mainly decide whether a successive electron transfer reaction proceeds or not.

The reaction mechanism is now being examined in detail.

Formation and Pyrolysis of Bis(chloroalkyl)tellurium Dichloride

Masao OGAWA

Central Research Laboratory of Showa Denko K. K., Tamagawa, Ota-ku, Tokyo

(Received September 17, 1968)

The present work was undertaken in connection with the tellurium-catalyzed allylic chlorination of olefins.[1] Little is known as to the reaction of tellurium tetrachloride(I) with olefins.[2,3]

The treatment of I with excess cyclohexene at 5°C afforded bis(2-chlorocyclohexyl)tellurium dichloride(II) in a 80% yield (based on I) as colorless needles (from acetic acid); mp 134—135.5°C (decomp). Found: C, 33.4; H, 4.9; Cl, 33.1%. Calcd for $C_{12}H_{20}TeCl_4$: C, 33.2; H, 4.6; Cl, 32.8%. Previously De Moura Campos and Petragnani[3] had reported the formation of 2-chlorocyclohexyltellurium trichloride(III), mp 113°C(decomp). III was obtained when I was allowed to react with an equivalent amount of cyclohexene in carbon tetrachloride. Thus, whether a 1/1 or a 1/2 adduct is formed depends on the reaction conditions.

The pyrolysis of II (at 150°C, under 1 mmHg pressure) gave, besides hydrogen chloride and inorganic telluride, cyclohexene (41%), chlorocyclohexane(33%), benzene (11% based on II), and a small amount of 3-chlorocyclohexene. The formation of chlorocyclohexane shows that tellurium-catalyzed hydrogen transfer occurs between the alkyl groups of II.

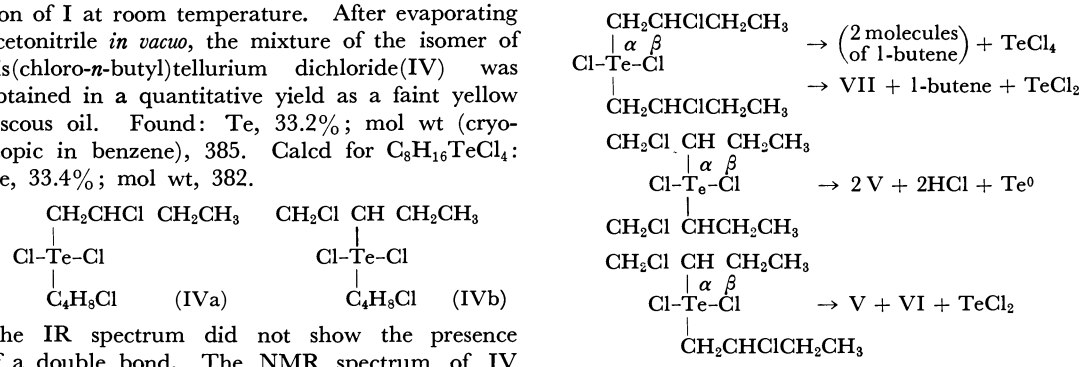
Butene-1 was bubbled into an acetonitrile solution of I at room temperature. After evaporating acetonitrile *in vacuo*, the mixture of the isomer of bis(chloro-*n*-butyl)tellurium dichloride(IV) was obtained in a quantitative yield as a faint yellow viscous oil. Found: Te, 33.2%; mol wt (cryoscopic in benzene), 385. Calcd for $C_8H_{16}TeCl_4$: Te, 33.4%; mol wt, 382.

(IVa)

(IVb)

The IR spectrum did not show the presence of a double bond. The NMR spectrum of IV in deuteriochloroform showed bands at 6.3 ppm from benzene as the internal standard (a pair of triplets; for methyl, relative area 3), 5.5 ppm (a multiplet; for methylene; relative area 2), and 2.5—3.7 ppm (multiplets; for chloromethyl and methine protons; relative area 3). If methyl protons of IVa absorbed at a higher field than those of IVa, the ratio of formation, IVa/IVb, was estimated to be about 0.6.

IV was pyrolyzed at 150°C, under 1 mmHg pressure, and the products except inorganic compounds were analyzed by gas chromatography. The liquid contained 1-chloro-2-butene (V, 52%), 2-chlorobutane (VI, 21%), 3-chloro-1-butene (14%), and 1,2-dichlorobutane (VII, 13%). The gaseous products were 1-butene (88%), *cis*- and *trans*-2-butenes (3%), butadiene (4%), and an unidentified compound (5%). The absence of vinylic chloride suggests that the preliminary formation of the carbonium cation at α-carbon is not probable as a mechanism of the pyrolysis. By postulating that chlorine is more preferentially attacked than hydrogen when both chlorine and hydrogen are bonded to the same carbon atom, most of the products can be explained by β-Cl elimination, β-Cl transfer, β-H elimination, or β-H transfer, as is shown in the following equations, respectively.



However, the formation of 3-chloro-1-butene and 2-butene, which were produced in minor amounts, cannot be accounted for by the above schemes, and a sort of allyl or π-allyl intermediate should be considered for their formation in the course of pyrolysis. The results with other olefins will be reported elsewhere.

Bromination of 2-Oxo-5β-steroids

Yasuo SATOH, Akira HORIUCHI, Tadaaki MATSUKURA and Akira HAGITANI

Department of Chemistry, College of Science, St. Paul's University (Rikkyo Daigaku), Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received September 20, 1968)

In the bromination of any given keto-steriod, Corey has proposed a means of predicting the configuration of bromine in the product.[1] The bromination of keto-5α-steroids which possess a carbonyl group on each position in ring A has been thoroughly investigated,[2] and the configuration of the brominated product in every case was in agreement with Corey's prediction. In the case of the bromination of keto-5β-steroids, however, only that of the 3-oxo derivative has been reported.[3]

The authors wish to report on the bromination of 2-oxo-5β-steroids and on the relation between these products and Corey's prediction.

5β-Chlestan-2-one[4] (4.24 g) was dissolved in acetic acid (100 ml) and a few drops of 49% hydrogen bromide were added, followed by addition of bromine (1.75 g) in acetic acid (10 ml) with stirring for 25 min at 18°C. The reaction mixture was cooled and then the crystals formed were collected. The crystals were dissolved in ether and the ethereal solution was washed, dried and evaporated. Crystallization of the residue from methanol-ether gave needles (3.82 g), mp 128—130°C. IR (KBr disk): 1714 ($\nu_{C=O}$) and 668 cm^{-1} (ν_{C-Br}). NMR (in $CDCl_3$) τ: 4.32 (singlet, one proton). ORD (*c* 0.52, Di) at 26°C: $[\alpha]_{589}$ +9.6°, $[\alpha]_{400}$ +421°, $[\alpha]_{336}$ +2187° (peak), $[\alpha]_{314}$ 0°, $[\alpha]_{288}$ −2369° (trough). Found: C, 69.78; H, 9.80%. Calcd for $C_{27}H_{45}OBr$: C, 69.65; 9.74%.

The bromination of methyl 2-oxocholanate (834 mg)*1,5 was carried out using the technique as described above. The reaction mixture was taken up in ether and the ether extracts were washed, dried and evaporated. On chromatography of the residue on silica gel (50 g), elution with benzene gave an oily product (650 mg). The crystallization of this product from methanol afforded needles (81 mg), mp 138—140°C. IR (KBr disk): 1735, 1710 ($\nu_{C=O}$), 1171 (ν_{C-O-C}) and 673 cm^{-1} (ν_{C-Br}). NMR (in $CDCl_3$) τ: 5.66 (singlet, one proton) and 6.35 (singlet, three protons). ORD (*c* 0.62, Di) at 25°C: $[\alpha]_{589}$ +67.7°, $[\alpha]_{400}$ +271°, $[\alpha]_{335}$ +1394° (peak), $[\alpha]_{313}$ 0°, $[\alpha]_{289}$ −1468° (trough). Found: C, 63.33; H, 8.00%. Calcd for $C_{25}H_{39}O_3Br$: C, 64.24; H, 8.41%. An oily product from the mother liquor was identical with the above crystals in IR- and NMR-spectra.

These compounds are 1β-bromo-2-oxo-5β-steroids, not 1α- or 3-bromo isomers. This has been confirmed by signs of the Cotton effect, Δ[A]- (+233 for 5β-cholestan-2-one and +164 for methyl 2-oxocholanate) and $\Delta\lambda_1$-values (+20 and +18 mμ, respectively) in ORD, by the shifts of C=O stretching bands (+4 and +2 cm^{-1}, respectively) in the IR spectra and by the patterns of the NMR spectra.

In connection with the above investigation, we carried out the enol acetylation of 5β-chloestan-2-one according to directions of Djerassi *et al.* described for the 5α-series.[2] The reaction product was chromatographed in petroleum ether on silica gel. Elution with benzene gave 5β-cholest-1-en-2-ol acetate, mp 103—105°C, $[\alpha]_D^{26}$ +52.0° (*c* 0.997, in $CHCl_3$), from ethanol. IR (KBr disk): 1750 ($\nu_{C=O}$), 1687 ($\nu_{C=C}$) and 1215 cm^{-1} (ν_{C-O-C}). NMR (in $CDCl_3$) τ: 4.66 (singlet, one proton) and 7.93 (singlet, three protons). It has been found, moreover, that bromination of this enol acetate with bromine in acetic acid gave the same product as described above for 5β-cholestan-2-one.

From these results, we may conclude that the enolization of the 2-oxo-5β-steroids occurs in the direction of C_1, not C_3, and that the bromination of these ketones forms the 1β-bromo-2-oxo derivatives. The configuration of these bromoketones is consistent with Corey's prediction for the 2-oxo-5β-steroids.[1]

Further details will be published later.

A Method of Preparing Dicyano Cobalt(III) Complexes with a *Trans*-Configuration

Nobufumi MAKI, Setsuro ITO and Shukichi SAKURABA

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received September 30, 1968)

Recently, Konya *et al.*[1] reported the preparation of cyano-ammine and amine cobalt(III) complexes in a water solution, while Yoneda *et al.*[2] independently described the synthesis of the dicyanobis(ethylenediamine)cobalt(III) complex in dimethyl sulfoxide (DMSO).

In the present communication, the step-by-step substitution method *via* the monocyanomonochloro complex of the $[Co(CN)ClN_4]$-type has been attempted in DMSO and found to be suitable for replacing a chloro-ligand with a CN^- ion without disrupting the complex. This method has been used in the preparation of *trans*-$[Co(CN_2)(NH_3)_4]NO_3 \cdot H_2O$ and *trans*-$[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$ (a new compound). The direct substitution in DMSO *via* the dichloro complex was not adequate for obtaining dicyano-ammine complexes, since the substitution was always accompanied by a disproportionation.

Preparation of *trans*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$. The dimethyl sulfoxide (500 m*l*) in which 3.00 g of KCN had been completely dissolved at 60°C was transferred into a three-necked flask equipped with a reflux condenser and a mechanical stirrer. To this solution were added 11.7 g of *trans*-$[Co(CN)Cl(NH_3)_4]NO_3$.[3] The suspension was heated on a water bath at 70—85°C for three hours. After the solution had been allowed to stand overnight, orange-yellow crystals separated from the solution, they were then filtered and washed with acetone. The crude complex was recrystallized from hot water. The yield was 53.4% of theory. Found: Co, 22.51; C, 9.08; N, 37.72; H, 5.60%. Calcd for $[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$: Co, 22.74; C, 9.27; N, 37.84; H, 5.45%.

Preparation of *trans*-$[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$. The complex was prepared according to the following reaction steps: *trans*-$[Co(CN)(SO_3)(NH_3)_4] \cdot 2H_2O$[4] $\xrightarrow{en}$ *cis*-$[Co(CN)(SO_3)en(NH_3)_2]$ $\xrightarrow{HCl}$ *cis*-$[Co(CN)Clen(NH_3)_2]Cl$ $\xrightarrow[\text{in DMSO}]{KCN}$ *trans*-$[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$. (1) The water solution (100 m*l*) containing 30 g of *trans*-$[Co(CN)(SO_3)(NH_3)_4] \cdot 2H_2O$[4] was treated with ethylenediamine (8.6 g) at 80°C for two hours. The starting complex was once dissolved completely in a solution, evolving ammonia; then again deeper-colored brown crystals deposited from the solution. This reaction mixture was further heated for four hours, filtered, and washed with hot water, ethanol, and ether. The product of *cis*-$[Co(CN)(SO_3)en(NH_3)_2]$ (12 g) was used for the next reaction without further purification, since it is insoluble in water. (2) Thirty grams of *cis*-$[Co(CN)(SO_3)\ en(NH_3)_2]$ were treated with 300 m*l* of concentrated HCl at 80—85°C for five hours. Red crystals of *cis*-$[Co(CN)Clen(NH_3)_2]Cl$ were obtained by adding 200 m*l* of ethanol to the solution under ice cooling. (3) Analogously to the case of the dicyanotetra-ammine complex, 6 g of *cis*-$[Co(CN)Clen(NH_3)_2]Cl$ were continuously stirred in small portions into 300 m*l* of dimethyl sulfoxide containing 2.3 g of KCN, and then the mixture was heated at 80°C for an hour. The yellow solution soon became muddy as the reaction proceeded, it was filtered and washed with acetone. The crude product was recrystallized from hot water below 60°C.

Found: Co, 22.63;C, 18.50; N, 32.61; H, 6.39%. Calcd for $[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$: Co, 22.79; C, 18.58; N, 32.49; H, 6.24%.

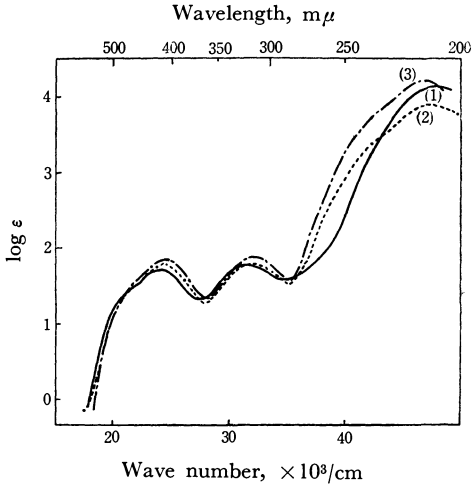

Fig. 1. The absorption spectra of the dicyanocobalt(III) complexes: (1) —— *trans*-$[Co(CN)_2(NH_3)_4]NO_3 \cdot H_2O$; (2) ····· *trans*-$[Co(CN)_2en(NH_3)_2]Cl \cdot H_2O$; (3) — — — *trans*-$[Co(CN)_2en_2]NO_3$.

The Reaction of Copper(II) Acetylacetonates with 2,2-Diphenyl-1-picrylhydrazyl in Benzene

Kaku UEHARA, Makoto TANAKA and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received October 2, 1968)

Sutcliffe and Walkley[1] have pointed out that the redox reaction of metal acetate with 2,2-diphenyl-1-picrylhydrazyl (DPPH) in anhydrous acetic acid gives first-order kinetics for each reactant and that the rate is reduced by the addition of benzene.

This communication relates to a novel reaction of DPPH with metal complexes. Copper(II) acetylacetonates were allowed to react with DPPH in benzene at various temperatures. It was observed that as the reaction proceeded the absorption of DPPH at 525 mμ disappeared and that the reaction was accelerated by the presence of air. Furthermore, the rate was enormously enhanced in a frozen solution. In the experiments to be described below, the reaction mixture was degassed by a modified method because the conventional freeze-thaw cycle was unsuitable for this study.

The rate of the reaction varied remarkably with the structure of the ligand. As is shown in Table 1, the order of the reactivity of the copper(II) chelates was as follows:

$$A > B \gg C > D \gg E \gg F(\text{no reaction})$$

The order is essentially the same as that of the activity in the radical polymerization of styrene and the degree of extension of the ultraviolet tail of the copper(II) chelates[2] into the visible region.

a Frozen benzene solution.

In a frozen benzene solution (3°C), the rate of the reaction was enormously enhanced. A similar acceleration of rate was also observed in frozen *p*-dioxane and *p*-xylene.

The kinetic studies of this reaction were carried out with Cu(II) chelate A_1 in the range from 10 to 30°C. 0.6-order kinetics for DPPH and first-order kinetics for the Cu(II) chelate were observed. The activation energy of the reaction in the liquid benzene was 7.5 kcal/mol. The rate was reduced by the addition of 2,2-diphenyl-1-picrylhydrazine (DPPH-H), but increased by the addition of pyridine.

$Mn(acac)_3$, which is an effective initiator of the radical polymerization,[3] also reacts with DPPH in benzene and shows an enhanced rate in a frozen solution.
