If the concentration of the sulfite solution, while passing through the cell, drops remarkably, the concentration polarisation increases and proceeds nonuniformly, *i. e.*, at the outlet increases more than at the inlet. Owing to this fact, some lower portions of the anion exchanger are converted into the hydroxide form only, and the removal of dissolved oxygen will cease. Therefore, the sulfite solution concentration can be reduced only slightly on passing the cell.

The results, obtained in experiments with distilled water and 0.002 N sulfuric acid solution are given in Table 1. It has been shown possible to reduce the dissolved oxygen content below 10 ppb, and simultaneously to remove all anions present in solution (electrical conductivity of the treated solution at the outlet $\kappa = 1.3\ m\mho \cdot cm^{-1}$) (Table 1, Run 6).

Concurrent Oxygen Exchange and Racemization Reactions of Diaryl Sulfoxides in Phosphoric Acid*[1]

Norio KUNIEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received October 6, 1967)

Several works have been reported on the acid-catalyzed oxygen exchange and racemization reactions of sulfoxides.[1)]

In this note, we wish to report that phosphoric acid[2)] can also cause the concurrent oxygen exchange and racemization reactions of various diaryl sulfoxides while recovering of the sulfoxides is quantitative when quenched with a large amount of water.

For a typical run, 100 mg of ^{18}O-labeled[3)] (0.97 atom% ^{18}O) or optically active[4)] ($[\alpha]_D=+27.1°$, $c=3.6$ $l=1$, in ethanol) *p*-tolyl phenyl sulfoxide was dissolved in 5.0 m*l* of 85% phosphoric acid, and the solution was kept for 2 hr at 120°C; then the resulting pale blue solution was diluted with 30 m*l* of normal water or 30 m*l* of ^{18}O-enriched water (0.45 atom% ^{18}O). The sulfoxide can be recovered as crystalline solid almost quantitatively from the aqueous solution, and its melting point and IR spectrum were found to be identical to those of the starting sulfoxide. The sulfoxides thus recovered under the two different conditions were found to be racemized and also incorporated with ^{18}O of the same concentration of ^{18}O as shown in Table 1.

Mislow, T. Simmons, J. Millow and A. L. Ternay, *J. Am. Chem. Soc.*, **86**, 1452 (1964). c) In Polychloroacetic Acid: S. Oae, M. Yokoyama and M. Kise, unpublished work.

2) Day and Cram have reported that (+)*p*-tolyl methyl sulfoxide was recemized in polyphosphoric acid; J. Day and D. J. Cram, *J. Am. Chem. Soc.*, **87**, 4398 (1965).

3) ^{18}O-Labeled sulfoxides were prepared by the oxidation of the corresponding sulfides with bromine complex of pyridine and ^{18}O-enriched water (1.63 atom%); S. Oae, Y. Onishi, S. Kozuka and S. Oae, This Bulletin, **39**, 364 (1966).

4) Optically active sulfoxides were prepared from (−)menthyl (−)-*p*-toluenesulfinate according to the method developed by Andersen; K. K. Andersen, *Tetrahedron Letters*, **1962**, 93.

Table 1. Oxygen exchange and racemization of *p*-tolyl phenyl sulfoxide in 85% phosphoric acid at 120°C

	^{18}O-Concentration (atom%)	Rotation $[\alpha]_D$ (in EtOH)
Starting sulfoxide	0.97	+27.1° (c=3.6 l=1)
Recovered sulfoxide		
Quenched with $H_2{}^{18}O$ (0.45 atom%)	0.28	
Quenched with H_2O	0.29	+3.8° (c=3.0 l=1)
Natural CO_2	0.21	

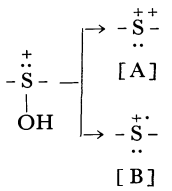
In order to understand the nature of these concurrent oxygen exchange and racemization reactions, we have compiled a substantial amount of kinetic data on the reactions of the diaryl sulfoxides. None of the sulfoxides used was found to undergo thermal racemization under the present condition. The kinetic data of both oxygen exchange and racemization are listed in Table 2.

Table 2. Rate constants of oxygen exchange and racemization of *p*-CH_3-C_6H_4-SO-R[3,4] in 85% phosphoric acid

No.	R[a]	Temp. °C	$k_r \times 10^4$ sec^{-1}	$k_{ex} \times 10^4$
1	C_6H_5	110	0.871±0.046	
2[b]	C_6H_5	120	1.98±0.11	1.93±0.11
3	C_6H_5	130	4.20±0.22	
4	*m*-CH_3-C_6H_4	120	1.91±0.08	
5[c]	*p*-Cl-C_6H_4	120	1.25±0.05	1.27±0.06
6	*o*-Cl-C_6H_4	120	0.543±0.013	

a) Sulfoxide=0.1 mol/l
b) k_{ex}/k_r=0.975, E_a=24.1 kcal, $\Delta S^{\neq}$=−15.7 e.u.
c) k_{ex}/k_r=1.02

The rate of the oxygen exchange was identical to that of the racemization (See; Run No. 2 and 5 of Table 2), which is presumed to suggest that the reaction proceeds through a S_N1 like S–O bond cleavage of the sulfoxide.[5] The whole pattern of substituent effects is quite similar to that of the concurrent oxygen exchange and racemization reactions of diaryl sulfoxides in sulfuric acid.[1a] Apparently, the diaryl sulfoxide dissociates in phosphoric acid to form the hydroxysulfonium ion,[6] and then the partial cleavage of the S–O bond will take place at the transition state. As for the cleavage of the S–O bond, two different ways are conceivable; the one is the heterolysis of the S–O bond to form the sulfidonium ion [A] and the other is the homolysis to form the radical cation [B].



The very small polar effects of substituents on the rates of both oxygen exchange and racemization reactions seem to suggest that the reaction follows the homolytic cleavage.

Diphenyl sulfone was found not to undergo these reactions under the same reaction condition.

The detailed studies of these reactions and ESR measurements now in progress in our laboratory will shed further light on these problems.

Experimental

Kinetic Procedures of the Oxygen Exchange and Racemization Reactions of Diaryl Sulfoxides. An aliquot of ^{18}O-labeled[3] or an optically active[4] sulfoxide was dissolved in 85% phosphoric acid, maintaining the concentration of the sulfoxide to be 0.1 mol/l, at a preset temparature. An aliquot portion (5.0 ml) of the solution was taken up from time to time for 5—7 times and was quenched with ice water. Then the sulfoxide was recovered for both the ^{18}O-analysis and the optical activity measurement by the same procedure described in our previous paper.[1a]

Rotational Isomers in the Crystals of DL-α-Amino-n-butyric Acid

Tadayoshi ICHIKAWA, Yoichi IITAKA and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received October 12, 1967)

For DL-α-amino-n-butyric acid, two crystalline modifications were previously found.[1] They were called as A- and B-forms. A-form is monoclinic, with the space group of $P2_1/a$, and with the unit cell dimensions: $a=9.85$ Å, $b=4.77$ Å, $c=11.94$ Å, $\beta=101°$, $Z=4$. B-form is tetragonal, with $P4_2/n$, $a=13.40$ Å, $c=5.82$ Å, and $Z=8$. By our recent X-ray analyses, it has now been established that all of the three rotational isomers (I, II, and III) shown in Fig. 1 are coexisting in the A-form crystal, whereas only one conformation (II in Fig. 1) is found in the B-form crystal.

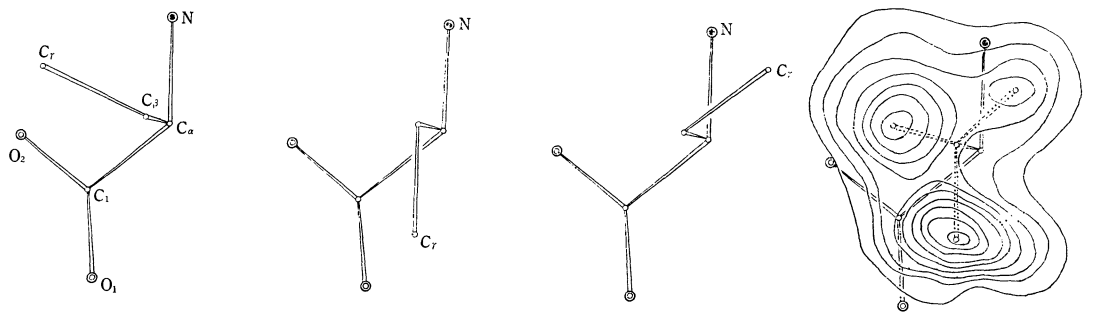
Three-dimensional intensity data were collected from multiple-film equi-inclination Weissenberg photographs taken with filtered Cu$K\alpha$ radiation. For the A-form crystal, data of 809 reflections were used. First, the sharpened three-dimensional Patterson function was calculated. From this function, approximate coordinates of two oxygen atoms were estimated. The signs based upon these coordinates were used in the first three-dimensional Fourier synthesis. The coordinates of all the heavy atoms except those of the γ-carbon could be obtained in the Fourier map. In the course of the refinement, the γ-carbon atom was found to be distributed over the three positions corresponding to the three rotational isomers shown in Fig. 1. Therefore, the site occupancy factors of the γ-C in the three positions were set as parameters in the least squares refinement. After two cycles of full matrix least squares calculation with anisotropic temperature factors, the R factor dropped to 0.13. At the right end of Fig. 1, an electron density map of a section through the centers of the three possible methyl groups is given, which is obtained from the difference Fourier synthesis. This map shows how the methyl group (and two hydrogen atoms) on the β-carbon are distributed among the possible sites in the internal rotation around the C_α–C_β axis. The dihedral angles $C_\gamma C_\beta C_\alpha N$ determined are given in Table 1.

TABLE 1. DIHEDRAL ANGLES[a] $C_\gamma C_\beta C_\alpha N$ IN α-AMINO-n-BUTYRIC ACID

A-form	I	72.4°	(36%[b])
	II	−174.6	(40%)
	III	−53.8	(24%)
B-form		−176.0	

a) This angle is defined so that it is zero when C_β–C_γ bond comes at the eclipsed position with respect to the C_α–N bond. The positive direction is defined as that of the anticlockwise rotation of the C_β–C_γ bond, when viewed along the $C_\beta \rightarrow C_\alpha$ bond as shown in Fig. 1.

b) Normalized site occupancy factors as determined by the least squares calculation.



I II III Observed (A-form)

Fig. 1. Rotational isomers I, II, and III expected for α-amino-n-butyric acid. What is given at the right end is a section of the electron density map at the CH_3 group of A-form. This was obtained by a difference Fourier synthesis by the use of the structure factors calculated on the basis of all the heavy atoms except the γ-carbon. In this synthesis, there appeared three maxima corresponding to the three stable positions of C_γ, and this section was prepared through the plane determined by these three points. The figure is the projection along the c-axis of this section. Contours are drawn at 0.1, 0.2,···, 0.9 electron Å^{-3}.

1) M. Tsuboi, Y. Iitaka, S. Suzuki and S. Mizushima, This Bulletin, **32**, 529 (1959).

For the B-form crystal, intensities of 630 reflections were measured. The Harker section at $w=1/2$ allowed us to estimate only two-dimensional (x and y) coordinates of oxygen atoms and it was not possible to estimate the z parameters from the Patterson function. Accordingly, the analysis was started with two dimensional Fourier methods. After the x and y coordinates of all the heavy atoms (except C_γ) were determined, the approximate z coordinates of these atoms were estimated on the basis of a model-building. The first three-dimensional Fourier synthesis was made on the basis of the estimated coordinates of the two oxygen and one nitrogen atoms. All the carbon atoms including C_γ appeared at reasonable positions. C_γ appeared at the trans position to the NH_3^+ group, with the dihedral angle of $-176°$ (II of Fig. 1). It was ascertained that C_γ takes only this site by a three-dimensional difference Fourier synthesis based upon the coordinates of the heavy atoms except C_γ. After three cycles of least squares refinement with isotropic temperature factors, the R value reached 0.12.

More detailed crystallographic data as well as a full account of the crystal structures of the A- and B-forms of this amino acid will be given elsewhere.

Potential Step Reduction of the Surface Oxide of Platinum Electrodes

Masaki Ioi

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

and Kazuo Sasaki

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Sendamachi, Hiroshima

(Received October 24, 1967)

In previous papers,[1,2] we reported that the cathodic reduction of the surface oxide of a platinum electrode obeys a second order rate law with respect to the fractional coverage of the oxide. An empirical rate equation we proposed for the reaction concerned was

$$i = n\boldsymbol{F}kq^2 \exp(\alpha n\boldsymbol{F}E/\boldsymbol{R}T) \qquad (1)$$

where q is the quantity of the surface oxide to be reduced expressed in g atoms per square centimeter. Two constants in this equation were determined as $k=1.3$ cm^2 mol^{-1} sec^{-1} at 1.3 V SCE and $\alpha=0.26$.

The discussions therein made were mainly based on the results of cyclic voltammetry and chronopotentiometry. In this paper, we shall describe the results obtained by a potential step method.

Basic Concept. Generally, when an electrode reaction accompanied by a simultaneous detachement of an ad-layer at the electrode surface obeys one of the following rate equations

$$i = n\boldsymbol{F}k \exp(\alpha n\boldsymbol{F}E/\boldsymbol{R}T + \gamma q) \qquad (2)$$

$$i = n\boldsymbol{F}kq \exp(\alpha n\boldsymbol{F}E/\boldsymbol{R}T) \qquad (3)$$

or $$i = n\boldsymbol{F}kq^2 \exp(\alpha n\boldsymbol{F}E/\boldsymbol{R}T) \qquad (1)$$

then the current transient at a constant electrode potential should obey one of the following equations, respectively.

$$1/i = \gamma t/nF + 1/i_0 \qquad (2a)$$

$$i = i_0 \exp(-At); \qquad i_0 = nFAq_0 \qquad (3a)$$

or $$1/q = At + 1/q_0 \qquad (1a)$$

where A stands for $k \exp(\alpha n\boldsymbol{F}E/\boldsymbol{R}T)$ and q_0 is the total quantity of the surface oxide to be reduced (g atom/cm^2).

These equations will be examined in the following part of this paper.

Results. In order to confirm the validity of Eq. (1) and hence Eq. (1a), we carried out a series of experiments in 1 N sulfuric acid solutions. A potentiostaic rectangular pulse (repeating frequency: 1 cps, duty ratio: 1) was applied to the working electrode by means of NS-2 model pulse generator of Nichia-Keiki Co. The current transient was photographed using a 50 MC synchroscope (Model 502-A, Matsushita Communication Ind. Co.). Anodic pulse level was kept at 1.2 V against a saturated calomel reference electrode and the cathodic potential was varied between 0.2 to 0.4 V. A cross section of a 1 mm platinum wire sealed in a soft glass tube was used as the working electrode.

In Fig. 1, a typical current transient observed when the potential was stepped down from 1.2 to 0.4 V is shown. It was confirmed that Eq. (1a) best fitted for this curve. This is shown in

1) K. Ohashi, K. Sasaki and S. Nagaura, This Bulletin, **39**, 2066 (1966).
2) K. Sasaki and K. Ohashi, *Electrochim. Acta*, **12**, 366 (1967).

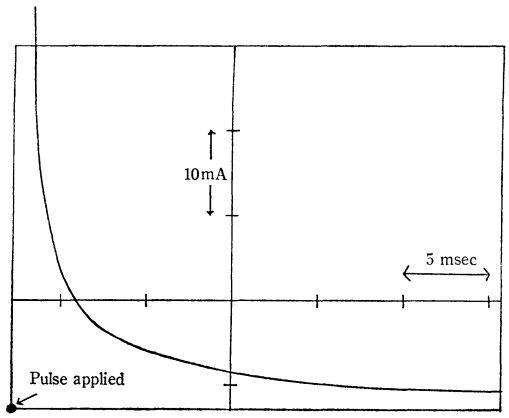

Fig. 1. The transient current for the reduction of surface oxide electrode potential stepped down from 1.2 V to 0.4 V SCE.

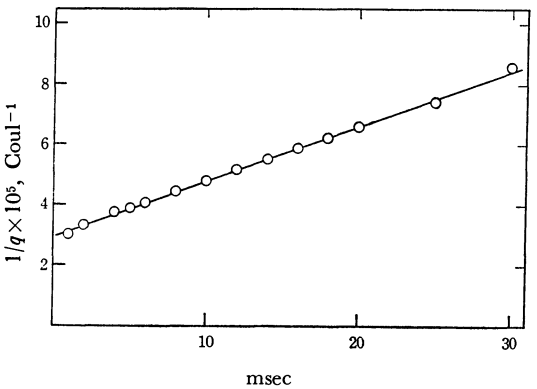

Fig. 2. Examination of Eq. (1a).

Fig. 2 where the reciprocal of the amount of the surface oxide to be reduced is plotted against time. According to Eq. (1a), the slope of the curve must be $k\exp(\alpha nFE/RT)$ so that the logarithmic expression of the slope is

$$\ln s = \ln k + \alpha nFE/RT \quad (4)$$

Accordingly, the transfer coefficient α should be determined from the determination of the slope at various cathodic potentials. The rate constant k will also be determined from the intersect of the $\ln s$ *vs.* E curve. This is shown in Fig. 3. The two constants determined from Fig. 3 were $\alpha = 0.25_5$ and $k = 2.8$ cm^2/mol sec at 1.3 V SCE, respectively. These are in good agreement with the values mentioned in the first of this paper.

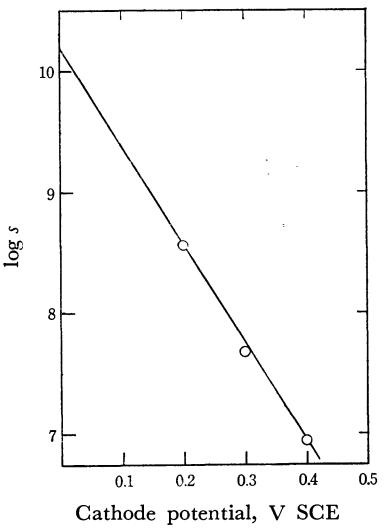

Fig. 3. Graphic representation of Eq. (4).

We are indeed grateful to Professor S. Nagaura for his constant encouragement. We are also grateful to Mr. K. Ohashi for his valuable discussions.

SHORT COMMUNICATIONS

Solvent Effects on ^{14}N Chemical Shifts in Formamides

Hirotake KAMEI

Electrotechnical Laboratory, Tanashi, Tokyo

(Received February 5, 1968)

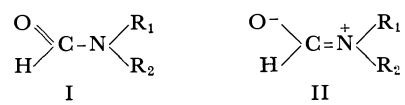
Small chemical shifts in the ^{14}N resonance due to solvent effects have been lost in the experimental error in usual determinations.[1,2] In the present work, ^{14}N chemical shifts in formamide and its derivatives in acetone and methanol solutions were determined at various concentrations by a ^{1}H-{^{14}N} partial irradiating double resonance method. By this method, the chemical shifts can be determined more precisely than by direct, or usual indirect methods, and the small shifts are easily detectable.

Measurements were carried out on a JEOL JNM-3H-60 spectrometer equipped with a ^{1}H-{^{14}N} double resonance attachment.[3] The second radio-frequencies were measured which produced maximizations in the peak heights of the proton resonance lines. The nitrogen-14 resonance frequency of each sample was obtained from an average of the frequencies of the lines in a formyl proton multiplet. The reference was a 4.5 M solution of ammonium nitrate in 3 N aqueous hydrochloric acid. The nitrogen-14 resonance frequency of the ammonium ion was determined within ± 0.1 Hz. The chemical shifts of the amides were obtained relative to the ammonium ion and converted to the nitrate ion scale. The chemical shift of the ammonium ion relative to the nitrate ion has been taken as 353.5 ppm.[1] Extrapolated chemical shifts of amides at infinite dilution are given in Table 1.

TABLE 1. ^{14}N CHEMICAL SHIFTS IN FORMAMIDES
(In ppm referred to NO_3^-)

Compound	Chemical shifts		
	Neat	Infinite dilution acetone	Infinite dilution methanol
F	265.5±0.4	274±2.0	268±1.5
NMF	266.4±0.7	272±2.0	267±1.5
DMF	272.3±0.5	273±1.5	264±1.5
NEF	247.1±0.7	253±2.0	247±1.5
DEF	246.5±0.5	247±1.5	237±1.5

In the acetone solutions of formamide (F), *N*-methyl formamide (NMF) and *N*-ethyl formamide (NEF), high field shifts are observed on dilution. In the methanol solutions of *N,N*-dimethyl formamide (DMF) and *N,N*-diethyl formamide (DEF), the ^{14}N resonances are shifted to low field on dilution. Detectable dilution shifts are not found in methanol solutions of NMF and NEF, and in acetone solutions of DMF and DEF. These solvent shifts are attributed to the hydrogen bonding interaction involving the carbonyl oxygen of the amide. The amide group is generally represented by the canonical forms I and II.



I II

It has been postulated that the ^{14}N chemical shifts is dominated by the paramagnetic term σ_p.[1] Because of the greater asymmetry of the electronic structure around the nitrogen nucleus, the ^{14}N resonance of form II would be expected to occur at lower field than that of form I. Hydrogen bond formation on carbonyl oxygen should increase the contribution of form II, and causes a low field shift. The effect of substituent on the chemical shift is also observed. The above facts indicate that chemical shifts at infinite dilution in inert solvents are needed for detailed discussions on substituent shifts.

Unstable Intermediates. The Electronic Structures of Benzynes and Hetarynes

Teijiro YONEZAWA, Hideyuki KONISHI and Hiroshi KATO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 18, 1968)

Benzynes are known to be typical unstable intermediates on the basis of many experimental results.[1] Hetarynes, benzyne analogues derived from heteroaromatic compounds, such as 3,4-pyridyne,[2],*1 4,5-pyrimidyne[3] and 2,3-thiophyne[4] may also be supposed to be unstable intermediates. Calculations have been carried out for benzyne and 3,4-pyridyne by several authors,[5-8] but the electron interaction has never explicitly been taken into account in these treatments. In the present paper, calculations on these intermediates and their isomers are performed using a semi-empirical SCF MO method for valence electron systems previously reported on by us.[9] Here, however, our procedure is simplified by assuming the zero-differential overlap.*2

To estimate the unknown bond lengths of arynes, we utilize such a SCF procedure as has been proposed by Coulson,[5] a procedure which makes use of an empirical curve relating the bond order to the bond length.[10] In the present treatment, we use the following relation between the bond order and the total electronic energy, E_{AB}, of the AB bond:

$$E_{AB} = \sum_{r}^{A} \sum_{s}^{B} P_{rs}(H_{rs} + F_{rs})$$

where $\sum_{r}^{A}$ denotes the summation over all the valence AO's which belong to the A atom, and P_{rs}, H_{rs} and F_{rs} are, respectively, the bond order, the core-resonance integral, and Fock's operator between the rth and the sth AO's. The curve is obtained by plotting the E_{AB} values *vs.* the observed bond lengths, R_{AB}, for typical molecules (for example, C_2H_6, C_2H_4, C_6H_6, C_2H_2, *etc.* as to the carbon-carbon bonds). The iteration is repeated until a self-consistency between the initial R_{AB} and that graphically-obtained.

The bond lengths after iteration for the carbon-carbon "triple" bond, presumed to be so at the beginning of the calculations, are as follows (in Å units): 1.29 for benzyne, 3,4-pyridyne, and 2,3-pyridyne; 1.31 for 4,5-pyrimidyne; 1.26 for 2,3-thiophyne and 1.33 for 3,4-thiophyne. These bonds are probably triple bonds in view of their short lengths and large π and π' bond orders. Calculation shows further that the highest occupied (HO) and the lowest vacant (LV) molecular orbitals of arynes may be approximately described as linear combinations of nonbonding sp^2-type hybrids[11] of the carbon atoms in the C≡C bond.

TABLE 1. THE CALCULATED LOWEST TRANSITION ENERGIES (σ-σ^*) OF ARYNES (eV)

	State	Singlet	Triplet
Benzyne	B_2	3.73	1.65
3,4-Pyridyne	A′	3.44	1.82
2,3-Pyridyne	A′	3.13	1.60
4,5-Pyrimidyne	A′	2.56	1.46
2,3-Thiophyne	A′	2.80	0.85
3,4-Thiophyne	B_2	2.91	0.86

The calculated lowest transitions are the σ-σ^* type transitions between HO and LV levels mentioned above; the transition energies are presented in Table 1. In Table 1, it may be seen that the lowest triplet states of such arynes as thiophynes lie very close to the ground states. The calculated energies of n-π^* type transitions (4.20 eV for the pyridine $^1B_1$ state, 5.02 eV for the 3,4-pyridyne $^1A''$ state, and 5.95 eV for the 2,3-pyridyne $^1A''$ state) indicate that there exist blue shifts of the bands, taking pyridine as the basis. The larger shift in 2,3-pyridyne than in 3,4-pyridyne may be due to the stronger interaction between the lone pair on the nitrogen atom and the nonbonding sp^2-type hybrids on the carbon atoms. Full details will be published in the near future.

*1 This may also be called 3,4-dehydropyridine.

*2 Full details of the present treatment will be published in the near future.

Novel Reactions of Iodosobenzene with Various Organic Compounds

Takao TAKAYA, Hiroji ENYO and Eiji IMOTO

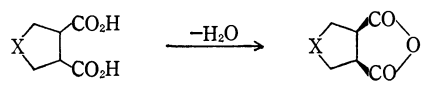
Department of Applied Chemistry, School of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received January 24, 1968)

Little attention has so far been paid to the chemistry of iodosobenzene[1] with various organic compounds. When a solution of an alcohol (RCH_2OH, 10 mmol) and iodosobenzene (11 mmol) in dry dioxane (20 m*l*) was refluxed for 12 hr in a stream of nitrogen gas, the corresponding aldehydes (RCHO) were obtained in the following yields[2]: (R, %); (C_6H_5–, 85), (*p*-CH_3-C_6H_4–, 98), (*p*-CH_3O-C_6H_4–, 67), (*p*-Cl-C_6H_4–, 79), (C_6H_5CH=CH–, 88), (CH_2=CH–, 56), (H–, 40)[3], (CH_3–, trace)[3], (*n*-C_3H_7–, trace), and (2-furyl, 31). Glyoxal was obtained from ethylene glycol in a 15% yield. When 20 mmol of iodosobenzene were used to 10 mmol of benzyl alcohol, the yield of benzaldehyde was 86%. This result seems to show that the oxidation of benzaldehyde to benzoic acid does not proceed. In fact, when benzaldehyde was treated with iodosobenzene under similar conditions, benzaldehyde was recovered in a 90% yield.

Compounds other than primary alcohols were also oxidized by iodosobenzene under conditions similar to those described above. The results are summarized in Table 1.

Another interesting reaction of iodosobenzene is the dehydration of the dibasic acid of the *cis*-Ia[4] or Ib[4] type to the corresponding anhydride, IIa[4] or IIc, and that of 1,4-butanediol to tetrahydrofuran (see Table 1):



Ia: X=CH_2 IIa: X=CH_2
Ib: X=S
Ic: X=SO IIc: X=SO

After the *cis*-Ib (10 mmol) and iodosobenzene (20 mmol) in dioxane (20 m*l*) had been refluxed for 12 hr, the reaction mixture was evaporated to dryness *in vacuo* and the residue was recrystallized from acetone to give IIc in a 78% yield; mp 205—207°C. *trans*-Ib did not afford IIc, but instead the sulfoxide *trans*-Ic was obtained in a 27% yield; mp 170—171°C from ethanol-acetone. Similarly, *cis*-Ia gave the anhydride IIa in a 65% yield, but the use of *trans*-Ia resulted in its recovery in a 70% yield. Under the above reaction conditions, no formation of an anhydride, IIa or IIc, from *cis*-Ia or Ib was observed in the absence of iodosobenzene.

TABLE 1. OXIDATION OF COMPOUNDS OTHER THAN PRIMARY ALCOHOLS*1

A solution of compounds (10 mmol) and iodosobenzene (11 mmol) in dioxane was refluxed in each run.

Compound	Reaction time hr	Product	Method of isolation	Yield, %
$C_6H_5CH_3$	12	C_6H_5CHO	a	17

A New Organometallic Compound with a Ga–Mn Bond

Satoru ONAKA, Toschitake IWAMOTO and Yukiyoshi SASAKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received February 7, 1968)

In this communication, we report a compound having a Ga–Mn bond, $Cl_2GaMn(CO)_5 \cdot C_4H_8O$, which was synthesized through a reaction between $GaCl_3$ and $NaMn(CO)_5$ in THF (tetrahydrofuran, C_4H_8O). This compound has a very intense absorption at 149 cm^{-1} in the far-infrared region, which suggests the presence of direct bonding between gallium and manganese. The method of synthesis is as follows: Equimolar amounts of gallium chloride and sodium pentacarbonylmanganate(−I) were separately dissolved in THF, and heated together at 30—40°C under dry nitrogen for 2 hr, and excess THF subsequently distilled off under reduced pressure. The residue was recrystallized from a mixture (1 : 5) of THF and *n*-pentane. A yellow crystalline powder was obtained. Yield 80%. Found: Cl, 17.57; Ga, 17.88; Mn, 12.51%. Calcd for $C_9H_8O_6Cl_2GaMn$: Cl, 17.42; Ga, 17.11; Mn, 13.48%. mol wt, Found: 441 (osmometry in methyl ethyl ketone). Calcd: 408.

TABLE 1. INFRARED ABSORPTION BANDS (cm^{-1})*

2010 s		
1996 vs		
1991 vs		
193 w	120 m	274 vs
149 vs	113 m	123 s
	106 m	73 m

* Only absorption bands below 300 cm^{-1} are listed in the far-infrared region.

** Carbon tetrachloride solution in the carbonyl region, and the Nujol mull in the far-infrared region.

The compound is hygroscopic, but stable in a dry air. It is soluble in several organic solvents, especially in acetone. In solution it was unstable and decomposed in a day or two. Under conditions of 80°C and 0.1 mmHg, it decomposed without melting or sublimation. Thermogravimetry in a nitrogen atmosphere revealed a weight loss of about 60% in a temperature range of 80—220°C. The decrement is in fairly good agreement with the value of 52% calculated for the loss of one THF and five carbon monoxide molecules. The observed infrared absorption bands are shown in Table 1. In the carbonyl region, no absorption band due to bridging carbonyl was observed. The strong absorption band at 149 cm^{-1} can be assigned to a Ga–Mn stretching vibration from its position and intensity. Considering the analytical results, the molecular weight determined, the thermal decomposition behavior and the infrared spectrum, this compound may have the structure shown in Fig. 1. So far, a compound having a Ga–Mn bond has not been obtained. A detailed analysis of the infrared spectrum in the carbonyl region will be reported in following papers.

Dipole Moment, Molecular Conformation and Crystal Structure of 1,4-Bis(dicyanomethylene)cyclohexane

Ariyuki AIHARA, Chikazu KITAZAWA and Fujiko IWASAKI

Department of Materials Science, University of Electro-Communications, Chofu, Tokyo

(Received February 20, 1968)

With the aim of obtaining some knowledge of the molecular conformation of 1,4-bis(dicyanomethylene)cyclohexane,*1 a dipole moment measurement in dioxane solution, and a three dimensional X-ray analysis of the crystal structure were carried out.

The increase in dielectric constant of the solution with concentration (0.416×10^{-3}—1.677×10^{-3} weight fractions) was measured at three temperatures with the use of a heterodyne-double-beat oscillator(1 MHz) constructed in this laboratory, and a pycnometer was used to determine densities. Values of total polarization were then calculated using both the Halverstadt-Kumlers and Guggenheim-Smiths equations. Dipole moment results obtained through the above procedures are shown in Table 1.

TABLE 1. DIPOLE MOMENT OF 1,4-BIS(DICYANOMETHYLENE)CYCLOHEXANE IN DIOXANE (Debye)

Temperature °C	μ(H-K procedure)	μ(G-S procedure)
40.2	2.14	2.31
50.1	2.20	2.36
59.9	2.42	2.53

As can be seen in the table, the dipole moments thus obtained are fairly large and also show a marked temperature dependence. Since the contribution from atomic polarization,[1] which is supposed to play a significant role in this case, has been neglected in calculating the dipole moment values, we must admit, apart from the possibility of a solvent effect, that these values might not necessarily represent the true dipole moment. Still, considering the symmetrical positions of the two dicyanomethylene substituents on the cyclohexane skeleton, and also the two possible conformations of the skeleton (a chair and a twisted-boat), the results obtained here seems to suggest that the molecule of 1,4-bis(dicyanomethylene)cyclohexane exists predominantly as a flexible twisted-boat form in solution. Molecules in a rigid chair conformation should exhibit a much smaller dipole moment temperature dependence,[1] if they showed any real moment due to distortion of molecular symmetry through solute-solvent interactions. The possibility of complex formation, such as a charge-transfer complex,[1,2] is also excluded in the light of the positive temperature dependence of the dipole moment.

Thus, it seems most probable that the molecule exists as a flexible twisted-boat conformer in solution, the libration of the two highly polar substituents on the central skeletion thereby giving rise to a larger value for the average dipole moment.

On the other hand, a three dimensional X-ray analysis of the crystal structure clearly revealed that the molecule of 1,4-bis(dicyanomethylene)-cyclohexane takes a chair conformation in the crystalline state. This fact is an interesting contrast with the case of 1,4-cyclohexanedione, where the molecule is known to behave as a flexible twisted-boat conformer, both in solution,[3-5] and in the crystal.[6,7] A strong interaction between adjacent molecules through highly polar and bulky dicyanomethylene substituents, in the 1,4-bis-(dicyanomethylene)cyclohexane crystal, must be responsible for the preference of the chair conformation to that of a flexible one which is more preferable for the 1,4-cyclohexanedione molecule because of the possible contribution of its high entropy term to decreasing the free energy.

Crystallographic data are as follows:

Monoclinic; Space group: $P2_1/n$
$a=10.625+0.005$ Å
$b=7.073+0.005$ Å
$c=7.250+0.005$ Å
$\beta=92.30+0.08°$
$Z=2$

Details will be published later in this Bulletin.

The Electron Spin Resonance of Mn^{2+} Ion in Polyphosphate

Masaji MIURA, Akinori HASEGAWA and Masayuki WATANABE

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received August 3, 1967)

A part of cation in polyphosphate was replaced with Mn^{2+} ion. Zero-field splitting parameter D due to the crystal field with axial symmetry was estimated according to Allen's method from the ESR spectrum of Mn^{2+} ion. The value of D changes with the change in the state of polyphosphate, crystalline or glassy. As the degree of polymerization of sodium polyphosphate glass decreases, the value of D increases and approaches to the value corresponding to the crystalline state. These phenomena were interpreted as due to the disorderness of glassy state. The value of D was found to change with the variation of the kind of cation in polyphosphate. This was explained in terms of the effective cationic field.

Many solid substances can have two states, that is, glassy and crystalline. Polyphosphate also has these two states.[1] Many phosphates having different kinds of cations and various degrees of polymerization are included under the name of polyphosphate. The characters of solid polyphosphate, therefore, are affected by these factors.

The environment of one of lattice points, atom or ion, is regular in crystalline state, whereas it is irregular in glassy state. So it is expected that the crystal field in solid polyphosphate is affected not only by the kind of cation and the degree of polymerization, but also by the state, glassy or crystalline. On the studies of the crystal field, the phenomena of the zero-field splitting in ESR spectrum offer many valuable informations.[2]

Allen has recently advanced the method by which zero-field splitting parameter D can be estimated from the relative intensities of the hyperfine structure of the ESR spectrum of Mn^{2+} doped in methanol and 12 N HCl, each of which can take two states, glassy and crystalline.[3]

In the present paper, a part of the cation of polyphosphate was replaced with Mn^{2+} and its ESR spectrum was observed. The zero-field parameter D due to the crystal field with axial symmetry in polyphosphate was estimated with Allen's method.

Theoretical

As Mn^{2+} ion has $S=5/2$ and $I=5/2$, the hyperfine and fine structures are expected to occur in its spectrum. The spin Hamiltonian, therefore, is given by

$$\mathscr{H} = g\beta\mathbf{H}\cdot\mathbf{S} + D[S_z^2 - \frac{1}{3}S(S+1)] + A\mathbf{S}\cdot\mathbf{I} \quad (1)$$

The first term of the right side represents the Zeeman effect and the next term indicates the fine structure interaction induced by the crystal field with axial symmetry. The last term shows the hyperfine interaction between the electron spin and the ^{55}Mn nuclear spin. The ESR spectra for glassy and polycrystalline states consist predominantly of hyperfine structures of the allowed transitions from $|-1/2m>$ to $|1/2m>$ state and the forbidden transitions from $|-1/2m>$ to $|1/2m+1>$ or $|1/2m-1>$ state, where $-1/2$ and $1/2$ denote the electronic spin magnetic quantum numbers and m is the nuclear spin magnetic quantum number.

For glassy and polycrystalline states, Allen[3] has derived the equation of the intensities of the allowed transitions by using the first-order perturbation theory.

$$I_m \propto 2 - \frac{A^2(35-4m^2)}{2(g\beta H)^2} - \frac{5.334D^2}{(g\beta H)^2} - \frac{D^2(34.14)(35-4m^2)}{(g\beta H)^2} + \frac{D^4(208)(35-4m^2)^2}{(g\beta H)^4} \quad (2)$$

Using $A=95$ gauss and $H=3245$ gauss and extrapolating the relation between the relative intensity and the D value to larger D value, Allen's graph was obtained as shown in Fig. 1. This graph gives the relation between the ratios of the intensity of the hyperfine line of $m=-5/2$ to those of $m=-1/2$ and $-3/2$ and the zero-field splitting parameter D. These intensities were estimated from the signal height of the first derivative, although the line width must be included in the interpretations of the intensity. As the line width is broadest in $m=$

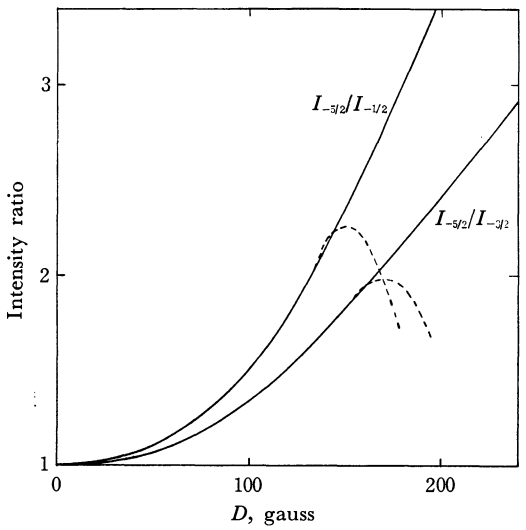

Fig. 1. Intensity ratios plotted against D. The dashed line shows the curve from Eq. (2), the solid line the extrapolated curve from the calculated curve up to $D=120$ gauss.

$-5/2$ line, the estimated value of D must become larger, if the line width is taken into account. These widths of the hyperfine structures, however, showed no detectable change in any cases. Accordingly, no substantial problems as to the line width remain at the discussion in this paper.

Experimental

Manganese hydrogen phosphate dihydrate ($MnHPO_4 \cdot 2H_2O$), which was used as the source of Mn^{2+} ion, was purified by the recrystallization from its aqueous solution. The salt was added to the aqueous solution of sodium dihydrogen phosphate dihydrate ($NaH_2PO_4 \cdot 2H_2O$), to give the molar ratio of the former to the latter of 10^{-4} : 1. The solution was evaporated to dryness. The product was heated at a temperature between 300 and 900°C in a furnace and then quenched with ice water.

Sodium polyphosphate melts at about 580°C. By the heat treatment at a temperature higher than 580°C, the glass of sodium polyphosphate was obtained, whereas by the treatment below its melting point, the crystal was gained. The crystal was also grown in the melt by slow cooling after heating at 900°C and seeding it.[1]

The samples used for studying the effects of crystallization water and polymerization on the D value were prepared by the following procedures. The crystal of $NaH_2PO_4 \cdot 2H_2O$ incorporated with Mn^{2+} ion was obtained by the recrystallization from the aqueous solution of their mixture. This crystal was evacuated and heated in a sample tube for ESR measurement. This treatment results in the elimination of water from the crystal following the polymerization of the orthophosphate. The amount of the water eliminated was determined gravimetrically. The progress of the polymerization was observed by paper chromatography.[4]

Polyphosphate glasses having various degrees of polymerization were prepared from $NaH_2PO_4 \cdot 2H_2O$ and disodium hydrogen phosphate dodecahydrate ($Na_2HPO_4 \cdot 12H_2O$) by varing their mixing ratio. The degree of polymerization was determined by the pH titration method.

The glass and the crystal of polyphosphates with different cations were obtained by heating and then quenching the mixtures of phosphoric acid (H_3PO_4) and the following orthophosphates: dilithium hydrogen phosphate (Li_2HPO_4), magnesium hydrogen phosphate trihydrate ($MgHPO_4 \cdot 3H_2O$), calcium hydrogen phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$) and barium hydrogen phosphate ($BaHPO_4$). Potassium polyphosphate was prepared from potassium hydrogen phosphate (KH_2PO_4).

ESR measurements of these polyphosphates were carried out at room temperature, except for the case particularly denoted, by using the spectrometer described elsewhere.[5]

Results and Discussion

The Effect of the Concentration of Mn^{2+} Ion. The effect of the concentration of Mn^{2+} ion on the ESR spectrum was examined for sodium polyphosphate glass. When the relative concentration of Mn^{2+} ion to phosphorus atom was lower than 10^{-3}, the line width observed was practically constant. Therefore, the relative concentration of 10^{-4} was selected for Mn^{2+} ion in the present work. One of the ESR spectra was shown in Fig. 2.

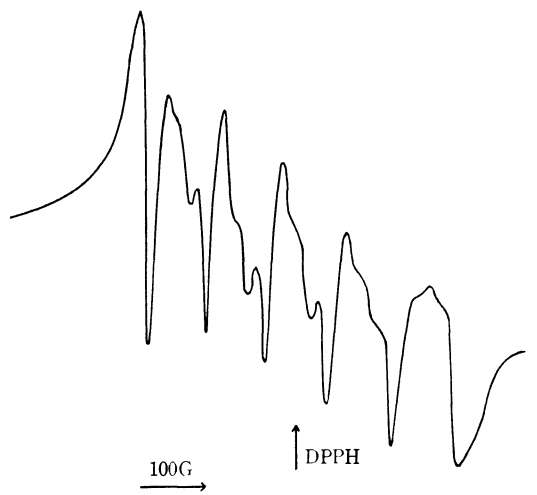

Fig. 2. ESR spectrum of Mn^{2+} in sodium polyphosphate glass.

The Effect of Heat Treatment Temperature on the Value of D. Sodium polyphosphate incorporated with Mn^{2+} ion was obtained by heating and quenching. The zero-field splitting parameter D of the Mn^{2+} ion estimated with Allen's graph is shown in Fig. 3 in relation to the heat treatment temperature. This figure shows that the parameter

5) A. Hasegawa and M. Miura, This Bulletin, **40**, 2553 (1967).

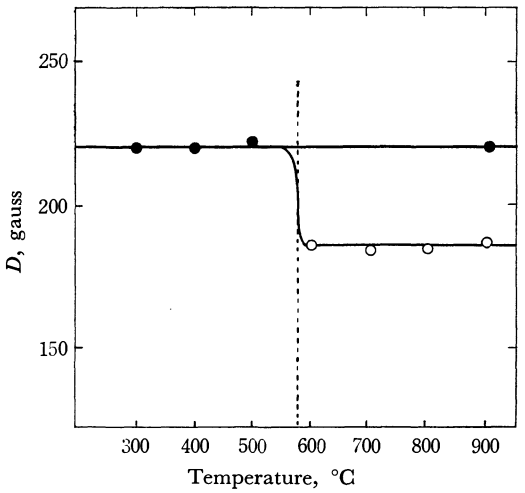

Fig. 3. The relation between D value and heat treatment temperature of sodium polyphosphate. ●: crystal; ○: glass. Dotted line shows the melting point.

D takes the value about 10% lower when treated above 580°C than that when heated below 580°C. This temperature is coincident with the melting point of sodium polyphosphate. By the treatment at a lower temperature than this, the crystal of sodium polyphosphate was obtained, whereas by that at higher temperature, the glass was obtained. The crystal of sodium polyphosphate was also obtained from the melt by cooling and seeding after heating at 900°C. The last crystal is known as Kurrol's sodium salt having very high degree of polymerization, *ca.* 10^4,[6] the D value of which is the same as that for the crystal obtained by heating at a temperature below the melting point. Thus, the D value depends largely on the state, crystalline or glassy, and has no relation to the degree of polymerization in case of the crystalline state.

The Effect of Water of Crystallization on the Value of *D*. The variation of the D value with the amount of the water of crystallization was investigated for $NaH_2PO_4 \cdot 2H_2O$ and the result obtained is given in Fig. 4.

The value of D increases first gradually, then abruptly with the progress of the elimination of water and finally takes a value which agrees with that for polyphosphate crystal. The water was removed by evacuating $NaH_2PO_4 \cdot 2H_2O$ in the initial stage at 50°C and finally at 260°C. Until almost all the crystallization water was eliminated, polymerization did not practically occurred, which was ascertained by a paper chromatographic method in both acidic and basic solvents.[4] The increase in the D value after the removal of all the crystallization water is due to the formation of pyrophosphate which was also ascertained by paper chromatography. The

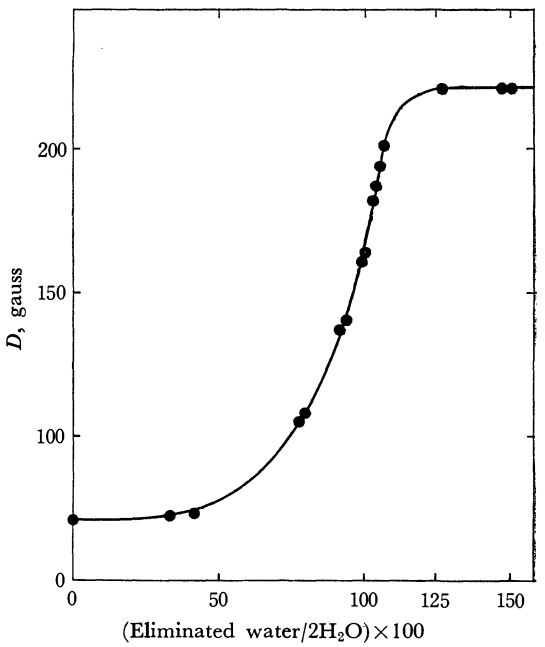

Fig. 4. The variation of D value with the elimination of water from $NaH_2PO_4 \cdot 2H_2O$. The positions of 50, 100, 125 and 150 on the abscissa mean the elimination of one of the crystallization waters and two of them and the formation of pyrophosphate and Kurrol's salt, respectively.

water of crystallization behaves to reduce the value of D. The water may coordinate to Mn^{2+} ion with high symmetry and shield the crystal field caused by phosphate anion from Mn^{2+} ion, resulting the decrease in the value of D.

The difference between the D values for the glass and the crystal of sodium polyphosphate, which is seen in Fig. 3, is due to the amount of distortion on Mn^{2+} ion. When Mn^{2+} ion exists as an impurity in infinite regular lattice of crystal, certain amount of perturbation may be exerted to lattice by Mn^{2+} ion. The lattice thus perturbed produces the distortion on Mn^{2+} ion. In glassy state, however, such perturbation and distortion may be weakened by lack of the regular structure.

The interpretation described above, however, may encounter the following criticism. As the random structure in glassy state gives the D value having some distribution, the value obtained with Allen's method is an average one. Whereas, the D value in crystalline state is directly evaluated with the method because of the lack of the distribution. The variation in the D value due to the difference of the state may depend upon the distribution.

The Effect of the Degree of Polymerization. The glasses having different degrees of polymerization were prepared and their D values were estimated (Fig. 5). The value increases with the decrease in the degree of polymerization. The value extrapolated to triphosphate was coincident with the value

6) M. Miura and Y. Kubota, *ibid.*, **40**, 466 (1967).

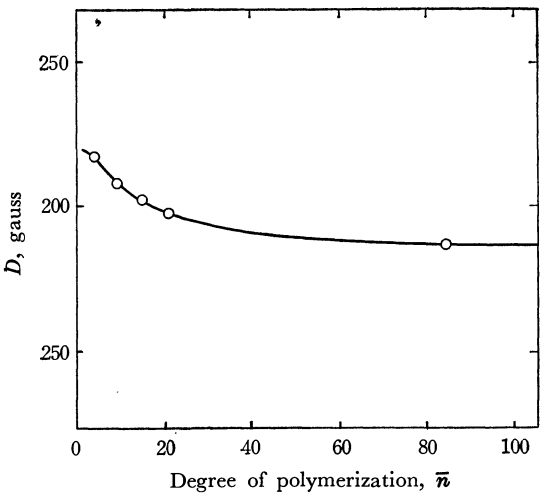

Fig. 5. The variation of D value with degree of polymerization of sodium polyphosphate glass.

obtained for the crystal of polyphosphate. This is closely correlated with the fact that the glass of triphosphate was not obtained by the method described here. The D value decreases accompanied with the increase in the degree of polymerization and approaches to the value for the glass in Fig. 3. This change, therefore, corresponds to the shift from crystalline state to glassy one, accompanied with the increase in the degree of polymerization of sodium polyphosphate glass. In the glass with low degree of polymerization, the environment of Mn^{2+} ion is considerably regular and is close to that in crystal.

The Effect of the Kind of Cation in Polyphosphate on the Value of D. The D values were also estimated for the glasses and crystals of polyphosphates having different kinds of cations. The

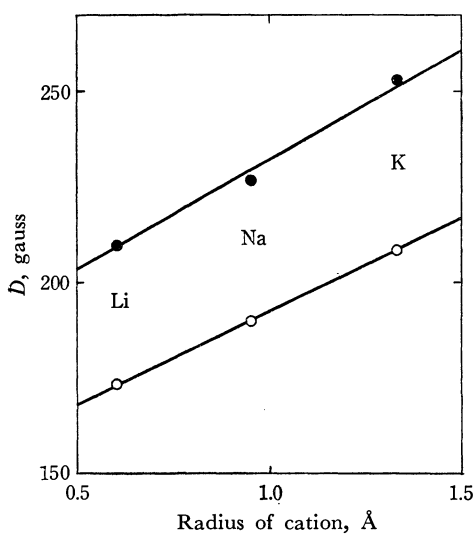

Fig. 6. The relation between D and radius of cation in alkali polyphosphate.
○: glass; ●: crystal

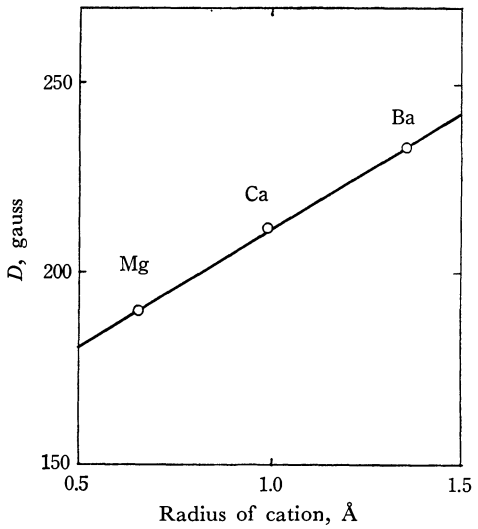

Fig. 7. The relation between D and radius of cation in alkaline-earth polyphosphate glass.

D values for the crystalline states of polyphosphates with alkaline earth cations could not be estimated owing to their peculiar spectra. The difference between the cases of alkali and alkaline earth cations, therefore, can be insufficiently discussed with these data. Almost linear relations, as shown in Figs. 6 and 7, exist between the value of D and radius of cation[7]; the decrease in radius of cation causes the decrease in the D value.

When cation with small radius strongly attracts the oxygen anions in polyphosphate by high effective cationic field, preferential coordination of the oxygen anion to Mn^{2+} ion is weakened. Thus, the center of the lone pair of oxygen may become more distant from Mn^{2+} ion and the value of D is considered to be reduced.

The Effect of Temperature on ESR Spectrum. ESR measurements of the glass and crystal of sodium polyphosphate were done at room temperature and the temperature of liquid nitrogen. ESR spectra obtained at both temperatures are essentially the same with each other. It may be concluded from this result that the value of D is not influenced by temperature and that the line width in the ESR spectrum of Mn^{2+} is not affected by relaxation mechanism.[8]

The authors wish to express their hearty thanks to Dr. B. T. Allen of University of Oregon Medical School for his kind answer to our question. Special thanks are also extended to Professor Junkichi Sohma of Hokkaido University for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1039—1045 (1968)

Dissociation Pressures of Various Metallic Oxides

Kumasaburo KODERA, Isao KUSUNOKI and Shinkichi SHIMIZU*1

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 28, 1967)

Gases evolved during a vacuum heat treatment of various oxides were analyzed by means of an omegatron mass spectrometer. Carbon dioxide, carbon monoxide and water were detected as main gases evolved at lower temperatures. Oxygen due to thermal dissociation of ZnO, CdO, NiO, CuO, Cu_2O, and WO_3 was found at high temperatures. In the case of MoO_3, however, evolution of oxygen was not observed. The equilibrium pressures of the evolved gases over these oxides have been measured with a McLeod gauge and a Knudsen gauge. The oxygen dissociation pressures of ZnO, CdO, NiO, CuO, and Cu_2O were measured and compared with the calculated values.

The properties of metallic oxides were studied by many investigators from the various points of view. Especially, the semiconductivity of these oxides has been studied in relation to catalytic activities. However, the catalytic activity and the electrical conductivity of an oxide depend on the method of preparation and pretreatment.

In the case of *n*-type oxides (*e.g.*, ZnO, CdO, *etc.*), it is well known that the activity and conductivity are enhanced through a vacuum heat treatment. These effects may be attributed to the loss of oxygen from the stoichiometric composition. Baumbach and Wagner[1] found that the electrical conductivity of the oxides which were reduced by hydrogen or carbon monoxide depends on the equilibrium pressure of oxygen, and said that this is due to thermal dissociation accompanied with oxygen evolution represented by the following formula;

$$Zn^{2+}O^{2-} \rightleftarrows \frac{1}{2}O_2(g) + Zn^{+}(o) + e. \qquad (1)$$

However, thermal dissociation pressures of oxygen of these oxides are uncertain and few reports[2] have described the reason why non-stoichiometric oxides are produced at temperatures lower than their thermal decomposition temperatures.

Recently one of the present authors (I. K.)[3] pointed out that the loss of oxygen may be due to the reduction by impurity carbon contained in oxides, and in dirty vacuum the oxides may also be reduced by residual vapors of hydrocarbons. In the present work, we tried to obtain quantitative data about the dissociation pressures of oxygen of various oxides and to study the mechanism of dissociation.

The evolved gases during the heat treatment in vacuum were analyzed by an omegatron mass spectrometer. Up to the present, most of the investigators measured only the total pressure of the evolved gases, but it is very important to identify the gaseous species. In the present experiment, we found that carbon dioxide, carbon monoxide, and water were the main species evolved at lower temperatures, and that oxygen due to thermal dissociation of oxides such as ZnO, CdO, NiO, CuO, Cu_2O, and WO_3 was observed at higher temperatures.

Experimental

Figure 1 shows a schematic diagram of the apparatus, which is composed of two parts. Main part is made up of a decomposition cell made of fused quartz, and total pressure gauges. An omegatron mass spectrometer is in the other part. These parts are connected by a variable leak valve. The vacuum lines were constructed of molybdenum glass, and a copper sealed metal valve was used to cut off the main part from a pumping system. The apparatus was bakable at 450°C and its ultimate vacuum was 5×10^{-9} Torr. With liquid nitrogen traps no hydrocarbon was found in residual gases.

As a total pressure gauge a Knudsen gauge or a McLeod gauge was used. The Knudsen gauge of Klumb-Schwarz type was made in our laboratory[4] and calibrated with the McLeod gauge.

The omegatron tube, a modified simple box type with a rhenium electron emitter filament, was made by Mitsubishi Electronic Company. A large permanent magnet of about 4500 gauss with poles of 60 mm diameters and 35 mm gap was used. The resonance ion current of the omegatron was measured by a Takeda TR-84H vibrating reed electrometer. By combining these parts the following performance of the omegatron was obtained;

Samples of oxides were of extra pure grade and were used without further purification. In the decomposition cell 1 mmol of a powdered sample was placed and evacuated for a day in high vacuum at room temperature. After this treatment the main part of the apparatus, the volume of which is about 1 *l*, was cut off from the pump by the metal valve and the sample was heated in a furnace. The temperature was measured by a chromel-alumel thermocouple.

The total pressure of the evolved gases was measured by the McLeod gauge or the Knudsen gauge at regular intervals. Usually, after about a few hours it attained a stationary value. Then, the gas was introduced into the omegatron through the variable leak valve and analyzed. After the measurement, the apparatus was evacuated and the same procedure was repeated from room temperature up to 1200°C. The oxygen partial pressure evaluated from the omegatron measurement was taken to be the decomposition pressure of the oxide at the corresponding temperature. Confirmation of the equilibrium by varying the pressure or the temperature a little was not undertaken, because it would take unpractically long time for one run.

The oxide once heated to the highest temperature was cooled in vacuum and again the same procedure was repeated. In this second procedure, evolution of gases other than oxygen was reduced extremely, but the pressure of oxygen at the corresponding temperature was identical within the experimental error. This suggests that the equilibrium was not disturbed by the presence of the other gases.

Result and Discussion

Evolution of Carbon Monoxide and Carbon Dioxide.[3] All metallic oxides evolve large amount of carbon monoxide and carbon dioxide between 200 and 800°C. The gases adsorbed or combined with the oxides might constitute some fractions of the evolved gases. However, the main part of them seems to be produced by the reduction of metallic oxides by impurity carbon in them or by adsorbed or residual hydrocarbons on the oxide surface or in vacuum system, because the color and electrical conductivity of these oxides changed with carbon dioxide evolution. For example, the color of tungsten trioxide and molybdenum trioxide changed to dark gray after evolution of these gases. In our experiment performed in " hydrocarbon free " system, no hydrocarbon peak was observed in the spectra at any temperature. Therefore, the reduction by impurity carbon seemed to be more important than that by adsorbed or residual hydrocarbons, and the origin of non-stoichiometry of the metallic oxides should be attributed to the existence of some impurity carbon.

The Dissociation Pressure of Zinc Oxide. Mass spectra of evolved gases from zinc oxide at 600°C and 890°C are shown in Fig. 2. Above 750°C oxygen due to thermal decomposition begins to be observed. An example of the total equilibrium pressure of the evolved gases and its component is shown in relation to the temperature in Fig. 3. Above 900°C oxygen gas was a main component. In Fig. 4 the equilibrium pressures of oxygen are plotted

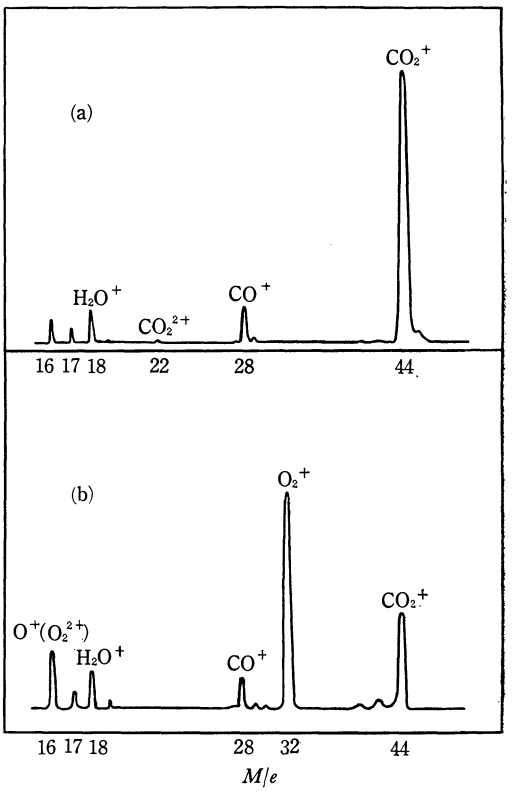

Fig. 2. Mass spectra of gases evolved from zinc oxide. (a) 600°C, (b) 890°C

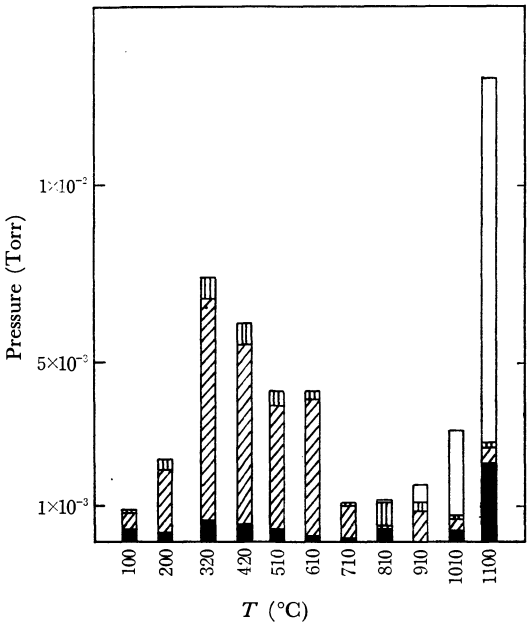

Fig. 3. Partial pressures of gases evolved from zinc oxide *versus* temperature.

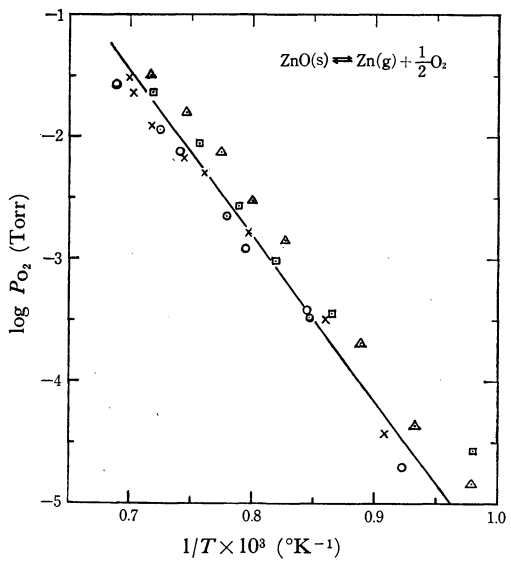

Fig. 4. Dissociation pressure of solid zinc oxide *vs.* $1/T$.
The values of different symbols show different runs.

against the reciprocal of the absolute temperatures. Then a good straight line, though the values by each run showed a little deviation from the line, was obtained. Over the range of 750—1200°C, the line is represented by the following equation;

$$\log P_{O_2}(\text{Torr}) = -\frac{13500}{T} + 8.01 \qquad (2)$$

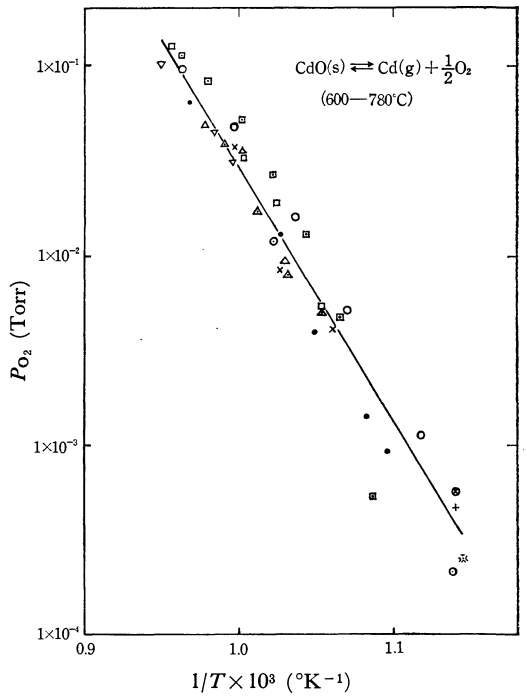

Fig. 5. Dissociation pressure of solid cadmium oxide *vs.* $1/T$.

If the following equilibrium is established at high temperature,

$$\text{ZnO(s)} \rightleftarrows \text{Zn(g)} + \frac{1}{2}\,\text{O}_2\,, \qquad (3)$$

the equilibrium constant ($K_p = P_{Zn} \cdot P_{O_2}{}^{1/2} \simeq 2P_{O_2}$) is represented by the relation;

$$\log K_p(\text{atm}^{3/2}) = -\frac{20250}{T} + 8.00\,, \qquad (4)$$

hence the value of standard free energy change, ΔG°, for the reaction, $\text{ZnO(s)} \rightleftarrows \text{Zn(g)} + \frac{1}{2}\text{O}_2$, is given by;

$$\Delta G^\circ(\text{cal}) = 92664 - 36.65T. \qquad (5)$$

On the other hand, the values of ΔG° for this reaction, which are obtained by combining the known values for other reactions, are as follows;

$$\Delta G^\circ(\text{cal}) = 112170 - 49.03T \qquad (6)^{5)}$$

or;
$$\Delta G^\circ(\text{cal}) = 114640 - 51.65T. \qquad (7)^{6)}$$

The difference of these values are not so large in the temperature range of measurement.

This result conflicts with Seeco's report[7] that an equilibrium constant for the dissociation of solid zinc

5) E. C. Truesdale and R. K. Waring, *J. Am. Chem. Soc.*, **63**, 1610 (1961).
6) J. A. Kitchener and S. Ignatowicz, *Trans. Faraday Soc.*, **47**, 1278 (1951).
7) E. A. Seeco, *Can. J. Chem.*, **38**, 596 (1960).

oxide into the gaseous elements was greater than that calculated from Eq. (6) by a factor of 10^8. One possible reason of this discrepancy might be due to the existence of other gases than oxygen. Because no instrument such as mass spectrometer to identify gaseous species was used in Seeco's experiment, it is not unreasonable to suppose that Seeco considered all the evolved gases as oxygen and overestimated its pressure.

The Dissociation Pressure of Cadmium Oxide. At lower temperatures (20—500°C) main components of the evolved gases were carbon dioxide, carbon monoxide, and water. The oxygen gas due to thermal decomposition was found above 500°C. In Fig. 5 the measured equilibrium pressures of oxygen are plotted against $1/T$. The straight line obtained can be represented by the following equation;

$$\log P_{O_2}\,(\text{Torr}) = -\frac{13800}{T} + 11.6 \qquad (8)$$

The pressure of oxygen is about twenty times as large as those of the other author's,[8] which were obtained by flow methods or calculated from thermodynamical data. This discrepancy may be attributable to the inhomogeneity of temperature in the experimental system. That is, as the cadmium has larger vapor pressure compared to other metals its vapor was condenced at the cold part of the apparatus and removed quickly from the dissociation cell before the equilibrium of $CdO(s) \rightleftarrows Cd(g) + \frac{1}{2}O_2$ was attained.

The Dissociation Pressure of Nickel Oxide. Nickel oxide is one of the important p-type oxide-semiconductor. However, there are few reports[9] published about the thermal decomposition. Johnson and Marshall obtained a vapor pressure equation of nickel oxide by measuring the rate of vaporization from a metallic nickel ring slightly oxidized its surface to nickel oxide. The value for the vapor pressure of nickel oxide is somewhat larger than the calculated dissociation pressure of nickel oxide. Therefore, they concluded that the dissociation of solid nickel oxide was negligible between 1438 and 1566°K. On the other hand, Brewer and Mastick[10] criticized Johnson and Marshall's conclusion, and concluded that vaporization by dissociation is the major process in case of nickel oxide.

In the present experiment, oxygen gas produced by thermal decomposition was identified with the omegatron and the formation of thick nickel deposit was observed on the wall of the colder part of the cell. A thin film of nickel oxide was also observed at the part of higher temperature. This might be explained by oxidation of the deposited metal film, *i.e.*, the same phenomenon observed in case of zinc oxide.[11] In Fig. 6 the dissociation pressure are plotted against $1/T$. When an untreated sample was examined, abnormally large pressures of dissociation with a maximum was observed, shown as curve A. On the contrary, the sample which was treated in vacuum at 1100°C for a few hours gave normal dissociation pressures, shown as curve B. Curves C and D were obtained from the samples with longer heat treatment in vacuum at 1100°C (for about 40 hr). The following equation for the dissociation pressure is obtained from the curve C;

$$\log P_{O_2}\,(\text{Torr}) = -\frac{23810}{T} + 11.33. \qquad (9)$$

Two processes of the dissociation of nickel oxide can be assumed as follows;

$$NiO(s) \rightleftarrows Ni(s) + \tfrac{1}{2}O_2,$$

$$Ni(s) \rightleftarrows Ni(g); \qquad (10)$$

or;

$$NiO(s) \rightleftarrows Ni(g) + \tfrac{1}{2}O_2. \qquad (11)$$

Equation (9) is in good agreement with the values calculated by the first process and not by the second process. Therefore, the standard free energy change

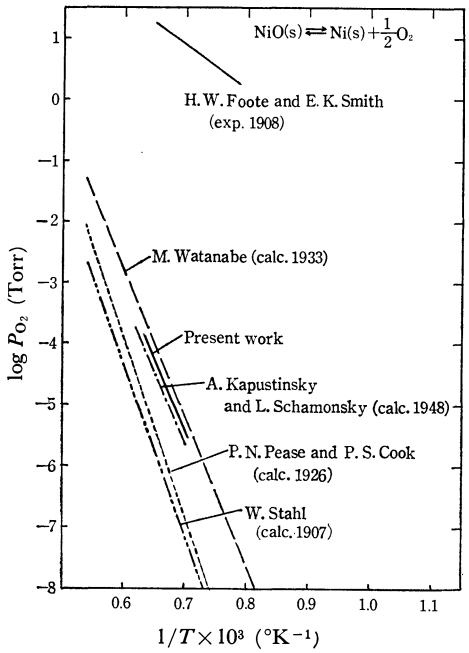

Fig. 7. Comparison of experimental and calculated pressures of oxygen in equilibrium with solid nickel oxide.

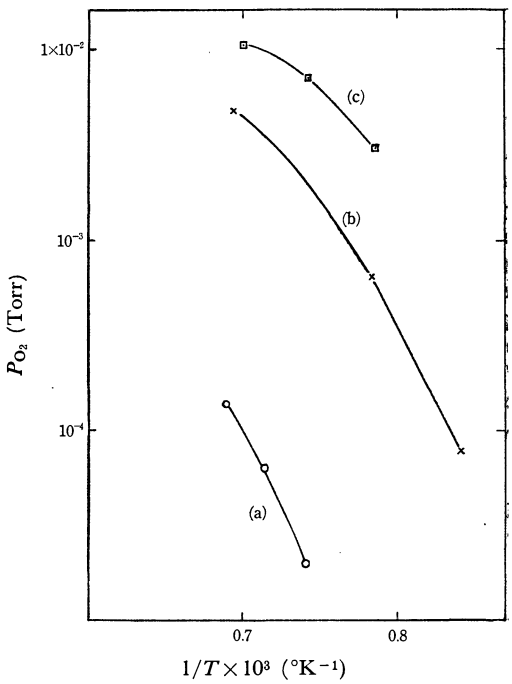

Fig. 8. Measured dissociation pressure in equilibrium with tungsten trioxide, (1), an untreated sample; (b), a sample treated in vacuum at 800°C for about 10 hr; (c), a sample treated in vacuum at 950°C for a couple of days.

of $NiO(s)\rightleftarrows Ni(s)+\frac{1}{2}O_2$ is obtained from Eq. (9);

$$\Delta G^\circ(\text{cal}) = 54500 - 19.35T,$$
$$1400^\circ\text{K} \leq T \leq 1570^\circ\text{K}. \qquad (12)$$

In Fig. 7 the oxygen dissociation pressure is compared with literature data, most of which are calculated from the thermodynamical data obtained by the reduction of nickel oxide. Foote and Smith[12] reported very large value for the dissociation pressures of nickel oxide. However, as they did not analyze the gases, it is possible that they mistook other gases as oxygen. The values obtained by our experiment are in good agreement with the calculated ones. Therefore, the curve C in Fig. 6 shows that the sample treated in vacuum has a stoichiometric composition. The curve A shows that the untreated sample had excess oxygen over the stoichiometric component.

Molybdenum Trioxide. Main species of evolved gases were found to be carbon dioxide and carbon monoxide. The evolution rate of carbon dioxide increased considerably above 200°C and its color changed to gray. Moreover, it was observed that molybdenum trioxide sublimed above 630°C. However, we could not detect any oxygen gas due to thermal decomposition.

Tungsten Trioxide. It has not been reported that oxygen due to thermal decomposition of tungsten trioxide was observed. However, the origin of non-stoichiometry of the oxide is often considered to

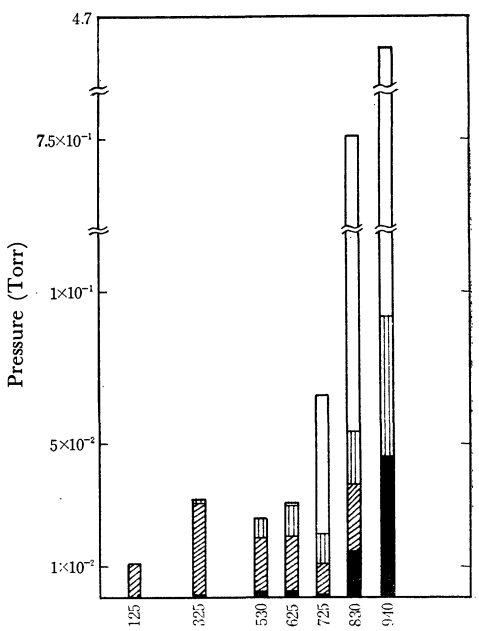

Fig. 9. Partial pressures of gases evolved from copper(II) oxide *vs.* temperature.
□, oxygen; ▨, carbon monoxide; ▨, carbon dioxide; ■, water

12) H. W. Foote and E. K. Smith, see Ref. 9.

be due to thermal dissociation.[13] In a previous paper, one of the authors (I. K.)[3] pointed out that the reduction of tungsten trioxide under vacuum heating at temperatures lower than 500°C was taken place by impurity carbon contained in the oxide.

In the present experiment, it was found that the sublimation of tungsten trioxide was accompanied with oxygen evolution above 950°C. Sometimes the oxygen dissociation pressure amounted to 1×10^{-2} Torr but the reproducibility of the measurement was not good among different runs. This may be due to the dissociation accompanied by sublimation. In Fig. 8 the examples of measured dissociation pressures are shown.

The Dissociation Pressure of Copper(I) and Copper(II) Oxides. In Fig. 9 the gaseous species evolved from copper(II) oxide are shown in relation to the temperature. Oxygen was observed above 590°C. Moreover, it was confirmed by X-ray analysis that copper(II) oxide transformed completely into cuprite (copper(I) oxide) under heat treatment in vacuum above 900°C. Therefore, the equilibrium of $2CuO(s)\rightleftarrows Cu_2O(s)+\frac{1}{2}O_2$ is only realized over the range of 600 to 900°C. In Fig. 10 the oxygen pressures are plotted against $1/T$. A good straight line is obtained over this range and the oxygen dissociation pressure is represented by;

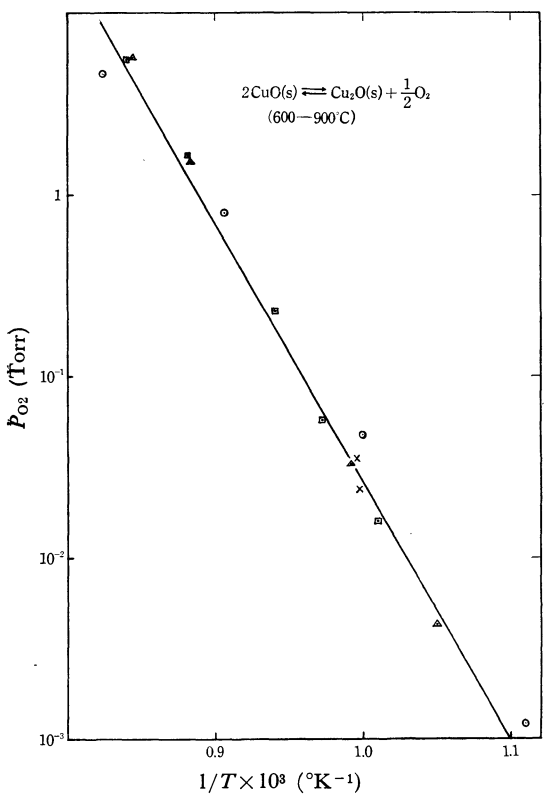

Fig. 10. Dissociation pressure of copper(II) oxide.

13) R. J. Ackermann and E. G. Rauch, *J. Phys. Chem.*, **67**, 2596 (1963).

$$\log P_{O_2}(\text{Torr}) = -\frac{14150}{T} + 12.61. \quad (13)$$

Therefore, the free energy change for the reaction of $2CuO=Cu_2O+\frac{1}{2}O_2$ is given by;

$$\Delta G^\circ(\text{cal}) = 32400 - 22.28T,$$
$$870^\circ\text{K} \leq T \leq 1170^\circ\text{K}. \quad (14)$$

Brewer and Mastick[10] thought that the stability of gaseous copper(II) oxide is proved by the measurement of the vapor pressure of solid oxide by Mack, Osterhof, and Krauer.[14] The vapor pressures of gaseous copper(II) oxide between 873 and 1223°K were higher by factors of 10^6—10^8 than those of gaseous copper which is in equilibrium with solid copper(II) oxide. However, we found only the deposit of cuprite and not that of copper(II) oxide. This observation shows copper(II) oxide does not vaporize.

In the present experiment, the sample of cuprite was prepared by heating of copper(II) oxide in vacuum at 900°C for a couple of days, and identified by X-ray analysis. Above 900°C cuprite began to deposit on the hot wall and then decomposed with oxygen evolution. In Fig. 11 the dissociation pressures of oxygen are plotted against $1/T$, and expressed by;

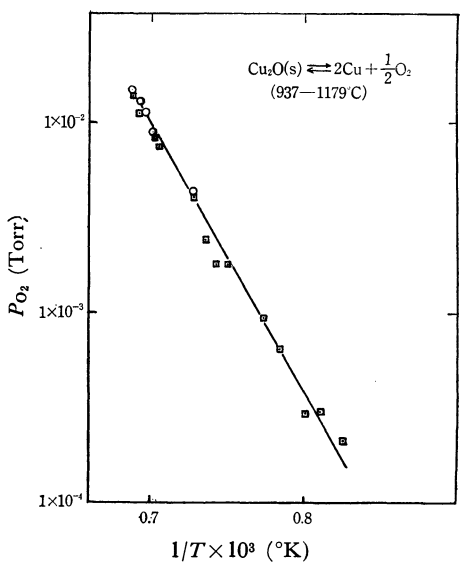

Fig. 11. Dissociation pressure of copper(I) oxide.

Metallk*, **28**, 1567 (1960); V. V. Kondakov, D. I. Ryzhonkov and I. A. Titova, *Chem. Abstr.*, **58**, 7408b (1963).

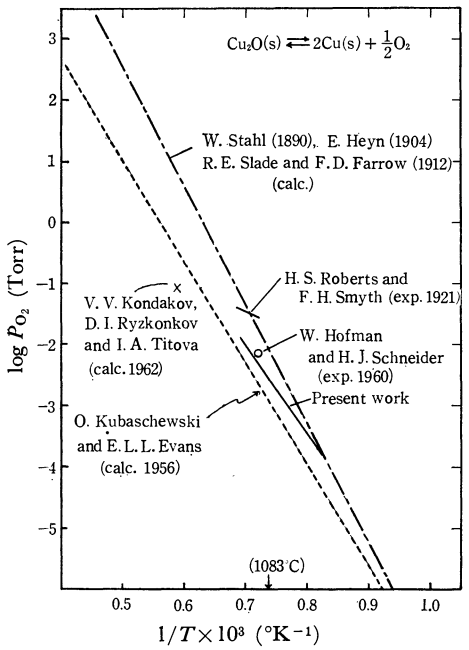

Fig. 12. Comparison of experimental and calculated pressures of oxygen in equilibrium with solid copper(I) oxide.

$$\log P_{O_2}\,(\text{Torr}) = -\frac{14100}{T} + 7.85. \qquad (15)$$

The free energy change for the reaction of $Cu_2O(s) = 2Cu(s) + \frac{1}{2}O_2$ or $Cu_2O(s) = 2Cu(l) + \frac{1}{2}O_2$ was given by;

$$\Delta G^\circ(\text{cal}) = 32200 - 11.4T,$$
$$1200^\circ\text{K} \leq T \leq 1420^\circ\text{K}. \qquad (16)$$

The melting point of copper is at 1083°C. However, we could not observe any change at this point. In Fig. 12 our result is compared with other author's values,[15] most of which were calculated from the thermodynamical data.

Summary

Carbon dioxide and carbon monoxide were often the main gaseous species evolved from various oxides at lower temperatures. Oxygen due to the thermal dissociation of tungsten trioxide was detected with the omegatron for the first time. In the case of nickel oxide, the excess oxygen contained in the p-type semiconductor was evolved at the first stage during a heat treatment in vacuum. Dissociation pressure of zinc oxide, cadmium oxide, nickel oxide copper(II) oxide, and cuprite were measured and were in good agreement with the calculated values from the standard free energy data.

The authors wish to thank Dr. Masaru Onchi for his valuable advice and one of authors (I. K.) is grateful for financial support from the Sakkokai Foundation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1046—1055 (1968)

Electronic Spectra and Electronic Structures of Benzonitrile *N*-Oxide and Its Derivatives

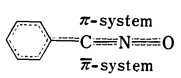
Masumi YAMAKAWA, Tanekazu KUBOTA, Hideko AKAZAWA and Itaru TANAKA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received September 18, 1967)

The electronic spectra of 2,6-dimethylbenzonitrile *N*-oxide and its some derivatives were recorded in *n*-heptane and were compared with those of benzonitrile and phenylacetylene. The analyses of the electronic spectra of aromatic nitrile *N*-oxides were done by the following procedures. First, simple molecular orbitals (SMO) of benzonitrile and phenylacetylene were calculated using some parameters determined by the use of the overlap integrals and valence state ionization potentials. Then, by comparing the eigenvalues of the SMO thus obtained with the observed spectra the spectroscopic exchange integrals have been obtained for $^1A_1$ and $^1B_1$ bands, where interactions between two configurations were taken into consideration for the $^1B_1$ bands. The SMO of benzonitrile *N*-oxide was next calculated on reference to the physicochemical nature of aromatic nitrile *N*-oxides studied before. The parameters were chosen so as to fit with the observed values of dipole moments of benzonitrile *N*-oxide and its some methyl derivatives. Electronic spectra of the nitrile *N*-oxides were then analyzed using the above SMO's and spectroscopic exchange integrals. The substituent effect on the electronic spectrum of benzonitrile *N*-oxide was also discussed by the similar treatment. Characteristic strong band appearing in the near UV region was assigned to the $^1A_1$ band having a change transfer (CT) nature, where the CT from the oxygen atom to the residual conjugated system makes a larger contribution than that of the reverse direction. In addition, the physicochemical nature and reactivity of nitrile *N*-oxides were discussed on the basis of their molecular diagrams, which were obtained from the SMO's mentioned above.

In the previous papers,[1,2] the electronic spectra of substituted benzonitrile *N*-oxides and 9-anthronitrile *N*-oxide were recorded in various solvents and compared with those of the corresponding nitriles. In addition, molecular complexes of aromatic nitrile *N*-oxides with iodine, β-naphthol and phenol were studied quantitatively by electronic and infrared (IR) spectroscopic methods.[1-3] Discussions were made from the viewpoints of solvent and substituent effects on the above electronic spectra and of charge-transfer (CT) type complexing ability. It was concluded that the π-conjugated systems of benzonitrile *N*-oxide (BNO) are well illustrated as I,



(I)

where the CNO group has a character of a partial triple bond consisting of π and $\bar{\pi}$ system (see I) This conclusion was led from the experimental evidences that (i) CT type complexing ability of aromatic nitrile *N*-oxides is very weak, (ii) the N–O stretching vibration, $\tilde{\nu}_{NO}$, appears at higher frequency than that of pyridine *N*-oxide, and (iii) substituted benzonitrile *N*-oxides exhibit an absorption band with high intensity ($\varepsilon > 10000$) in a near ultraviolet (UV) region where the corresponding nitriles do not show such a high intensity band. The absorption band pertinent to the nitrile *N*-oxides was found to undergo a blue shift with an increasing polarity of solvents, although the shift is small compared with some other kinds of tertiary amine *N*-oxides. It seems to be now interesting to examine the stated experimental results from theoretical points of view. The present paper describes the molecular orbital (MO) treatment of BNO and its derivatives to discuss the UV spectra and other physicochemical natures. The results will be compared with those of nitrones reported previously,[4,5] because benzylidene methylamine *N*-oxide (BMANO)[6] and BNO are isoelectronic on the π-electron system except for the presence of $\bar{\pi}$-system in BNO (see I).

Experimental

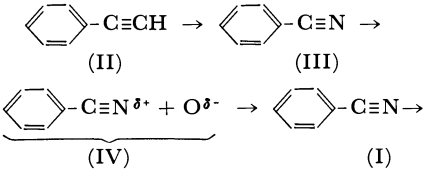
Measurement of electronic and IR spectra and the purification of solvents employed were the same as were described in the foregoing papers.[1,2]

Materials. In addition to the aromatic nitrile *N*-oxides reported already,[1] 4-dimethylamino-2,6-dimethylbenzonitrile *N*-oxide (DMABNO) was newly synthesized to get the spectra. DMABNO (new compound) was obtained by the reaction of the corresponding oxime with NaOBr according to Grundmann's method,[7] and was recrystallized several times with methanol: mp 134.0—136°C; IR, $\tilde{\nu}_{NO}=1341$ cm^{-1} and $\tilde{\nu}_{C\equiv N}=2287$ cm^{-1} in CCl_4. The above oxime, 4-dimethylamino-2,6-dimethylbenzaldoxime (new compound, mp 135.0—137.5°C, a mixture of syn and anti forms) was prepared by the reaction of hydroxylamine with the corresponding aldehyde (mp 82.5—83.5°C) which was obtained by Vilsmeyer-Haackschen's method[8] from *N*,*N*-dimethyl-3,5-dimethylaniline (125°C/37 mmHg) prepared by dimethylation of 3,5-dimethylaniline with trimethylphosphate ($(CH_3O)_3PO$).[9]

The nitrile, DMABN, corresponding to DMABNO was synthesized by the dehydration of 4-dimethylamino-2,6-dimethylbenzaldoxime mentioned above with acetic anhydride.[10,11] The pure material of DMABN, mp 89°C, was obtained by chromatograph passing through the alumina and by recrystalliation from petroleum ether; $\tilde{\nu}_{C\equiv N}=2213$ cm^{-1} (CCl_4). The main absorption maxima (mμ) and intensities (ε_{max}), latter being shown in parentheses, of DMABNO and DMABN in *n*-heptane are: 292.7 (22900), 229.0 (11500), and 206.8 (23000) for DMABNO and 282.3 (27600), 233.7 (14100), 227.2 (14700), 206.2 (19300), and 188.0 (17800) for DMABN. The purity of the samples was carefully checked on by elementary analyses and UV, IR, and NMR spectroscopic measurements. Commercial phenylacetylene (GR grade of Kanto Chemical Co.) and benzonitrile (special grade of Wako Chemical Co.) were first purified by repeated distillations. Then these were subjected to rectifying distillation through a good efficient column to collect the middle portions; bp 142.4°C and 46.0—46.5°C/5 mmHg for phenylacetylene (PA) and benzonitrile (BN), respectively.

Calculation and Experimental Results

As was mentioned in the introductory section of this paper the π-electronic structures of aromatic nitrile oxides and nitrones seem to bear some resemblance to each other. Therefore, the calculations of MO and transition energies were carried out with the similar treatment to that adopted to interpret the electronic spectra and electronic structures of BMANO.[4],*1 Namely, based on simple MO (SMO) calculation, and taking account of configuration interaction (CI) partly, the character of electronic spectra of BNO and its derivatives has been analyzed using the spectroscopic exchange integrals, β_s's, for the series of the following compounds,[14] in which the spectra of II[15] and III[16-18] were already analyzed by several authors.



Hypothetical molecule, IV, is obtained by dividing I into the composite systems consisting of the oxygen atom, $O^{\delta-}$, and its residual part, IV. It seems to be valuable to compare the π energy level of the $O^{\delta-}$ with the levels of IV.

SMO Calculation of I—IV. First we evaluated the parameters for SMO calculations of II, III and IV. The parameters pertaining to an atom, X, and a bond, X=Y, are, respectively, expressed by k_X in the Coulomb integral $\alpha_X=\alpha+k_X\cdot\beta$, and by ρ_{XY} in the resonance integral $\beta_{XY}=\rho_{XY}\cdot\beta$. The valence state ionization potential (IP) due to a π electron of carbon and nitrogen atoms is insensitive for the change of σ-core hybridization from sp^2 to sp type[19,20] whether or not these atoms are neutral or cation.[19,20] Thus it may be allowed to assume that the k_X values for the atoms appearing in -C≡N and -C≡N$^{\delta+}$ (IV) bonds are the same as those reported previously for pyridine[21] and benzylidene methylamine[4] and its hypothetical molecule[4]  . That is, the values are as follows: $k_C=0$ and $k_N=0.5$ for C≡N bond, and in the case of IV $k_{N^{\delta+}}=1.6$ and

*1 This type of theoretical treatment was originally applied by Baba and Suzuki,[12] and Goodman and Shull[13] to the analyses of the electronic spectra of substituted aromatic hydrocarbons.

inductive effect $=(1/3)^n \times k_N{}^{\delta+}$ for carbon atoms. Adopting the Mulliken approximation,[22] $\rho_{C\equiv N}$ was estimated using Eq. (1), where $\beta_{C\equiv N}$ is for pyridine type C≡N bond. Here the relation $\beta_{C\equiv N} \approx \beta_{C=C\equiv}\beta$ was assumed, this assumption being commonly employed in our previous calculations of nitrone,[4] pyridine *N*-oxide and their related compounds[21b,c] and also in usual SMO calculation of *N*-heterocyclic compounds.[21a,23]

$$\rho_{C\equiv N} \approx \frac{\beta_{C\equiv N}}{\beta_{C=N}} \approx \frac{(1/2)\cdot K\cdot S_{C\equiv N}(IP_C{}^{sp}+IP_N{}^{sp})}{(1/2)\cdot K\cdot S_{C=N}(IP_C{}^{sp_2}+IP_N{}^{sp_2})} \propto \frac{S_{C\equiv N}}{S_{C=N}} \qquad (1)$$

It would be understood that Eq. (1) is satisfied, since $IP_{C\text{ or }N}{}^{sp} \approx IP_{C\text{ or }N}{}^{sp_2}$ is closely held for a π electron as was discussed before. The Mulliken Table[24] for overlap integrals, *S*'s, gave the values: $S_{C\equiv N}{}^{\pi} = 0.302$ at 1.15 Å (triple covalent bond length) and $S_{C=N}{}^{\pi} = 0.199$ at 1.37 Å, so that we got $\rho_{C\equiv N} = 1.52$. As a reference, this value should be referred to 1.50[16] and 1.35[17] for $\rho_{C\equiv N}$ estimated from the data in literatures.[16,17,25] We have now used the $\rho_{C\equiv N} = 1.50$ for C≡N and C≡C bonds in I, II, III, and IV for the sake of simplicity.[26]

Next our attention was paid to the parameters of ρ_{NO} and k_O in I. Keeping in mind the conclusion of previous studies[1,2] that the net electronic charge on the oxygen atom in nitrile oxides would be decreased because of a partial triple bond nature of an N→O bond in C≡N→O group, the following boundary conditions are expected. Namely, both the k_O and ρ_{NO} in the present case is larger than those of BMANO[4] and pyridine *N*-oxide,[21b,c] *etc.* The values of $k_O = 1.2$ for BMANO, $k_O = 0.8$ for pyridine *N*-oxide, and $\rho_{NO} = 1$ for both the compounds were already derived. Many calculations were carried out so as to fit with the observed dipole moments of BNO and 2,4,6-trimethylbenzonitrile *N*-oxide (TMBNO), *etc.* by using the various sets of k_O and ρ_{NO} under the above boundary conditions.[27] The best values were determined as $k_O = 1.55$ and $\rho_{NO} = 1.2$. The energy levels of MO's were thus calculated for I, II, III, and IV using the above mentioned parameters, and the results were drawn in Fig. 1 with the symmetry and numbering of each orbital.

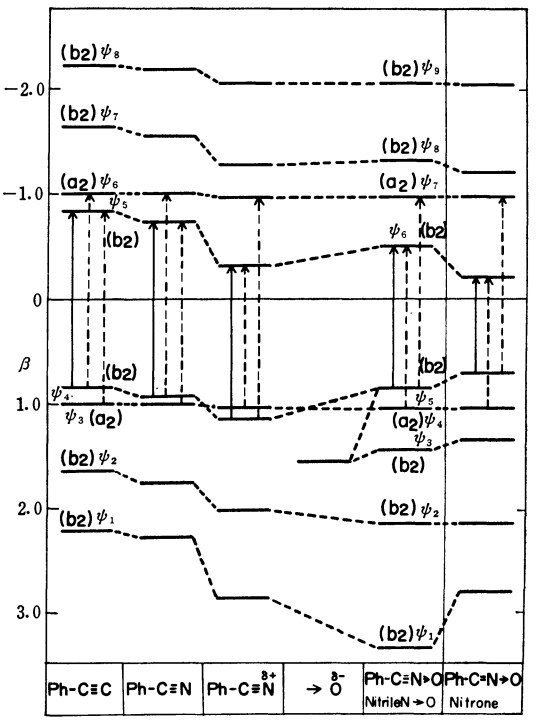

Fig. 1. The orbital energies and their numberings of phenyl acetylene, benzonitrile, and benzonitrile *N*-oxide and its composite ststems. The values of nitrone are cited from a previous paper[4] for comparison. Solid and broken vertical lines represent, respectively, $^1A_1$ and $^1B_1$ transitions responsible for near UV spectra. See "Appendix" for calculating conditions.

The present calculation of dipole moment has been based on the summation of σ and π moments. The values used for the former were cited from our previous paper[21c] and the latter values were taken from the present MO calculations. The molecular dimension of BNO was determined from molecular diagrams by employing the same treatment as in the previous work.[4] However, in the present molecule there are two π conjugated systems (π and $\bar{\pi}$) which are orthogonal to each other, and therefore MO calculation results for these two systems were taken into consideration to obtain the bond order and charge density. Although the bond length of the N→O bond (R_{NO}) is unknown, it was estimated as about 1.25 Å by the aid of N→O stretching frequency ($\tilde{\nu}_{NO} = \sim 1350\ cm^{-1}$) and $\tilde{\nu}_{NO}$-bond length relationship.[28] In the present study we used the

value ranging from 1.21 to 1.30 Å tentatively, but uncertainty of the R_{NO} in this range resulted in only small differences in the calculated dipole moments. The lone pair moment ($\vec{\mu}_{1\cdot sp^2}$) of N atom in sp^2 hybridization was previously assessed 1.0 D.U.[21c] The N atom of C≡N group is, however, in sp hybridization, so that its lone pair moment ($\vec{\mu}_{1\cdot sp}$) was estimated to be 1.06 D.U. from the equation, $\vec{\mu}_{1\cdot sp} = [\vec{\mu}^{cal.}_{1\cdot sp}/\vec{\mu}^{cal.}_{1\cdot sp^2}] \times \vec{\mu}_{1\cdot sp^2}$. Here $\vec{\mu}^{cal.}_{1\cdot sp}$ and $\vec{\mu}^{cal.}_{1\cdot sp^2}$ are, respectively, the calculated lone pair moments for sp and sp^2 hybridized orbitals by the aid of the Slater orbital. Since both atoms of C≡N bond is in the sp type, the σ moment for the C≡N bond was here put as 0.00 D.U. because of the same reason as that for the C=N bond mentioned in the previous work.[21c] The σ-moment of the N→O dative bond assumed to be the same (4.55 D, see Ref. 21c) among three kinds of the bonds; aliphatic type $\rightarrow$N→O, pyridine *N*-oxide type $\gg$N→O, and nitrile *N*-oxide type ≡N→O; although some difference in the N-atom σ-donor orbital (that is, sp^3, sp^2, and sp orbitals in the above given order) would cause somewhat the variation of σ-electron distribution in the N→O σ bond itself as was discussed in Ref. 2. On the other hand, the non-bonding electrons at the oxygen atom in the N→O bond would be in almost no-hybridization[29] just like the oxygen atom in free carbonyl group,[30] so that no lone pair moment was supposed for the oxygen atom. Now, dipole moments of BNO, benzonitrile, and acetonitrile were calculated and compared with those observed.[31]

Evaluation of Spectroscopic Exchange Integrals, β_s's. In Fig. 2 are depicted the absorption spectra of PA, BN and 2,6-dimethylbenzonitrile *N*-oxide (DMBNO) in *n*-heptane. The band position of a quite strong band ($^1A_1$ under C_{2v}) appearing in 210—250 mμ region is considerably different to each other between PA and BN, but that the ^1L_b band ($^1B_1^-$ under C_{2v}) occurs in almost the same wavelength region for both compounds. As will be mentioned later it would be allowed that the β_s value ($\beta_s(^1A_1)$) for the former band ($^1A_1$) is evaluated on the basis of a single electronic configuration. However, this resulted in two relatively different $\beta_s(^1A_1)$ values for PA and BN, mainly because of different band ($^1A_1$) positions. Some difference in intramolecular interaction ability of -C≡CH and -C≡N groups with phenyl residue might be the principal origin for observed difference in the band ($^1A_1$) position, because the $^1A_1$ band in question is closely associated with the above mentioned intramolecular interaction. Hence, the $\beta_s(^1A_1)$ value was estimated from the observed band position of BN. This $^1A_1$ band will be mainly attributed to a one electron transition from ϕ_4 to ϕ_5, $^1\chi_{4\to5}$. Assuming the calculated energy difference ($^1\chi_{4\to5} = 1.653\,\beta$) to be equal to the observed value (5.510 eV) of BN, we get $\beta_s(^1A_1) = 3.33$ eV. This value will be used to discuss the $^1A_1$ bands in the UV spectra of BNO. It is worthwhile to point out that the other transitions having the symmetry $^1A_1$ seem to occur at much shorter wavelength than in $^1\chi_{4\to5}$, as is seen in Fig. 3, in which the calculated energy levels of excited states are shown. Therefore, the interaction of $^1\chi_{4\to5}$ transition with the other $^1A_1$ configurations would be small. The assumption to derive the above $\beta_s(^1A_1) = 3.33$ eV may be qualitatively allowed.

Next the evaluation of β_s for $^1B_1$ bands was carried out. The mutual interaction between two one-electron transitions, $^1\chi_{4\to6}$ and $^1\chi_{3\to5}$, may be the main origin for the $^1B_1$ bands appearing in near UV region. Assuming that the contribution to the $^1B_1$ bands from the other configurations might be neglected, two $^1B_1$ states, $^1B_1^-$ and $^1B_1^+$, of PA and BN are respectively written as Eqs. (2) and (3).

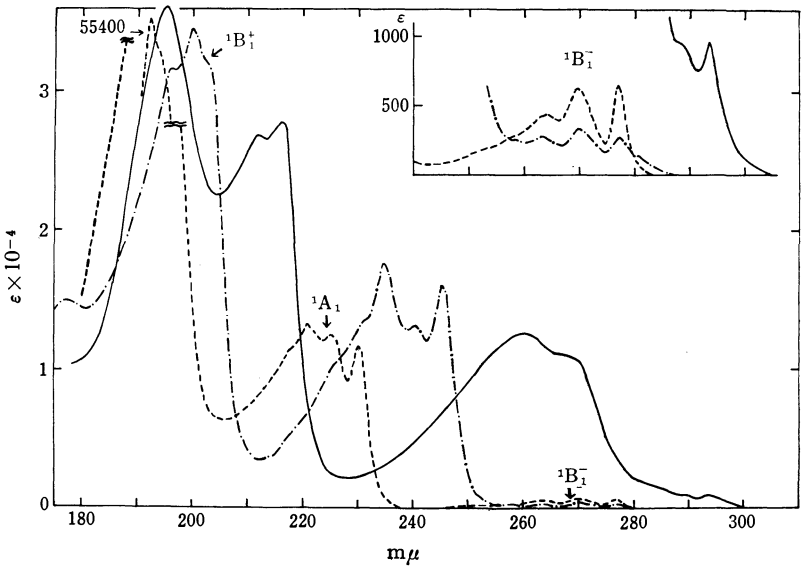

Fig. 2. Absorption spectra of phenylacetylene (—·—·), benzonitrile (------), and 2,6-dimethylbenzonitrile *N*-oxide (———) in *n*-heptane.

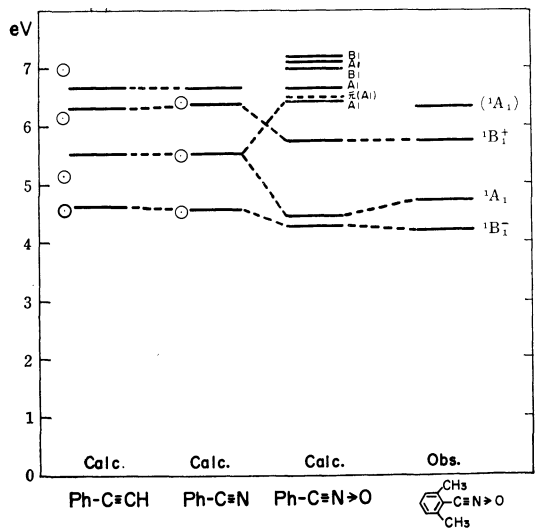

Fig. 3. The calculated and observed transition energies of the compounds indicated in this figure. Observed values for phenyl acetylene and benzonitrile are shown by circles.

$$(^1B_1^- \text{ or } ^1B_1^+) = \frac{1}{\sqrt{2}}(^1\chi_{3\to5} \mp {}^1\chi_{4\to6}) \qquad (2)$$

$$(^1B_1^- \text{ or } ^1B_1^+) = a^1\chi_{3\to5} \mp b^1\chi_{4\to6} \qquad (3)$$

Here, minus and plus signs on the right hand side of the equations stand for the $^1B_1^-$ and $^1B_1^+$, respectively. The interaction energy is given by $\mathscr{H}_{4\to6}^{3\to5} = \langle {}^1\chi_{4\to6}|\mathscr{H}|{}^1\chi_{3\to5}\rangle = 2\langle 36|G|54\rangle^{MO} - \langle 36|G|45\rangle^{MO}$. Using the one-center and two-center π-Coulomb repulsion integrals, which were already given by Eq. (5) in Ref. 4, $\mathscr{H}_{4\to6}^{3\to5}$ is calculated to be 0.8653 eV for PA and 0.8583 eV for BN. In the case of PA the $\mathscr{H}_{4\to6}^{3\to5}$ will be also given experimentally by the half of energy difference between the two absorption bands of 4.59 eV and 6.20 eV (see Fig. 4) under the above assumption to derive Eqs. (2) and (3). The value of 0.804 eV thus derived is a value consistent with the theoretical ones stated above.

Figure 4 shows the relation of the transition energy obtained by SMO calculation to the observed $^1B_1^-$ and $^1B_1^+$ bands. The spectroscopic exchange integral, $\beta_s(^1B_1)$, for $^1B_1$ state was evaluated to satisfy the observed values using the theoretical $\mathscr{H}_{4\to6}^{3\to5}$ values mentioned above and the SMO transition energies shown in Fig. 4. For the case of PA we obtained the $\beta_s(^1B_1) = 2.978$ eV and 2.911 eV for $^1B_1^-$ and $^1B_1^+$ excited states, respectively. The mean values is 2.945 eV. However, the spectrum of BN gave $\beta_s(^1B_1) = 2.983$ eV and 3.029 eV for $^1B_1^-$ and $^1B_1^+$ bands, respectively. The mean value results in 3.006 eV, and in this case the values of *a* and *b* for $^1B_1^-$ state in Eq. 3 were found to be 0.8142 and 0.5806, respectively. We would now understand that PA and BN give almost the same value of $\beta_s(^1B_1)$ as far as the $^1B_1^\mp$ bands are concerned. The value of $\beta_s(^1B_1) = 3.006$ eV was then used to discuss the spectra of BNO and its related compounds in relation to the choice for the $\beta_s(^1A_1)$ value mentioned before.

Calculation of Transition Energies and Oscillator Strength. Combination of the SMO calculation results and the values of $\beta_s(^1A_1)$ and $\beta_s(^1B_1)$ make it possible to calculate the transition energies and their oscillator strengths, f_{calc}, the latter being carried out by the standard method.[29,32] The re-

a) The f value estimated experimentally is not very accurate, because the absorption bands corresponding to $^1B_1^+$ state overlapped quite strongly with the other absorption bands of higher transition energies.

b) See footnote 18. The value of $f_{obs}=1.6$ was reported[18] for the case where the integration was carried out over the three far UV bands in vapor phase; 6.61, (6.88), and 7.44 eV.

c) In addition to the absorption bands listed in this row another band with a high intensity was observed at 6.352 eV ($f_{obs}=0.768$, $\varepsilon=36100$).

sults for compounds I, II, and III are listed in Table 1 with the state functions obtained and with the observed transition energies. The transition moment, $\vec{Q}$, is given by

$$\vec{Q} = \langle \Psi_g(^1\Gamma)|\sum\vec{r}|\Psi_{exc}(^1\Gamma)\rangle,$$

where $\Psi_g(^1\Gamma)$ and $\Psi_{exc}(^1\Gamma)$ are singlet state wave functions in the ground and excited states, respectively (see Table 1). In Table 1 are included the oscillator strengths, f_{obs}, obtained experimentally from the recorded spectra by the aid of the equation: $f_{obs}=4.32\times10^{-9}\int\varepsilon(\tilde{\nu})d\tilde{\nu}$. The integrated intensity $\int\varepsilon(\tilde{\nu})d\tilde{\nu}$, was obtained using a planimeter from an enlarged absorption curve which was divided into each electronic transition component by the usual method.[29]

The Effect of Electron Donating Substituents on the Electronic Spectrum of 2,6-Dimethylbenzonitrile *N*-Oxide (DMBNO). It is of interest to elucidate theoretically the substituent effect on the UV spectrum of DMBNO. Some experimental results obtained here and reported in the foregoing paper[1] are shown in Table 2. The substituent effect was now introduced in the SMO calculation by such a way that k_x of Coulomb integral (α_x) for a substituent is varied in the range of 0.5—3.5, while ρ_{C-x} for the resonance integral (β_{C-x}) between a substituent and a benzene ring carbon atom to which the substituent is attached is assumed to be unity. Then many MO calculations were carried out using different values of the parameters. The calculation of transition energy is based on the same treatment as that in the preceding chapters except that $\beta_s(^1A_1)=3.55$ eV, which reproduces completely the 259.7 mμ band of DMBNO, is employed in stead of $\beta_s(^1A_1)=3.33$ eV mentioned before. Calculations were made using the above two $\beta_s(^1A_1)$ values, but the two $^1A_1$ curves calculated were nearly parallel to each other. That is, the two $\beta_s(^1A_1)$ values give almost the same results, as far as

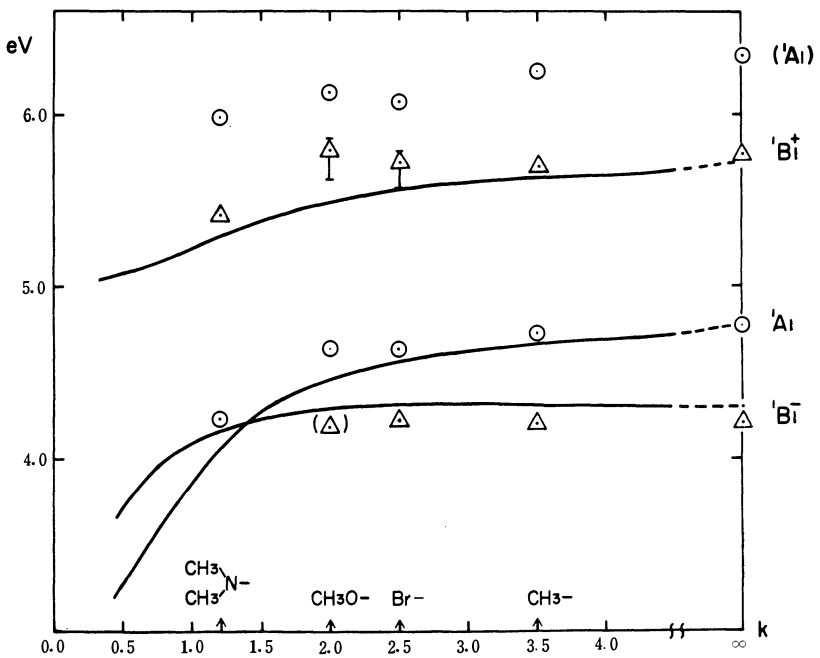

Fig. 5. The effect of substituents on the transition energies of 2,6-dimethylbenzonitrile *N*-oxide. Calculated and observed values are, respectively, shown by solid lines and by circles and triangles.

the comparison of magnitude of substituent effect is concerned. Altnough the present choice of the $\beta_s(^1A_1) = 3.55$ eV is somewhat arbitrary, we deem that it would lead to more satisfactory results in the investigation of the substituent effect and in the deviation of the calculated $^1A_1$ state energies from the observed ones when the 259.7 mμ band of DMBNO is taken as a standard. The results are shown in Table 2 and drawn in Fig. 5, in which the observed values are plotted at the following parameter positions:

$k_{N(CH_3)_2} = 1.2$, $k_{OCH_3} = 2.0$, $k_{Br} = 2.5$ and $k_{CH_3} = 3.5$.

These are determined by referring the values recommended by Baba,[12] and by Goodman and Shull.[13]

Discussion

Electronic Spectra of Benzonitrile *N*-Oxide and Its Related Compounds. As Table 1 shows, the comparison of the calculated and the observed results on the absorption spectrum of DMBNO indicates clearly that the 259.7 mμ band with high intensity should be assigned to $^1A_1$ band having the transition moment along the long axis of DMBNO (C_2 asis under C_{2v}). Now we may say that the $^1A_1$ band occurs in quite longer wavelength than in $^1A_1(^1L_a)$ band of benzonitrile, and thus would be thought to be a characteristic band for benzonitrile *N*-oxides. This is due to the fact that the 2pπ

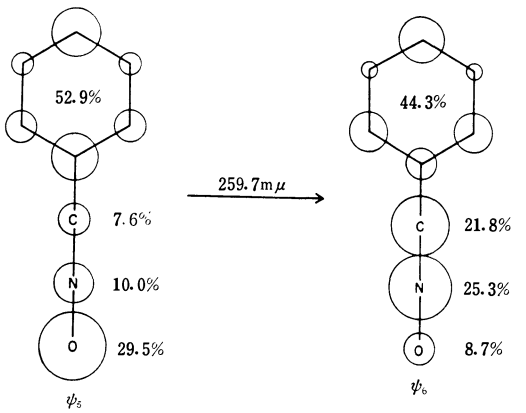

Fig. 6. The electron distribution in the highest occupied (ψ_5) and the lowest vacant (ψ_6) orbitals of benzonitrile *N*-oxide.

electrons of the oxygen atom coordinated to benzonitrile group can newly enter into π-conjugation, so that the charge transfer of $2p\pi$ electrons on the oxygen atom to the residual electron system, as well as the charge transfer of the reverse direction to the above, is brought about. In Fig. 6 we showed the change of orbital charge distribution caused by the $^1A_1$ (259.7 mμ) transition of DMBNO, which mainly consists of the $^1\chi_{5\to6}$ configuration. It is seen that the charge density on the oxygen atom decreases at the $^1\chi_{5\to6}$ excited state because of the charge transfer from the oxygen atom to the residual π-electronic system. However, calculations showed that the above charge transfer at the $^1A_1$ state is weaker than in the cases of BMANO[4,33] and pyridine *N*-oxide,[33] indicating that the solvent effect on the absorption band of nitrile *N*-oxides is less than that found in the case of nitrones and heterocyclic *N*-oxides, with which the considerable effect was observed.[1] The other two bands of DMBNO which appeared at 293.5 mμ and 215 mμ were assigned to $^1B_1^-$ (^1L_b, weak intensity) and $^1B_1^+$ (^1B_b, strong intensity) bands, respectively. The assignment was made by comparing the experimental results with the calculated ones as shown in Fig. 3. The band assignment made hitherto was consistent with that derived experimentally from the substituent- and solvent-effects and from the intensity consideration.[34] Tentative assignment of absorption bands appearing in far UV region are also given in Fig. 3. The assignment, however, would not be certain from the present study, because configuration interaction seems to play an important role for interpreting the electronic spectra in the above region. We suppose that the above band assignment, except for the one in far UV region, is also supported from the comparison of the calculated and experimental results concerning the substituent effect on the spectra of DMBNO, as is seen in Fig. 5. It is found there that the results of the calculation are parallel to the experimental ones at least semiquantitatively.

As was mentioned in the introduction of the present paper, nitrone and nitrile *N*-oxide have the π-electronic system similar to each other. The main difference in their UV spectra is the position of longer wavelength $^1A_1$ band. The band for nitrone occurs at longer wavelength than that of the corresponding nitrile *N*-oxide. For example, the $^1A_1$ band (259.7 mμ) of DMBNO in *n*-heptane appears at shorter wavelength than that (298.3 mμ)[5] of BMANO, a typical nitrone. It has been already known that the longer wavelength $^1A_1$ band is sensitive to substituents and shows an apparent red shift when electron donating power of substituents becomes stronger, as was reported for the system of mono-substituted benzenes.[12,13] The above difference in the $^1A_1$ band position between nitrone and nitrile *N*-oxide would be explained by the larger values of parameters k_O and ρ_{CN} for C≡N→O group, which make the separation of the lowest vacant and the highest occupied orbitals larger (see also Fig. 1).[35]

Molecular Diagrams and Physicochemical Natures of Nitrile *N*-Oxides. In connection with the analyses of the UV spectra discussed above it seems to be also valuable to make the discussion on the correlation between the molecular diagram and some physicochemical natures of nitrile *N*-oxides in the ground state. The molecular diagrams calculated for BN and BNO are designated in Fig. 7. Since these compounds have the two resonance systems, π and $\bar{\pi}$, their bond orders and charge densities are relatively different from those of benzylidenemethylamine and BMANO except for benzene part, where the above differences are not very large. Let us now consider the nature of –C≡N→O group. The π-bond order (0.779) of ≡N→O bond in BNO is much larger than that (0.406) of BMANO,[4] although partial bond order for π and $\bar{\pi}$ systems is less than the above 0.406. At the same time the C≡N bond order is also large (1.704), indicating that the bond exhibits a triple bond nature. These values should now be compared with those given by Wagner[36] who calculated the molecular diagram of fulminic acid, H–C≡N→O, by the method

33) T. Kubota and M. Yamakawa, This Bulletin, **35**, 555 (1962).

34) It is noted that the oscillator strengths calculated for $^1A_1$ band appearing in near UV region of PA, BN, and BNO are high from the quantitative viewpoint. The same tendency was also found for the calculated results of *p*-substituted DMBNO. Although MO calculation gives usually oscillator strength larger than that obtained experimentally, the above discrepancy would be ascirbed to the model of calculation which is not rigorous for the present case.

35) The spectral change similar to the above is naturally found between BN (225 mμ) and benzylidenemethylamine[5] (244.0 mμ), and between PA (240 mμ) and styrene (247.5 mμ).[4]

36) E. L. Wagner, *J. Chem. Phys.*, **43**, 2728 (1965).

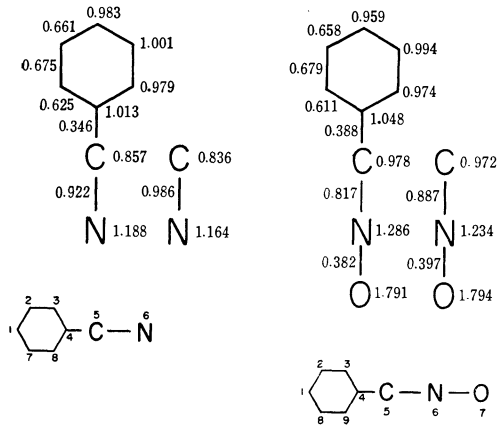

Fig. 7. Molecular diagrams of benzonitrile and its *N*-oxide.

of linear combination of group orbitals, and obtained the values: 0.939 and 1.729 for the π-bond order of N→O and C≡N bonds, respectively. Both his and our results seem to reflect the character of C≡N→O bond well. Therefore we may say that the stretching vibration of N→O bond, $\tilde{\nu}_{NO}$, of BNO occurs in higher frequency than in pyridine *N*-oxide, *etc.* Actually this prediction was verified experimentally as we discussed in the foregoing paper.[1]

It is known that $\tilde{\nu}_{NO}$ has the close correlation with N–O bond distance, R_{NO}. Using Lüttke's correlation curve[28] and also applying the Kharitonov's equation[37] which connects $\tilde{\nu}_{NO}$ and R_{NO}, the N–O bond distance was estimated to be 1.25 and 1.22 Å, respectively. On the other hand, the examination of the relation between $\tilde{\nu}_{NO}$ and R_{NO} reported for many aromatic and aliphatic amineoxides, oximes, nitroso compounds, *etc.*[1,4,5,38] led to $R_{NO}=1.28$—1.23 Å. Anyway it appears likely that R_{NO} of nitrile *N*-oxides in free state becomes relatively short.

Finally attention is directed to the π-electron density of BNO, *etc.* Comparing the molecular diagrams of BNO (see Fig. 7) and BMANO,[4] we can find that the charge distributions in the benzene ring are not very different between those of BNO and BMANO, but large change occurs in the part of C≡N→O group. Total π-electron net charges on the oxygen- and C_5 carbon-atoms (see Fig. 7) are +0.415 and +0.050 for BNO, but were +0.283 and +0.017 for the corresponding values of BMANO.[4] The increment of the positive net charge on the oxygen atom of BNO is responsible for weak complexing ability of aromatic nitrile *N*-oxides. Although the π net charge on the oxygen atom of C≡N→O group is positive, as has been discussed above, it is sure that the total charge on the oxygen atom is negative. This is because the N→O σ dative bond (σ moment, $\vec{\mu}_{NO}=4.55$ D.U.)[21c] shows a large shift of charge in the σ system. If we define $q_O=q_O^{\sigma}+q_O^{\pi}=(\vec{\mu}_{NO}/R_{NO})+q_O^{\pi}$, the value of $q_O\approx-0.368$ is derived. In addition to that, the net charge on the carbon atom of C≡N→O group (see Fig. 7) is positive and its value is considerably larger than that for C=N→O in BMANO, whereas the π net charge on nitrogen atom of C≡N→O is negative. These results may suggest that nitrile *N*-oxide group can also be expressed as a resonance formula, $-C^{\delta+}\equiv\ddot{N}-O^{\delta-}$. This fact seems to be the reason why nitrile *N*-oxides are rich in reactivity[39] and bring about easily the reaction of 1.3 dipole addition[39] unless bulky substituents prevent the reagent from coming closely enough to nitrile *N*-oxide groups.[7]

The authors wish to express their thanks to Professor Saburo Nagakura of the Institute for Solid State Physics, the University of Tokyo and to Professor Noboru Mataga of Osaka University for discussions.

Note Added in Proof: After the manuscript of this paper had been sent to the Chemical Society, we learned of two papers in which the N→O bond length (R_{NO}) of nitrile *N*-oxide group was reported. One is a paper by M. Winnewisser and H. K. Bodensch, *Z. Naturforsch.*, **A22**, 1724 (1967), in which they reported R_{NO} of H–C≡N→O molecule to be 1.207 Å based on the analyses of the microwave spectrum. Another paper by M. Shiro *et al.* in our laboratory showed R_{NO} of 4-methoxy-2,6-dimethylbenzonitrile *N*-oxide to be 1.249 Å by the method of X-ray analyses at about −140°C; the paper presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April 1968. The above R_{NO} values pertinent to nitrile *N*-oxide group are short and almost agree with theoretically predicted values reported in this paper.

Appendix

The MO's obtained here for BNO and its related compounds are listed below for the sake of comparison with those of BMANO and its related compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1056—1063 (1968)

Primary Processes in the Photoreduction of Acridine in Various Alcohols

Masao KOIZUMI, Yoshinori IKEDA and Hiroshi YAMASHITA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 23, 1967)

The effect of the addition of biacetyl on the quantum yield of photoreduction of acridine in methanol, ethanol, *n*- and iso-propanol has been studied under the aerated and deaerated conditions. From the analysis of the results, the quantum yields for four mechanisms Φ^{S}_{M} (S means that a reactive state is singlet excited states, S*, and M denotes a molecular mechanism), Φ^{S}_{R} (R denotes a radical mechanism), Φ^{T}_{M} (T indicates that a reactive state is a state other than S* and T(π–π*), most likely T(n–π*) and Φ^{T}_{R} have been decided, assuming that oxygen does not deactivate T(n–π*). The values are

for methanol,	$\Phi^{S}_{M}(0.027)$	$\Phi^{S}_{R}(0.039)$	$\Phi^{T}_{M}(0.006)$	$\Phi^{T}_{R}(0.057)$
for ethanol,	$\Phi^{S}_{M}(0.043)$	$\Phi^{S}_{R}(0.067)$	$\Phi^{T}_{M}(0)$	$\Phi^{T}_{R}(0.019)$
for *n*-propanol,	$\Phi^{S}_{M}(0.030)$	$\Phi^{S}_{R}(0.036)$	$\Phi^{T}_{M}(0)$	$\Phi^{T}_{R}(0.022)$
for isopropanol,	$\Phi^{S}_{M}(0.03)$	$\Phi^{S}_{R}(0.058)$	$\Phi^{T}_{M}(0)$	$\Phi^{T}_{R}(0)$

The quenching constants of biacetyl on the fluorescence of acridine have been found to agree with the ones on the reaction at S* in all alcohols; the rate constants approximate diffusion controlled. In addition it has been confirmed by a flash method that biacetyl does not attack the T(π–π*) nor the semi-reduced acridine; this justifies the present method of analysis.

It is well known that acridine dissolved in some H-containing solvents, undergoes photoreduction and yields acridan, its derivatives or diacridan according to the experimental conditions.[1-5] Since all these products have no absorption from 350 to 400 mμ where the absorption of acridine is large, disappearance of acridine can be followed very accurately by the change in the optical density at 365 mμ and some interesting feature of the reaction was obtained from such kinetic studies.[6,7] Recent flash photolytic investigations performed by our group,[8] have revealed that two independent primary processes are involved in this photoreduction. One is a radical mechanism in which half-reduced acridine is formed as an intermediate, and the other is a mechanism in which acridan or its derivative (perhaps a compound in which a solvent fragment is attached to 9-position[3-5] is produced so quickly that no intermediate is observed by an ordinary flash technique. This mechanism was designated conventionally as a molecular mechanism.

Kellmann and Dubois, on the other hand, proposed that the reactive state of acridine in methanol is most likely the n–π* triplet state instead of the lowest π–π* triplet state.[9] They did not, however, exclude the possibility of singlet excited state participating in the reaction. We also confirmed by energy transfer experiments, using eosine as triplet energy acceptor, that the lowest triplet is not a reactive state.[10]

Under such status, we have planned to make the experiments which will make clear the contributions of singlet excited state and of n–π* triplet state to the entire reaction and the experiments which will decide for each state the contribution of radical and molecular mechanisms. Such experiments consist of investigating the effect of biacetyl (used as a triplet energy acceptor) concentration on the rate of photoreduction both in the absence and in the presence of oxygen. We have made such studies using methanol, *n*- and iso-propanol as H-containing solvents, and have obtained some interesting results. It was not a long while since we had finished the present experiments that a paper by Van der Donckt and Porter appeared,[11] which has raised some doubt on the conclusion of Kellmann and Dubois; they have

claimed that an excited singlet state is an only reactive state in the photoreduction of acridine in *isopropanol*.

According to our present results, however, four alcohols behave more or less in different manner and in particular, isopropanol and methanol show distinctly different features in the effect of biacetyl on the photoreduction, which lead to the conclusion that the reactive states is in the former case only singlet excited state in agreement with Porter's conclusion, whereas in the latter case, are singlet and $T(n-\pi^*)$ state as Kellmann and Dubois proposed. Hence it seems timely to report the details of our experiments although we have not yet succeeded in interpreting the unexpected differences found in four kinds of alcohols.

Since Dubois and Kellmann's conclusion was based on the assumption that inhibiting action of biacetyl is due to the energy transfer according to $A^{T(n-\pi^*)}+B \rightarrow A+B^T$ (where A is acridine and B is biacetyl), it is desirable to examine whether biacetyl does not affect the lowest $T(\pi-\pi^*)$ of acridine by a different mechanism than energy transfer and further to examine whether it does not react with the half reduced acridine. Therefore we have investigated at first by the flash technique using methanol and ethanol as solvents, the effect of the addition of biacetyl on the decays of $T(\pi-\pi^*)$ of acridine and of the half reduced acridine. In addition, we have made investigations on the effect of the addition of biacetyl on the yield of $T(\pi-\pi^*)$, AH and AH_2, the results of which have supported the view of Kellmann and Dubois to some extent. These experiments are described in Part I. In Part II, the steady illumination experiments are described. The data, being more accurate than those from flash experiments, are analysed and interpreted on the basis of four alternative processes, and the quantum yields Φ_M^S, Φ_R^S, Φ_M^T and Φ_R^T (where S and T denote singlet excited state and $T(n-\pi^*)$ state and where M and R denote respectively molecular and radical) are separately decided.

Part I.*1 Flash Photolysis Studies

Experimental

Apparatus, procedures and samples are essentially similar as in the previous papers.[8,10] The decays and yields of $T(\pi-\pi^*)$ of acridine and of the half-reduced form of acridine were examined respectively at 440 and at 278 mμ (or in some cases as 520 mμ). The yield of acridan was investigated from the increase of optical density at 290 mμ. The concentration of acridine was always 4.8×10^{-5} M and the concentration of biacetyl was changed from zero to 1.1×10^{-2} M. By using a suitable filter only acridine was excited.

Results and Discussion

T-T Absorption Spectra of Biacetyl. Transient absorption spectra of biacetyl in methanol are shown in Fig. 1.

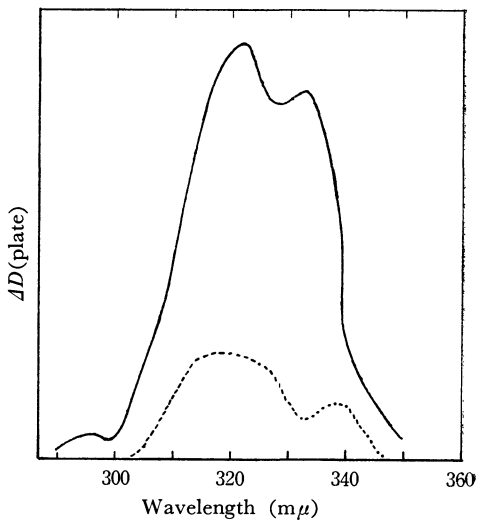

Fig. 1. Transient absorption spectra of biacetyl.
—— after 93 μsec, - - - after 360 μsec

The decay at 320 mμ is of the first order with a rate constant $k\simeq4\times10^3 sec^{-1}$. The comparison with the data in literatures[9,12,13] confirms that this species is the triplet state of biacetyl.

The Effect of the Addition of Biacetyl on the Decay of $T(\pi-\pi^*)$ of Acridine. The decay was not essentially affected by the addition of biacetyl up to 1.1×10^{-2}M. Some of the values of the first order rate constants are given in Table 1.

The Effect of the Addition of Biacetyl on the Decay of Half Reduced Acridine. The decay of half reduced acridine is second order and the rate

constant was evaluated from the plot of $1/D$ against t, D being measured at 520 mμ. The results are shown in Table 2. The analysis of the changes in the optical density at 278 mμ by the method employed in the previous paper,[8] also gave essentially the similar results. Thus the possibility of such a reaction AH+B→A+BH occurring, can safely be ruled out. The results given in Tables 1 and 2 justifies Kellmann and Dubois' interpretation of their results.

The Effect of [B] on the Yield of T(n–π^*) of Acridine. If the reactive state is T(n–π^*), then there is a possibility that the yield of T(π–π^*) is increased by the addition of biacetyl as inferred from the following reasoning. It is quite reasonable to presume that the intersystem crossing occurs *via* the following scheme,[14]

$$S^*(\pi\text{-}\pi^*) \rightarrow T(n\text{-}\pi^*) \xrightarrow{k_d'} T(\pi\text{-}\pi^*)$$
$$\Big\downarrow{\scriptstyle k_r'}$$
$$\longrightarrow \text{reaction}$$

In the absence of biacetyl, a portion of T(n–π^*) disappears through the reaction with the solvent; this portion, if biacetyl is present, will be affected by biacetyl according to $A^{T(n-\pi^*)}+B\rightarrow B^T+A$. The produced B^T then gives its excitation energy back again to acridine according to $B^T+A\rightarrow B+A^{T(\pi-\pi^*)}$ (The occurrence of such a process was demonstrated by Kellmann and Dubois and was reconfirmed by the present authors (see Part II).). Then the quantum yields of the production of T(π–π^*), $\phi_{\pi\pi}$ should be given by the following equations, provided biacetyl does not affect the intersystem crossing.

In the absence of B

$$\phi_{\pi\pi} = k_d'/(k_r'+k_d')\cdot\phi_{n\pi}.$$

In the presence of B

$$\phi_{\pi\pi} = (k_d'+k[B])/(k_r'+k_d'+k[B])\cdot\phi_{n\pi}.$$

The results are shown in Fig. 2, where the optical densities at 440 mμ immediately after flashing, are plotted against [B].

It seems that there is a slight increase at the largest biacetyl concentration, but in view of the crudeness of the data one should say rather that there is no essential effect. This suggests $k_r' \ll k_d'$. By the way, the optical densities at 440 mμ immediately after flashing in methanol, ethanol and isopropanol are respectively ~0.36, ~0.33 and ~0.37. Thus the yields are essentially the same in three alcohols. These data may be of some importance for the general discussion.

The Effect of [B] on the Yield of AH. The lifetime of singlet excited state of acridine in ethanol is 7.2×10^{-10} sec,[15] and that of T(n–π^*) was estimated by Kellmann and Dubois as ~10^{-8}sec. Therefore, if the reactive state were only S*, the addition of ~10^{-2}M of biacetyl would scarcely affect the yield of AH. On the other hand, if the reactive state were only T(n–π^*), the addition of this magnitude of biacetyl should decrease the yield to some extent. The yield of AH was estimated from the

15) H. Kokubun, to be published.

optical densities at 278 mμ directly after flashing. The results are shown in Fig. 3. Although the data are not very accurate, still there is a clear tendency that the yield decreases with the increase of [B]. At 5×10^{-3} M of B, the decrease in methanol and ethanol is approximately ~1/4 and 1/8 and at 1×10^{-2}M of B it is ~2/3 and 1/2. These results strongly suggest the participation of T(n–π^*) state in these two solvents.

The Effect of [B] on the Yield of AH_2. This was examined from the similar reasoning as above. The yield of AH_2 was evaluated from the optical density at 290 mμ a long time after flashing, D_∞^{290}. The results are shown in Fig. 4. The decrease in the yield of AH_2 by adding 5×10^{-2}M of biacetyl in methanol and ethanol are equally about 1/3 while at 1×10^{-2}M of the added biacetyl, it is respectively ~2/3 and 1/2. Although the above data are not very accurate, they lead us to suspect that T(n–π^*) as well as S* participates in the reaction. It may be added that the above data in combination with the oxygen effect on the yield of AH_2[8] enable us in principle, to evaluate Φ_M^S, Φ_R^S, Φ_M^T and Φ_R^T. But since it is difficult to get the exact data from the flash photolytic experiments, it seems wiser to leave the quantitative investigation to the steady light studies.

Part II.*2 Steady Light Experiment

Preliminary Experiments for the Effect of the Addition of Biacetyl on the Photochemical Reduction of Acridine. Figure 5 shows a typical example of the spectral change when the deaerated solution of acridine, 1×10^{-4} M in methanol containing some quantity of biacetyl, is irradiated by 365 mμ. In the early stage of irradiation, the peak of acridine declines accompanied with the rise in the height of the peak at ~290 mμ. An isosbestic point is seen at ~325 mμ. The above behavior substantiates that the similar photoreduction as in the absence of biacetyl is occurring in the early stage. In the later stage, however, the absorption around 350 mμ gradually rises again and the absorption in the shorter wavelength region declines with no isosbestic point. This suggests the occurrence of some unknown reaction between biacetyl and acridan. Such a phenomenon was observed in all the alcohols investigated but it was most prominent in methanol. The similar phenomenon was observed in the air-saturated solution. It was checked that the alcoholic solution of biacetyl alone scarcely undergoes any reaction even by the irradiation for one hour.

Figure 6 gives some typical examples of the $\ln(e^{acd}-1)$ *vs.* t plots. In consistence with the above spectral change, the plots are satisfactorily linear in the early stage indicating the occurrence of a simple photoreduction of acridine whereas in the later stage they gradually deviate and finally show slow and apparently linear increase. The above results ensure us to investigate the retarding effect of biacetyl by

comparing the initial slope of the $\ln(e^{acd}-1)$ *vs.* t plots.

The Effect of [B] on the Quantum Yield of Photoreduction. This was investigated for four kinds of alcohols and for both the aerated and deaerated solutions. Some corrections were made for the absorption of biacetyl when its concentration was high. The values of quantum yields for the four kinds of alcohol (in the absence of biacetyl) were redetermined and were found essentially the same as the previously reported ones.[6,7] In Fig. 7, some of the plots of Φ_0/Φ *vs.* [B] (Φ_0, the quantum yield in the absence of biacetyl) are given.*3

It is quite astonishing that the plots are essentially different in the four alcohols. Thus in methanol the plot clearly consists of two linear portions a and b, for both the aerated and deaerated conditions. In ethanol and *n*-propanol the similar curve as in methanol is obtained only in the deaerated solutions, but in the aerated solutions, the plot consists of a single straight line the slope of which is of the similar magnitude as the ones for the b-parts of the above mentioned plots. In the case of isopropanol the plot for both the aerated and deaerated solutions is satisfactorily reproduced by a single straight line.

From the above results, one may safely conclude that in the case of methanol, ethanol and *n*-propanol (for the latter two alcohols only in the deaerated condition) the two states participate in the reaction, whereas in isopropanol and the aerated solutions of ethanol and *n*-propanol only one state is involved in the reaction. It is most plausible that the latter state is a singlet excited state and the former two states are S* and T(n–π*). These conclusions agree with that of Kellmann and Dubois for methanol on one hand, and that of Porter for isopropanol.

Quenching Action of Biacetyl on the Fluorescence of Acridine. To confirm the participation of S* in the reaction further, the quenching action of B on the fluorescence of acridine has been studied and has been compared quantitatively with the retarding effect of B on the photoreduction (in the high concentration region of B). In Fig. 8, the emission spectra for the following three solutions are given (a) [A]$=1\times10^{-4}$ M, (b) [B]$=5\times10^{-2}$ M and (c) [A]$=1\times10^{-4}$ M, [B]$=5\times10^{-2}$ M. The absorption spectra of biacetyl are also dipicted for later consultation.

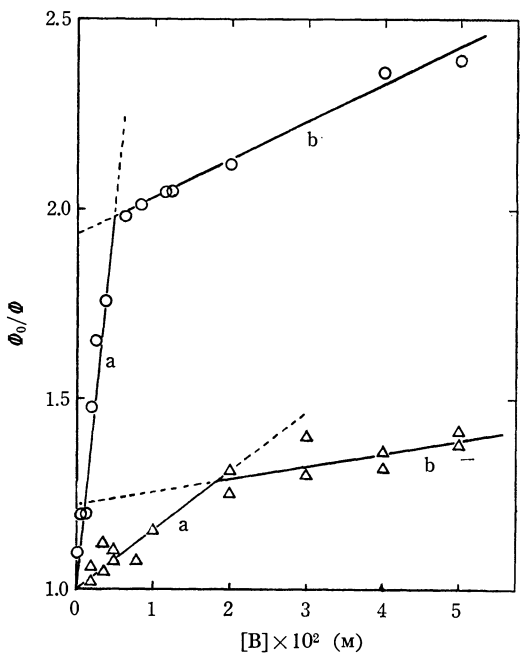

Fig. 7-1

*3 Comparing these results with the ones in the flash experiment, one may say that the effect of [B] agrees in the two cases for methanol but the disagreement for ethanol seems to exceed the experimental error

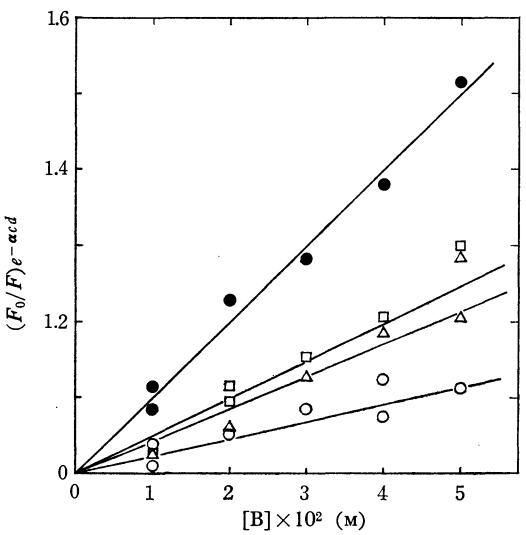

Fig. 9. Stern-Volmer plots for quenching of fluorescence of acridine by biacetyl.
○ methanol, □ ethanol, △ *n*-propanol, ● isopropanol

As is well known, the emission of B consists of fluorescence (shorter wavelength) and phosphorescence[16] (longer wavelength). It is apparent from the emission spectra of System C, that biacetyl quenches the fluorescence of acridine and that the phosphorescence of biacetyl is quenched by acridine. The latter

16) H. Bäckström and K. Sandros, *Acta Chem. Scand.*, **14**, 48 (1960).

phenomenon is due to the process $B^T + A \rightarrow B + A^{T(\pi-\pi^*)}$ as Kellmann and Dubois have established.[9] Systematic studies on the quenching action of B have been made at the emission peak, 410 mμ of acridine, choosing 365 mμ as an exciting light. Stern-Volmer plots for the four alcohols are shown in Fig. 9. The quantity for the ordinate, $(F_0/F)e^{-\alpha cd}$ contains a correction term, $e^{-\alpha cd}$ for the reabsorption of fluorescence by biacetyl (*cf.* Fig. 8) where α is the absorption coefficient of biacetyl at 410 mμ, where c is the concentration of biacetyl and where d is the length of fluorescence light path. d is approximated as 1/2 cm. From the slopes one can evaluate $k_Q\tau$; approximating τ as 10^{-9}sec for all the alcohols, one obtains the rate constant k_Q for the quenching process. The results are given in Table 3.

TABLE 3

		k_q ($M^{-1}sec^{-1}$)	k_Q ($M^{-1}sec^{-1}$)
Methanol	(dea)	1.2×10^{10}	0.3×10^{10}
	(aer)	0.4×10^{10}	
Ethanol	(dea)	1.4×10^{10}	0.7×10^{10}
	(aer)	0.8×10^{10}	
n-Propanol	(dea)	0.8×10^{10}	0.5×10^{10}
	(aer)	0.5×10^{10}	
Isopropanol	(dea)	1.7×10^{10}	1.0×10^{10}
	(aer)	0.9×10^{10}	

It is worthwhile to note that the k_Q-values are essentially the same for the aerated and deaerated solutions.

Quantitative Discussion about the Retarding Effect of B on the Photoreduction. Since the reaction occurring in the high concentration region of B is considered to be concerned with S*, the reaction scheme for it may be written as follows,

$$A + h\nu \rightarrow A^* \quad I_{ab}$$
$$A^* \rightarrow A \quad k_d$$
$$A^* + RH_2 \rightarrow Prod \quad k_r$$
$$A^* + B \rightarrow A + B \quad k_q$$

where A* is the singlet excited state of acridine. The following relations are derived straightforwardly.

$$\Phi = k_r/(k_r + k_d + k_q[B]) \quad (1)$$
$$\Phi_0 = k_r/(k_r + k_d) \quad (2)$$
$$\Phi_0/\Phi = 1 + (k_q/(k_d + k_r))[B] \quad (3)^{*4}$$

Since $k_r + k_d = 1/\tau$, k_q can easily be evaluated from the plots given in Fig. 7. The results are given in Table 3. The agreement between k_q and k_Q are satisfactory especially for the k-values for the aerated solutions. Somewhat larger k_q values for the deaerated solutions might be due to the participation of the T(n-π^*) state. Rate constants for the encounter-controlled reaction evaluated from the relation $k = 8RT/3000\eta$ for methanol, ethanol and *n*-propanol are respectively 1.2×10^{10}, 0.6×10^{10}, 0.3×10^{10} $M^{-1}sec^{-1}$. These values are close to those of k_q amd k_Q. Thus the above results lead to the conclusion that the part of the reaction occurring in the high concentration of biacetyl, is concerned with S* and that biacetyl quenches the reaction at an encounter-controlled rate.

The participation of T(n-π^*) state is very prominent only in the case of the deaerated methanol. Hence the accurate treatment can be made only on this case. If one assumes that biacetyl does not affect the intersystem crossing, equations corresponding to (1) and (2) are

$$\Phi = \frac{k_r'}{k_r' + k_d' + k_q'[B]}\varphi_{ST} \quad (1')$$

$$\Phi_0 = \frac{k_r}{k_r' + k_d'}\varphi_{ST} \quad (2')$$

where φ_{ST} is the quantum yield of intersystem crossing S*→T(n-π^*). The similar relation to (3) exactly holds also in this case. Making a suitable correction for the participation of the singlet excited state and assuming the calculated k_q' value, one can evaluate the lifetime of T(n-π^*). The result is 8.9×10^{-8}sec which agrees with the one proposed by Kellmann and Dubois.

Analyzing the experimental data along the above reasoning, the values of $(k_d+k_r)/k_r$ or $(k_d'+k_r')/k_r'\cdot\varphi_{ST}$ may be evaluated. The results are given in Table 4. The reliable value of φ_{ST} is still unknown. If one assumes $\varphi_{ST}\simeq0.3$,[*5] k_d' is several times larger than k_r' in the case of the deaerated methanol. In ethanol and *n*-propanol the ratio is considered to be still larger. This is consistent with the result obtained from the flash experiment, that

TABLE 4

		S* $(k_d+k_r)/k_r$	n-π^* $(k_d'+k_r')/k_r'\varphi_{ST}$
Methanol	(dea)	15	17
	(aer)	37	~170
Ethanol	(dea)	8.3	~ 50
	(aer)	23	—
n-Propanol	(dea)	15	~ 50
	(are)	33	—
Isopropanol	(dea)	11	—
	(are)	32	—

*4 In the presence of O_2, k_d+k_r should be replaced by $k_d''+k_r''$ with $k_r''<k_r$, but the sum of the two rate constants is the same.

*5 The maximum quantum yield for the photochemical reaction between acridine and acridan in benzene solution is ~0.25.[17] (In this case, the reactive state of acridine is T(π-π^*).) Furthermore, acridine-sensitized photooxidation of leucouranine in the aqueous solution leads to $\varphi_{ST}=0.24$ provided the efficiency for the reaction between T(π-π^*) of A and leuco-uranine is 1.[18]

the yield oi T(π-π*) is scarcely affected by the addition of biacetyl.

Evaluation of Φ_M^S, Φ_R^S, Φ_M^T and Φ_R^T. From the results given in Fig. 7, one can estimate these quantities if one assumes that T(n-π*) is not deactivated by oxygen contained in the aerated solution. Singlet excited state of acridine is not affected by oxygen as has been verified in the present experiment. That AH is not attacked by biacetyl is also verified by the present flash experiment.

Taking methanol for instance, the evaluation can be made in the following way. The quantum yield for the deaerated solution in the absence of biacetyl gives $\Phi_M^S+\Phi_R^S+\Phi_M^T+\Phi_R^T$. The aerated solution in the absence of biacetyl gives $\Phi_M^S+\Phi_M^T$, since oxygen quickly reverts semi-reduced acridine to acridine. The extrapolation of the b-part of the plot for the deaerated solution to [B]=0, gives $\Phi_M^S+\Phi_R^S$ and the similar extrapolation of b-part of the plot for the aerated solution gives Φ_M^S. From these values, each Φ can be determined separately. The results are given in Table 5. The second column for each alcohol is the respective value allotted to one α-H atom.

Although the data are not very accurate and still provisional, it is believed that the general feature will not be altered by more accurate experiments. Generally speaking, the singlet excited state makes a more important role than T(n-π*) for the photoreduction of acridine. There seems to be a tendency that more of the T(n-π*) reacts with alcohols with the increase of the number of α-hydrogen atoms. Molecular mechanism does not occur or scarcely occurs in T(n-π*) state. The reaction at S* increases in the order, methanol<ethanol<isopropanol for both molecular and radical mechanisms when the number of α-hydrogen is taken into account. This agrees with the general tendency of these alcohols when they act as hydrogen donors. Although conspicuous difference in methanol and isopropanol, *i.e.* the result that in methanol about 50% of the total reaction occurs at T(n-π*) whereas in isopropanol the entire reaction occurs at S*, cannot be interpreted in the present stage, one may say at least in the following way. Firstly, any reactions at singlet excited states may not affect the value of φ_{ST} so much since $\Phi_M^S+\Phi_R^S$ is rather small, *i.e.* $\sim$0.1 at most. In fact, as mentioned in Part I, the yield of T(π-π*) is essentially the same in methanol, ethanol and isopropanol. This is naturally expected if Φ_{ST}-(n-π*) is about equal and if T(n-π*) produced mostly goes to T(π-π*). The latter remark has been verified in the present experiment.

Hence, the cause for the difference in methanol and isopropanol should be sought in the step of reaction of T(n-π*) with an alcohol molecule. Steric effect might be a factor chiefly controlling the situation. To make clear the cause of this difference, it is desirable to extend such studies to other solvents. It is also desirable to make experiments using other triplet energy donors and acceptors. Further it is hoped that the reliable value of φ_{ST} is determined.

The Non-Newtonian Viscosity of Dilute Aqueous Solution of Methylcellulose

Naomichi Iso and Daijiro YAMAMOTO

Faculty of Agriculture, Meiji University, Ikuta, Kawasaki

(Received October 30, 1967)

The viscometric behavior of a dilute aqueous solution of methylcellulose was studied by tilting capillary viscometers. The intrinsic viscosity was obtained by the extrapolation of Martin's plots on the assumption that the plots were linear down to an infinite dilution. The intrinsic viscosity obtained increased with the rate of shear over the range of 200—1200 sec^{-1}. Huggins' constant, k', the temperature coefficient of the intrinsic viscosity, $d[\eta]/dT$, and the energy of the activation of flow, E_v, decreased with the rate of shear. From the data of $d[\eta]/dT$ and E_v thus obtained, it has seemed reasonable to assume that the methylcellulose chain has a relatively small flexibility and a strong tendency toward alignment with a flowing stream. This may be the main reason why the viscosity of the dilute aqueous solution of methylcellulose is non-Newtonian.

Methylcellulose is a kind of cellulose-ether used extensively in food products as a thickener, a stabilizer, a swelling agent, a coating agent, a molding agent, and a binder. During the course of an investigation into the viscosity of a concentrated methylcellulose solution,[1,2] our attention was called to the viscosity of a dilute solution of the same sample. Although the viscosity of a dilute solution of methylcellulose has been studied by several workers[3-5] in recent years, little attention has been paid to the non-Newtonian viscosity of the dilute solution.

On the other hand, the shear-rate dependence of the intrinsic viscosity of a high polymer solution has been investigated both theoretically and experimentally, and these results have been reviewed by several workers.[6-9] Most experiments and theories have found that the intrinsic viscosity decreased with the shear rate,[6,10-17] although theories which do not give a shear-rate dependence of the viscosity have been reported, too.[18-19] Furthermore, a few theories and experiments have shown that the intrinsic viscosity increases with the shear rate in some cases.[8,20,21]

The purpose of this study is to extend the investigation of the viscometric behavior of methylcellulose solutions to a low rate of shear and to a low concentration of the solution. The temperatures measured range from 25°C to 45°C, for it is found that a gelation of the solute takes place above about 50°C.[2] In that region the energy of the activation of the flow of the solution and the temperature dependence of the intrinsic viscosity have also determined in order to discuss the non-Newtonian viscosity of the solution.

Experimental

Materials. The methylcellulose was a product of Shinetsu Chemical Ind. (trade name, " Metolose 90 SH 15000 "). The manufacturer reported that the density was 1.31 g/cm^3; the degree of methylation of this sample was 1.08—1.42. The white powder of the sample was dissolved in distilled water without further purification; the concentration of the original solution was 0.3030 g/100 ml.

Viscosity Measurement. Four tilting capillary viscometers[22] were used. Each viscometer was a modification of the dilution suspended-level viscometer. The

capillaries of these viscometers ranged from 0.34 to 0.84 mm in diameter. Aqueous solutions of sucrose were used for the calibration of the viscometers, for Bingham and Jackson[23] have shown that an aqueous solution of sucrose is suitable for this purpose.

The relative viscosity, η_r, is given by the following equation:[17]

$$\eta_r = [4(t_s/t_0)/\{3 + (t_s/t_0)(dt_s/dt_0)\}] \times [1 + (V^2/\pi R^4 \boldsymbol{g} h)(1/t_0^2 - 1/t_s^2)], \quad (1)$$

where V is the total volume flowing in time t, while the suffixes s and 0 denote the solution and the solvent respectively. R is the radius of the capillary, h is the mean head of the liquid, and $\boldsymbol{g}$ is the acceleration due to gravity. The rate of shear at the capillary wall is expressed by:

$$g(F) = 4V/\pi R^3. \quad (2)$$

The intrinsic viscosity, $[\eta]_{g(F)}$, at a constant rate of shear is calculated from Martin's equation:[24]

$$\log(\eta_{sp}/c) = \log[\eta] + k[\eta]c, \quad (3)$$

where η_{sp} is the specific viscosity, c is the concentration of the solution, and k is a constant.

Results and Discussion

Figure 1 shows an example of the shear-rate dependence of the relative viscosity. As the figure shows, the viscometric behavior of the dilute solution of methylcellulose was non-Newtonian; this non-Newtonian behavior of the solution decreased with a decrease in the concentration of the solution. The values of $\log(\eta_{sp}/c)$ at a constant rate of shear were plotted against the concentration according to Martin's equation. An example of the plots of $\log(\eta_{sp}/c)$ *versus* c is shown in Fig. 2.

The intrinsic viscosity at a constant rate of shear was obtained by the extrapolation of each plot of $\log(\eta_{sp}/c)$ *versus* c to an infinite dilution. The values of $[\eta]_{g(F)}$ are shown in Table 1. As the table shows, all the intrinsic viscosities somewhat increased with the rate of shear over the range of 200—1200 sec^{-1} within the limit of experimental error. Although each plot of $\log(\eta_{sp}/c)$ *versus* c was linear, as Fig. 2

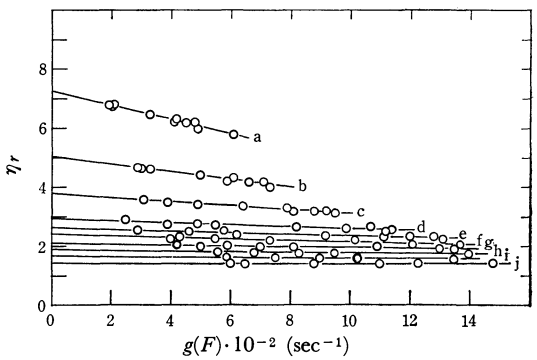

Fig. 1. Shear rate dependence of the relative viscosity of methylcellulose solution at 45°C; a, 0.3030 g/100 ml; b, 0.2424; c, 0.2020; d, 0.1731; e, 0.1515; f, 0.1359; g, 0.1212; h, 0.1010; i, 0.0866; j, 0.0606.

rate-shear dependence of $[\eta]_{g(F)}$ can be concluded to have been obtained on the assumption that Martin's plots are linear down to an infinite dilution. The positive rate-shear dependence of $[\eta]_{g(F)}$ obtained on this assumption was similar to those of aroclor solutions of polymethylmethacrylate,[21] although the highest value of the $[\eta]_{g(F)}/[\eta]_{g(F)=0}$ ratio in our case was 1.08 at 30°C, $g(F)=800$ sec^{-1}, while that in a polymethylmethacrylate solution was over 2.0. Peterlin[8] has predicted that, in an extreme case in which the usual flexible polymer molecule is very long and the solvent is extremely viscous, the intrinsic viscosity would be expected to increase with the shear gradient over a limited range. In our case, however, the first condition of the polymer molecule being very long was not met; the molecular weight of this methylcellulose was calculated to be about $(3—4)\times10^5$ by using the relationship between the intrinsic viscosity and the molecular weight reported in Ref. 4. The molecule with a molecular weight of about $(3—4)\times10^5$ cannot be considered to be very long. On the other hand, the viscosity of the solvent, water, is about 1 centi-poise at 20°C and so is not very large, either. Therefore, the shear-rate dependence of the intrinsic viscosity of a methylcellulose solution seems to be due to the small flexibility of the chain. In general, cellulose derivatives have a relatively extended form in solution and take the configuration of the free draining model. The increase in the intrinsic viscosity with the rate of shear is considered to come from the specific property of the cellulose derivative.

The constant, k, in Martin's equation is related to Huggins' constant, k', as $k=k'/2.3$. The values of k' obtained at constant $g(F)$ are shown in Table 2. These values decreased with $g(F)$ and increased with the temperature. Uda[4] has reported that the Huggins' constant of a dilute solution of methylcellulose decreased with the temperature over the range from 20°C to 45°C. However, his values were not those at a constant rate of shear. Since the flow time in the capillary decreases exponentially with an increase in the temperature and as, consequently, the rate of shear increases, the correction of the rate of shear may be necessary for any discussion of the temperature dependence of k'. Furthermore, the fact that the increase in k' comes from a decrease in solubility seems to support the positive temperature dependence of k'.

Generally the intrinsic viscosity of cellulose derivatives has a large negative temperature coefficient. Some workers[25-28] have attributed this behavior to the increase in the flexibility of chain, and others[4] to the decrease in the degree of hydration, with the increase in temperature. In view of the fact that the solubility decreased with the temperature, as has been described above, the latter interpretation seemed to be more reasonable. For the value of $-\mathrm{d}[\eta]/\mathrm{d}T$ where T is the temperature, values of 0.28—0.31 (100 ml/g·deg) were obtained over the range of the rate of shear from 200 to 800 sec^{-1}; these values are shown in Table 1. Since the value of $\mathrm{d}[\eta]/\mathrm{d}T$ decreased with the $g(F)$, the methylcellulose molecule in a dilute solution seems to be not sphere but an ellipsoid and it seems to correspond with the increase in intrinsic viscosity described above.

Kahn and Witnauer[29] pointed out that the energy of the activation of flow and the entropy of flow would be measures of the particle alignment in a solution; they treated their viscosity data according to the theory of rate process.[30]

According to Eyring's theory,[30] the viscosity is given by the following equation:

$$\eta = (\boldsymbol{N}\boldsymbol{h}/V)\exp(-\Delta S/\boldsymbol{R})\exp(E_v/\boldsymbol{R}T), \quad (4)$$

where $\boldsymbol{N}$ is Avogadro's number, $\boldsymbol{h}$ is Plank's constant, V is the molar volume of the solute, ΔS is the entropy of flow, $\boldsymbol{R}$ is the gas constant, E_v is the energy of the activation of flow, and T is the absolute temperature. From Eq. (4) we have:

$$\ln\eta = \ln(\boldsymbol{N}\boldsymbol{h}/V) - (\Delta S/\boldsymbol{R}) + E_v/\boldsymbol{R}T. \quad (5)$$

Some examples of the plots of $\log\eta$ *versus* $(1/T)$ are shown in Fig. 3. The values of E_v were calculated from the slopes of the plots. The values of E_v obtained are shown in Table 3. From Table 3 it is

clear that a high energy is required for the flow in the high-concentration range and at a low rate of shear. The values of E_v obtained in this system were somewhat higher than the 5.8 kcal obtained in the aqueous solution of solubilized calf-skin collagen.[29] From these results, it seems that methylcellulose shows a strong tendency toward alignment with a flowing stream. The statement seems to be essentially consistent with the shear-rate dependence of $[\eta]$ and $\mathrm{d}[\eta]/\mathrm{d}T$ described above. For lack of the value of the molar volume of methylcellulose, however, the entropy of flow could not be discussed here. The effects of the molecular weight and the molecular-weight distribution on the non-Newtonian viscosity of the dilute solution are also awaiting discussion. The non-Newtonian viscosity of the dilute aqueous solution of methylcellulose, however, seems to come from the small flexibility of the chain and from a strong tendency toward alignment with a flowing stream.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1068—1073 (1968)

A Study of Charge-Transfer Complexes. VII. Interactions between the Alkyl- or Arylsubstituted Pyrroles and Chloranil or Tetracyanoethylene*1,*2

Taku MATSUO*3 and Hideto SHOSENJI

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received November 1, 1967)

The charge-transfer (CT) bands of complexes of alkylsubstituted pyrroles and chloranil or tetracyanoethylene (TCNE) were found to consist of two closely situated peaks. The peaks were assigned to transitions originated from the highest occupied, and second-highest occupied orbitals of the donor. The energy of the CT absorption band is hardly affected even by the presence of a bulky substituent such as a *t*-butyl group at the pyrrole nitrogen. Hence, the acceptor molecules were thought not to be close to the 1-position of the pyrryl group. In the case of 1-phenylpyrrole, the first CT bands are at almost the same positions as those of the corresponding complexes of 1-methylpyrrole. The bands show red shifts if methyl groups are introduced either on the pyrryl group or on the phenyl group, so that the planes of the two groups are twisted around the N-C bond between them. Thus the acceptor molecules were concluded to interact mainly with the pyrryl group.

The electronic spectra of pyrrole derivatives have been less investigated than those of benzene derivatives. The situation is the same for the intermolecular charge-transfer (abbreviated to CT hereafter) absorption bands of these compounds.[1] Only a few examples have been known of CT complexes of pyrrole derivatives.[3a,3b] In the present paper, the results of a systematic study on the nature of the CT absorption bands of alkyl- or aryl-substituted pyrroles will be described.

Results and Discussion

(A) Chloranil Complexes of Alkylpyrroles. The CT spectra of chloranil complexes of alkylpyrroles consist of two peaks, which overlap each other as shown in Fig. 1. The wave numbers for the peak positions are summarized in Table 1. In the case of chloranil complexes of *N,N*-dimethylaniline analogues, which will be described later, there are no signs of absorption bands within 10 kK of the first CT band. Therefore, the two peaks of the pyrrole complexes should be due to the intrinsic nature of the donor molecule. As suggested by several investigators,[3a,3b] the first and second CT bands of pyrrole complexes may be assigned to electronic transitions originated from the highest occupied, and

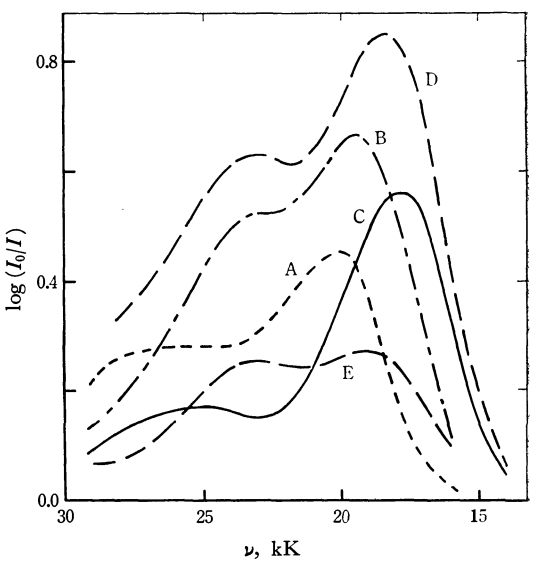

Fig. 1. The CT bands of the chloranil complexes of alkylpyrroles in carbon tetrachloride. The donors are indicated by the capital letters as the following: pyrrole (A), 1-methylpyrrole (B), 2-methylpyrrole (C), 3-methylpyrrole (D), 1-*t*-butylpyrrole (E). The concentrations of the acceptor are 0.0013 mol/*l*; the concentrations of the donors are 0.33 (A, C, D, E) or 0.073 mol/*l* (B).

Table 1. The CT bands of the chloranil complexes of alkylpyrroles in carbon tetrachloride[a)]

Donor	The 1st band	The 2nd band
Pyrrole	20.1±0.1	26.2±0.5
1-Methylpyrrole	19.5±0.1	24.0±0.2
2-Methylpyrrole	17.8±0.1	25.3±0.5
3-Methylpyrrole	18.4±0.1	23.8±0.2
1-*t*-Butylpyrrole	18.9±0.1	22.9±0.2

a) The values are in kilokayser units.

second-highest occupied orbitals of pyrrole, respectively. The semiempirical SCF-LCAO-MO method of Pariser-Parr-Pople was utilized to study the π electronic structure of pyrrole by Solony *et al.*[4] According to the calculation, the highest occupied orbital of pyrrole is antisymmetric with respect to the C_2 axis of the molecule. The second highest occupied orbital, on the other hand, is symmetric with respect to the same axis. In other words, the nitrogen atom of the pyrrole molecule is involved in the second highest occupied orbitals but not in the highest occupied orbital. The separation between the energy levels of the two orbitals is estimated to be only 0.4 eV. The above assignment of the CT bands of pyrrole complexes is in good agreement with the predicted natures of the two occupied molecular orbitals; the second CT band is approximately 0.7 eV higher than the first band, and methyl substitution at a carbon atom causes an appreciably larger red shift of the first CT band than that at a nitrogen atom.

To a first order approximation, the effect of methyl substitution may be treated as an increase in the Coulomb integral for the atom to which the methyl group is attached. According to simple LCAO-MO theory, a variation in the Coulomb integral for the rth atom ($\delta\alpha_r$) is expected to cause the following change in the energy level of the ith orbital:

$$\delta\varepsilon_i = C_{ir}^2\delta\alpha_r + \sum_{k(\neq i)}^{n} \frac{(C_{ir}C_{kr})^2}{\varepsilon_i - \varepsilon_k}(\delta\alpha_r)^2 + \cdots \quad (1)$$

where ε_i and C_{ir} have the usual meaning. Using the coefficients (C_{ir}) obtained by Solony *et al.*,[4] the effect on the highest occupied orbital is calculated as summarized in Table 2. The experimental values for the red shifts of the first CT bands, as measured by taking unsubstituted pyrrole as standard, are also tabulated in the same table for comparison. The value of $\delta\alpha_r$ is positive for methyl substitution. It is clear, then, that the red shifts of the first CT bands correlated well with the perturbation effects of the methyl group on the highest occupied orbital.

Table 2. The effect of methyl substitution on the π energy levels of pyrrole molecule

Substitution position	C_{ir}^2	$\sum(C_{ir}C_{kr})^2/(\varepsilon_i-\varepsilon_k)$	Red shift of the 1st band
1	0.0	0.0	0.6±0.1 kK
2	0.34	0.12	2.3±0.1
3	0.16	0.12	1.7±0.1

In the case where 1-*t*-butylpyrrole is used as the π donor, the first CT band, as well as the second band, moves to lower wave numbers in comparison with the case of 1-methylpyrrole. The red shift may be explained as due to the fact that the inductive effect of the *t*-butyl group raises the π-energy levels of the pyrryl group. If the steric effect of the *t*-butyl group is of any importance, on the other hand, just the opposite shift will be expected because the increased donor-acceptor distance reduces the value of the electrostatic term C in the following equation:

$$h\nu_{CT} \cong I_p - E_A - C \quad (2)$$

Since the actual shifts are more or less bathochromic, the present authors speculate that the chloranil molecule is not close to the 1-position of the pyrryl group.

(B) Tetracyanoethylene Complexes of Alkylpyrroles. It is known that tetracyanoethylene (TCNE) reacts with pyrroles to form tricyanovinyl compounds.[5] In the present experiment, the CT bands were observed to decay with time. In return, new absorption bands appeared in the region between 300 and 500 mμ, which were due to the accumulation of reaction products. In the case of the

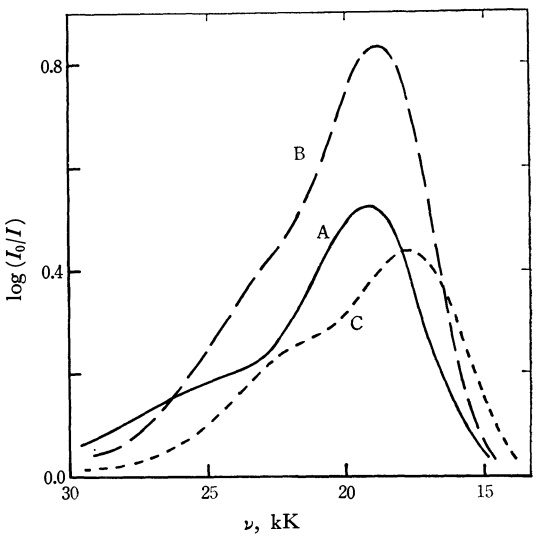

Fig. 2. The CT bands of the TCNE complexes of alkylpyrroles in *n*-hexane. The donors are indicated by the capital letters as follows: pyrrole (A), 1-methylpyrrole (B), 1-*t*-butylpyrrole (C). The concentrations of the acceptor are 3.0×10^{-4} mol/*l*; the concentrations of the donors are 0.10 (A), 0.15 (B) or 0.20 mol/*l* (C).

a) The values are in the same units as in Table 1.
b) In carbon tetrachloride.
c) In tetrachloroethane.
d) The measurement was unsuccesful because the reaction was rapid.

2-methylpyrrole-TCNE system, the decay of the CT bands was so rapid that the complete spectra could not be followed even by using the fastest scanning speed. A solution of the 3-methylpyrrole-TCNE system also shows extraordinary behavior. The spectra are not only time dependent, but also consist of several sharp peaks indicating at least three species besides the component molecules. Thus, the location of the CT bands could not be definitely determined. A detailed study of this peculiar system is under way, and the results will be reported in the near future. The time dependences of the TCNE complexes of pyrrole, 1-methylpyrrole and 1-*t*-butylpyrrole are small enough to be measured without any appreciable change taking place during measurement, if measurement is made within five minutes of mixing the acceptor and donor components. The spectra thus measured in *n*-hexane are shown in Fig. 2. Analogous to the cases of chloranil complexes, one can observe two CT bands for each system. The second CT band, however, is much weaker than the first band, and the former appears just as a shoulder of the latter. Both the first and second bands show similar red shifts as the solvent is changed in the order of *n*-hexane, carbon tetrachloride and tetrachloroethane, as summarized in Table 3. The shapes of the spectra are quite alike in all solvents. Thus, it is suggested that the nature of the donor-acceptor interactions between TCNE and alkylpyrroles is essentially the same as that of the chloranil-alkylpyrrole system.

(C) Chloranil and TCNE Complexes of 1-Phenylpyrrole Analogues. On the basis of the size of the dipole moment, 1-phenylpyrrole has been suggested to have a nearly planar structure, where the π-electrons of the pyrryl group are easily delocalized to the phenyl group without much disturbance.[6] The suggested conformation may be reasonable because the van der Waals radii of the protons at the 1- and 1′-positions barely overlap each other. In the case of 1-phenyl-2,5-dimethylpyrrole, however, the dipole moment[6] and the electronic spectra[7,8] indicate that the dimethylpyrryl group and the phenyl group are twisted around the N–C bond axis joining the two groups. The electronic spectra of 1-(2′,6′-xylyl)-pyrrole also have been interpreted as indicating the presence of twisting around the N–C bond axis. This twisting is, of course, due to the steric hindrance exerted by the methyl groups. A more or less similar situation is expected for the conformation of 1-(*o*-tolyl)-pyrrole. These compounds were also used as the electron donors in the present experiment. The CT absorption spectra of the chloranil complexes are shown in Fig. 3. The wave numbers for the absorption maxima, together with those for the TCNE complexes, are summarized in Table 4. In either series, the

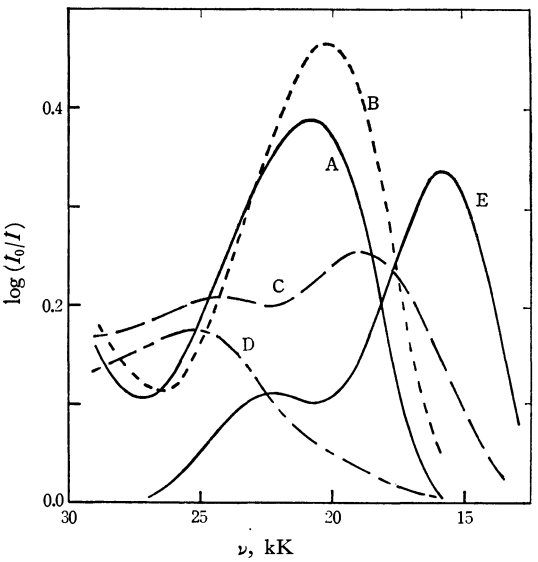

Fig. 3. The CT bands of the TCNE complexes of 1-phenylpyrrole analogues with methyl substituents in carbon tetrachloride. The donors are indicated by the capital letters as the following: 1-phenylpyrrole (A), 1-*p*-tolylpyrrole (B), 1-*o*-tolylpyrrole (C), 1-(2′,6′-xylyl)-pyrrole (D), 1-phenyl-2,5-dimethylpyrrole (E). The concentrations of the acceptor are 0.0013 mol/*l*; the concentrations of the donors are 0.33 (A, B, C, D) or 0.12 mol/*l* (E).

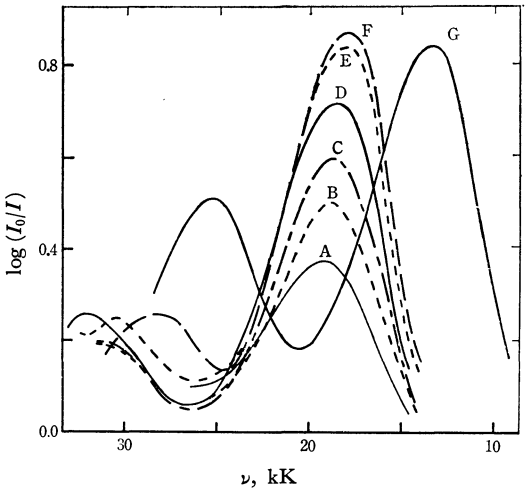

Fig. 4. The CT bands of the chloranil complexes of 1-(*p*-substituted phenyl)-pyrroles in the tetrachloroethane. The substituents are indicated by the capital letters as follows: acetyl (A), bromo (B), chloro (C), hydrogen (D), methyl (E), methoxy (F) and dimethylamino (G). The concentrations of the acceptor are 0.0020 mol/*l*; the concentrations of the donors are 0.10 (A, B, D, E, F), 0.12 (C) or 0.013 mol/*l* (G).

wave numbers for the absorption maxima of the first CT bands are in the following order: 1-phenyl-2,5-dimethylpyrrole < 1-(2′,6′-xylyl)-pyrrole < 1-(*o*-tolyl)-pyrrole < 1-(*p*-tolyl)-pyrrole ≈ 1-phenylpyrrole. It is interesting that the CT bands for donors with twisted conformations are at a lower energy than for those with planar structures. It should be noticed also that the first CT bands of 1-phenylpyrrole complexes are at almost the same positions as those of the corresponding complexes of 1-methylpyrrole. These observations appear to be against the general expectation that the ionization potential of an aromatic molecule decreases as the degree of conjugation is extended. An explanation may be the fact that the π-electrons of the pyrryl group are withdrawn to the more electronegative phenyl group. As a consequence, the energy level for the highest occupied orbital is lower than the case where conjugation between the two groups is forbidden. From this point of view, the rather large red shift of the first CT band for the chloranil complex of 1-phenyl-2,5-dimethylpyrrole may also be understood as due to the inductive effect of the methyl group on the π-electron system of the pyrryl group. Thus, it is suggested that the acceptor molecules interact mainly with the pyrryl group rather than with the phenyl group. In other words, the electronic state of the pyrryl group may be the most important factor determining the energy of the first CT band of the 1-phenylpyrrole analogues with alkyl substituents.

Table 5. The CT bands of the chloranil and TCNE complexes of 1-(*p*-substituted phenyl)-pyrroles[a)]

Substituent group	Chloranil complex[b)] 1st band	TCNE complex[c)] 1st band	TCNE complex[c)] 2nd band

a) The values are in the same units as in Table 1.
b) In carbon tetrachloride.
c) In tetrachloroethane.

In order to obtain further information on the role of the phenyl group, the CT spectra of various 1-(*p*-substituted phenyl)-pyrrole complexes were also investigated (Fig. 4, Table 5). Since the variations of the first CT bands of the chloranil complexes in Table 5 are almost the same as those of the TCNE complexes, the substituent effects on the former may be taken as representative. For comparison, the first CT bands of the chloranil complexes of *p*-substituted *N*,*N*-dimethylanilines were also measured (Table 6, Fig. 5). As for substituents other than the *N*,*N*-dimethylamino group, the effects observed in the 1-(*p*-substituted phenyl)-pyrrole complexes are slightly less than those in the *p*-substituted aniline

Table 6. The CT bands of the chloranil complexes of *p*-substituted *N,N*-dimethylanilines in carbon tetrachloride[a)]

Substituent group	1st band
Acetyl	15.8±0.1 kK
Bromo	15.0±0.1
Chloro	15.2±0.1
Hydrogen	15.5±0.1
Methyl	14.9±0.1
Methoxy	13.9±0.1
Dimethylamino	11.2±0.1

a) There are no signs of absorption bands within 10 kK from the first CT bands in these systems.

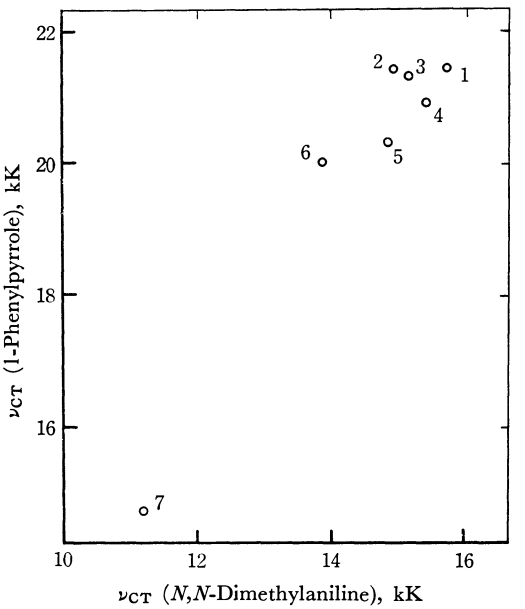

Fig. 5. The comparison of the first CT band of the chloranil complexes of 1-(*p*-substituted phenyl)-pyrrole with that of *p*-substituted *N,N*-dimethylaniline in carbon tetrachloride. The substituents are indicated by numbers as follows: acetyl (1), bromo (2), chloro (3), hydrogen (4), methyl (5), methoxy (6) and dimethylamino (7).

complexes. In the case of the dimethylamino group, the first CT bands are at considerably longer wavelengths than in the cases of other substituents. In comparison with the first CT bands of the chloranil complex of 1-phenylpyrrole, for example, the corresponding band of 1-(*p*-*N,N*-dimethylaminophenyl)-pyrrole is shifted to the longer wavelength side by 6.2 kK. The corresponding red shift in the *p*-*N,N*-dimethylaniline series, on the other hand, is only 4.3 kK. This interesting effect may be due to the fact that the *N,N*-dimethylaminophenyl group is a stronger electron donor than the pyrryl group, as may be seen by comparing the values in Table 1 with those in Table 6. As pointed out in the preceding paragraph, the acceptor molecules appear to be coordinated to the pyrryl group in 1-phenylpyrrole. The situation may be unchanged if the substituent at the phenyl group is either an electron-withdrawing or weakly electron-donating one. In the case of 1-(*p*-*N,N*-dimethylaminophenyl)-pyrrole, the electron-donating ability of the pyrryl group is exceeded by that of the substituent. As a consequence, the acceptor molecule may be coordinated to the *p*-*N,N*-dimethylamino group rather than to the pyrryl group.

Experimental

Measurements of the CT Spectra. Solutions of CT complexes were prepared by properly adjusting the concentrations of the donor (0.02—1.0 mol/*l*) and the acceptor molecules (0.00015—0.05 mol/*l*) in suitable solvents. The spectra were measured at room temperature (17—20°C) by the use of either a Bausch & Lomb Spectronic 505, or a Hitachi model EPS-2 recording spectrophotometer. The absorptions due to the donor and the acceptor were numerically subtracted from the recorded spectra to obtain the absorption bands of the pure complexes.

Materials. Carbon tetrachloride, *n*-hexane and tetrachloroethane were purchased from the Wako Pure Chemicals Co., Ltd., and purified by standard procedures. Chloranil (mp 292.5—293.0°C), pyrrole (bp 60—61°C/55 mmHg), 1-methylpyrole (bp 44.9°C/42.5 mmHg), *N,N*-dimethylaniline (bp 85°C/20 mmHg), *N,N*-dimethyl-*p*-aminoacetophenone (mp 108.2—108.7°C), *N,N*-dimethyl-*p*-bromoaniline (mp 55.2— 55.9°C), *N,N*-dimethyl-*p*-chloroaniline (mp 34.5—35.0°C), *N,N*-dimethyl-*p*-toluidine (bp 114—115°C/34 mmHg), *N,N*-dimethyl-*p*-anisidine (mp 48.0—48.5°C) and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (mp 51.0—52.0°C) were reagent-grade chemicals as supplied by the Wako Pure Chemicals Co., Ltd., and were repeatedly purified until they showed the melting points or boiling points given above. The following compounds were synthesized according to methods given in the references in parentheses: TCNE (Ref. 9, mp 199—200°C), 2-methylpyrrole (Ref. 10, bp 82.5°C/70 mmHg), 1-phenyl-2,5-dimethylpyrrole (Ref. 11, mp 51.5—52.5°C), 1-*p*-bromophenylpyrrole (Ref. 12, mp 96.2—96.5°C), 1-(*p*-*N,N*-dimethylaminophenyl)-pyrrole (Ref. 12, mp 152.5—153.2°C), 1-*o*-tolylpyrrole (Ref. 12,*4 bp 80°C/3 mmHg), 1-2',6'-xylylpyrrole (Ref. 12,*4 mp 47.2—47.6°C), 1-*p*-acetylphenylpyrrole (Ref. 12,*4 mp 120.0—121.0°C), 1-*t*-butylpyrrole (Ref. 13,*4 bp 65°C/38.5 mm-

*4 The materials used in the present syntheses are different from those in the references. The method, however, are essentially the same except for a little modification.

Hg), 1-phenylpyrrole (Ref. 13, mp 58.1—58.3°C), 1-*p*-chlorophenylpyrrole (Ref. 13,*4 mp 87.9—88.3°C), 1-*p*-tolylpyrrole (Ref. 13, mp 82.2—82.7°C) and 1-*p*-anisylpyrrole (Ref. 13,*4 mp 111.0—111.5°C). The synthesis of 3-methylpyrrole was accomplished by the alkali fusion of 3,5-dicarbethoxy-4-methyl-2-pyrrolecarboxylic acid, bp 76°C/53 mmHg. The purities of the above synthesized materials were determined by means of elementary analyses, NMR spectra and gas chromatography, where possible.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1073—1087 (1968)

Phase Changes in Crystalline and Glassy-Crystalline Cyclohexanol*[1]

Keiichiro ADACHI, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received November 6, 1967)

It has been known that cyclohexanol has low-temperature form (crystal-II) and high-temperature form (crystal-I) and that the supercooled crystal-I shows in its heat capacity curve an anomalous jump resembled to that associated with glass transition. In order to clarify whether this anomaly arises from relaxation phenomenon or not, we have reinvestigated the heat capacity of this substance from 14°K to 320°K and obtained the values of 8827 J/mol, 265.31°K, 1782 J/mol and 299.09°K for heat of transition, transition point, heat of fusion and melting point respectively. Comparing the ideal gas entropy of cyclohexanol calculated from thermal data and that from statistical-mechanical data, we have estimated that the residual entropy of the crystal-II is of zero and that the potential barrier of internal rotation of *OH* group is 7.0 kJ/mol. From these results, the residual entropy of the supercooled crystal-I amounts to 4.72 J/(mol deg K). We have discussed the glass transition of this crystal and proposed a new term **glassy crystal.** We have also studied the heat capacity of metastable phase (crystal-III) and obtained the results 244.8°K and 8640 J/mol for transition point and heat of transition. The residual entropy of the crystal-III has determined to be zero.

Thermal study of cyclohexanol crystal from liquid hydrogen temperature was first carried out by Kelley.[1)] He drew main two conclusions. First, this substance had two crystalline phases, the high-temperature phase (crystal-I) and the low-temperature one (crystal-II).*[2] The crystal-I was found to be supercooled easily and the heat capacity curve of the supercooled phase showed anomalous jump closely resembled to that associated with the glass transition of a supercooled liquid. Second, the supercooled crystal-I and the crystal-II had the same value of entropy at 0°K within the experimental error. In other words, the anomalous jump of the heat capacity curve of the supercooled crystal-I was considered to be second order transition in the sense of thermodynamics. Thereafter, Ôtsubo and Sugawara[2)] reinvestigated this anomaly of the heat capacity under the various annealing conditions and concluded that this anomaly was looked upon as a relaxation phenomenon associated with the glass transition. This stands in contrast to the conclusion by Kelley that the supercooled crystal-I is in the internal equilibrium state. However, they have given no discussion about the residual entropy which is a kind of measure for the degree of internal equilibrium. We have accordingly reinvestigated the low-temperature heat capacities of various crystalline phases accurately and also studied the kinetics of the relaxation in order to clarify the problem that the glass transition characteristic to amorphous state takes place also in the crystalline state in the sense of relaxation phenomenon. If this glass transition phenomenon is a real relaxation effect, the second conclusion of Kelley is contradicting to the fact of zero residual entropy. As to the substances which have been hitherto known to show the anomalous jump of the heat capacity similar to the glass transition in the crystalline state there are only *cis*-1,2-dimethylcyclohexane[3)] and the molecular compound

*1 Read before the 20th Annual Meeting of the Chemical Society of Japan (1967), Tokyo and partially presented at the symposium on New Investigations in Thermodynamics, Thermochemistry and Transport Properties (1967), Heidelberg.

1) K. K. Kelley, *J. Am. Chem. Soc.*, **51**, 1400 (1929).

*2 Following Smyth, Ôtsubo and Sugawara designated this modification as form-III and metastable one as form-II. We changed, however, this nomenclature as described in the text, since the metastable crystal-III in the text has lower transition point as described later.

2) A. Ôtsubo and T. Sugawara, *Sci. Rep. Res. Inst. Tohoku Univ.*, **A7**, 583 (1955).

between 2,3-dimethylbutane and 2,2-dimethylbutane.[4] It should be noted here that both of these substances and cyclohexanol belong to the so-called plastic crystals defined by Timmermans.[5] Aside from this problem, Ôtsubo and Sugawara also reported the occurrence of three kinds of metastable intermediate phases in the course of irreversible transformation from the supercooled crystal-I to the crystal-II. In the present study we have also studied the metastable crystalline phase (crystal-III) and the thermodynamic stability-relationship of the crystal-I, II and III were further determined in terms of Gibbs energy. On the basis of the data of the heat capacities, the vapor pressure and of the heat of vaporrization which were previously reported in this laboratory,[6] the residual entropies of the crystal-I, II and III have been determined by comparing the experimentally obtained entropies of ideal gas state with that calculated by statistical-mechanical method. The potential barrier of the internal rotation of *OH* group has been also estimated.

Experimental

Material. Commercial " Special-grade " cyclohexanol (Nakarai Chemicals) was fractionally distilled twice and further purified through vacuum distillation (10^{-3} mmHg) with baked calcium oxide. The calorimetric determination of the melting point (see below) revealed that the impurities in the sample were found to 0.025 mol% assuming no formation of a solid solution. Only a kind of impurity, presumably cyclohexanone, was detected by gas chromatography (Shimadzu Gas Chromatograph model GC-1B equipped with hydrogen flame ionization detector) and this impurity was calculated to be 0.02 mol% from the peak area of the chromatogram.

Apparatus. The heat capacity of cyclohexanol was measured between 14 and 320°K by the low-temperature adiabatic calorimeter with platinum resistance thermometer. The details of the apparatus, procedure, temperature scale and accuracy were previously described.[7] The purified sample was transferred into the cell of the calorimeter (whose capacity is about 30 cc) by vacuum distillation. The weight of the sample employed was 27.548 g and 1.3×10^{-4} mol of helium gas for heat exchange was introduced (about 1 atm in a room temperature).

For the preliminary study of the occurrence and the thermal properties of metastable crystalline phases, differential thermal analysis was carried out. The apparatus was previously reported[8] also.

The infrared spectra were obtained by a Nihon Bunko Co. Double-beam Spectrometer (model DS-402G) between 600 cm^{-1} and 4000 cm^{-1} and by a Hitachi Co. Spectrometer (model No. FIS-001) between 200 cm^{-1} and 600 cm^{-1}. In the measurement above 400 cm^{-1}, the sample which was the same as that used in the measurements of the heat capacity was put between the polished plates of KBr single crystal. Because of the high hygroscopy of this substance, the preparation of this sample was carried out in the dry nitrogen atmosphere.

Experimental Results

Studies of the Polymorphism of Cyclohexanol with Differential Thermal Analysis (D.T.A.). D.T.A. curves under various conditions are shown in Fig. 1. Run-1 is a cooling curve with the rate of -1.5°K/min. The peak at about 299°K corresponds to the freezing point of the crystal-I. Even with the more rapid cooling rate, the freezing point was observed always at the same point and supercooling of the liquid state has never been observed. On the other hand the crystal-I is easily supercooled and shows no remarkable anomaly due to the transition to other crystalline phase. However, irregular small anomalies seemingly due to the sluggish transitions from the supercooled crystal-I to other phases were observed below 200°K (see curve Run-1), so the glass transition*3 (the jump of the heat capacity of the crystal-1) was not clearly found. Run-2 shows a heating curve with the rate of about 1°K/min after the crystal-I was supercooled to about 80°K with cooling rate of -10°K/min. The anomaly due to the glass transition reported by Kelley and by Ôtsubo and Sugawara was observed about 150°K,

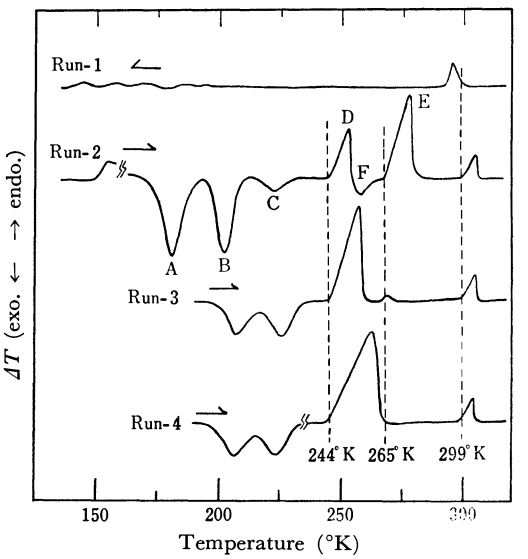

Fig. 1. D. T. A. curves of cyclohexanol. In Run-2 the mark ≀ shows the change of the sensitivity and in Run-4 the change of heating rate, respectively.

8) H. Suga, H. Chihara and S. Seki, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **82**, 24 (1961).

*3 As is described below, it has been confirmed that the anomalous jump of the heat capacity of the supercooled crystal-I at about 150°K is attributable to a relaxation phenomenon. Accordingly we call this anomaly as a glass transition in spite of the phenomenon observed in the crystalline state.

* These specimens were anneald for 25 hr at respective temperatures. In the calculation of the heat capacities, anomalous temperature drift due to the stabilization (relaxation) is treated as if it were arizen from thermal leakages.

and there exist the exothermic irreversible transitions at about 180°K, 200°K, 220°K and 254°K (in Fig. 1, the peaks A, B, C and F, respectively) and the endothermic transitions at 244°K and at 265°K (peaks D and E, respectively). Ôtsubo and Sugawara studied these phase transformations by X-ray analysis in parallel with the thermal studies and concluded that peak A corresponded to the irreversible transition from the supercooled crystal-I to the metastable intermediate mixed crystalline phases and that peak B corresponded to the transition from these metastable phases to other metastable crystalline (crystal-III) or to low temperature form (crystal-II). But they did not find the existence of the peak C. The peaks D and E correspond to the transitions from the metastable crystal-III to the crystal-I and that from the crystal-II to the crystal-I, respectively. The exothermic anomaly F is probably the irreversible transition from the crystal-I occurred by III-I transition to the crystal-II. For the purpose of the measurement of the heat capacity of the metastable phase crystal-III, the condition of preparing the pure crystal-III was investigated by D. T. A. and the typical results are indicated by Runs 3 and 4. Run-3 is a heating curve of the supercooled crystal-I with the rate of about 1.1°K/min followed after rapid cooling from 280°K to 190°K with cooling rate of about −10°K/min. There exists a very small peak due to II-I transition at 265°K. But if one increase the heating rate from 1.1°K/min to 2.5°K/min at 235°K after the same cooling and heating operations as Run-3, the peak at 265°K is scarcely found as shown in Run-4. This fact may be explained in such a way that in Run-3 small peak of II-I transition appears because of the formation of the crystal-II between 244°K and 265°K due to the irreversible transition from I to II, although the almost pure metastable crystal-III is produced at 235°K. While in Run-4, it is considered that a detectable amount of the crystal-II was not produced on account of the rapid heating. For the measurement of the heat capacity of crystal-III, we prepared this modification by cooling the sample after stopping Run-3 around at 235°K.

Measurement of the Heat Capacities. The molar heat capacities are listed in Table 1 and plotted in Fig. 2, where are shown the data of Kelley and those of Ôtsubo and Sugawara for reference. Kelley's data agree well with our data for crystal-II between 14 and 65°K. They deviate, however, from −1.2 to −3% in the ranges between 65 and 170°K, from +1 to +5% between 180 and 230°K and more than 10% between 240 and 260°K, respectively.

—●— crystal-II
—△— crystal-III
------ estimated heat capacity curve of supercooled crystal-I
——— Ôtsubo and Sugawara's data near T_g
– – – Kelley's data of crystal-II

For the crystal-I or the supercooled crystal-I, the smoothed values of his experiment agree fairly well with our data except for the region between 130 and 150°K, where the deviation is approximately +2%. Kelley's data for the crystal-II in the temperature region between 65 and 170°K coincide rather with the data of the crystal-III in the present measurement. Comparison with the data of Ôtsubo and Sugawara was not done because they did not give any numerical values. The heat capacities of the supercooled crystal-I below 160°K have been measured after the specimen was chilled with cooling rate of about −6°K/min from room temperatures and the heat capacities between 245 and 265°K have been measured after the specimen was slowly chilled with a cooling rate of −0.5°K/min from 310°K (liquid state) to 245°K. Crystal-II has been prepared as follows: The crystal-I supercooled below the glass transition temperature was heated up to about 255°K and slowly cooled from this temperature to about 240°K in 13 hr. The crystal-III (metastable phase) has been prepared after the condition investigated by D.T.A. as described above. In the course of the measurement of the heat capacities of this metastable phase, no remarkable irreversible transition to other phase was observed.

Thermal Data Associated with the Phase Transitions. The equilibrium temperatures during the fusion process are listed in Table 2. The temperatures of transitions are shown in Table 3 with those of Ôtsubo and Sugawara. The transition temperature of the crystal-III to the crystal-I could not be determined from the measurement of the heat capacity due to the sluggish irreversible transition from the crystal-I to the crystal-II, so we listed the value determined by D.T.A. Table 4, 5 and 6 summarize the data for the heat of transitions and of fusion together with the data of Kelley and of Ôtsubo *et al.* for comparison. As shown in Table 4 the heat of transition from the crystal-III to the crystal-I was

obtained by measuring the enthalpy difference between the crystal-I above 265°K and the crystal-II, because of the instability of the crystal-I below 265°K.

The Entropy of Cyclohexanol in the Ideal Gas State from the Thermal Data. The molar entropy of cyclohexanol in the ideal gas state at 280°K is calculated by a third-law path *via* II-I transition and summarized in Table 7. The contribution below 14°K is determined by means of the Debye theory with 125°K for Θ_D and assuming 6 degrees of freedom. The data of the heat of sublimation and the vapor pressure were reported previously.[6] Due to the lack of the critical data or the virial coefficients of this material, the magnitude of the gas imperfection correction was estimated from the critical data of *n*-propanol, phenol and cyclohexane by using the Berthelot equation. The correction is, however, negligibly small due to the low vapor pressure at 280°K (0.149 mmHg).[6]

The Entropy from Statistical Data and Residual Entropy of the Crystal-II. The Raman effect of this material was reported by Neelakantan[9] from 300 cm^{-1} to 4000 cm^{-1}. But a normal coordinate analysis was not carried out. Since the far-infrared spectra of this material have not been reported, we measured the infrared spectra down to 200 cm^{-1}. They are summarized in Table 8. The frequencies of the normal modes were estimated by comparison with those of cyclohexane which were assigned by Takahashi *et al.*[10] These are listed in Table 9. Measurements in the region from 200 cm^{-1} to 300 cm^{-1} were not reliable on account of the noise effect, so we considered that the weak absorptions at 220 cm^{-1} and 240 cm^{-1} corresponded to the normal mode of cyclohexane at 248 cm^{-1} which is of doubly degenerated skeletal vibration. Taking 1.54, 1.09, 1.43 and 0.96 Å for the *C–C*, *C–H*, *O–C* and *O–H* bond distances respectively and 109° for both of

C-C-X (*X-H*, *C* or *O*) and *C-O-H* bond angles, one obtaines 3.63×10^{-113} g^3cm^6 for the product of three principal moments of inertia. This value is for the chair form with mean value of those for the axial (polar) and the equatorial conformations. The energy difference between the axial and the equatori-

al conformers was reported by Masschelein[11] as 1.57 ±0.21 kJ/mol from the temperature dependence of the intensity of infrared absorptions. The mixing entropy of both conformers was calculated by using this value. The value of this entropy amount is, however, somewhat ambiguous, since the result of our reinvestigation on the intensity of infrared absorption at low temperatures shows a little difference from that measured by Masschelein*4 (Fig. 3). Here, we have employed the value of the energy differences in the crystalline state in place of that in the gaseous state. As the mixing entropy is not so sensitive to the change of this value as far as the energy difference is smaller than RT, the error due to this ambiguity may be small. The entropy of internal rotation of *OH* group is left unknown and this value was determined so that the third-law entropy coincided with the statistical one. As shown in Table 10, it was found to be 6.9±2.9 J/(mol degK). Assuming the three-fold symmetry for hindering potential, the barrier height for internal rotation was then determined as 7.0 kJ/mol using the Pitzer and Gwinn table.[12] The value seems to be reasonable compared with those obtained for some aliphatic alcohols, *i.e.*, 3.3 kJ/mol for ethanol and 4.5 kJ/mol for methanol. These results constitute reasonably a third-law verification

11) W. Masschelein, *ibid.*, **10**, 161 (1961).

*4 Masschelein calculated the energy difference from the temperature dependence of the intensity of the bands at 1070 cm^{-1} and 970 cm^{-1} which were estimated to be those of the C–O stretching vibration of equatorial and axial forms, respectively. These absorption bands in the spectra of his measurement, however, did not show any such a splitting observed by us.

12) K. S. Pitzer and W. Gwinn, *J. Chem. Phys.*, **10**, 428 (1942).

Table 12. The difference of entropy of the supercooled crystal-I at 0°K and the crystal-I at 265.51°K

Temp.(°K)	Contribution	ΔS(J/mol degK)
0—13.75	Debye extrapolation	2.28±0.12

		171.4 ±1.0

* Calculated from Eqs. (1) and (2).

of the crystal-II. That is, we can safely conclude that the residual entropy of crystal-II is equal to zero.

Residual Entropies of Respective Phases. Calculations of the differences of entropies between that of the crystal-I at 265.51°K and those of the supercooled crystal-I, the crystal-II and the crystal-III at 0°K are shown in Table 11, 7 and 12, respectively. Since the supercooled crystal-I is unstable between 160 and 240°K, the heat capacity in this temperature region in Table 12 was calculated by using the following interpolation equations [unit; J/(mol degK)]:

$$C_p = 75.421 + 0.29368\mathrm{T} \quad (160—217°\mathrm{K}) \qquad (1)$$

and

$$C_p = 47.340 + 0.42290\mathrm{T} \quad (217—240°\mathrm{K}) \qquad (2)$$

These equations are derived based on our data and Kelley's value at 217°K and the error in determining the entropy is estimated to be ±0.5 J/(mol degK) in this temperature range. The contributions below 14°K were determined by using the Debye functions taking 102.3° and 127.6° for the Θ_D of the supercooled crystal-I and the crystal-III respectively. Comparison of Table 10, 6 and 11 shows that the residual entropy of the supercooled crystal-I amounts to 4.72±1.6 J/(mol degK) and that of the crystal-III −0.23±1.3 J/(mol degK). Accordingly, we may conclude that the crystal-III has actually no residual entropy. It may be noted that the crystal-III is in internal equilibrium notwithstanding that it is a metastable phase.

Finally based on the above data, the thermodynamic functions are calculated and these are listed in Table 13. Gibbs energies relationship of respective phases are shown in Fig. 4.

Discussion

Frozen-in State. What kind of degree of freedom would be involved in the relaxation process of the supercooled crystal-I is an interesting problem. In the ordinary glassy substances, they are usually

represented by a kind of quasi-particle "hole"[13,14] conventionally. Because the crystal-I has positional order (face-centered cubic),[15,16] the degree of freedom frozen in the glass transition of this crystal are expected as follows:

(a) Orientation of overall molecule,
(b) Number of the hydrogen bonds in the crystal,
(c) Orientation of *OH* group around a *C–O* bond,
(d) Tautomerism between the axial and the equatorial forms,
(e) Number of the defect.

We shall first discuss the contributions from the intramolecular terms (c) and (d). If it is assumed that the energy difference between the axial and the equatorial forms at T_g is equal to the value which

was reported by Masschelein and that this degree of freedom is frozen at T_g, the contribution of the mixing entropy of these tautomers to the residual entropy amounts to 4.5 J/(mol degK). This value seems to be large compared with the residual entropy (4.7 J/(mol degK)) and it may be considered that the energy difference will increase at low temperature. Focussing our attention to the intensity of the absorption of bands at 1070 cm^{-1} and at 970 cm^{-1} whose intensities had been studied by Masschelein, we reinvestigated the infra-red spectrum of supercooled crystal-I at low temperatures. The results are given in Fig. 3, where is also shown the temperature dependence of the *OH* stretching band. Masschelein assigned the bands at 1070 cm^{-1} and at 970 cm^{-1} to *C–O* stretching vibration of the equatorial and the axial forms, assuming these bands were single. However both of them are apparently composed of a pair of bands respectively and the individual bands of each pair show remarkable temperature dependence. Since it is very difficult to separate accurately the piled bands in two parts, we did not analyze the intensities of these bands quantitatively. From the fact that the bands do not change between 150°K and 80°K, it may be concluded that the degree of freedom of the tautomerism is frozen below T_g.

As to the contribution to the residual entropy of the orientation of the *OH* group for the rotation around a *C–O* bond, it should be also small. The quantitative discussion about it is, however, difficult at the present stage of our knowledge. If one attributes the residual entropy only to these intra molecular degrees of freedom ((c) and (d)), the jump of the heat capacity at T_g can not be explained, because these degrees of freedom offer the Schottky

heat capacity which is very small compared with the actual jump of the heat capacity at T_g.

We discuss now about the effects of (a) and (b). Meakins[17] and Corfield and Davies[18] have studied the dielectric dispersion of the crystal-I and also of supercooled one. Comparing with the results of cyclohexanone and chlorocyclohexane,*5 they concluded that the chains of hydrogen bonds are formed in this cyclohexanol crystal. If one extraporated the $\log(f_{max})$ *vs.* $1/T$ plots to low-temperature, the $1/f_{max}$ becomes from 1 sec to 1 hr at T_g, where the f_{max} indicated the frequency of maximum dispersion. Although these behaviors are also known in the ordinary glassy materials, this result shows that the orientation of the overall molecule is frozen at T_g. The careful examination of the possibility of the point defects in this crystal, as well as other plastic crystals by Staveley *et al.*,[19] has given no definite conclusion about the numbers of defects in these crystals. Accordingly, the role of the defects to the glass transition are still in question. In conclusion, we may only say that the residual entropy of the supercooled crystal-I may arise from frozen-in state partly of reorientational, and partly of conformational freedoms of the molecule in the lattice. The supercooled crystal-I below T_g is considered as a kind of new state of aggregation of pure material in the sense that the crystalline material has glass transition point and we should like to propose a term **glassy crystal** to this phase.

Debye Temperature. Debye temperatures of the supercooled crystal-I and the crystal-II are shown in Fig. 5. These calculations are based on the method of Wulff.[20] In Fig. 5, (1) and (2) are obtained by assuming 6 degrees of freedom. Debye temperatures due to 3 degrees of translational freedom are plotted in (3) and (4), where 3 degrees of torsional freedom are represented by a kind of Einstein function, whose average frequency is determined by a trial and error method. The lowering of the Debye temperature of the supercooled crystal-I above 90°K shows the existence of some configurational degrees of freedom which contribute to the heat capacity. Recently, Green and Scheie[21] determined the Debye temperature of the crystal-I between −40°C and 20°C from the study of the velocity of ultrasonic wave in the crystal. The result agrees fairly well with that of present low-temperature study. They have also reported that the velocity of ultrasonic wave in the crystal-III is larger than that in the crystal-II. This result is consistent with

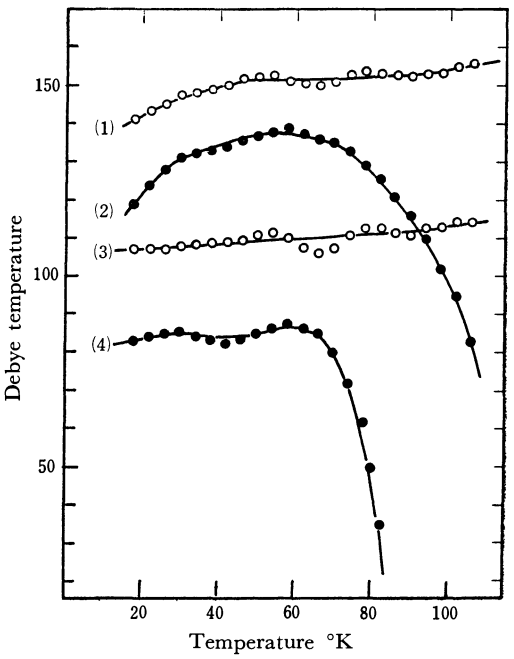

Fig. 5. Debye temperature of the supercooled crystal-I and the crystal-II.

present result that the heat capacity of the crystal-III is smaller than that of the crystal-II.

Relaxation Phenomenon of the Supercooled Crystal-I. We have investigated the relaxation phenomena of the supercooled crystal-I below T_g with annealing treatment under different conditions. Figure 6 shows the contribution to the enthalpy from the degrees of freedom of configurations and conformations; in other words, the contributions from the intermolecular potential energy and intramolecular one. We call these terms conventionally configurational enthalpy. The experimental procedure for obtaining the configurational enthalpy $\Delta H_{conf.}$ is as follows: for instance, the difference of the total enthalpy between 155°K and 141°K is experimentally determined from the adiabatically supplied electric energies which is necessary to raise the temperature of the supercooled crystal-I from 141°K to 155°K. The increment of the kinetic energy and the energy of expansion due to the lattice vibration and internal vibration between 141°K and 155°K is calculated from the estimated heat capacity of vibrations that is represented by the following equation,

$$C_p \text{ (vib.)} = 22.81 + 0.41256T \text{ (J/mol degK)}. \quad (3)$$

This equation was determined so that the Debye

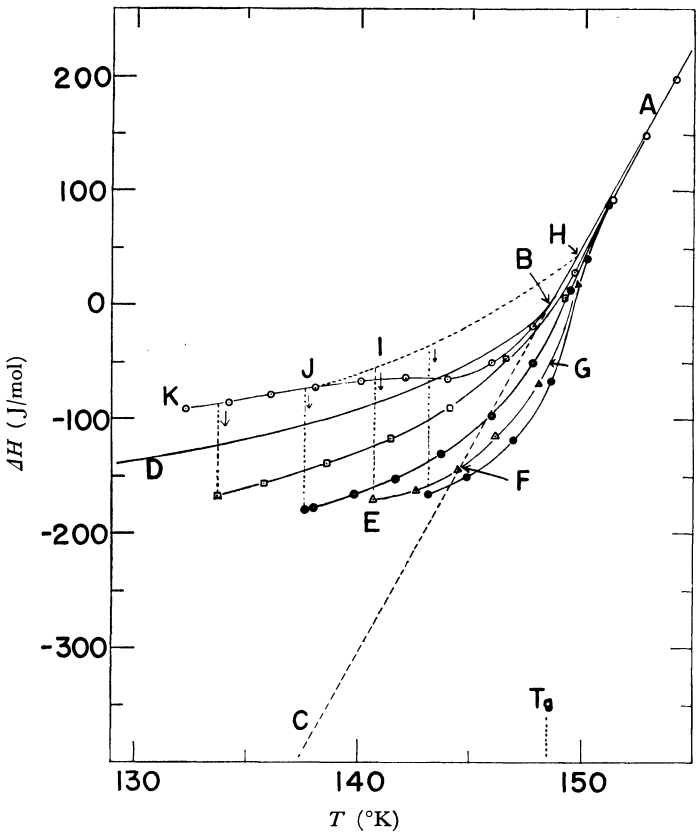

Fig. 6. Configurational enthalpy *vs.* temperature curves.

temperature calculated from above equation maintained nearly the same value as one at 90°K. The difference of the configurational enthalpy $\Delta H_{\text{conf.}}$ is determined by subtracting the increment of the kinetic energy from the total increment of enthalpy. Since the details about the origin of the anomalous heat capacity (C_p(obs)—C_p(vib)) is not known, it has some uncertainty whether this anomalous heat capacity is completely attributed to the degree of freedom of the configuration. Instead of this method, the $\Delta H_{\text{conf.}}$ is also calculable by the integration of the (C_p(obs)—C_p(vib)). In Fig. 6, curve A–B–C shows the estimated equilibrium curve assuming that the equilibrium heat capacity below T_g is represented by Eq. (1). A–B–D is obtained from the experimental heat capacity data (Table 1). In the measurement of the heat capacity of the supercooled crystal-I below T_g, the anomalous temperature drift due to the stabilization is treated as if the drift were arisen from thermal leakages.*6 This procedure below T_g provides the heat capacity eliminating the effect of relaxation. In other words, this heat capacity corresponds to the value for infinitely rapid measurement. If one takes this effect into consideration, the heat capacity curve shows a hump at T_g as shown by the data of Ôtsubo *et al.*, in Fig. 2. Accordingly, A–B–D shows the enthalpy changes for infinitely rapid heating. Other curves were determined from electric energy supplied under adiabatic condition. K–J–B–A shows the enthalpy increment when heated with the rate of about 1.5°K/hr as soon as cooled down to 130°K with the cooling rate of −6°K/min. The dotted line H–I–K is estimated curve for the cooling rate of −6°K/min. Annealing experiments were made at 144°K, 141°K, 137°K and 133°K for 25 hr, respectively, after cooling to these temperatures with cooling rate of −6°K/min from the liquid state at 300°K. For example, the enthalpy at 141°K changes from I to E in 25 hr and then traces the curve E–F–G upon heating. Assuming the exponential decay of enthalpy during the annealing period, the time constants (in hours) were calculated and summarized in Table 14. Here, it is assumed that the enthalpy at time zero lies on the curve A–H–I–J–K and on the curve A–B–C after infinite time. The Arrhenius plot of log τ against $1/T$ deviated from a straight line as shown in Fig. 7. The activation

*6 See Ref. 7.

energy calculated from the nearly straight portion of this curve is of 28.8 kJ/mol. As is well known, the relaxation time of dielectric or viscoelastic relaxation of supercooled liquid near T_g deviates from Arrhenius equation and is represented by the equation $\tau = \tau_0 \exp(E/(T-T_2))$, where T_2 is the temperature at which the relaxation time becomes infinite. But in these experiments, the deviation of the plot in Fig. 7 from the Arrhenius equation is the inverse to the deviation of the type of above equation. The origin of this result is apparently considered to be experimental error due to the incompleteness of adiabatic condition. But as shown in Fig. 7, the extent of this

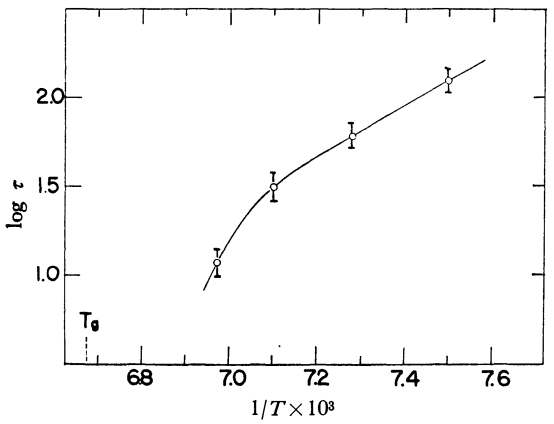

Fig. 7. $\log \tau$ *vs.* $1/T$ curve.
In this figure, $\overset{\top}{\underset{\perp}{\circ}}$ shows the limit of the experimentanl error due to incompleteness of adiabatic condition.

error is too small to change the behavior of the result. Another origin may be the ambiguity of the estimation of equilibrium curve (A–B–C). Assumption of exponential decay is also considered to be the possible source of the result. But if this result is accurate, it is seemingly explained by assuming the co-existence of different relaxation processes having respective characteristic time constants. The observed temperature drifts due to the stabilization also support this assumption. In general, the frozen-in state whose enthalpy is larger than that of equilibrium state should show the exothermic stabilization. Accordingly, behaviors of stabilization at all the points which are above the equilibrium curve (A–B–C) in Fig. 6 should be exothermic. But in this experiments, all the annealed specimen, *i.e.* at the points of ⊡, ◎, ● and ◬ in Fig. 6 showed net endothermic stabilization. This fact can be explained as follows: Although some degrees of freedom are frozen-in in this state, some other degrees of freedom which have shorter time-constant are already in equilibrium. So, when the temperature is raised up, the endothermic relaxation due to the degree of freedom having shorter relaxation time contributes largely to the stabilization.

T_2-Temperature. Gibbs and Adam[22] proposed a theory to solve the so-called Kauzmann's paradox[23] and the existence of a temperature denoted by T_2 where the relaxation time becomes infinite and the configurational entropy would vanish only if one supercooled a liquid infinitely slowly. Assuming that the heat capacity of the equilibrium state of glassy state corresponds to the extraporation of the heat capacity above T_g (Eq. (1)), we determined T_2 of the supercooled crystal-I to be 128°K. It is known that the ratio of T_g and T_2 of ordinary glassy substance is about 1.3, whereas the value amounts to 1.18 in this crystal.

Summary

(1) The heat capacities of cyclohexanol have been determined from 14°K to 320°K. The temperatures and the heats of transitions and of fusion for respective modifications were determined and the following results were obtained: *i.e.*, 265.50°K and 8827 J/mol for the phase transition of crystal-II—I, 244.8°K and 8638 J/mol for crystal-III—I and 299.05°K and 1782 J/mol for crystal-I—liquid.

(2) Comparing the entropy of ideal gas state calculated from thermal data with that from statistical-mechanical method, we have estimated that the residual entropy of the crystal-II is equal to zero and that the potential barrier of the internal rotation of *OH* group amounts to about 7.0 kJ/mol.

(3) Based on the estimation that the crystal-II has no residual entropy, the residual entropies of the supercooled crystal-I and of the crystal-III were determined. The residual entropy of the supercooled crystal-I amounted to 4.72 J/(mol degK) whereas that of the crystal-III was found to be zero within the experimental error.

(4) The Gibbs energies of the supercooled crystal-I, the crystal-II and of the crystal-III were calculated. From these results as well as that of the residual entropy, we can conclude that the crystal-III is of metastable but in the internal equilibrium state.

(5) It was confirmed that the anomalous jump of the heat capacity of the supercooled crystal-I at T_g ($\approx$150°K) arises from relaxation phenomena and the time constants in the relaxation process in enthalpy were determined.

(6) The origin of the residual entropy of the supercooled crystal-I was discussed and we proposed a new term **glassy crystal** for a crystalline material having glass transition temperature.

(7) Debye temperatures for the crystal-I and the crystal-II, and T_2 temperature were determined.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1088—1090 (1968)

Microwave Spectrum of *o*-Difluorobenzene*[1]

Aritada HATTA, Chiaki HIROSE and Kunio KOZIMA

Laboratory of Chemical Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 9, 1967)

The microwave spectrum of *o*-difluorobenzene has been studied in the 7.8- to 28-Gc/sec region, R- and Q-branch transitions of the a-type being assigned for the lowest vibrational state. The rotational constants obtained are $A=3263.55$ Mc/sec, $B=2227.91$ Mc/sec, and $C=1323.87$ Mc/sec. Four possible sets of structural parameters were obtained. It seems probable that the angle made by two C–F bonds is larger than 60°. The value of the dipole moment obtained is 2.46 ± 0.03 D.

An electron diffraction investigation[1] has established that the molecule of *o*-dibromobenzene is planar or nearly planar, that the angle made by two C–Br bonds is larger than 60°, and that the opening of this angle may be due to the repulsive force between the bromine atoms. However, no such opening of the angle has been reported in the study of the microwave spectrum of *o*-fluorochlorobenzene.[2]

The present study was undertaken in the hope of determining the structure of *o*-difluorobenzene in detail, especially the angle made by two C–F bonds.[2]*

Experimental

The spectrum was measured over the frequency range from 7800 to 22600 Mc/sec with a conventional Stark-modulation microwave spectrometer, employing 110-kc/sec square-wave modulation. All measurements were made at room temperature. The frequencies were measured by comparison with a frequency standard which was monitored against the standard signals from Station JJY. The spectrum was displayed on an oscilloscope and, for weak absorptions, on a recorder.

o-Difluorobenzene was prepared from commercial *o*-fluoroaniline by the method of Schiemann and Pillarsky.[3]

Results and Discussion

Assignments of the spectrum were difficult because of the richness of the spectrum. Qualitative Stark patterns of the observed transitions were very helpful in identification. Since the C_2 axis coincides with the a-axis, only a-type transitions were observed.

The B and C rotational constants were calculated from the $1_{10}\rightarrow2_{11}$ and the $2_{21}\rightarrow3_{22}$ transitions, which occur at frequencies of $(3B+C)$ and $(3B+3C)$ respectively. The A constant was calculated from the observed Q-branch transitions. It is estimated that the A, B, and C rotational constants are accurate to ±0.015 Mc/sec. The rotational constants thus obtained agree with those of Nygaard *et al.* Since we used lower J-transitions in our determination than they did, the effect due to centrifugal distortion will be disregarded.

The measured frequencies and the assignments in the ground state are listed in Table 1, together with deviations between the measured frequencies and those calculated by the use of the rigid-rotor rotational constants given in Table 2. The agreement shown in Table 1 is such that it can be said that centrifugal distortion is not an important effect in the transitions studied. The transition frequencies and the rotational constants in terms of the geometrical parameters of the molecule were all calculated on a FACOM 222 digital computer.

The principal moments of inertia derived from the rotational constants are listed in Table 2. As is shown in Table 2, the inertia defect is 0.049 amu. Å^2 The small value of the inertia defect is strongly indicative of the planar configuration.

Since the molecule is planar, only two of these moments of inertia are independent. Therefore, a number of assumptions or approximations are required in order to extract any structural information. First of all, it may safely be assumed that the symmetry of the molecule is C_{2v}. Even if we assume that all the C–C bonds and all the C–H bonds are of equal length, and that the C–F bonds and the C–H bonds are located along the C–C–C angle bisectors,

* Conversion factor: 5.05375×10^5, corresponding to $^{12}C=12$ atomic weight scale.

we find that there are still four undetermined structural parameters. In addition, if we assume that the valency angle of carbon, ∠C–C–C, is 120°, three structural parameters, *i.e.*, the C–C distance, r_{C-C}, the C–H distance, r_{C-H}, and the C–F distance, r_{C-F}, remain to be determined. On these assumptions, however, we could not obtain any set of reasonable parameters to fit the observed moments of inertia.

Therefore, by assuming the values of the three bond lengths to be those reported by Kökeritz and Selén,[2] the valency angle α, ∠C–C–C, of the carbon atom to which the fluorine atom attaches and the angle, θ, made by two C–F bonds were determined. The parameters thus obtained are shown in Table 3 as set I. For the II, III, and IV sets, the values of r_{C-F} and α were determined by assuming that the C–F bond is located along the bisector of α, that the value of r_{C-C} is one of those reported previously,[2,4-6]

TABLE 3. STRUCTURAL PARAMETERS OF *o*-$C_6H_4F_2$

	Set I	Set II	Set III	Set IV
r_{C-C}	1.397*	1.395*	1.397*	1.402*Å
r_{C-H}	1.084*	1.084*	1.084*	1.084*Å

θ	60°22′	60°40′**	60°44′**	60°53′**

α: The valency angle of the carbon, ∠C–C–C, to which the F atom attaches.
θ: The angle made by two C–F bonds.
* Assumed by taking into account the data reported in Refs. 2, 4, 5, and 6.
** For these cases the C–F bonds are assumed to be along the bisectors of α.

and that the value of r_{C-H} is 1.084 Å. The parameters obtained are shown in Table 3 as the II, III, and IV sets.

The evaluation of $\partial R_j/\partial X_j$ was very useful in estimating the structural parameters, where R_j represents the jth rotational constant of the assumed structure and X_i is the ith structural parameter. All of the sets of the structural parameters were determined so as to get agreement between the calculated and observed values for the moments of inertia of I_a and I_b.

TABLE 4. STARK COEFFICIENTS AND DIPOLE MOMENT OF *o*-$C_6H_4F_2$

Transition		$\Delta\nu/E^2$(Mc/sec)/(V/cm)²×10⁵ observed	calculated
$1_{10} \rightarrow 2_{11}$	$M=0$	4.7±0.1	4.7
	$M=1$	−37.7±0.8	−38.0

$\mu=2.46\pm0.03$D

4) B. Bak, D. Christensen, L. Hansen-Nygaard and E. Tannenbaum, *J. Chem. Phys.*, **26**, 134 (1957); R. L. Poynter, *ibid.*, **39**, 1962 (1963).
5) E. Rosenthal and B. P. Dailey, *ibid.*, **43**, 2093 (1965).
6) H. Forest and B. P. Dailey, *ibid.*, **45**, 1736 (1966).

It is probable that the angle made by two C–F bonds is larger than 60°, inasmuch as the values of r_{C-C}, r_{C-F}, and r_{C-H} are not very different from those previously reported.

Stark effect coefficients were measured for the $M=0$ and 1 components of the $1_{10}\rightarrow 2_{11}$ transition. The data are shown in Table 4. The cell was calibrated using the $J=0\rightarrow 1$ transition of OCS, taking the dipole moment of OCS to be 0.7124 D.[7] The value of the dipole moment obtained is 2.46 ± 0.03 D. This value is in agreement with that of 2.38 D obtained by a solution method,[8] and slightly different from that of 2.59 ± 0.02 D obtained by Nygaard *et al.*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1090—1096 (1968)

Radicals Produced by UV Irradiation of Acridan and Acridine in Glassy and Crystalline Medium at 77°K

Shigeya NIIZUMA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received November 9, 1967)

Choosing two groups of solvent a) methanol, ethanol, isopropanol (glassy at liquid nitrogen temperature) and b) *t*-butanol, benzene, tetrahydrofuran (crystalline at liquid nitrogen temperature), ESR studies have been made on the irradiated solutions of A] acridine (A)+acridan (AH_2) (1 : 1), B] A alone, and C] AH_2 alone at 77°K. 1) 365 mμ irradiation of A] and B] in the solvents of a) group does not cause any photochemical reaction, whereas in the solvents of b) group, the $A^* + AH_2 \rightarrow 2AH\cdot$ reaction occurs. A resultant singlet ESR line has been assigned to AH·. 2) Irradiation of A] and C] with the entire output from a superhigh pressure mercury lamp gives, for solvents of group a), the ESR spectra which can be attributed mainly to alcohol radicals ($R\dot{C}HOH$) but gives electronic absorption spectra ascribed only to AH· ; for the solvents of group b) the results were almost the same as in 1).

In a series of papers dealing with the kinetics of the photoreduction of acridine, the participation of semi-reduced acridine, AH·, appears to be fully substantiated.[1-4] In particular, there is scarcely any doubt about the assignment of a transient species observed in flash experiments as AH·[1,4] in view of spectroscopic and kinetic evidence. However, the direct evidence for its radical nature is still lacking. ESR studies, although most promising for detecting a radical species, cannot be applied to the similar systems as employed in the kinetic studies, because the lifetime of AH· is too short. Hence, various attempts have been made to catch the ESR signal of AH· at liquid nitrogen temperature. At first, three kinds of alcohol, in which appreciable photoreduction of acridine occurs at room temperature, have been used as solvents. Irradiation by 365 mμ of the solutions of acridine and acridan as well as of acridine alone, has failed to give any sign of reaction. Irradiation of the solution of acridan by the total output from a superhigh pressure mercury lamp has given a certain species light brown in color, which is rather stable at liquid nitrogen temperature. The electronic spectra of this species agree with the ones in the flash experiment[1] and yet, the ESR spectra consist of the lines mainly originating from alcohol molecules.

Secondly, a group of solvents (benzene, *t*-butanol and tetrahydrofuran) which is known to take the crystalline form at liquid nitrogen temperature has been attempted with some success. It has been found that after dissolving acridine and acridan in these solvents at room temperature and irradiation with 365 mμ at liquid nitrogen temperature, the samples become colored in light brown and give ESR signals which are practically common to three solvents and are most likely attributed to AH·. The same signals as well as the same tint of color have been obtained with the samples containing only acridan on irradiation with a total output from a mercury lamp. We believe that most of the findings

obtained in the present investigation, are interesting from the standpoint of the reactivity of acridine and of acridan in general and of the sensitized decomposition of alcohols, not to speak of the confirmation of ESR spectra from AH·.

Experimental

ESR Spectrometer. A Nippon-Denshi P-10 type-ESR spectrometer was used.

Light Source. Light from a superhigh prssure mercury lamp (500 W and 100 W) was used without or with filters (in the latter case mainly 365 mμ but including 334 mμ).

Sample. *Benzene, Methanol and Isopropanol.* G. R. samples from Wako Junyaku were used without further purification.

Ethanol and t-Butanol. Reagents from Wako Junyaku were submitted to distillation. Tetrahydrofuran was distilled after refluxing over sodium. The solvent was kept over sodium and potassium metals. The concentrations of acridine and acridan were usually 10^{-2}—10^{-3} M. When the mixture of acridine and acridan was used, the composition was always 1 : 1.

Results

A) Glassy Medium. After having established that 365 mμ irradiation of the solution of acridine or of the solution of acridan and acridine in ethanol, methanol and isopropanol, did not cause any reaction, the samples were irradiated with the total output from a mercury lamp without filters. Since the results obtained are essentially the same as those in the solutions of acridan alone, both of them will be described here at the same place. It was checked that the irradiation of the solvents alone gives no appreciable signals under the similar conditions.

Methanol. A typical example for the deaerated solution is shown in Fig. 1. The radicals produced are quite stable at this temperature, the shape of the signal showing no change 1.5 hr after irradiation. In the presence of oxygen, the central three lines become somewhat unsymmetric. Three central lines (triplet) and the other two lines outside (doublet) are assigned to two different species, because the dependence on irradiation time of these two groups are different. Table 1 gives the relative height of the peak neighboring a central one and of the outermost peak, in reference to the height of the central peak. Figure 2 and 3 give respectively the build-up curves of the doublet and of the triplet. S-shape character for the former indicates that the doublet

is produced not primarily but in the secondary reaction. Comparing the present results with the ones reported in the literature,[5-7] the triplet and the doublet may be assigned to methanol radical, $\cdot CH_2OH$ and formyl radical $H\dot{C}O$, respectively. The signal intensity of triplet is proportional to the light intensity, as is clear from Fig. 2. Therefore the main reaction is a one-photon process.

Ethanol. Figure 4 gives one example of the variation of the ESR spectra with the time of irradiation. Broadly speaking, the spectra consist of five lines which are due to $CH_3\dot{C}HOH$. The continued irradiation causes a slight but obvious change; an

additional line appears and becomes gradually larger in between the central and the next line. The height of the peaks at the initial stage is 1 : 2 : 4 : 2 : 1. ESR spectra labeled by d are the ones when c was kept in the dark for 50 min. It is seen that the two lines existing in the later stage have almost disappeared. In spite of this structural change, the integrated intensity remains the same within ±5%. At this stage, the height of the peaks is approximately in the ratio 1 : 3 : 5 : 3 : 1. It has been established that the signal intensity is proportional to the light intensity. A signal obtained in the aerated sample is unsymmetrical from the initial stage of irradiation (Fig. 5a); when it is kept in the dark for 30 min, it turns into a peroxide-like signal (Fig. 5b). The formation of peroxide is reasonable, but it is not certain whether the spectra are due to peroxide radical or $C_2H_5O\cdot$.[8,9] It is remarkable that 4 min irradiation of the deaerated solution dissolving 1×10^{-3} M of acridan produces $\sim2\times10^{-3}$ M of radical (at the stage of about half saturation).

Isopropanol. In the absence of oxygen, the signal at the initial stage of irradiation consists of septet attributable to $(CH_3)_2\dot{C}OH$[5,6] and small additional bands which decay very gradually in the dark. Figure 6 gives one example. The integrated intensity decreases about several percent in 1.5 hr.

Electronic Spectra for Alcoholic Solutions. In the ESR spectra the signals to be ascribed to AH· are lacking or very insignificant, but all the solutions, after having been irradiated, become light brown and show blue emission with a long duration suggesting the existence of AH··. Preliminary measurement of the absorption spectra has been attempted. Since the results are essentially the same for three alcohols, they will be described all together. Absorption spectra of the ethanol solution of acridine and acridan (both in 2.5×10^{-4}M) before irradiation are shown in Fig. 7. The spectra in methanol and isopropanol are quite similar. A large and broad peak around 280 mμ belongs to acridan. Other peaks are due to acridine. Figures 8 and 9 are the absorption spectra of the above solution after 30 min irradiation with the total output from a superhigh pressure mercury lamp at liquid nitrogen temperature. It is seen that the acridan absorption near 280 mμ has completely disappeared. A very sharp band near 280 mμ and the new bands appearing at 520—522 mμ and around 485 mμ agree with the bands which were assigned to AH· in the flash studies.[1,4] A remarkable change in the spectral shape in the region from 345—365 mμ indicates that AH· has an appreciable absorption in this region. It is worth while to add that a small peak near 570 mμ was lacking in the previous flash experiment where the solution of acridine in ethanol was used. Since the above changes are essentially

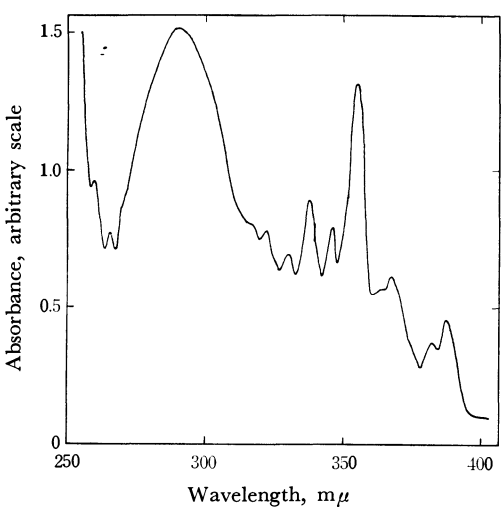

Fig. 7. UV absorption spectrum of deaerated acridine and acridan (both 0.25×10^{-3}mol/l) in ethanol at 77°K, before irradiation. It has no absorption in the visible region.

common to methanol and isopropanol solutions, they are all interpreted to be concerned with acridan. Various radicals originating from alcohols which have been amply confirmed by ESR spectra, give no appreciable absorption from 250 to 600 mμ. When the irradiated solution was warmed up to room temperature and cooled again to 77°K, it gave essentially the same spectra as the ones of the non-irradiated solutions. This implies that acridine does not participate in the eventual reaction and that most of the half-reduced acridine in a fluid state, reconverts to either acridan or diacridan (The latter has the absorption spectra not differing so much from those of acridan.). It was checked that the 365 mμ irradiation of the above samples and the solutions of acridine alone for more than an hour, does not give any change in the absorption spectra.

B) Crystalline Medium. Benzene, *t*-butanol and THF are the solvents which have crystalline state at liquid nitrogen temperature. When the samples containing acridine and acridan in 1 : 1, were irradiated by 365 mμ at 77°K, they were colored in light brown and gave a prominent single ESR line. ΔH_{msl} values were 16.7, 17.5 and 22 for benzene *t*-butanol and THF, respectively. There is scarcely any doubt that these signals arise from the interaction of excited acridine and acridan, although there is some possibility of the participation of solvent molecules, because weak side bands depend upon the solvent used. Irradiation by a total emission from a mercury lamp gave essentially the same result. This may be due partly to the high intensity of 365 mμ of a light source. Of course it was checked that no signal was detected in the cases of solvents alone.

○ Signal in the deareated condition
× No signal in the deaerated condition
◎ Signal in the aerated condition
⚹ No signal in the aerated condition

When THF and *t*-butanol containing acridan alone were irradiated by a mercury lamp without filters, they gave the similar signal as the above systems. In a very sharp contrast to *t*-butanol and THF, acridan solution of benzene did not give any ESR spectra.

t-Butanol. Figure 10 gives the ESR spectra obtained by irradiating with 365 mμ the deaerated solution of acridine and acridan. In the aerated system, the relative height of the central peak was somewhat low.

Benzene. As Fig. 11 shows, ESR spectra have four weak side bands in addition to a main line with $\Delta H_{msl}=16.7$ and $g=2.003$. The decay of the main line was measured at -95, -57 and -27°C. It increases with the rise of temperature, but the signal can be observed even near 0°C.

Tetrahydrofuran. Figure 12 gives the ESR spectra obtained by irradiating (without filters) the system of acridine and acridan in THF. In addition to a main single line, a broad absorption and a doublet 508 gauss apart, which is due to hydrogen atom, are apparently observed. Table 2 gives a brief summary of the present ESR studies.

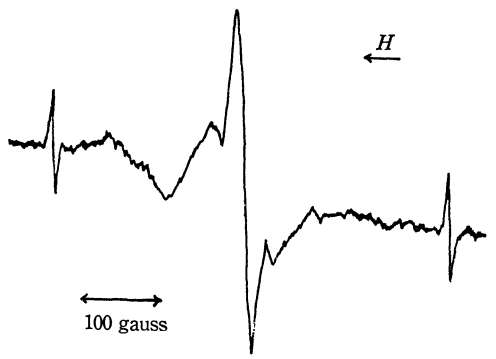

Fig. 12. ESR signal obtained by irradiating aerated acridine and acridan in tetrahydrofuran at 77°K with 365 mμ of mercury lamp.

It is to be noted that the results in glassy media and crystalline media are quite distinctive.

Discussion

It is well-known that acridine is photoreduced in various kinds of H-containing solvents in the fluid state. The reactive states of acridine, according to Kellmann *et al.*,[10] Porter *et al.*[11] as well as to our group,[12] are mainly singlet excited state and partly n-π^* triplet state, the lifetimes of which are respectively $\sim 10^{-10}$ and $\sim 10^{-8}$sec. Furthermore, we have established that part of the reaction goes *via* molecular mechanism without forming semiquinone,[1,12] and that acridine and acridan react photochemically (by 365 mμ) forming diacridan in benzene, the reactive state in this case being the lowest π-π^* triplet of acridine.[3,4]

In view of these results it is somewhat remarkable that no photochemical reaction (by 365 mμ) occurs at all in B) a) group at liquid nitrogen temperature. The reason may be that for the reaction to occur, reorientation of solvent molecules surrounding an excited acridine molecule is necessary and that at liquid nitrogen temperature such reorientation is impossible during the lifetime of the excited states. In the case of acridine and acridan, A) a) group, the two solute molecules are separated by solvent molecules so far apart that no reaction can occur. In crystalline medium on the other hand, acridine and acridan molecules (A) b) group) deposited from the medium, may be close to one another and in such a relative orientation to allow the reaction $A^*+AH_2 \rightarrow 2AH$ to occur. It is very natural that benzene and *t*-butanol with no easily detachable hydrogen, do not easily react with AH·. Thus the main ESR spectra are due to AH· (singlet).

Turning to the cases of irradiation without filters, the formation of AH· in alcohols, as verified by the electronic spectra, is due to the $AH_2 \rightarrow AH\cdot + H\cdot$ reaction. The produced hydrogen atom is expected to react with alcohol molecules, for instance according to $H\cdot + C_2H_5OH \rightarrow H_2 + CH_3\dot{C}HOH\cdot$. AH· is thought to be quite stable even photochemically, because the intensity of the electronic spectra, after reaching the saturation value, does not decrease by the continued irradiation. Thus the results from the electronic spectra implies that at liquid nitrogen temperature, AH· does not react thermally nor photochemically with any other radicals originating from alcohol or with alcohol molecules themselves. This leads to the expectation that in ESR the singlet line due to AH· should superpose on the signals of the radicals originating from alcohol molecules. It is difficult, however, to verify this unambiguously from the present data. There is also another problem, as to the quantity of radicals produced. If the production of all the radicals are initiated by such reactions, $AH_2 \rightarrow AH\cdot + H\cdot$, $H\cdot + C_2H_5OH \rightarrow CH_3\dot{C}HOH + H_2$, the finding that the quantity of the total radicals exceeds that of the original acridan even at a stage of half saturation, is difficult to understand. It seems necessary to consider that the formation of more than two radicals from one radical is occurring in secondary processes. Reactions such as $\dot{C}H_2OH \xrightarrow{h\nu} CH_2O + H\cdot \rightarrow \dot{C}HO + H\cdot + H\cdot$ which Sullivan *et al.*[13] suggested in the case of methanol, might be occuring. In the case of crystalline medium

containing only acridan Reaction, $AH_2 \rightarrow AH\cdot + H\cdot$ occurs in *t*-butanol and tetrahydrofuran just as in the case of alcohols but the reaction of atomic hydrogen with solvent molecules is not so significant as with alcohol molecules. Detection of a signal of atomic hydrogen in tetrahydrofuran also supports this conclusion. The absence of the reaction in benzene may be due to easy occurrence of the back reaction.

As to the radical species produced in the alcoholic solutions of acridan, there is no doubt that most of them are of the RC(OH)R′ type. There appears to be many problems about the secondary reactions that follow, which however, are out of the scope of the present aim. Our greatest concern is how the existent AH· radicals are affecting the observed ESR spectra. But the exact and quantitative answer to this problem also awaits further studies.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1096—1104 (1968)

Infrared Spectra of Crystalline $CHCl_3$ and $CDCl_3$

Arata KIMOTO and Haruka YAMADA

Department of Chemistry, Kwansei Gakuin University, Nishinomiya

(Received November 9, 1967)

The infrared spectra for the fundamental absorption bands, ν_1, ν_2, ν_4 and ν_5, of $CHCl_3$ and $CDCl_3$ have been measured in polycrystalline films. For the C–H or C–D bending band a triplet has been observed in the pure crystal. The spectra of a mixed crystal ($CHCl_3$: $CDCl_3$) have also been studied over the entire concentration range. The space group of crystalline chloroform has been determined to be D_{2h}^{16}. The intensity of the band changes, going from the gas to the solid, depending on the symmetry species to which the vibrational mode belongs ; the A_1 bands increase in intensity, while the E bands decrease. The C–H stretching band shows an especially remarkable increase.

Recently the infrared spectra of chloroform in the solid state have been reported on by several investigators.[1-3] The crystal spectra observed so far, however, do not always agree with one another. For instance, a triplet was found for the C–H bending band by Lisitsa and Tsiashchenko,[1] while a doublet was found by Maklakov, Nikitin and Purkina[2] and by Denariez.[3] We have here studied carefully the infrared spectra of crystalline chloroform and deutero-chloroform, and obtained the definite spectra for the stable, well-annealed phase.

A qualitative analysis of crystalline spectra generally establishes only the site group of the molecule, but it can sometimes make possible the unique determination of the space group. In the present work, the spectra are also measured for the $CHCl_3$: $CDCl_3$ mixed crystals at various concentrations ; this is done to clarify the mechanism of the band splittings. The splittings observed in the crystal field can make it possible to determine the space group, when used in connection with the results of X-ray diffraction and the Raman spectra.

On the other hand, considerable attention has been paid to the infrared intensities in condensed phases.[4-11] The absolute intensities have already been measured for a number of simple molecules in the solid state. These studies attempted to compare the intensities in the solid state with those in the gaseous state. Large intensity changes are observed in benzene and ethylene, especially for the C–H stretching bands, while the intensity changes in carbon disulfide and carbon tetrachloride are relatively small and are interpreted as " ideal field effects." However, the observed intensity changes are not yet fully understood. The intensity behavior observed in chloroform may be useful in making theoretical progress on this problem, as our preliminary data[12] suggested.

Experimental

Extra pure chloroform (Wako Pure Chemical Industries Ltd.) was washed with water in order to remove any alcohol present as a preservative. It was then dried over calcium chloride and distilled (bp 61.0—61.5°C). Deuterated chloroform was obtained from the Showa Denko, Ltd.; the purity stated was 99.8%. In the infrared spectrum of $CDCl_3$ some weak bands of $CHCl_3$ were discerned, from which the amount of $CHCl_3$ was estimated to be less than 0.7%. Commercial, extra-pure CS_2 and CCl_4 were used as solvents.

The technique for obtaining the spectrum has been described in the literature.[4-7] The sample in the gas phase was sprayed through a needle valve (VLV-II, Shinsei Sangyo Ltd.) onto a KRS-5 window, which was kept at the temperature of liquid nitrogen in a cold, glassy cell. Although the present study has been mostly concerned with sprayed samples, sample film was also made by cooling the liquid in a cold, metallic cell with KRS-5 windows. The temperature of the sample was determined to be 100°K in both of cases by use of a copper-constantan thermocouple.

The sample film was annealed as follows: after the sample film had been prepared at 100°K, it was gradually warmed 40 degrees and then again cooled down to 100°K. This process was repeated until the spectrum no longer showed any change. The spectrum varied with the deposition rate of the sample. The spectrum of the sample without annealing was slowly transformed to that of well-annealed film. That is, the slower the deposition, the better-annealed the film was obtained. The deposition rate, controlled by opening the needle valve, was 4—6 min per μ of thickness. The film thickness was measured from the interference fringes observed at 2.5 μ. The spectra of well-annealed films prepared by the two different methods coincided completely with each other. In order to detect any preferred orientation of the film, spectra were also measured in polarized light. No appreciable changes in the spectra were found, however.

The spectra were obtained using a Jasco DS-402G spectrometer in the 400—4000 cm^{-1} region. The spectral slitwidths were 0.7—1.0 cm^{-1} for ν_1, 0.8 cm^{-1} for ν_4, and 0.6—1.4 cm^{-1} for ν_2 and ν_5.

The index of refraction of the sample film was estimated to be $n^{100°K}=1.61$ for both $CHCl_3$ and $CDCl_3$; estimation was made from the Lorenz-Lorentz equation using the following values: [13]

$n_D^{288°K}=1.448$, $d^{288°K}=1.498$, $d^{100°K}=1.93$

for $CHCl_3$ and

$n_D^{293°K}=1.445$, $d^{293°K}=1.500$ and $d^{100°K}=1.95$

for $CDCl_3$.

The integrated absorption intensity was obtained from the curve of the absorbance *vs* the wave number, according to:

$$B = (\rho l)^{-1}\int \ln(T_0/T)d\nu \qquad (1)$$

where the concentration, ρ, was calculated to be 16.2 mol/*l* from the densities for both $CHCl_3$ and $CDCl_3$. Intensities in solutions were measured using a 0.1 mm cell with KRS-5 windows.

For the measurement of mixed crystals, the vapor of mixtures of $CHCl_3$ with $CDCl_3$ were deposited onto the cold substrate; the films deposited were also annealed. The ($CHCl_3/CDCl_3$) ratios were assumed to be equal to those in the liquid.

Results and Discussion

Figures 1 and 2 show the four fundamentals observed for crystalline $CHCl_3$ and $CDCl_3$. The dotted lines represent the curves of unannealed samples, and the solid lines, those of well-annealed samples. After annealing, the ν_1 and ν_2 bands belonging to A_1

species shift to the low-frequency side, while the ν_4 and ν_5 bands belonging to E species split into three components. Three peaks are clearly resolved in the ν_4, C–H bending band. The ν_1 and ν_2 bands are slightly asymmetric, suggesting that there are additional peaks on the low-frequency sides. The observed frequencies at the band peaks are listed in Tables 1 and 2.

In order to ascertain why the spectra obtained for the unannealed samples differed considerably from those for the well-annealed samples, a differential thermal analysis of $CHCl_3$ has been undertaken. No thermal anomaly, however, was detected over the 300—390°K temperature range, with the exception of that at the melting point, 209°K. This means that solid $CHCl_3$ does not show any phase transition. This is consistent with the results of the pure quadrupole resonance study by Gutowsky and McCall.[14] The spectra obtained for the unannealed samples, therefore, are those of the metastable or amorphous form, partly mixed with those of the stable form.

The C–H and C–D bending bands, ν_4(E), in the mixed crystals ($CHCl_3$: $CDCl_3$) are shown in Figs. 3

and 4 at various concentrations. Figure 5 shows the frequencies of the absorption maxima in both the ν_4-$CHCl_3$ and ν_4-$CDCl_3$ regions for the mixtures of $CHCl_3$ and $CDCl_3$. In the mixed crystal four peaks are observed for the ν_4 bands. As the concentration of $CHCl_3$ decreases, the two inner peaks increase in intensity, while the two outer peaks decrease. When $CHCl_3$ was considerably diluted with $CDCl_3$ (97.4%), the two outer peaks disappeared and a complete doublet at 1213.8 and 1220.0 cm^{-1} was observed. The spacing of the two inner peaks remains almost constant at 6—8 cm^{-1}, independent of the concentration. Let us now designate the four peaks as ν_4^1, ν_4^2, ν_4^3, and ν_4^4 respectively, from high to low frequencies. Then ν_4^2 and ν_4^3 can be assigned to the components split by the site group or by removing the degeneracy in the crystal field, and ν_4^1, ν_4^3 and ν_4^4 in the pure $CHCl_3$ or $CDCl_3$, to the components split by the factor group. One of the factor group components overlaps with ν_4^3, the site group component. The four peaks observed in the mixed crystal, therefore, may be interpreted as a superposition of the components split by the site group upon those split by the factor group at various rates. The C–D bending band behaves in the same way as the C–H bending band, but its splitting is relatively small.

Fig. 3. Spectra in ν_4-$CHCl_3$ region for mixture of $CHCl_3$ and $CDCl_3$.

Although the spectra of the $CHCl_3$: $CDCl_3$ mixed crystal have already been reported by Maklakov *et al.*[2] and by Denariez,[3] their sets of results coincide with neither each other nor the present spectra. Maklakov *et al.*, observing a singlet at a very dilute solid solution, concluded that a factor-group splitting is predominant in crystalline $CHCl_3$. On the contrary, Denariez observed a doublet at the concentration of 1%, indicating that a site-group splitting is rather predominant. These differences may be caused by the use of unannealed or incompletely annealed films. In many cases, the crystal splittings observed are not in harmony with those theoretically predicted, even for simple molecules, because the

natural abundance of isotopic molecules and sometimes the Fermi resonance[15] complicate the crystal spectra or because the magnitudes of the band splittings are small. However, the C–H bending band of $CHCl_3$ is not affected by these influences. Here it is a typical example for the site- and factor-group splittings.

The structure of crystalline chloroform may be inferred from the results of group theoretical analysis.[16] In the mixed crystal of $CHCl_3$ diluted by $CDCl_3$, the A_1 bands remain single, while the E bands split into two components. On the other hand, in the pure crystal the A_1 bands probably split into two components (if we count the asymmetric tail as a peak), while the E bands split clearly into three components. The unit-cell groups which explain these splitting are C_{2v}, D_{2h}, C_{3v}, *etc.* (20 altogether), all with the C_s-site symmetry. Referring to the Raman spectrum of crystalline $CHCl_3$,[17] we note that none of the peak frequencies of the infrared spectrum coincide with those of the Raman spectrum. This suggests that there exists a mutual exclusion between the infrared and Raman spectra, namely, the inversion symmetry in the unit-cell group.

An X-ray diffraction study of the chloroform single crystal has been made in our university,[18] and the possible space group has been found to be either C_{2v}^9 or D_{2h}^{16} with four molecules per unit-cell. While we were making this X-ray study, Fourme and Renaud[19] reported the crystal structure independently, giving the same space group. From the vibrational spectra described above, we can easily discard the possibility of C_{2v}^9 with the C_1 site symmetry. Consequently, the space group of crystalline $CHCl_3$ must be D_{2h}^{16} with the C_s site symmetry. The correlation diagram is shown in Fig. 6.

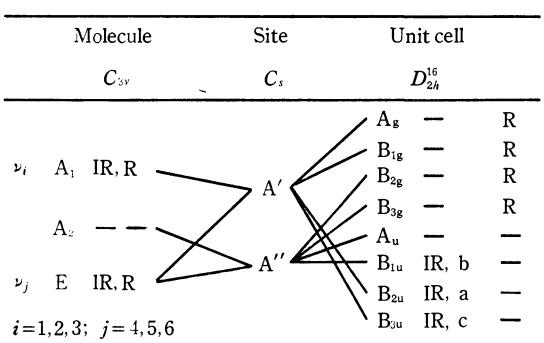

Fig. 6. Correlation diagram for crystalline $CHCl_3$.

17) M. Ito, *ibid.*, **40**, 3128 (1964). In this article only two components have been reported for the E species. In later works three components have been observed (private communication).

18) Y. Tomiie *et al.*; The cell dimension is determined to be a=7.14, b=9.80 and c=5.84 Å, Z=4.

Returning to Figs. 3 and 4 for the C–H and C–D bending vibration, ν_4, $\nu_4{}^4$ should be assigned to the B_{1u} component, since it is the strongest among the three peaks in the pure crystal. $\nu_4{}^1$ and $\nu_4{}^3$ are assigned to B_{3u} and B_{2u}, respectively or *vice versa*. $\nu_4{}^4$ is almost equal in intensity to the sum of $\nu_4{}^1$ and $\nu_4{}^3$. Thus, $\nu_4{}^1$, $\nu_4{}^3$ and $\nu_4{}^4$ correspond to the c, a, and b (or to be a, c, and b)-axis components of the crystal respectively, and the C–H bond of $CHCl_3$ lies on the ac plane. Taking the angle between the C–H bond and the a axis θ, the infrared intensities of B_{2u} (a) and B_{3u} (c) components are related as:

$$I(B_{2u})/I(B_{3u}) = \tan^2\theta,$$

if the oriented gas model can be assumed. The observed intensity ratio gives $\theta = 25°$. The parameters for the $CHCl_3$ crystal reported by Fourme and Renaud lead to a value of 14° for this angle. Notwithstanding the ambiguity in separating each component of the ν_4 band and the assumption of the oriented gas model, these are in good agreement. Assuming the molecular orientation shown in Fig. 7,[19] we may expect the B_{3u} (c) component of the A_1 band, as well as the B_{2u} (a) component of the E band, to be very weak. This may be the reason why the splittings of A_1 bands are not resolved clearly in the pure crystal.

The crystal structure of $CDCl_3$ is considered isomorphous to that of $CHCl_3$, since the same trends in band splittings are observed.

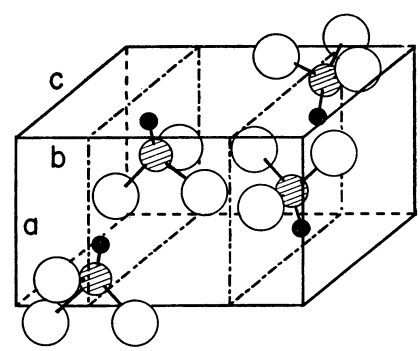

Fig. 7. Molecular orientation in the crystal. (After the structure given by Fourme and Renaud.)

As has been mentioned above, the band splittings may be well interpreted as the factor group for the pure crystals and as the site group for the dilutely-mixed crystals, in accordance with the crystal structure. It is of great interest for us what kind of forces give rise to such splittings of the bands; in other words, what kind of intermolecular potentials contribute to the splittings. As has been indicated by

19) R. Fourme and M. Renaud, *Compt. rend.*, **263B**, 69 (1966); The parameter for H atom z/c=0.7200 should be corrected to be 0.0720 (private communication).

Hexter[20] and Dows,[21] when the dipole-dipole interaction potential is predominant, the isotopic relation governing any particular factor group holds:

$$\frac{\Delta\nu_H}{\Delta\nu_D} = \frac{\nu_D}{\nu_H}\frac{I_H}{I_D} \qquad (2)$$

Here, $\Delta\nu$ represents the magnitude of band splitting, ν, the wavenumber, and I, the intensity of the band. $CHCl_3$ and $CDCl_3$ are denoted by the suffixes H and D respectively. Examining this formula for the ν_4 band, we must take $|\nu(B_{2u})-\nu(B_{3u})|$ as $\Delta\nu_H$ or $\Delta\nu_D$ for the factor-group splitting. The observed values are $\Delta\nu_H=15\ cm^{-1}$ and $\Delta\nu_D=9\ cm^{-1}$. Then, the left side in Eq. (2) gives 1.7, while the right side gives a quite different value, 0.23, using the gas-phase intensities. Even though we substitute I_H and I_D for the solid intensities, the right side still gives the same value. This suggests that some potential other than the dipole-dipole potential plays an important role in the splitting of the ν_4 band. Presumably atom-atom potentials, H···Cl interactions, contribute to the coupling of the ν_4 vibration, which is similar to the vibrations which arise primarily from hydrogen motions, of methylchloride[21,22] and ethylene.[23] On the other hand, the $\nu_5(E)$ of the C–Cl stretching vibration may split due to the dipole-dipole coupling, much as does the ν_3 of methyl chloride,[20-22] because the intensity of this band is extremely large. Detailed calculations of the splittings will be published elsewhere.

The absolute intensities of the fundamental bands in the crystals are given in Tables 3 and 4, while the intensities between different phases are compared in Tables 5 and 6. The maximum error involved in the intensity measurements is 15% for the solids. Lambert's law plots of $B\rho l$ *vs.* l are shown in Fig. 8. As for the solid intensities of $CHCl_3$, Lisitsa *et al.*[1] early reported values for the polycrystalline films

obtained by cooling the liquid. Their values, shown in Table 3, are quite small, being only about 15% of the present values. As has been previously discussed for crystalline benzene,[24] measurement by cooling the liquid makes for considerable errors in determining the intensity, because the assumption that the product, ρl, of the concentration and the path length remains constant as it was frozen from the liquid to the solid will be in error.

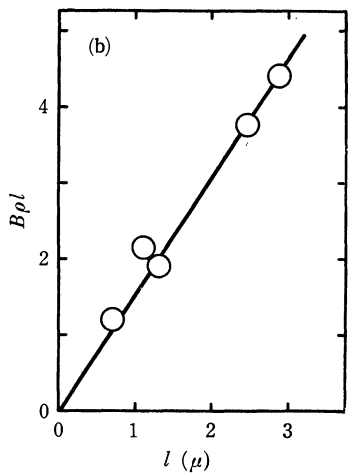

Fig. 8. (b) Lambert's law plots for ν_2 of crystalline $CDCl_3$.

For $CHCl_3$, the ν_1 and ν_2 bands increase in intensity going from the gas to the solid, while the ν_4 and ν_5 bands decrease. As may be seen from the Table 5, these trends can be roughly seen to be in order from the gas to the solution and to the solid. The increase in intensity for the ν_1 band of $CHCl_3$, going from the gas to the solid, is remarkable. However, most of this increase is observed when it goes from the gas to the solution. Some of the authors[25] who measured the intensity of the ν_1 band in dilute solutions (in CCl_4 and CS_2) attributed it to the effect of molecular association, similar to hydrogen bonding, though this point is not clear.

An interesting phenomenon has been reported that for this ν_1 vibration, the first overtone is much stronger in intensity than the fundamental band, suggesting an abnormal weakness of the fundamental ν_1 in the gas phase.[26]

In the crystal the interatomic distances between an H atom and its nearest Cl atoms are calculated from previously-reported data[19] to be as follows: molecule whose central carbon lies on the same C_s plane as the H atom), 3.12 Å for H···Cl (for a Cl atom of another molecule whose central carbon also lies in the same C_s plane), and larger than 3.7 Å for all others. Comparing these values with the van der Waals distance, 3.00 Å, for H···Cl, it seems that the hydrogen is surrounded by the three Cl atoms and that no special H···Cl linkage is formed. It is doubtful, therefore, that the observed intensity changes are due to any special association of the molecules.

At any rate, it is worth noting that the bands belonging to A_1 species of the molecule increase in intensity, while the bands belonging to E species decrease, going from the gas to the solid. That is, the intensity varies depending on the symmetry species of the vibrational mode. Since the molecular axis of chloroform coincides with the short axis of the molecular ellipsoid, the field effects predict that the intensity will increase for the A_1 modes and decrease for the E modes. Thus, the qualitative trends observed are the same as those expected from the field effects, though the magnitudes of the observed changes are considerably larger than those predicted. If we compare the intensities of $CDCl_3$ between the solution and the solid, the A_1 bands increase in intensity from the solution to the solid, while the E bands remain unchanged or decrease. Similar trends are observed in $CHCl_3$.

The intensity behavior observed in chloroform is quite different from those observed in benzene[4] and ethylene.[5] It also differs from those observed in CCl_4[10] and CS_2[7] where the "ideal field effects" is concerned. As for the C–H stretching bands, the intensity increases in $CHCl_3$ as well as in acetylene,[6] while it decreases in benzene and ethylene. If we interpret this behavior in terms of the "delocalization moment," M_D,[10] M_D should have the same sign as that of the intrinsic moment or exceed the intrinsic moment greatly.

We wish to thank to Professor K. Suzuki for his useful discussions, especially concerning the metastable phase. Thanks are also due to Professor S. Seki for making available the facilities of Osaka

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1104—1109 (1968)

Electric Conductance and Density of Molten Salt Systems: $I_2 + SbI_3$, $SbBr_3 + SbI_3$, and $SbCl_3$

Kenji SAITO, Kazuhiko ICHIKAWA and Mitsuo SHIMOJI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 4, 1967)

Measurements of electric conductance as a function of temperature have been made for the pure liquids; I_2, $SbCl_3$, $SbBr_3$ and SbI_3, and the mixtures; I_2+SbI_3 and $SbBr_3+SbI_3$, from 100 to 250°C. Furthermore, measurements of density by a pycnometric method as a function of temperature have also been made for these mixtures, from 100 to 300°C. The conductivities of these liquids lie in the range from 5×10^{-4} to 1×10^{-5} ohm^{-1} cm^{-1}, and are about 10^{-4} times lower than those of alkali halide melts. In these poorly-conducting pure liquids, the molecules may be considered as constituting a solvent in which slightly dissociated ions are contained. The negative temperature coefficient of conductivity for iodine is in marked contrast to the antimony halide melts, and may be interpreted in terms of the ionic conduction and electron hopping mechanism rather than the metallic one.

A few measurements concerning the electric conductance of pure molten iodine and antimony halides (or group VA metals) have been reported so far,[1-4] and some discrepancies in experimental data have been found. Furthermore, no full datum has been obtained for the electric conductance of mixtures of these antimony halides. The present communication reports the experimental results of density measurements for I_2+SbI_3 and $SbBr_3+SbI_3$ solutions, and of conductivity measurements for I_2+SbI_3, $SbBr_3+SbI_3$ and $SbCl_3$. The measurement of the conductivity of I_2+SbI_3 was made in order to investigate the change in transport properties of an iodine melt due to the addition of antimony iodide. This system is in striking contrast to the molten antimony+antimony halide mixture reported in an earlier paper.[5]

Experimental

Materials. Guaranteed reagent-grade $SbBr_3$ and $SbCl_3$ were dried under vacuum to remove surface and some hydrated water. All samples (guaranteed reagent-grade I_2, SbI_3, $SbBr_3$ and $SbCl_3$) were purified once or twice by distillation or sublimation *in vacuo*.

Apparatus and Procedure. Conductivity measurements were made with a Jones bridge,[6] constructed of the grounding circuit and measuring one. Alternating current was detected by a " tuned " null detector. The pyrex conductance cell[5] previously described was used with some modification. In particular, the sample of $SbCl_3$, distilled twice *in vacuo*, was directly distilled into the conductance cell through an extension tube, in order to prevent an apparent conductivity due to traces of moisture, and the cell was then sealed off under vacuum. Good precision was obtained by adjusting a variable condenser (0.45—0.70 μF) connected in parallel with the standard resistor. A pyconometric method[7] was used to measure the densities of liquid I_2+SbI_3 and $SbBr_3+SbI_3$ mixtures as a function of temperature and composition. The height of the liquid column was measured with a cathetometer within ±0.005 cm. In order to prevent condensation on the stem wall above the liquid, the top of the stem, which was fitted with a heating coil,

was maintained at a temperature slightly higher (from 3 to 4°C) than the liquid temperature. The Archimedean method may be unsuitable because of the change in composition due to the appreciable vapour pressures of the samples of interest.

Results and Discussion

The specific conductance κ and the density d_t of I_2+SbI_3 and $SbBr_3+SbI_3$, and κ of $SbCl_3$ were measured over a temperature range from 100 to 350°C above their liquidus temperatures. The temperature dependence of conductivity for each system is shown in Figs. 1, 2 and 3. Table 1 shows the linear relations for the density of the mixtures I_2+SbI_3 and

and Jander and Weis.[8] Table 2 shows the temperature dependence of the molar conductance Λ (or the product $\Lambda=\kappa V$ of the specific conductance κ and molar volume V) as well as κ for the pure melts I_2, $SbCl_3$, $SbBr_3$ and SbI_3. The specific conductance may be represented by the exponential function,

$$\kappa = \exp\left(\frac{-B}{T-T_0} - CT + E\right) \qquad (1)$$

which is almost similar to the equation due to Yaffe and Artsdalen,[9] though another expression which is a quadratic function[10] of temperature has often been employed. Two parameters (C and T_0) and two constants (B and E) in Eq. (1) are given in Table 3.

(A) Conductivities for Pure Melts. In poorly-conducting melts; I_2, $SbCl_3$, $SbBr_3$ and SbI_3, the molecules may be considered as constituting a solvent medium in which slightly dissociated ions (often univalent ions) exist, and with which they are in dynamic equilibrium with respect to the process of ionization. According to Jander *et al.*,[2,3] the fused $SbCl_3$ and $SbBr_3$ are regarded as a "waterlike ionizing solvent" for a considerable number of organic and inorganic compounds, especially for covalent ones. These melts may therefore be expected to obey Walden's rule[11] ($\Lambda\eta$=constant, with η the viscosity) to the extent to which the conditions for Stokes' law[12] holds. An estimate of the degree of dissociation, α, of the electrolytes which obey Walden's rule is possible using Greenwood and Martin's equation,[13]

$$\alpha = \frac{\Lambda\eta}{100}. \qquad (2)$$

From the values (see Table 4) calculated from Eq. (2), it may be seen that these pure melts are slightly dissociated, by about 5×10^{-8} per cent.

Table 4. Degree of dissociation α of some molten salt, such as $SbCl_3$, $SbBr_3$ and I_2

Salt	t°C	$10^3\,\Lambda$ ohm^{-1} cm^2 mol^{-1}	η cp	$10^5\,\alpha$
$SbCl_3$	150	7.06	1.01	7.1
$SbBr_3$	150	5.05	1.20	6.1
I_2	150	0.747	1.80	1.3

$SbCl_3$: viscosity data[19]
$SbBr_3$: viscosity data[19]
I_2 : viscosity data[20]

i) I_2 (see Table 2 and Fig. 1). Published values[1] for the conductivity of pure liquid iodine range from 0.092 to 1.68×10^{-4} ohm^{-1}cm^{-1} at 140°C. As seen in Fig. 1, our conductivity data for pure liquid iodine are in good agreement with the data of Bearcroft and Nachtrieb[1] (their work was presented shortly after our measurements had been completed, and their measurements were limited to the temperature range of 139—146°C). However, there exist large discrepancies between the above data and those reported by Rabinowitsch,[1] and it is of interest that the values for the I_2+10 mol% SbI_3 system in our work are similar to those of the I_2 melt of Rabinowitsch at 121°C (see Fig. 1). It is found to have negative temperature coefficient, or $d\kappa/dT=-3.1\times10^{-8}$ ohm^{-1} cm^{-1} deg^{-1} (-4.3×10^{-8}, Bearcroft and Nachtrieb, and -2.2×10^{-7}, Rabinowitsch). It is uncertain whether the conduction phenomena may be interpreted (Rabinowitsch[1]) in terms of the metallic conduction mechanism only, in view of the negative temperature coefficient obtained for the conductivities. It is desirable to investigate other transport properties, such as the Hall effect. Riggleman and Drickamer[14] proposed that a discontinuity in the slope of the resistance-pressure curve at 235 K bar represented the beginning of metallic conduction for solid iodine. The decrease in interatomic distance due to high pressure may bring about the transition from ionic conduction to metallic conduction. On the other hand, another point of view is that electron hopping occurs, as well as ionic conduction. Liquid iodine may consist of a neutral species nI_2 with I^-_{2n-1} and I^+ ions, through the reaction (Bearcroft and Nachtrieb[1])

$$nI_2 \rightleftarrows I^+ + I^-_{2n-1} \qquad (3)$$

just as in aqueous solution. As shown in Table 4, the degree of dissociation α of liquid I_2 is small, about one fifth of that of the antimony halide melts. It is well known that the ionization constant in aqueous solutions of some weak electrolytes often has a maximum at a particular temperature; that is to say, the heat content change on the ionization of weak electrolytes is often negative at high temperatures.[15] Then, it is of interest to examine whether or not an analogous result is obtained in liquid iodine containing partially auto-dissociated ions. The temperature dependence of the number density n_j, given by $n_j \propto \exp(-\Delta H_j/2RT)$, can be calculated from Eq. (3) for the chemical reaction (particularly for $n=1$), and from Greenwood and Martin's Eq. (2). Figure 4 shows that the calculated heat content change on ionization ΔH_j is negative and nearly independent of temperature in this temperature range (about -5.7 kcal·mol^{-1}). For such a slightly dissociated molecular melt, the temperature dependence of the

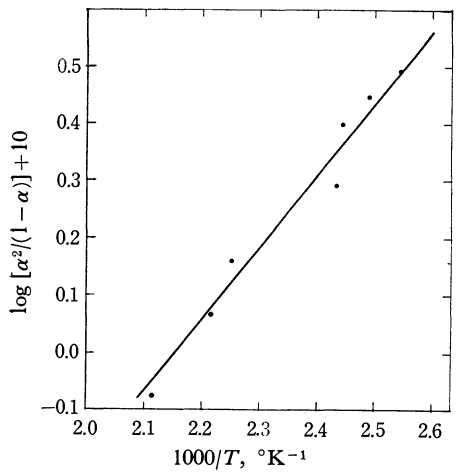

Fig. 4. Log $\alpha^2/(1-\alpha)$ as a function of reciprocal temperature for pure I_2 melt.

carrier concentration may be appreciable compared with that of the mobility due to ionic migration as well as electron hopping. For example, the negative temperature dependence for conductivities of HgI_2 have been interpreted in terms of such an ionic conduction mechanism.[16] Bearcroft and Nachtrieb[1] have recently proposed that I^- is transferred from I^-_{2n-1} ions to neighbouring I_2 molecules, and the mobility of I^- is large compared with that of I^+. It is to be noted that the surface self-diffusion coefficient D^* of species I^- for both mono- and multilayers of I_2 adsorbed on metals in the temperature range 145—235°C has an order of magnitude of 10^{-6} cm^2 sec^{-1} according to Arnikar and Mehta.[17] This charge transfer may also be interpreted in terms of the electron hopping mechanism proposed here.

ii) *$SbCl_3$* (see Table 2). According to previous papers,[2] the conductivity of pure $SbCl_3$ melt has been found to vary from 0.85×10^{-6} to 1.69×10^{-4} ohm^{-1} cm^{-1} immediately above the melting point, though it was not investigated as a function of temperature. Our experimental results (see Table 2), obtained as a function of temperature, lie in the midpoint of the above data. Jander and Swart[2] has proposed that electric conduction results from the self-dissociation reaction

$$SbCl_3 \rightleftarrows x SbCl_2^+ + x Cl^- \cdot (1-x)SbCl_3, \quad (4)$$

where $xCl^-\cdot(1-x)SbCl_3$ refers to xCl^- ion solvated by $(1-x)SbCl_3$ molecules. The observed conductivity κ is put equal to the sum of each conductivity. According to our formula for ionic conductivity,[5] the mobility μ_i of the ionic species i is

$$\mu_i \simeq (d_i^2 \nu_i Z_i e/kT)\exp[-B_i/(T-T_{0i}) - \Delta h_i/kT] \quad (5)$$

In view of the size and mass of each species contributing to the conductivity, the mobility of $SbCl_2^+$ may be much larger compared with that of $xCl^-(1-x)\cdot SbCl_3$. It seems that the conduudctivity κ may be nearly equal to $\kappa_{SbCl_2^+}$.

iii) *$SbBr_3$* (see Table 2). The specific conductance of molten $SbBr_3$ obtained in our investigation is smaller by about one tenth, compared with the data

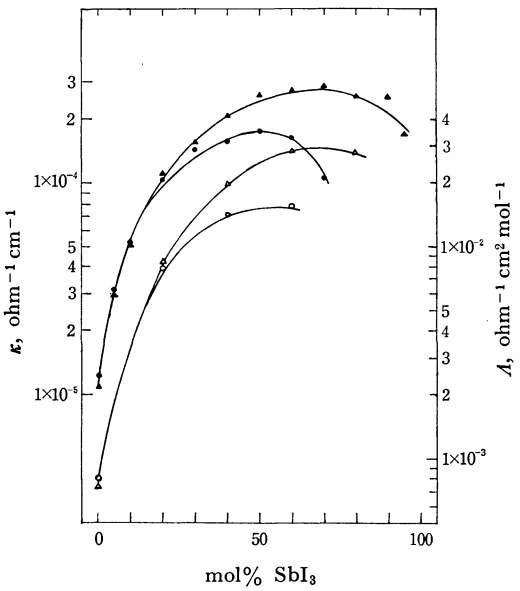

Fig. 5. Specific (● and ▲) and molar (○ and △) conductances of I_2+SbI_3 solutions (▲ and △ at 445°K, ● and ○ at 400).

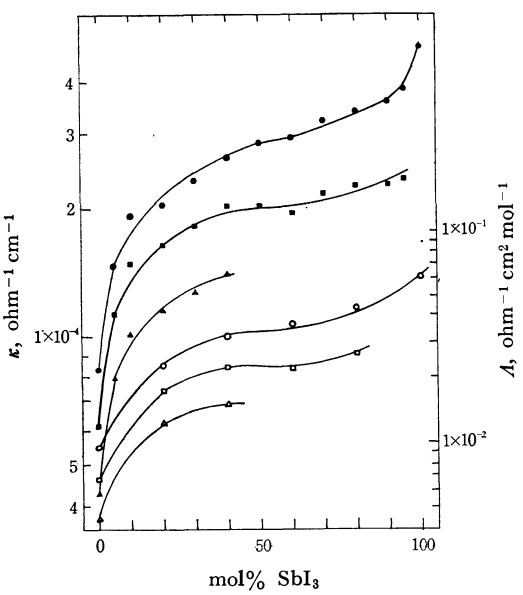

Fig. 6. Specific (●, ■ and ▲) and molar (○, □ and △) conductances of $SbBr_3+SbI_3$ solutions (● and ○ at 525°K, ■ and □ at 455, ▲ and △ at 400).

16) G. J. Janz and J. D. E. Mclutyre, *J. Electrochem. Soc.*, **109**, 842 (1962).
17) H. J. Arnikar and O. P. Mehta, *J. Phys. Chem. Solids*, **24**, 1633 (1963).

due to Hevesy,[3] in the range from 100 to 200°C. The values of κ due to Izbekow and Plotnikow,[3] and due to Jander and Weis[3] were respectively 2.25×10^{-5}, and 1.0×10^{-5} ohm^{-1}cm^{-1} at 100°C, though the temperature dependence of the conductivity was not observed by them. According to Jander and Weis,[3] slight dissociation should be considered, as for pure $SbCl_3$. Then, the species which contributes to the electric conduction may be chiefly $SbBr_2^+$, that is, $\kappa\simeq\kappa_{SbBr_2^+}$.

iv) *SbI_3* (see Table 2). The conductivities of molten SbI_3 are, within experimental accuracy, in agreement with those due to Hevesy.[4] The degree of self-dissociation in pure SbI_3 may be larger, by about ten times, relative to that for pure $SbCl_3$ or $SbBr_3$ in view of the difference between the conductivities of SbI_3, and those of $SbCl_3$ or $SbBr_3$.

(B) Conductivities for Mixtures of Molten Salts.

i) *I_2+SbI_3*. The composition variations in the specific and molar conductances Λ for I_2+SbI_3 are given in Fig. 5. It is of interest that the conductivities increase steeply within the region from 0 to 40 mol% SbI_3 as SbI_3 is added. This may be due to the dissociation of the dissolved SbI_3, as for aqueous electrolytes. With further increase in SbI_3 content, the value of κ has a weak maximum, and then falls monotonically.

ii) *$SbBr_3+SbI_3$*. The composition dependence of κ and Λ for $SbBr_3+SbI_3$ is shown in Fig. 6. The values of κ increase steeply over the range from 0 to 10 mol% SbI_3, because of the dissociation of SbI_3, as for the I_2+SbI_3 solution. With further increase in SbI_3 content, the value of κ increases monotonically.

For poorly-conducting melts, such as I_2+SbI_3, $SbBr_3+SbI_3$ and $SbCl_3$, which are only slightly dissociated, the degree of ionization is an important factor in analyzing the temperature dependence of the conductivities. Then the pre-exponential factor A_i, involved in Eq. (A11) in the previous paper due to Ichikawa and Shimoji,[5] should be regarded as the temperature dependent function since the value of A_i is proportional to the number density n_i of the ionic species i contributing to the conductivity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1109—1112 (1968)

A New Determination Method of Relative Rate Constants for Reactions with OH-radicals in Radiolysis of Aqueous Solutions*[1]

Makio MORITA and Masao FUJIMAKI

Department of Agricultural Chemistry, Faculty of Agriculture, The University of Tokyo, Hongo, Tokyo

(Received December 4, 1967)

Radioactivity of water increased linearly with dose when aqueous solution of ^{3}H-formate (2 μC_i/ml and 2×10^{-3} M) was irradiated with γ-rays in the presence of oxygen. The increase of the radioactivity was found to be reciprocally proportional to the non-labeled formate concentration where the amount of ^{3}H-formate was kept invariable. Addition of ferrocyanide and 2-propanol, effective OH-radicals scavengers, depressed the radioactivity increase to near zero. These facts show that the abstraction of tritium from ^{3}H-formate by OH-radicals causes the increase of the radioactivity of water. A competition method to measure relative rate constants for reactions with OH-radicals was deviced on the present results. Some values obtained by this method were in agreement with published data.

In measuring the relative rate constants for reactions with H atoms, Scholes and Simic[1] have established a competition method in the radiolysis of neutral aqueous systems using deuterioformate as a competitor. Formate undergoes the following reactions (1) and (2) by the attacks of H atoms and OH-radicals, respectively.

Hydrogen deuteride is evolved by the reaction (1) in this method and can be distinguished from the other source evolution of hydrogen.

$$HCO_2^- + H \xrightarrow{K_1} H_2 + CO_2^- \quad (1)$$

$$HCO_2^- + OH \xrightarrow{K_2} H_2O + CO_2^- \quad (2)$$

If tritiated formate ($^3HCO_2^-$) is used, H and OH attacks to formate will be indicated by formation of H^3H and H^3HO, respectively. Attempts were made to measure the rate constants for reactions with H and OH by using $^3HCO_2^-$ as a competitor, based

*1 This report was presented at the third Annual Meeting of Jap. Res. Assoc. Food Irradiation, Dec. 6th, 1967, as a part of "Radiation Chemistry of Foods, Part I."

1) G. Scholes and M. Simic, *J. Phys. Chem.*, **68**, 1738 (1964).

on detections of ^3H in H_2 and H_2O in the radiolysis of neutral aqueous solutions. The rate constants for reactions with OH could be readily measured in the presence of oxygen as a reducing species scavenger while those for reactions with H could not be obtained so readily as the former, because of much lower evolution of H^3H or much lower increase of radioactivity in the evolved hydrogen.

Experimental

The water used was triply distilled in a continuous Pyrex system (first from alkaline permanganate, second from acidic dichromate, and finally without any additive). Sodium ^3H-formate was supplied by the Radiochemical Centre (Amersham, England). Sodium formate, potassium ferrocyanide, sodium nitrite, potassium iodide, methanol, ethanol, 2-propanol, acetone, naphthalene, and dioxane (G. R. grade) were supplied by Kanto Chem. Co., Inc. (Tokyo) and were used as received. PPO (2,5-diphenyloxazole) and POPOP (1,4-bis-2-(5-phenyloxazolyl)-benzene) were Packard scintilater grade.

The stock solution of $^3HCO_2^-$ was 100 μCi/m*l* and 10^{-2} M, and was purified immediately prior to use as follows; to 2—5 m*l* of the stock solution was added 10—20 m*l* of water and the solution was lyophilyzed to dryness. This evaporation was repeated until the sublimed water showed desirably low radioactivity and the final residue of sodium formate was dissolved in water to make up the solution of the original concentration.

Solutions to be irradiated (2.5 m*l*, 20 μCi/m*l*, and 2×10^{-3} M formate) were made up of 0.5 m*l* of the stock solution and 2.0 m*l* water containing solutes tested. Irradiation of the solution was done in 5 m*l* Pyrex tubes (1.5 cm in outer diameter) fitted to standard taper joint covered with plastic film. Irradiation was carried out on ^{60}Co γ-ray source, the dose rate (2.4×10^{16} eV ml^{-1} min^{-1}) being determined by the Fricke dosimeter, taking $G(Fe^{III})=15.6$ and $\varepsilon_{(Fe^{III})}=2130$ at 305 mμ (22°C).

Prior to measuring radioactivity, water was sublimed under high vacuum from the irradiated solutions and condensed in dry ice-ethanol traps, and was passed through a small column (5—6 mm in diameter and 30—40 mm in length) packed with mixed ion exchangers (Amberlite IR 120-H and Dowex 2-OH, 1 : 1, completely dried at 100°C and stored in desiccator) at the top half and with charcoal (dried at 100°C) at the bottom half. A portion (0.1 m*l*) of the eluate from the column was mixed with 10 m*l* scintillator solution (7 g PPO, 0.3 g POPOP, and 100 g naphthalene in 1 *l* dioxane, 95 parts and water, 5 parts) and the radioactivity was determined on a liquid scintillation counter (Baird-Atomic, Inc., Liquid Scintillation Detector Model 845) at 0°C.

Results and Discussion

When the stock solution of $^3HCO^-_2$ was not purified, the count of the blank sample or the sample not irradiated was extremely high (47404 cpm/0.1 m*l*) as shown in Table 1, and if this sample were irradiated the count increase would not be, therefore, detectable. Three or four times repeated purifications described in the experimental section were required to lower the blank count to desirable level (1145 cpm/0.1 m*l*, after the four repeatings). However, after the purification, rapid increase of the blank count was observed with the lapse of time of the storage or the procedures.

Table 1. Effects of the purification and the pretreatment on blank count in the measurement of radioactivity (cpm/0.1 m*l*)

Repeating of sublimation	Sublimed water	Eluate from ion exchangers	Eluate from ion exchangers and charcoal
1	244358	128044	47404
4	63333	—	1037

This radiochemical impurities may occur from the decomposition of formate by β-radiation of tritium. The series of the procedures including the purification, γ-irradiation, and the measurement of the radioactivity was carried out within the short period of two or three days and the blank sample not irradiated was taken with irradiated one. It was necessary for the measurement of radioactivity to decrease the radioactivity not occurring from the irradiation to low level. For the sake, each of the three components of the pretreatment, sublimation of water, passage through ion exchangers, and passage through charcoal, was indispensable, since the former separated non-volatile materials to prevent the saturation of the latter two adsorbents, and the latter two decreased considerably the blank counts as shown in Table 1.

When the samples containing no additional solute were irradiated under the aerated condition with different doses, 1, 2/3, and $1/3\times7.2\times10^{17}$ eV ml^{-1}, a plot of count *vs.* dose made a straight line as shown in Fig. 1 and G (count-increase) was independent of dose. The linearity and the independent G (count-increase) suggested that the reaction concerning to the increase of count on irradiation was simple.

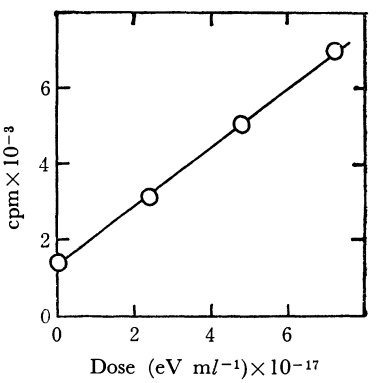

Fig. 1. Plot of count *vs.* dose.

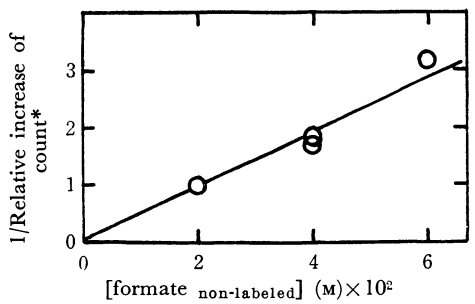

Fig. 2. Reciprocal proportion of count increase to the concentration of non-labeled formate.
* Count increase of the sample without additional non-labeled formate=1.00

Count decreased in reciprocal ratio with increase of the concentration of non-labeled formate, when the dose and the amount of $^3HCO_2^-$ were kept invariable, as shown in Fig. 2, in which 1/count-increase *vs.* [formate$_{non\text{-}labeled}$] was plotted. This reciprocal correlation implies that there is a simple competition between the reaction in which an active species removes tritium from $^3HCO_2^-$ to water and that in which the species is scavenged with non-labeled formate. When both $^3HCO_2^-$ and HCO_2^- are kept constant, the count increase may be, therefore, proportionate to the amount of the active species scavenged by non-labeled formate.

The count increase is probably caused by OH-radicals attack to $^3HCO_2^-$ as in the following reaction.

$$OH + {}^3HCO_2^- \rightarrow H^3HO + CO_2^- \qquad (2')$$

Count increase was effectively depressed to near zero by addition of ferrocyamide or 2-propanol of higher concentration (10^{-1} M) as shown in Table 2. They are known as effective scavengers for OH,[2-4] especially the former is a specific scavenger for OH. This depression of the count increase to near zero with ferrocyanide or 2-propanol may exclude the possibility that secondary species given by the reactions of reducing species, H and e^-_{aq}, with oxygen, HO_2, and O_2^-, contributed to the increase of count, because if these secondary species did so, ferrocyanide or 2-propanol should not reduce the count increase to near zero.

Table 2. Radioactivity in water from the irradiated solutions containing $^3HCO_2^-$

Exp. No.	Dose*	Solute added	(M)	Count	Count Increase (cpm/0.1 m*l*)
1	0	—		1465	—
1	1	—		6975	5510
1	1	$Fe(CN)_6^{4-}$	10^{-1}	1431	−34
2	0	—		1850	—
2	1	*i*-PrOH	10^{-1}	1817	−33

* 7.2×10^{17} eV ml^{-1}

Direct attack of e^-_{aq} to $^3HCO^-_2$ seems impossible under the aerated condition, since formate is known to be a poor scavenger for e^-_{aq}, while oxygen is much more effective one. It is calculated from the published datum[5] that the attack of H atoms to formate is decreased by oxygen under this experimental condition to about one tenth.

When 2-propanol was added to the solution in different concentrations, a plot of $\Delta count_0/\Delta count$ *vs.* [2-propanol]/[formate] is linear as shown in Fig. 3, where count increase is designated as Δ count, and Δ count$_0$ is that without 2-propanol added.
Assumption that the reaction (2) simply competes the reaction (3),

$$OH + (CH_3)_2CHOH \xrightarrow{K_3} (CH_3)_2\dot{C}OH + H_2O \qquad (3)$$

should lead to the following equation (i),

$$\frac{1}{G(\text{-formate})_{OH}} = \frac{1}{G(OH)}\left(1 + \frac{K_3}{K_2}\frac{[\text{2-propanol}]}{[\text{formate}]}\right) \qquad (i)$$

where $G(\text{-formate})_{OH}$ is $G(\text{-formate})$ by the attack of OH.

Moreover, assuming that the count increase is proportionate to the amount of degradation of non-labeled formate with OH, Eq. (i) should be modified as

$$\frac{1}{\Delta count} = \frac{1}{\Delta count_0}\left(1 + \frac{K_3[\text{2-propanol}]}{K_2[\text{formate}]}\right) \qquad (ii)$$

Table 3. Relative rate constants of some substances with OH-radicals

	this work	published data[4]
formate	1.00	1.00
2-propanol	4.5×10^{-1}	5.3×10^{-1}
ethanol[a]	5.3×10^{-1}	4.6×10^{-1}
methanol[b]	3.0×10^{-1}	2.7×10^{-1}
iodide[c]	3.8	3.6
nitrite[d]	3.0	1-5.2

a) ethanol=5×10^{-3} M and relative increase of count=0.430
b) methanol=8×10^{-3} M and relative increase of count=0.456
c) KI=8×10^{-4} M and relative increase of count=0.394
d) $NaNO_2=10^{-3}$ M and relative increase of count =0.397

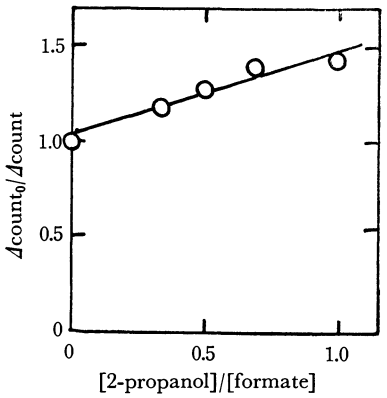

Fig. 3. Test of simple competition for OH radicals between formate and 2-propanol.

The slope of the straight line in Fig. 3 or the relative rate constant, $K=K_{(2\text{-propanol}+OH)}/K_{(\text{formate}+OH)}=0.45$, is in agreement with a published value, 0.53.[4]

The relative constants of ethanol, methanol, iodide, and nitrite were also calculated from data at each one concentration point and the listed in Table 3. They agree with published data, except the rate constant of nitrite, which has been reported as widely varied values, for the reactivity of nitrite to OH-radicals may markedly depend on pH.

In addition to the abstraction reaction (2′), an addition reaction of OH-radicals to $^3HCO_2^-$ may occur as in the reaction (4).

$$OH + {}^3HCO_2^- \rightarrow {}^3H(HO)\,C\langle^{O^-}_{O} \qquad (4)$$

When the other solute capable to scavenge OH is added to the system, the reaction (4) as well as (2′) will be depressed by simple competition for OH. Formation of H^3HO from the radical ion given by the reaction (4) will be, however, complicatedly influenced from the active species produced by the reactions concerning to the added solute. If the reaction (4) were not negligible in comparison with (2′), the total yield of H^3HO would not, therefore, obey simple competition rule in the presence of other solute. Results in Fig. 3 and Table 3 suggest that the reaction (4) may not, at least, be important, similarly as addition reaction in non-labeled formate may not be.[6-8]

The accuracy of this method is limited mainly by the error in the liquid scintillation counter measurement. The error seems to occur from the variation of counting efficiency by the incomplete stabilization of temperature. Consequently, the accuracy will be much more improved if the measurement is carried out on a counter set at more stabilized temperature.

We are indebted to Mr. Shinkichi Katsura for the operation of irradiation.

The Crystal and Molecular Structure of an Isomer of Bis-(1,2-diethoxycarbonyl-ethyl)tin Dibromide

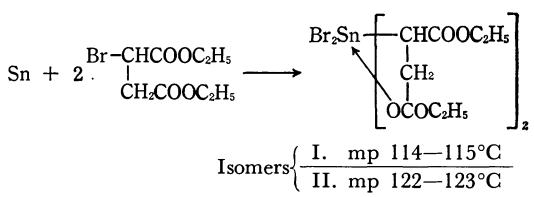
Mamoru YOSHIDA,*1 Tatzuo UEKI, Noritake YASUOKA, Nobutami KASAI,*2 Masao KAKUDO, Iwao OMAE, Shoichi KIKKAWA and Sumio MATSUDA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-Kami, Suita, Osaka

(Received December 4, 1967)

Low mp isomer of bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide (mp 114—115°C) crystallizes in a monoclinic form: $a=11.85$, $b=20.24$, $c=9.79$ Å, $\beta=101.3°$; space group, $P2_1/a$; and four molecules are contained in a unit cell. Crystal structure was established by the heavy atom method. The coordination about the tin atom is nearly octahedral. Two bromine atoms attached to the tin atom are in *cis*-positions. Two ligands, 1,2-diethoxycarbonyl-ethyl groups, are both bound to the tin atom by carbon and oxygen, forming five-membered rings. These rings are rather puckered, and one is in *d*-form and another in *l*-form.

Present authors (S. M., S. K., and I. O.) obtained bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide by the direct reaction between tin foil and diethyl bromosuccinate. From the reaction products they had two isomers isolated; their mp's being 114—115°C and 122—123°C respectively.[1)]



Isomers { I. mp 114—115°C / II. mp 122—123°C }

This paper describes the three-dimensional structure analysis of the isomer crystal I.

Experimental

The crystals were obtained by recrystallization from ethanol as colorless needles developed along the c axis. For the determination of the lattice parameters, oscillation and Weissenberg photographs were taken around the a, b, and c axes. Debye lines of aluminum were superposed on the Weissenberg photographs for calibration.

Layers 0 through 5 around the c axis were recorded by multi-film equi-inclination Weissenberg photographs with nickel-filtered Cu$K\alpha$ radiation. $0kl$ and $1kl$ reflections were also collected mainly for the use of the inter-layer scaling.

Intensities were estimated visually by using a calibrated standard scale. Lorentz and polarization corrections were carried out, but no absorption correction was made. 2109 non-zero reflections were finally obtained.

Crystal Data

Compound: Low mp isomer of Bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide, $Br_2SnC_{16}H_{22}O_8$
mp=114—115°C,
MW=620.9

Unit Cell: (Cu$K\alpha$ radiation, $\lambda=1.5418$ Å)
$a=11.85$ Å, $Z=4$
$b=20.24$ Å, $U=2302.5$ Å^3
$c=9.79$ Å, $D_m=1.80$ g·cm^{-3}
$\beta=101.3°$, $D_x=1.79$ g·cm^{-3}

Space Group: $P2_1/a$
(uniquely determined from the systematic absences of reflections)

Determination and Refinement of the Structure

Crystal structure was established by the heavy atom method. From a three-dimensional Patterson function approximate parameters of tin and two bromine atoms were obtained. Positions of all the light atoms except hydrogen were then found in the three-dimensional Fourier maps, with phases based on the heavy atoms. Successive block-diagonal least-squares refinement was carried out on a HITAC 5020E computer at the University of Tokyo. After three cycles of refinement for heavy atoms, Sn and Br's, the discrepancy factor $R=\sum||F_o|-|F_c||/\sum|F_o|$ was reduced to 0.154. In this refinement unit weight for all the reflections was assigned. Refinement was then made for all of the non-hydrogen atoms and the following weighting scheme was applied in the least-squares refinements hereafter: 1.0 for $|F_o|>0.1$ and 0.1 for $|F_o|\leqq 0.1$.

$R=0.116$ was obtained after 2 cycles. Anisotropic temperature factors were introduced at this stage, and three cycles of refinement gave the $R=0.098$.

Atomic and thermal parameters are listed in Table 1. In Table 2 listed are the observed and calculated structure factors.

Description of the Structure and Discussion

The molecular structure of the complex is shown in Fig. 1. The bond lengths and angles in the environment of tin atom are listed in Table 3. As seen in Fig. 1 and also in Table 3, the tin atom is coordinated by two bromine atoms in cis-positions as assumed before,[1] and also by two oxygen and two carbon atoms from 1,2-diethoxycarbonyl-ethyl groups. The coordination about the tin atom is a six-coordinated, distorted octahedron, and this may probably be the first structure of the six-coordinated organotin compounds analysed by means of X-ray diffraction.

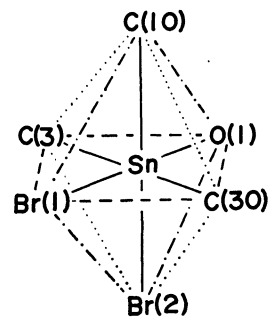
Sn-Br distances are 2.52 and 2.59 Å respectively, and these values are close to the sum of the covalent radii of tin and bromine atoms, 2.54 Å. The deviations may be due to distortion of the configuration from the regular octahedron (Table 3) and also to different contacts between bromine atoms and other atoms in the adjacent molecules.

Two equal Sn–C distances, 2.26 Å, seem to be slightly longer than the sum of the covalent radii, 2.17 Å, and also longer than that in SnH_3CH_3,[2] 2.15 Å, in which the tin atom takes an usual tetrahedral configuration.

As regards the Sn–O bonds, the distances 2.44 and 2.46 Å are much longer than the sum of covalent radii, 2.06 Å. These Sn–O distances may be the longest values hitherto reported, and this suggests that the Sn–O are weak coordination bonds.

Two ligands, 1,2-diethoxycarbonyl-ethyl groups, are bound to the tin atom by carbon and oxygen atoms, forming rather puckered five-membered rings. Each pair of corresponding atoms in two rings deviate from the least-squares planes in a similar way (Fig. 2). C(3) and C(30) show the largest deviations from the planes, 0.35 and 0.31 Å respectively. The three planes Br(1)–O(10)–O(1)–Br(2), Br(1)–C(3)–O(10)–C(30), and C(3)–Br(2)–C(30)–O(10), all centered with tin, make dihedral angles,

TABLE 3. BOND LENGTHS AND ANGLES IN THE ENVIRONMENT OF Sn



Br(1)-Sn-C(3)	100°	Sn-Br(1)	2.516 Å
O(1)-Sn-C(3)	72	Sn-Br(1)	2.588
O(1)-Sn-O(10)	78	Sn-O(1)	2.46
Br(1)-Sn-O(10)	93	Sn-O(10)	2.44
C(3)-Sn-O(10)	88	Sn-C(3)	2.26
C(30)-Sn-O(10)	72	Sn-C(30)	2.26
Br(1)-Sn-O(1)	168	Br(1)-Br(2)	3.88
C(3)-Sn-C(30)	148	-O(10)	3.61
O(10)-Sn-Br(2)	166	O(1)-Br(2)	3.61
Br(1)-Sn-C(30)	105	-O(10)	3.07
O(1)-Sn-C(30)	80	Br(1)-C(3)	3.65
O(1)-Sn-Br(2)	91	-C(30)	3.80
Br(1)-Sn-Br(2)	99	O(1)-C(3)	2.79
C(3)-Sn-Br(2)	97	-C(30)	3.03
C(30)-Sn-Br(2)	98	C(3)-O(10)	3.27
		-Br(2)	3.63
		C(30)-O(10)	2.75
		-Br(2)	3.67

The standard deviations of bonds in Sn-Br are 0.006 Å, in Sn-C 0.05 Å, in Sn-O 0.03 Å, Br-C 0.05 Å, Br-O 0.03 Å and C-O 0.05 Å. Those for the angles are of the order of 3°.

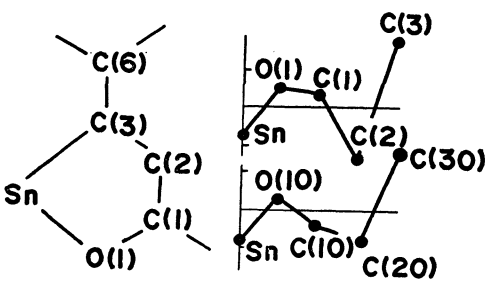

Fig. 2. Deviations of atoms from the least-squares planes in Sn-O(1)-C(1)-C(2)-C(3) and Sn-O(10)-C(10)-C(20)-C(30) rings.

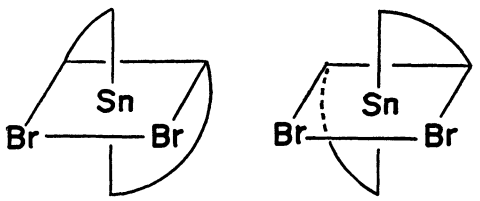

Fig. 3. Two optically active antipodes.

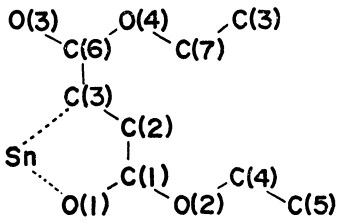
85°, 88°, and 91° each other. Some atoms in these planes show deviations more than 0.2 Å. The coordination configuration is the distorted octahedron as mensioned before. The bond lengths and angles in the ligands are shown in Table 4. The estimated standard deviations for these values are too big to discuss the dimensions of ligand groups in detail.

Table 4. The average bond lengths and angles in two ligand groups of molecule



Sn-O(1)	2.45 Å	O(1)-Sn-C(3)	72°
Sn-C(3)	2.26	Sn-O(1)-C(1)	112
C(1)-O(1)	1.18	O(1)-C(1)-O(2)	123
C(1)-O(2)	1.34	O(1)-C(1)-C(2)	125
C(1)-C(2)	1.46	O(2)-C(1)-C(2)	113
C(4)-O(2)	1.52	C(1)-O(2)-C(4)	116
C(4)-C(5)	1.52	O(2)-C(4)-C(5)	103
C(3)-C(2)	1.57	C(1)-C(2)-C(3)	109
C(3)-C(6)	1.48	Sn-C(3)-C(2)	108
C(6)-O(3)	1.29	Sn-C(3)-C(6)	107
C(6)-O(4)	1.27	C(2)-C(3)-C(6)	117
C(7)-O(4)	1.56	C(3)-C(6)-O(3)	116
C(7)-C(8)	1.51	C(3)-C(6)-O(4)	118
		O(3)-C(6)-O(4)	126
		C(6)-O(4)-C(7)	117
		O(4)-C(7)-C(8)	100

The standard deviations for the bonds between light atoms are estimated to be 0.04—0.06 Å, and for angles about 4°.

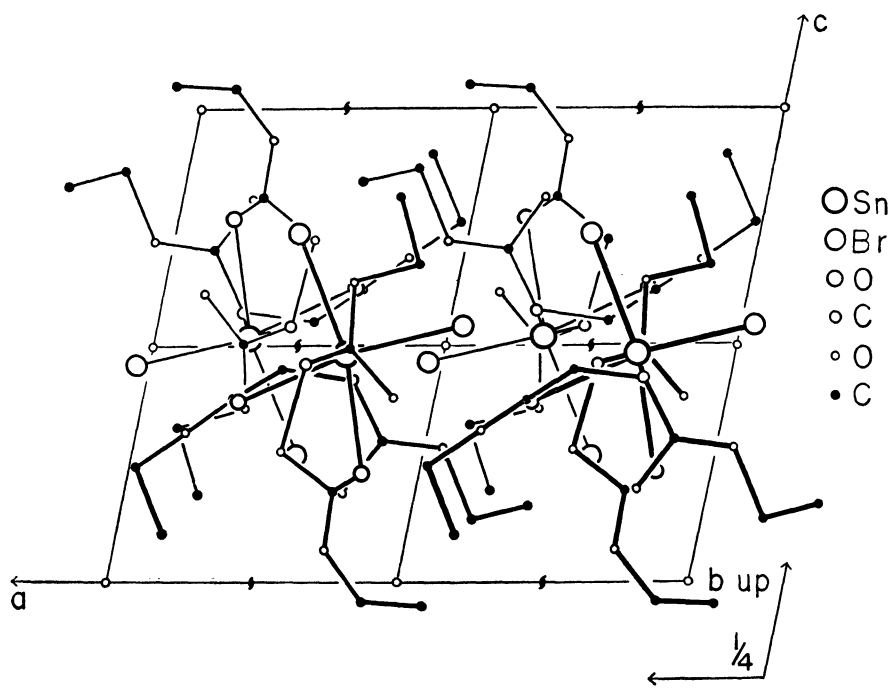


Fig. 4. Crystal structure of bis-(1,2-diethoxycarbonyl-ethyl)tin dibromide.

Both ligands in a molecule contain an asymmetric carbon atom, C(3) and C(30) respectively, of which one is in *d*-form and another in *l*-form, and the optical activity due to the asymmetric carbon atom does not exist. However, the whole molecule is still asymmetric and the molecule must possess the optical activity due to such molecular asymmetry. Since there are glide planes in the unit cell of this crystal (space group: $P2_1/a$) and since a unit cell contains four molecules, there are equal numbers of molecules of two optically active antipodes (Fig. 3) in the crystal. Therefore, the crystal, as a whole, exhibits no optical activity.

TABLE 5. SOME CLOSE INTERMOLECULAR ATOMIC CONTACTS IN THE CRYSTAL
(those less than 4.0 Å are listed)

i $1/2+x,\ 1/2-y,\ z$
ii $-x,\ -y,\ -z$
iii $1+x,\ y,\ z$
iv $x,\ y,\ 1+z$

The crystal structure is shown in Fig. 4. There are not so many close intermolecular atomic distances. The shortest intermolecular contacts are O(3)-C(7^{ii}), 3.15 Å, and C(4)-O(30^{i}), 3.38 Å, and other contacts less than 4.0 Å are all listed in Table 5.

The three-dimensional structure analysis of another isomer crystal, II (mp 122—123°C), is now being carried out.

The authors are very much indebted to Miss Nobuko Kanehisa who joined them at the final stage of the refinement. Through this study, two computer programs in the UNICS,[3] HBLS IV and DAPH (both written by Professor T. Ashida) were used, for which the authors are very grateful. The present study was supported partly by a Scientific Research Grant from the Ministry of Education.

Hydrogen Formation in the Radiolysis of Liquid Olefins. The Role of Hot Hydrogen Atoms and Superexcited States

Yoshihiko HATANO, Shoji SHIDA and Shin SATO

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 7, 1967)

The γ-radiolysis of liquid olefins was undertaken to obtain reliable evidence for a possible role of hot hydrogen atoms and superexcited states in radiation chemistry. The contribution of thermal hydrogen atoms may reasonably be excluded in this system. The effect of various electron or positive-ion scavengers on hydrogen formation in the radiolyses of liquid propylene and ethylene has been examined. The hydrogen formation is not appreciably affected by these additives, which indicates ionic species may not play an important role in the hydrogen formation. The liquid-phase radiolyses of C_3H_6-C_3D_6 and C_2H_4-C_2D_4 mixtures have also been investigated and compared with those previously reported of C_4H_8-1 - C_4D_8-1 and *trans*-C_4H_8 - 2-*trans*-C_4D_8-2 mixtures. The data indicate that the hydrogen from the olefins except ethylene may be formed for the most part by bimolecular processes. A large part of the hydrogen from liquid ethylene may be interpreted in terms of the molecular detachment of a hydrogen molecule, while from the other olefins it may be interpreted in terms of the hydrogen-atom abstraction reaction of hot hydrogen atoms formed by direct excitation which must at least partially involve superexcitation. To attempt quantitative substantiation of the above viewpoint a simple calculation has been made based on the so-called optical approximation. Calculated yields of the hydrogen formation are apparently in good agreement with observed ones.

The role of a hot hydrogen atom as a reaction intermediate in radiation chemistry has often been indicated complementarily by many authors,[1] who have presented little experimental confirmations of its role. Moreover, there have been some criticizing comments[2] on the hot-hydrogen-atom process. It has so far been difficult to distinguish the hot-hydrogen-atom process from bimolecular physical interactions or from the hydrogen-atom abstraction reaction by thermal hydrogen atoms. In a previous paper[3] on the radiolyses of liquid butene-1 and *trans*-butene-2, however, these difficulties as described above could appreciably be removed and evidence was presented for a possible role of hot hydrogen atoms in the radiation chemistry of hydrocarbons. Namely, the hydrogen formation was interpreted in terms of the hydrogen-atom abstraction reaction of hot hydrogen atoms formed by direct excitation which must, at least partially, involve superexcitation. The purpose of the present investigation is twofold: firstly to report new data on liquid propylene and ethylene and to compare these data with those previously reported[3] on liquid butene-1 and *trans*-butene-2, the result for ethylene being in striking contrast to those for the other olefins, and secondly to attempt quantitative substantiation based on the so-called optical approximation of the previous viewpoint.[3] Preliminary results of such work have already been reported,[4] and so the details are presented here.

Experimental

Materials. Research-grade propylene and ethylene from Takachiho Trading Co. were used after the usual degassing and trap-to-trap distillations. Gas-chromatographic analyses of the propylene and the ethylene showed no impurity except for less than 0.1% propane and 0.1% ethane, respectively.

Propylene-d_6 was synthesized from methylacetylene-d_4 by using a palladium catalyst. The methylacetylene-d_4 was obtained[5] from magnesium tricarbide by passing deuterium oxide vapor (99.8 at.% D) in an evacuated system over the carbide at 200°C which was prepared[6]

by passing *n*-pentane vapor over a few grams of finely divided magnesium metal in a quartz tube heated to 700°C. The methylacetylene-d_4 was then treated with an equal volume of deuterium over 1 g of palladium catalyst[7] at 150°C until the calculated pressure fall had taken place. The catalyst was initially placed in an evacuated system at room temperature and reduced for 8 hr with deuterium at 180°C. The deuterium was replaced several times to remove any adsorbed hydrogen. The propylene-d_6 produced was used after a gas chromatographic purification and trap-to-trap distillations. No chemical impurity was detected by gas chromatography using dimethylsulfolane, benzyl ether, and $AgNO_3$-benzylcyanide columns operated at room temperature. The isotopic purity was determined mass spectrometrically to be 99 at.% D.

Ethylene-d_4 was synthesized from acetylene-d_2 by using a palladium catalyst in a way similar to the case of propylene-d_6. The acetylene-d_2 was obtained from calcium carbide by passing deuterium oxide vapor in an evacuated system over the purified carbide at room temperature. The ethylene-d_4 produced was used after a gas chromatographic purification and trap-to-trap distillations. No chemical impurity was detected by gas chromatography using squalane and $AgNO_3$-benzylcyanide columns operated at room temperature. The isotopic purity was determined mass spectrometrically to be again 99 at.% D.

Nitrous oxide (minimum purity: 99.9%), ammonia (>99.5%), and sulfur hexafluoride (>98.0%) were used without further purification. Carbon tetrachloride and methanol (spectral grade) were used after the usual degassing and distillation.

Irradiation. Measured amounts of propylene, ethylene, or the mixtures were sealed *in vacuo* at −196°C in glass ampules 5 mm in diameter and 50 mm long fitted with break-off-tips. The samples were irradiated in the facilities of Tokyo Institute of Technology (6 kCi ^{60}Co) at a dose rate of 6.9×10^{19} eV/g hr. Unless otherwise specified, samples were irradiated to a total dose of 4.3×10^{20} eV/g at −78°C using dry ice and methanol slushes. The dose rate was determined by Fricke dosimetry using $G(Fe^{3+})=15.6$.

Analysis. After irradiations, the sample tubes were attached to a vacuum line and the seals were broken. The products, noncondensable at −210°C, hydrogen and methane, were collected and measured by an analysis device composed of a Toepler pump, a gas burette, a a McLeod gauge, and a copper oxide furnace kept at 250°C. In this furnace, hydrogen was oxidized into water which was then trapped at −196°C.

In the case of isotopic experiments, the relative amounts of H_2, HD, and D_2 were determined with a Hitachi RMU-5 mass spectrometer.

Results

Figure 1 shows the variation of hydrogen formation as a function of the energy absorbed in the radiolyses of liquid propylene and ethylene at −78°C. The hydrogen formation is directly proportional to the energy absorbed; that is, the *G* value, the number of molecules formed per 100 eV of the energy absorbed in the system, is independent of the total energy absorbed. The *G* values of hydrogen formation in the radiolyses of pure liquid propylene and

7) T. Kabe and I. Yasumori, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **85**, 410 (1964).

ethylene at −78°C have been estimated as 0.82 and 1.24 from Fig. 1, respectively.

Various types of reagents possessing a high reactivity for ionic species, electrons or positive ions, were used. They were also selected on the basis of their ionization potentials being higher than that of propylene or ethylene. Table 1 shows the effect of various electron or positive-ion scavengers, *i.e.*, nitrous oxide, carbon tetrachloride, sulfur hexafluoride, ammonia, and methanol, on the hydrogen formation. The hydrogen formation is scarcely suppressed even at high concentrations above 100 mM of the electron scavengers and above 1 M of the positive-ion scavengers.

These results in Fig. 1 and Table 1 show a marked contrast to those in the radiolysis of saturated hydrocarbons as described in the previous paper,[3] in which a detailed comparison was made.

Table 2 shows the relative amounts of H_2, HD and D_2 evolved from the radiolyses of C_3H_6 - C_3D_6 and C_2H_4 - C_2D_4 mixtures. From the kinetic analysis as described previously,[3] when the value of

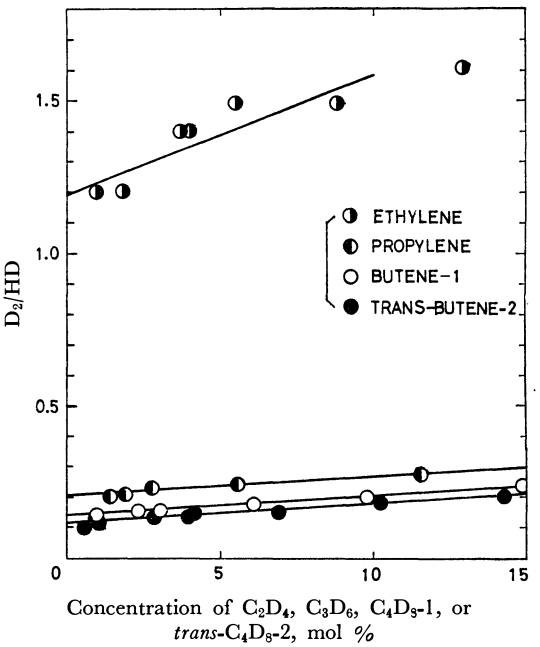

Fig. 2. D_2/HD *vs.* concentration of the perdeuterated olefins in the liquid-phase radiolyses of C_2H_4-C_2D_4, C_3H_6-C_3D_6, C_4H_8-1 - C_4D_8-1,[3] and *trans*-C_4H_8 - *trans*-2-C_4D_8-2[1] mixtures.

D_2/HD is extrapolated to zero concentration of C_3D_6 or C_2D_4, it is found to be one-half of the ratio of unimolecular to bimolecular processes in the hydrogen formation. Values of D_2/HD are listed in the last column of Table 2, and are plotted against the concentration of C_3D_6 or C_2D_4 in Fig. 2. The values of D_2/HD at zero concentration are determined to be, respectively, 0.20 and 1.2 for C_3H_6 - C_3D_6 and C_2H_4 - C_2D_4 mixtures. Thus, 71% and 29% of total hydrogen from propylene and ethylene, respectively, may be formed through bimolecular processes. The results for butene-1 and *trans*-butene-2, reported previously,[3] are also plotted in Fig. 2 and listed in Table 3 for ready comparison. Figure 2 or Table 3 shows that the result for ethylene is in striking contrast to those for the other olefins. For ethylene the bimolecular hydrogen formation is less important, while for the other olefins it is most important.

TABLE 3. PERCENTAGES OF UNIMOLECULAR (DENOTED BY I) AND BIMOLECULAR (II) PROCESSES FOR HYDROGEN FORMATION IN THE RADIOLYSIS OF LIQUID OLEFINS

Olefin	$G(H_2)$	$(D_2/HD)_0$[a]	I (%)	II (%)	$G(H')$[b]
trans-C_4H_8-2[c]	1.22	0.11	18	82	1.0
C_4H_8-1[c]	0.74	0.14	22	78	0.6
C_3H_6	0.82	0.20	29	71	0.6
C_2H_4	1.24	1.2	71	29	0.3

a) $(D_2/HD)_0$ means the value of D_2/HD extrapolated to zero concentration of the perdeuterated olefins.
b) H′ means the precursor for bimolecular hydrogen formation in the radiolysis of liquid olefins, probably a hot hydrogen atom.
c) Ref. 3.

Discussion of the Experimental Results

A fairly large quantity, about one molecule per 100 eV energy absorbed, of hydrogen formation has been observed in the radiolysis of some liquid olefins.[8-11] This cannot be explained by processes involving thermal hydrogen atoms, since for them olefins, RH_2, have a high reactivity; and the addition reaction (1) is dominant compared with the abstraction reaction (2):[12]

$$H + RH_2 \rightarrow RH_3 \quad (1)$$
$$\searrow$$
$$H_2 + RH. \quad (2)$$

Thus, Reaction (2) or thermal hydrogen atoms must be unimportant for hydrogen formation in the radiolysis of liquid olefins.

The hydrogen formation is scarcely suppressed by the addition of an appreciable concentration of various scavengers for ionic species, as shown in Table 1 and in the previous paper.[3] Consequently, from the discussion similar to that previously reported,[3] it seems reasonable to assume that ionic species, electrons and various positive ions, do not play an important role in the formation of observed hydrogen in the radiolysis of liquid olefins. The excited olefin molecule, RH_2^*, which is formed by recombination of the parent olefin ion and an electron may not be acting as a precursor for the product hydrogen, but rather as a precursor for a thermal hydrogen atom which will eventually be scavenged by olefin itself:

$$RH_2^+ + e^- \rightarrow RH_2^* \quad (3)$$
$$RH_2^* \rightarrow H + RH \text{ or } 2H + R \quad (4)$$
$$H + RH_2 \rightarrow RH_3. \quad (5)$$

The probability of hydrogen formation through various ion-molecule reactions in olefins may also be eliminated.

The most reasonable conclusion to be drawn from available data is that the excited olefin molecules RH_2' formed by direct excitation are essential to the hydrogen formation. Since, as described above, excited states which are formed by recombination of the parent olefin ion and an electron do not play an important role in the hydrogen formation, excited states lying below the ionization potential which are formed by direct excitation may also be of minor importance. Thus, the entities RH_2' may be in highly excited states lying above the ionization potential, which are called superexcited states.[13] The importance of direct excitation has never been indicated explicitly in the radiation chemistry. The hydrogen may be formed by the molecular detachment from RH_2',

$$RH_2 \rightsquigarrow RH_2' \quad (6)$$
$$RH_2' \rightarrow H_2 + R, \quad (7)$$

or by the hydrogen-atom abstraction reaction of a hot hydrogen atom H',

$$RH_2' \rightarrow H' + RH \quad (8)$$
$$H' + RH_2 \rightarrow H_2 + RH, \quad (9)$$

where a part of the highly excited states RH_2' may undergo the following autoionization:

$$RH_2' \rightarrow RH_2^+ + e^-. \quad (10)$$

The former is a unimolecular process and the latter bimolecular. Since, for ethylene, a greater part of the total hydrogen is formed by a unimolecular process as shown in Table 3, Reaction (7) is essential to hydrogen formation in the radiolysis of liquid ethylene. For the olefins except ethylene, on the other hand, Reactions (8) and (9) are important for the hydrogen formation as shown in Table 3.

It has well been known[14] from a mass spectrometric investigation that an ion of mono-olefin tends to rupture giving an allyl type ion fragment. Thus, particularly for propylene, the possibility of the following process giving a hot hydrogen atom might be considered:

$$C_3H_6^{+*} \rightarrow H' + C_3H_5^+, \quad (11)$$

where $C_3H_6^{+*}$ is an excited ion of propylene. As shown in Table 3, however, it can not be found for propylene to be characteristic of Reaction (11). Thus, the possibility of hot-hydrogen-atom formation through Reaction (11) may be eliminated.

Calculations and Their Discussion

The collisions of electrons, photons, or excited atoms with various molecules have been studied since long ago. Especially in recent years a number of studies have been made on the measurements of electron-energy loss or photoionization spectra providing significant information about the nature of higher excited states of molecules. And, moreover, theory is now able to provide at least an approximative quantitative description of the primary stage of radiolysis. A simple calculation has been made in this paper based on the optical approximation introduced by Platzman.[15]

The yield g_s, per 100 eV energy absorbed, of primary decomposition channel s may be estimated by the optical approximation. Thus, g_s can be taken

as proportional to an effective dipole-matrix-element squared for s in atomic units:

$$M_s^2 = \int_{J_s}^{\infty} \phi_s(E) \frac{\boldsymbol{R}}{E} \frac{df}{dE} dE, \quad (12)$$

where E is the excitation energy in eV, $\boldsymbol{R}$ the Rydberg energy, df/dE the differential oscillator strength, $\phi_s(E)$ the probability of decomposition s upon excitation at E, and J_s the threshold excitation energy for s. Utilizing data on ionization, namely the W value (in eV) and M_i^2, the dipole matrix-element squared for ionization,[16]

$$M_i^2 = \int_{I}^{\infty} \eta(E) \frac{\boldsymbol{R}}{E} \frac{df}{dE} dE, \quad (13)$$

we may write[15]

$$g_s = \frac{100}{W} \frac{M_s^2}{M_i^2}. \quad (14)$$

In Eq. (13), I is the ionization energy and $\eta(E)$ is the probability of ionization upon excitation at E. Since the G value for hydrogen formation measured in our experiment is considered to represent the combined yield of hot hydrogen atoms and molecularly detached hydrogen:

$$RH_2' \rightarrow H' + RH \quad (15)$$

$$\searrow \; H_2 + R, \quad (16)$$

we can compare $G(H_2)$ with g_s calculated from Eqs. (12), (13), and (14) taking these two decomposition modes as the channel s.

In calculating g_s by numerical integrations in the above equations, we have relied upon the following sources of information. The differential oscillator strength df/dE is deduced from photo-absorption[17] and electron energy loss data.[18] The former has been mainly used and is shown in Fig. 3. The spectrum of butene-1 has not been reported in the region of large E. In the region of small E (<12 eV), however, it has been reported[17] that the spectrum of butene-1 is very similar to that of butene-2. Then, it is supposed that the quantity M_s^2 for butene-1 is nearly equal to that for butene-2. For ethylene, the data of Metzger and Cook somewhat differ from those of Schoen, which we have primarily relied upon.[17] The differential oscillator strength df/dE is proportional to the absorption cross section at E, and $\eta(E)$ is equal to the ratio of the ionization cross section to the total absorption cross section at E. The quantity M_i^2 is taken from ionization cross sections for fast electrons.[19] The W value is quoted

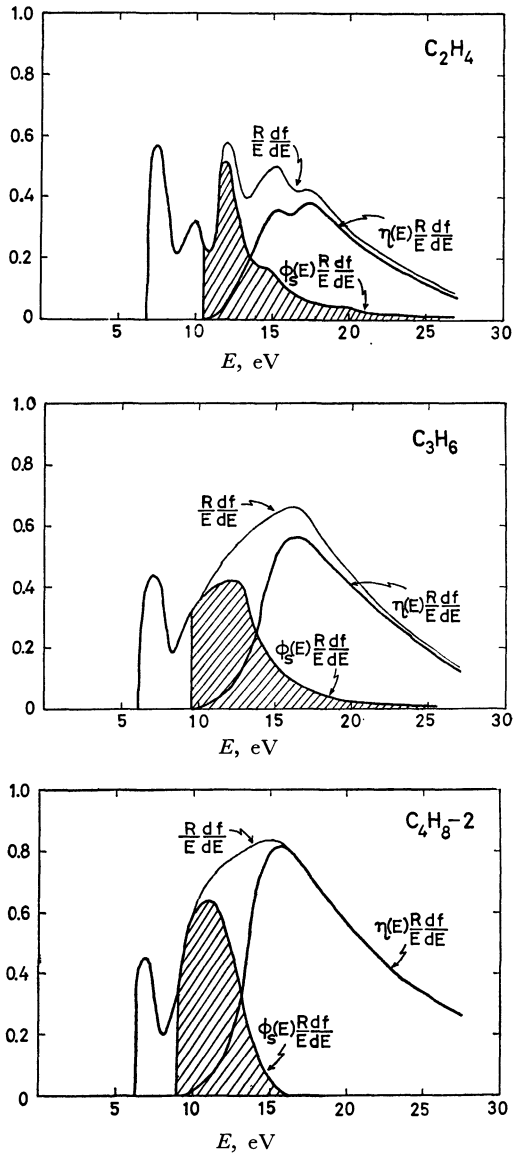

Fig. 3. Exitation spectra of olefins.

from the existing paper,[20] with an assumption that no artifacts disturbing total ionization such as the Jesse effect are operative. As to the probability $\phi_s(E)$ for the decomposition into a hot hydrogen atom and into a hydrogen molecule, lack of directly relevant information forces us to consider a reasonable model. Namely, we shall tentatively assume that the above decomposition corresponds to all the pathways, except for ionization, by which superexcited states decay:

$$\phi_s(E) = 1 - \eta(E), \quad I<E. \quad (17)$$

The highly exploratory nature of the model must be

emphasized. Firstly, contribution of hot hydrogen atoms from excitation in the region $J_s<E<I$ are not included:

$$\phi_s(E) = 0, \quad J_s<E<I. \tag{18}$$

The value of J_s is difficult to be estimated *a priori*. A reasonable assumption, however, is that J_s is near I, because neutralization has been experimentally found not to contribute appreciably to the hydrogen formation as described in the last section. Secondly, other decomposition modes, C–C bond ruptures, have been disregarded. Presently available evidence does not seem to allow a conclusive statement as to this point,[21] although a recent study indicates the predominance of the C–H bond rupture in photolysis of ethylene at 11.6—11.8 eV.[22] Finally, influence of condensed phase on primary activation[15] has been neglected.

The results are listed in Table 4. Apparently g_s is in good agreement with $G(H_2)$. Although these results are still very tentative owing to approximate nature of estimation, they definitely lend some support to a significant role of superexcited states of hydrocarbons in the radiolysis.

In Table 4 the experimentally estimated yields of hot hydrogen atoms, $G(H')$, in the radiolysis of these olefins are also listed. As indicated in footnote 18 of the previous paper[3] it is a question whether the hot hydrogen atom H′ is a ground-state atom with appreciable kinetic energy or an electronically excited one. If we assume that H′ is electronically excited, its precursor requires at least about 14 eV of the excitation energy that is the sum of the C–H bond dissociation energy, about 4 eV, and the threshold energy, 10.2 eV, for the production of H(2P). Optical data in Fig. 3 show that superexcitation above 14 eV occupies relatively a small fraction of the absorption spectrum except in the case of ethylene. Thus, the majority of the hot hydrogen atoms in the other cases appears to be the ground-state atoms with kinetic energies rather than electronically excited ones.

As described in the last section, the experimental result for ethylene is in striking contrast to those for the other olefins. When, in Fig. 3, it is found for the spectrum of ethylene to be characteristic, it might be considered that the above two facts have some relations with each other.

The authors wish to thank Dr. M. Inokuti of Argonne National Laboratory for valuable suggestions. They are also indebted to Dr. H. Yamazaki of this Institute and Dr. K. Katsuura of Kurashiki Rayon Co. for their helpful discussions.

Excitation from Superexcitation of Hydrocarbons. Estimation of Their Yields by the Optical Approximation

Yoshihiko HATANO

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received December 7, 1967)

A simple calculation has been made based on the so-called optical approximation to obtain the yields of excitation from superexcitation of the hydrocarbons, methane, ethane, propane, *n*-butane, *n*-pentane, ethylene, propylene, butene-1, butene-2, 1,3-butadiene, acetylene, and cyclopropane. Their dipole-matrix-elements squared for excitation from superexcitation, M_d^2, have been found to be directly proportional to the number of carbon atoms in the hydrocarbons, and the ratio of M_d^2 to M_i^2, the dipole-matrix-element squared for ionization, is about 0.2. Thus, the yields, per 100 eV energy absorbed, of excitation from superexcitation are nearly equal to 0.8 for all the hydrocarbons described here.

A possible role of neutral fragments in radiation chemistry, which are formed by dissociation of superexcited molecules, was first suggested by Platzman.[1-3] Since then, however, little evidence has been presented for their role in radiation chemistry. On the other hand, reliable evidence has been required for the role of a hot hydrogen atom as a reaction intermediate in radiolysis.[4,5] Recently, however, evidence has been presented for a possible role of hot hydrogen atoms and superexcited states in radiation chemistry.[4-6] Namely, the hydrogen formation in the radiolysis of liquid olefins except ethylene is interpreted[4,5] in terms of the hydrogen-atom abstraction reaction of hot hydrogen atoms formed by direct excitation which must partially involve superexcitation. Moreover, a simple calculation has been made[6] based on the so-called optical approximation to attempt quantitative substantiation of the above viewpoint. In recent years studies have been made by Ausloos and his collaborators[7] of the primary decomposition processes in photolysis of various hydrocarbons at the photon energies a little higher than the ionization potential.

If, according to Platzman's theory, a polyatomic molecule AB receives energy of radiation, this energy may be utilized in direct ionization as

$$AB \rightarrow AB^+ + e^- \qquad (1)$$

with a probability δ, or in the formation of a superexcited state

$$AB \rightarrow AB' \qquad (2)$$

with a probability $(1-\delta)$. This is followed by

$$AB' \rightarrow AB^+ + e^-, \text{ pre-ionization,} \qquad (3)$$

$$\searrow A + B, \text{ "dissociation".}^{*1} \qquad (4)$$

It has been suggested[1] that the probability δ is much less than unity, and that there is, consequently, a real competition between Processes (3) and (4). The optical approximation introduced by Platzman[2,8] is now able to provide at least an approximative quantitative description of these processes. The yield g_d, per 100 eV energy absorbed, of the formation of the superexcited states followed by Process (4) may be estimated by the optical approximation. Namely, the yield g_d is taken as proportional to M_d^2, the dipole-matrix-element squared for excitation from superexcitation.*2 Thus, the role of the neutral fragments in radiation chemistry may be estimated by the quantity M_d^2. This paper presents the quantity M_d^2 for various hydrocarbons of which the optical spectra have already been known.

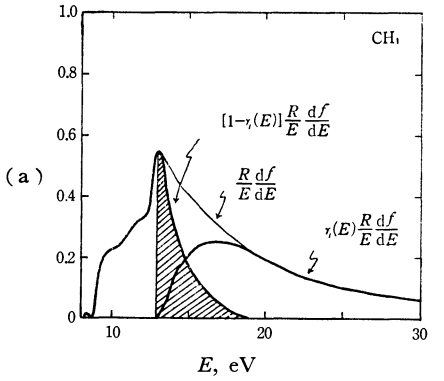
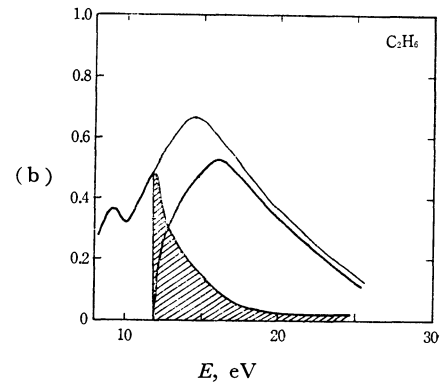
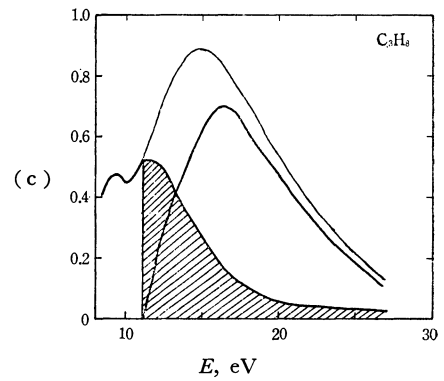
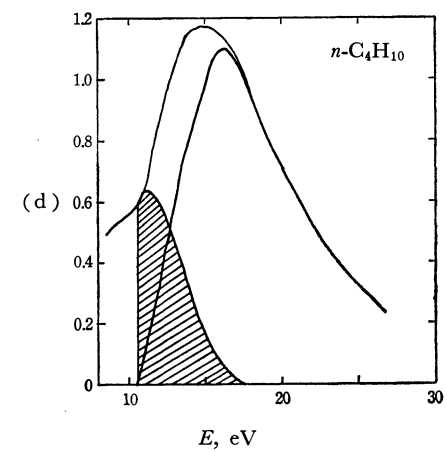
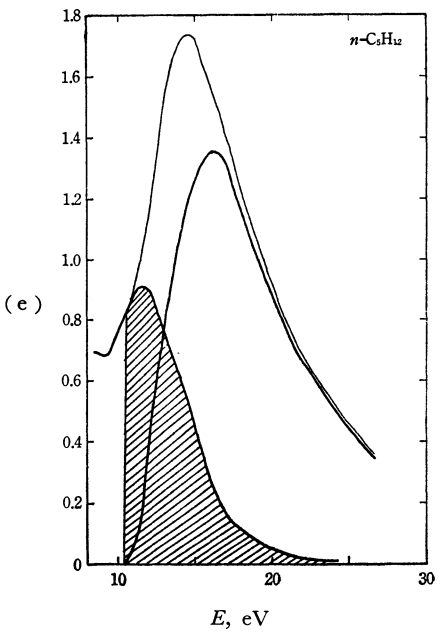
*2 The term "excitation from superexcitation" means formation of the superexcited states followed by the processes except for ionization, namely by the "dissociation" processes.[2]

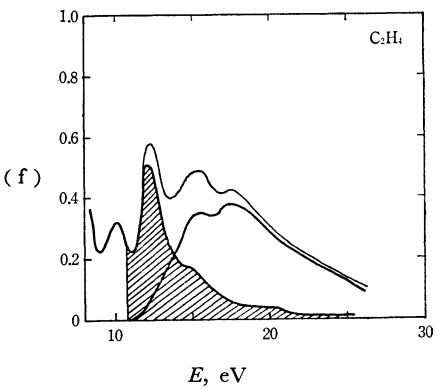












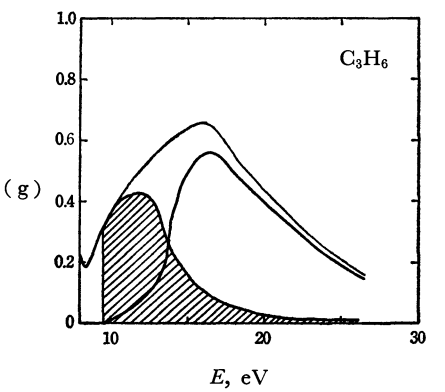


Fig. 1 (a)～(k). Excitation spectra of various hydrocarbons.

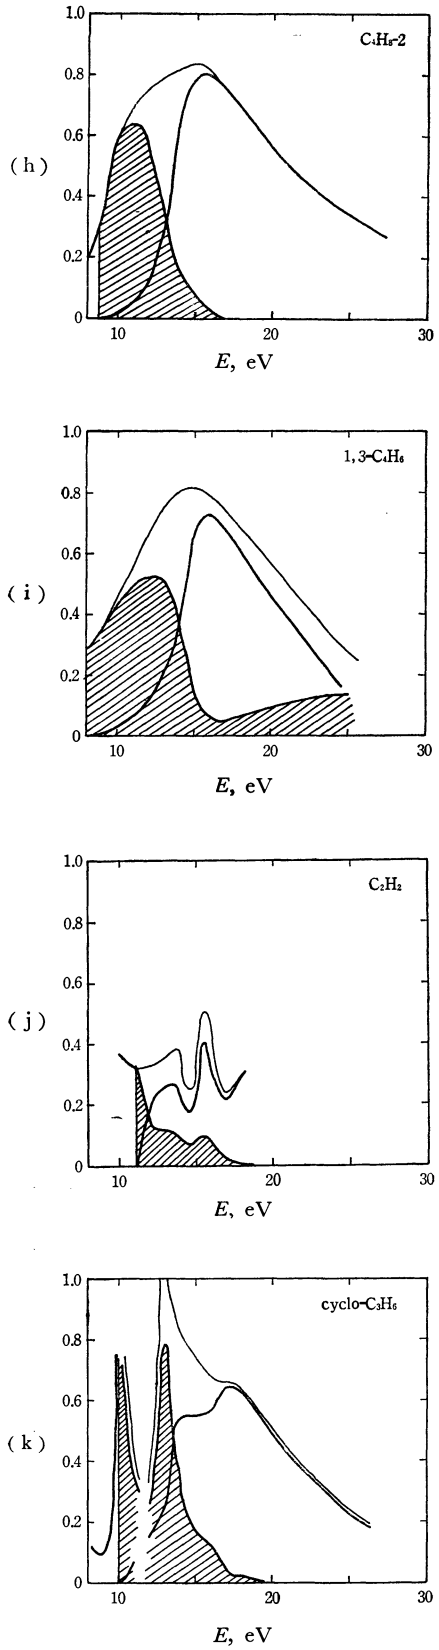

Calculation and Discussion

The yield g_d is proportional to the quantity M_d^2 (in atomic units):

$$M_d^2 = \int_I^\infty [1 - \eta(E)] \frac{\boldsymbol{R}}{E} \frac{df}{dE} dE, \qquad (5)$$

where E is the excitation energy, $\boldsymbol{R}$ the Rydberg energy, I the ionization energy, df/dE the differential oscillator strength, $\eta(E)$ the probability of ionization upon excitation at E. Now, attention has to be paid to a slight difference between the quantity M_d^2 in Eq. (5) and the quantity M_s^2 in the previous paper.[5,6] The latter is determined by the decomposition mode s, namely the threshold excitation energy J_s for s. Since, however, a reasonable assumption, $\phi_s(E) = 1 - \eta(E)$ at $I < E$ and $\phi_s(E) = 0$ at $J_s < E < I$ where $\phi_s(E)$ is the probability of decomposition s upon excitation at E, was introduced in the previous paper,[5,6] the value of the above two quantities have eventually been identical. Utilizing data on ionization, namely the W value and M_i^2, the dipole-matrix-element squared for ionization,[1] we may write $g_d = (100/W)(M_d^2/M_i^2)$.

In calculating M_d^2 by numerical integration in Eq. (5), we have utilized the following sources of information. The differential oscillator strength df/dE and the probability $\eta(E)$ are deduced from photoabsorption data[2,9,10] and are shown in Fig. 1

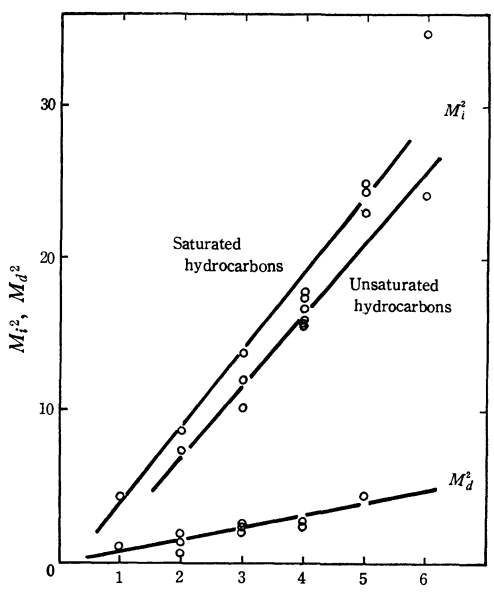

Fig. 2. Values of M_d^2 and M_i^2 for various hydrocarbons against the number of carbon atoms. The values of M_i^2 are quoted from the data by Schram *et al.*[11] Each circle corresponds to a particular hydrocarbon. Refer to Table 1.

(a)—(k), all of which are drawn on the same scale. Thus, in the first instance, it has been found in these figures that the quantities M_d^2 increase with increasing the number of carbon atoms in the hydrocarbons, while that the oscillator-strength spectra of the hydrocarbons are almost in infinite variety. In the spectra of ethylene, acetylene, and cyclopropane, for example, the marked structures stand in contrast to the smoothness in the spectra of alkanes. The quantities M_d^2 estimated are listed in the first column of Table 1, and are plotted in Fig. 2 against the number of carbon atoms in the hydrocarbons. The data show that the quantities M_d^2 are directly proportional, still very roughly owing to the lack of more reliable basic data, to the number of carbon atoms in the hydrocarbons.*3 There has been, to the author's knowledge, no report with any result such as that shown in Fig. 2, although such result may be easily expected. The quantities M_i^2 taken from ionization cross sections for fast electrons measured by Schram *et al.*[11] are also plotted in Fig. 2. Although the quantities M_i^2 may also be determined by graphical integration in Fig. 1, it forces us to make a rough extrapolation of Schoen's data[9] to higher excitation energies. Figure 2 shows that the values of M_d^2/M_i^2 are nearly equal to 0.2 for all the hydrocarbons described here. Assuming that the W values of the hydrocarbons are equal to 25 eV, we get the values of g_d to be about 0.8. Namely, no peculiarity has been able to be found in the values g_d or M_d^2 at least for all the hydrocarbons under consideration. Going into details and using the W values quoted from the existing paper,[12,13] on the other hand, we get each one of the values g_d to be listed in the last column of Table 1.

Finally, we may add that more reliable and more accurate basic data such as df/dE, W, and $\eta(E)$ are greatly desirable.

The author wishes to thank Prof. S. Shida of this Institute for valuable suggestions. He is also indebted to Dr. S. Sato and Dr. H. Yamazaki of this Institute and Dr. M. Inokuti of Argonne National Laboratory for their helpful discussions.

13) P. Adler and H. K. Bothe, *Z. Naturforschg.*, **20a**, 1700 (1965).
*3 If M_d^2 and M_i^2 are plotted against the number of valence electrons in the hydrocarbons, better-fit lines are obtained for both the quantities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1130—1132 (1968)

Formation Constants of Maleatochromium(III) Complexes and Some Properties Thereof in the Solid State*[1]

Takeshi TOMITA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 12, 1967)

The formation constants of the chromium(III) complexes with maleic acid have been determined by the pH method to be $\log k_1 = 5.4 \pm 0.1$, $\log k_2 = 3.0 \pm 0.1$, and $\log k_3 = 1.9 \pm 0.2$ at an ionic strength of $\mu = 0.1$ and at 25°C. We also attempted to prepare the solid of the chromium(III) complex with maleic acid. Though it was an amorphous solid to X-ray diffraction measurement, its composition was presumed to be $[Cr(mal^{*2})(OH)(H_2O)_3]$. After it had been dried in a desiccator for a few days, when it was exposed to moist air we observed the curious phenomenon that the solid was made jumping due to the absorption of water vapor.

The formation constants of the chromium(III) complexes with succinic and with phthalic acids have been reported by one of the present authors in earlier papers.[1,2] The curious jumping property of the latter complex in the solid state after it had been dehydrated was also noted.[2] In continuation of the above works, the formation constants of chromium(III) complexes with maleate have been determined. All the three anions described above can make similar coordination bonds to chromium(III) through the seven-membered chelate ring; there is only a fine structural difference originating from the ligand molecules themselves. The effect of such differences in the structure upon the formation constants of the chromium(III) complexes concerned will be discussed below.

Experimental

Formation Constant Measurement. The formation constants were determined by means of pH measurements in a mixed solution of hexaaquochromium(III) perchlorate and maleic anhydride at an ionic strength of $\mu = 0.1$ and at 25°C in a manner similar to that described in an earlier paper.[2] The maleic anhydride used as a ligand material was of a special grade and had been obtained from Wako Pure Chemical Industries, Ltd.

Attempt of Preparation of the Solid Maleatochromium(III) Complex. We attempted to prepare the maleatochromium(III) complex in the solid state by the procedure reported in an earlier paper.[2] To a mixed solution of 6 g (1/60mol) of chromium(III) nitrate nonahydrate and 5 g (1/20 mol) of maleic anhydride, we added 13 g (1/7 mol) of ammonium carbonate; the resulting solution was then evaporated to some extent until the film-like substance covering the surface of the solution began to appear. Then it was scooped on the filter and dried in the desiccator. About 2 g of the product were obtained. The product was amorphous to X-ray diffraction measurements.

The product showed the curious property of jumping when it was exposed to moist air, just as the phthalatochromium(III) complex did.[2] The analysis of the sample after it had absorbed enough water vapor gave the chromium content of 21.51%, a value of which is in good agreement with the calculated value, 21.93%, for the chemical formula, $[Cr(mal)(OH)(H_2O)_3]$.

Results and Discussion

Comparison of the Formation Constants of Maleatochromium(III) Complexes with Those of Phthalato- and Succinatochromium(III) Complexes. The relevant values of the first and second acid dissociation constants of maleic acid required for determining the formation constants of the complexes were taken from the literature—$pK_1 = 1.92$[3] and $pK_2 = 5.79$[4] respectively at an ionic strength of $\mu = 0.1$ and at 25°C.

The methods of calculating the average number of coordinated maleate anions as ligands per gram-ion of the chromium, $\bar{n}$, and the concentration of the non-coordinated anions, $p[A^{2-}]$, in solution, are the same as those described in an earlier paper.[5] The plots of $\bar{n}$ *vs.* $p[A^{2-}]$ for the maleatochromium(III) system are shown in Fig. 1, together with those for the succinato- and phthalatochromium(III) systems.

By applying the successive approximation method to the tentative values of the formation constants

(The numerals in parentheses are the values estimated by extrapolating the formation curve.)

obtained from the formation curve shown in Fig. 1, the step-by-step formation constants were obtained; they are listed in Table 1, together with those of the succinato- and phthalatochromium(III) complexes.

It is obvious from Table 1 that the formation constants of the maleato and phthalato complexes are rather smaller than those of the succinato complexes. This is due to the structural differences among the ligand molecules used.

The phthalate and maleate anions may be forced to hold the planar structure in a complex formation because of the presence of a benzene ring in the former and that of the double bond between two carbon atoms instead of the benzene ring between two carboxylate groups in the latter. Since the distance between two oxygen atoms which can coordinate to the metal ion in these two carboxylate anions is presumed to be about 1.6 Å on the basis of the crystal structure of the maleic acid,[6] a remarkable strain may be predicted to occur in the chelate formation when they coordinate to a metal ion using the above two oxygens as the bidentate ligand.

On the other hand, since the succinate anion[7] has neither a benzene ring nor a double bond between two carbon atoms within itself, the free rotation of the ethylene linkage placed between two carboxylate groups is possible without any steric hindrance. As a result, it may not always make a planar coordination structure. Therefore, in this case, little strain should appear in the chelate formation. It may be concluded that the difference in the original structure in the ligand coordinated to metal as mentioned above is the main contribution to the lower stability of the phthalato and maleato complexes than that of the succinato complexes.

When we compare the formation constants of the phthalato and maleato complexes in Table 1, we find that the latter are relatively smaller than the former. The phthalate and maleate must commonly form similar seven-membered planar chelate rings as a result of the double-bond character involved in their chelate rings.

6) M. Shahat, *Acta Cryst.*, **5**, 763 (1952).

7) J. S. Broadley, D. W. J. Cruickshank, J. D. Morrison, J. M. Robertson and H. M. M. Shearer, *Proc. Roy. Soc. (London)*, **251A**, 441 (1959).

Since, while the phthalate anion has a benzene ring, the maleate one has none, the double-bond character between the two carbon atoms combining with two carboxylate groups seems to be weaker in the former than in the latter. This results in the lesser electronic density at the oxygen atoms coordinating to metal in the latter than in the former. Therefore, it may be suggested that the basicity of the maleate anion is rather smaller than that of the phthalate. The values of the total acid dissociation constants of these acids given in Table 1 support this idea.

In short, the lesser stability of the maleato complexes than that of the phthalato complexes can be well explained by the facts that the acid dissociation constant of the maleic acid is smaller than that of the phthalic acid.

Jumping Property of the Solid Maleatochromium(III) Complex. The solid maleatochromium(III) complex prepared and dried in a desiccator showed jumping when it was exposed to moist air, as in an earlier experiment.[2] The fact that the phenomena took place as a result of the absorption of water vapor was ascertained by the presence of a stronger and broader absorption band in the range of 3200—3600 cm^{-1} of the IR spectra after jumping than before jumping.

It was observed that, even after the sample had absorbed water vapor enough to cause it to cease jumping, the jumping property re-appeared when it was again exposed to moist air.

The weight loss of the sample which had absorbed water vapor in the moist air and had ceased jumping was measured by the thermobalance; it is plotted in Fig. 2. The figure shows that a metastable dehydrated compound is formed by a weight loss of 20—24% at about 200°C; this is approximately consistent with the calculated value, 22.8%, for the following reaction:

$$[Cr(mal)(OH)(H_2O)_3] \xrightarrow{-2H_2O} [Cr(mal)(OH)(H_2O)].$$

It was also found that the sample which had thermally lost the water vapor in the amount corresponding to the expression in this equation began jumping again in the moist air, as in the case of the phthalatochromium(III) complex in the solid state reported on in an earlier paper.[2]

Bromine to Chlorine Ratios in Igneous Rocks

Tsutomu SUGIURA*1

Department of Earth Sciences, Nagoya University, Chikusa, Nagoya

(Received November 13, 1967)

Samples were decomposed by fusion with Na_2O_2 and benzoic acid in a Parr-bomb, then halogens were separated from other elements by distillation and determined colorimetrically; chlorine by the thiocyanate method and bromine by the rosaniline method. The chlorine and bromine contents of rocks cover a very wide range with no relation to the type of rock. The Br/Cl ratio, however, is in a relatively narrow range from 1×10^{-3} to 16×10^{-3} by weight, mostly from 1×10^{-3} to 6×10^{-3}, and evidently lower than those reported by previous investigators. The average Br/Cl ratio is $(3\pm2)\times10^{-3}$, about one-seventh of the value generally accepted for igneous rocks. The halogen content of quartz and feldspar is usually so small that it was not usually determined. The Br/Cl ratio in biotite seems to be rather small and certainly is smaller than 3×10^{-3} on the average. The Br/Cl ratios in volcanic rocks are similar to those in volcanic gases for any one volcano studied.

Sugiura *et al.*[1] (1963) reported that the Br/Cl ratio in volcanic gases is very alike at every volcano, and evidently smaller than the Br/Cl ratio in igneous rocks reported by Behne[2] (1953). This fact seemed interesting for the consideration of their behavior in volcanic emanations.

The bromine content of igneous rocks was first determined by Fellenberg and Lunde in 1926 (Behne,[2] 1953), and again by Selivanow[3] in 1940 and Behne in 1953. Behne's data had been accepted until Filby[4] (1964) reported the bromine contents of the standard rocks, granite G-1 and diabase W-1. His values are appreciably lower than the average values given by Behne.

Krasitseva[5] (1964) postulated that the Br/Cl ratio in ocean water has been decreasing through geologic time. One important fact supporting his hypothesis is that the average Br/Cl ratio in igneous rocks seems to be far higher than that in present-day ocean water.

From the above, it seems to be very important and urgent to obtain true average Br/Cl ratio for igneous rocks. In the present study, the author has determined the chlorine and bromine contents of volcanic and plutonic rocks. In order to examine the average Br/Cl ratio obtained the relations between the Br/Cl ratio in biotite and in coexisting quartz and feldspar, and also the ratios in volcanic rocks and volcanic gases from one volcano were investigated.

Experimental

Total Chlorine and Total Bromine. About 1 kg of rock sample was taken at each locality, and 50 to 100 g of sample crushed in a steel mortar and ground to approximately 200 mesh in an agate mortar, taking special precaution against any possibility of chlorine or bromine contamination. The powdered sample was decomposed by fusion with sodium peroxide, and chlorine and bromine separated from other elements by distillation. Chlorine was determined by the method of Iwasaki *et al.*[6] (1957), and bromine by a modification of the method of Hunter and Goldspink[7] (1954).

Separation of Chlorine and Bromine. The sample (1 to 3 g) was decomposed by fusion with 15 g of sodium peroxide and 0.5 g of benzoic acid in a Parr-bomb.*2 The cake was put into 100 m*l* of distilled water. The solution was condensed to about 50 m*l* on an electric heater, and transferred into a 150 m*l* distilling flask. Two milliliters and 50 m*l* of 2 N potassium hydroxide solution were added to trap A and trap B, respectively (Fig. 1). Forty milliliters of 14 N sulfuric acid and 10 *l* of 10% potassium permanganate solution were added to the distilling flask. The solution was heated to boiling and air bubbled in at the rate of 100 m*l*/min. Distillation was continued to obtain 50 m*l* of distillate. A half milliliter of 30% hydrogen peroxide was added to the distillate. The solution was boiled on a water-bath to decompose the surplus hydrogen peroxide, and made up to 5.0 m*l*.

Chlorine. One milliliter of the solution of chlorine

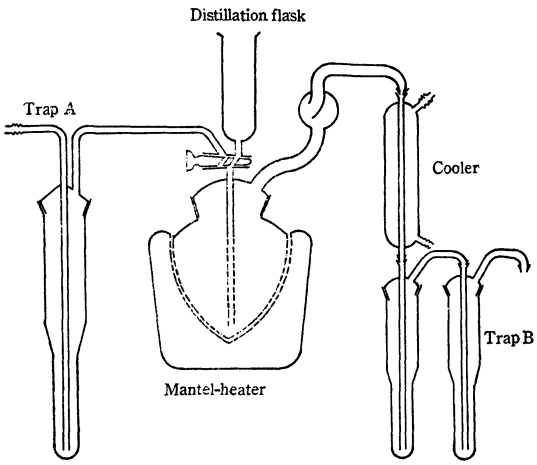

Fig. 1. Apparatus for distillation of chlorine and bromine.

and bromine, 1 m*l* of mercuric thiocyanate solution (0.3 g of $Hg(SCN)_2$ in 100 m*l* of C_2H_5OH) and 2 m*l* of ferric ammonium sulfate solution (6 g of $Fe_2(SO_4)_3(NH_4)_2SO_4 \cdot 24H_2O$ in 100 m*l* of 6 N NHO_3) were added to a 20 m*l* testtube, in that order. The volume of the solution was made up to 20 m*l* with distilled water and mixed well. The absorbance of this colored solution was measured at 460 mμ. Ten μg of chlorine in the colored solution can be determined within 10% by this colorimetric method, and chlorine in samples with more than 0.01% (100 ppm) chlorine can also be determined within 10%, by taking one-fifth of the distillate. The precision of this distillation method, which actually was examined in detail on the determination of bromine, is presented in Table 2.

Bromine. Four milliliters of the solution of chlorine and bromine, 1.0 m*l* of 1 N dihydrogen sodium phosphate solution (to adjust pH to about 6.3) and 0.5 m*l* of 1 N sodium hypochlorite solution (1 N NaClO in 0.1 N NaOH sol.) were added to a testtube which was kept in the boiling water for 15 min, and cooled with tap water for a few minutes. A half m*l* of 50% sodium formate solution was added. The testtube was again warmed in boiling water for 15 min, and cooled with tap water for 30 min. On the other hand, 0.5 m*l* of bromide-molybdate solution (0.15 g of KBr and 3.0 g of $(NH_4)_67Mo_7O_{24} \cdot 4H_2O$ in 100 m*l* of H_2O), 0.5 m*l* of rosaniline solution (0.006 g of $C_{20}H_{20}N_3OH$ in 100 m*l* of 2 N H_2SO_4 sol.) and 1 m*l* of 14 N sulfuric acid were put into a 20 m*l* flask in this order and mixed well. The above prepared solution was added slowly to this flask and stirred. After precisely 5 min, 10 m*l* of *t*-butyl alcohol ($(CH_3)_3COH$ containing 5% C_2H_5OH) was added and mixed well. After 5 min, 1 m*l* of 14 N sulfuric acid was added. The volume of the solution was made up to 20.0 m*l* with distilled water and mixed well. The absorbance of the colored solution was measured at 570 mμ. The smallest detectable amount of bromine in specimens is 0.5 μg, and the error in determination less than 0.5 μg. Hence, as 3 g of sample can be treated at a distillation, bromine in samples with more than 0.00002% (0.2 ppm) bromine can be determined with an error of less than 0.2 ppm. The relationship between the recovery of bromine and the volume of the distillate and precision of the determination are presented in Tables 1 and 2, respectively.

TABLE 1. RELATIONSHIP BETWEEN THE RECOVERY OF BROMINE AND THE WATER VOLUME DISTILLED

Analysis number	Watere volume distilled (m*l*)	Amount of bromine (μg)		Recovery (%)

Soluble Chlorine and Bromine. Two grams of sample per determination were soaked in 50 m*l* of water for 24 hr at room temperature, and stirred occasionally. One drop of concentrated nitric acid was added to the solution, and it centrifuged. The precipitate was soaked again in 50 m*l* of water containing one drop of concentrated nitric acid for 24 hr, and centrifuged. This procedure was repeated till the amount of leached chlorine in the water becomes negligibly small. The process usually was repeated two or three times. The amounts of chlorine and bromine leached in water were determined separately by the method described above.

Samples

Samples for the present study consist of 28 volcanic and 14 plutonic rocks collected from various parts of Japan. Rock species and localities of specimens are briefly described in Tables 3 and 4, to-

gether with the chlorine and bromine contents. The analyzed minerals were roughly separated first with a magnetic separater, and then hand-picked under a microscope.

Result and Discussion

1) Br/Cl Ratios in Volcanic Rocks. Results of the determinations of chlorine and bromine in volcanic rocks are given in Table 3.

Kuroda and Sandell[8] (1953) and Iwasaki *et al*[6] (1957) have stated that the amount of water-soluble chlorine is generally very small compared with the total amount of chlorine in rocks which are fresh and not contaminated by sea-water. Also Iwasaki and Katsura[9] (1964) stated that the amount of water soluble chlorine in Hawaiian lavas is small and almost constant, and a rather large amount of the water-soluble chlorine found in rock specimens is supplied by sea-water. The present author determined the amount of water-soluble chlorine to see if the chlorine in rocks is due to secondary contamination. The results showed that the amount of water-soluble chlorine in rocks was within 30% of the total chlorine content, except in specimens Nos. 4 and 6. This percentage is normal for previously reported fresh rocks. Moreover, in the discussion of the Br/Cl ratio, such an amount of water-soluble chlorine does not seriously affect the ratio, even if almost all of this water-soluble chlorine is secondary. Most of the water-soluble chlorine in specimens No. 4 and No. 6 might be secondary, however, the Br/Cl ratio in them falls in the range for ordinary rocks. In Table 3, it is noticed that both chlorine and bromine contents are scattered over a wide range, from 30 to 1020 ppm for chlorine, and from 0 to 5.5 ppm for bromine. The abundance of these lements, however, does not show any marked relationship to the type of rock, as shown in Figs. 2 and 3. Some glassy rocks show much higher chlorine and bromine contents. These results coincide with what has been given by Iwasaki *et al.*[6] (1957) on the chlorine content of volcanic rocks in Japan, and by Kokubu[10] (1956) on fluorine. Figure 4 shows the relationship between chlorine and bromine contents. No distinct linear relationship is seen between them. Br/Cl ratios, however, are mostly involved in the range from 1×10^{-3} to 6×10^{-3}, apparently lower than those reported by Behne. On the average: 200 ± 100 ppm for chlorine, 0.3 ± 0.2 ppm for bromine and $(3\pm2)\times10^{-3}$ for Br/Cl ratio. A comparison of the values of Behne and those of the present author gives about the same value for chlorine, about one-tenth for bromine and about one-seventh for the Br/Cl ratio. This discrepancy for bromine is too large to be accounted for only by the difference in methods of determintion.

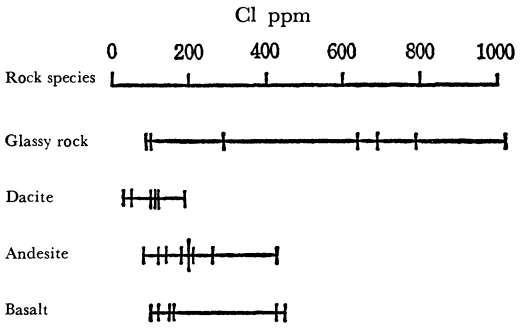

Fig. 2. Relationship between chlorine content of rocks and rock species.

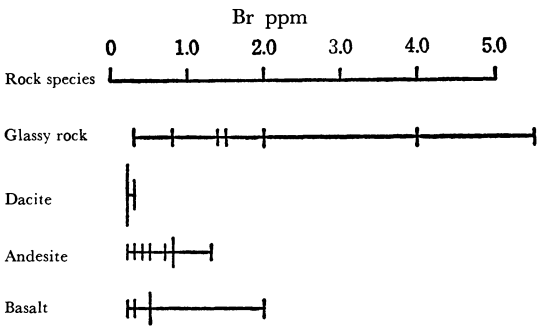

Fig. 3. Relationship between bromine content of rocks and rock species.

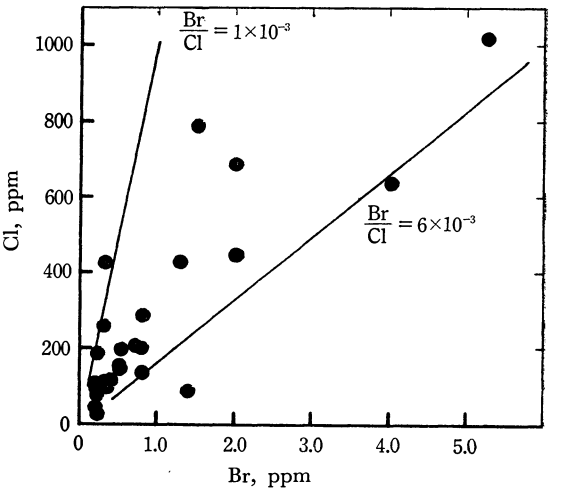

Fig. 4. Relationship between chlorine contents and bromine contents.

2) Br/Cl Ratios in Plutonic Rocks. The results are presented in Table 4, together with the chlorine and bromine contents of minerals in the rocks. Of plutonic rocks, only pegmatite, granite and a few other types of rocks have been analyzed, since it became clear in an early stage of this study

8) P. K. Kuroda and E. B. Sandell, *Anal. Chem.*, **22**, 1144 (1950).

9) B. Iwasaki and T. Katsura, This Bulletin, **37**, 1827 (1964).

10) N. Kokubu, *Kyushu Univ. Ser. C., Chemistry*, **2**, 95 (1956).

that the abundance of bromine in plutonic rocks is generally very small and the exact determination of bromine impossible for most specimens by the method employed. The chlorine content of the rocks analyzed, which contained negligibly small amounts of water-soluble chlorine and were believed to be uncontaminated by sea-water or other sources of contamination, is ordinarily 10—40 ppm, and a maximum of 100 ppm. The amount of chlorine in most rocks in this study is too small to be accurately determined. The situation is the same for bromine. The calculated Br/Cl ratios for these rocks are, of course, uncertain. However, the average Br/Cl ratio in plutonic rocks certainly is not as high as 21×10^{-3}, which was given by Behne. The highest value in any determination was 10×10^{-3}. The average Br/Cl ratio would then be the same as the average in volcanic rocks, $(3\pm2)\times10^{-3}$ or less.

3) Br/Cl Ratios in Biotite and Coexisting Quartz and/or Feldspar. Br/Cl ratios in plutonic rocks are still uncertain for most specimens. In order to examine the ratios obtained for these rocks, the author determined the Br/Cl ratios in biotite, and in quartz and feldspar coexisting with biotite. Biotite is considered to contain the greatest amount of chlorine in plutonic rocks, and is said to contain an appreciable amount of halogen in its crystal lattice. Chlorine and bromine in quartz and feldspar occur in quite a different manner from biotite. However, as shown in Table 4, bromine could not be determined accurately for most specimens, even for biotite containing a considerably high amount of chlorine. Yet, from these values, it was found that the Br/Cl ratio in these plutonic rocks is considerably smaller than the value reported by Behne, because the Br/Cl ratio in biotite, which seems to contain most of the chlorine found in these rocks, is certainly very small, 2×10^{-3} at maximum.

4) Relationship between the Br/Cl Ratios in Volcanic Rocks and in Volcanic Gases. Table 5 shows the chlorine and bromine contents and also the Br/Cl ratios in volcanic rocks and gases from a few volcanoes in Japan. For the Br/Cl ratio in volcanic gases, as mentioned above, it was confirmed in an earlier study[1] (1963) that they are more or less affected by many factors, and are usually in the range from 1×10^{-3} to 3×10^{-3} in weight ratio. The Br/Cl ratios in volcanic gases presented here are representative of the values obtained for each volcano in an earlier study[1] (1963). The Br/Cl ratio in rocks is somewhat larger than that in gases at Showashinzan, Fujusan and Issaikyoyama, while it is a little smaller than that at Chausuyama and Miharayama.

TABLE 5. THE CHLORINE AND BROMINE CONTENTS OF VOLCANIC ROCKS AND VOLCANIC GASES FOR 5 VOLCANOES IN JAPAN

5) Average Br/Cl Ratio in Igneous Rocks. Concerning the Br/Cl ratio in volcanic rocks, Kogarko and Gulyayeva[11] (1965) studied the halogen contents of the alkaline rocks of the Lovozero massif, and revealed that the chlorine and bromine contents of these rocks are normally in a linear log relationship independent of the rock species, and that the average Br/Cl ratio in the Lovozero rocks is about 1×10^{-3}. There are few determinations of the Br/Cl ratio in plutonic rocks. Filby[4] (1964) determined the bromine contents of standard rocks, granite G-1 and diabase W-1, by a neutron activation analysis developed by himself, and obtained values of 0.484 and 0.496 ppm for bromine of G-1 and W-1, respectively. These values are considerably lower than the averages for granites and basalts previously reported by Behne. The Br/Cl ratios of the standard rocks calculated with the chlorine contents determined by Kuroda *et al.*[12,13] (1950, 1951) are 5.7×10^{-3} for G-1, and 2.3×10^{-3} for W-1.

Most of the fluorine and chlorine in plutonic rocks is generally thought to exist in apatite or in minerals which contain OH^- in their crystal structure, replacing OH^-. This would be the case for bromine in rocks, also. The bromine to chlorine ratio, however, would be smaller in such minerals than in the liquid phase. The reason for this would be that the ionic radius of chlorine (1.81 Å) is closer to that of OH^- (1.40 Å) than that of bromine (1.96 Å), and the electron affinity of chlorine (3.82) is also stronger than that of bromine (3.54). It is realized that the Br/Cl ratio in biotite was very small in this study.

The Br/Cl ratio in volcanic rocks was roughly the same as that in volcanic gases at each volcano studied. However, as the Br/Cl ratio in volcanic gases has been reported to be $(1-3)\times10^{-3}$ in general, the average ratio obtained for volcanic rocks, $(3\pm2)\times10^{-3}$, is in rather good agreement with these values.

From the above, the average Br/Cl ratio obtained in this study is thought to be more reliable than previous values.

12) P. K. Kuroda and E. B. Sandell, *Anal. Chem.*, **22**, 1144 (1950).
13) P. K. Kuroda and E. B. Sandell, *ibid.*, **22**, 1304 (1951).

Summary

1) Both chlorine and bromine contents of volcanic rocks are distributed over a wide range with no relation to rock types. The Br/Cl ratios, however, are restricted within a rather narrow range independent of their amounts in rocks, and the average value is $(3\pm2)\times10^{-3}$ by weight.

2) The average Br/Cl ratio in plutonic rocks is not so large as previously reported, but is the same as or less than the average in volcanic rocks.

3) The bromine contents of biotite, quartz and feldspar have not been determined accurately for most specimens, but it is certain that the Br/Cl ratio in biotite which contains most of chlorine in the rocks is very small.

4) The Br/Cl ratio in volcanic rocks and in volcanic gases at each volcano are nearly same in all volcanoes studied.

5) Taking account of these results together with the reports of Kogaruko and Gulyayeva[11] (1965), and others, the average Br/Cl ratio, $(3\pm2)\times10^{-3}$ in volcanic rocks seems to be more acceptable than the previous one, 21×10^{-3}.

Thanks are particularly due to Professor S. Oana, Department of Earth Sciences, Nagoya University who gave guidance throughout this study. Thanks are also due to Dr. N. Nakai, Department of Earth Sciences, Nagoya University for his valuable advice. The present author wishes to express his hearty thanks to Dr. Y. Mizutani, Department of Earth Sciences, Nagoya University who encouraged him with many useful suggestions and Mr. K. Shiraki who supplied him with many excellent samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1139—1142 (1968)

Kinetics of Isotopic Exchange between 8-Quinolinol-^{14}C and Tris-8-quinolinolato Complexes of Tervalent Typical Elements

Kazuo SAITO, Michihiko TAKAHASHI, Yukio MIYAKAWA*[1] and Kazuyo MASUDA

Chemistry Department, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 20, 1967)

Rate of isotopic exchange between 8-quinolinol-^{14}C and the 8-quinolinolato (oxinato) complexes of aluminum, gallium and indium has been studied in chloroform. Pure yellow complexes are precipitated by adding petroleum ether to the reaction mixture. The exchange rate decreased in the sequence In>Al>Ga, and a detailed kinetic study can be substantiated only with the gallium complex below 0°C. The rate is proportional to the concentration of the complex, but is independent of that of free 8-quinolinol (quinolH) and the Arrhenius activation energy is 18 kcal per mole. The reaction is accelerated by acid and presumably by water. It appears as if one of the ligands is present as unidentate under the given condition and the break of the remaining bond would be the rate determining step. Any reagent that can retard the recombination of the free end of unidentate ligand would catalyse the exchange reaction.

Typical elements of group III in the periodic table are regarded as substitution labile.[1] One of us, however, exemplified that trisacetylacetonato- and tris-8-quinolinolatoindium exchange radioactive indium at a measureable rate in chloroform at room temperature.[2] Recently we studied the isotopic exchange kinetics of trisacetylacetonatoaluminum in tetrahydrofuran.[3] The reaction mechanism was a dissociative nature and the break of unidentate ligand seemed to be the rate determining step. The reaction was accelerated by water and some kinds of organic acids, which appear to retard the recombination of the free end of unidentate acetylacetonate. It seems thus particularly interesting to examine the rate of isotopic exchange of 8-quinolinolato complexes, having a more rigid framework structure, and oxygen and nitrogen as coordinating atoms.

The solubility of tris-8-quinolinolato complexes of aluminum, gallium, indium and thallium(III) has been extensively examined in a variety of organic solvents, and it was found that the aluminum, gallium and indium complexes are precipitated in a pure state from their chloroform solutions by adding petroleum ether. However, the same procedure was not useful for obtaining pure thallium(III) complex, and

3) K. Saito and K. Masuda, This Bulletin, **41**, 384 (1968).

the exchange rate was studied with only the three kinds of complex. The precipitation is not affected by excessive ligand and some kinds of organic acid including *m*-toluic.

The rate of exchange decreased in the sequence indium, aluminum and gallium and detailed kinetic studies have been made only with the gallium complex below 0°C. The influence of the concentration of the complex, the free ligand and other ingredients has been carefully examined and a probable reaction mechanism posturated.

Experimental

Materials. 8-Quinolinol-^{14}C was synthesized by Scraup's method modified to suit for small scale preparation.[4] Aniline-^{14}C (0.1 mCi, 5.3 m*l*), glycerin (17.2 m*l*), nitrobenzene (3.5 m*l*), iron(II) sulfate (heptahydrate 2.0 g) and concentrated sulfuric acid (10.0 m*l*) were boiled for about five hours, cooled to about 100°C, and steam-distilled for 30 min, to remove unchanged nitrobenzene. The residual solution was neutralized with 40% sodium hydroxide solution (*ca.* 30 m*l*) and the quinoline steam-distilled together with remaining aniline. The organic layer of the distillate was treated with concentrated sulfuric acid (3.8 m*l*), cooled to 0—5°C, treated with excessive saturated sodium nitrite solution (5.0 m*l*), warmed on a steam bath for about an hour, and steam-distilled to remove volatile materials. The product treated with 40% sodium hydroxide solution (15.0 m*l*) and steam-distilled to collect crude quinoline, which was distilled and the dry colorless distillate (*ca.* 5 m*l*) was dropped into fuming sulfuric acid (10.0 m*l*) below 90°C. The darkcolored solution was warmed at 70°C for about 40 hr in anhydrous atmosphere, cooled and poured into cold water. Precipitated colorless prisms were filtered off, washed with water, recystallized from hot water and dried (6.27 g). Sodium hydroxide (12.0 g) and water (3 m*l*) were heated at 270°C with stirring, mixed with the quinoline 8-sulfonic acid powder, kept at the temperature for 10 min and chilled. The cake was broken, dissolved in an excess of hydrochloric acid (5 N 70 m*l*), neutralized, and steam-distilled. (Yeild 2.1 g 8-quinolinol-^{14}C)

8-Quinolinolato complexes of aluminum, gallium and indium were prepared by the method ordinarily used for gravimetric analysis, from commercial 8-quinolinol and appropriate salts of the metals.

Commercial chloroform was shaken with concentrated sulfuric acid, then 5% sodium hydroxide solution and water, dried with phosphorus pentoxide and distilled immediately before use.

m-Toluic acid was recrystallized from water and sublimed at 105°C at 5 mmHg. Commerical anisol was shaken with sodium hydroxide solution, dried with calcium chloride, refluxed with sodium and distilled. *p*-Terphenyl was recrystallized from xylene. *p*-Di-(5-phenyl-2-oxalozyl)-benzene (POPOP) was of scintillation grade and used without further purification. Other chemicals were of all chemically pure grade.

Experimental Procedure. Weighed amounts of the complex (65 to 250 mg) and the ligand (18 to 73 mg) were dissolved in 10 m*l* portions of chloroform separately (both $\simeq 10^{-2}$ M). Other reagents such as *m*-toluic acid were previously added to the solvent whenever necessary. Both solutions were kept in a bath at −5.0 or −20°C, and mixed after their temperature reached constant. At appropriate intervals, an aliquot ($\simeq$2 m*l*) was added to chilled petroleum ether (20 m*l*) to stop the reaction. Pure 8-quinolinolato complex was separated instantaneously free from excessive ligand. The precipitate was swiftly filtered off with filter paper, washed with petroleum ether, and dried at 110°C. The time required for this separation was about 2 min. Purity of the precipitate was checked by its absorption spectrum and the chemical analysis of the metal with EDTA. Absorption spectra of the reaction mixture disclosed that no reaction other than isotopic exchange was taking place in the reaction mixtures.

Measurement of Radioactivity. One mg of the precipitate was dissolved in 15.0 m*l* anisol, and mixed with 15.0 m*l* of anisol solution containing 0.02% POPOP and 0.8% *p*-terphenyl. The counting rate was measured by the scintillation technique with a coincidence liquid scintillation counter.[3] The 8-quinolinolato complexes have yellow color and provide quite significant quenching effect. The influence was examined with standard ^{14}C-benzoic acid and the inactive 8-quinolinolato complexes, to obtain calibration curves, with which the counting rate was duly corrected. The scintillation efficiency was *e.g.* 50.0% in the presence of 1.0 mg of the gallium complex in 30 m*l* of the liquid scintillator. The counting rate at the end of isotopic exchange reaction (infinite time) was calculated from that of the 8-quinolinol-^{14}C and the used amounts of the respective complexes.

Water contents in the chloroform and the reaction mixtures were determined by Karl Fischer titration. The ultraviolet absorption spectra were measured with Hitachi EPU-3 spectrophotometer and the infrared absorption spectra with Hitachi FIS-1, and EPI-2G spectrophotometer.

Results

The experimental data were treated with McKay's equation

$$R = -2.303\frac{3ab}{3a+b}\cdot\frac{\log(1-F)}{t} \qquad (1)$$

where a and b express the concentrations of the 8-quinolinolato complex (containing 3 mol of exchangeable ligands per mole) and 8-quinolinol, respectively. F is the fraction of reaction and t the lapse of time (in minutes). The plots of $\log(1-F)$ *vs.* t were all linear to permit the treatment with Eq. (1). The approximate rates of the ligand exchange of 8-quinolonolato complexes were as follows:

Indium complex, too rapid to be measured

Aluminum complex, half period ($t_{1/2}$), 10 min at −20°C, a=0.01 M

Gallium complex, measurably slow below 0°C.

Detailed kinetic studies were substantiated only with the gallium complex. About 10% zero-time exchange was observed throughout the studies with the gallium complex. The figure is reproducible and seems to be separation induced exchange. The

4) G. E. McCasland, *J. Org. Chem.*, **11** 277 (1946).

time zero of each kinetic run was taken as that the first aliquot was taken from the reaction mixture, *e.g.* 5 min after the mixing of the solutions. The experimental error involved in obtaining indiviual R values was less than 9%. The temperature deviated by less than 1°C from one kinetic run to another, but remained unchanged within an error less than 0.2°C during a given run.

The dependence of R on a and b is indicated in Fig. 1 and Table 1, respectively. They show that R is proportional to a and independent of b in the examined concentration ranges. Hence, R is expressed by Eq. (2).

$$R = k[\text{complex}] = ka \qquad (2)$$

The influence of water could not be examined. Saturated water concentration in chloroform at −20°C was 0.019 M. In the presence of more water, excessive water freezes on the surface of chloroform. The best dehydrated chloroform contained 0.016 M water immediately after distillation. However, even such a batch gave floating ice on the surface, whenever used as reaction medium, presumably owing to absorption of moisture from atmosphere. Thus the reaction mixture should be regarded as always saturated with water at the given temperature.

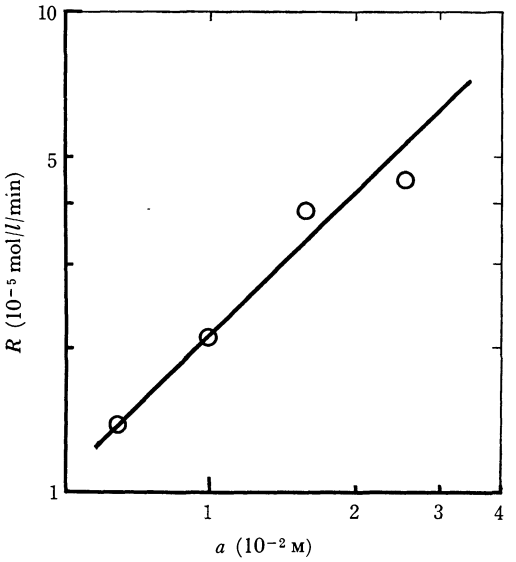

Fig. 1. Influence of the concentration of the gallium complex (a) on the exchange rate in chloroform. (−21.2°C, b=0.010 M)

Table 1. Influence of the concentration of free ligand (b) on the exchange rate of gallium in chloroform (a, 0.010 M)

t, °C	b, M	R,mol/ l /min
−5.0	0.010	2.1×10^{-4}
	0.030	1.8×10^{-4}
	0.040	1.9×10^{-4}
−20.2	0.010	2.4×10^{-5}
	0.016	2.6×10^{-5}
	0.025	2.6×10^{-5}

The temperature dependence of R was measured at −5.0, −10.4, −21.2°C. Arrhenius activation energy was 18.6 kcal per mole.

This reaction is catalyzed by acid, although the kinds of acid used for this examination were limited owing to the solubility. The influence of *m*-toluic acid upon R is shown in Fig. 2. Hence R is expressed as Eq. (3).

$$R = ka = a(k_0 + k_a[\text{acid}]) \qquad (3)$$

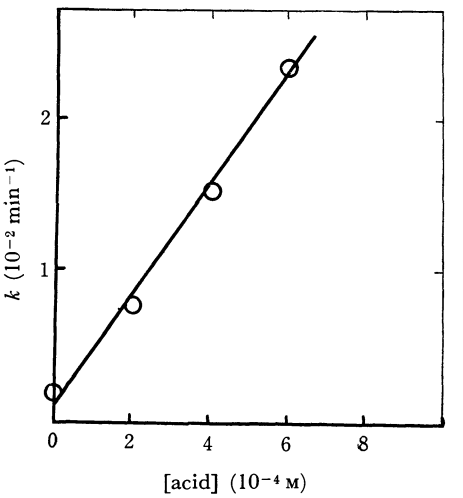

Fig. 2. Influence of the concentration of *m*-toluic acid on the exchange rate constant of gallium complex in chloroform. (−21.2°C, a=0.010 M)

Discussion

The mechanism would be of dissociative nature, because the exchange rate is independent of concentration of the free ligand. Since simultaneous break of two bonds, Ga–O and Ga–N, is not probable, we have to consider either that one of the ligands is present as unidentate and break of the remaining bond would be the rate-determining step, or that the break of one of the metal ligand bonds is the rate determining step and the liberation of unidentate ligand quite fast. In a kinetic study of isotopic exchange of trisacetylacetonato aluminum complex in THF, which gives similar kinetic formula, the two possible mechanisms were discriminated by examining the influence of water content upon the exchange rate.[3] In the present case, such a discrimination cannot be expected because we could not change the water content in chloroform. Hence Eq. (3) is only an apparent formula at a given concentration of water, in that the participation of water is not taken into consideration.

Nevertheless, the catalytic action of *m*-toluic acid could provide useful information. The proton could

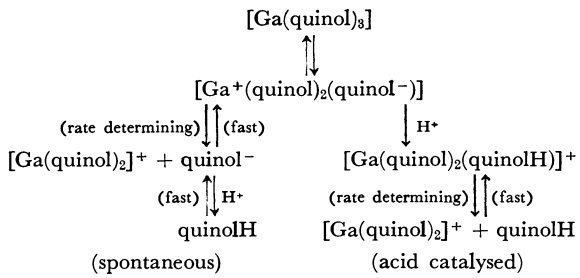

Fig. 3. Apparent mechanism of isotopic exchange for the gallium complex.

be transferred either to the free end of the unidentate ligand or to the coordinated oxygen. (Transfer to the negatively charged oxygen would be more feasible than to the nitrogen.) It remains again uncertain whether the proton is carried by the acid itself or by the hydronium ion, because the influence of water content upon the rate was neither known in the presence of acid. However, the proton would be more readily transferred to the negatively charged free end of unidentate ligand from the carrier, rather than the carrier reaches the co-ordinated oxygen atom making its way through the ligand sphere entangled with the bidentate chelates. Hence the plausible reaction mechanism would be postulated as seen in Fig. 3.

Eigen measured the exchange rate of coordinated water of various metal ions and found that the rate increases with increase in radii of ions with a given charge.[1] Hence the order of increasing reactivity among tervalent typical ions was aluminum, gallium, indium and thallium. The energy of hydration of the aquo complexes decreases in the same sequence and Eigen's order of reactivity is in accord with this order.

Our results are not consistent with his. The reason should be sought for in some factors characteristic of tris-8-quinolinolato complexes. If all the three complexes underwent isotopic exchange through similar dissociation mechanisms as exemplified by the gallium complex, their reactivity would be reflected, at least partly, in the stability of the tris complexes.

No reliable data are, however, available concerning the stability of tris-8-quinolinolato complexes of these metals. They form molecular lattice crystals and the solubility product[5] cannot be a good measure of stability. The shift of characteristic bands of the ligand in ultraviolet region due to complex formation was claimed to provide useful information concerning the stability of complexes with similar skeletal structure and symmetry.[6] Such a correlation cannot be always substantial, as exemplified by the comparison between the stability constants[7] and the absorption peaks of trisacetylacetonato complexes of these metals. The infrared absorption spectra in the region from 200 to 5000 cm^{-1} are too complicated for unambiguous band assignments to be made, and there is no concrete evidence that the force constant of metal-ligand bonds is simply interrelated with stability or lability of the complex.

Pritchard and Skinner compiled the electronegativity data of elements measured by various methods, and gave most probable values.[8] Since then, Allred and Rowchow[9] gave slightly different values obtained by electrostatic calculation, and Laubengayer *et al.*[10] compared the values for aluminum and gallium from proton magnetic resonance .data. All these estimations are consistent with one another in that the values for aluminum and indium are almost equal and that for gallium is significantly greater. Although the value for indium could become greater in some kinds of compound,[11] gallium seems always more electronegative than aluminum. If the reactivity of these complexes were governed by both the stability related to the electronegativity and the general reactivity represented in Eigen's experiment, the order of reactivity of tris-8-quinolinolato complexes, *i.e.* gallium < aluminum < indium, would not be very unreasonable.

The authors thank Nishina Memorial Foundation for grand in aid and Mrs. Yoshiko Doi (*née* Aizawa) for help in experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1143—1146 (1968)

Kinetics and Mechanisms of Thermal Decomposition Reactions of Cobalt(III) Complexes. Hexammine-, Halogenoammine- and Oxalatoamminecobalt(III) Complexes

Nobuyuki TANAKA and Kenzo NAGASE*1

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Saburo NAGAKURA

Institute of Solid State Physics, The University of Tokyo, Minato-ku, Tokyo

(Received November 29, 1967)

Kinetics of the thermal decomposition reactions of hexammine-,halogenoammine- and oxalatoamminecobalt(III) complexes in solid state has been studied by following the change in the cobalt(III) contents with time. It was found that the decomposition of these complexes was initiated by the change of the valence state of cobalt(III) to cobalt(II), and that these electron-transfer reactions were kinetically of a first order. The first-order rate constants, the activation energies and the frequency factors of these electron-transfer reactions were obtained. The values of the activation energies were found to increase in parallel with the increase in the difference between t_{2g} and e_g orbitals of the cobalt(III) complexes investigated. (The notations, t_{2g} and e_g, are used in the expression of an O_h-symmetry approximation for halogenoammine- and oxalatoamminecobalt(III) complexes.)

It has been reported that the thermal decomposition of cobalt(III) complexes in solid state is caused by the change of the valence state of cobalt(III) to cobalt(II); Tanaka and his co-workers[1-5] proposed that the decomposition of cobalt(III) and iron(III) complexes was initiated by an electron transfer from a ligand or an outer-sphere anion to the central metal(III) cation. Wendlandt *et al.*[6-8] also found the change of the valence state on the thermal decomposition of cobalt(III) and manganese(III) complexes.

In order to proceed a general consideration of the electron-transfer reactions on the thermal decomposition of cobalt(III) complexes, the present authors have undertaken the determination of the rates of these reactions. The activation energies and frequency factors were calculated from the first-order rate constants using the Arrhenius equation, and the mechanisms of the electron-transfer reactions were discussed.

Experimental

The apparatus and the procedure are described in a previous paper.[3] $[Co(NH_3)_6]X_3$(X=Cl, Br, I), $[Co(en)_3]Cl_3\cdot 3H_2O$, $[CoX(NH_3)_5]Y_2$(X, Y=Cl, Br), *trans*-$[CoCl_2(NH_3)_4]Cl\cdot H_2O$, $[Co(ox)(NH_3)_4]Cl$, $K[Co(ox)_2(NH_3)_2]\cdot H_2O$ and $M_3[Co(ox)_3]\cdot 3H_2O$(M=Na, K) were prepared according to the methods given in the literature (see Refs. 3 and 4).

Results

The preliminary measurements carried out with varied initial amounts of the samples had confirmed the relation given by the equation,

$$-dN/dt = kN \quad (1)$$

where N represents the number of cobalt(III) ions in the sample and k the first-order rate constant. Figure 1 shows the dependence of the reaction rate on the initial amount of the sample, indicating that the reaction follows the first-order rate law.

For the convenience of the treatment, Eq. (1) was modified to

$$\ln(1-x) = -kt \quad (2)$$

where x is the mole fraction of cobalt(II) in the sample. A plot of $\log(1-x)$ *versus* time was made for each complex at various temperatures, and nearly

$[Co(en)_3]Cl_3\cdot 3H_2O$	1.67(196), 1.99(199), 3.65(207)	34.9	2×10^{11}

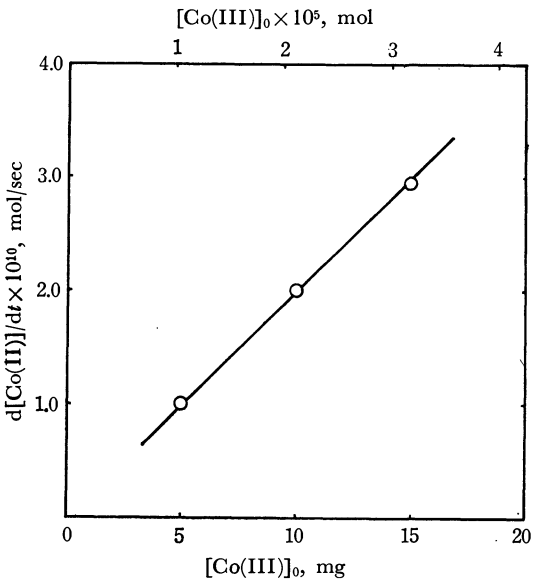

Fig. 1. Reaction rate as a function of the initial amounts of the sample ($[Co(III)]_0$) obtained with $K_3[Co(ox)_3]\cdot 3H_2O$ at 87°C.

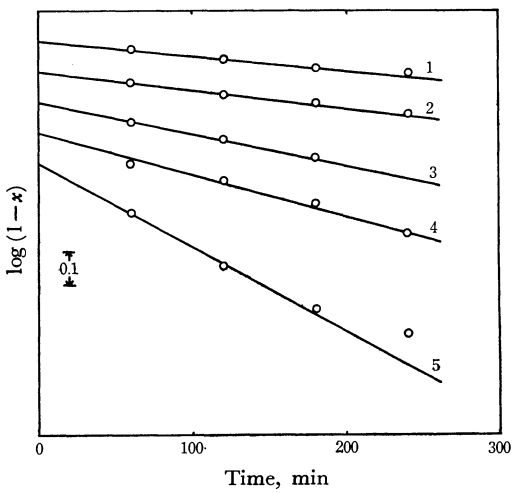

Fig. 2. Relation of $\log(1-x)$ *versus* time for $K_3[Co(ox)_3]\cdot 3H_2O$ at (1) 66, (2) 71, (3) 76, (4) 81 and (5) 87°C.

straight lines were obtained. The plots for $K_3[Co(ox)_3]\cdot 3H_2O$ are shown in Fig. 2 as an example. In the case of $[CoCl(NH_3)_5]Br_2$, $[CoBr(NH_3)_5]Cl_2$, $[CoBr(NH_3)_5]Br_2$ and $[Co(ox)(NH_3)_4]Cl$, the rate was considerably accelerated as the reaction took place and the plots showed a tendency of departing from the straight lines.

The first-order rate constants were determined from the plots of $\log(1-x)$ *versus* t at various temperatures, from which the activation energies and frequency factors were calculated. The kinetic parameters obtained are given in Table 1.

Discussion

The observed activation energies increase in parallel with the increase in the difference of e_g and t_{2g} levels, though they are somewhat lower than the transition energies of the A band of the absorption spectra of cobalt(III) complexes. This relation is shown in Fig. 3*1; the energies of the A bands are taken from the literatures.[9,10]

The cobalt(III) complexes investigated in this study have a singlet ground state and a triplet lowest excited state. Their symmetry notations are $^1A_{1g}$ and $^3T_{1g}$, respectively, in the expression of an O_h-symmetry approximation. The potential energy curves of the ground state of the cobalt(III) complexes and the lowest triplet state may be represented schematically with curves 1 and 2 in Fig. 4, respectively. The energy state given by curve 2 may

*1 Figure 1 in Ref. 5 should be replaced by this figure, in which the values of $\Delta E(^3T_{1g}-{}^1A_{1g})$ were recalculated.

mainly consist of electron configurations T_1 and T_2 which are shown in Fig. 5.*2 The latter is the charge-transfer configuration in the sense that it is

*2 Besides these two configurations, T_3 configuration which is given in Fig. 5 may contribute to the lowest triplet state. Its energy, however, is undoubtedly higher than that of T_2 and the contribution of T_3 to the lowest triplet state may conceivably be small. Therefore, it may safely be disregarded in the qualitative consideration made in the present paper.

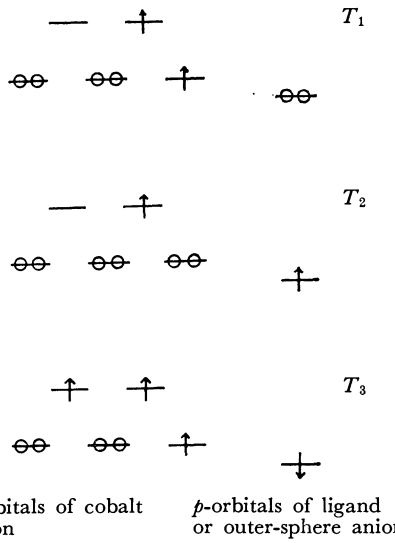

Fig. 5. Electron configurations of the triplet states of cobalt complexes.

brought about by an electron transfer from a ligand or an outer-sphere anion (X^-) to the central metal cation. The potential energy curves of T_1 and T_2 are also schematically shown in Fig. 4.*3 Curve 2 can be obtained as the result of the configuration interaction between T_1 and T_2.

At or near the point which corresponds to the equilibrium position of the reaction coordinate, T_1 is more stable than T_2, and therefore T_1 is the most important configuration in the lowest triplet state. With the increasing distance in the reaction coordinate, however, T_2 gradually approaches T_1, and they cross each other at point b. At more distant points, T_2 contributes to the lowest triplet state to a

*3 T_1 is stabilized by electrostatic interaction with decreasing distances between X^- and Co^{3+}. On the other hand, we can not expect the large electrostatic attraction in T_2 where X^- approaches Co^{2+}.

*4 It is difficult to discuss this point quantitatively, because the electron affinity of the central metal cation is very sensitive to its effective charge; namely 35.03 eV for Co^{3+}, 18.29 for Co^{2+} and 5.44 for Co^+. Let us now take as an example the case where X^- is an outer-sphere chloride anion. The energy difference between T_2 and T_1 in the infinite separation may be represented by $E_{T_2}-E_{T_1}=I_{X^-}-A_{Co^{\delta+}}+\Delta$, where I_{X^-} and $A_{Co^{\delta+}}$ are the ionization potential of X^- and the electron affinity of $Co^{\delta+}$, respectively, and Δ is the change in the electrostatic interaction energy between the central metal ion and ligands caused by the electron transfer. The value of Δ is also largely dependent on the δ value, because the positive charge on a ligand molecule, say NH_3, increases with the decreasing δ value.

In the case of $\delta=1$, Δ may be negative, because the electrostatic repulsion between $Co^{\delta+}$ and ligands with positive charge disappears, or at least decreases to a great extent, as the result of the electron transfer. $I_{X^-}-A_{Co^{\delta+}}$ is also negative for $\delta=1$, since $I_{X^-}=3.70$ eV and $A_{Co^+}=5.44$ eV. Therefore, $E_{T_2}-E_{T_1}$ turns out to have a negative sign and T_2 may be expected to be more stable than T_1 in the infinite separation. The above conclusion may conceivably be satisfied for the other δ values than 1.

greater extent than T_1. This may be inferred from the fact that, in the infinite separation between X^- and Co^{3+}, T_2 may conceivably be more stable than T_1.*4 From a similar reason, T_2 or curve 2 crosses curve 1 at point c in the reaction coordinate, as is shown in Fig. 4.

According to the potential energy curves shown in Fig. 4, the electron-transfer process leading to the decomposition of the complexes seems to occur passing through point c as is indicated by arrows given in Fig. 4. In other words, the transfer of the system from curve 1 to curve 2 occurs at point c being accompanied by the change in multiplicity and the electron transfer from a ligand or an outer-sphere anion to Co^{3+}.

In view of the different multiplicity in curves 1 and 2, the probability of the transfer will be small, and consequently the reaction will have a small transmission coefficient, which in turn will give a small value of the frequency factor. The observed frequency factors given in Table 1 support this consideration. The reactions which are kinetically of a first order have in usual the frequency factor of about 10^{13}.

Activity Measurements in Orthosilicate and Metasilicate Solid Solutions. I. Mg_2SiO_4-Fe_2SiO_4 and $MgSiO_3$-$FeSiO_3$ at 1204°C

Kenzo KITAYAMA and Takashi KATSURA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 7, 1967)

The activity-composition relations in ortho-, and metasilicate solid solutions in the FeO-MgO-SiO_2 system are determined at 1204°C on the basis of the measurement of equilibrium oxygen partial pressures. Both the olivine and the pyroxene solid solutions show significant deviations from ideality. Using the present data, the standard free energy change of formation of ferrosilite (hypothetical compound, $FeSiO_3$) is calculated to be -41.7 ± 0.2 kcal/mol on the basis of the equilibrium between metallic iron and silica, and to be -1.6 ± 0.2 kcal/mol on the wüstite (" FeO ") and silica.

Recently, much efforts are being concentrated on the thermodynamic properties of ortho-, and metasilicate equilibria found in some ternary oxide systems at high temperatures under one atmospheric pressure. Of these, the relationship between activity and composition of the olivine-components (orthosilicate) and the pyroxene-components (metasilicate) is no doubt of the fundamental problem to exactly understand the stable co-existence of these solid solutions. Schwerdtfeger and Muan[1] have determined the activities of a component Fe_2SiO_4 in olivine and of a component $FeSiO_3$ in pyroxene solid solutions in the FeO-MnO-SiO_2 system at 1150°C on the basis of the CO_2/CO ratio in the gas phase in equilibrium with co-existing solid solutions, and concluded that both solid solutions behave ideally. In their Appendix, Darken and Schwerdtfeger[2] made clear statistically the expression of activity of the component Fe_2SiO_4 in the olivine solid solution to be written as $a_{FeSi_{0.5}O_2}$ as empirically had been accepted by many investigators. Masse, Rosen, and Muan[3] also published the activity-composition relations in Co_2SiO_4-Fe_2-SiO_4 solid solution at 1180°C, and showed a slightly positive deviation from ideality. Biggers and Muan[4] presented the relations in ortho-, and meta-silicate solid solutions found in the MnO-CoO-SiO_2 system at 1200 and 1250°C. On the basis of these results, Muan[5] emphasized the importance of the conjugation lines between co-existing solid solutions. However, the activity-composition relations to the olivine and pyroxene in the FeO-MgO-SiO_2 system has not yet been experimentally studied.

Generally, it has been assumed that the olivine composing of iron and magnesium may behave ideally, and the various thermodynamic calculations have

been made on the basis of the ideality. For instance, Bowen and Schairer[6] calculated the molal heat of fusion of fayalite (Fe_2SiO_4) and forsterite (Mg_2SiO_4) in their classical paper, and Lamberg and DeVore[7] also postulated the ideality to calculate the distribution constant of iron and magnesium in co-existing olivine and pyroxene by using mole fraction. Bradley[8] found that the olivine solid solution is ideal, on the basis of the molal heat of fusions of fayalite and forsterite. Sahama and Torgesson[9] also presented the linearity found in the relationship between the heat of solution and the Mg/Fe ratio in the natural forsterite-fayalite series by means of the solution calorimetry, and indicated that the replacement of Fe and Mg in the olivine structure is thermally perfect. They also stated that the replacement of Fe to Mg in orthorhombic pyroxene structure is perfect too.

The present objectives are to find the activity-composition relations in the olivine and the pyroxene solid solutions in the FeO-MgO-SiO_2 system and to confirm whether or not these solid solution aresideal just as expected by many investigators.

Methods of Calculation of the Activities

The approximate diagram for the subsolidus phase equilibria in the FeO-MgO-SiO_2 system is known from the study by Bowen and Schairer[6] under low oxygen partial pressures, and Fig. 1 shows an isothermal section at 1204°C. In this system, there exist three solid solution series; the oxide, MgO-FeO, the olivine, Fe_2SiO_4-Mg_2SiO_4, and the pyroxene, $FeSiO_3$-$MgSiO_3$. The oxide and olivine solid solutions are continuous, but the pyroxene solid solution is a limiting as shown in Fig. 1, because of the instability of ferrosilite in ordinary temperature and pressure. From the present study, we found a point A and a point B in Fig. 1 to be 62 mol% fayalite and 48 mol% ferrosilite at 1204°C, respectively. The activity-composition relation in the oxide solid solution, FeO-MgO, has already been studied by Hahn, Jr., and Muan[10] in the temperature interval from 1000 to 1300°C, and they concluded that the system showed a considerable positive deviation from the Raoult's law.

Based on Fig. 1, it may be convenient to calculate the activity of the component Fe_2SiO_4, $a_{FeSi_{0.5}O_2}$, in the olivine solid solution and the activity of the component $FeSiO_3$, a_{FeSiO_3}, in the pyroxene solid solution as follows:

1) The Activity of Fe_2SiO_4 in Composition Ranging from Pure Fe_2SiO_4 to a Point A. Consider the following reaction,

$$FeSi_{0.5}O_2 = Fe + \tfrac{1}{2}\,SiO_2 + \tfrac{1}{2}\,O_2 \qquad (1)$$

in which pure fayalite dissociates to metallic iron, silica, and oxygen gas. For this reaction, the equilibrium constant, K_1, is expressed as

$$K_1 = [a_{Fe} \cdot a_{SiO_2}^{1/2} \cdot P_{O_2}^{1/2}(1)]/a_{FeSi_{0.5}O_2\text{-}(p)} \qquad (2)$$

where a represents the activity of each component shown by subscripts, in which $FeSi_{0.5}O_2$-(p) means for pure fayalite, and where $P_{O_2}(1)$ implies an oxygen partial pressure. Since the composition of fayalite is stoichiometric as confirmed by Kitayama and Katsura,[11] then the equilibrium constant, K_1, may be written as

$$K_1 = P_{O_2}^{1/2}(1) \qquad (3)$$

In the case of the solid solution, the same treatment is applied as follows,

$$(FeSi_{0.5}O_2)_{ss} = Fe + \tfrac{1}{2}\,SiO_2 + \tfrac{1}{2}\,O_2 \qquad (4)$$

in which the fayalite component in the olivine dissociates to form pure metallic ion and pure silica as in the reaction (1). The subscript ss means a solid solution, and the equilibrium constant, K_4, is also expressed as

$$K_4 = P_{O_2}^{1/2}(4)/a_{(FeSi_{0.5}O_2)_{ss}\text{-}(1)} \qquad (5)$$

where the subscript $(FeSi_{0.5}O_2)_{ss}$-(1) means the limiting solid solution from pure fayalite to the point A. From Eqs. (3) and (5), we get the following relation by using pure fayalite as the standard state for the activity of $FeSi_{0.5}O_2$,

$$a_{(FeSi_{0.5}O_2)_{ss}\text{-}(1)} = P_{O_2}^{1/2}(4)/P_{O_2}^{1/2}(1) \qquad (6)$$

because K_4 is equal to K_1.

2) The Activity of Fe_2SiO_4 in Composition Ranging from the Point A to Pure Mg_2SiO_4. In this region, the reaction of olivine is different from that of Eq. (4). If we follow experimentally the appearance of metallic iron by changing the oxygen partial pressure, then olivine solid solution may first dissociate as follows,

$$(FeSi_{0.5}O_2)_{ss} = \tfrac{1}{2}\,Fe + \tfrac{1}{2}\,(FeSiO_3)_{ss} + \tfrac{1}{4}\,O_2 \qquad (7)$$

The equilibrium constant, K_7, is

$$K_7 = [a_{(FeSiO_3)_{ss}}^{1/2} \cdot P_{O_2}^{1/2}(7)]/a_{(FeSi_{0.5}O_2)_{ss}\text{-}(2)} \qquad (8)$$

where the subscript $(FeSi_{0.5}O_2)_{ss}$-(2) means the range from the point A to pure Mg_2SiO_4. The pyroxene thus appeared will subsequently decompose at an oxygen partial pressure defined by the following Eq. (9),

$$\tfrac{1}{2}\,(FeSiO_3)_{ss} = \tfrac{1}{2}\,Fe + \tfrac{1}{2}\,SiO_2 + \tfrac{1}{4}\,O_2 \qquad (9)$$

The equilibrium constant, K_9, is expressed as

6) N. L. Bowen and J. F. Schairer, *Am. J. Sci.*, **29**, 151 (1935).
7) H. Lamberg and G. DeVore, *J. Geol.*, **59**, 193 (1951).

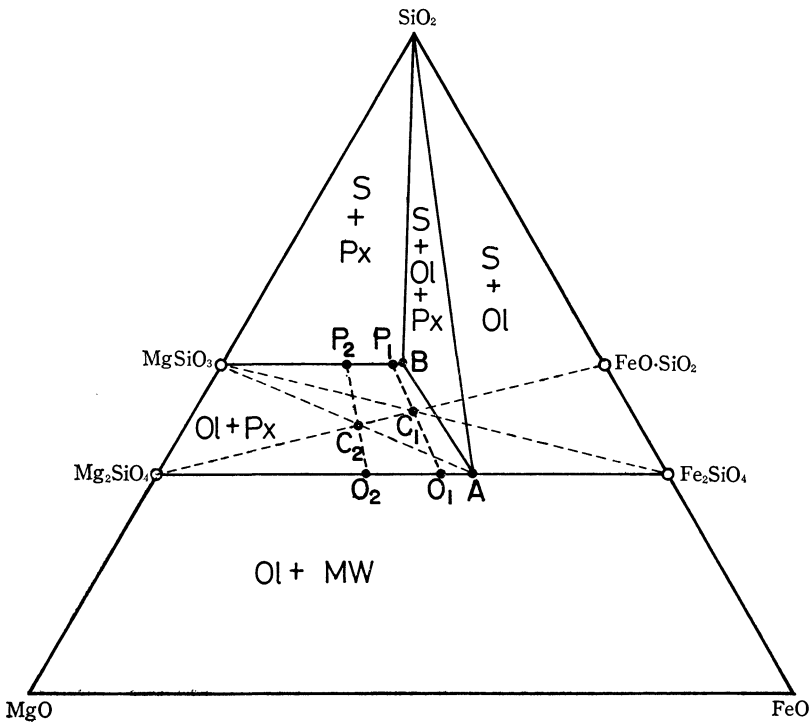

Fig. 1. The isothermal section for the system MgO-FeO-SiO_2 at 1204°C.
S: silica, Px: pyroxene, Ol: olivine, MW: magnesiowüstite

$$K_9 = P_{O_2}^{1/4}(9)/a_{(FeSiO_3)_{ss}}^{1/2} \qquad (10)$$

In the reaction (9), pure silica and iron appear as shown in Fig. 1, and there exists a relation, $K_4 = K_7 \cdot K_9$. Thus, we may obtain the Eq. (11), taking the pure fayalite as the standard state,

$$a_{(FeSi_{0.5}O_2)_{ss}} = [P_{O_2}^{1/4}(7) \cdot P_{O_2}^{1/4}(9)]/P_{O_2}^{1/2}(1) \qquad (11)$$

3) The Activity of $FeSiO_3$ in the Pyroxene Solid Solution. The activity of $FeSiO_3$ in the pyroxene solid solution is obtained by the same method as described above. As for the solid solution is concerned, the activity of $FeSiO_3$ is given by Eq. (10), taking an arbitrary composition as the standard state for the component $FeSiO_3$. If we want to take pure ferrosilite as the standard state, then we have to apply the extrapolation method. Here, we may apply the α-function method[12,13] to determine an oxygen partial pressure at which ferrosilite may decompose as shown in Eq. (9). After obtaining the oxygen partial pressure for pure ferrosilite, P_{O_2}(9-p), the activity of the component $FeSiO_2$ in pyroxene solid solution may be derived as

$$a_{(FeSiO_3)_{ss}} = P_{O_2}^{1/2}(9)/P_{O_2}^{1/2}(9\text{-p}) \qquad (12)$$

Experimental

Preparation of Olivine Solid Solution. Reagent grade chemicals are used. Ferric oxide is reduced to ferrous at 1200°C in an atmosphere of $CO_2/H_2 = 1$. After analyzing the ferrous content, the oxide is mixed with silica to prepare the stoichiometric fayalite having the Fe/Si ratio 1/2. The mixture is then heated at 1300°C to prepare the fayalite in the same atmosphere by using a Pt alloy (20%Rh) as a container which was previously saturated with iron. The melt is quenched and powdered. Forsterite is prepared as follows; Silica and magnesium oxide are stoichiometrically mixed and made uniform by using an alumina pot mill. The powder is heated at 1700°C by using a zirconia or a Pt alloy container. The quenched sample is powdered, and repeatedly heated at 1700°C. The iron content in fayalite and the magnesium in forsterite are analyzed by potassium permanganate and EDTA titration methods respectively. Both samples with various mole fractions are mixed to prepare the olivine solid solution.

About 5 g of each mixture is heated for 5 hr at 1200 to 1300°C by using a Pt alloy container under the atmosphere of $CO_2/H_2 = 1$. The prepared olivine solid solutions are checked by X-ray diffraction method and by chemical analysis. Yoder and Sahama,[14] and Eliseev[15] measured the d_{130} spacing of natural and

synthetic olivines, and showed the linearity between the d_{130} value and the composition. The relationship between the d_{130} value and the composition by the present study is in good accordance with those of the literature.

Preparation of Pyroxene Solid Solution. The silica and magnesium oxide are thouroughly mixed by a pot mill to prepare enstatite ($MgSiO_3$). The mixture is repeatedly heated at 1700°C by using a Pt alloy container to make it homogeneous solution. The glass thus obtained is finally crystallized at 1200°C to get the monoclinic structure. Since ferrosilite cannot synthesize in the present conditions, then ferrous oxide is mixed with silica so as to maintain the Fe/Si ratio of 1 for the "ferrosilite." The mixture with various ratios of enstatite and "ferrosilite" are heated at 1200°C to prepare the homogeneous pyroxene solid solutions. The pattern of the X-ray diffraction of the solid solution is complicated, but systematically changes with increasing ferrosilite component. The problem of the structure of pyroxene has not yet been solved as summarized by Morimoto,[16] but Dr. Kushiro[17] found the proto-type pyroxene in the present samples.

Apparatus. The furnace, the gas mixer, the electric controller system for temperature are the same as those used in a previously study.[18] Mixed gases of CO_2 and H_2 are used to obtain the oxygen partial pressure.

Procedure. The standard quenching techniques are adopted under controlled atmospheric condition. A sample of either olivine or pyroxene solid solution is kept at 1204±2°C and at a desired level of the oxygen partial pressure. After 24 hr, the sample is quenched in the brass tube connected to the bottom of the furnace tube. Then an oxygen partial pressure, at which metallic iron appears in the sample, is determined. The presence of metallic iron is detected by dipping the sample into a dilute hydrochloric acid solution as previously described.[19]

A Direct Determination of the Oxygen Partial Pressure. The actual oxygen partial pressure of the gas phase is determined by a solid electrolyte cell, and the details of the design and the measurement were described by Katsura and Hasegawa.[20]

Results and Discussion

Determination of Conjugation Lines between Olivine and Pyroxene Solid Solution. In order to determine the activity of $a_{(FeSi_{0.5}O_2)\text{-}(2)}$, the conjugation lines between olivine and pyroxene solid solutions must be determined; for this purpose, various mixtures of Mg_2SiO_4 and "ferrosilite," or of Fe_2SiO_4 and $MgSiO_3$ are heated at 1204°C and at an oxygen partial pressure of $10^{-11.0}$ atm to avoid an appearance of metallic iron or ferric oxide. The samples are quenched after a reasonable period of time, and the d_{130} value of the olivine phase coexisting with pyroxene is measured to determine the composition of the olivine by comparing with the d_{130} of the standard. In order to criticise the reasonable period of time for the equilibrium state, different combinations of the two solid solution series, but with the same bulk composition are used just at the same conditions. Examples are illustrated in Fig. 1 as points C_1 and C_2. From the careful measurement of d_{130} value, it was found that 48 hr heating is sufficient to the equilibrium state throughout the study. The conjugation lines are, then, drawn so as to pass the two points, for example, C_1–O_1, or C_2–O_2 in Fig. 1 to determine the composition of pyroxene solid solution, P_1 or P_2. The result of the equilibrium co-existence of olivine and pyroxene solid solutions are graphically illustrated in Fig. 2.

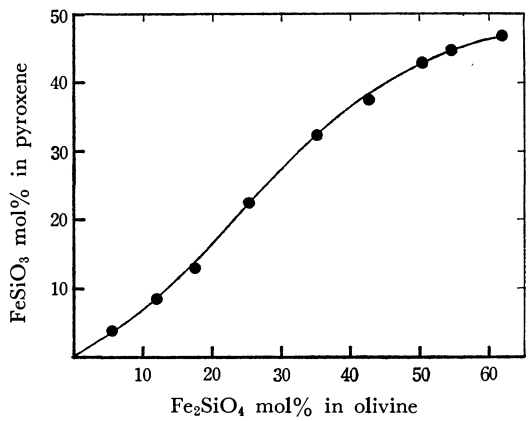

Fig. 2. The equilibrium composition between olivine and pyroxene solid solutions in terms of fayalite component in olivine and of ferrosilite component in pyroxene.

The Pyroxene Solid Solution. The values of the oxygen partial pressures of P_{O_2} (9) are given in Table 1, with the width of experimental errors. Activities calculated on choosing the composition of 48 mol% ferrosilite as an arbitrarily selected standard are also given in Table 1. The relationship between $[\log N_{FeSiO_3} - \frac{1}{2}\log P_{O_2}(9)]$ and $(1-N_{FeSiO_3})^2$, which is related to the α-function,[13] are illustrated in Fig. 3. An extrapolated value of $\log P_{O_2}$(9-p) for pure ferrosilite is determined to be -12.35 ± 0.03.

19) T. Katsura, B. Iwasaki, S. Kimura and S. Akimoto, *J. Chem. Phys.*, **47**, 4559 (1967).
20) T. Katsura and M. Hasegawa, This Bulletin, **40**, 561 (1967).

Activities calculated on the basis of choosing pure ferrosilite as standard are given in Table 1, and activity-composition relations are illustrated in Fig. 4, together with a curve for a_{MgSiO_3} calculated by a graphical integration of the Gibbs-Duhem equation. As may be seen in Fig. 4, the pyroxene system shows a significant positive deviation from ideality.

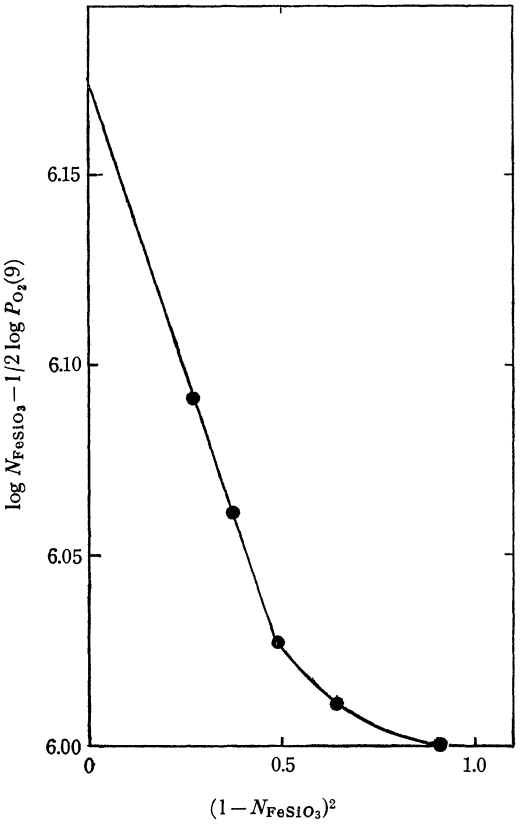

Fig. 3. Relationship between [log N_{FeSiO_3} − ½ log P_{O_2}(9)] and $(1-N_{FeSiO_3})^2$.

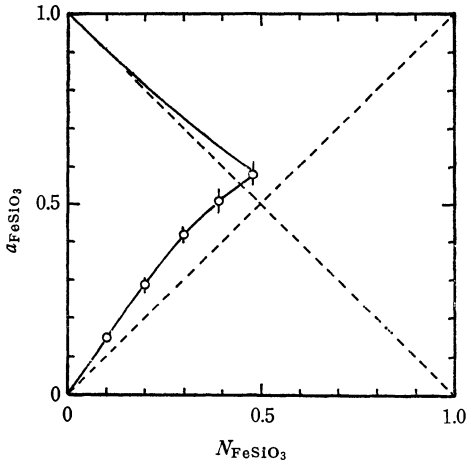

Fig. 4. Activity-composition relations in pyroxene solid solution at 1204°C.

Using the value of P_{O_2}(9-p), the standard free energy change of formation of ferrosilite, Fe(metal) + SiO_2(tridymite) + ½O_2 = $FeSiO_3$, is calculated to be −41.7±0.2 kcal/mol at 1204°C. Combining this with the value of the standard free energy change of formation of wüstite at 1204°C obtained by Darken and Gurry,[21] the free energy change of formation of ferrosilite from wüstite and silica is determined to be −1.6 kcal/mol. Akimoto *et al.*[22] gave the value of −1.4 kcal/mol at 1204°C on the basis of their high pressure synthesis of orthoferrosilite, Schwerdtfeger and Muan[1] gave −1.3±0.3 kcal/mol at 1150°C, and Muan *et al.*[13] gave −1.3±0.3 kcal/mol for the same reaction. Thus the present value is agreed well with those values obtained by different methods of determination.

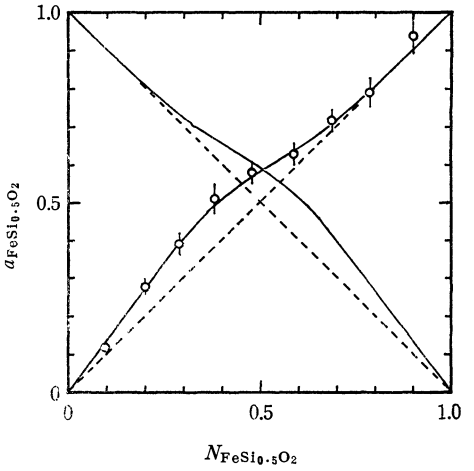

Fig. 5. Activity-composition relations in olivine solid solution at 1204°C.

The Olivine Solid Solution. The results for the olivine solid solution are given in Table 2. The values in the second and third columns are of the oxygen partial pressures of P_{O_2}(7) and P_{O_2}(4), respectively. The fourth column shows the composition of pyroxene co-existing with olivine with the composition in the first column, and obtained from Fig. 2. The fifth column shows the values of the P_{O_2}(9) obtained by interpolation of the values in Table 1.

The activity-composition relation in olivine solid solution is graphically illustrated in Fig. 5 with the experimental errors. A curve for $a_{MgSi_{0.5}O_2}$ is also drawn by a graphical integration of the Gibbs-Duhem equation. As may be seen in Fig. 5, the system displays a significant positive deviation from the ideality.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1151—1153 (1968)

The Reaction of the Ester with Acyl Chloride in the Presence of Aluminum Chloride. VIII.[1] The Attempted Synthesis of the Carbethoxy Derivative of Polymalonylphenylene*[1]

Kiyotada MATSUI, Masatoshi MOTOI, Tetsuro NOJIRI and Kohtsuchi WAKABAYASHI*[2]

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa

(Received December 17, 1966)

The treatment of ethyl acetoacetate with terephthaloyl chloride in the presence of two equivalents of aluminum chloride in nitrobenzene at 55°C affords a polymer which may be designated as an aluminum chelate of the polymalonylphenylene derivative with some carbethoxy groups.

Recently we have reported that aluminum chloride is an effective agent for the acylation of active methylene group in compounds, such as diethyl malonate[2] or ethyl acetoacetate,[1,3] with acid chloride. For example, the reaction of ethyl acetoacetate with two equivalents of benzoyl chloride in the presence of a small amount of aluminum chloride in nitrobenzene at 35°C gave ethyl benzoylacetate, a small amount of ethyl benzoylacetoacetate, and traces of ethyl dibenzoylacetate and dibenzoylmethane. When the reaction was carried out by bubbling dry nitrogen gas into the reacting mixture, the yields of the above β-diketo esters and of dibenzoylmethane were increased and that of ethyl benzoylacetate was decreased. Under similar conditions, however, the use of a larger amount of aluminum chloride at the temperature of 55°C afforded dibenzoylmethane and its aluminum chelate in higher yields, besides small amounts of ethyl benzoylacetate, ethyl dibenzoylacetate, and tribenzoylmethane. Thus, the pathway of this reaction may be expressed as follows:

1) Part VII: T. Nojiri and K. Matsui, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **87**, 880 (1966).

*1 Presented at the 19th Annual Meeting of the Chemical Society of Japan, Yokohama, April, 1966.

*2 Present address: Teijin Co., Matsuyama Plant, Ehime.

2) H. Kaneyuki, This Bulletin, **35**, 519, 523, 713 (1962).

3) K. Matsui and T. Nojiri, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **86**, 531 (1965).

$$CH_3COCH_2COOC_2H_5 \rightleftarrows CH_3COCHCOOC_2H_5 \rightleftarrows C_6H_5CO$$

$$C_6H_5COCH_2COOC_2H_5 \rightleftarrows$$

$$(C_6H_5CO)_2CHCOOC_2H_5 \rightarrow (C_6H_5CO)_2CH_2 \rightleftarrows (C_6H_5CO)_3CH$$

In view of the above facts, the fact that the formation of di- and tri-benzoylated methane derivatives is accompanied by cleavages of carbon-carbon linkages suggests that ethyl acetoacetate may behave as a polyfunctional molecule toward acid chloride. It is the purpose of this paper to report the possibility of the formation of a polymer bearing the β-diketo structure, which will be formed by the above condensation reaction with terephthaloyl chloride.

Some reports on the synthesis of this kind of polymer have been published. Oda[4] and Furukawa *et al.*[5] prepared the polymer by treating ketene or diketene with aluminum chloride, but its purification was difficult owing to the contamination of aluminum. Nose *et al.*[6] also reported how polymers could be prepared from dimethyl terephthalate and the *p,p'*-diacetyl derivative of diphenyl ether or diphenylmethane by the use of metallic sodium.

When ethyl acetoacetate was treated with an equimolar amount of terephthaloyl chloride at 30°C by blowing nitrogen gas through the reaction mixture in the presence of a 0.5 equivalent of aluminum chloride in nitrobenzene, the resulting mixture was separated into ethyl *p*-carboxybenzoylacetate (I), diethyl terephthaloyldiacetate (II), an acidic (III) and a neutral polymer-like substance (IV), and a metal chelate polymer (V). Both III and IV are fusible, are soluble in ethanol or ether, and contain traces of aluminum, which combines to form a chelate more firmly than does aluminum chelating with dibenzoylmethane molecules.[1] In another run similar to the above, the viscous reaction mixture of the early stage was treated immediately with aqueous sodium hydroxide under the Schotten-Baumann conditions described in the Experimental section. The resulting mixture gave products similar to the above, but the acidic fraction, III, was of a relatively high molecular weight.

The infrared spectrum of III shows a broad absorption band, which corresponds to the β-diketo and carbethoxy absorption bands. Since this acylation reaction is often accompanied not only by a deacetylation reaction but also by a certain decarbethoxylation reaction, the structure of this substance is identified as that of a polymalonylphenylene derivative which does not contain as units, $-COCH_2COC_6H_4-$.
many carbethoxy groups as malonylphenylene

This substance was treated with aqueous sodium carbonate at room temperature in an attempt to hydrolyze its ester linkings. The infrared spectrum of the resulting product shows an absorption peak at 1362 cm^{-1} due to acetyl and the above-mentioned broad absorption, which is weakened in one region, as shown in Fig. 1. These features appear to be attributable to the ketonic hydrolysis of β-diketone linkings in the molecule. It should be noted that

the substance partly undergoes fission, although all of its ester linkings may not be hydrolyzed. The yields of products and some molecular weights are summarized in Table 1.

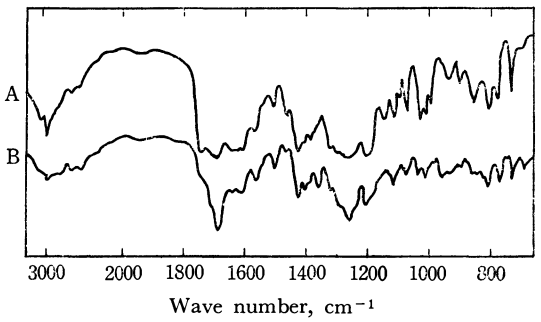

Fig. 1. Infrared spectra of carbethoxy derivative of polymalonylphenylene (KBr) (A) and its hyrdolyzed polymer (B).

When a similar treatment was carried out at 55°C in the presence of two equivalents of aluminum chloride but without passing nitrogen gas through, a vapor which seemed to be composed of carbon dioxide, hydrogen chloride, ethyl, and acetyl chloride bubbled out in a manner analogous to that in the reaction of ethyl acetoacetate with benzoyl chloride. The resulting product gave, in a very good yield, a polymer corresponding to V without any III and IV. It appears clear that this polymer was formed by the further condensation of the reaction intermediates corresponding to the substances, from I to V, though having its carbethoxy groups decreased markedly, as was expected from the above benzoylation reaction. The polymer is infusible, insoluble in ordinary organic solvents, swollen with ethanol on heating, and contains aluminum which can not be removed by any means. These findings suggest that aluminum is incorporated into stable intermolecular chelate linking to form the polymer. From the formation of tribenzoylmethane mentioned above, moreover, there is a possibility of a three-dimensional structure with some methine carbon atoms.

Experimental

Materials. The terephthaloyl chloride was prepared from phosphorus pentachloride and terephthalic acid which had been obtained by the hydrolysis of dimethyl terephthalate supplied by the Teijin Co., Ltd. Commercial ethyl acetoacetate was used after purification by distillation *in vacuo*.

Reaction of Ethyl Acetoacetate with Terephthaloyl Chloride. To a solution of aluminum chloride and terephthaloyl chloride in dry nitrobenzene, ethyl acetoacetate was added, and the mixture was kept in a thermostat at a given temperature. When it became gelatinous or viscous, the reaction mixture was poured into a mixture of hydrochloric acid and crushed ice. The aqueous solution containing aluminum chloride was removed from the organic layer by a centrifuge. The organic layer, after the removal of the nitrobenzene by steam distillation *in vacuo*, gave a solid which was then triturated with ether and filtered from an ether-insoluble chelate polymer. The filtrate was separated into an acidic and a neutral fraction by shaking with aqueous sodium bicarbonate. The former was extracted with hot water and purified by several reprecipitations from ethanol to water, thus giving an amorphous polymer-like substance. The hot-water extract obtained gave a crystal on cooling. Similarly, the latter, neutral fraction was separated into a crystal and a rather polymer-like substance by the use of ethanol and water. After the removal of the ether-insoluble substance which had formed during the above separations, the acidic, polymer-like substances generally melted at 120—130°C and the neutral, at 80—90°C. The molecular weights of the former were determined by the ebulioscopic method, using diethyl ether as a solvent.

Reaction under Schotten-Baumann Conditions. A viscous reaction mixture obtained as above was treated with ether (about 20 m*l*) and a 33% sodium hydroxide solution under conditions similar to those of the Schotten-Baumann reaction described in the literature.[7] The resulting mixture was separated into two layers by a centrifuge. Each layer was filtered to remove a rather insoluble substance. The organic layer gave a little viscous liquid on steam distillation *in vacuo*. The aqueous layer was then stirred into 6 N hydrochloric acid to give a solid of an acidic nature. The liquid and the solid were treated individually as above. A part of the acidic polymer-like substance was dissolved in aqueous sodium carbonate, left to stand for about 14 days at room temperature, and then acidified with hydrochloric acid to give a hydrolyzed polymer.

Ethyl p-Carboxybenzoylacetate (*I*). The crystal obtained from the acidic fraction was recrystallized from ethanol. Mp 151°C.

Found: C, 60.96; H, 4.96%. Calcd for $C_{12}H_{12}O_5$ C, 61.05; H, 5.12%. When refluxed with 20% sulfuric acid for 5 hr, this crystal gave colorless needles melting at 209—210°C (ethanol), (lit.,[8] mp 205°C of *p*-acetylbenzoic acid). Its methyl ester melts at 95—96°C (water) (lit.,[9] mp 92°C).

Diethyl Terephthaloyldiacetate (*II*). The neutral crystal was recrystallized from ethanol, mp 70°C (lit.,[10] mp 70°C). (Found: C, 63.01; H, 5.88%).

The authors are grateful to Mr. Yoshitaka Itatani of the Faculty of Pharmacy, Kanazawa University, for his elemental analysis.

Metal Ion-catalyzed Glycolysis of Terephthalonitrile

Takashi IKEDA, Michitoshi KITABATAKE, Masatomo ITO and Yoshitaka NOGUCHI

The Central Research Laboratory, Showa Denko K.K., Tamagawa, Ohta-ku, Tokyo

(Received June 2, 1967)

The effects of various metal compounds on the glycolysis of terephthalonitrile were studied in the presence of water at 185°C. The catalytically-active species were found to be metal ions. Their catalytic activities were correlated with the acid ionization constants, pK_a, of metal ions. The active catalysts were limited to the metal ions with pK_a values larger than 7. The study of the reaction mechanism suggests that, while one group of metal ions accelerates the formation of glycol and hydroxyl anions, the other involves catalytic acceleration through the coordination of metal ions. The metal ions with pK_a values of less than 7 showed no catalytic activities. These results were interpreted in terms of the tendency of the metal ions to form too stable coordination intermediates. Most of these metal compounds also served to inhibit the reactions. For a series of salts derived from a given metal, the catalytic activities were found to decrease with a decrease in their solubilities in water. On the other hand, metal oxides and hydroxides had high catalytic activities.

The glycolysis of nitriles to the corresponding esters is known to proceed under non-catalytic conditions. The reaction may also be catalyzed by acids and bases.[1] Recently the glycolysis of aromatic nitriles has been reported to be promoted by heavy metal salts and by oxides.[2,3] On the other hand, the metal ions are known to promote the hydrolyses of esters,[4] of amides,[5] and of Schiff bases,[6] and the glycolysis of esters.[7]

A basic study of the metal ion-catalyzed glycolysis of nitriles was, therefore, of interest in order to get a better understanding of the role of the metal ions in the metal-ion catalysis.

We will attempt in this paper to clarify the catalytic effects of metal compounds in the glycolysis of terephthalonitrile.

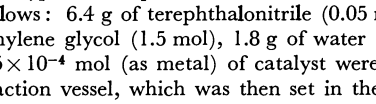
Experimental

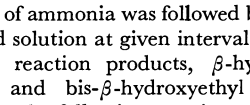
Experimental Apparatus and Procedure. The reaction was carried out in a 100-m*l* three-necked glass flask equipped with a reflux condenser, a thermometer, and a nitrogen gas inlet; the flask was immersed in an oil bath with an electric heating system. During the reaction the reactants in this flask and an ammonia-absorbing solution prepared in another flask were stirred by the magnetic stirring device.

A typical example of the determination of reaction rate follows: 6.4 g of terephthalonitrile (0.05 mol), 93.0 g of ethylene glycol (1.5 mol), 1.8 g of water (0.1 mol), and 2.5×10^{-4} mol (as metal) of catalyst were added to the reaction vessel, which was then set in the oil bath preheated at 185°C. Nitrogen gas was bubbled into the reaction mixture at a rate of 40 m*l*/min. The nitrogen flux was introduced through a reflux condenser to the ammonia-absorbing solution kept at 25°C. The reaction was then carried out at 185°C.

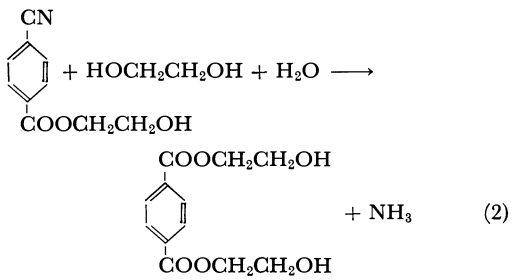
The resulting ammonia, carried with the nitrogen flux, was absorbed into the sulfuric acid solution. The rate of the formation of ammonia was followed by the titration of a sulfuric acid solution at given intervals.

As the main reaction products, β-hydroxyethyl *p*-cyanobenzoate, and bis-β-hydroxyethyl terephthalate were obtained by the following reaction sequence:





(1)



These products were analyzed by gas-liquid chromatography (column: 25 wt% of Apiezon L on Chromosorb W) for β-hydroxyethyl *p*-cyanobenzoate, and by fractionation and ultraviolet spectroscopy for bis β-hydroxyethyl terephthalate.

Materials. Terephthalonitrile (mp 224°C) was prepared by the ammoxidation of *p*-xylene and was purified by recrystallization from dioxane. Ethylene glycol (bp 197°C) used was of the reagent grade. The metal compounds were all extra pure, commercially-available products, with the exception of lead glyceroxide, which was prepared according to the procedure proposed by Nitschman.[8]

Results and Discussion

According to the kinetics of this reaction, which will be reported in a separate paper, the rate of the reaction of terephthalonitrile is not necessarily equal to the rate of the formation of ammonia, but the conversion of terephthalonitrile is parallel to the formation of ammonia. The catalytic activities of metal compounds can be correlated with the rate of the formation of ammonia.

The rates of formation of ammonia are shown in Fig. 1 for the different initial nitrile concentration; they are independent of the concentration of terephthalonitrile in the initial stage of the reaction, up to a 30% conversion to ammonia. This fact indicates that the rate of the formation of ammonia follows the first-order rate law with respect to the terephthalonitrile at a low range of conversion.

above conditions. The catalytic activities, therefore, have to be compared with the specific rate constants, $K-K_0$, adjusted by substracting the specific rate constants in the absence of any catalyst, K_0, from those in the presence of catalysts, K.

Table 1 lists the first-order specific rate constants obtained after the first 30% of the reaction for the glycolysis of terephthalonitrile in the presence of various catalysts.

The metal compounds with catalytic activities were those derived from metals which belong to the Ia, IIa, IIIa, VIIb, VIII, Ib, IIb, and IVa groups in the periodic charts of the elements.[9] Considering the reaction conditions and the results, it appears that the active species of the catalysts may be ascribed to the metal ions. Even the zinc metal itself showed catalytic activity, as Table 1 shows. From this fact, it appears that the effectiveness in this glycolysis can be ascribed to the metal ions in the final reaction state.

The catalytic activities in the glycolysis were found, with a few exceptions, to have a good correlation with the stability constants[10] of the oxine complex of metal ions. These correlations are shown in Fig. 2. From these facts, the coordinations of the reagent to metal ions may be considered to play an important role.

Accordingly, the electron affinity of the metal ions, which determines the coordinating tendency, may be closely related to the catalytic activity. By adopting the acid ionization constants[11,12] of the metal ions as a measure of the electron affinity of the metal

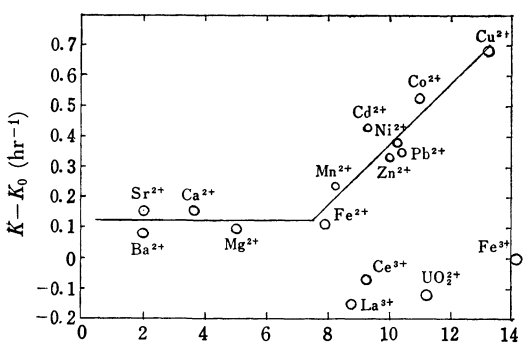

Fig. 2. Correlation between catalytic activities and stability constants of oxine complex of metal ions.

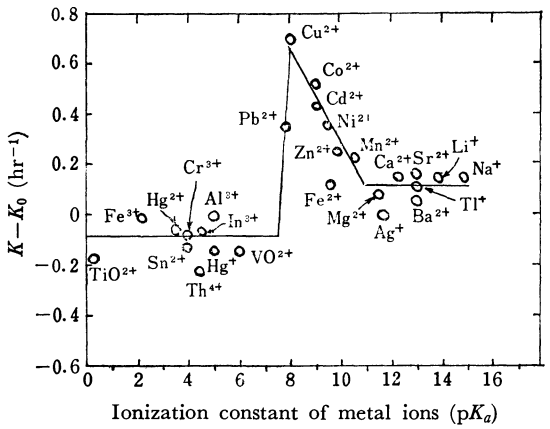

Fig. 3. Correlation between acid ionization constants (pK_a) and rate of the glycolysis of terephthalonitrile.

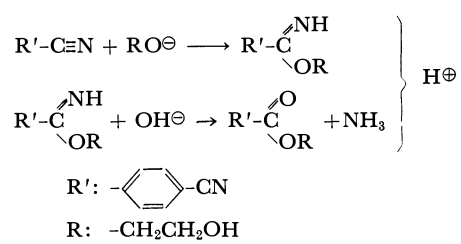
ions,[13] the aforementioned relationship may be illustrated as in Fig. 3. The catalytic activities as given by $K-K_0$ are distributed on volcano-type plots. The catalytically-active metal ions are limited to those having acid ionization constants, pK_a, larger than 7. They may be divided into two groups; one comprises alkali, alkaline earth, and thallium(I) metal ions derived from Ia, IIa, and IIIa, while the other includes the metal ions derived from VIIb, VIII, Ib, IIb, and IVa in the periodic chart of the elements.[9]

Metal ions of either group promote the reaction of glycolysis, but possibly by different reaction mechanisms. The former group seems to promote the reaction by accelerating the formation of glycol and hydroxyl anions, which promote the imidate formation and the imidate hydrolysis, as illustrated as follows:



The latter group seems to promote the reaction by accelerating the formation of carbonium cations of the imidate through the coordination of metal ions:

claimed that an excited singlet state is an only reactive state in the photoreduction of acridine in *isopropanol*.

According to our present results, however, four alcohols behave more or less in different manner and in particular, isopropanol and methanol show distinctly different features in the effect of biacetyl on the photoreduction, which lead to the conclusion that the reactive states is in the former case only singlet excited state in agreement with Porter's conclusion, whereas in the latter case, are singlet and $T(n-\pi^*)$ state as Kellmann and Dubois proposed. Hence it seems timely to report the details of our experiments although we have not yet succeeded in interpreting the unexpected differences found in four kinds of alcohols.

Since Dubois and Kellmann's conclusion was based on the assumption that inhibiting action of biacetyl is due to the energy transfer according to $A^{T(n-\pi^*)}+B \rightarrow A+B^T$ (where A is acridine and B is biacetyl), it is desirable to examine whether biacetyl does not affect the lowest $T(\pi-\pi^*)$ of acridine by a different mechanism than energy transfer and further to examine whether it does not react with the half reduced acridine. Therefore we have investigated at first by the flash technique using methanol and ethanol as solvents, the effect of the addition of biacetyl on the decays of $T(\pi-\pi^*)$ of acridine and of the half reduced acridine. In addition, we have made investigations on the effect of the addition of biacetyl on the yield of $T(\pi-\pi^*)$, AH and AH_2, the results of which have supported the view of Kellmann and Dubois to some extent. These experiments are described in Part I. In Part II, the steady illumination experiments are described. The data, being more accurate than those from flash experiments, are analysed and interpreted on the basis of four alternative processes, and the quantum yields Φ_M^S, Φ_R^S, Φ_M^T and Φ_R^T (where S and T denote singlet excited state and $T(n-\pi^*)$ state and where M and R denote respectively molecular and radical) are separately decided.

Part I.*1 Flash Photolysis Studies

Experimental

Apparatus, procedures and samples are essentially similar as in the previous papers.[8,10] The decays and yields of $T(\pi-\pi^*)$ of acridine and of the half-reduced form of acridine were examined respectively at 440 and at 278 mμ (or in some cases as 520 mμ). The yield of acridan was investigated from the increase of optical density at 290 mμ. The concentration of acridine was always 4.8×10^{-5} M and the concentration of biacetyl was changed from zero to 1.1×10^{-2} M. By using a suitable filter only acridine was excited.

Results and Discussion

T-T Absorption Spectra of Biacetyl. Transient absorption spectra of biacetyl in methanol are shown in Fig. 1.

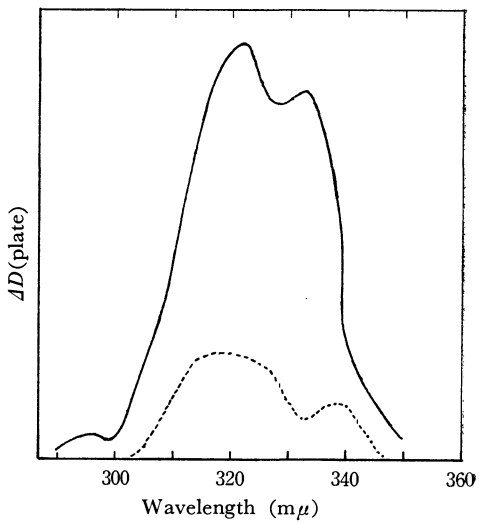

Fig. 1. Transient absorption spectra of biacetyl.
—— after 93 μsec, - - - after 360 μsec

The decay at 320 mμ is of the first order with a rate constant $k\simeq4\times10^3 sec^{-1}$. The comparison with the data in literatures[9,12,13] confirms that this species is the triplet state of biacetyl.

The Effect of the Addition of Biacetyl on the Decay of $T(\pi-\pi^*)$ of Acridine. The decay was not essentially affected by the addition of biacetyl up to 1.1×10^{-2}M. Some of the values of the first order rate constants are given in Table 1.

The Effect of the Addition of Biacetyl on the Decay of Half Reduced Acridine. The decay of half reduced acridine is second order and the rate

metal are quite applicable to that of the glycolysis of dimethyl terephthalate,[7c] it seems that the catalytic reaction mechanisms for this reaction are similar to those for the glycolysis of dimethyl terephthalate.

The reaction mechanisms and kinetics of the metal ion-catalyzed glycolysis of benzonitrile will be discussed in a succeeding paper.

The authors wish to thank Dr. Tajiro Oga and Messrs. Masashi Tanabe and Noriyoshi Aotsuka for their valuable discussions. Thanks are also given to Messrs. Masasuke Muto and Kazuharu Katagiri for their technical assistances.

A Kinetic Study of the Metal Ion-catalyzed Glycolysis of Benzonitrile

Takashi IKEDA, Michitoshi KITABATAKE, Masatomo ITO and Yoshitaka NOGUCHI

The Central Research Laboratory, Showa Denko K.K., Tamagawa, Ohta-ku, Tokyo

(Received August 3, 1967)

The kinetics of the lead ion-catalyzed glycolysis of benzonitrile were studied in the presence of water. The experimental results indicated that the rate of the formation of ammonia followed the first-order rate law with respect to the concentrations of benzonitrile and of water. For the concentration of the catalyst, the rate found was of a 0.44 order. It was observed that the product, β-hydroxyethyl benzoate, exhibited an inhibiting effect on the glycolysis. The effects of substituents on benzonitrile were found to fit the Hammett rule. The reaction was remarkably influenced by the type of glycol used. The reaction also proceeded through the hydrolysis of benzonitrile, followed by the glycolysis of the benzamide thus formed. The rate of the glycolysis of benzamide was about one-third that of benzonitrile, which is the main reaction in the system. The reaction of imidate formation possessed a small equilibrium constant at a high temperature, but it had a high reaction rate. The proposed mechanism for these glycolysis reactions is as follows: the addition of glycol to benzonitrile yields imidate, which then forms a chelate compound with a metal ion. The imidate activated by the formation of the chelate is easily hydrolyzed by water to form ester and ammonia. This ester tends to chelate to the metal ion and so inhibits the reaction.

The effectiveness of the various kinds of metal compounds on the metal ion-catalyzed glycolysis of terephthalonitrile has been discussed in a previous paper.[1] The heavy metal ions, such as cupric, lead, and zinc ions, have been found to promote the glycolysis of terephthalonitriles. Their catalytic activities have been correlated with the coordination tendency of metal ions.

Kinetic studies of the metal ion-catalyzed glycolysis of benzonitrile are, therefore, important in order to gain a better understanding of the reaction mechanisms. However, no kinetic study of the glycolysis has been found in the literature.

We will attempt here to investigate the reaction kinetics and to propose a mechanism for the metal ion-catalyzed glycolysis of benzonitrile to yield β-hydroxyethyl benzoate.

Experimental

Kinetic Measurements for the Glycolysis of Nitriles and Amides. The experimental procedure and the methods of measurements for the glycolysis of nitriles and amides were similar to those described in a previous work.[1]

A typical set of reaction conditions used was as follows: a reaction mixture of 0.1 mol of nitrile or amide, 1.5 mol of glycol, 0.1 mol of water, and 0.001 mol of a catalyst was reacted at the reaction temperature of 170°C.

The rate of the formation of ammonia was determined by the titration of samples of the sulfuric acid solution taken from the ammonia-absorbing flask at given intervals. Further, the determination of the rate of the reaction of benzonitrile was carried out by analyzing the samples from the reaction mixture by gas-liquid chromatography at set intervals.

The analytical conditions used were as follows: the heated liquid product in the reaction state was quickly sampled with a micro-syringe (50 μl) and analyzed by gas-liquid chromatography on a 2 m × 6 mm stainless steel column of 25wt% Apiezon L on Chromosorb W at 205°C, using helium as a carrier gas and naphthalene as an internal-standard substance.

The formation of the ester, the main reaction product, was also examined by using gas-liquid chromatography and infrared spectroscopy.

1) T. Ikeda, M. Kitabatake, M. Ito and Y. Noguchi, This Bulletin, **41**, 1154 (1968).

Studies of Imidate Formation from Nitriles.[2] A reaction mixture of 1.85 g (0.0125 mol) of *m*-nitrobenzonitrile, 124 g (2 mol) of ethylene glycol, and 0.014 g (0.25×10^{-4} mol) of sodium metal was reacted at a given reaction temperature in a 100-m*l* flask immersed in an electrically-heated oil bath stirred by a magnetic apparatus.

Aliquots (5 cc) were withdrawn at intervals, added to a mixture of excess dilute hydrochloric acid and methanol (100 m*l*), and, after 30—45 min, backtitrated to the methyl-orange endpoint.

Materials. Isophthalonitrile and terephthalonitrile were prepared by the ammoxidation of *m*- and *p*-xylene respectively; they were purified by recrystallization from dioxane to melting points of 160—161°C and 222—224°C respectively.

The *p*-cyanoacetophenone (mp 54—56°C) was prepared according to the directions proposed by Mowry *et al.*[3]

p-Chlorobenzonitrile (mp 93—94°C) was prepared by the usual method from *p*-chloroaniline.

β-Hydroxyethyl *p*-cyanobenzoate (mp 58°C) was prepared by reacting ethylene chlorohydrine with *p*-cyanobenzoic acid sodium salt in a water solution and by recrystallization from water, evaporating under reduced pressure.

β-Hydroxyethyl benzoate was similarly prepared; bp 146—148°C at 10 mmHg.

m-Nitrobenzonitrile was a commercial product and was purified by recrystallization from methanol-chloroform; mp 148°C.

Lead acetate, a typical metal ion catalyst, was commercially available with a sufficient purity.

The other materials used in this study were the best commercial products available and were purified by distillation.

Results and Treatment of Data

Glycolysis of Benzonitrile. The conversion of benzonitrile in the presence of water and a catalyst is shown in Fig. 1 as a function of the reaction time. The rates of the formation of ammonia and *β*-hydroxyethyl benzoate are also given. These results indicate that, in the initial stage of the reaction, the rate of the consumption of benzonitrile is of nearly the same magnitude as the rates of the formation of ammonia and of *β*-hydroxyethyl benzoate.

In order to ascertain the mass-transfer effect of the rate of reaction, a few experiments were carried out at a faster gas flow rate of nitrogen, while the other conditions were kept constant. The rates of the formation of ammonia were not affected by the nitrogen gas flow rate. It was thus confirmed that the mass-transfer effect was insignificant in this system.

The first-order rate plots of the formation of ammonia observed at 170°C are shown in Fig. 2 for two initial concentrations of benzonitrile. The formation of ammonia and the consumption of benzonitrile are both first-order reactions at low conversions (up to 30% of benzonitrile). A higher conversions, however, the slope of the curve tends to decrease. The difference between the two first-order rate constants in Fig. 2 may be caused by the inhibiting effect of *β*-hydroxyethyl *p*-cyanobenzoate, which will be discussed later.

The first-order rate constants obtained from the initial rate of reaction for the glycolysis of benzonitrile

k_0: rate constant in the absence of catalyst

in the presence of various concentrations of lead acetate, a typical metal ion catalyst, are plotted in Fig. 3. It should be recalled here that the reaction proceeds slowly even in the absence of any catalyst.[1)]

In consideration of such complications, the first-order rate constants, k (hr^{-1}), in the glycolysis of benzonitrile can be represented by Eq. (1):

$$k = 0.046 + 4.75\ [\text{catalyst}]^{0.44} \qquad (1)$$

The rate of the formation of ammonia may be expressed by an identical equation.

The first-order rate constants in the glycolysis of benzonitrile obtained at 170°C and 150°C are plotted against the initial concentration of water in Fig. 4. The formation of ammonia was found to proceed considerably even in the absence of water. However, the first-order rate of the formation of ammonia increased remarkably with an increase in the concentration of water at the optimum reaction temperature, 170°C. Since the reaction mixture starts refluxing at a concentration of water higher than

△ Reaction temperature 150°C

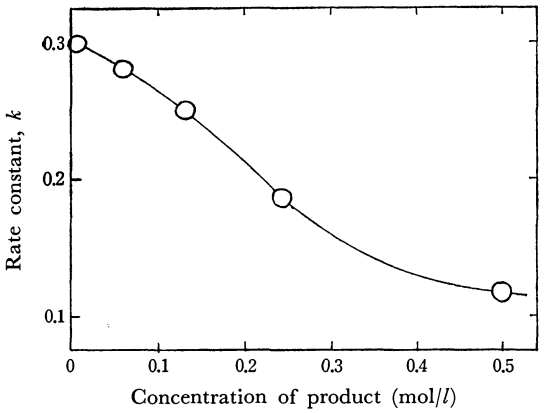

Fig. 5. The effect of the product in the glycolysis of benzonitrile.

1 mol/l, the reaction could not be carried out at the above-mentioned temperature, 170°C. The aforementioned first-order rate constant increased gradually up to the concentration of water of 1 mol/l at a lower temperature, 150°C. The effect of water when its concentration is higher than 1 mol/l will be reported in the succeeding paper, as well as the mechanism in the absence of any water in the glycolysis. The chemical equivalent volume of water to benzonitrile is 1 mol/l in the reaction system.

In order to ascertain the inhibiting effect exerted by the product, β-hydroxyethyl benzoate, the glycolysis of benzonitrile was carried out in the presence of extra β-hydroxyethyl benzoate at 170°C. The results obtained are shown in Fig. 5. The initial rate constant decreases from 0.3 to 0.12 as the concentration of β-hydroxyethyl benzoate varies over the range from 0 to 0.5 mol/l. It is evident here that the product tends to inhibit the glycolysis reaction

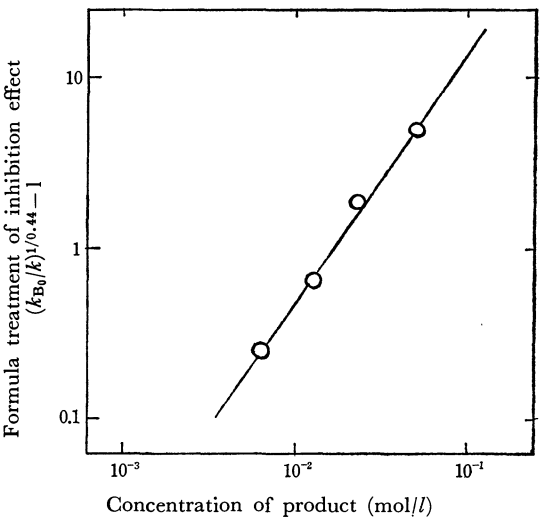

Fig. 6. The graphical analysis of the inhibiting effect of the product in the glycolysis of benzonitrile.

The rate of the formation of ammonia can be presented as follows:

$$k = k_{B_0}/(1 + C[\text{product}]^n)^{0.44} \quad (2)$$

where k_{B_0} represents the rate constant when no product is added, and where C and n are the constants.

Moreover, by treating the rate data as shown in Fig. 6, the inhibiting effect of the product in the glycolysis of benzonitrile is found to fit the above formula and may be represented as Eq. (2') for the rate of the formation of ammonia:

$$k = k_{B_0}/(1 + 330[\text{product}]^{1.50})^{0.44} \quad (2')$$

where k_{B_0} represents the above-described rate constant.

The Arrhenius plots of the first-order rate constant in the glycolysis of benzonitrile at a given concentration of the reactant are shown in Fig. 7. The apparent activation energy for the formation of ammonia in the temperature range of 150—170°C was 18.0 kcal/mol.

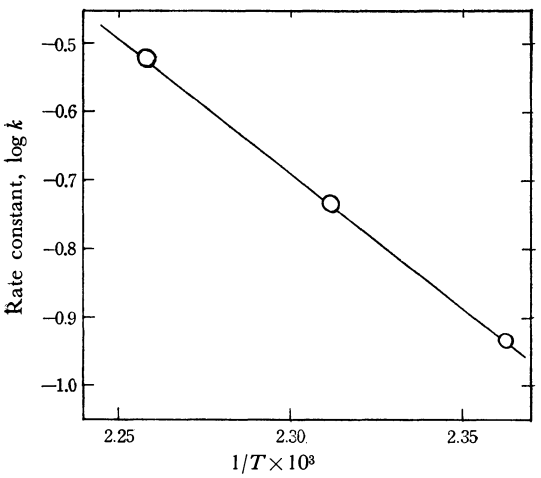

Fig. 7. Arrhenius plot of the first-order rate constant in the glycolysis of benzonitrile.

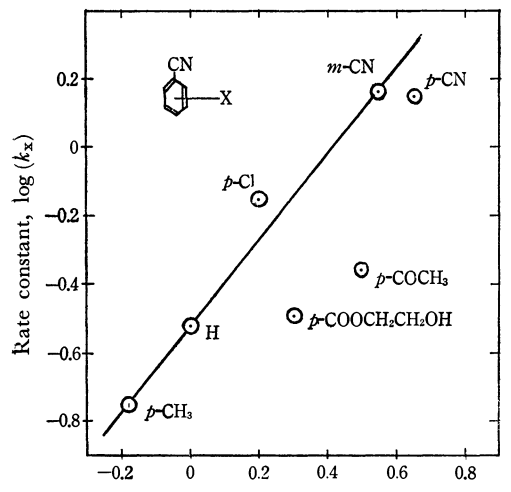

Fig. 8. Hammett correlation of $\log k_x$ *vs.* σ in the glycolysis of substituted benzonitrile.

The glycolysis reactions were also carried out with various substituted benzonitriles. The reaction rate constant is plotted against the Hammett constant, σ,[4] in Fig. 8.

The Hammett correlation gives a straight line except for substituted benzonitriles with the carbonyl group, such as β-hydroxyethyl *p*-cyanobenzoate and *p*-cyanoacetophenone. The Hammett reaction constant, ρ, calculated from the slope in Fig. 8 is 1.2.

The effects of the types of glycol on the glycolysis of benzonitrile at 150°C may be seen in Table 1. Here the rate of reaction decreases rapidly with an increase in the number of the carbon atoms between the two hydroxy groups.[5] The rate also decreases as the order of hydroxy group involved becomes higher. Thus, primary>secondary>tertiary.

Glycolysis of Benzamide. In order to examine to what extent the reaction proceeds through another path where benzamide is known to participate as an intermediates, we studied the reaction of benzamide with glycols under catalytic conditions. Here the benzamide may be formed through the hydrolysis of benzonitrile. The apparent first-oder rate constants in the glycolysis of benzamide are listed in Table 2. With ethylene glycol, the rate of reaction in the glycolysis of benzamide is about one-third that observed in the glycolysis of benzonitrile. The rate of the reaction in the glycolysis of benzamide with tetramethylene glycol is, however, in the same range as that with ethylene glycol.

Thus, with tetramethylene glycol, the rate of reaction in the glycolysis of benzamide is much greater than that in the glycolysis of benzonitrile. These results suggest that the glycolysis of nitrile may be different in mechanism from that of amide.

Reaction of *m*-Nitrobenzonitrile with Glycols. Since the rate of the glycolysis of benzonitrile was found to be remarkably affected by the type of glycol used (Table 1), we studied the kinetics of the formation of imidate from nitrile and alcohol.

The results of the kinetic investigation of the formation of imidate from *m*-nitrobenzonitrile with ethylene glycol under various conditions are summarized in Table 3. The equilibrium constants for the reaction with a series of butanols are also indicated. The equilibrium constant, K, between benzonitrile and imidate in the presence of ethylene glycol under the reaction conditions described in the Experimental Section is not different from that for *n*-butanol. With secondary or tertiary butanol, however, the reaction to imidate hardly proceeded at all.

The temperature dependence of the equilibrium

constant is presented in Fig. 9. The heat of reaction for the imidate formation was found to be −5.9 kcal/mol. By extrapolation from these results, the equilibrium constant for the imidate formation at 170°C was estimated to be *ca.* 0.01 $(mol/l)^{-1}$. The data listed in Table 3 also indicate that the rates of the

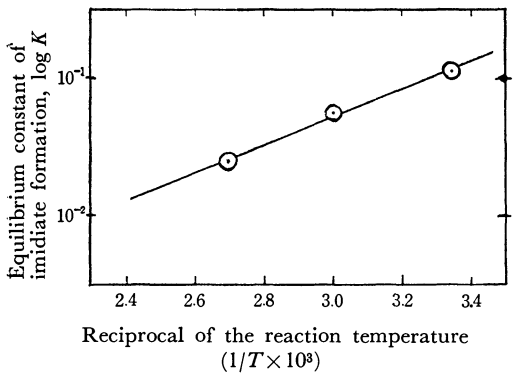

Fig. 9. Correlation of equilibrium constant log K *vs.* the reciprocal of reaction temperatures in the imidate formation reaction of benzonitrile. Reaction condition: *m*-NBN: 0.0125 mol, E.G: 2 mol, Na: 0.625 mg atom

formation of imidate in the presence of sodium metal are very fast at 170°C.

The data of Tabe 3 suggest that the formation of imidate can not be catalyzed by lead chloride, though it is known to promote the reaction of glycolysis.[1] The formation of imidate is not influenced by the presence of water or of bis-β-hydroxyethyl terephthalate, which inhibited the glycolysis reaction. The rates of the lead-ion catalyzed glycolysis of benzonitrile at 170°C were not affected by the addition of sodium metal (2.5×10^{-4} g atom) and were about five times faster than that of the sodium-catalyzed glycolysis of benzonitrile (2.5×10^{-4} g atom sodium).

Discussion

The experimental results presented above suggest that the rate-controlling step in the glycolysis reaction is the chemical reaction in the reaction mixture, while the rates of the desorption of ammonia are rapid. An analysis of the reaction rate data suggests that the formation of β-hydroxyethyl benzoate is accompanied by the formation of ammonia and that the rates of reaction may be inhibited by the presence of the product, β-hydroxyethyl benzoate. These may be the reasons why the rate of ammonia formation tends to deviate from the first-order reaction scheme at higher conversions and at different initial concentrations of benzonitrile, as is shown in Fig. 2. From the fact that *p*-cyanoacetophenone also inhibits the reaction, as is shown in Fig. 8, the inhibiting effect may be ascribed to the carbonyl group. Since the reaction was promoted by the metal ions, such as cupric, lead, and zinc ions, with a coordination tendency, as has been presented in the previous report,[1] the inhibition by the ester might be caused by the coordination of the carbonyl groups of the product to the lead ion, thus forming a more stable complex than the reaction intermediates. The deviation at the Hammett plots illustrated at Fig. 8 may be caused by the same factor.

The Hammett reaction constant for the glycolysis of variously substituted benzonitriles ($\rho=1.2$) is of the same magnitude as those for the alkaline hydrolysis of substituted benzonitriles ($\rho=1.5$) and of benzamides[6] ($\rho=1.75$) and that for the formation of imidate from benzonitrile[2] ($\rho=1.9$). This may suggest that the nucleophilic attack on benzonitrile is involved in the reaction mechanism.

From the results of the glycolysis of benzamide, the reaction route through the formation of benzamide from nitrile with water seems insignificant.

The addition of nitrile to glycols, the imidate formation, may be suggested to be involved in the reaction mechanism, since the rate of the reaction of glycols with a secondary or tertiary hydroxy group is smaller than that of ethylene glycol, and this tendency is similar to that in imidate formation. The presence of excess glycols, the effect of the type of glycol, and the effect of the substituted group of benzonitrile are other reasons to support the formation of imidate.

The reaction of the imidate formation of benzonitrile with glycol could not be promoted in the presence of a lead catalyst. The lead ion - catalyzed glycolysis of benzonitrile was found not to be promoted especially by the co-presence of alkaline metal and to be considerably faster than that of the sodium ion - catalyzed glycolysis of benzonitrile. Therefore, it seems likely that the reaction of imidate formation proceeds quickly under the given conditions.

Contrary to the lead ion-catalyzed trans-esterification of dimethyl terephthalate, in which the rate of the reaction with ethylene glycol is of a magnitude similar to that with tetramethylene glycol, the effect of the methylene sequence length of the two hydroxy groups is remarkable in the glycolysis of benzonitrile. Taking account of the effect of the neighboring hydroxy group's assistance in the alkaline hydrolysis of the ester,[7] the reaction mechanism may be considered to involve the internal solvation of the critical transition state by the neighboring hydroxy group.

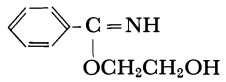
In the basence of water, the rate of ammonia formation was slow and the amount of β-hydroxyethyl benzoate formed was very little in the glycolysis reaction, while in the presence of water the rate of ammonia formation was remarkably promoted and there was a sizable formation of β-hydroxyethyl benzoate. These facts obviously suggest the participation of water in the rate-determining step in the ester formation.

In view of the above facts, the following reaction mechanism may be proposed for the lead ion-catalyzed glycolysis of benzonitrile :

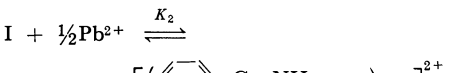
6) L. A. Cohen and W. M. Jones, *J. Am. Chem. Soc.*, **84**, 1625 (1962).

7) 1) T. C. Bruice and T. H. Fife, *ibid.*, **84**, 1973 (1962). b) T. C. Bruice and S. J. Benkovic, "Bioorganic Mechanism" Vol. 1, W. A. Benjamines Inc., New York, N.Y. (1966), p. 146. c) T. Yamanaka, A. Ichihara, K. Tabe and T. Matsumoto, *Shokubai* (*Catalysis*), **6**, 304 (1964).

(BN) (EG)

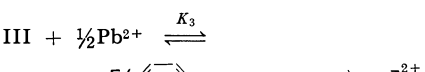


(I) (3)



(II) (4)

(III) (5)



(IV) (6)

Here we consider that Eq. (5) represents the rate-determining step, in which the internal solvation of the critical transition state by the neighboring hydroxy group is involved. The above mechanism leads to Eqs. (7)—(11) for the rate of ammonia formation in the lead ion-catalyzed glycolysis of benzonitrile:

$$\frac{d[NH_3]}{dt} = k[II]^{1/2}[H_2O] \quad (7)$$

$$[II]^{1/2} = K_2[I][Pb^{2+}]^{1/2} \quad (8)$$

$$[I] = K_1[BN][EG] \quad (9)$$

$$[IV]^{1/2} = K_3[III][Pb^{2+}]^{1/2} \quad (10)$$

$$[Pb^{2+}] = [Pb^{2+}]_0 - [II] - [IV] \quad (11)$$

As the electronegativity of oxygen is larger than that of nitrogen, it is presumed that $K_3 > K_2$. In addition, as the concentration of [II] is very small under the given reaction conditions, in consideration of the mass balance, Eq. (11) may be simplified to Eq. (12):

$$[Pb^{2+}] \fallingdotseq [Pb^{2+}]_0 - [IV] \quad (12)$$

where $[Pb^{2+}]_0$ is the initial concentration of lead ions.

By combining Eq. (10) with Eq. (12), we have Eq. (13):

$$[Pb^{2+}] = \frac{[Pb^{2+}]_0}{1 + K_3^2[III]^2} \quad (13)$$

Thus, Eq. (7), replaced by Eqs. (8), (9), and (13), can be formulated as follows:

$$\frac{d[NH_3]}{dt} = kK_1K_2[BN][EG][H_2O]\left\{\frac{[Pb^{2+}]_0}{1 + K_3^2[III]^2}\right\}^{1/2} \quad (14)$$

Therefore, the initial rate of the formation of ammonia in the presence of excess ethylene glycol can be presented as follows:

$$\frac{d[NH_3]}{dt} = k'K_1K_2[BN][H_2O]\left\{\frac{[Pb^{2+}]_0}{1 + K_3^2[III]^2}\right\}^{1/2} \quad (15)$$

On the other hand, the observed initial rate of the lead ion-catalyzed glycolysis of benzonitrile, neglecting the reaction in the absence of any catalyst and of water, may be presented as in Eq. (16):

$$\frac{d[NH_3]}{dt} = k''[BN][H_2O]\left\{\frac{[Pb^{2+}]_0}{1 + 330[III]^{1.5}}\right\}^{0.44} \quad (16)$$

This equation agrees satisfactorily with Eq. (15).

Thus, the kinetic studies obviously support the afore-mentioned reaction mechanisms for the metal ion-catalyzed glycolysis of benzonitrile.

The reaction of non-catalytic glycolysis and that in the absence of water occured simultaneously in the above glycolysis of benzonitrile. These reactions are presumed to have more complicated reaction routes than that of the above-mentioned glycolysis; they will be discussed in the succeeding paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1165—1169 (1968)

The Kinetics of the Metal Ion-catalyzed Glycolysis of Terephthalonitrile

Takashi IKEDA, Michitoshi KITABATAKE, Masatomo ITO and Ryoji ISHIOKA

The Central Research Laboratory, Showa Denko K.K., Tamagawa, Ohta-ku, Tokyo

(Received September 14, 1967)

The kinetics of the lead ion-catalyzed glycolysis of terephthalonitrile have been studied in the absence of and in the presence of water. In the absence of water, scarcely any formation of β-hydroxyethyl *p*-cyanobenzoate is observed, but some orthoesters are formed. The reaction rate data obtained in the absence of water are found to fit a reversible consecutive reaction scheme in which some basic compounds are involved as the intermediates. In proportion to the increase in the concentration of water, such intermediates as the orthoesters and basic compounds are hydrolyzed more rapidly to form β-hydroxyethyl *p*-cyanobenzoate, but simultaneously the hydrolysis of terephthalonitrile and the basic intermediates also takes place in the reaction mixture, thus yielding amide.

The effectiveness of the various kinds of metal compounds on the metal ion-catalyzed glycolysis of terephthalonitrile[1] and the kinetics of the metal ion-catalyzed glycolysis of benzonitrile[2] have been discussed in previous papers.

The heavy metal ions, such as cupric, lead, and zinc ions, have been found to promote the glycolysis of nitriles. Their catalytic activities have been correlated with the coordinating tendency of metal ions.

Benzonitrile first affords imidate upon the addition of glycol, and then two moles of the thus-derived imidates are chelated to a metal ion. The imidates activated by forming the chelate can be easily hydrolyzed by water to form esters and ammonia. However, these esters tend to chelate to the metal ions thus inhibiting the reaction.

The kinetic study of the metal ion-catalyzed glycolysis of terephthalonitrile is, therefore, important in order to have a better understanding of the reaction mechanisms and various reaction routes. No kinetic study of the glycolysis has been found in the literature.

We will attempt here to clarify the reaction routes and mechanisms of the metal ion-catalyzed glycolysis of terephthalonitrile in the absence of and in the presence of water.

Experimental

Kinetic Measurements. The procedure and measurements for the glycolysis of terephthalonitrile were similar to those employed in previous works.[1,2]

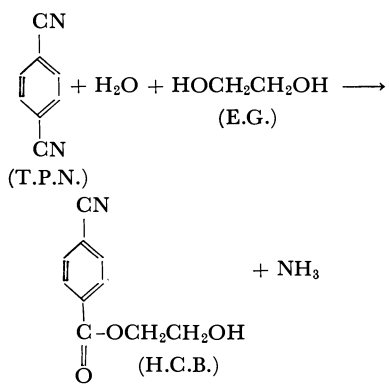
A typical set of reaction conditions employed is as follows: A reaction mixture of 0.05 mol of terephthalonitrile (T.P.N.), 1.5 mol of ethylene glycol (E. G.), 0.1 mol of water, and 0.00025 mol of a catalyst was reacted at the reaction temperature of 170°C. The reaction was carried out under a nitrogen atmosphere, nitrogen being bubbled into the mixture at the rate of 40 m*l*/min.

A 100-m*l* three-necked glass flask equipped with a reflux condenser, a thermometer, and a nitrogen gas inlet was used as the reaction vessel. The reaction mixture in the flask was immersed in an electrically-heated oil bath stirred by a magnetic apparatus. The ammonia formed during the reaction was absorbed in a dilute sulfuric acid solution stirred by a magnetic stirrer set in the flask.

The rate of the formation of ammonia was determined by the titration of samples of the sulfuric acid solution taken from the ammonia-absorbing flask at given intervals. The rate of the conversion of terephthalonitrile was determined at given intervals by using gas-liquid chromatography. The rates of the formation of both β-hydroxyethyl *p*-cyanobenzoate (H.C.B.) and bis-β-hydroxyethyl terephthalate (B.H.T.) were examined by using gas-liquid chromatography and ultraviolet spectroscopy.

The heated liquid product in the reaction state was quickly sampled with a micro-syringe (50 μ*l*) and analyzed by gas-liquid chromatography on a 2 m×6 mm stainless steel column of 25% Apiezon L on Chromosorb W at 190°C, using helium as a carrier gas and α-naphthol as an internal-standard substance.

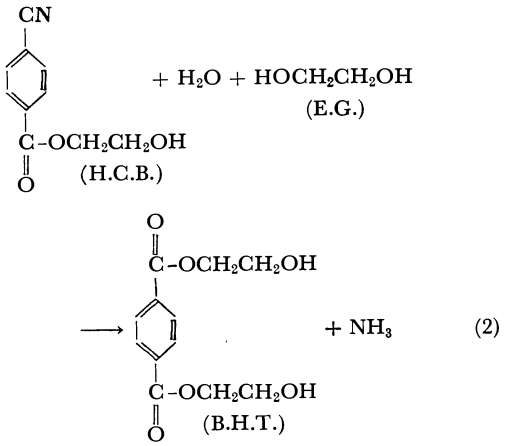
The reaction of the glycolysis of terephthalonitrile proceeds as in the following sequence:



(1)

1) T. Ikeda, M. Kitabatake, M. Ito and Y. Noguchi, This Bulletin, **41**, 1154 (1968).

2) T. Ikeda, M. Kitabatake, M. Ito and Y. Noguchi, *ibid.*, **41**, 1158 (1968).



The reaction routes and the mechanism of the glycolysis of terephthalonitrile discussed here are limited to the first stage of the overall reaction.

Materials. Terephthalonitrile (mp 224°C) was prepared by the ammoxidation of *p*-xylene and was purified by recrystallization from dioxane.

Ethylene glycol (bp 197.2°C) and dipropylene glycol (bp 231.8°C) used were of reagent grades.

Lead acetate, a typical metal compound catalyst, was commercially available with a sufficient purity.

Results and Discussion

The influence of the concentration of water on the conversion rate of terephthalonitrile was investigated.

Data on the conversion of terephthalonitrile and on the formation of ammonia and β-hydroxyethyl *p*-cyanobenzoate for each concentration of water are shown in Figs. 1 and 2 in relation to the reaction time. The reactions were carried out under the standard reaction conditions described above except for the amount of water. These figures indicate that the conversion rate of terephthalonitrile increases with an increase in the amount of water below a 2-molar ratio of water to terephthalonitrile. The rate of the formation of β-hydroxyethyl *p*-cyanobenzoate has the same tendency, but scarcely any β-hydroxyethyl *p*-cyanobenzoate is formed in the absence of water, though the formation of ammonia is recognized.

The rate of the conversion of terephthalonitrile is usually greater than that of the formation of ammonia. This fact indicates that nitrogen compounds may be present as intermediates in the routes from nitrile to the ester and/or that a side reaction such as the hydrolysis of nitrile to amide may exist.

The basic compounds which react with sulfuric acid were actually observed in the reaction mixture, as shown in Fig. 3. Since the desorption of ammonia from the reaction mixture was rapid under the given conditions, the amount of ammonia in the reaction mixture was insignificant. These basic compounds in the reaction mixture had a tendency to decrease with an increase in the concentration of water. Besides, at high concentrations of water,

there were quite large differences between the amount of the conversion of terephthalonitrile and that of both β-hydroxyethyl *p*-cyanobenzoate and the basic compounds, suggesting the formation of amide.

It is shown in Fig. 2 that scarcely any β-hydroxyethyl *p*-cyanobenzoate is formed in the absence of water, though the amounts of terephthalonitrile reacted and of ammonia formed increase considerably. However, the ester was observed to be formed, as shown in Fig. 4, when water was added to this non-aqueous reaction mixture in the course of the reaction. This fact indicates that the compounds other than the ester are formed in the absence of water and are susceptible to being hydrolyzed to the ester.

In Fig. 5 the experimental data on the concentration of unchanged terephthalonitrile, the amounts of the basic compounds titrated by sulfuric acid in the reaction mixture, and the formation of orthoester-type compounds are plotted against the reaction time at 170°C in the absence of water.

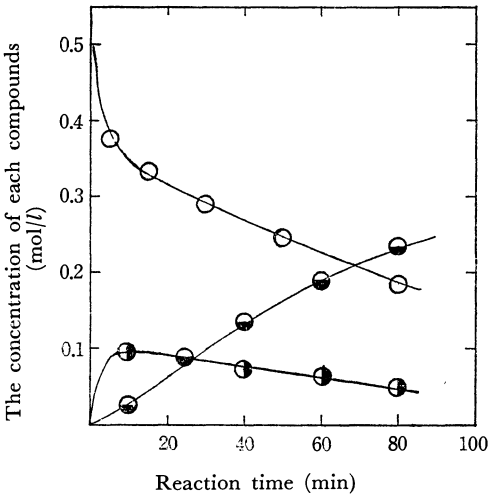

Fig. 5. The experimental data of the concentration of terephthalonitrile, orthoester and basic compound represented by marks and the calculated results with analog computer represented by real curved lines in the absence of water.
-○-: the concentration of terephthalonitrile unchanged
-◒-: the formation of orthoester (ammonia)
-◑-: the formation of basic intermediate compounds
Reaction conditions: E.G/TPN=30, $Pb(OAc)_2$/TPN=1/200, H_2O=0 at 170°C

The total amounts of ammonia formed and of the basic compounds in the reaction mixture in the absence of water correspond to the amounts of terephthalonitrile reacted. On the other hand, the rate of the reaction of terephthalonitrile was found to be first-order for the concentration of terephthalonitrile at a low conversion rate of terephthalonitrile.[1)]

In view of the above facts, the following rate expressions for the reaction scheme (Eq. (3)) were chosen:

$$\text{T.P.N.} \underset{k_2,\ HOCH_2CH_2OH}{\overset{k_1}{\rightleftarrows}} \text{B} \xrightarrow[HOCH_2CH_2OH]{k_3} \text{C} + NH_3 \quad (3)$$

B: basic compounds
C: orthoester-type compounds

The curves calculated by an analog computer according to Eqs. (4), (5) and (6) are presented in Fig. 5 by real curved lines, which are more agreeable to the experimental data.

$$d[TPN]/dt = k_2[B] - k_1[TPN] \quad (4)$$

$$d[B]/dt = k_1[TPN] - k_2[B] - k_3[B] \quad (5)$$

$$d[C]/dt = k_3[B] \quad (6)$$

The rate constants of the three reaction paths, k_1, k_2, and k_3, were 0.129 min^{-1}, 0.343 min^{-1}, and 0.033 min^{-1} respectively.

In order to get information about the C intermediate, initial reaction rates of the terephthalonitrile at different initial concentrations of ethylene glycol were investigated in an inert solvent such as dipropylene glycol; the following rate expression were chosen:

$$r_0 = k_1[TPN]_0[EG]_0^n \quad (7)$$

r_0: initial reaction rate of terephthalonitrile

Plots of k_1 in relation to the initial concentration of ethylene glycol give a straight line, as shown in Fig. 6, and the reaction order of ethylene glycol is nearly equal to 2. This fact suggests that two moles of ethylene glycol participate in the formation of the intermediate, B, or the product, C.

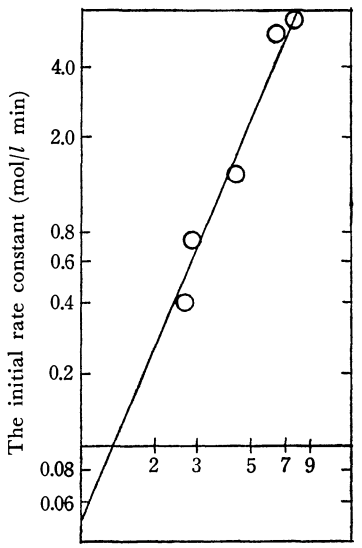

Fig. 6. The correlation between the initial rate constants and the initial concentration of ethylene glycol.
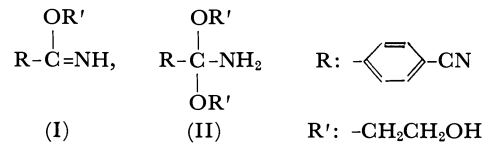
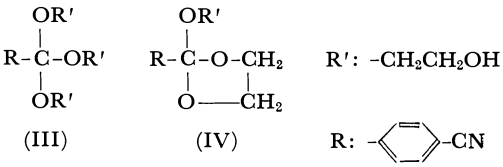
Reaction condition: $Pb(OAc)_2$/TPN=1/200 at 170°C

The reaction intermediate, B, is, in the absence of water, a substance which reacts with sulfuric acid. It may, therefore, be expected to have the following structures:



(I) (II)

The product, C, is presumed to be a orthoester-type compound:

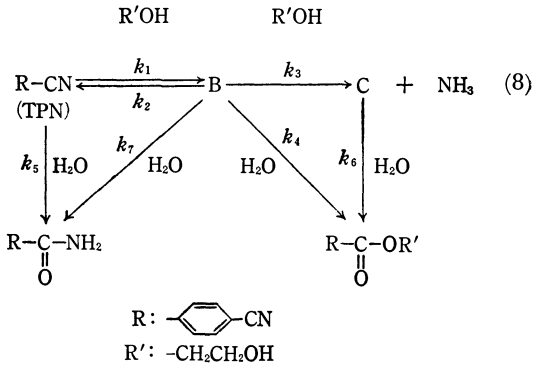


(III) (IV)

In Fig. 6 the straight line intercepts the vertical axis at the value of 0.0055. Using the values of 0.0055 and the initial concentration of terephthalonitrile of 0.448 mol/l, the rate constant, k_1, is calculated to have the value of 0.123 min^{-1}, a value which is almost equal to the above calculated value, k_1= 0.129 min^{-1}. These results indicate that the proposed reaction scheme and kinetics are consistent with all the experimental observations.

Even in the presence of water, the reaction to form B from the nitrile and that to give C from B may take place successively. Water is considered to participate in the reaction steps to form the ester and the amide.

Thus the following reaction scheme and rate equations may be considered for the first step of the glycolysis reaction:



$$\frac{d[TPN]}{dt} = k_2[B] - k_1[TPN] - k_5[TPN][H_2O] \quad (9)$$

$$\frac{d[B]}{dt} = k_1[TPN] - k_2[B] - k_3[B] - k_4[B][H_2O] - k_7[B][B_2O] \quad (10)$$

$$\frac{d[C]}{dt} = k_3[B] - k_6[C][H_2O] \quad (11)$$

$$\frac{d[RCOOR']}{dt} = k_4[B][H_2O] + k_6[C][H_2O] \quad (12)$$

$$\frac{-d[H_2O]}{dt} = k_5[TPN][H_2O] + k_4[B][H_2O] + k_6[C][H_2O] + k_7[B][H_2O] \quad (13)$$

$$\frac{d[NH_3]}{dt} = k_3[B] + k_4[B][H_2O] \quad (14)$$

In Fig. 7 the experimental data of the concentration of unchanged terephthalonitrile, the amounts of basic compounds titrated by sulfuric acid in the reaction mixture, and that of the formation of ammonia and β-hydroxyethyl *p*-cyanobenzoate are plotted against the reaction time at 170°C in the presence of water.

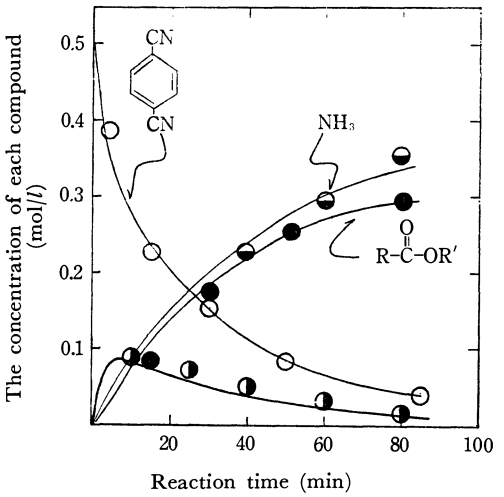


Fig. 7. The experimental data of the concentration of terephthalonitrile, ammonia, basic intermediate compounds and ester (H.C.B.) represented by marks and the calculated results with analog computer represented by real curved lines in the presence of water.
-○-: the concentration of TPN
-◒-: the formation of NH_3
-◑-: the formation of basic intermediate compound
-●-: the formation of ester (H.C.B.)
Reaction conditions: E.G./TPN=30, $Pb(OAc)_2$/TPN=1/200 H_2O/TPN=2, at 170°C

On the basis of the experimental data in Fig. 7, theoretical curves, as calculated by the analog computer, are shown in Fig. 7 by real curved lines using the above equations, (9), (10), (11), (12), (13), and (14). These rate constants at 170°C are obtained as follows:

$k_1 = 0.129\ min^{-1}$

$k_2 = 0.343\ min^{-1}$

$k_3 = 0.033\ min^{-1}$

$k_4 = 0.055\ min^{-1}\ mol^{-1}l$

$k_5 = 0.011\ min^{-1}\ mol^{-1}l$

$k_6 = 0.071\ min^{-1}\ mol^{-1}l$

$k_7 = 0.040\ min^{-1}\ mol^{-1}l$

The above results are also supported by the facts that scarcely any formation of the intermediate, C, is observed in the presence of water and that the rate constant of the direct hydrolysis of terephthalonitrile to amide in dipropylene glycol is very small, even in the presence of water.

It may, therefore, be considered that the glycolysis of terephthalonitrile to form β-hydroxyethyl*p*-cyanobenzoate may proceed *via* the hydrolysis of an ortho-ester-type compound, C, especially at a low concentration of water, and *via* an imidate- or amine-type intermediate, B, at a high concentration of water. Furthermore, at a higher concentration of water the formation of amide becomes a little more significant.

The authors wish to thank Messrs. Yoshitaka Noguchi and Ichiro Hashimoto for their valuable discussions. Thanks are also due to Mr. Katsumi Terayama for his technical assistance.

Intramolecular Hydrogen Bonding in Monoterpene Alcohols Containing π-Electronic System[1]

Tsuyoshi SHISHIBORI

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received July 26, 1967)

The nature of intramolecular hydrogen bonding in diastereoisomeric pairs of 10-nor-8-oxomenthols (VIII and IX) and 10-nor-8-oxocarvomenthols (X and XI) has been studied by infrared spectroscopy. It was found that 10-nor-8-oxoneomenthol (IX) contains the OH···O type intramolecular hydrogen bond, while 10-nor-8-oxomenthol (VIII) contains the OH···π interaction in addition to the OH···O hydrogen bond. 10-Nor-8-oxocarvomenthols (X and XI) were internally unbonded. In addition, the extent and the limitation of the intramolecular OH···π interaction has been investigated for the diastereoisomeric pairs of a series of *p*-menth-8-enols: *p*-menth-8-en-4-ols (I and II), isopulegols (III and IV), dihydrocarveols (V and VI), and *trans*-β-terpineol (VII). Thus, the hydroxyl group in α- or β-unsaturated alcohols I, II, III and IV was found to be internally bonded to the π-electrons on the double bond; the other isomers are internally unbonded.

The facts that intramolecular hydrogen bonding depends on the configuration and the conformation of compounds containing a hydroxyl group are of great potential utility for the structure elucidation and the conformational analysis.[2,3] The relationship between the configuration and the infrared spectral parameter has been studied extensively for the open chain and the cyclic compounds.[3] However, little data are available on intramolecular hydrogen bonding in cyclohexanol derivatives bearing the hydrogen accepting group, such as an isopropenyl, an acetyl, or a hydroxyisopropyl group. For the cyclohexanol derivatives having one of these groups, the rotational conformations of the group are possible in addition to the chair-chair interconversion of the ring. It is expected that the conformation of the group can be suggested from the examination of intramolecular hydrogen bonding.

In this paper, the spectral parameters relating to the intramolecular hydrogen bond between the hydroxyl and carbonyl groups in a diastereoisomeric pair of 10-nor-8-oxomenthols (VIII and IX) were compared with the ones of the OH···O hydrogen bond and the OH···π interaction in the diastereoisomeric pairs of isopulegols (III and IV) and *p*-menthane-3,8-diols (XII and XIII). In addition, the extent and the limitation of the intramolecular interaction between the hydroxyl group and the π-electrons has been investigated for the diastereoisomeric pairs of a series of *p*-menth-8-enols: *p*-menth-8-en-4-ols (I and II), isopulegols (III and IV), dihydrocarveols (V and VI) and *trans*-β-terpineol (VII).

Results and Discussion

In Figs. 1 and 2 are shown the actual O–H stretching absorption curves of the monoterpene alcohols (III, IV, VIII and IX). An unresolved band was divided by graphical separation,[4] assuming that the band is an overlapping of the symmetric bands. The data of the hydroxyl bands divided are summarized in Table 1.

***trans*- and *cis*-*p*-Menth-8-en-4-ols (I and II).** The spectra of I and II exhibited the principal band 3606 and 3604 cm^{-1} with a weak shoulder at 3622 and 3621 cm^{-1} respectively. In both I and II, the strong band at the low frequency side is attributed to the hydroxyl group which interacts with the π-electrons of the isopropenyl group, and the weak, high-frequency band corresponds to the unbonded tertiary hydroxyl band, which has been reported[5-7] to appear at 3613—3619 cm^{-1}. The separation by 16 and 17 cm^{-1} between the free and bonded hydroxyl bands in I and II, respectively, agrees with 15.4 cm^{-1} of allyl alcohol.[8,9] It is possible to say roughly

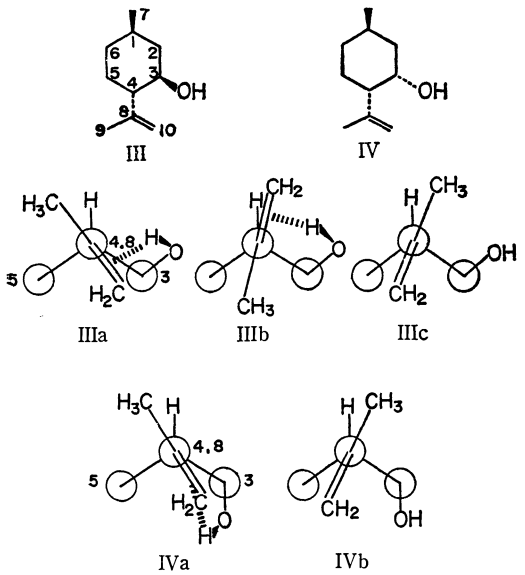
that the $\varepsilon b/\varepsilon f$ value reflects the relative population of the bonded and free species,[3] where εb is the molecular extinction coefficient of the bonded hydroxyl and εf is that of the free hydroxyl group. The $\varepsilon b/\varepsilon f$ values were 4.9 for I and 12.3 for II. Comparison of these values with the value (1.8) of allyl alcohol[10] reveals that the population of such an internally hydrogen-bonded molecules as Ia and IIa is larger in *p*-menth-8-en-4-ols (I and II) than in allyl alcohol. The reason for this appears to be that the axial hydrogens on C-2 and C-6 in Ib and IIb may sterically repel the hydrogen of the tertiary hydroxyl group, forcing to direct it to the outer side of the cyclohexane ring, and towards the double bond of the isopropenyl group, as in Ia and IIa, whereas such repulsion is absent in allyl alcohol.

Isopulegol (III) and Neoisopulegol (IV). Neoisopulegol (IV) showed two distinct bands at 3626 and 3575 cm^{-1}. This carbinol may take the intramolecularly hydrogen bonded conformation IVa and unbonded one IVb. The former band is ascribed to a free hydroxyl group in IVb, because a free axial secondary hydroxyl frequency has been reported[5-7] to appear at 3627 to 3632 cm^{-1}. The latter is assigned to the band due to such a hydroxyl group interacted with the π-electrons as in IVa. On the other hand, isopulegol (III) showed an unresolved band, which was divided into three by graphical separation as shown in Fig. 1. The peak at 3625 cm^{-1} may be attributed to the free equatorial secondary hydroxyl group, a peak of which is said[5-7] to appear at 3623 to 3630 cm^{-1}. The peak at 3578 cm^{-1} indicates the presence of the OH$\cdots\pi$ interaction. The third band, which appeared at 3593 cm^{-1} seems to be due to either a hydrogen bonded hydroxyl or a conformational heterogeneity about the C–OH bond. Menthol corresponding to the saturated compound of III showed an unsymmetric band at 3626 and 3608 cm^{-1} owing to the conformational heterogeneity. The wave number of the third band of III is different by 15 cm^{-1} from the low-frequency band of menthol. Hence, the third band of III must be due to an intramolecularly interacted hydroxyl group. Thus, isopulegol (III) is considered to possess two intramolecularly interacted forms as shown in IIIa and IIIb.

The $\varepsilon b/\varepsilon f$ values were 0.9 and 3.5 for III, and 4.8 for IV. Comparison of these values with the value (0.45) of 3-buten-1-ol[10] reveals that the population of the internally hydrogen bonded molecules, such as IIIa and IVa, is larger in isopulegols (III and IV) than in 3-buten-1-ol. This can be explained in the following way. For 3-buten-1-ol, there are three internal rotational degrees of freedom about the alpha and the beta carbon-carbon single bonds and the carbon-oxygen bond. Isopulegols (III and IV) have one less internal rotational degree of freedom, since the incorporation of the C_3–C_4 bond into the

10) This value was calculated from the data of allyl alcohol in Ref. 8.



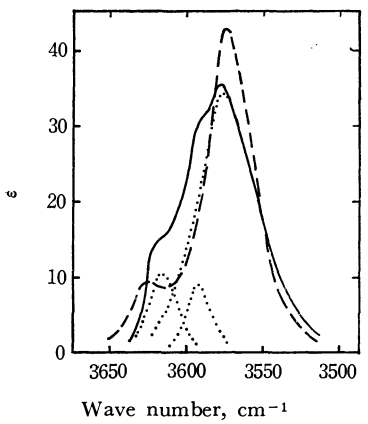


Fig. 1. IR spectra of isopulegol (III) (——; separated ·····) and neoisopulegol (IV) (- - -) in 0.005M CCl_4 solution.

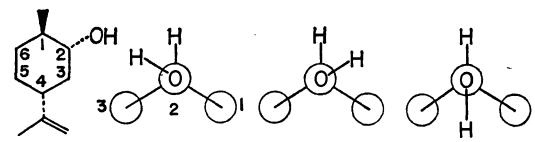
cyclohexane ring restrains the rotation of this bond, and this restriction makes the hydroxyl group favorable towards the isopropenyl group. Hence, the opportunity of hydrogen bonding is larger in isopulegols than in 3-buten-1-ol.

Dihydrocarveol (V), Neodihydrocarveol (VI) and *trans*-β-Terpineol (VII). Dihydrocarveol (V) having an equatorial secondary hydroxyl group showed a peak at 3630 cm^{-1} with a shoulder at 3610 cm^{-1}. This unsymmetrical band is not attributable to the presence of the interaction between the hydroxyl group and the π-electrons, but rather to the presence of isomers (Va, Vb and Vc) due to the rotational conformations of the hydroxyl group about the C–O axis.[11] The corresponding saturated alcohol, carvomenthol, also revealed an unsymmetrical band at 3631 and 3612 cm^{-1}, whereas the epimeric alcohol, neocarvomenthol, showed a symmetrical one at 3633 cm^{-1}. Therefore, the band at 3630 or 3631 cm^{-1} observed in dihydrocarveol (V) and carvomenthol with an equatorial secondary hydroxyl group is attributable to the conformers Va and/or Vb, and the low-frequency bands at 3610 or 3612 cm^{-1} to the conformer Vc. On the other hand, neodihydrocarveol (VI) and *trans*-β-terpineol (VII) showed a symmetrical band at 3633 and at 3617 cm^{-1} respectively, which correspond to the free axial secondary hydroxyl and the free tertiary hydroxyl band.[5-7] Therefore, these alcohols are considered to be internally unbonded.



Thus, the intramolecular interaction between the hydroxyl group and the π-electrons on a double bond of *p*-menth-8-enols takes place only in the case of the hydroxyl group at the α- or β-position to the double bond. This kind of interaction can not be found in the case of hydroxyl group at farther than γ-position.

10-Nor-8-oxomenthol (VIII) and 10-Nor-8-oxoneomenthol (IX). The spectrum of VIII showed an unresolved band, which can be divided into three by graphical separation (Fig. 2). The peak at 3625 cm^{-1} is attributed to the free hydroxyl group and the peak at 3535 cm^{-1} to the OH···O intramolecularly hydrogen bonded hydroxyl group of the type of VIIIc, in which the hydroxyl group makes bonding to the lone pair electrons on the carbonyl oxygen atom. On the other hand, the intermediate band at 3599 cm^{-1} was separated only by 26 cm^{-1} from the free hydroxyl band. This small separation seems to indicate that the hydroxyl group interact with π-electrons on the carbonyl group,[12] as shown in VIIId and VIIIe. The spectrum of IX showed two peaks at 3626 and 3537 cm^{-1}, the former being attributed to the free hydroxyl group (IXc) and the latter to the intramolecularly hydrogen bonded hydroxyl group of the type IXd in which the hydroxyl group bonds to the lone pair electrons on the carbonyl oxygen atom.

The difference of interactions in VIII and IX was explained as follows: These keto alcohols may take two interconvertible chair-forms VIIIa and VIIIb, and IXa and IXb, respectively. However, the forms VIIIb and IXb containing three or two axial

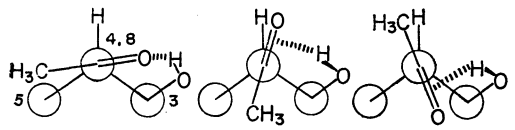
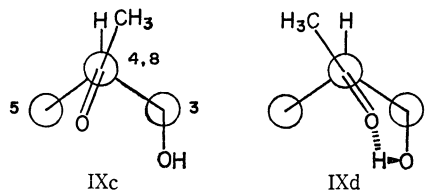
IXb



VIIIc VIIId VIIIe



IXc IXd

groups are neglected on the basis of the consideration of the thermodynamic stability.[13] Furthermore, the internal rotation of the acetyl group must be considered to explain the difference of the interaction. Intramolecular hydrogen bonding between the axial hydroxyl group and the lone pair electrons on the carbonyl oxygen in IX is favorable in conformer IXd, in which the interaction between the 9-methyl group and the 5-methylene is not present. On the other hand, conformer VIIIc having the short OH···O distance is unfavorable, because the 9-methyl group eclipses the 5-methylene. Therefore, the compound VIII seems to take conformation VIIId or VIIIe, in which no such unfavorable interaction occurs. In these conformations VIIId and VIIIe, the angle made by the direction of the carbonyl n-orbital and the line connecting the hydroxyl hydrogen with the carbonyl oxygen atoms amounts to *ca.* 60°, and the hydroxyl group is thought to interact rather with the π-electrons than with the lone pair electrons of the carbonyl group.

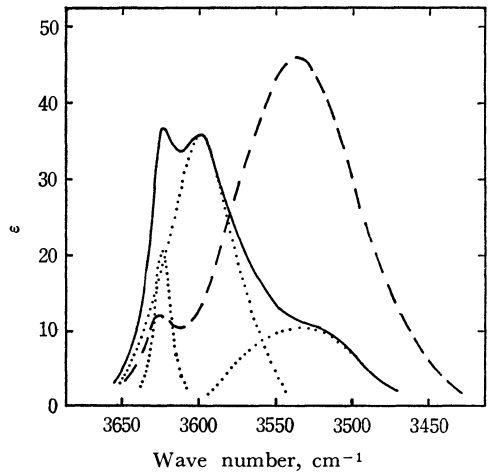


Fig. 2. IR spectra of 10-nor-8-oxomenthol (VIII) (——; separated ·····) and 10-nor-8-oxoneomenthol (IX) (- - -) in 0.005M CCl_4 solution.

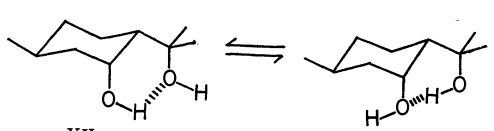
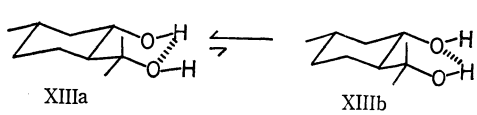
10-Nor-8-oxocarvomenthol (X) and 10-Nor-8-oxoneocarvomenthol (XI). The spectrum of 10-nor-8-oxocarvomenthol (X) showed an unsymmetrical band at 3630 cm^{-1} with a weak shoulder at 3608 cm^{-1}. The shape of this band as well as the wave number of the peak and the shoulder are very similar to those of carvomenthol and dihydrocarveol (V). Hence, the unsymmetrical band of X must be due to the conformational heterogeneity about the C–OH bond. 10-Nor-8-oxoneocarvomenthol (XI) revealed a symmetrical band at 3634 cm^{-1} corresponding to the free axial secondary hydroxyl band. No intramolecular interaction between the hydroxyl and carbonyl groups was observed for γ-keto alcohols such as 10-nor-8-oxocarvomenthols (X and XI).

***cis*- and *trans*-*p*-Menthane-3,8-diols (XII and XIII).** The spectrum of XII gave two bands at 3615 and 3522 cm^{-1}; the higher frequency band has a shoulder at *ca.* 3622 cm^{-1}. Concerning the *cis*-diol XII with the secondary axial hydroxyl group, the band at 3615 cm^{-1} is attributed to the free tertiary hydroxyl group in XIIa, while the weak band at 3622 cm^{-1} is due to the free secondary hydroxyl group in XIIb. This is supported by the fact that these frequencies agree with those of the ordinary



XIIa XIIb



XIIIa XIIIb

13) The differences in free energy between the equatorial and axial forms of the hydroxyl and methyl groups are −0.7[14] and −1.7 kcal/mol respectively. The energy of 1,3-diaxial interaction between the 7-methyl and hydroxyl groups in conformer VIIIb is 1.9—2.4 kcal/mol.[14] As the difference has been unknown for the acetyl group, we assumed to be nearly equal to −1.8 kcal/mol[14] given for the ethyl group. The difference of the conformational energy for VIIIa—VIIIb and IXa—IXb was estimated as −5.2 and −2.8 kcal/mol,[15] respectively. These differences would give a room temperature equilibrium mixture containing >99% of VIIIa or IXa, and <1% of VIIIb or IXb.

15) Estimated approximately by adding the corresponding values for a hydroxyl, a methyl and an acetyl groups, and for the 1,3-diaxial interaction between the hydroxyl and methyl groups, since such summations have been said to be approximately correct in some cases.[16]

16) Ref. 14, p. 58.

free tertiary hydroxyl and secondary hydroxyl groups.[5-7] The strong band at 3522 cm^{-1} is attributable to both the bonded secondary and tertiary hydroxyl groups in XIIa and XIIb respectively. On the other hand, the spectrum of XIII showed two resolved peaks at 3614 and 3509 cm^{-1}. The band at 3614 cm^{-1} is assigned to the band due to the free tertiary hydroxyl group in XIIIa and the strong band at 3509 cm^{-1} is mainly due to the bonded secondary hydroxyl group in XIIIa, since the band corresponding to the free hydroxyl is absent. Therefore, the preferential formation of the hydrogen bond seems to be in the case, where the secondary hydroxyl group is bonded to the oxygen atom of the tertiary hydroxyl group.

Experimental

Infrared Measurements. The infrared absorption was measured with a Perkin-Elmer Model 621 Grating Infrared Spectrometer, the spectral slit width being 3.5 cm^{-1} in the region required. Spectro Grade carbon tetrachloride was used as a solvent. A salt absorption cell, 2 cm in length, was used and the concentration of the solution was 0.005 mol/*l* at which the association of the solute negligible. Measurements were made at 25°C.

***trans*- and *cis*-*p*-Menth-8-en-4-ols (I and II).** These *p*-menth-8-en-4-ols (I and II) kindly supplied by Dr. Klein were prepared from 4(8)-*p*-menthene by the photosensitized oxidation.[17]

(−)-Isopulegol (III) and (+)-Neoisopulegol (IV). These two alcohols were isolated by the partial esterification of an isopulegol mixture.[18] III showed the following properties: bp 65—66°C/3 mmHg, n_D^{25} 1.4684, d_4^{25} 0.9062, $[\alpha]_D^{25}$ −22.51° (homog.) (lit.,[18] n_D^{26} 1.4690, d_4^{26} 0.9062, $[\alpha]_D^{26}$ −23.6°), 3,5-dinitrobenzoate of III, mp 104—105°C (lit.[18] mp 104—104.5°C). IV showed the following properties: bp 81—81.2°C/9 mmHg, n_D^{25} 1.4695, d_4^{25} 0.9115, $[\alpha]_D^{25}$ +33.27° (homog.) (lit.,[18] n_D^{26} 1.4708, d_4^{26} 0.9121), 3,5-dinitrobenzoate of IV, mp 133—134°C (lit.,[18] 133—133.5°C).

(−)-Dihydrocarveol (V). This alcohol was prepared from (−)-carvone by the reduction with sodium-aqueous ammonia[19] and had following properties: bp 99—99.5°C/10 mmHg, n_D^{25} 1.4725, d_4^{25} 0.9162, $[\alpha]_D^{25}$ −34.15° (homog.) (lit.,[19] n_D^{23} 1.4748, d_{20}^{23} 0.9202, $[\alpha]_D^{23}$ −33.25°), 3,5-dinitrobenzoate of V, mp 122—123°C (lit.,[19] mp 121.5—122.5°C).

(+)-Neodihydrocarveol (VI) and *trans*-*β*-terpineol (VII). These alcohols were prepared from (+)-limonene monoxide by the reduction with lithium aluminum hydride.[20] The former VI was isolated from a reduction product by converting into the *p*-nitrobenzoate derivative followed by hydrolysis and showed the following properties: bp 107—107.9°C/19 mmHg, n_D^{25} 1.4763, d_4^{25} 0.9225, $[\alpha]_D^{25}$ +35.16° (homog.) (lit.,[20a] n_D^{20} 1.4798, d_4^{25} 0.9337, $[\alpha]_D^{25}$ +32.8°), *p*-nitrobenzoate of VI, mp 106—107°C (lit.,[20] 106°C).

The unesterified portion of the reduction product was fractionally distilled under a reduced pressure, and afforded *trans*-*β*-terpineol (VII): bp 100—100.5°C/17 mmHg, mp 30—31°C, n_D^{25} 1.4746, d_4^{25} 0.9230, $[\alpha]_D^{25}$ 0° (lit.,[20a] mp 31—31.5°C n_D^{20}, 1.4749, d_4^{25} 0.9235).

(−)-10-Nor-8-oxomenthol (VIII). A solution of 1.0 g of III was ozonized in glacial acetic acid. The reaction mixture was stirred with zinc powder (1.0 g), 20 m*l* of ether, and 15 m*l* of water for 2 hr. The usual work-up gave 0.56 g of VIII: mp 45—46°C, $[\alpha]_D^{25}$ −48.5° (*c* 0.34, methanol), 3,5-dinitrobenzoate of VIII, mp 152—153°C (Found: C, 54.68; H, 5.20%).

Found: C, 69.38; H, 10.52%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

(+)-10-Nor-8-oxoneomenthol (IX). (+)-Neoisopulegol (IV) (1.0 g) was ozonized in glacial acetic acid (20 m*l*). On treatment as in the case of VIII, the ozonized mixture gave 0.8 g of IX: mp 59—60°C, $[\alpha]_D^{25}$ +17.7° (*c* 0.37, methanol), 3,5-dinitrobenzoate, mp 93—94°C (Found: C, 54.96; H, 5.37%).

Found: C, 68.90; H, 10.48%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

(−)-10-Nor-8-oxocarvomenthol (X). When (−)-dihydrocarveol (V) (2.0 g) was ozonized in glacial acetic acid in the same way as in the case of VIII, it gave a crystalline mass (1.1 g) of X: mp 58—59°C, $[\alpha]_D^{25}$ −43.1° (*c* 0.21, methanol), 3,5-dinitrobenzoate, mp 126—126.5°C (Found: C, 54.77; H, 5.42%).

Found: C, 69.42; H, 10.50%. Calcd for $C_9H_{16}O_2$: C, 69.19; H, 10.32%.

(+)-10-Nor-8-oxoneocarvomenthol (XI). On ozonization in the same way as in the case of VIII, (+)-neodihydrocarveol (VI) (2.0 g) gave 1.2 g of XI as an oil: bp 107—108°C/2 mmHg, n_D^{25} 1.4732, d_4^{25} 1.0165, $[\alpha]_D^{25}$ +29.41° (homog.); 3,5-dinitrobenzoate, mp 136—137°C (Found: C, 54.58; H, 5.39%).

***cis*- and *trans*-*p*-Menthane-3,8-diols (XII and XIII).** These diols kindly supplied by Dr. Arai were prepared from (+)-citronellal by the acid-catalyzed cyclization[21]; XII, mp 73—74°C; XIII, mp 60—61°C.

The author wishes to express his hearty gratitude to Professor Tamon Matsuura and to Dr. Takayuki Suga for their guidance and encouragement, to Dr. E. Klein of DRAGOCO, Holzminden, for a gift of *p*-menth-8-en-4-ols, to Dr. Mannosuke Arai of Tohoku University, for *p*-menthane-3,8-diols, to Takasago Perfumery Co., Ltd., Tokyo, for spearmint oil and isopulegol, to Hasegawa Co., Ltd., Tokyo, for limonene. Microanalyses were performed at Faculty of Pharmacy of Kyoto University, Kyoto.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1175—1179 (1968)

Stereochemical Studies of Monoterpene Compounds. V.[1] The Rotational Conformation of the Acetyl Group of 10-Nor-8-oxomenthols and 10-Nor-8-oxocarvomenthols[2]

Takayuki SUGA, Tsuyoshi SHISHIBORI and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

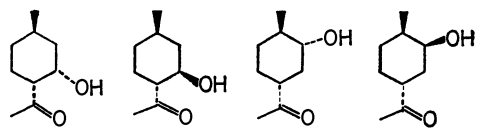
(Received September 30, 1967)

The preferred rotational conformation of the acetyl group of (+)-10-nor-8-oxoneomenthol (I), (−)-10-nor-8-oxomenthol (II), (−)-10-nor-8-oxocarvomenthol (III), and (+)-10-nor-8-oxoneocarvomenthol (IV) has been examined by a combination of conformational analysis by *a priori* calculation and variable-temperature circular dichroism and infrared spectrum measurements. Compound I exhibited an inversion in the sign of the Cotton effect upon a change in the solvent. This phenomenon was interpreted as indicating the conformational change Ia⇄Ib. The cause of the change was ascribed to the formation and subsequent rupture of the intramolecular hydrogen bond. Compound II exhibited a solvent-depending circular dichroism curve similar to the curve of I; this was explained as indicating the existence of a conformational equilibrium between the free conformer, IIa, and the internally-hydrogen-bonded conformers, IIb, IIc, and IId. Furthermore, compounds III and IV were found to take preferentially the IIIa—IIIb and IVa—IVb conformations respectively.

In recent years, optical rotatory dispersion and circular dichroism (CD) measurements have been useful in assigning the rotational conformation of the 17-acetyl group of 20-ketosteroids[3] because of the peculiar sensitivity of this method to subtle conformational alterations. However, the conformation of the acetyl group of the cyclohexane derivatives has not yet been reported. 2- and 3- Acetylcyclohexanols seem to represent an interesting example of such a conformational alteration, since intramolecular hydrogen bonding can be expected in them, together with a rotational conformation of the acetyl group. For this paper the preferred rotational conformation of the acetyl group of (+)-10-nor-8-oxoneomenthol (I), (−)-10-nor-8-oxomenthol (II), (−)-10-nor-8-oxocarvomenthol (III) and (+)-10-nor-8-oxoneocarvomenthol (VI) has been examined by a combination of conformational analysis by *a priori* calculation and variable-temperature CD and infrared (IR) spectrum measurements.

Results and Discussion

Compounds I, II, III and IV were prepared from (+)-neoisopulegol, (−)-isopulegol, (−)-dihydrocarveol and (+)-neodihydrocarveol respectively by ozonolysis; the configurations are as shown in Fig. 1.



I II III IV

Fig. 1.

In the conformational analysis of compounds I, II, III and IV, the conformation of the cyclohexane ring will be assumed throughout the following discussion to take the 1,4-diequatorial chair-form.[1] We must next consider the problem of the rotational barrier about a bond joining a carbonyl group to a tetrahedral carbon in a molecule of the acetone type. As Fig. 2 shows, the conformational energies of the acetyl group of compounds III and IV were estimated by using the energy functions given by the conformational analysis of the acetyl-side chain of pregnan-20-one.[4]

Compd.	The sign of cotton effect predicted											
I	±	+	+	+	+	+	−	−	−	−	−	−
II	+	+	+	+	+	+	−	−	−	−	−	+
III	+	+	+	+	+	±	−	−	−	−	−	±
IV	+	+	+	+	+	±	−	−	−	−	−	±

Fig. 2. Conformational energies calculated for the rotational conformation of the acetyl groups of I—IV as a function of θ: —— for III and IV, - - - for I, ····· for II. The signs of the Cotton effect predicted for each conformation were estimated from models as illustrated in Fig. 3.

With respect to compounds I and II, the functions of the van der Waals interaction between the C_3-hydroxyl and 9-methyl groups and between the C_3-hydroxyl group and the oxygen of the acetyl group must be superimposed upon the energy function for compound III or IV. The maximum of the former interaction in compound I should come around $\theta = 330°$, where θ corresponds to a dihedral angle of V, and should be similar to the 1,3-diaxial hydroxyl-methyl interaction, with a value of 2.1 kcal/mol.[5] Judging from the distance between the hydroxyl and methyl groups, this value should have fallen to less than 0.35 kcal[6] at $\theta = 270°$ and 30°, but to have a value of more than 0.35 kcal at $\theta = 300°$ and 360°. As the interaction between the C_3-hydroxyl group and oxygen of the acetyl group has been unknown, we assumed it to be nearly equal to the 1.9 kcal/mol[5] given for the 1,3-diaxial hydroxyl interaction. The maximum of this interaction should come around $\theta = 150°$. The rest of the curve is taken as proportional to the curve of the methyl-hydroxyl function, displaced appropriately. For compound II, the maximum of the interactions between the C_3-hydroxyl and 9-methyl groups and between the C_3-hydroxyl group and oxygen of the acetyl group are at $\theta = 270°$ and 90° respectively. The magnitudes of the interaction are equal to those of I.

5) E. L. Eliel, N. L. Allinger, S. J. Angyal and G. A. Morrison, "Conformational Analysis," Interscience Publishers, New York, N. Y. (1965), p. 52.

6) The energy of interaction and the distance between an equatorial methyl and an equatorial or axial hydroxyl groups on adjacent carbon atoms in cyclitols are 0.35 kcal/mol[7] and 2.8 Å respectively.

7) Ref. 5, p. 356.

If this function represents the relative energy of the conformations, the conformer with $\theta = 210°$ to 240° in compound I would be preferred over the conformer with $\theta = 120°$ by 1.0 kcal/mol. Concerning compound II, the conformer with $\theta = 150°$ to 210° would be preferred over the conformer with $\theta = 0°$ by 0.8 kcal/mol.

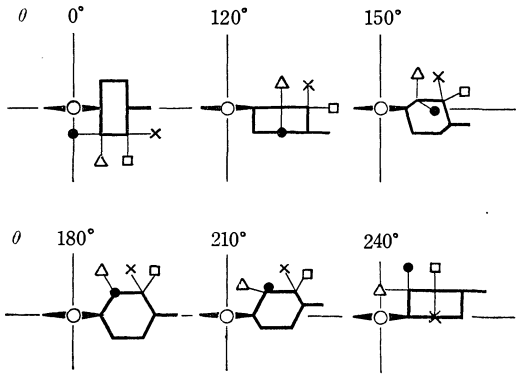

Fig. 3. Illustrations of the octant-rule projections used to predict the Cotton effect of the various rotational conformations of the acetyl group. Only the conformations eventually considered to be preferred are shown. Carbon skeleton is in heavy line; ○ for carbonyl oxygen; ● for OH of I; △ for OH of II; □ for OH of III; × for OH of IV.

Models[8] of each conformation were examined, and the signs of the Cotton effect were predicted according to the octant rules[9] (Fig. 3). As shown in Fig. 2, the results showed that the conformers with $\theta = 0°$ to 150° should exhibit a positive Cotton effect, and the conformers with $\theta = 180°$ to 300°, a negative one, in all compounds.

(+)-10-Nor-8-oxoneomenthol (I). As shown in Fig. 4, the CD curves of I exhibited a strong solvent-dependence, that is, a positive Cotton effect in isooctane and in carbon tetrachloride, but a negative one in methanol and in dimethyl sulfoxide. Such an inversion of the sign of the Cotton effect upon a change in solvent can be ascribed to the change in the equilibrium of the rotational conformation of the acetyl group; an inversion of the sign has been observed in α-hydroxycyclohexanone derivatives[10] and explained by the idea that intramolecular hydrogen bonds were present in carbon tetrachloride, but these bonds were ruptured, resulting in a conformational

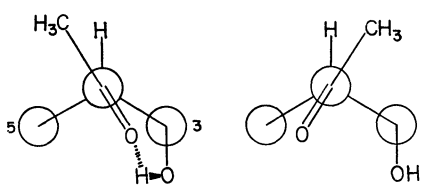
change in the methanol. A similar change in hydrogen-bonding may occur in compound I.

The IR spectrum of I in a 0.005 M carbon tetrachloride solution showed a concentration-independent band at 3537 cm^{-1} (ε 46) resulting from the hydroxyl function, which is intramolecularly hydrogen bonded with the lone-pair electrons on the carbonyl oxygen atom. This OH···O hydrogen bond is favorable in the Ia conformation with $\theta = 150°$. On the other hand, the IR spectrum of I in dimethyl sulfoxide solution exhibited a broad band at 3330 cm^{-1} attributable to the formation of an intermolecular hydrogen bond between the hydroxyl group and the solvent. The CD and IR data, together with the results of conformational analysis (Fig. 2), suggest that the Ia conformer with $\theta = 150°$ is preferential in nonpolar solvents, whereas Ib conformer with $\theta = 120°$ is preferential in polar ones.



Ia Ib

This agrees with the expectation that the population of Ia will increase in a nonpolar solvents, because the destabilizing electrostatic interaction between the carbonyl and hydroxyl groups in Ib is overcome by the formation of an intramolecular hydrogen bond in Ia. On the other hand, methanol and dimethyl sulfoxide are solvents which would be expected to form an intermolecular hydrogen bond with the carbonyl and/or the hydroxyl groups, and the population of Ia decreases concomitantly in a polar solvent because the stabilizing intramolecular hydrogen bond is broken.

A correlation between the rotational strength, R_0^{25}, and Kosower's *Z* values[11] (an empirical index of solvent polarity) is shown in Fig. 5. An anomalous decrease in the rotational strength appears at *Z* values of from 65 to 70. This seems to signify that the intramolecular hydrogen bond of I is broken in solvents with the values of 65—70.

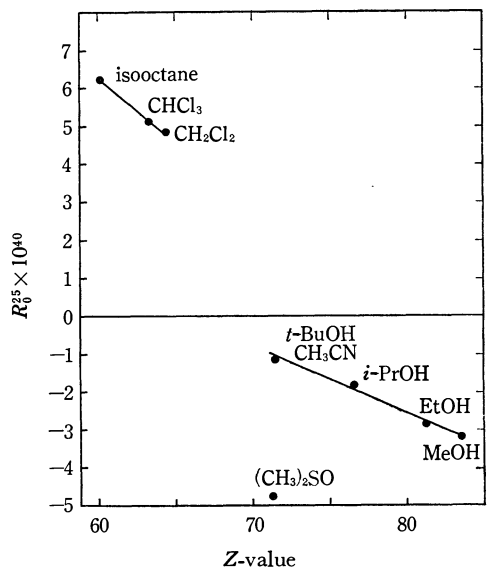


Fig. 5. Plot of rotational strength (R_0^{25}) of (+)-10-nor-8-oxoneomenthol (I) in various solvents *vs.* *Z*-value.

The variable-temperature CD curves of I in EPA[12] and in MI[13] are shown in Fig. 6. The CD curves in EPA exhibited a strong negative Cotton effect at −74°C, in contrast with the room-temperature CD curve. This signifies that the negatively rotating conformer, Ib, is energetically more favored at a low temperature in such a polar solvent. The CD curves in MI showed a positive Cotton effect and an increase in strength upon a lowering of the temperature. This implies that the positively-rotating, hydrogen-bonded conformer Ia is favored at a low temperature in a nonpolar solvent.

11) E. M. Kosower, *J. Am. Chem. Soc.*, **80**, 3254 (1958).
12) EPA solvent is composed of ether-isopentane-ethanol in the ratio 5 : 5 : 2 by volume.
13) MI solvent is composed of methylcyclohexane-isopentane in the ratio 1 : 3 by volume.

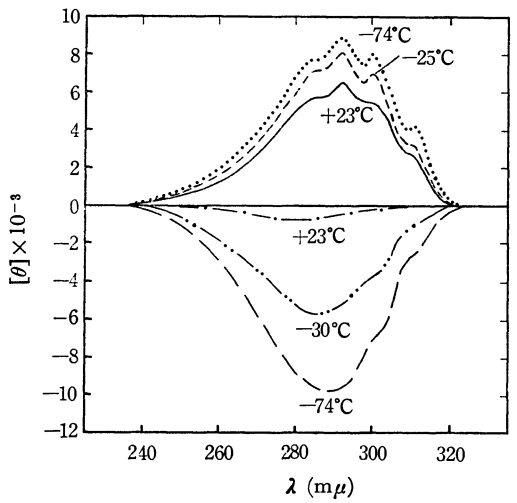

Fig. 6. CD curves of (+)-10-nor-8-oxoneomenthol (I) in EPA (—·—·, —··—, — —) and in MI (——, - - -, ····) at various temperatures.

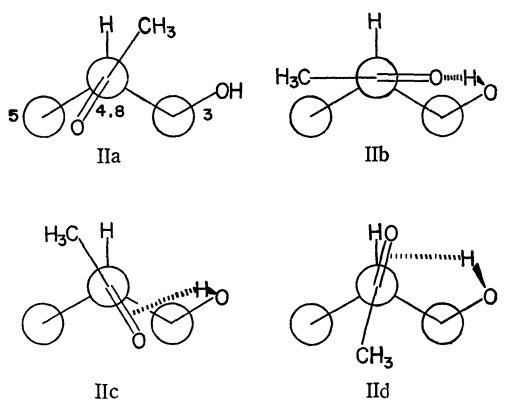
(−)-10-Nor-8-oxomenthol (II). The IR spectrum of II showed two peaks, at 3625 (ε 20) and 3599 cm^{-1} (ε 35), and a shoulder at 3535 cm^{-1} (ε 9) in a 0.005 M carbon tetrachloride solution. The band at 3625 cm^{-1} was attributed to such a free hydroxyl group as in the IIa conformation with θ= 150°—210°, and the weak band at 3535 cm^{-1} to such an OH···O-type intramolecular hydrogen bond as in the IIb conformation with θ=90°. The band at 3599 cm^{-1} was also ascribed to an intramolecular, hydrogen-bonded hydroxyl group, and the small shift ($\Delta\nu$=26 cm^{-1}) of this band from the free hydroxyl band seems to indicate that the hydroxyl group interacts with the π-electrons on the carbonyl group,[14] as in IIc and/or IId. The IR spectrum in a dimethyl sulfoxide solution revealed the same results as in compound I.



As Fig. 7 shows, the CD curves of II exhibited a solvent-dependence similar to those of I, but the negative curve was observed only in dimethyl sulfoxide. This phenomenon can be explained in terms of the conformational equilibrium, IIa⇄IIb, IIc and IId, resulting from the formation and the subsequent rupture of the intramolecular hydrogen bond, in view of the IR-spectra results described above. The acetyl group of II would preferentially exist in positively-rotating, internally-bonded conformations, IIb, IIc, and IId, in a nonpolar solvent. In a polar medium, the stabilizing intramolecular hydrogen bond is broken and the population of the IIb, IIc, and IId conformations decreases, in contrast to the increasing population of the negatively-rotating conformer, IIa, with θ=150—210°. Thus, a decrease in the rotational strength of the positive curve was observed upon changing from a nonpolar solvent to a polar one, and a negative curve appeared in dimethyl sulfoxide (Fig. 7). As shown in Fig. 8, the CD curves of II in EPA exhibited a weak positive Cotton effect at +23°C and a weak negative one at −74°C. This signifies that the nonbonded conformer, IIa, is energetically favorable at a low temperature in a polar medium.

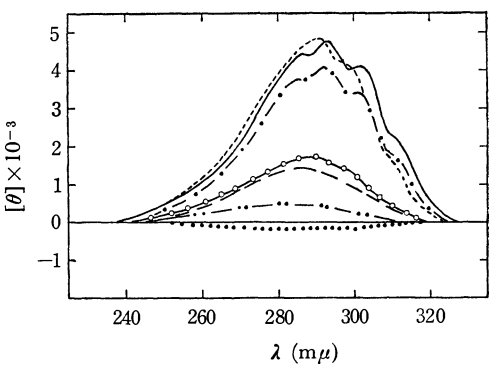


Fig. 7. CD curves of (−)-10-nor-8-oxomenthol (II) in selected solvents at 23°C: —— in isooctane; —·—· in CCl_4; - - - in $CHCl_3$; -o-o- in dioxane; —··— in *t*-BuOH; — — in MeOH; ···· in $(CH_3)_2SO$.

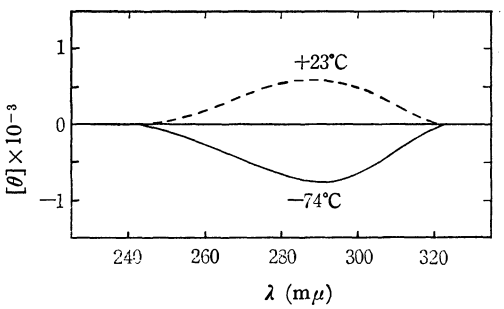

Fig. 8. CD curves of (−)-10-nor-8-oxomenthol (II) in EPA at +23°C and −74°C.

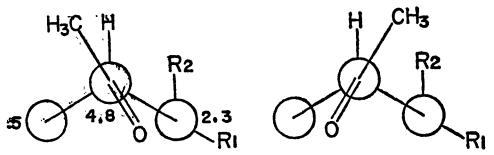
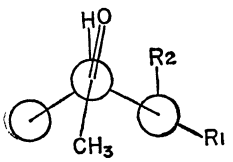
14) M. Ōki and H. Iwamura, Preprints for the 20th Annual Meeting of the Chemical Society of Japan, Tokyo (April, 1967), Part III, p. 128.

(−)-10-Nor-8-oxocarvomenthol (III) and (+)-10-Nor-8-oxoneocarvomenthol (IV). Furthermore, the rotational conformation of the acetyl group of III and IV has been examined. The IR spectra of III and IV in a 0.005 M carbon tetrachloride solution exhibited only a free hydroxyl band at 3630 (ε 42) and 3634 cm^{-1}(ε 80) respectively, showing the absence of a hydrogen bond between the carbonyl and hydroxyl groups. Thus, the rotational conformation of the acetyl group of III and IV is not affected by the hydrogen bond, and the acetyl group may be expected, from the conformational analysis (Fig. 2), to be situated near $\theta = 120$—$240°$ or $0°$.



IIIa: R_1=OH, R_2=H IIIb
IVa: R_1=H, R_2=OH IVb



IIIc
IVc

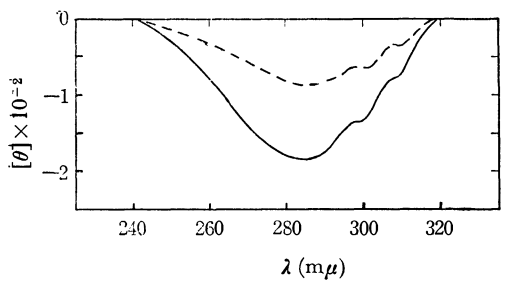


Fig. 9. CD curves of (−)-10-nor-8-oxocarvomenthol (III) in EPA at +23°C and −74°C.

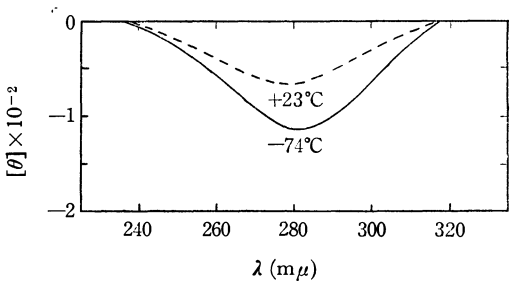

Fig. 10. CD curves of (+)-10-nor-8-oxoneocarvomenthol (IV) in EPA at +23°C and −74°C.

The CD curves of III in EPA showed a small increase in molecular ellipticity upon lowering of the temperature (Fig. 9). The CD curves of IV in EPA showed a similar tendency (Fig. 10). These results imply that the less stable, positively-rotating conformers, IIIc and IVc, with $\theta = 0°$, diminish, and that the stable ones, IIIa—IIIb and IVa—IVb, with θ = 120—240°, are favored at a low temperature.

Experimental

Materials. The (+)-10-nor-8-oxoneomenthol (I), (−)-10-nor-8-oxomenthol (II), (−)-10-nor-8-oxocarvomenthol (III), and (+)-10-nor-8-oxoneocarvomenthol (IV) were the same as were prepared in a preceding paper[1] of this series.

Spectral Measurements. The IR spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer Model 621 Grating Infrared Spectrometer. A salt absorption cell, 20 mm long, was used, and the concentration of the solution was 0.005 mol/*l* at which value the association of the solute is negligible. The measurements were made at 25°C. The CD curves were obtained by a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a circular dichroism attachment. The low-temperature CD curves were obtained by the same spectrometer, using a low-temperature CD cell[15] designed and constructed by the authors. These measurements were carried out using a cell 10 mm long and *c* 0.1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1180—1184 (1968)

Stereochemical Studies of Monoterpene Compounds. VI.[1] The Stereochemistry of 2-Hydroxypinocamphone and Its Reduction Products[2]

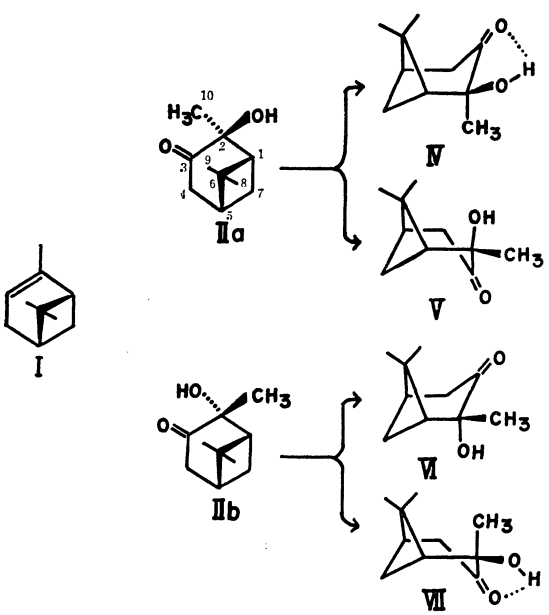
Takayuki SUGA, Tsuyoshi SHISHIBORI, Toshifumi HIRATA and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received October 18, 1967)

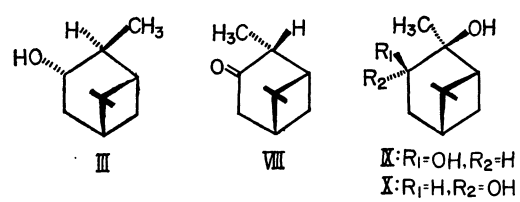
The stereochemical structure of (+)-2-hydroxypinocamphone (II), which was obtained from (−)-α-pinene (I) by the permanganate oxidation, was examined by a combination of physico-chemical methods. It was thus found that the C-2 methyl group is trans with respect to the C-6 bridge and that the preferred conformation is V having an axial hydroxyl group. In addition, the preferred conformation of *cis*-α-pinene glycol (IX) and *trans*-α-pinene glycol (X), which were produced from II by the lithium aluminum hydride reduction, was found to be IXa and Xa respectively.

The configuration of C-2 in 2-hydroxypinocamphone (II) obtained by the potassium permanganate oxidation of α-pinene (I) is represented by IIa or IIb. Schmidt[3] has reported the configuration to be cis (IIb) on the basis of the fact that compound II gave isopinocampheol (III),[4] when reduced with sodium-ethanol. However, the assignment of this configuration seems not to be reliable, since the epimerization may occur at the 2-position during the sodium-ethanol reduction. In this paper the stereochemical structure of the hydroxyketone II was examined by a combination of such physico-chemical methods as ultraviolet, infrared and nuclear magnetic resonance spectra, optical rotatory dispersion, and circular dichroism measurements. In addition, an examination about the preferred conformation of a diastereoisomeric pair of α-pinene glycols (IX and X) was made, which were derived from II by the lithium aluminum hydride reduction.



Results and Discussion

(+)-2-Hydroxypinocamphone (II) was prepared from (−)-α-pinene (I) in the same manner as in the case of Schmidt.[3] The lithium aluminum hydride reduction of II yielded a 63 : 37 mixture of α-pinene glycols, (IX) mp 55.5—56.0°C and (X) 160—161°C.



These glycols coincided with those reported by Schmidt[3] as cis- and trans-forms concerning the hydroxyl groups respectively. Both the diols were converted into the original ketone II by the potassium permanganate oxidation or by the chromium trioxide-pyridine complex oxidation.

Stereochemistry of 2-Hydroxypinocamphone (II). The compound II in question is formulated either by IIa or IIb, and each of these epimers may take interconvertible conformations IV and V, and VI and VII, respectively, as shown above. In the

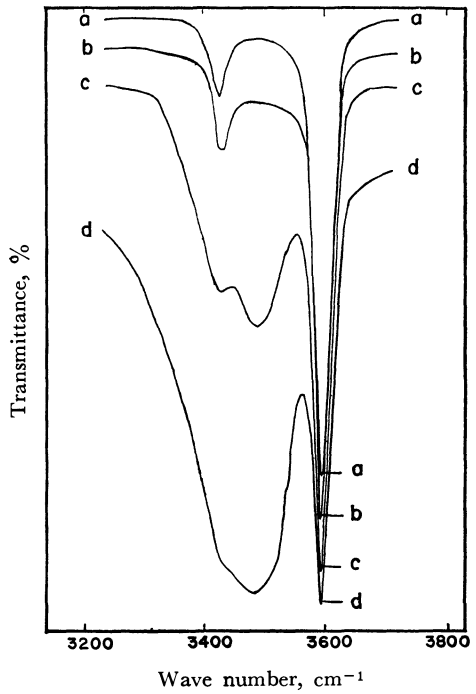

Fig. 1. Infrared spectra of 2-hydroxypinocamphone (II) in a carbon tetrachloride solution of various concentrations: a, 0.0025 M; b, 0.01 M; c, 0.05 M; d, 0.25 M.

first place, the preferred conformation of the hydroxyketone II was examined by IR, UV and NMR spectral measurements.

Intramolecular hydrogen bonding between the hydroxyl and carbonyl groups is possible in conformers IV and VII which have an equatorial hydroxyl group, whereas such bonding is impossible in V and VI having an axial one. The infrared spectra of II in the hydroxyl stretching region showed the concentration-depending bands at 3594 and 3474 cm^{-1} as shown in Fig. 1.*1 The nuclear magnetic resonance in a carbon tetrachloride solution exhibited a pronounced high-field shift of 1.36 ppm of the hydroxyl signal on dilution, and also this signal was shifted to the higher field by 0.67 ppm when the temperature was varied from 20°C to 60°C. These facts showed the hydroxyl group at the C-2 not to be intramolecularly bonded, and the group appeared to be axial.

This assignment of the hydroxyl group was confirmed by the fact that the carbonyl $n\rightarrow\pi^*$ band of II in the ultraviolet absorption spectrum (*cf.* Fig. 4) exhibited the bathochromic shift[5-7] by 13 mμ in methanol, as compared to the band of (−)-pinocamphone (VIII) lacking in the hydroxyl group. Furthermore, the axial orientation of the hydroxyl group of II was emphasized by the effect of benzene[8,9] on the C-2 methyl resonance in the nuclear magnetic resonance. When the nuclear magnetic resonance of II was measured on passing from deuteriochloroform to benzene solution, each of 8- and 9-methyl resonances suffered an upfield shift by 0.30 ppm, whereas the signal of the C-2 methyl group moved to the higher field by only 0.04 ppm as shown in Fig. 2. This fact indicates the C-2 methyl to be equatorial, and therefore the C-2 hydroxyl group must be axial. Thus, the preferred conformation of 2-hydroxypinocamphone (II) has been assigned as either V or VI, where the configuration of V is *S*-configuration[10] at C-2 and that of VI must be *R*-configuration.

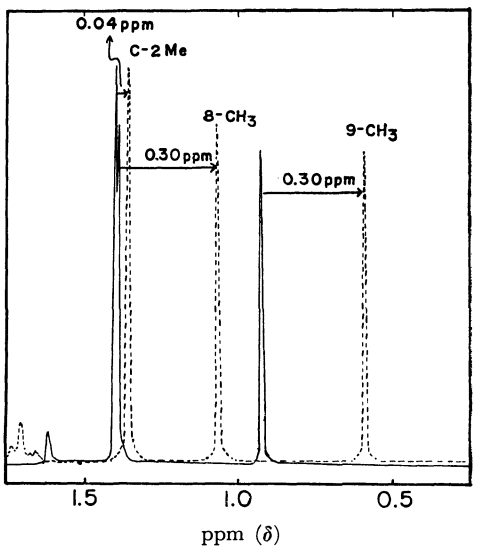

Fig. 2. The methyl resonances in the NMR spectra of 2-hydroxypinocamphone (II) in deuteriochloroform (the full line) and in benzene (the broken line).

In order to determine the configuration at the 2-position of II through ORD and CD measurements, models[11] were constructed for two conformers V and VI, the octant projection diagrams of which are shown in Fig. 3. The sign of the Cotton effect was predicted from this diagrams on assuming the octant

*1 A small peak at 3426 cm^{-1} is due to the overtone of the carbonyl stretching absorption.

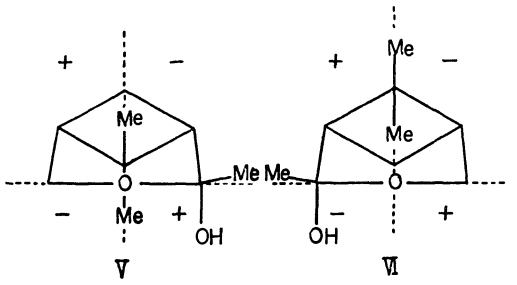

Fig. 3. The octant projections of conformers V and VI.

rule[12] to be applicable to the pinane skeleton. The conformer V was thus expected to exhibit a positive Cotton effect, whereas the conformer VI a negative one.

The ORD and CD curves of II in carbon tetrachloride showed the positive Cotton effect as shown in Fig. 4. The solvent-independent, positive ORD and CD curves were also observed in the other solvents, isooctane, dioxane, acetonitrile, dimethyl sulfoxide and methanol (see experimental section). These results imply that the C-2 methyl group is trans to the C-6 bridge, in contrast with Schmidt's report[8] in which the methyl group has been assigned

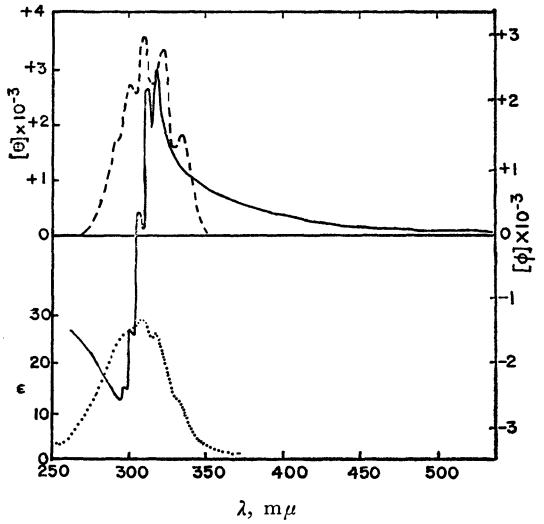

Fig. 4. Optical rotatory dispersion (the full line) and circular dichroism curves (the broken line) and ultraviolet spectrum (the dotted line) of (+)-2-hydroxypinocamphone (II) in carbon tetrachloride.

to be cis to the C-6 bridge. Consequently, it was confirmed that the stereochemical structure of (+)-2-hydroxypinocamphone (II) is V.

Conformation of *cis*- and *trans*-α-Pinene Glycols (IX and X). (−)-*cis*-α-Pinene glycol (IX)

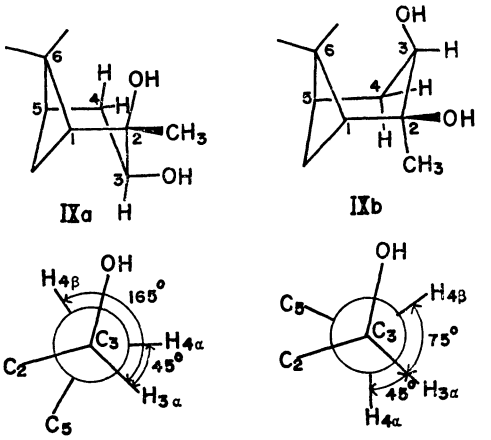

Fig. 5. The possible conformations for *cis*-α-pinene glycol (IX), and the dihedral angles between the C-3 proton and the C-4 protons in the conformers IXa and IXb.

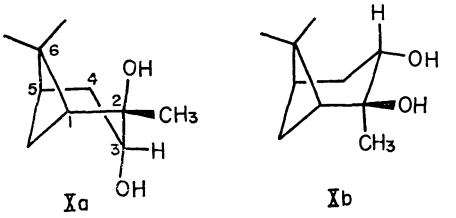
may take two interconvertible forms IXa and IXb (Fig. 5). The hydroxyl stretching absorption in a dilute, carbon tetrachloride solution was found at 3614 and 3545 cm^{-1}. The former peak was attributed to a free hydroxyl group and the latter to an intramolecularly bonded one. In this case, the conformational preference between IXa and IXb cannot be determined only on the basis of $\Delta\nu$ in the infrared spectrum, because of the equality of the OH···O distance[11] (*ca.* 2.2 Å) in both IXa and IXb.

However, the NMR spectrum of the *cis*-diol IX afforded the reliable evidence for the conformational assignment. The C-3 proton of the *cis*-glycol IX exhibited a signal at 3.94 ppm (double doublets, $J=5.4$ and 9.3 cps). The coupling constants for the C-3 proton of the two possible conformations were calculated by the equation of Karplus.[13] The dihedral angles used in the calculation were estimated from the models[11] and are shown in Fig. 5. The calculated coupling constants for IXa were $J_{3\alpha,4\alpha}=3.9$ cps and $J_{3\alpha,4\beta}=8.5$ cps, and the constants for IXb were $J_{3\alpha,4\alpha}=3.9$ cps and $J_{3\alpha,4\beta}=0.1$ cps. The observed spectrum agrees nearly with the calculated coupling constants for IXa. Therefore, the preferred conformation of (−)-*cis*-α-pinene glycol (IX) was found to be IXa.

On the other hand, (−)-*trans*-α-pinene glycol (X) may take two interconvertible forms Xa and Xb.



12) W. Moffitt, R. B. Woodward, A. Moscowitz, W. Klyne and C. Djerassi, *J. Am. Chem. Soc.*, **83**, 4013 (1961).

13) M. Karplus, *ibid.*, **85**, 2870 (1963).

Since the OH···O distances[11] are *ca.* 4.0 Å in Xa and *ca.* 2.5 Å in Xb, intramolecular hydrogen bonding is possible in conformer Xb having two equatorial hydroxyl groups, but such bonding is impossible in conformer Xa having two axial hydroxyl groups. The hydroxyl stretching absorption of *trans*-α-pinene glycol (X) in a dilute, carbon tetrachloride solution was found at 3610 and 3626 cm^{-1}, which would be attributed to the free, tertiary and secondary hydroxyl groups, respectively. It may be said *trans*-glycol X not to form the intramolecular hydrogen bond. Thus, the orientation of two hydroxyl group of glycol X was diaxial. As the C-2 configuration of the hydroxyketone II is retained in the lithium aluminum hydride reduction, it was seen that the conformation of (−)-*trans*-α-pinene glycol (X) is shown as Xa.

Experimental

The IR spectra were recorded by a Hilger H-800 Spectrophotometer (calcium fluoride prism) and a Perkin-Elmer Model 621 Grating Infrared Spectrometer. The ORD and CD spectra were measured at 25°C with a Japan Spectroscopic Co., Ltd. Model ORD/UV-5 Spectropolarimeter. The NMR spectra were recorded with a Hitachi Perkin-Elmer, R-20, and a Varian Associates, A-60, high-resolution spectrometers using tetramethylsilane as an internal standard. The variable-temperature NMR spectra were measured with a Japan Electron Optics Lab., JNM-C-60H. Microanalysis was done at the Microanalytical Center in the Faculty of Pharmacy of Kyoto University.

(+)-2-Hydroxypinocamphone (II). To a mixture of 579 g of (−)-α-pinene (I) (bp 71.0°C/51 mmHg, n_D^{25} 1.4626, d_4^{25} 0.8556, $[\alpha]_D^{25}$ −39.92°) and 5570 m*l* of 90% aqueous acetone was added 300 g of powdered potassium permanganate in small portions in a period of 8.5 hr at −5—5°C. The mixture was stirred for further 24 hr at 5°C. The filtrate free from manganese dioxide was treated as performed by Kuwata,[4] and gave 142 g of a neutral product boiling at 115—125°C/12.5 mmHg. This product solidified as a crystalline mass in a refrigerator. 2-Hydroxypinocamphone (II) was obtained by recrystallization from *n*-hexane and showed the following properties: mp 32.5—34.0°C (lit.[3] mp 34.5—35.3°C); $[\alpha]_D^{25}$ +21.1° (*c* 4.64, ethanol) (lit.[4] $[\alpha]_D^{25}$ −18.56° (*c* 14.44, ethanol), from (+)-α-pinene), $[\alpha]_D^{25}$ +38.1° (*c* 3.12, chloroform) (lit.[3] $[\alpha]_D$ −41.2° (chloroform), from (+)-α-pinene). UV: $\lambda_{max}^{CCl_4}$ 309 mμ (ε 29.6), $\lambda_{max}^{isooctane}$ 309 mμ (ε 24.6), $\lambda_{max}^{dioxane}$ 309 mμ(ε 27.8), $\lambda_{max}^{acetonitrile}$ 307 mμ (ε 26.1), $\lambda_{max}^{dimethyl\ sulfoxide}$ 309 mμ (ε 30.0), $\lambda_{max}^{methanol}$ 308 mμ (ε 28.0). ORD: $[\phi]_{336}^{CCl_4}$ +2410, $[\phi]_{288}$ −2501; $[\phi]_{338}^{isooctane}$ +2457, $[\phi]_{290}$ −2319; $[\phi]_{338}^{dioxane}$ +2227, $[\phi]_{289}$ −2014; $[\phi]_{337}^{acetonitrile}$ +2034, $[\phi]_{228}$ −1979; $[\phi]_{337}^{dimethyl\ sulfoxide}$ +2212, $[\phi]_{288}$ −2240; $[\phi]_{337}^{methanol}$ +1684, $[\phi]_{296}$ −1943. CD: $[\theta]_{310}^{CCl_4}$ +3793, $[\theta]_{310}^{isooctane}$ +3281, $[\theta]_{311}^{dioxane}$ +3281, $[\theta]_{310}^{acetonitrile}$ +3083, $[\theta]_{321}^{dimethyl\ sulfoxide}$ +3326, $[\theta]_{311}^{methanol}$ +2736.

The IR spectra in the hydroxyl stretching region were measured in 0.0025, 0.01, 0.05 and 0.25 M carbon tetrachloride solutions using salt absorption cells of 40.0, 10.0, 2.0 and 0.4 mm in length respectively.

The hydroxyl proton signal of the NMR spectrum appeared at δ 3.57 ppm in 20% carbon tetrachloride solution and at δ 2.21 ppm in 2.5% solution. This signal in 10% carbon tetrachloride solution was observed at δ 3.05 ppm at 20°C and at δ 2.38 ppm at 60°C. The methyl proton signal appeared at δ 0.88 ppm (C-9, 3H), 1.38 (C-8, 3H) and 1.39 (C-2 methyl, 3H) in 10% deuteriochloroform, and 0.58 (C-9, 3H), 1.08 (C-8, 3H) and 1.35 (C-2 methyl, 3H) in 10% benzene at 20°C.

(−)-*cis*- and (−)-*trans*-α-Pinene Glycols (IX and X). To 3.5 g of lithium aluminum hydride suspended in 200 m*l* of dry ether was added 22.0 g of II in a period of 3 hr at room temperature. Then, the reaction mixture was refluxed for 4 hr. After being left at room temperature for a day, the mixture gave 21.0 g of a crude diol, which was chromatographed on silica gel column with a mixture of ethyl acetate and *n*-hexane to separate into two components. The first eluate gave 9.6 g of a diol and the second eluate afforded 5.6 g of another diol. The homogeneity of these glycols separated was checked by chromatostrip analysis.

Properties of the First Eluate (cis-Glycol): mp 55.5—56.0°C (from petroleum benzine), $[\alpha]_D^{25}$ −0.89° (*c* 7.91, chloroform) (lit.[3] mp 55.5—56.0°C, $[\alpha]_D$ +3.3° (ethanol), from (−)-II).

The hydroxyl stretching absorption in 0.0021 M carbon tetrachloride solution was found at 3614 and 3545 cm^{-1}.

The NMR spectrum of the glycol was measured in 5 w/v% deuteriochloroform solution at 20°C.

The solution of 2.5 g of the glycol dissolved in 27 m*l* of 90% aqueous acetone was oxidized with 2.4 g of potassium permanganate for 12 hr at −5°C, and the original ketol II (1.7 g) was obtained, which was confirmed by comparison of the IR spectrum. Thus, the first eluate is *cis*-α-pinene glycol (IX).

Properties of the Second Eluate (trans-Glycol): mp 160—161°C (from ethanol), $[\alpha]_D^{25}$ −33.13° (*c* 4.8, ethanol) (lit.[3] mp 159—160°C, $[\alpha]_D^{25}$ +49° (ethanol), from (−)-II).

Found: C, 69.74; H, 10.68%. Calcd for $C_{10}H_{16}O_2$: C, 70.55; H, 10.66%.

The hydroxyl stretching absorption in 0.00079 M carbon tetrachloride solution appeared at 3626 and 3610 cm^{-1}.

A sample of 0.2 g of the second eluate was oxidized with a solution of 0.5 g of chromium trioxide in 5 m*l* of pyridine for 2 hr at room temperature, and 0.1 g of the original ketol II was obtained, which was confirmed by comparison of the IR spectrum. Thus, the second eluate is *trans*-α-pinene glycol (X).

(−)-Pinocamphone (VIII). Following the procedure reported,[14] 20 g of (+)-isopinocampheol (III) (mp 55—57°C, $[\alpha]_D^{25}$ +31.6° (*c* 10, benzene)), which was prepared from (−)-α-pinene (I) ($[\alpha]_D^{25}$ −39.32°) through hydroboration,[15] was oxidized with sodium dichromate to produce 17.8 g of (−)-isopinocamphone: bp 66°C/5 mmHg, n_D^{25} 1.4725, d_4^{25} 0.9618, $[\alpha]_D^{25}$ −9.77° (neat) (lit.[15] bp 54—56°C/1 mmHg, n_D^{25} 1.4745, α_D^{25} +10.3°, from (−)-III); 2,4-dinitrophenylhydrazone, mp 153°C (lit.[16] mp 151—152°C); semicarbazone, mp 227—228°C (lit.[4] mp 228°C).

14) H. C. Brown and C. P. Garg, *J. Am. Chem. Soc.*, **83**, 2952 (1961).
15) G. Zweifel and H. C. Brown, *ibid.*, **86**, 393 (1964).
16) A. Kergomard, *Bull. Soc. chim. France*, **1958**, 394.

Furthermore, following the method reported,[15] 0.50 g of (−)-isopinocamphone was added to the solution prepared by dissolving 0.12 g of metallic sodium in 25 m*l* of absolute ethanol, and then a mixture was stood for 24 hr at room temperature. The usual treatment of the mixture gave 0.35 g of the ketone VIII: $[\alpha]_D^{25}$ −18.56° (*c* 1.99, ethanol) (lit.[16] α_J −15°), λ_{max}^{MeOH} 295 mμ (ε 26.7).

The authors wish to express their hearty thanks to Takasago Perfumery Co., Ltd., Tokyo, for a gift of (−)-α-pinene, to Professor Shô Ito of Tohoku University, for measuring the NMR spectra by a Varian Associates, A-60, spectrometer, and to Japan Electron Optics Lab., Tokyo, for the variable-temperature NMR spectra measurement.

Preparation of Acetylene-Alcohol Dicobalt Hexacarbonyls and Their Reactivity towards Acid

Pu-Jun KIM and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received October 16, 1967)

A series of acetylene-alcohol dicobalt hexacarbonyls was prepared from acetylene-alcohols and dicobalt octacarbonyl. The reactivity towards aqueous sulfuric acid in boiling methanol was investigated. From the ethynyl carbinol complexes, $R^1R^2C(OH)C{\equiv}CH \cdot Co_2(CO)_6$, trinuclear cobalt complexes, $R^1R^2CHCH_2CCo_3(CO)_9$, were obtained accompanying the reduction of C–OH to a C–H moiety. On the other hand, from the butynediol complexes, $R^1R^2C(OH)C{\equiv}CC(OH)R^1R^2 \cdot Co_2(CO)_6$, binuclear cobalt complexes, $R^1R^2CHC{\equiv}CCHR^1R^2 \cdot Co_2(CO)_6$, or 1,1,4,4-tetraphenyl-1,3-butadiene were obtained. The structures of all these compounds have been confirmed by analytical measurements and by a study of their absorption spectra.

It is well known that acetylenes readily displace the two bridge carbonyl groups in dicobalt octacarbonyl to yield acetylenic dicobalt hexacarbonyls.[1,2] As a part of the study of the chemical behavior of these complexes, the reaction of acetylenic dicobalt hexacarbonyls, $RC{\equiv}CH \cdot Co_2(CO)_6$, (derived from terminal acetylenes) with aqueous mineral acids in boiling alcohol to yield trinuclear cobalt complexes, $RCH_2CCo_3(CO)_9$, has been reported on.[3]

In this paper, the preparation of various acetylene-alcohol dicobalt hexacarbonyls derived from the ethynyl carbinols and the butynediols, and the treatment of these complexes with aqueous sulfuric acid in boiling methanol will be reported.

Results and Discussion

Preparation of Acetylene-alcohol Dicobalt Hexacarbonyls. Various ethynyl carbinols and butynediols have now been treated with dicobalt octacarbonyl in diethyl ether or petroleum ether at room temperature under nitrogen for 2 hr to give red to reddish-brown acetylene-alcohol dicobalt hexacarbonyls. The properties of and analytical data on these complexes are summarized in Table 1. The spectra of each of the acetylene-alcohol dicobalt hexacarbonyls contain characteristic groups of three or four sharp bands in the range from 2000 to 2200 cm^{-1}; these bands are attributable to the terminal carbonyl groups. The band characteristic of the bridge carbonyl groups near 1800 cm^{-1} is absent. The band of the acetylenic C–H stretching at 3300 cm^{-1} in the starting materials was shifted by the complex formation to 3100 cm^{-1}, a characteristic olefinic C–H stretching frequency. The band characteristic of the carbon-carbon triple bond is absent. The PMR spectrum of ethynyl carbinol complexes shows a sharp singlet signal near τ 4.0 assignable to the coordinated terminal acetylenic proton.

Reactivity towards Aqueous Sulfuric Acid in Boiling Methanol. Ethynyl carbinol dicobalt hexacarbonyls have been treated with aqueous sulfuric acid in boiling methanol for 2 hr. Sublimable crystals, from dark purple to dark brown, were obtained. They were easily soluble in petroleum ether and were crystallized from methanol by deep cooling. The trinuclear structure for these compounds is supported by the results of the elemental analy se

and of the molecular-weight determinations (cryoscopy in benzene), and by their absorption spectra. The infrared spectra of these compounds show the absence of a hydroxyl group and the presence of terminal carbonyl groups. The stretching frequency of the C–Co bond was observed to be as shown in Table 2. The band near 650 cm^{-1} is susceptible to the alkyl groups, while those in the 470—560 cm^{-1} region are almost independent of the alkyl groups.[4] The PMR spectra of these trinuclear cobalt complexes are summarized in Table 3. The spectra are in good agreement with the $R^1R^2CHCH_2$-$CCo_3(CO)_9$ structure. The chemical shift of the methylene proton neighboring the $CCo_3(CO)_9$ group is observed in the lower field, *e.g.*, near τ 6.3. This may be caused by the strong electron affinity of the $Co_3(CO)_9$ group.

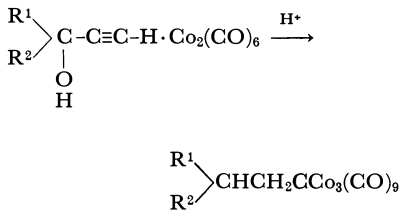
Table 3. Proton magnetic resonance data of $R^1R^2CHCH_2CCo_3(CO)_9$ complexes at 60 Mc/sec

Compound	Band position, τ	Relative intensity	Assignment	Coupling constant
$CH_3CH_2CCo_3(CO)_9$	8.46 (triplet)	3	CH_3	J=7.5 cps
	6.22 (quartet)	2	CH_2	J=7.5 cps
$CH_3CH_2CH_2CCo_3(CO)_9$	8.84 (triplet)	3	CH_3	J=7.0 cps
	8.09 (multiplet)	2	CH_2	
	6.35 (triplet)	2	CH_2	J=7.0 cps
$(CH_3)_2CHCH_2CCo_3(CO)_9$	8.81 (doublet)	6	CH_3	J=5.5 cps
	7.8—8.3 (multiplet)	1	CH	
	6.33 (doublet)	2	CH_2	J=5.5 cps



The $(CH_3)_2CHCH_2CCo_3(CO)_9$ complex was also formed from the ether complex $(CH_3)_2C(OCH_3)C{\equiv}CH\cdot Co_2(CO)_6$ under conditions analogous to those described above. The $CH_3CH_2CH_2CCo_3(CO)_9$ complex has also been obtained from vinylacetylene dicobalt hexacarbonyl $CH_2{=}CH{-}C{\equiv}CH\cdot Co_2(CO)_6$ by treatment with aqueous sulfuric acid in boiling methanol.[5]

Secondly, butynediol dicobalt hexacarbonyls have been treated with aqueous sulfuric acid in boiling methanol for 30 min. From tetramethylbutynediol dicobalt hexacarbonyl, brown crystals were obtained. The infrared spectra of this compound showed the absence of a hydroxyl group and the presence of terminal carbonyl groups. The PMR spectra in hexadeuterobenzene showed a doublet centered at τ 8.91*1 and a multiplet in the range from τ 6.9 to 7.6 with a relative intensity of 6 : 1. The analytical data of the elements were consistent with the composition in which two oxygen atoms were eliminated from the starting compound. Therefore, this compound seems to be di-isopropylacetylene dicobalt hexacarbonyl.*2 On the other hand, from tetraphenylbutynediol dicobalt hexacarbonyl, 1,1,4,4-tetraphenyl-1,3-butadiene was obtained.

In the well-known Meyer-Schuster Rearrangement free acetylenic carbinols are rearranged into unsaturated ketones or aldehydes by acidic reagents. In the present study, acetylenic carbinols coordinated to cobalt atoms were found not to take the Meyer-Schuster Rearrangement, but to be reduced and to form trinuclear cobalt complexes. As cobalt sulfate was recognized in an aqueous solution, the reduction of acetylene-alcohol may occur through the oxidation of Co^0 to Co^{2+} by the partial decomposition of the starting cobalt(0) complex. The hydrido cobalt carbonyl intermediate has been postulated for the formation of the trinuclear cobalt complex.[6] However, the reaction of $(CH_3)_2C(OH)C{\equiv}CH\cdot Co_2(CO)_6$ with $HCo(CO)_4$ in methanol was found to yield $(CH_3)_2CHC{\equiv}CH\cdot Co_2(CO)_6$*3 as the reduction product. The trinuclear cobalt complex $(CH_3)_2CHCH_2CCo_3(CO)_9$ was not formed. It remains to be proved how the reduction of C–OH to the C–H moiety occurs in the progress of the formation of the trinuclear cobalt complex.

Experimental

All melting points are uncorrected; they were measured by a micro melting point apparatus, Yanagimoto Model MP-S2. The infrared spectra were obtained by a Jasco Model DS-402 G grating spectrometer. The PMR spectra were recorded by a Varian Model A-60 instrument in carbon tetrachloride using tetramethylsilane as an internal standard. The molecular weights were measured by the cryoscopic method in benzene, using the vaporphase osmometer instrument developed by Dr.-Ing. Herbert Knauer.

Materials. The propargyl alcohol and 1-butyne-3-ol (35% in water) were of a Tokyo Kasei Reagent Grade. The 3-methyl-1-butyne-3-ol, 3-hexyne-2,5-diol, and 2,5-dimethyl-3-hexyne-2,5-diol were obtained from our laboratory. The ethynylbenzhydrol,[7] 3-phenylethynylbenzhydrol,[8] 1,1,4,4-tetraphenyl-2-butyne-1,4-diol,[9] and dicobalt octacarbonyl[10] were prepared by the methods described in the literature.

The Preparation of Acetylene-alcohol Dicobalt Hexacarbonyls. The ethynyl carbinols or butynediols and dicobalt octacarbonyl were allowed to react at room temperature for 2 hr in diethyl ether under a nitrogen atmosphere. Stoichiometric amounts or an excess of the acetylene-alcohols were used, depending upon the subsequent purification procedure. The reaction mixture was usually filtered to remove any insoluble impurities, and the filtrate was evaporated *in vacuo*. The residue was then purified by recrystallization from methanol on deep cooling or by molecular distillation.

A description of the compounds and the analytical data are given in Table 1. The preparation of $(CH_3)_2C(OH)C{\equiv}CH{\cdot}Co_2(CO)_6$ will be described in detail below: To a solution of 4.3 g (51 mmol) of $(CH_3)_2C(OH)C{\equiv}CH$ in 100 m*l* of diethyl ether, there were added 14 g (41 mmol) of dicobalt octacarbonyl under nitrogen. The mixture was stirred for 2 hr and then filtered. The filtrate was concentrated by a water aspirater and crystallized from methanol at −78°C. Red crystals, mp 42—43.5°C, were obtained (yield, 15 g, 98%).

The Preparation of 3-Methyl-3-methoxyl-1-butyne Dicobalt Hexacarbonyl, $(CH_3)_2C(OCH_3)C{\equiv}CH{\cdot}Co_2(CO)_6$. To a solution of 1.5 g (14.6 mmol) of 3-methyl-3-chloro-1-butyne[11] in 60 m*l* of diethyl ether, there were added 7.5 g (21.9 mmol) of dicobalt octacarbonyl under a nitrogen atmosphere. The mixture was stirred for 2 hr. Twenty milliliters of methanol were then added, after which the mixture was stirred for 45 min, washed with water, and extracted with diethyl ether. After drying over sodium sulfate and concentration, the residue was submitted to molecular distillation at 60—70°C/1 mmHg with a cold finger cooled by dry ice-acetone. 2.83 g of a deep red oil were obtained (yield, 50.5%). PMR: τ 8.50 (s) (CH_3), 6.77 (s) (OCH_3) and 3.99 (s) (CH) with a relative intensity of 6 : 3 : 1.

Found: C, 38.14; H, 2.61%. Calcd for $C_{12}H_{10}O_7Co_2$: C, 37.53; H, 2.62%.

The Formation of Trinuclear Cobalt Complexes $R^1R^2CHCH_2CCo_3(CO)_9$. $CH_3CH_2CCo_3(CO)_9$. Propargyl alcohol dicobalt hexacarbonyl (prepared from 2 g of propargyl alcohol and 5 g of dicobalt octacarbonyl) was dissolved in 60 m*l* of methanol. To this solution 10 m*l* of 10 N sulfuric acid were added, and the mixture was refluxed for 2 hr. After it had then been cooled to room temperature, the reaction mixture was diluted with 120 m*l* of water and extracted with petroleum ether. The organic layer was concentrated, and the residue was crystallized from methanol by cooling at −78°C. Violet crystals were obtained (yield, 560 mg).

Found: C, 30.46; H, 1.19%; mol wt, 477. Calcd for $C_{12}H_5O_9Co_3$: C, 30.67; H, 1.07%; mol wt, 470.

$CH_3CH_2CH_2CCo_3(CO)_9$. From $CH_3CH(OH)C{\equiv}CH{\cdot}Co_2(CO)_6$, dark violet crystals were obtained by a method analogous to that described above. Mp 110°C (dec.).

Found: C, 32.79; H, 1.49%. Calcd for $C_{13}H_7O_9Co_3$: C, 32.27; H, 1.48%.

$(CH_3)_2CHCH_2CCo_3(CO)_9$. *a) From the Alcohol Complex:* A mixture of $(CH_3)_2C(OH)C{\equiv}CH{\cdot}Co_2(CO)_6$ (2 g), methanol (40 m*l*), and 10 N sulfuric acid (8 m*l*) was refluxed for 2 hr. After it had then been worked up, reddish violet crystals were obtained. Mp 105°C (yield, 270 mg).

Found: C, 34.12; H, 1.96%; mol wt, 517. Calcd for $C_{14}H_9O_9Co_3$: C, 33.76; H, 1.82%; mol wt, 498.

b) From the Ether Complex: A mixture of $(CH_3)_2C(OCH_3)C{\equiv}CH{\cdot}Co_2(CO)_6$ (1.1 g), methanol (20 m*l*), and 10 N sulfuric acid (4 m*l*) was refluxed for 2 hr. After it had then been worked up, reddish violet crystals were obtained. The infrared spectra of this compound were consistent with those of that obtained in *a*).

$(C_6H_5)_2CHCH_2CCo_3(CO)_9$. From a mixture of $(C_6H_5)_2C(OH)C{\equiv}CH{\cdot}Co_2(CO)_6$ (2 g), methanol (40 m*l*), and 10 N sulfuric acid (8 m*l*), brown crystals were obtained after a 2-hr reaction. Mp 124°C (dec.). (Yield, 310 mg).

Found: C, 46.17; H, 2.00%; mol wt, 643. Calcd for $C_{24}H_{13}O_9Co_3$: C, 46.33; H, 2.11%; mol wt, 622.

Di-isopropylacetylene Dicobalt Hexacarbonyl. A mixture of $(CH_3)_2C(OH)C{\equiv}CC(OH)(CH_3)_2{\cdot}Co_2(CO)_6$ (2 g), methanol (20 m*l*), and 10 N sulfuric acid (8 m*l*) was refluxed for 30 min. After it had been cooled to room temperature, the reaction mixture was filtered and the precipitates were washed with water and dissolved in methanol. The filtrate was cooled by dry ice to give brown crystals, mp 95°C. (Yield, 370 mg).

Found: C, 42.19; H, 3.48%. Calcd for $C_{14}H_{14}O_6Co_2$: C, 42.45; H, 3.56%.

1,1,4,4-Tetraphenyl-1,3-butadiene. To a solution of 1 g of $(C_6H_5)_2C(OH)C{\equiv}CC(OH)(C_6H_5)_2{\cdot}Co_2(CO)_6$ in 20 m*l* of methanol, 4 m*l* of 10 N sulfuric acid were added. The reaction mixture was then refluxed for 30 min. Yellow crystals were thus precipitated. These were filtered, washed with water, and dried. Recrystallization from benzene gave pale yellow prisms with a pale green fluorescence, mp 192(sinter)—204°C. (Yield, 162 mg). Recrystallization from ethanol gave pale yellow needles with a pale green fluorescence, mp 197—198°C.

Found: C, 93.72; H, 5.99%. Calcd for $C_{28}H_{22}$: C, 93.81; H, 6.19%.

Polymerization Catalyst of the Triethylaluminum-Chloral Hydrate System. I. Triethylaluminum-Chloral Hydrate Reaction and Catalyst Activity in Cationic Polymerization

Takeo SAEGUSA, Hiroyasu FUJII, Takashi UESHIMA and Katsumi TANAKA*1

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received October 28, 1967)

In reaction of $AlEt_3$ with chloral hydrate has been investigated. The reaction system was examined by means of infrared and NMR spectra and by the vapor-phase chromatographic analysis of the acidolysis product of this system. The gas evolved during the reaction was also analyzed. The $AlEt_3$-chloral hydrate system was proved to contain the linkages of $>AlOCH_2CCl_3$, $>AlOCH(CCl_3)OAl<$, $>AlOCH(Et)CCl_3$, $>AlOAl<$, $>Al-Et$ and $>Al-Cl$. This system showed a very high catalytic activity for the cationic polymerization of *i*-butyl vinyl ether. Tetrahydrofuran, 3,3-bis(chloromethyl)oxacyclobutane, α-methylstyrene, and styrene were also polymerized by this catalytic system. The acid strength of the $AlEt_3$-chloral hydrate system was examined by two methods, the Hammett indicator method and shift of the infrared carbonyl band of xanthone caused by coordination to Lewis acid. It has been shown that the acid strength of this system is as strong as $AlEt_3$-H_2O (1 : 0.8) and Et_2AlCl. The relation between the strong acid character of the $AlEt_3$-chloral hydrate system and its structure was discussed.

We have studied the polymerizations of aldehydes and cyclic oxides by the catalyst systems derived from aluminum alkyls.[1-10] Additives, such as water and alcohol, improve or markedly change the catalyst properties of the parent aluminum alkyl. In cationic polymerization, it is quite interesting that when $AlEt_3$ is treated with a controlled amount of water (about an equimolar amount), the acid strength is increased and, hence, the catalyst activity is much enhanced.[2]

In the present study, we have examined the reaction of $AlEt_3$ with chloral hydrate and the catalyst activity of the reaction product.

Experimental

Reagents. *$AlEt_3$.* A commercial reagent was rectified under a reduced nitrogen atmosphere, bp 83—84°C/4 mmHg.

Chloral Hydrate. A commercial reagent was dried over phosphoric anhydride.

The monomers and solvents were dried and purified by the usual methods.

Reaction of $AlEt_3$ with Chloral Hydrate. A typical example was as follows. A solution of 5 mmol of chloral hydrate in 100 m*l* of toluene was added, drop by drop, into 100 m*l* of a toluene solution containing 10 mmol of $AlEt_3$ with stirring at −50——60°C. The mixture was gradually warmed to room temperature over a 2-hr period, and then kept at 40°C for additional 2 hr. The reaction systems were homogeneous unless the molar ratios of chloral hydrate to $AlEt_3$ exceeded 1.5.

Analyses of Reaction Products. *Acidolysis.* The volatile matters were distilled off under reduced pressure (2—3 mmHg) at temperatures from room temperature to 40°C, and the residue was decomposed with an excess of glacial acetic acid. The acid decomposition product was analyzed by vapor-phase chromatography.

Vapor-phase Chromatography (VPC) Analysis. An apparatus, Model 2C, of the Shimadzu Co. (Japan) was used. In the analysis of the acid-decomposition mixture, a silicon column (3 m) was used (column temperature: 125°C; carrier gas: hydrogen; gas speed: 40 m*l*/min). Ethane and ethylene gases were analyzed by using a column of silica gel (3 m) at 40°C, with hydrogen as the carrier gas (flow rate: 60 m*l*/min).

Analysis of Inorganic Chlorine. The aluminum-chlorine linkage was formed in the chloral hydrate-$AlEt_3$ reaction. This inorganic chlorine was determined by the silver

nitrate method after the reaction product had been decomposed by nitric acid.

Nuclear Magnetic Resonance (NMR) Measurements. The NMR spectra were taken with a Varian 60 MC spectrometer; the peak positions were determined by using tetramethylsilane as the internal reference.

Measurement of Acid Strength. *Indicator Method.* The acid strength of the catalytic system was measured by a method similar to that described in a previous paper.[8]

Xanthone Method. The shift of the carbonyl band in the infrared spectrum of xanthone coordinating onto the catalytic systems was examined by the method of Cook.[11] Solutions of the catalyst system and xanthone, both in a concentration of 0.5 mol/*l*, were mixed at room temperature, and the difference between the free and the shifted carbonyl bands was determined.

Results and Discussion

Reaction of $AlEt_3$ with Chloral Hydrate. Chloral hydrate exists in the following equilibrium:

$$Cl_3CCH\begin{matrix}OH\\OH\end{matrix} \rightleftarrows Cl_3CCHO + H_2O \quad (1)$$

Therefore, five possible ways of reaction may be postulated:

$$>Al\text{-}Et + H_2O \rightarrow$$

$$>Al\text{-}OH + EtH \xrightarrow{>AlEt} \underset{I}{\underline{>Al\text{-}O\text{-}Al<}} + EtH \quad (2)$$

$$>Al\text{-}Et + Cl_3CCHO \rightarrow$$

$$\underset{II}{\underline{>Al\text{-}OCH_2CCl_3}} + CH_2{=}CH_2 \quad (3)$$

$$>Al\text{-}Et + Cl_3CCHO \rightarrow \underset{III}{\underline{>Al\text{-}O\overset{Et}{\overset{|}{C}}HCCl_3}} \quad (4)$$

$$>Al\text{-}Et + Cl_3CCH\begin{matrix}OH\\OH\end{matrix} \rightarrow$$

$$>Al\text{-}OCHOH \xrightarrow{>Al\text{-}Et} \underset{IV}{\underline{>Al\text{-}O\overset{CCl_3}{\overset{|}{C}}HO\text{-}Al<}} \quad (5)$$

$$\begin{matrix}|\\CCl_3\\+\ EtH\end{matrix} \qquad \begin{matrix}\\\\+\ EtH\end{matrix}$$

The linkage (IV) has not yet been known; it is a special aluminum alkoxide.

The reaction mixture of $AlEt_3$ with chloral hydrate was decomposed by glacial acetic acid and analyzed by VPC. The results are shown in Table 1.

In the reaction in both ether and toluene, the linkage (II) derived from the reduction of chloral with the Al-Et linkage by Eq. (3) was mainly produced. The linkage (III) was formed very little in ether, but it was formed to a considerable extent in toluene. The regeneration of chloral by the acidolysis suggests the presence of the linkage (IV), because, before the acidolysis, the reaction mixture did not exhibit the absorption bands characteristic of OH and >C=O groups. The amount of linkage (I) was taken to be equal to be the sum of the linkages (II) and (III), because the reaction mixture did not show any indication of the presence of OH (water) or >C=O (free chloral).

Table 1. Analysis of acid decomposition mixture of $AlEt_3$-chloral hydrate (2 : 1) reaction system

Product	Mol% in ether	Mol% in toluene
Cl_3CCHO	22	32
Cl_3CCH_2OH	72 (70)[a]	44
$Cl_3CCH(Et)OH$	trace	4
$Cl^{\ominus}$	2	20

a) The value in the parenthesis was calculated from volume of ethylene gas evolved in the course of the reaction.

The formation of a considerable amount of inorganic chloride, especially in the reaction in a toluene solvent, is due to the reaction between the trichloromethyl group and the Al–Et group. This reaction seems very complicated. No dichloroacetaldehyde, monochloroacetaldehyde, or acetaldehyde, or any of their derivatives were detected by the VPC analyses of the acidolysis mixture.

The volume of the gas evolved in the course of the reaction was then measured using a gas burette. By VPC analysis, the gas was shown to be a mixture of ethane and ethylene. From the volume of ethylene, the amount of linkage (II) was calculated (see Table 1). The two values, the one from the ethylene and the other from the Cl_3CCH_2OH in the acidolysis mixture, agreed with each other.

Further support was given by the NMR spectra of this system. Chemical shifts of 5.6—5.7 τ and 4.4—4.6 τ were observed in the spectra of this system; these shifts were assigned to the protons of >Al–OCH_2CCl_3 and >Al–$OCH(CCl_3)$O–Al< respectively. The area ratios of the two peaks (>AlO-CH_2CCl_3/>Al–$OCH(CCl_3)$O–Al<) were 6.5 (in ether) and 2.8 (in toluene); these values are in fairly good agreement with the values calculated from Cl_3CCH_2OH and Cl_3CCHO in the acidolysis mixture (*cf.* Table 1).

Catalyst Behavior in Cationic Polymerization. The reaction mixture of $AlEt_3$ and chloral hydrate showed a high catalytic activity in the cationic polymerizations of isobutyl vinyl ether and tetrahydrofuran (Tables 2 and 3). Isobutyl vinyl ether was polymerized especially rapidly by this catalytic system.

The results shown in Table 2 indicate that the $AlEt_3$-chloral hydrate system is fairly active in initiating cationic polymerizations. The activating effect of the treatment with chloral hydrate has been well

11) D. Cook, *Can. J. Chem.*, **41**, 526 (1963).

demonstrated. No additional cocatalyst is required. It may be assumed that a part of the hydroxy group of chloral hydrate remains unreacted, thus affording the initiator proton. Even at low catalyst concentrations (0.2 mol% to monomer), the $AlEt_3$-chloral hydrate system induced the vinyl ether polymerization at a fairly high rate. The product polymers contained no methyl ethyl ketone-insoluble (crystalline) part. The lack of stereospecificity in the polymer produced by the $AlEt_3$-chloral hydrate system is unlike the case with the $AlEt_3$-water system, which gives the crystalline polymer of isobutyl vinyl ether.[6,7]

The polymerization of tetrahydrofuran by the $AlEt_3$-chloral hydrate-epichlorohydrin system is illustrated in Table 3.

The $AlEt_3$-chloral hydrate system also induced the

polymerizations of 3,3-bis(chloromethyl)oxacyclobutane (BCMO), α-methylstyrene (α-MeST), and styrene (St) (Table 4).

It has been established that, in many cases, a Lewis acid alone does not cause the cationic polymerization of vinyl monomers or four- and five-membered cyclic ethers. Therefore, a cocatalyst or a promoter[5,12] was used in the present study.

From one observations in the polymerizations of several monomers (Tables 2, 3, and 4), it is certain that the $AlEt_3$-chloral hydrate system is a cationic polymerization catalyst. Therefore, the acid strength of this system was examined by the Hammett indicator method and by the extent of the shift of the infrared carbonyl band ($\Delta\nu_{C=O}$) by the xanthone method[11] (Table 5).

Table 5 shows that the $AlEt_3$-chloral hydrate systems are strong acids, much stronger than $AlEt_3$ itself. The systems of $AlEt_3$/chloral hydrate = 1.0 and 2.0 are as strong as $AlEt_3/H_2O$ (1/0.8) and Et_2AlCl.

It is interesting to compare the strong acid character of the $AlEt_3$-chloral hydrate system with the acid nature of the $AlEt_3$-H_2O-EtOH (1 : 0.8 : 0.4) system. It has previously been reported by us[7] that the systems containing aluminum alkoxide linkages are generally weaker acids. $AlEt_3$-H_2O-EtOH is a weaker acid (Table 5) and does not induce the cationic polymerization of vinyl ether. Although the $AlEt_3$-chloral hydrate system contains considerable amount of aluminum alkoxide linkages (Eqs. (2) to (5)), it is a strong acid.

Such a characteristic behavior of this system may be attributed to the electron-withdrawing effect of the trichloromethyl group of the alkoxyl groups in the $AlEt_3$-chloral hydrate system. In fact, aluminum trichloroethoxide prepared by the reaction of $AlEt_3$ with trichloroethanol shows great acid strength[13] and high catalytic activities in cationic polymerizations.[13]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1192—1194 (1968)

Polymerization Catalyst of the Triethylaluminum-Chloral Hydrate System. II. Copolymerization of Acetaldehyde with Chloral

Takeo SAEGUSA, Hiroyasu FUJII and Katsumi Tanaka*1

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received October 28, 1967)

It has been found that the $AlEt_3$-chloral hydrate system induces the random copolymerization of acetaldehyde with chloral. The homogeneity of the product polymer was confirmed by a study of the infrared spectra and by turbidimetric titration. The thermal stability of the copolymer was much better than that of homopolyacetaldehyde. The copolymer was soluble in chloroform, and films were cast from chloroform solutions.

In our previous paper,[1] we reported the reaction of $AlEt_3$ with chloral hydrate and the cationic polymerizations of several monomers using the reactions mixture as the catalyst. In the present paper, we wish to report on the characteristic catalyst behavior of the $AlEt_3$-chloral hydrate system in the copolymerization of acetaldehyde with chloral.

The copolymerization between acetaldehyde and chloral was once performed using $AlEt_3$ as the catalyst; the product polymer was always 1 : 1 alternating copolymer.[2] Several aluminum alkoxides, such as $Et_2AlOC_4H_9$-*s*, $Et_2AlOCH_2CCl_3$, $Et_2AlOCH(Et)$-CCl_3, and some aluminum trialkoxides have been applied to the polymerization system of an acetaldehyde-chloral mixture. None of these aluminum alkoxides, however, caused any copolymerization; they gave only acetaldehyde homopolymers with low molecular weights.[2] The difference in catalytic behavior between $AlEt_3$ and aluminum alkoxides has been explained in terms of the mechanism of coordinate anionic polymerization.

The $AlEt_3$-chloral hydrate system of the present study is distinguished by its catalyst activity inducing random copolymerization between acetaldehyde and chloral.

Experimental

Reagents. *Acetaldehyde.* Acetaldehyde was prepared and purified by a method similar to that of the previous paper.[2]

The other reagents were purified by a method similar to that of another preceding paper.[1]

Preparation of Catalyst System. Catalytic systems were prepared similarly as has already been described in the preceding paper.[1]

Copolymerization. The monomer mixture and the solvent were placed in a glass tube under a nitrogen atmosphere and cooled to −78°C. After a catalyst solution had been added, drop by drop, to this cold mixture, the polymerization mixture was kept standing at −78°C for a definite reaction time. Then the polymerization was stopped by adding methanol. The copolymers were fractionated to methanol-soluble and chloroform-soluble (methanol-insoluble) fractions. The compositions of the copolymers were calculated from the

chlorine and carbon contents determined by elemental analyses.

Turbidimetric Titration. Turbidimetric titration was carried out using a photo-electric turbidimeter of the Shimadzu Co. (Kyoto, Japan). The copolymer sample was a chloroform-soluble (methanol-insoluble) fraction composed of CH_3CHO and Cl_3CCHO units in the ratio of 72/28; this fraction had been prepared using the $AlEt_3$-chloral hydrate (2/1) system. In 100 m*l* of chloroform, 20 mg or 40 mg of the sample were dissolved, and methanol was added to the mixture at a rate of 1.6 m*l*/min at 16°C. The light scattered was measured at an angle of 90°.

Results and Discussion

Copolymerization of Acetaldehyde with Chloral. In the copolymerization between acetaldehyde and chloral, the 1 : 1 alternating copolymerization by the $AlEt_3$ catalyst[2] was the sole example up to the present study. Several aluminum alkoxides have brought about the formation of the acetaldehyde homopolymer.

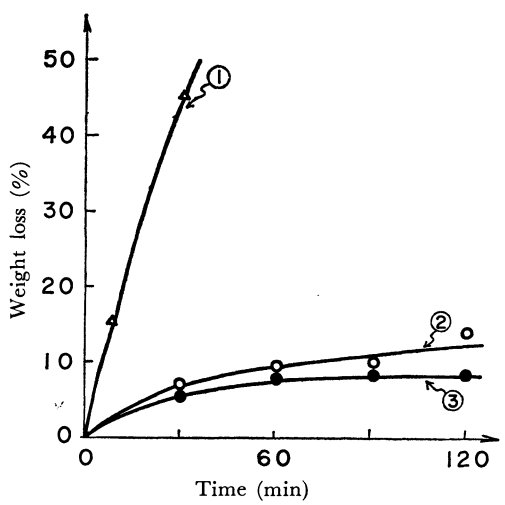

Fig. 3. Thermal decompositions of polyaldehydes at 105°C under nitrogen atmosphere.

①△: Polyacetaldehyde
②○: CH_3CHO-Cl_3CCHO (63 : 37) Copolymer [$AlEt_3$-$Cl_3CCHO \cdot H_2O$ catalyst)
③●: Alternating copolymer ($AlEt_3$ catalyst)

The results of the copolymerization by the $AlEt_3$-chloral hydrate system are illustrated in Tables 1 and 2.

As shown in Table 1, the product polymers can be fractionated into methanol-soluble and chloroform-soluble (methanol-insoluble) fractions. However, no difference was observed in the infrared spectra of these two fractions; only the difference in the molecular weights of the copolymers induced the fractionation.

The infrared spectra of the product copolymers of various compositions in Table 2 are shown in Fig. 1, where they are compared with those of the acetaldehyde homopolymer and the alternating copolymer prepared by the $AlEt_3$ catalyst. As shown in Fig. 1, the spectra of the copolymers gradually vary with the change in composition. The absorption bands at 1187, 973, and 845 cm^{-1} observed in homopolyacetaldehyde decrease with the increase of chloral units in the copolymer and vanish in the alternating copolymer, whereas the bands at 995 and 895 cm^{-1}, which are not observed in homopolyacetaldehyde, appear and gradually increase in the copolymers. These observations suggest that the copolymer produced by the $AlEt_3$-chloral hydrate system is a real random copolymer and not a mixture of homopolyacetaldehyde and the 1 : 1 alternating copolymer.

The homogeneity of the product copolymer was supported by turbidimetric titration. The results are shown in Fig. 2. It is there shown that the product copolymer is fairly homogeneous and does not contain homopolyacetaldehyde or the 1 : 1 alternating copolymer.

It is worthy of mention that copolymers prepared using the $AlEt_3$-chloral hydrate system are of fairly high molecular weights, as indicated by their intrinsic viscosity values in chloroform (*cf.* Table 1). The alternating copolymerization by $AlEt_3$ catalysts always gave polymers with lower intrinsic viscosities.[2)]

The thermal stability of the copolymer is much better than that of homopolyacetaldehyde (Fig. 3).

The copolymer is soluble in chloroform, and films can be cast from the chloroform solution. The copolymer, however, decomposes at 180 ± 5°C without melting.

Preparation and Properties of Aluminum and Zinc Haloalcoholates

Takashi UESHIMA, Shimpei TOMITA and Takeo SAEGUSA

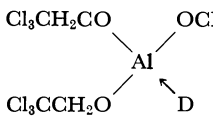
Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received October 28, 1967)

Seven haloalcoholates of aluminum and zinc were prepared by the reactions of haloalcohols with metal alkyls in ethyl ether, and their properties were examined. The following differences have been observed between these haloalcoholates and the usual alcoholates, those with no halogen in the alkyl groups. (1) The metal haloalcoholates are unstable to heat and decompose at 90—220°C. Except for $Al(OCH_2CF_3)_3$, they are neither distilled nor sublimed even *in vacuo*. The usual aluminum alcoholates, such as ethoxide and isopropoxide, are easily distilled under reduced pressures. (2) The haloalcoholates are stronger Lewis acids than the usual alcoholates. The acid strength of some aluminum haloalcoholates is even higher than triethylaluminum. The strong acid nature of the aluminum haloalcoholate can be ascribed to the electron-withdrawing effect of halogen. (3) As expected from their strong acid strength, the haloalcoholates induce the cationic polymerizations of vinyl monomers and cyclic ethers, such as styrene, α-methylstyrene, isobutyl vinyl ether, 3,3-bis-(chloromethyl)oxacyclobutane, and tetrahydrofuran. The usual metal alcoholates are weaker acids and do not cause the polymerizations of these monomers. In the ethylene oxide polymerization, both the haloalcoholates and the usual alcoholates showed catalytic activity. However, these two types of alcoholates differ from each other in the catalysis mechanism. For the polymerization of ethylene oxide by the haloalcoholate catalyst, a cationic polymerization mechanism was assumed on the basis of the formation of dioxane as a by-product. The polymerization by the usual alcoholate catalysts is assumed to be of a coordinate anionic mechanism.

In the course of studies upon the polymerization catalyst behavior of metal alkyls and alcoholates, we have shown that aluminum and zinc alcoholates of unsubstituted alcohols are weak Lewis acids which do not induce the cationic polymerizations of vinyl monomers and cyclic ethers, but which do cause the

coordinate anionic polymerizations of alkylene oxides and acetaldehyde.[1,2] Recently, we reported the preparation of aluminum trichloroethoxide, $Al(OCH_2CCl_3)_3$, and showed its peculiar properties as compared with those of the usual aluminum alcoholates, such as aluminum isopropoxide and *t*-butoxide.[3] The dissociation of $Al(OCH_2CCl_3)_3$ to the monomeric form (I) in the presence of donor molecules (for example, dioxane, tetrahydrofuran, and pyridine) has been observed; this is in sharp contrast to the strong association tendency of the usual aluminum alcoholates even in the presence of the above donors.



(I) (D: donor molecule)

It has also been found, from the results of the acid-strength measurements by the IR method[4,5] using xanthone as the reference base, that $Al(OCH_2CCl_3)_3$ is a fairly strong acid; it is as strong as $AlEt_3$ and much stronger than the usual aluminum alcoholates.

In the present experiments, several haloalcoholates of aluminum and zinc have been prepared and their properties, especially as polymerization catalysts, have been examined.

Experimental

Reagents. Commercially-available materials were purified carefully by the usual procedures. 1,1,1-Trifluoroethanol,[6] 1,1,1-trichloroethanol,[7] 1,1,1-tribromoethanol,[7] and 1,1-dichloroethanol[8] were prepared by the procedures described in the literatures and were purified by distillation. Tribromoethanol was further purified by recrystallization from a mixture of *n*-pentane and ethyl ether.

Preparation of Haloalcoholates. A typical procedure was as follows. $AlEt_3$ (0.1 mol) in ethyl ether (20 m*l*) was added, drop by drop, with vigorous stirring into a mixture of a haloalcohol (0.3 mol) and ethyl ether (60 m*l*) at −78°C. After the addition was complete, the reaction system was allowed to warm gradually to room temperature and finally heated to reflux for 2 hr. In the cases of $Al(OCH_2CCl_3)_3$ and $Al(OCH_2CBr_3)_3$, products separated from the reaction solutions; these

products were isolated, washed with cold ethyl ether, and dried *in vacuo*. In other cases ethyl ether was removed from the reaction mixture under reduced pressure to give a white solid. The haloalcoholates were isolated and purified by the procedures presented in Table 1.

The products were usually analyzed as follows: a weighed sample was decomposed by excess 1 N hydrochloric acid. The alcohol thus produced was then extracted with ethyl ether and analyzed by vapor-phase chromatography (v.p.c.). In the case of $Al(OCH_2CF_3)_3$, a sample was treated with excess acetic acid, while CF_3CH_2OH was analyzed directly by v.p.c. without the procedure of extraction. The results of the analyses are also shown in Table 1.

$EtZnOCH_2CCl_3$ and $Zn(OCH_2CCl_3)_2$ were prepared by the same procedure, using diethylzinc.

Polymerization Procedures and After-treatments. Ethylene oxide and a catalyst were placed in a sealed tube, and the tube was heated for 24 hr. Then the reaction mixture was poured into a large amount of *n*-pentane in order to isolate the product polymer as a white precipitate, which was then dried and extracted with benzene to remove the catalyst residue. In the pentane layer, dioxane, the dimer of ethylene oxide, was searched for and its quantity, if it was present, was determined by v.p.c.

The other polymerization procedures and after-treatments were performed as described before.[2,9,10]

Spectroscopic Measurements. All the samples were prepared under a nitrogen atmosphere. The NMR spectra were measured at room temperature with a Varian A-60 spectrometer, with tetramethylsilane used as the internal standard. The infrared spectra measurements were carried out with a model 402G (Japan Spectroscopic Company), using a KBr liquid cell.

Results and Discussion

Aluminum and zinc haloalcoholates were first prepared in our series of studies by means of the reactions of metal alkyls with halogen-substituted alcohols carried out in ethyl ether. It is important to employ ethyl ether as the reaction solvent in order to suppress the side reactions between the halogen-carbon bond and metal alkyls. The product of a metal haloalcoholate is sometimes insoluble in ether and separates from the reaction mixture. The reaction in ethyl ether is thus recommended.

The following differences have been observed between haloalcoholates and the usual alcoholates:

(1) **Heat-stability.** The usual aluminum alcoholates, such as aluminum ethoxide, isopropoxide, and amyloxides, are known to be distillable under reduced pressure at considerably high temperatures (160°C—250°C). Even unstable aluminum *t*-butoxide can be sublimed *in vacuo*. On the contrary, most aluminum haloalcoholates decompose without melting. Most of them can not be sublimed even under reduced pressures, as is shown in Table 1. Only $Al(OCH_2CF_3)_3$ can be sublimed at 80°C (0.18 mmHg). $Al(OCH_2CH_2Cl)_3$, which carries the minimum number of chlorine atoms, melts at 180°C, however, it is not distilled without decomposition.

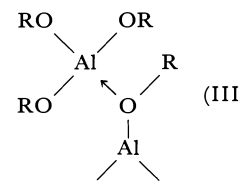
(2) **Acid Strength (Interaction with Donor Molecules).** Acid-strength measurements of various haloalcoholates as well as of the usual alcoholates were done using infrared techniques and an indicator method.[1] From the magnitude of the $\Delta\nu_{C=N}$ of pyridine (the shift to a higher wavelength) and the $\Delta\nu_{C=O}$ of xanthone (the shift to a lower wavelength) caused by the coordination of these donor molecules to aluminum alcoholates, the following order of acid strength (acceptor powers of metal atoms) was found;

$Al(OCH\langle^{CH_2Cl}_{CH_2Cl})_3 \rangle Al(OCH_2CF_3)_3 \gtrsim Al(OCH_2CCl_3)_3 \gtrsim Al(OCH_2CBr_3)_3 > Al(OCH_2CHCl_2)_3 > Zn(OCH_2CCl_3)_2 > EtZnOCH_2CCl_3 > Al(OCH_2CH_2Cl)_3$, $Al(OR)_3$ (R: Et, *i*-Pr, *t*-Bu, *etc.*), EtZnOEt, and $Zn(OEt)_2$. The usual alcoholates and $Al(OCH_2CH_2Cl)_3$ did not cause any shift of $\nu_{C=N}$ and $\nu_{C=O}$ at all.

The weak acid strength of usual aluminum alcoholates has been explained in two ways. First, because of the contribution of the resonance structure (II), the electron-acceptor power of aluminum is lower than that to be expected from the electronegativities of aluminum and oxygen in the $\overset{\delta+}{Al}\text{–}\overset{\delta-}{O}$ bond. Secondly, the electron-acceptor power (strong acidic nature) of aluminum is neutralized by

$$\rangle Al\text{–}OR \longleftrightarrow \rangle \overset{\ominus}{Al}\text{=}\overset{\oplus}{O}R \quad (II)$$

the coordination of the oxygen atom of the neighboring aluminum-alkoxy linkage to make the coordination number of aluminum four or more than four (III); therefore, aluminum alcoholates do not act as strong electron acceptors.



(III)

The examination of highly acidic aluminum haloalcoholates in the present study has an important bearing on this problem. The first explanation leads to the assumption that the electron-withdrawing effect of halogen is extended to aluminum through oxygen, thus increasing the acceptor power of the aluminum atom. In this case, a donor molecule coordinates to aluminum with an expansion of the coordination number of aluminum, as is illustrated by structure IV. According to the alternative explanation, the electron-withdrawing effect of a halogen atom decreases the basic strength of the oxygen of an alkoxy group. The association of the aluminum haloalcoholates is easily broken by a donor molecule, thus forming the acid-base complex of a

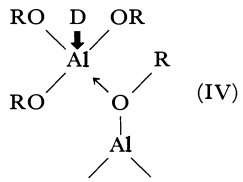
monomeric structure (I), where the coordination number of aluminum is four.



(IV)

As has been described in our previous paper[3] and in V. J. Shiner's work,[11] associated aluminum alcoholates carry more than two kinds of alkoxy groups, which are indicated by signals at different positions in the NMR spectra. In the NMR spectrum of the monomeric aluminum alcoholate - donor complex (structure I), only one type of alkoxy group is observed. In view of these considerations, the NMR spectra of the aluminum haloalcoholates were examined (see Table 2), and the following results obtained: (1) When a shift of the $\nu_{C=O}$ of xanthone or the $\nu_{C=N}$ of pyridine is observed, the three alkoxy groups in the NMR spectra are always equivalent in the donor-acceptor complexes. (2) When the IR shift is not caused by the alcoholate, the three alkoxy groups in the NMR spectrum are not equivalent in the alcoholate-donor mixture, as has been observed in such non-donating solvents as benzene.*1 From these findings, the strong acid nature of some aluminum haloalcoholates may be ascribed to the weak association tendency, which facilitates the formation of the monomeric donor-acceptor complex (structure I). The dissociation tendency is attributable to the decrease in the nucleophilicity of the oxygen atom in the alkoxy group by the electron-withdrawing effect of halogens.

It has also been realized, by comparing the magnitudes of $\Delta\nu_{C=N}$ and $\Delta\nu_{C=O}$, that the accepting power of aluminum alcoholates in the complexes (I) is affected to some extent by the kind and number of halogens in the haloalkoxy group. Thus, it is obvious that the electron-withdrawing effect of halogens directly influences the acceptor power of aluminum. The order of acid strength is as expected from the number and the electronegativities of halogen atoms, with the exception of $Al(OCH\langle^{CH_2Cl}_{CH_2Cl})_3$, whose alkoxy group has a structure very different from those of others. Although the acceptor powers of the aluminum haloalcoholates in the associated form were not measured by the above method, their order was supposed to be the same as that of the dissociated aluminum alcoholates if the coordination number of aluminum atoms is the same, which seems likely.

No difference in acid strength between $Al(OCH_2CH_2Cl)_3$ and the usual aluminum alcoholates was observed by the IR procedures. However, the indicator method[1] revealed that $Al(OCH_2CH_2Cl)_3$ was a stronger acid (see Table 3).

Nearly the same discussion is applicable to zinc haloalcoholates. Detailed studies of zinc haloalcoholates will be published elsewhere.[12]

TABLE 4. POLYMERIZATION OF TETRAHYDROFURAN BY ALUMINUM HALOALCOHOLATES*

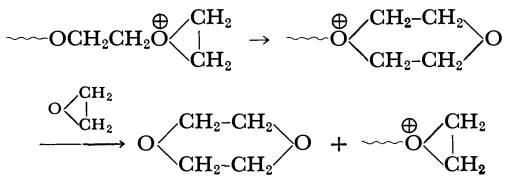
e) resineous solid f) in benzene 30°C

(3) Behavior as Polymerization Catalysts. It has already been established that the usual alcoholates of aluminum and zinc do not cause the cationic polymerizations of vinyl monomers and cyclic ethers, such as isobutyl vinyl ether, styrene, α-methylstyrene, 3,3-bis(chloromethyl)oxacyclobutane, and tetrahydrofuran.[1] On the contrary, the haloalcoholates in the present study induced the

cationic polymerizations of the above monomers, as was expected from the stronger Lewis acid character of the haloalcoholates. The polymerizations by haloalcoholate catalysts are illustrated in Tables 4 and 5. In the tetrahydrofuran polymerization, solid polymers with quite high molecular weights were produced in high yields by the catalysts of all aluminum haloalcoholates. Polytetrahydrofuran with $[\eta]$ values above 1 could be prepared at low catalyst concentrations. When a new tetrahydrofuran monomer was added to a system in which polymerization had proceeded nearly completely, the yield as well as the intrinsic viscosity of the polymer were increased (compare b and c in Table 4). In the second stage, however, the polymerization did not proceed beyond 10% of the added monomer, even after 5 days' reaction. This observation suggests slow termination.

Heterogeneous polymerization of isobutyl vinyl ether with haloalcoholate catalysts in toluene produced only amorphous polymers (Table 5).

The results of the polymerizations of alkylene oxides are summarized in Table 6. Polymerizations of these monomers by the usual alcoholates are known to proceed through the coordinate anionic mechanism. The polymerizations by haloalcoholates are different in some respects from those by the usual alcoholates: (1) The ethylene oxide polymerization is caused both by haloalcoholates and the usual alcoholates. However, only in the polymerization by the haloalcoholates, dioxane, a dimer of ethylene oxide, is formed as a by-product. Our previous work[13] has shown that dioxane is formed only by a cationic mechanism (Eq. (1)), not by a so-called coordinate anionic mechanism.



(1)

Therefore, it may be assumed that the haloalcoholates induce the cationic polymerization of ethylene oxide, whereas the usual alcoholates induce the coordinate anionic polymerization. (2) This assumption is consistent with the molecular weight of the product polymer. Polymers prepared using the haloalcoholates are oily or waxy (low molecular weights), whereas those prepared using the usual alcoholates were solid polymers with higher molecular weights. In the polymerizations of propylene oxide and epichlorohydrin, a similar tendency was observed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1201—1208 (1968)

The Synthesis of 4-Hydroxyfuro[2′,3′:7, 8]coumarins and 5*H*-Benzofuro[3,2-*c*]furo[2,3-*h*][1]benzopyran-5-one*[1]

Yoshiyuki KAWASE, Mutsumu NANBU and Hirokazu YANAGIHARA

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received November 1, 1967)

4-Hydroxyfuro[2′,3′:7,8]coumarin (16) and its 3-phenyl (10) and 3-(2-methoxyphenyl) (11) derivatives were prepared from the corresponding 4-hydroxy-5-benzofuranyl ketones (15, 8a and 8b) by the action of ethyl carbonate and sodium. The furocoumarin 11 thus obtained was converted to 5*H*-benzofuro[3,2-*c*]furo[2,3-*h*][1]benzopyran-5-one (18), a compound having a new pentacyclic ring system, by the demethyl-cyclization with pyridine hydrochloride, hydroiodic acid or aluminum chloride. The attempted preparation of these compounds through their dihydro compounds is also described; 2,3-dihydro-4-hydroxybenzofuran (1) was acylated with phenylacetic acid, with 2-methoxyphenylacetic acid or with 2,4,5-trimethoxyphenylacetic acid by the action of polyphosphoric acid to give a mixture of the 5- and 7-acylated compounds (3 and 2), and the formers were converted to the corresponding 4″,5″-dihydrofuro[2″,3″:7,8]isoflavones (6), 4″,5″-dihydro-2-methylfuro-[2″,3″:7,8]isoflavones (4) and 4′,5′-dihydro-4-hydroxyfuro[2′,3′:7,8]coumarins (7). The 2,3-dihydro-4-hydroxy-5-benzofuranyl benzyl ketone (3a) and the dihydrofuroisoflavones (4a and 4b) were also obtained by the catalytic reduction of the corresponding furo-compounds.

In previous papers, one of the authors and others reported the synthesis of furo[2″,3″ : 7,8]isoflavones,[1] 4-hydroxycoumarins,[2] and benzofuro[3′,2′:3,4]coumarins.[3] Now in this paper, the preparation of closely related 4-hydroxyfuro[2′,3′:7,8]coumarins (10, 11, 16, 17 and 19) and 5*H*-benzofuro[3,2-*c*]-furo[2,3-*h*][1]benzopyran-5-one (18) and the attempted preparation of them through their dihydro compounds will be reported. The synthesis of isomeric 4-hydroxyfuro[3′,2′ :6,7]coumarins[4] and 6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]-benzopyran-6-one derivative (erosnin),[4b] having linearly fused furan ring, has recently been reported by Fukui and Nakayama and others, and that of dimethylfuro-derivatives of 4-hydroxy-3-phenylcoumarin by the thermal condensation of dimethylhydroxybenzofurans with ethyl phenylmalonate has been reported by Royer *et al.*[5]

In the case of isomeric compounds, 2,3-dihydro-6-hydroxybenzofuran was acylated to give the 5-acyl compounds,[6] which were converted to the corresponding dihydrofuro-4-hydroxycoumarins[4,7] and -isoflavones[8] which were further dehydrogenated to the furo-compounds, as the direct acylation of hydroxybenzofurans to give the *o*-hydroxyketones, the convenient starting materials for 4-hydroxycoumarins and isoflavones, was not successful although the acetylation of 2-substituted[9] or 2,3-dimethyl[10] 6-hydroxy- or 6-methoxy-benzofurans gave the 5-acyl compounds. But the dehydrogenation to give 4-hydroxyfurocoumarins was accomplished only in some cases with difficulty or indirectly.[4] Accordingly, the furocoumarins were also prepared[4a,b] by the pyrone ring formation on hydroxybenzofuranyl ketones which were obtained by alkaline degradation of furoisoflavones or by hydrolysis followed by

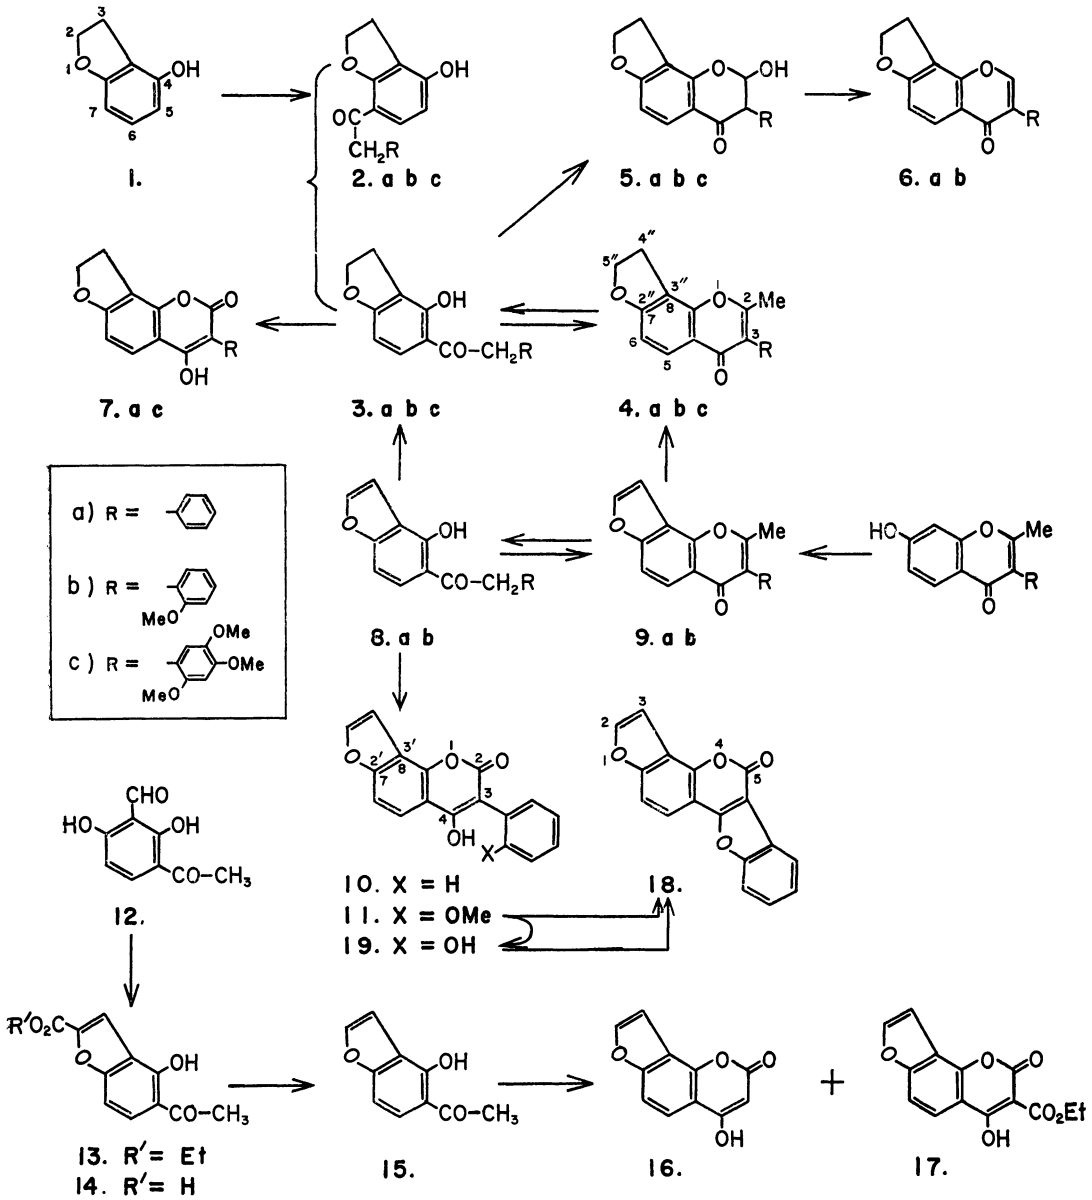
Chart



decarboxylation of acetyl-methoxybenzofuran-2-carboxylate.

Concerning the acylation of 2,3-dihydro-4-hydroxybenzofuran, Seetharamiah[11] reported the acylation of it according to the Hoesch reaction to give the 7-acyl compound while Miyano and Matsui[12] reported the analogous reaction of 2-alkyl compounds to give a mixture of the 5- and 7-acyl compounds, and Dyke *et al.*[13] reported the analogous reaction of 2-isopropyl derivative and the further convertion to the furoisoflavone through its dihydro-compound. On the other hand, Seshadri *et al.*[14] prepared 4″,5″-dihydro-4″-methylfuro[2″,3″ : 7,8]-isoflavone through another route and converted it to the furoisoflavone.

First, in the present experiments the acylation of

2,3-dihydro-4-hydroxybenzofuran (1) and the convertion of the products to dihydrofuro and then to furo derivatives of 4-hydroxycoumarins and isoflavones were studied. The acylation of 1 with phenylacetic acid, with 2-methoxyphenylacetic acid or with 2,4,5-trimethoxyphenylacetic acid by the action of polyphosphoric acid (PPA) furnished a mixture of the 5- and 7-acylated compounds (3a, b, c and 2a, b, c). The acylation by the Hoesch reaction with phenylacetonitrile furnished as well the ketones 2a and 3a, but with 2-methoxyphenylacetonitrile in poorer yield.

The 5-acyl compounds (3a, b, c), separated from the alkali-soluble isomeric 7-acyl compounds (2a,b,c), were converted to the corresponding 4″,5″-dihydro-2-methylfuro[2″,3″7,8]isoflavones (4a, b, c) by the action of acetic anhydride and sodium acetate, and the alkaline degradation of 4a furnished the starting ketone 3a. The ketone 3a and the dihydrofuroisoflavones 4a and 4b were also obtained by the catalytic reduction of the corresponding benzofuranyl ketone[1] (8) and furoisoflavones[1] (9a, b), respectively.

These experiments, their analyses, their infrared and ultraviolet spectra and the analogous acylation described before furnished the proof for the structures of the ketones (2a, b, c and 3a, b, c) and the isoflavones (4a, b, c).

The ketones (3a, b, c) were also converted to 4″,-5″-dihydro-2-hydroxyfuro [2″, 3″ : 7,8] isoflavanones (5a, b, c) by the action of ethyl formate and sodium, two (5a and 5b) among which were readily dehydrated to dihydrofuroisoflavones (6a and 6b). 4′,5′-Dihydro-4-hydroxyfuro[2′,3′:7,8]coumarins (7a and 7c) were also prepared from the ketones by the general method utilizing ethyl chlorocarbonate.

The attempts to dehydrogenate these compounds to the corresponding furo-compounds were unsuccessful.

Then, the 4-hydroxy-5-benzofuranyl ketones (8a and 8b) were prepared through another route by the alkaline degradation of the corresponding furoisoflavones[1] (9a and 9b), and 4-hydroxyfuro[2′,3′:7,8]-coumarins (10 and 11) were synthesized from these ketones by the general method utilizing ethyl carbonate and sodium. 4-Hydroxy-5-benzofuranyl methyl ketone[15] (15) was prepared, in the present experiments, from 2,4-dihydroxy-3-formylphenyl methyl ketone[16] (12) by the action of ethyl bromomalonate and potassium carbonate followed by the hydrolysis of the produced ester (13) and the decarboxylation of the acid (14). The action of ethyl carbonate and sodium on this ketone (15) furnished analogously 4-hydroxyfuro[2′,3′;7,8]coumarin (16) accompanied by a small amount of its 3-ethoxycarbonyl derivative (17); the formation of the latter seems to be the result of double ethoxycarbonylation of the ketone. The structures of these compounds were considered from their analyses and their infrared and ultraviolet spectra.

The 4-hydroxy-3-(2-methoxyphenyl)furocoumarin (11) thus obtained was converted to benzofuro-furobenzopyranone. The reported methods for the synthesis of 6*H*-benzofuro[3,2-c][1]benzopyran-6-ones are (a) by the demethyl-cyclization of 4-hydroxy-3-(2-methoxyphenyl)coumarins,[17] (b) by the hydrolytic cyclization of methoxy derivatives of α-benzoylacetonitrile,[3,18] (c) by the oxidative coupling of 4-hydroxycoumarins with catechol[19] and (d) by the oxidation of flavylium salts.[20] The isomeric 6*H*-benzofuro[3,2-*c*]furo[3,2-*g*][1]benzopyran-6-one derivative (erosnin) was synthesized by the method (c)[4] and the dihydrofuro analogues of it were synthesized by the methods (a),[21] (b),[22] and (c).[21]

In the present experiments, the method (a) was applied to the hydroxyfurocoumarin 11; the action of pyridine hydrochloride or hydroiodic acid on 11 furnished 5*H*-benzofuro[3,2-*c*]furo[2,3-*h*][1]benzopyran-5-one (18), a compound having a new pentacyclic ring system, and the action of aluminum chloride in nitrobenzene caused only the demethylation of the methoxy group to give 4-hydroxy-3-(2-hydroxyphenyl)furocoumarin (19), which was further converted to 18 by heating it with methanolic hydrogen chloride. The structures of these compounds were verified from their analyses and their infrared and ultraviolet spectra.

In the infrared spectra, the dihydrofuroisoflavones (4a, b, c and 6a, b) have their ν_{CO} at 1650—1635 cm^{-1}, characteristic for chromones, while dihydrofuro- (7a and 7c) and furocoumarins (10, 11, 16, 17 and 19) have their broad ν_{OH} at 3100—2950 cm^{-1} and their ν_{CO} at 1710—1660 cm^{-1}, characteristic for hydroxy-coumarins. Benzofuro-furobenzopyranone (18) has its ν_{CO} at somewhat higher wave number region, 1760 cm^{-1}. These data are comparable to those of the isomeric compounds having linearly fused furan ring.[4]

The ultraviolet absorption spectra were measured in ethanol and it proved that the dihydrofuroisoflavones (4a and 6a) have almost similar shape of absorption curves with that of the furo-compounds,[1] having high peaks at 245—250 mμ and low peaks at 305 mμ (Fig. 1), and the 3-(methoxyphenyl)

analogues (4b and 4c) have broader absorption at 220—240 mμ and higher peaks of the 300 mμ region (Fig. 2). Furocoumarins (16 and 17) have high peaks at about 235 mμ and lower ones at 290—300 mμ, and the 3-aryl derivatives (10, 11 and 19) have additional peaks at 217 mμ and broader absorption at 280—330 mμ, while the dihydrofurocoumarins (7a and 7c) have no peaks in the 210—270 mμ region and have higher peaks at about 320 mμ (Figs. 3 and 4). The benzofuro-furobenzopyranone (18) has high peak at 238 mμ and broader absorption at 280—345 mμ having four peaks (Fig. 4). These relations of the ultraviolet spectra are

comparable to those of the isomers,[4] except that the absorption band in the 300 mμ region of the isomers appears at the wave length longer by 20 mμ than that of the others.

In conclusion, it seems that the influence of furan ring appears fairly clearly in the absorption of 230—270 mμ region in the case of furocoumarins, but not so clearly in the case of furoisoflavones, probably as coumarins have not or have only weak absorption in that region[23] while isoflavones themselves have already strong absorption in that region,[24] which and that due to furan ring overlap each other.

Experimental*2

Materials. The compound 1 was prepared[11] by the catalytic reduction of the furo-compound and the ketone 8a and furoisoflavones 9a and 9b were prepared according to the Ref. 1. The compound 12 was prepared[16] by the formylation of ethyl resorcylate.

The Preparation of 2,3-Dihydro-4-hydroxy-5-benzofuranyl Ketones and Isomers. *a) By the Acylation of 2,3-Dihydro-4-hydroxybenzofuran* (1) *by Means of Carboxylic Acid and Polyphosphoric Acid (PPA)* (*Table 1*). A mixture of 1 (1 g), phenylacetic acid (1 g, 1 mol equivalent) and PPA (n=1.5, 25 g) was heated at 100°C for 30 min with stirring. The cooled mixture was poured into ice-water and was extracted with ether. The ethereal solution was washed with aqueous sodium bicarbonate, and then was extracted with 5% aqueous sodium hydroxide. The product obtained from the ethereal layer was crystallized from ethanol to give 2,3-dihydro-4-hydroxy-5-benzofuranyl benzyl ketone (3a), having a positive ferric chloride color reaction in ethanol.

The alkaline extract was acidified and extracted with ether. The product obtained from the ethereal solution was crystallized from methanol to give the isomeric 2,3-dihydro-4-hydroxy-7-benzofuranyl benzyl ketone (2a), having a negative ferric chloride color reaction in ethanol.

Similarly, 2,3-dihydro-4-hydroxy-5-benzofuranyl 2-methoxybenzyl ketone (3b) and 2,3-dihydroxy-4-hydroxy-5-benzofuranyl 2,4,5-trimethoxybenzyl ketone (3c) and the isomeric 2,3-dihydro-4-hydroxy-7-benzofuranyl 2-methoxybenzyl ketone (2b) and 2,3-dihydro-4-hydroxy-7-benzofuranyl 2,4,5-trimethoxybenzyl ketone (2c) were also obtained by this method.

b) By the Acylation of 1 by Means of the Hoesch Reaction. (*Table 1.*) Anhydrous powdered zinc chloride (2.5 g) was added to a solution of 1 (1 g) and phenylacetonitrile (1 g, 1 mol equivalent) in anhydrous ether (30 ml), and the mixture was saturated with dry hydrogen chloride with stirring and cooling, and then was left 2 days. The upper ethereal layer was decanted off and the residual viscous lower layer was heated on a water-bath for 1 hr with the addition of dilute hydrochloric acid. The cooled mixture was extracted with ether and the ethereal solution was treated similarly as described in the procedure a) to give the ketones 3a and 2a.

c) By the Hydrogenation of Benzofuranyl Ketone (8a). A mixture of 4-hydroxy-5-benzofuranyl benzyl ketone(8a)[11] (0.5 g), palladium carbon (25%, 0.5 g) and ethyl acetate (100 ml) was shaken with hydrogen at atmospheric pressure and room temperature until one mole equivalent

a) s: Shoulder

of hydrogen was absorped (about 8 hr). Then, the catalyst was filtered and the solvent was distilled off, and the residual product was crystallized to give the ketone 3a, 0.4 g.

d) By the Alkaline Degradation of Dihydrofuroisoflavone (4a). A mixture of dihydrofuroisoflavone 4a (0.5 g) and ethanolic (not methanolic) potassium hydroxide (1 g in 30 m*l* ethanol) was refluxed for 3 hr, then was diluted with water and acidified. The crystalline product formed was collected and recrystallized to give the ketone 3a, 0.3 g.

The Preparation of Dihydrofuroisoflavones (Table 2). *a) By the Action of Acetic Anhydride and Sodium Acetate on the Ketones (3).* A mixture of the ketone 3a (0.3 g), anhydrous sodium acetate (0.3 g) and acetic anhydride (10 m*l*) was refluxed for 12 hr and the cooled mixture was poured into ice-water and left overnight. The crystalline product formed was collected and recrystallized from ethanol to give 4″,5″-dihydro-2-methylfuro[2″, 3″: 7,8]isoflavone (4a).

Similarly, 4″,5″-dihydro-2′-methoxy-2-methylfuro-[2″,3″:7,8]isoflavone (4b) and 4″,5″-dihydro-2-methyl-2′,4′,5′-trimethoxyfuro[2″,3″: 7,8]isoflavone (4c) were also obtained by this method.

b) By the Hydrogenation of Furoisoflavones (9). A mixture of 2-methylfuroisoflavone 9a (0.5 g), palladium carbon (25%, 0.5 g) and ethyl acetate (30 m*l*) was shaken with hydrogen and was treated similarly as described for the ketone 8a to give the dihydrofuroisoflavone 4a.

Similarly, 4b was also obtained by this method through purification by chromatography with alumina and ethyl acetate as a solvent.

c) By the Action of Ethyl Formate and Sodium on the Ketones (3) through Dihydrofuroisoflavanone (5). Small pieces of metallic sodium (0.7 g) were added to cooled (−10°C) ethyl formate (10 m*l*), and to this suspension was added a solution of 3a (0.6 g) in ethyl formate (10 m*l*) with stirring and cooling at 0—2°C over a period of 40 min, then the mixture was stirred for 3 hr at room temperature and left overnight. Methanol was added to destroy the excess sodium, ice-water was added and the excess ethyl formate was removed under diminished pressure. The residual solution was acidified and extracted with ether, and the product obtained from the ethereal solution was crystallized from ethyl acetate to give 4″,5″-dihydro-2-hydroxyfuro[2″,3″:7,8]isoflavanone (5a). The shape of UV spectrum is quite different from that of isoflavones.

Similarly, 4″,5″-dihydro-2-hydroxy-2′,4′,5′-trimethoxyfuro[2″,3″:7,8]isoflavanone (5c) was also obtained by this method from the ketone 3c. In the case of the ketone 3b, the crude product obtained seemed from its spectrum to be a mixture of the hydroxyisoflavanone and isoflavone, therefore, it was purified by chromatography with alumina and ethyl acetate as a solvent to give the pure 4″,5″-dihydro-2′-methoxyfuro[2″,3″:7,8]-isoflavone (6b), but the corresponding hydroxyisoflavanone (5b) was not obtained in a pure form.

To convert the hydroxyisoflavanone (5a) to the isoflavone, 0.5 g of it was heated with acetic acid (30 m*l*) on a water-bath for 1 hr. The cooled mixture was diluted with water and the crystalline product formed was collected and recrystallized from ethanol to give 4″,5″-dihydrofuro[2″,3″:7,8]isoflavone (6a). The hydroxyisoflavanone 5c was not dehydrated by this procedure.

The Preparation of Benzofuranyl Ketones. *4-Hydroxy-5-benzofuranyl 2-Methoxybenzyl Ketone (8b).* A mixture of furoisoflavone 9b (1.7 g), aqueous potassium hydroxide (50%, 8 g) and ethanol (100 m*l*) was refluxed for 4 hr, then most of the ethanol was distilled off. The residual solution was diluted with water and acidified to give the crystalline product. Recrystallization from ethanol furnished 8b, 1.2 g (77%).

5-Acetyl-4-hydroxybenzofuran-2-carboxylic Acid (14). A mixture of 2,4-dihydroxy-3-formylphenyl methyl ketone[16] (12) (27 g), ethyl bromomalonate (28 m*l*), anhydrous potassium carbonate (80 g) and methyl ethyl ketone (1.2 *l*) was refluxed for 8 hr. The cooled mixture was filtered and the solvent was distilled off and then the residual product was crystallized from dilute acetone to give crude ethyl 5-acetyl-4-hydroxy-benzofuran-2-carboxylate (13), mp 134.5—136°C, ν_{max} cm^{-1}: 1710, 1625 (CO). This ester 13 was heated with aqueous potassium hydroxide (10%, 150 m*l*) on a water-bath for 1 hr. The cooled solution was filtered and acidified to give the crystalline acid. Recrystallization from dilute ethanol gave pure 14, 11.5 g (37% from 12).

4-Hydroxy-5-benzofuranyl Methyl Ketone (15). A mixture of the acid 14 (13.5 g), copper powder (13.5 g) and quinoline (380 m*l*) was refluxed gently for 1 hr under a stream of nitrogen. The cooled mixture was filtered and acidified with dilute hydrochloric acid and then extracted with ether. The ethereal solution was washed with aqueous sodium bicarbonate and then extracted with aqueous sodium hydroxide. The product obtained by acidifying the alkaline solution was crystallized from petroleum benzine to give the ketone 15, mp 84—85°C (lit[15] mp 86—87°C), yield 5.6 g (47%), ν_{max} cm^{-1}: 1630 (CO). (Found: C, 68.44; H, 4.27%).

The Preparation of Dihydrofuro- and Furocoumarins (Table 2). *a) By the Action of Ethyl Chlorocarbonate and Potassium Carbonate on the Ketones (3).* A mixture of the ketone 3a (0.3 g), ethyl chlorocarbonate (0.9 g), anhydrous potassium carbonate (2.5 g) and acetone (30 m*l*) was refluxed for 4 hr. The cooled mixture was diluted with water and acidified. The precipitates formed were collected and heated with aqueous sodium hydroxide (1 N, 50 m*l*) for 1 hr on a water-bath. The resulting solution was diluted with water and acidified to give the crystalline product. Recrystallization from ethanol gave 4′,5′-dihydro-4-hydroxy-3-phenylfuro [2′,3′,: 7,8]coumarin (7a).

Similarly,4′,5′-dihydro-4-hydroxy-3-(2,4,5-trimethoxyphenyl)furo[2′,3′:7,8]coumarin (7c) was also obtained by this procedure.

b) By the Action of Ethyl Carbonate and Sodium on the Ketones (8 and 15). Small pieces of metallic sodium (1.1 g) were added to a solution of the ketone 8a (0.9 g) in ethyl carbonate (25 m*l*), and the mixture was heated gradually to 100°C. The mixture was heated at that temperature for 1 hr, then methanol was added to the cooled mixture to destroy the excess sodium. The resulting mixture was diluted with water, washed with ether and then was acidified to give the crystalline product. Recrystallization from ethanol gave 4-hydroxy-3-phenylfuro[2′,3′: 7,8]coumarin (10).

Similarly, 4-hydroxy-3-(2-methoxyphenyl)furo[2′,3′: 7,8]coumarin (11) was also prepared by this procedure.

In the case of the ketone 15, the crude product was recrystallized from methanol or ethanol to give 4-hydroxyfuro[2′,3′: 7,8]coumarin (16), mp 268—269°C, having one molecule of water of crystallization. The water of crystallization was removed by drying over phosphorus

pentoxide at 120—130°C in vacuum. From the mother solution of crystallization, a small amount of ethyl 4-hydroxyfuro[2′,3′:7,8]coumarin-3-carboxylate (17) was obtained.

The Preparation of 5*H*-Benzofuro[3,2-*c*]furo-[2,3-*h*][1]benzopyran-5-one (18). *a) By the Action of Pyridine Hydrochloride on 11.* A mixture of 11 (0.35 g) and anhydrous pyridine hydrochloride (2 g) was refluxed gently for 40 min. The cooled mixture was acidified with dilute hydrochloric acid, and the crystalline product formed was collected and recrystallized from ethyl acetate and then from ethanol. Yield 0.08 g.

b) By the Action of Hydroiodic Acid on 11. The furocoumarin 11 (0.4 g) was added to a mixture of hydroiodic acid (10 m*l*), acetic acid (5 m*l*) and acetic anhydride (4 m*l*), and the mixture was refluxed gently under a stream of nitrogen for about 15 min. The cooled mixture was poured into ice-water (100 m*l*) containing a small amount of sodium bisulfite. The crystalline product formed was collected and recrystallized from ethanol then from acetone to give a small amount of 18.

c) By the Action of Aluminum Chloride on 11 through 4-Hydroxy-3-(2-hydroxyphenyl)furo[2′,3′:7,8]coumarin (19). Powdered anhydrous aluminum chloride (0.9 g) was added to a solution of the furocumarin 11 (0.6 g) in nitrobenzene (50 m*l*), and the mixture was heated on a water-bath for 1 hr. The cooled mixture was poured into ice-water containing a small amount of hydrochloric acid, the nitrobenzene was removed by steam-distillation, and the residual mixture was extracted with ethyl acetate. The ethyl acetate solution was extracted with 5% aqueous sodium hydroxide. The product obtained by acidifying the alkaline solution was crystallized from ethanol to give 19, 0.3 g.

A mixture of this furocoumarin 19 (25 mg) and methanol (100 m*l*) saturated with hydrogen chloride was refluxed for 7 hr, then the methanol was distilled off and the residue was diluted with water. The crystalline product formed was collected and recrystallized to give 18, 12 mg.

The authors are grateful to Messrs. N. Takamatsu, M. Kuramoto, M. Uchida, S. Yamaguchi, T. Kishi, N. Shimizu and F. Miyoshi for their assistance and to the Members of the Laboratory of Analysis, Faculty of Pharmacology of this University for microanalyses. The authors' thanks are also due to the Ministry of Education for its grant-in-aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1208—1220 (1968)

Acid-Catalyzed Isomerization of 1,3,4,5-Tetra-*O*-acetyl-2-deoxy-L-sorbopyranos-2,3-ene[1]

Mitsuru KATSUHARA, Shigeru WAKAHARA and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received November 18, 1967)

An acid-catalyzed reaction in acetic anhydride was found to isomerize 1,3,4,5-tetra-*O*-acetyl-2-deoxyl-L-sorbopyranos-2,3-ene (V) to four new unsaturated compounds. When the reaction was allowed to continue for a longer period, they underwent polymerization, but did not afford 2-hydroxyacetylfuran acetate (XXVIb). The reaction in acetic acid containing water was shown to mainly convert V into XXVIb. This reaction pathway was thought to be different from the above.

Dehydrochlorination of 1,3,4,5-tetra-*O*-acetyl-α-L-sorbopyranosyl chloride (IV),[2,3] derived from L-sorbose (I), through the agency of mercuric cyanide,[4,5] yields 1,3,4,5-tetra-*O*-acetyl-2-deoxy-L-sorbopyranos-2,3-ene (V). This communication is concerned with isomerizations of this unsaturated compound.

The isomerizations and other reactions of acylated aldo-1-enoses have recently received considerable attention.[6,7] The facile dissociation of the C_3-substituent in these compounds is readily understood as resulting from activation of the C_3-position toward carbonium ion formation by the allylic double bond.[8] The activation is especially strong for 1-enose structures since the ring oxygen can participate in charge

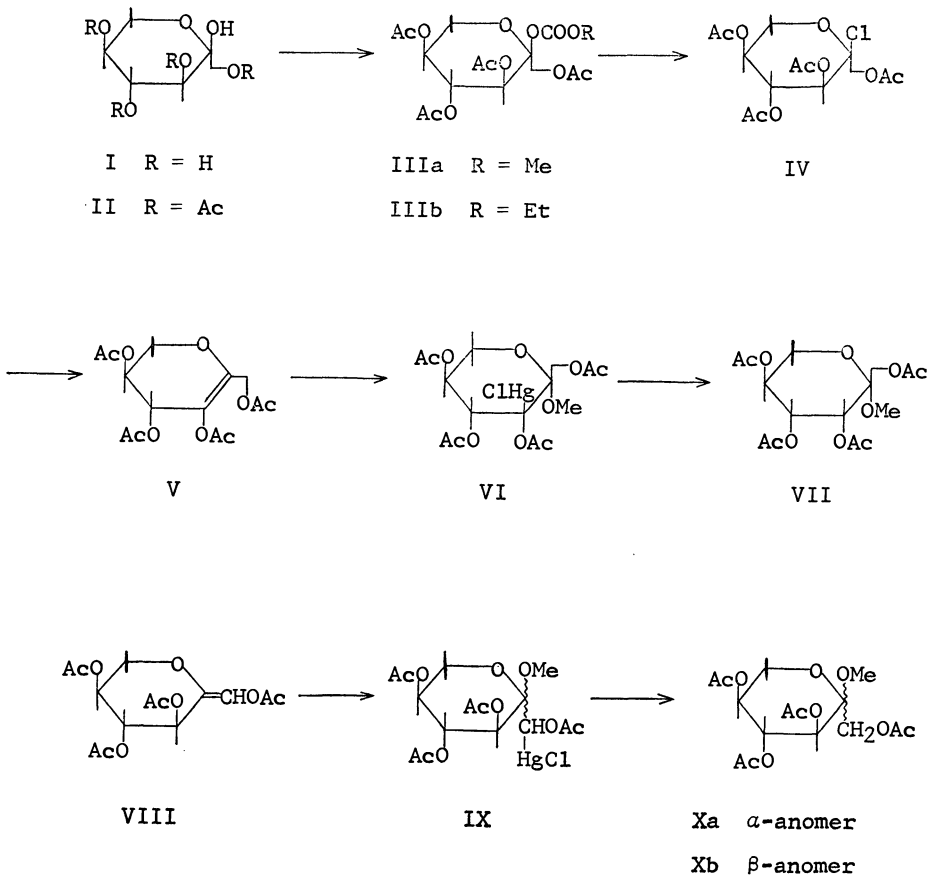

Chart 1.

delocalization.[9-13] It was anticipated that V would undergo similar isomerization, which pathway may provide interesting information regarding the acid-catalyzed degradation of ketohexose to 2-hydroxyacetylfuran (XXVIa)[14,15] through 2,3-enolization with the elimination of the hydroxyl group at the allylic C_4-position.[16,17]

The structure of V was confirmed by methoxymercuration[18] and NMR spectroscopy. NMR data obtained by 1st-order approximation are reported in Tables 1 and 2. The methoxymercuration of V gave a mercurichloride (VI). Reductive demercuration of VI with sodium borohydride in the presence of pyridine was accompanied by deacetylation, and yielded a methyl glycoside, which was isolated as a tetraacetate (VII).[19] Despite its large positive value of optical rotation, VII was not identical with methyl 1,3,4,5-tetra-*O*-acetyl-β-L-sorbopyranoside (Xb).[3] Thus, VII was concluded to be methyl 1,3,4,5-tetra-*O*-acetyl-β-L-tagatopyranoside.[20,21] The formation of the tagatopyranoside (VII) supports the structure of V, because another possible isomer VIII from the dehydrochlorination of IV should yield X *via* IX.

The NMR spectrum of V in chloroform-d (Fig. 1a) showed four singlets at about τ 7.9 due to acetoxyls, a somewhat broad singlet at τ5.39 due to H_1 (see also Fig. 1h) and signals due to H_6, $H_{6'}$, H_5, and H_4 as an ABXY pattern. This assignment

was confirmed by decoupling experiments (Fig. 1b—1g). Double irradiation at the center of resonance frequencies of H_6 and $H_{6'}$ (Fig. 1b) changed the 8-line multiplet of H_5 into a doublet ($J_{4,5}$ 2.7 cps) and the 8-line multiplet of H_4 into a somewhat broad doublet. By double irradiation on $H_{6'}$, the H_5 signal collapsed to a doublet-doublet ($J_{5,6}$ 2.4 cps), but no changes in the H_4 signal were observed (Fig. 1c). By double irradiation on H_6, the H_5 signal collapsed to a doublet-doublet and the H_4 signal to a somewhat broad doublet (Fig. 1d). Conversely, decouplings of H_4 (Fig. 1f) and H_5 (Fig. 1g) resulted in changes of the signals of H_5 and H_6 ($J_{5,6'}$ 1.5 cps) and of those of H_4, H_6 and $H_{6'}$ ($J_{6,6'}$ 12.3 cps and $J_{4,6}$ 1.3 cps), respectively. Decoupling of H_1 (Fig. 1e) made the broad signal

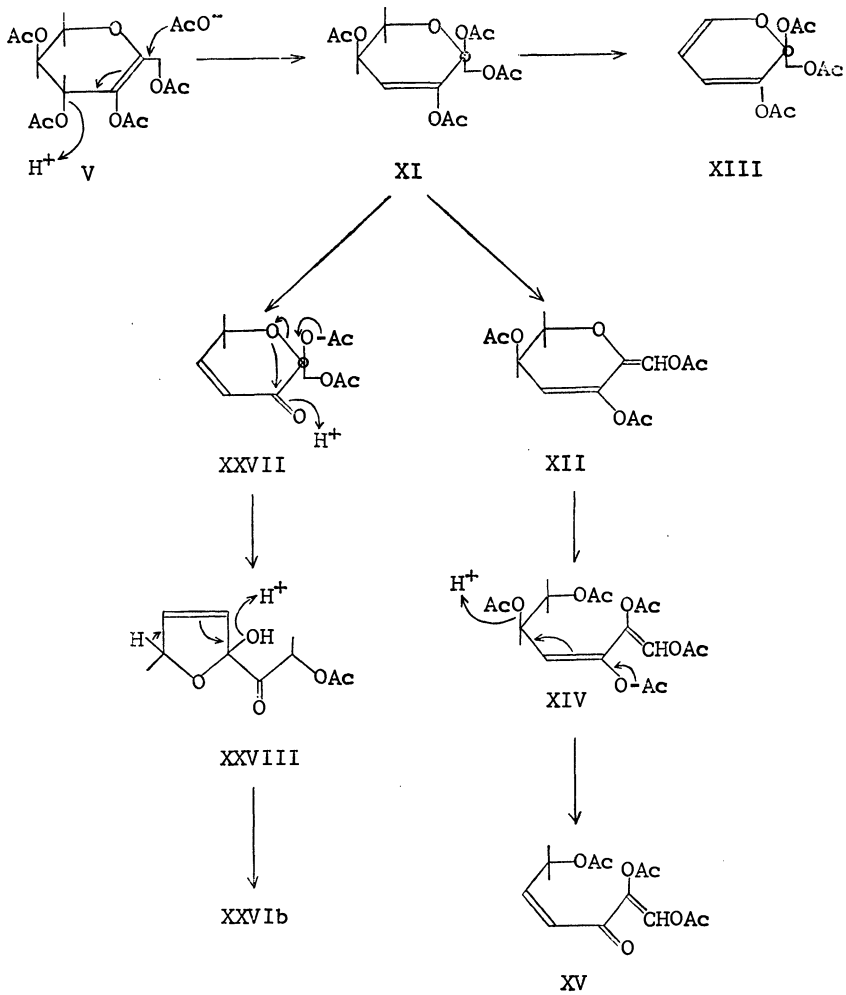

Chart 2.

of H_4 relatively sharper, showing the presence of homoallylic coupling between C_4 and C_1 protons. These observations provided evidence for the structure of V. Applying the Karplus correlation[22] for the coupling constants obtained and the "W-letter" rule[23] for the long-range spin coupling between H_4 and H_6, we reached the conclusion that V should exist in H_1 conformation.[24]

It was found that the treatment of V in acetic anhydride containing *p*-toluenesulfonic acid (TsOH) resulted in rapid formation of a mixture of at least four products (A, B, C, and D) in the thin-layer chromatograms. When the reaction was interrupted at the initial stages, the product A was mainly isolated. On the other hand, when the reaction was allowed to proceed for 48 hr, products B and C were detected as major products. These products could be resolved by preparative thin-layer chromatography using several solvent systems. The structures established for the new compounds described above were confirmed by the application of NMR spectroscopy with the use of spin decoupling to assign the origins of the signals. The assignment was also based on the chemical shifts with reference to those of V.

As it is expected that the reaction of V under acidic conditions undergoes allylic displacement of the C_4-ester grouping and the formation of a 3,4-unsaturated compound (XI),[8-13] the structure of compound A was thought to be XI or its derivative. The analytical data and the integration of an NMR spectrum determined it as a triacetate $C_{12}H_{14}O_7$, which was thought to be derived from XI by the elimination of one mole of acetic acid. The elimination may occur at the 1,2- or 5,6-position. Thus, the

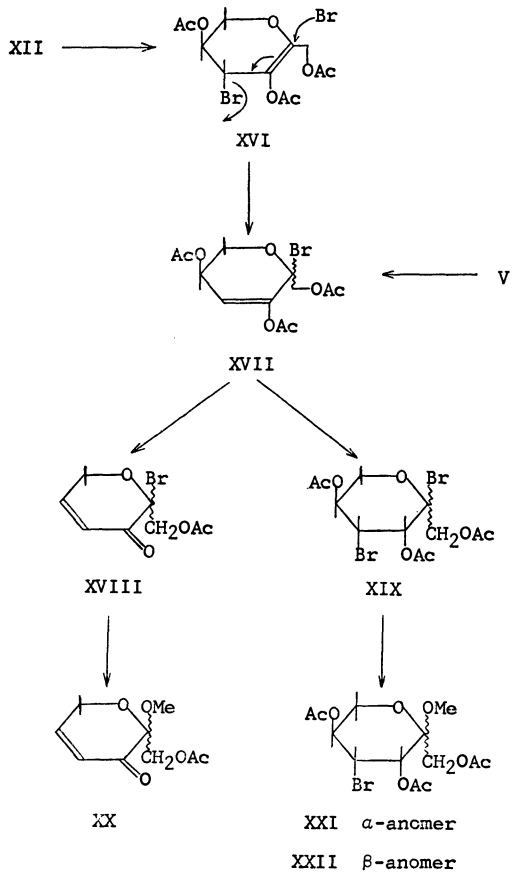

Chart 3.

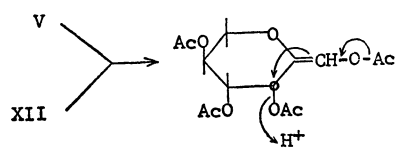

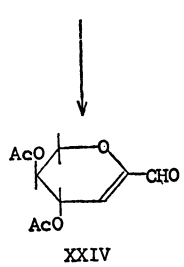

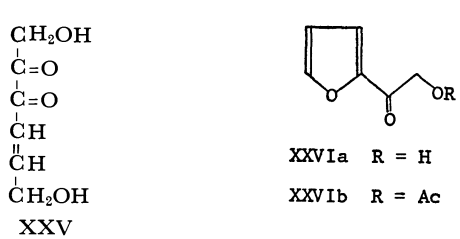

Chart 4.

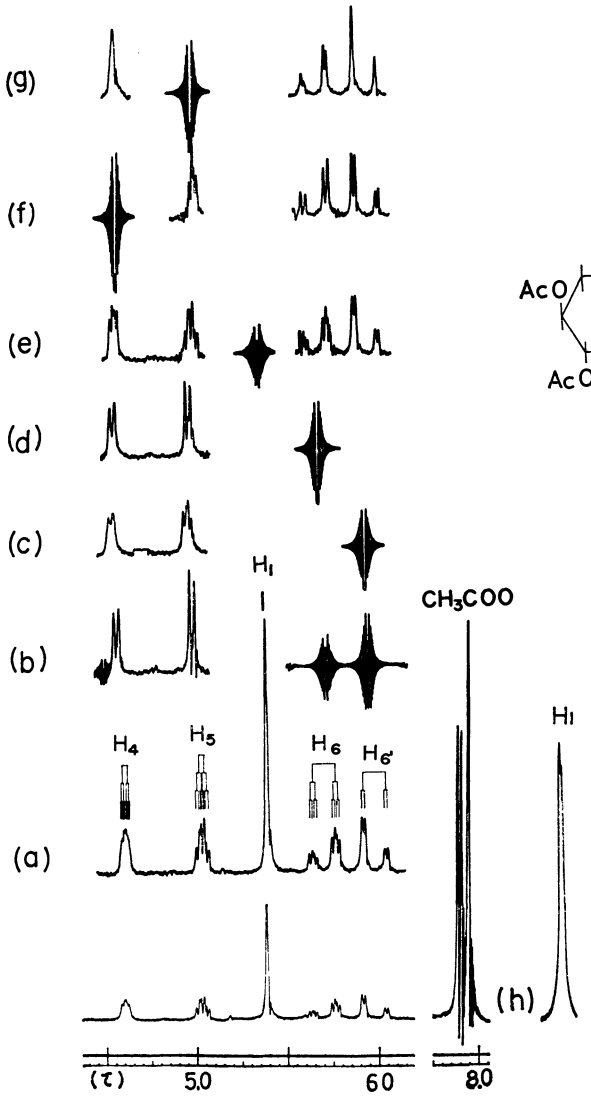
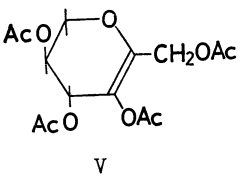
structure is proposed to be XII or XIII. The UV and IR spectra showed the characteristic bands due to a conjugated diene and the NMR spectrum (Fig. 2) revealed the presence of C_6-methylene protons and an olefinic C_1-proton. The results clearly support the structure of XII. Figure 2a shows the assignment of the NMR spectrum in benzene-d_6. The rough, 1-proton singlet at τ2.67 should arise from the olefinic H_1. Its lower chemical shift is understandable in view of acetoxy substituent on the ethylenic group. The signals of the other protons (H_6, $H_{6'}$, H_5 and H_4) appear as the pattern of ABXY system, an AB quartet at τ6.00 (H_6) and 6.24 ($H_{6'}$), an 8-line multiplet (X part) at τ4.85 (H_5) and a 6-line multiplet (Y part) at τ4.17 (H_4). On double irradiation at the C_6-methylene position, the H_5 multiplet collapsed to a sharp doublet ($J_{4,5}$ 6.2 cps) and the H_4 multiplet to a doublet-doublet (Fig. 2b), showing the presence of long-range coupling between H_1 and H_4 ($J_{1,4}$ 0.7 cps). Double irradiation at the H_6 position caused the H_4 multiplet to collapse to a doublet-doublet (Fig. 2c), but double irradiation at the $H_{6'}$ position did not cause any changes of the H_4 signal (Fig. 2d). These decoupling experiments confirmed the above-described assignment (Fig. 2a), which is consistent with structure **XII.**

The reaction of XII with hydrogen bromide in benzene followed by glycosidation with methanol gave three pyranosides XX, XXI and XXII as major products. XX gave analytical data corresponding to methyl glycoside monoacetate, $C_9H_{12}O_5$, and its IR and UV spectra revealed bands due to an α,β-unsaturated ketone. The NMR spectrum in chloroform-d (Fig. 3) showed two singlets at τ7.94 due to one acetyl methyl and at τ6.58 due to one methoxy methyl, 2-proton singlet at τ5.56 due to C_1-protons and an AB type quartet of ABXY system due to C_6-protons at about τ5.5. The above-described data established the structure XX. The remaining two 1-proton multiplets at τ2.94 and 3.89 due to olefinic protons were assignable to H_5 and H_4, which are coupled to each other (J 10.5 cps), and the latter showed allylic coupling with C_6-methylene protons. These observations provided further proof for the structure XX. Evidence bearing on the anomeric configuration of XX was not obtained.

Analytical data and optical rotation showed that XXI was a methyl bromo-tri-*O*-acetyl-α-L-glycoside, $C_{13}H_{19}O_8Br$. The NMR spectrum showed a 2-proton singlet at τ5.90 due to C_1-protons, an AB type quartet of ABX system at τ6.07 (H_6) and 6.56 ($H_{6'}$) due to C_6-protons, an 8-line multiplet at τ4.78 due to H_5, a doublet-doublet at τ5.50 due to H_4 and a doublet at τ4.52 due to H_3. The relatively lower chemical shifts of H_3 and H_5 than H_4 determined the position of the bromine to be at the C_4-position. The coupling constants ($J_{3,4}$ 3.1 cps and $J_{4,5}$ 10.8 cps) suggest that the relationship of H_3 and H_4 should be *cis* (equatorial-axial) and that of H_4 and H_5 be trans





V

Fig. 1. NMR spectra of V in chloroform-d at 100 Mc.

(axial-axial).[25] Therefore, the structure of XXI was clearly determined as methyl 1,3,5-tri-*O*-acetyl-4-bromo-4-deoxy-α-L-tagatopyranoside.[26,27]

Treatment of XXII with hydrogen chloride in benzene followed by glycosidation with methanol gave XXI. Thus, it was determined to be the β-anomer of XXI.

The reaction process of the formation of these pyranosides is considered as shown in Chart 3. The 1,4-addition of hydrogen bromide to XII afforded XVI, which was then converted into XVII by an allylic displacement reaction with hydrogen bromide. Two reaction pathways can exist for the further reaction of XVII. The first is the addition of hydrogen bromide to the 3,4-double bond yielding XIX which is transformed to glycosides XXI and XXII. The preferable formation of tagatopyranosides is thought to be caused by the anchimeric effect of the acetoxy group at the C_5-position.[28,29] The second is the formation of XVIII, which may be formulated

25) R. H. Bible, " Interpretation of NMR Spectra," Plenum Press, New York (1965), p. 35.

26) The evidence of NMR indicates that the favored conformation of XXI is the 1C chair form. See, Ref. 27.

27) F. W. Lichtenthaler and H. K. Yahya, *Tetrahedron Letters*, **1965**, 1805.

28) Formation of 4,5-acetonium ion[29] may be thought on the protonation of XVII. In this ion form, the C_3-acetoxy group might be expected to predominantly be trans to 4,5-acetonium group.

29) H. Paulsen, W. P. Trautwein, F. G. Espinosa and K. Heynes, *Tetrahedron Letters*, **1966**, 4131.

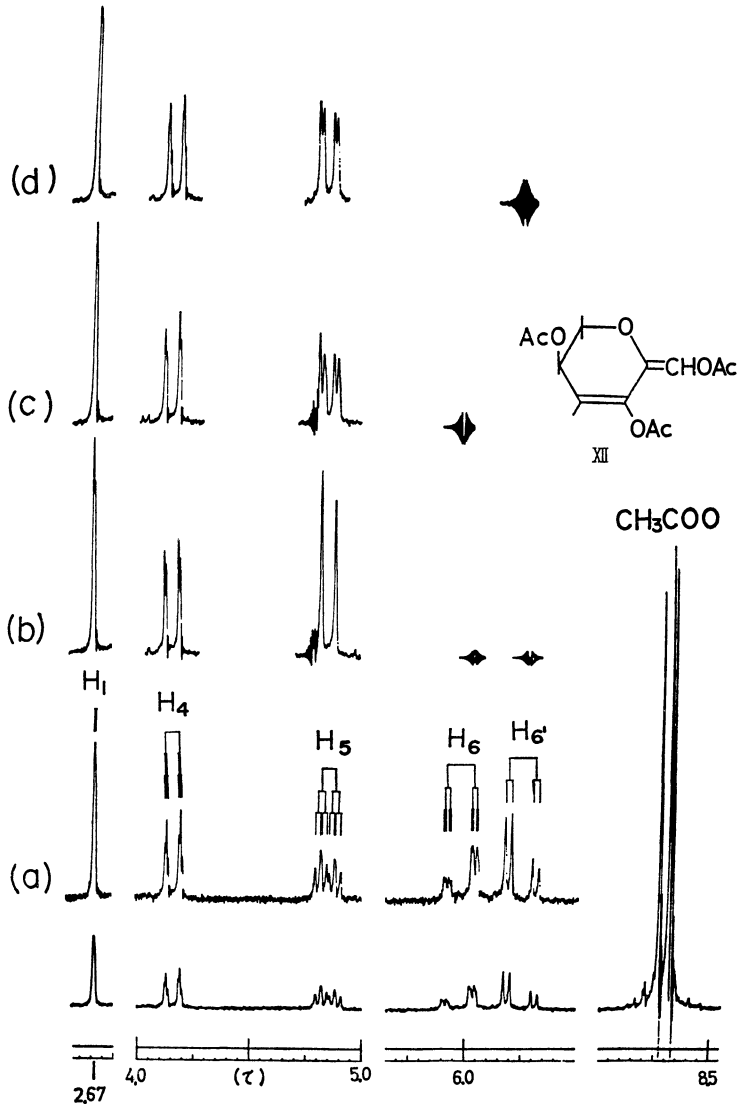


Fig. 2. NMR spectra of XII in benzene-d_6 at 100Mc.

as an elimination of the acetoxy group of the C_5-position to form an allylic cation, followed by loss of a C_3-acetyl cation. XVIII is converted into XX by methanolysis.

The same results were obtained in the treatment of V under the same reaction conditions, in which the formation of XVII is very probable. Therefore, the above pathway and, consequently, the structure XII were confirmed.

The compound B had the correct analysis for XII plus one mole of acetic anhydride and had a conjugate diene absorption in the infrared. It was also derived from the acid treatment of XII in acetic anhydride. Therefore, its structure should be XIV, which is the ring-open form of XII. The fact that the NMR data in chloroform-d are quite similar to those of XII supported this structure. The spectrum (Fig. 4a) contained singlets at about τ7.9 due to five acetoxyls, a noisy singlet at τ2.55 due to olefinic H_1, an AB type quartet of ABXY system at τ5.67 (H_6) and 5.95 ($H_{6'}$) due to C_6-protons, a 6-line multiplet at τ5.04 due to H_5 (X part) and a doublet-doublet at τ4.55 due to H_4 (Y part). Double irradiation at the H_4 position (Fig. 4b) caused the collapse of the H_5 and H_6 signals to doublet-doublets ($J_{5,6'}$ 1.8 and $J_{5,6}$ 2.7 cps), while double irradiation at the H_5 position caused the collapse of the H_4, H_6 and $H_{6'}$ signals to a somewhat broad doublet, a doublet-doublet ($J_{4,6}$ 1.5 cps) and a doublet ($J_{6,6'}$ 12.5 cps), respectively (Fig. 4c). The somewhat broad signals of H_4 and H_1 imply the presence of weak long-range spin coupling between them. Thus, the structure XIV was established.

The combined data of chemical analysis, the UV

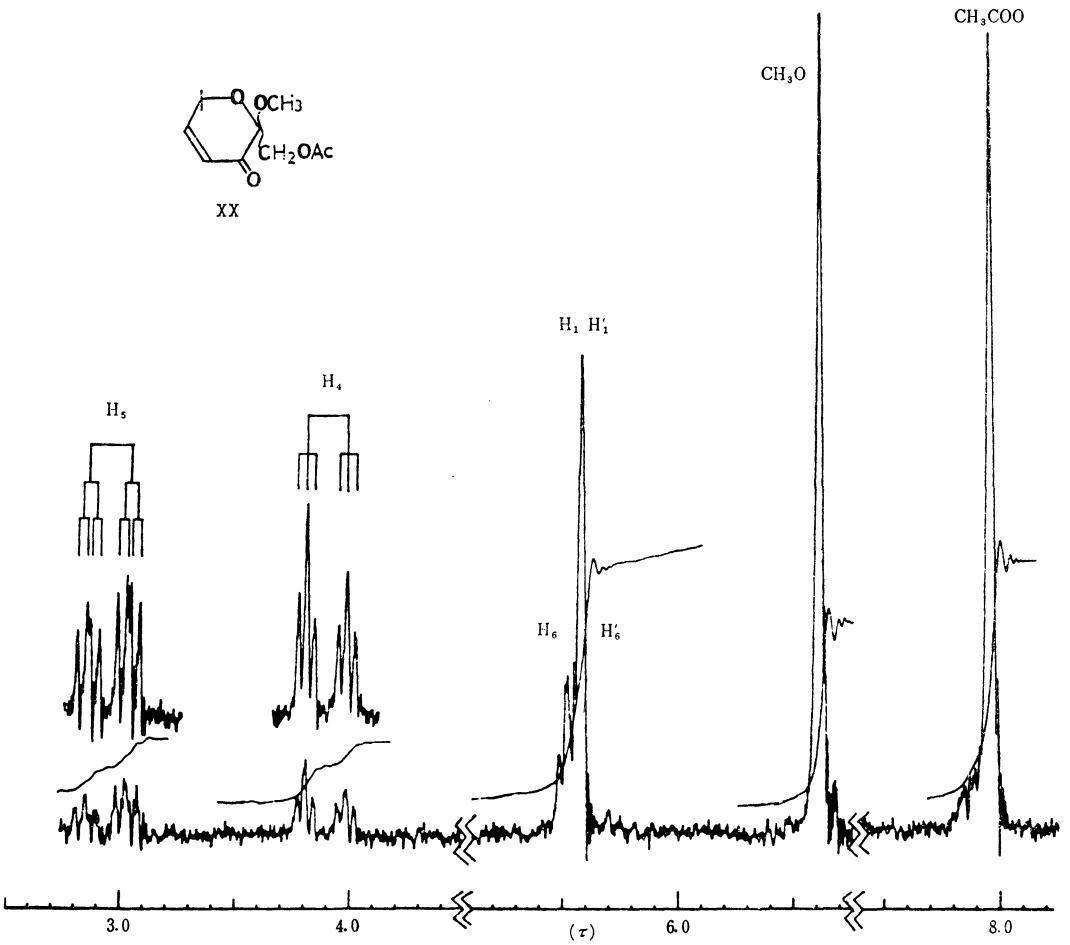

Fig. 3. NMR spectrum of XX in chloroform-d at 60Mc.

and IR spectra established that compound C was a conjugate ketone compound with an elementary composition corresponding to that of XIV minus one mole of acetic anhydride. It was also derived from the acid-treatment of XIV. As elimination of the acetoxy group at allylic C_5-position and an acetyl group at the C_6-position of XIV are reasonably expected,[30,31] its structure was concluded to be XV. In chloroform-d, XV displayed a well-resolved spectrum (Fig. 5) with three acetoxyl singlets at about τ7.9, a singlet at τ2.92 due to H_1 and an ABXY pattern of a 8-line multiplet at τ3.70 (Y part), an 8-line multiplet at τ2.88 (X part) and an AB quartet at τ5.23 and 5.38 due respective to olefinic H_4 and H_5, which are coupled to each other, and to methylene H_6 and $H_{6'}$. The double irradiation at the center of resonance of H_5 (Fig. 5b) changed the signals of H_4, H_6 and $H_{6'}$ into doublet-doublet. On double irradiation on C_6 protons (Fig. 5c), the signals of H_4 and H_5 collapsed into doublets ($J_{4,5}$ 11.0 cps), showing the presence of allylic coupling between C_4 and C_6 protons. These irradiation experiments supported the structure XV.

The formation of the compound D was also observed at the initial stage of the reaction of V as a minor product. The analytical data corresponded to a diacetate, $C_{10}H_{12}O_6$, showing IR bands due to an α,β-unsaturated aldehyde. Thus, this was tentatively assigned to XXIV. The NMR spectrum (Fig. 6a) showed unequivocally the presence of an aldehyde at τ0.74. An AB quartet due to C_6-methylene at τ5.61 and 5.94, multiplet at τ4.96 due to H_5 and at τ4.79 due to H_4 and a doublet-doublet at τ4.06 due to H_3 are also easily analyzed as an ABXY pattern. The chemical shifts show that H_3 should be an olefinic proton and acetoxy groups should be at the C_4- and C_5-positions. Therefore, the structure of compound D was determined to be XXIV. Double irradiation at H_3 (Fig. 6b), giving a pattern similar to that of V (Fig. 1), also supported the structure.

30) E. F. L. J. Anet, *Chem. & Ind.*, **1963**, 1035.
31) E. F. L. J. Anet, see Ref. 14, p. 195.

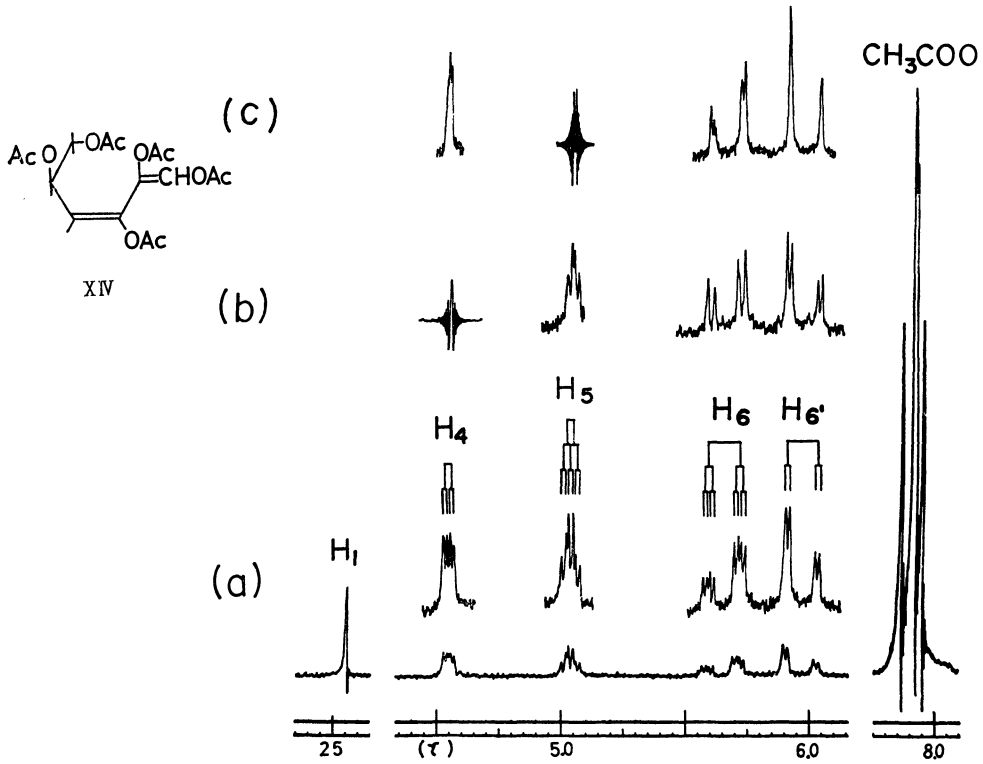

Fig. 4. NMR spectra of XIV in chloroform-d at 100Mc.

Thin-layer chromatographic studies on the above-described degradation of V in acetic anhydride showed that the initial products were primarily XII and a minor amount of XXIV. When the reaction was allowed to continue for longer periods of time, the amounts of XIV and XV increased at the expense of XII. Under similar acidic conditions, the conversion of XIV into XV was also observed, however, the reverse reactions XV→XIV and XIV→XII were not observed. Consequently, the reaction process of the degradation of V is concluded to proceed *via* a pathway of V→(XI)→XII→XIV→XV as shown in Chart 2.[32] No isolation of XI must be caused by its instability.[33]

It is quite natural to consider that the precursor of XXIV should be a 1,2-ene derivative, VIII or its epimer XXIII. The elimination of a protonated C_3 acetoxy group of VIII or XXIII, followed by the loss of C_1 acetyl cation yielded XXIV. For the formation of VIII or XXIII, two possible pathways can be proposed. One is the 3,4 addition of acetic acid to XII and the other is the rearrangement of the 2,3-double bond of V into 1,2-position; however, the latter is favorable, since thin-layer chromatographic data elucidated no formation of XXIV by acid-treatment of XII in acetic anhydride or in acetic acid.

Anet's mechanism for the acid-catalyzed degradation of hexose to furans proposed that a key intermediate is an unsaturated osone such as XXV which may be converted into XXVIa. As the deacetylated form of XV is quite similar to XXV, it is expected that XV may also be converted into XXVI. However, the possibility of the above-described intermediates XII, XIV and XV being the precursor of furans is excluded, since heating them in an acetic anhydride medium only gave polymeric substances.

The treatment of V in acetic anhydride also did not afford furans even under stronger conditions, however, treatment in acetic acid yielded XXVIb. Since the UV absorption spectrum of XXVIb gave an absorption maximum at 272 mμ, it was felt that furan formation could be followed by observing the appearance of this peak. Solutions were made of V (1%) in acetic acid containing different concentrations of water and the absorbance of each solution at 272 mμ was recorded after heating at 95°C for 4.5 hr. The results, as shown in Fig. 7, revealed that the formation of XXVIb tended to increase with increasing addition of water. Although XII was detected at the initial stages of these reactions, it yielded

32) This pathway *via* XI was thought to be more favorable than a pathway of V→XII→XIV→XV, since the formation of XX (XVII) was observed in the reaction of V with hydrogen bromide.

33) It was supposed that the two large substituents, of the C_2 position, OAc and CH_2OAc, make the molecule unstable.

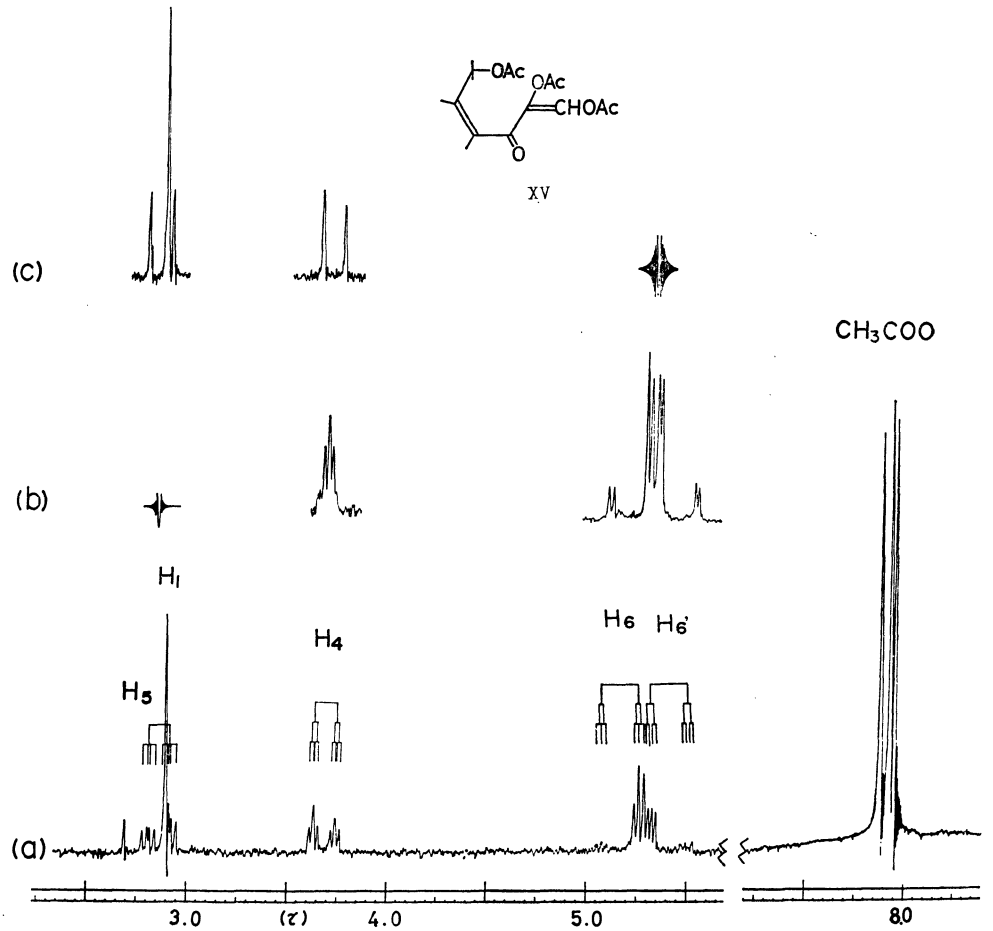

Fig. 5. NMR spectra of XV in chloroform-d at 100 Mc.

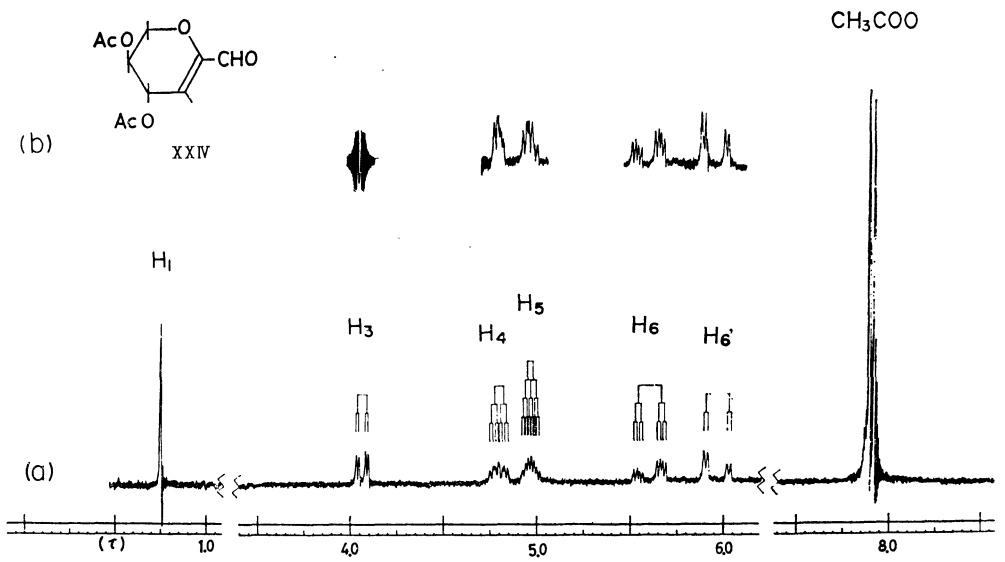

Fig. 6. NMR spectra of XXIV in chloroform-d at 100 Mc.

only traces of XXVIb under the same reaction conditions. Intermediates XIV and XV were hardly detected in the reaction mixtures and did not afford XXVIb in acetic acid-water. On the other hand, heating of another type of osone, XX, easily gave XXVIb. Therefore, the reaction process of the degradation of V to XXVIb is assumed to be as follows: V→XI→XXVII→XXVIII→XXVIb (see Chart 2). Attempts were made to isolate unknown osone XXVII from an acetic acid solution of V, but a complex mixture of products were isolated. By preparative thin-layer chromatography of the mixture, a compound showing IR and UV bands due to conjugate ketone and a quite similar pattern of NMR spectrum to XX was isolated, and was easily converted into XXVIb. Therefore, this thought to be XXVII, however, an adequate amount for determination of its correct structure was not obtained.[34-36]

It was somewhat surprising that the presence of water is very important for the degradation of V; it degradates to form polymeric substances under anhydrous conditions and to form furan XXVIb by aqueous treatment.

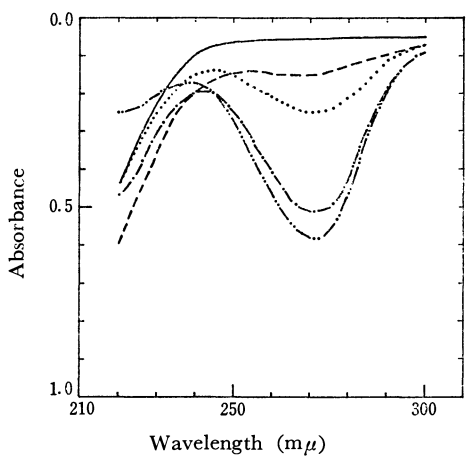

Fig. 7. The formation of XXVIb from V (at 95°C for 4.5hr).

Experimental

Melting points were determined on a Kofler block. The NMR spectra were measured on a Varian A-60 spectrometer at 60 Mc at room temperature using tetramethylsilane (TMS) as internal reference. Spectra at 100 Mc were obtained at room temperature from Varian HA-100 instrument internally locked on TMS in the frequency-sweep mode of operation. NMR data obtained by 1st-order approximation were summarized in Tables 1 and 2.

Thin-layer chromatography was performed on a silica gel plate. The solvent-systems used were ether-petroleum ether (3: 1, v/v, solvent A, 2: 1, v/v, solvent B and 1: 2, v/v, solvent C), benzene-ether (3: 1, v/v, solvent D), chloroform-acetone (60: 1, v/v, solvent E) and ethyl acetate-petroleum ether (2: 3, v/v, solvent F). The separated materials were developed with either iodine vapor or 0.2% resorcinol in 10% ethanolic phosphoric acid, and then heated in an oven.[37] In the cases of preparative thin-layer chromatography, the developed zones were extracted with acetone unless otherwise stated. The evaporation of the acetone under reduced pressure gave the materials.

The optical rotations were determined in a 10cm microtube in chloroform containing 1% of ethanol, and concentrations were recorded in percentage. The UV spectra were measured in ethanol.

1,3,4,5-Tetra-*O*-acetyl-2-*O*-carbomethoxy-α-L-sorbopyranose (IIIa). A mixture of II (10 g),[38] dimethyl pyrocarbonate (8 m*l*)[39,40] and potassium carbonate (0.1 g) was warmed at 50—60°C for 1.5 hr with stirring. The reaction mixture was filtered and washed with ether. The washings and the filtrate were combined and then evaporated under reduced pressure. The residue was recrystallized from ether to give colorless columns (6.9 g), mp 117—117.5°C, $[\alpha]_D^{22}$ −63.2° (*c* 1.038).

Found: C, 47.59; H, 5.58%. Calcd for $C_{16}H_{22}O_{12}$: C, 47.29; H, 5.46%.

1,3,4,5-Tetra-*O*-acetyl-2-*O*-carboethoxy-α-L-sorbopyranose (IIIb). A mixture of II (30 g), diethyl pyrocarbonate (23 m*l*) and potassium carbonate (0.3 g) was warmed at 50—55°C for 0.5 hr with stirring. IIIb (38.9 g) was obtained in a manner similar to IIIa. IIIb had mp 96—97°C, $[\alpha]_D^{22}$ −69.7° (*c* 1.116).

Found: C, 48.73; H, 5.92%. Calcd for $C_{17}H_{24}O_{12}$: C, 48.57; H, 5.76%.

1,3,4,5-Tetra-*O*-acetyl-α-L-sorbopyranosyl Chloride (IV). A solution of IIIb (30 g) in acetic acid (600 m*l*) saturated with anhydrous hydrogen chloride was kept at 0—5°C for 3.5 hr. The solution was added to chloroform (500 m*l*) and washed with ice-water, saturated aqueous sodium bicarbonate and ice-water,

34) Another new compound was isolated, which gave analytical data corresponding to $C_{12}H_{14}O_7$. Its NMR spectrum in chloroform-d at 60 Mc revealed three 3-proton singlets at τ 7.73, 7.92 and 7.94 due to acetoxyls, one 1-proton singlet at τ 3.51 and two 2-proton singlets at τ 4.99 and 5.01. Therefore, the structure was tentatively assigned to be 2,5-diacetoxymethyl-3-acetoxyfuran. Although further evidence seems to be required, a related experiment that D-glucal smoothly yielded 2-methoxymethyl-5-hydroxymethylfuran with methanolic hydrochloric acid seems support this structure (see Refs. 35 and 36).

and dired. Removal of the solvent gave a crude chloride (24.5 g) which was purified by silica gel chromatography with benzene. From 1.55 g of the crude syrup, using 30 g of silica gel, a colorless syrup (0.36 g) was obtained. The recrystallization of the syrup from ether and petroleum ether gave pure IV (0.15 g), mp 67.5—69.5°C, which was identical with an authentic sample.[2,3] IV was also prepared from IIIa in a similar way.

1,3,4,5-Tetra-*O*-acetyl-2-deoxy-L-sorbopyranos-2,3-ene (V). To a suspension of mercuric cyanide (19.9 g) in dry benzene (400 m*l*), a dry benzene solution (100 m*l*) of crude IV (24.5 g) was added. Traces of water were removed by azeotropic distillation with benzene (*ca.* 20 m*l*). After it had been refluxed for 8 hr with stirring, the reaction mixture was filtered and the filtrate was evaporated. The residue was extracted with chloroform (500 m*l*) and the chloroform was washed with 30% potassium iodide solution and then water and dried. Removal of the chloroform gave a dark brown syrup (18 g). The purification of the syrup on alumina column chromatography (135 g of alumina was used) with benzene gave V as a colorless syrup (13.7 g), $[\alpha]_D^{22}$ +217.6° (*c.* 1.032).

Found: C, 50.95; H, 5.51%. Calcd for $C_{14}H_{18}O_9$: C, 50.91; H, 5.49%. UV_{max} 209 mμ (ε 8800).

Methyl 1,3,4,5-Tetra-*O*-acetyl-3-*C*-chloromercuri-β-L-tagatopyranoside (VI). To a solution of mercuric acetate (1.05 g) in absolute methanol (20 m*l*), V (1.0 g) was added. After the mixture had stood overnight at room temperature, the solvent was removed and extracted with chloroform. The chloroform solution was shaken with saturated aqueous sodium chloride (100 m*l* ×2), washed with saturated aqueous sodium bicarbonate and water, dried and the solvent removed. The syrup (1.07 g) which was obtained was purified by preparative thin-layer chromatography (solvent A, R_f, 0.20). The purified syrup (0.21 g) was recrystallized from ethanol to give colorless columns (0.12 g), mp 184—189°C, $[\alpha]_D^{23}$ +71.1° (*c* 1.017).

Found: C, 30.72; H, 3.62; Hg, 32.96%; mol wt, 588. Calcd for $C_{15}H_{21}O_{10}HgCl$: C, 30.16; H, 3.54; Hg, 33.58%; mol wt, 597.385.

Methyl 1,3,4,5-Tetra-*O*-acetyl-β-L-tagatopyranoside (VII). Sodium borohydride (50 mg) was added as a solid in five portions, at intervals, to a pyridine solution (5 m*l*) of VI (0.7 g). After being kept at room temperature for 2.5 hr, the reaction mixture was filtered and washed with pyridine (5 m*l*). Acetic anhydride (10 m*l*) was added to a combined solution of the filtrate and the washings. The solution was allowed to stand overnight at room temperature, and then poured onto ice, made alkaline with sodium carbonate, and extracted with chloroform. The extract was washed with 5% sulfuric acid, water and dried, after which the solvent was removed under reduced pressure. The purification of the residue by preparative thin-layer chromatography (solvent A, R_f 0.38, extracted with chloroform) gave crude crystals (205 mg). Recrystallization of the crystals from ether and petroleum ether gave colorless columns (83 mg), mp 87—87.5°C, $[\alpha]_D^{22}$ +104.2° (*c* 0.947).

Found: C, 49.67; H, 6.12%. Calcd for $C_{15}H_{22}O_{10}$: C, 49.72; H, 6.12%.

Acid-catalyzed Isomerization of V in Acetic Anhydride.[41] A solution of V (6.68 g) in acetic anhydride (67 m*l*) containing 1% of TsOH was kept at 30°C for 24—48 hr (for 24 hr to obtain XII as a major product and for 48 hr to obtain XIV and XV as major products). The solution was then poured into ice-water (800 m*l*) under vigorous stirring, made alkaline with sodium bicarbonate and extracted with chloroform. The extract was washed with 5% aqueous sodium bicarbonate and water. The syrup (5.8 g) obtained on solvent removal from the dried extract was fractionated by preparative thin-layer chromatography. (i) From the syrup (3.6 g) obtained from the reaction for 24 hr, XII (0.40 g) was isolated as a syrup in a pure state by repeated preparative thin-layer chromatography (solvent D, R_f 0.65, extracted with ether). (ii) From the syrup obtained from the reaction for 48 hr, XIV, XV and XXIV were fractionated by thin-layer chromatography (solvent F, R_f 0.29 (XIV), 0.22 (XV), 0.4—0.7 (XXIV)). From the syrup (14.29 g), these were obtained in a crude state in the ratio of XIV (0.36 g), XV (0.46 g), and XXIV (0.94 g). XIV was recrystallized from ether (yield, 51 mg), and XV from ethanol (yield, 71 mg). XXIV was purified by repeated thin-layer chromatography (solvent E, R_f 0.61) (yield, 65.5 mg).

XII: Syrup $[\alpha]_D^{24}$ −88.0° (*c* 0.980). Found: C, 53.72; H, 5.73%; mol wt, 281. Calcd for $C_{12}H_{14}O_7$: C, 53.33; H, 5.22%; mol wt, 270.23. UV_{max} 261 mμ (ε 16100). IR_{film} 1635 cm^{-1} (conj. C=C).

XIV: Colorless columns, mp 110—111.5°C, $[\alpha]_D^{22}$ +198.8° (*c* 0.997). Found: C, 49,44; H, 5.23%; mol wt, 387. Calcd for $C_{16}H_{20}O_{10}\cdot H_2O$: C, 49.23; H, 5.68%; mol wt, 390.34. UV_{max} 213 mμ (ε 8970).

XV: Colorless columns, mp 111.5—113°C. Found: C, 51.43; H, 5.16%; mol wt, 298. Calcd for $C_{12}H_{14}O_7\cdot \frac{1}{2}H_2O$: C, 51.61; H, 5.41%; mol wt, 279.24. UV_{max} 230 mμ (ε 7280). IR_{CHCl_3} 1630, 1700 cm^{-1}(C=C-C=O).

XXIV: Syrup, $[\alpha]_D^{22}$ +236.8° (*c* 0.641). Found: C, 52.53; H, 5.55%. Calcd for $C_{10}H_{12}O_6$: C, 52.63; H, 5.30%. UV_{max} 253 mμ (ε 6390). IR_{film} 1640, 1705 cm^{-1} (C=C-C=O).

Reaction of XII with Hydrogen Bromide in Dry Benzene. A solution of XII (1.15 g) in dry benzene (21 m*l*) containing hydrogen bromide (2.34 g) was kept at 0—5°C for 1.5 hr. Evaporation of benzene under reduced pressure gave a dark red syrup, which was dissolved in methanol (8.4 m*l*) containing silver carbonate (1.53 g) and kept overnight at room temperature. The solution was filtered and evaporation of the filtrate gave a brown syrup. From the syrup, XX, XXI and XXII were isolated by preparative thin-layer chromatography (solvent B, R_f, 0.71 (XX), 0.93 (XXI), 0.85 (XXII), extracted with chloroform). Isolated materials were further purified by recrystallization or by preparative thin-layer chromatography.

XX: Syrup (purified by repeated preparative thin-layer chromatography, solvent D, R_f 0.50, yield, 0.1 g), $[\alpha]_D^{22}$ +66.6° (*c* 0.695). Found: C, 52.90; H, 5.97%. Calcd for $C_9H_{12}O_5$: C, 53.99; H, 6.04%. UV_{max} 226 mμ (ε 6800). IR_{film} 1635, 1690 cm^{-1} (C=C-C=O).

XXI: Colorless columns, mp 136—138°C (recrystallized from ether and petroleum ether, yield, 10 mg), $[\alpha]_D^{22}$ −30.9° (*c* 1.045). Found: C, 40.88; H, 5.01; Br, 20.93%. Calcd for $C_{13}H_{19}O_8$ Br: C, 40.74; H, 5.00; Br, 20.86%.

41) Products isolated from the reaction were rather unstable and should be stored in a refrigerator under strictly anhydrous conditions.

XXII:[42] Syrup (purified by repeated preparative thin-layer chromatography, solvent B, R_f 0.85, yield, 0.03 g), $[\alpha]_D^{23}$ +51.3° (*c* 0.825). Found: C, 41.42; H, 5.10; Br, 20.82%. Calcd for $C_{13}H_{19}O_8$ Br: C, 40.74; H, 5.00; Br, 20.86%.

Reaction of V with Hydrogen Bromide in Dry Benzene. When the above reaction was carried out by using V as the starting material, the same result was obtained.

Conversion of XXII into XXI. When the above reaction was carried out by using XXII as the starting material (instead of hydrogen bromide, hydrogen chloride was used), the formation of XXI was confirmed by thin-layer chromatography.

Acid-catalyzed Isomerization of XII. A solution of XII (0.25 g) in acetic anhydride (3 m*l*) containing 1% of TsOH was kept at 40—50°C for 7 hr. When the solution was worked up in a way similar to the acid-catalyzed isomerization of V, a crude syrup (0.18 g) was obtained from which XIV (38 mg) and XV (15 mg) were obtainable.

Acid-catalyzed Isomerization of XIV. A solution of XIV (15 mg) in acetic anhydride (0.3 m*l*) containing 1% of TsOH was kept at 50°C for 8 hr. The formation of XV was confirmed by thin-layer chromatography (solvent F, R_f 0.40).

Isomerization of V in Acetic Acid. (i) A solution of V (2.0 g) in acetic acid-water (1: 1, v/v) was kept at 95°C for 4.5 hr. The syrup obtained on solvent removal under reduced pressure was purified by repeated preparative thin-layer chromatography (solvent D, R_f 0.70). XXVIb (0.36 g) was obtained and was identical to an authentic sample.[43] (ii) A solution of V (0.54 g) in acetic acid was kept at 95°C for 6 hr. The solution was worked up in a way similar to the above. XXVIb (0.07 g) was obtained. 2,4-Dinitrophenylhydrazone of XXVIb was prepared in a usual way as red needles, mp 142.5—147°C (recrystallized from ethanol). Found: C, 48.42; H, 3.57; N, 15.89%, mol wt, 357. Calcd for $C_{14}H_{17}O_7N_4$: C, 48.28; H, 3.47; N, 16.09%; mol wt, 348.27.

Isomerization of XII in Acetic Acid. A solution of XII (0.13 g) in acetic acid-water (1: 1, v/v) (2 m*l*) was kept at 95°C for 2 hr. A syrup was obtained on solvent removal under reduced pressure. From the syrup, traces of XXVIb were isolated by repeated thin-layer chromatography (solvent D, R_f 0.70 and solvent C, R_f 0.28).

Isomerization of XX in Acetic Acid. A solution of XX (40 mg) in acetic acid-water (1: 1, v/v) (1.5 m*l*) was kept at 95°C for 6 hr. Evaporation of the solvent gave a syrup (20 mg), the thin-layer chromatography of which indicated XXVIb as a major component and XX as a minor one (the ratio was about 2: 1).

The authors wish to express their deep gratitude to Dr. Ken'ichi Takeda, Director of this Laboratory, for his encouragement.

42) The NMR data show that the favorable conformation of XXII is Cl chair form.

Oxygen Exchange and Racemization Reactions of Sulfoxides in Acetic and Chloroacetic Acid[1)]

Shigeru OAE, Mikihiko YOKOYAMA and Masahiro KISE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received November 22, 1967)

Oxygen exchange reaction of sulfoxides has been performed mainly in mineral acids such as sulfuric acid, aqueous hydrochloric and hydrobromic acids. We have found that concurrent oxygen exchange and racemization reactions take place also in carboxylic acids such as acetic, mono- and poly-chloroacetic acids. The pseudo first order reaction rates of both oxygen exchange and racemization reactions of *p*-tolyl phenyl sulfoxide have been determined using both optically active and ^{18}O-labeled *p*-tolyl phenyl sulfoxides in these acids. This reaction is found to be mainly dependent on the strengths of the acids; namely, the reaction velocity is faster in an acid of smaller pK_a value. Together with the fact that k(rac.)/k(exch.) is unity and the substituent effect is small, the reaction is suggested to proceed through an unimolecular type S–O bond cleavage, probably involving radical cation intermediate (II).

Sulfoxide, unlike sulfones, have been known to undergo concurrent oxygen exchange and racemizations in various acidic media, such as in concentrated sulfuric acid,[2,3)] hydrochloric acid in aqueous dioxane,[4)] hydrobromic acid in acetic acid,[5)] dinitrogen tetroxide,[6)] diluted nitric acid[7)] and acetic anhydride.[8)] In the course of our further extension of these concurrent oxygen exchange and racemization reactions of sulfoxides, we have recently found that sulfoxides undergo concurrent oxygen exchange and racemization reactions even in weak organic acids, such as acetic, monochloro-, dichloro- and trichloroacetic acids.

This paper will describe the detailed account of our kinetic and stereochemical investigations of various sulfoxides and their implications for the interpretation of the mechanism of the reaction.

Results and Discussion

Oxygen Exchange Reactions of Dimethyl-, Dibenzyl- and Diphenyl Sulfoxides. At the initial stage of this study, oxygen exchange reactions of sulfoxide were carried out in aqueous acetic acid. Namely, when ^{18}O-labeled diphenyl-, dibenzyl-, di-(*n*-butyl-) and dimethyl sulfoxides were treated separately in boiling 5 : 1 (w/w) glacial acetic acid-water mixture for three hours, a noticeable ^{18}O-exchange (13%) was observed only with dimethyl sulfoxide. However, under a prolonged heating at a somewhat higher temperature, the other sulfoxides were also found to undergo the oxygen exchange reaction. The Table 1 illustrates the amounts of oxygen-exchange of diphenyl-, dibenzyl- and dimethyl

sulfoxides after heating each sample in both glacial and aqueous acetic acids for 24 hr at 130°C. Dimethyl sulfoxide was quite reactive as was expected, however, decomposed under the prolonged heating with glacial acetic acid. Apparently it underwent the Punmerer type rearrangement forming methyl mercaptomethyl acetate, which upon quenching with water hydrolyzed spontaneously to give acetic acid, methylmercaptan and formaldehyde. In fact, we isolated methylmercaptan by converting it to mercuric methylmercaptide.

The other sulfoxides could be nicely recovered even after a prolonged heating with glacial acetic acids. The order of the reactivities of the three sulfoxides, *i.e.*, dimethyl>dibenzyl>diphenyl, follows apparently that of the basicities of the sulfoxides,[9] suggesting that the reaction may be acid-catalyzed.

Oxygen Exchange and Racemization Reactions of *p*-Substituted Diphenyl Sulfoxides. In order to shed further light on the nature of the oxygen exchange reaction and also to examine the possible concurrent racemization, both optically active and ^{18}O-labeled *p*-tolyl phenyl sulfoxides were prepared and subjected to the oxygen exchange and racemization reactions in four different acids of varying acid strength, namely, acetic, monochloro-, dichloro- and trichloroacetic acids. Pseudo first order rate constants of oxygen exchange and racemization reactions along with the activation parameters of these reactions were obtained from the usual kinetic determinations. In addition, the rates of the oxygen exchange reactions, of *p*-chlorophenyl phenyl and diphenyl sulfoxides were determined in trichloroacetic acid under the same condition, in order to compare the effects of polar substituents. The results were summarized in Tables 2 and 3. When the log$k$(s) were plotted against the pK_a(S) of these acids, a straight line, though rough, can be drawn as shown in Fig. 1, clearly depicting that the oxygen exchange reaction is dependent on the Brönsted acidity, as was expected; namely smaller the pK_a of acid used, faster was the reaction rate. This observation is well accord with our earlier assumption that dimethyl sulfoxide, being most basic is extremely reactive while the least basic diphenyl sulfoxide is the least reactive as was shown in Table 1. The nearly identical rates of both racemization and oxygen exchange suggest that the reaction proceed through a rate-determining unimolecular S–O bond cleavage process. This is quite different from the similar oxygen exchange reaction with acetic anhydride in which the rate of racemization of *p*-tolyl phenyl sulfoxide was twice of that of the oxygen exchange, while the rate of racemization with acetic anhydride is estimated to be about 770 times faster than that with glacial acetic acid at 120°C. Therefore S_N2 type mechanism, suggested for the similar oxygen exchange reactions with acetic anhydride can not be applied for the reactions in carboxylic acids. One notices in Table 3, however, that the entropies of activation for these reactions were of large negative values. This would imply that the protonated sulfoxide was considerably solvated by carboxylic acid in the transition state.

Table 3. Activation parameter for racemization reaction of *p*-tolyl phenyl sulfoxide (120—140°C)

Acid	E_a (kcal/mol)	$\Delta S^{\neq}$(eu) 120°C
$CH_2ClCOOH$	24.4	−23.4
$CHCl_2COOH$	19.6	−32.8
CCl_3COOH	18.6	−32.9

There are two different mechanisms that can fit in these observations; the one is the heterolysis of the S–O bond that involves the rate determining formation of the doubly charged " sulfidonium ion " intermediate (I) and the other is the homolysis to form radical cation intermediate (II).

The first process, involving the double-positive charged intermediate (I) would be highly energy consuming and is expected to be strongly accelerated by an electron-releasing substituent while retarded remarkable by the substitution of an electron-withdrawing group, when the geometry of the activated complex is similar to that of the carbonium ion forming

9) K. K. Anderson, W. H. Edmonds, J. B. Biasotti and R. A. Strecker, *J. Org. Chem.*, **31**, 2859 (1966).

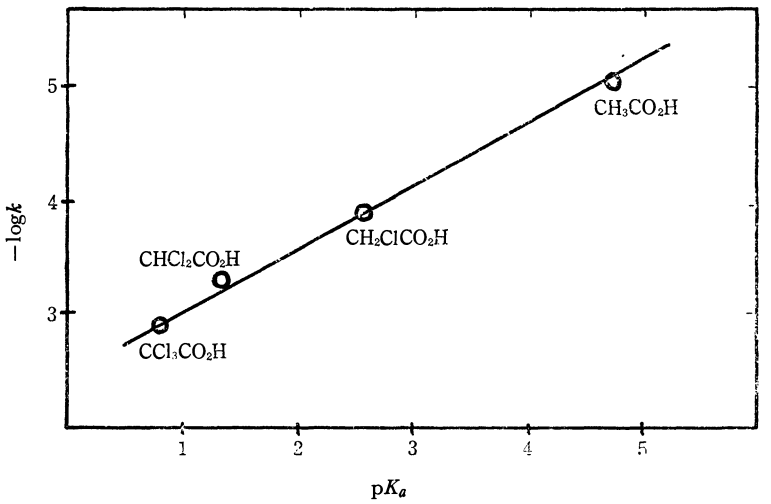

Fig. 1. The relation between the pK_a(s) of acids and the rates of racemization of optically active *p*-tolyl phenyl sulfoxide.

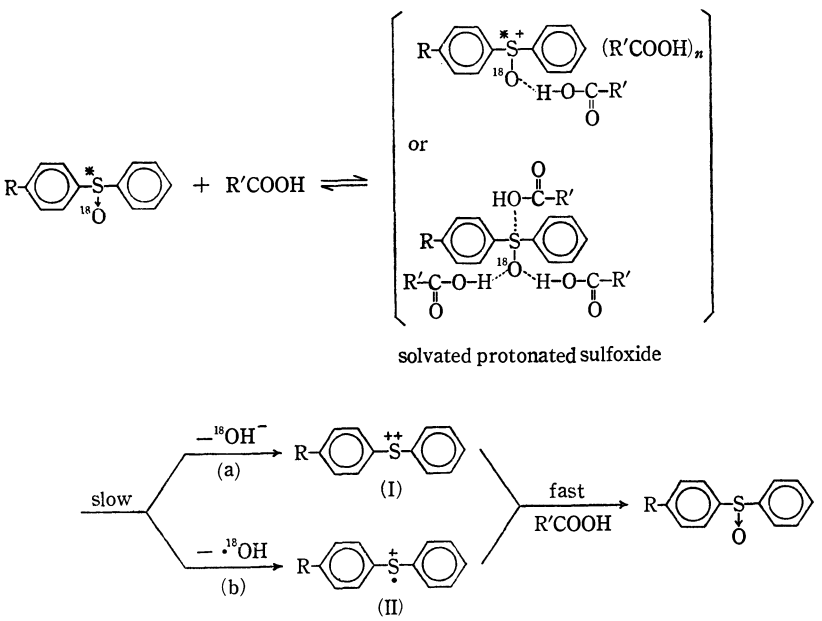

reaction (S_N1). The effect of the substituents would be similar to those observed in the solvolytic reaction of substituted benzhydryl compounds and correlated with the σ^+ values rather than the σ values. If, however, the hydroxy group of the sulfoxide would cleave without perturbing the original geometry of the molecular arrangement, the vacant *p*-orbitals of the leaving bond would overlap much less effectively with those π-molecular orbitals of the two aromatic ring due to the angular arrangement of the bonds around the sulfur atom and hence the effect of *p*-substituent would be rather small. Unfortunately very scant kinetic data or well-defined S_N1 (or A-1) type reaction on sulfur atom are available for comparison, especially the one forming any intermediate that bears double positive charges. However, this process, being unassisted by resonance, would be very highly energy-consuming and unlikely. The second path would be less energy consuming and not be effected markedly by the polar nature of the substituent, since there is not net charge variation before and after the reaction. The small effect of the substituents in this reaction ($\rho = -0.47$) and the rather facile nature of the reaction seem to suggest that the reaction follows

the homolytic cleavage process (b) of the protonated sulfoxide, as in other oxygen exchange and racemization reactions in mineral acids.

Experimental

Materials. *Optically Active p-Tolyl Phenyl Sulfoxide.* This sulfoxide was prepared by the method of Anderson[10] in which (−)menthyl (−)*p*-toluenesulfinate was reacted with phenylmagnesium bromide in ether. (Mp 91—93°C, $[\alpha]_D = +26.9$ in EtOH)

^{18}O-Labeled p-Tolyl Phenyl Sulfoxide. The corresponding sulfide was oxidized with bromine in the presence of pyridine in acetic acid-$H_2{}^{18}O$, according to our usual procedure.[11] (Mp 69.8—71°C ^{18}O-content 1.09 atom %)

Dioxane, obtained commercially, was purified according to the usual method, finally dried with sodium and ditilled (bp 101.5°C).

Acetic Acid, obtained commercially was treated with chromic anhydride and after refluxing for several hours, it was distilled (bp 117.5—118°C).

Monochloroacetic Acid, Dichloroacetic Acid and Trichloroacetic Acid. These acids, obtained commercially, were distilled under reduced pressure in a dry atmosphere. Contact with a moisture was intercepted very carefully.

Reaction of Dimethyl Sulfoxide with Acetic Acid. The mixture consisting of 1 g of dimethyl sulfoxide and 5 g of glacial acetic acid was refluxed under nitrogen stream, which was bubbled into methanol solution of mercuric chloride. White crystalline material was precipitated slowly. After the reaction, white crystalline material was collected by filteration and identified from the melting point and infrared spectrum by comparing with that of the authentic sample of dimethyl sulfide - $HgCl_2$ complex.

Kinetic Procedure. Oxygen exchange and racemization reaction was carried out at 120±0.03°C in sealed tubes while the molar ratio of sulfoxide to an acid was kept at 1 : 50. Namely, the mixture of sulfoxide (1/200 mol), acid (1/4 mol) and 30 m*l* of dioxane was divided in several sealed tubes and reacted. From time to time a sealed tube was drawn out from the paraffin bath and the content was poured into an excess water then neutralized with sodium hydroxide solution. The sulfoxide, separated out was extracted with carbon tetrachloride and dried with anhydrous magnesium sulfate. Carbon tetrachloride was distilled off and the resulting sulfoxide was recovered. The recovered sulfoxide was dried thoroughly and subjected to the measurement of both specific rotation and ^{18}O-analysis. The specific rotation was measured in ethanol at *c*: 3.00. While ^{18}O-analysis of the sulfoxide-oxygen was done as usual according to the modified Rittenberg-Porticorbo method.

Synthetic Studies of α-Tocopherol. I. Synthesis of α-Tocopheryl Acetate

Takehiko ICHIKAWA and Tetsuya KATO

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received December 4, 1967)

Geraniol (III) was reacted with trimethylhydroquinone (II) in the presence of boron trifluoride in benzene. The product was then acetylated to give a mixture of 2,5,7,8-tetramethyl-2-(4-methyl-3-penten-1-yl)-6-acetyloxychromane (VI) and 2,5,7,8-tetramethyl-2,3-(4,4-dimethylbutano)-6-acetyloxychromane (Vb). The VI was ozonized and decomposed with zinc and acetic acid to give 2,5,7,8-tetramethyl-2-(2-formylethyl)-6-acetyloxychromane (VII). Pseudoionone (VIII) was reduced with sodium borohydride to give pseudoionol (IX), but in certain cases the dehydration of IX occurred during the distillation. VII was condensed with IX by a Wittig reaction to give 2,5,7,8-tetramethyl-2-(4,8,12-trimethyl-3,5,7,11-tridecatetraen-1-yl)-6-acetyloxychromane (X), which was then hydrogenated to give α-tocopheryl acetate (I).

Tocopherols have long been known as a fertile factor, but only recently have its widespread physiological activities been discovered; now the importance of α-tocopherol is increasingly being recognized.[1] Many methods of synthesizing α-tocopherol have already been established,[2] but an attempt has now been undertaken to synthesize α-tocopheryl acetate (I) in short stages, as is illustrated in Scheme 1.

The condensation of geraniol (III) and trimethylhydroquinone (II) in the presence of zinc chloride

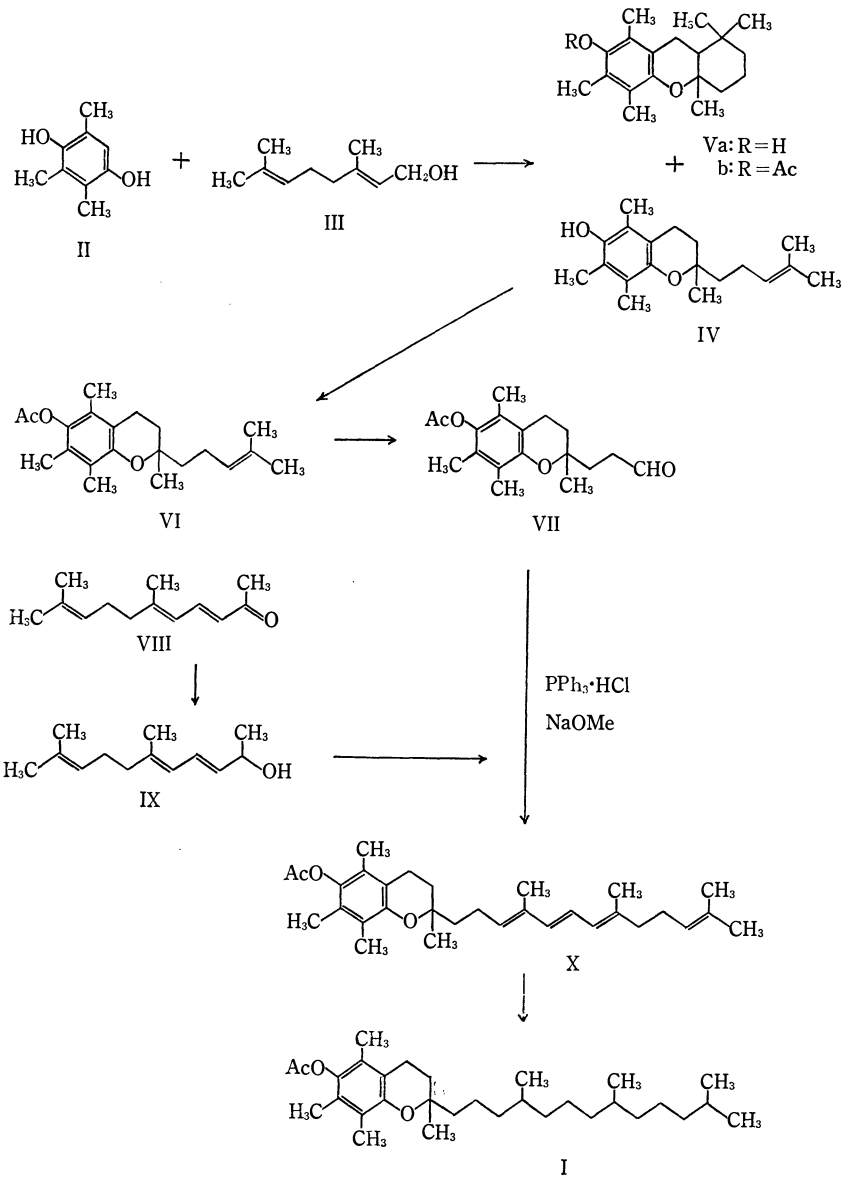

Scheme 1

was reported by Smith *et al.*,[3] but the structure of his product was ambiguous. Green *et al.* later obtained 2,5,7,8-tetramethyl-2-(4-methyl-3-penten-1-yl)-6-hydroxychromane (IV) by the condensation of II and III in dioxane with the aid of boron trifluoride.[4] In the present study, the condensation was achieved in benzene with boron trifluoride etherate. A fair yield of chromanol (λ_{max}^{EtOH} 294 mμ) was obtained; the results of the elementary analysis of this chromanol were consistent with the IV structure. Two moles of III to one mole of II were necessary; 0.1—0.2 mol of boron trifluoride to one mole of II were appropriate to obtain a good yield. The condensation did not proceed at all in dioxane in the presence of 0.1—0.2 mol of boron trifluoride. The acetylation of the product gave the corresponding acetate; a part of it crystallized to give white crystals melting at 137—138°C. A gas chromatogram*1 of the acetylated product showed a major peak (R_t 10.5 min) and two minor peaks (R_t 6.6 min and 12 min), and the crystalline compound corresponded to one of the

4) J. G. Green and D. McHale, British Pat. 949715 (1964); *Chem. Abstr.*, **60**, 13227d (1964).

*1 Column: SE-30 on Diasolid H, 4 mm×3 m; carrier gas: helium; flow rate: 46 ml/min; temp.: 205°C.

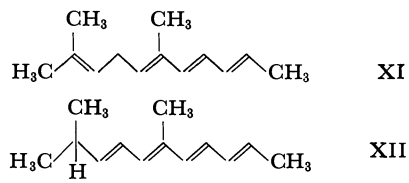
minor components (R_t 12 min). The results of the elementary analysis of the crystals were consistent with the experimental formula of $C_{21}H_{30}O_3$; hence, they may be considered to be isomers of 2,5,7,8-tetramethyl-2-(4-methyl-3-penten-1-yl)-6-acetyloxychromane (VI). The NMR spectrum in tetrachloromethane showed signals at δ 0.90 (singlet, 3H, $\underline{CH_3}$C–), 1.00 (singlet, 3H, $\underline{CH_3}$–C–), 1.16 (singlet, 3H, $\underline{CH_3}$C–O–), 2.35—2.6 (multiplet, 2H, Ar–$\underline{CH_2}$–); 1.3—1.8 (multiplet, 6H, –$\underline{CH_2}$–); 2.23 (singlet, 3H, $\underline{CH_3}$COO–), 2.05 (singlet, 3H, $\underline{CH_3}$–Ar), and 1.95 (6H, $\underline{CH_3}$–Ar), with no signal of the olefinic proton. The UV absorption was identical with that of α-tocopheryl acetate. These facts show the structure to be 2,5,7,8-tetramethyl-2,3-(4,4-dimethylbutano)-6-acetyloxychromane (Vb). The NMR spectrum of the original mixture of the acetate showed signals at δ 2.22 (singlet, 3H, $\underline{CH_3}$COO–); 2.06, 1.94, 1.90(singlets, 9H, $\underline{CH_3}$–Ar); 1.22 (singlet, 3H, $\underline{CH_3}$C–O–); 1.62, 1.56 (6H, $\underline{CH_3}$–$\underline{CH}$(CH$_3$)–$\underline{CH}$–); 2.4—2.7 (multiplet, Ar–$\underline{CH_2}$–) and 5.10 (1H, –$\underline{CH}$=C–), along with the small peaks of Vb. The signals of the other methylene protons (δ 1.3—2.3) were covered by other signals. Its IR spectrum ($\nu_{C=C}$ 1780 cm^{-1}) and the UV spectrum were also consistent with the VI structure.

The hydroboration of VI for the purpose of obtaining a ω-hydroxychromane derivative gave only a hydroborated product in a poor yield. The yield could not be improved, presumably because of the steric hindrance of the double bond.

The ozonolysis of VI in methylene chloride, followed by reductive decomposition by zinc and acetic acid, gave 2,5,7,8-tetramethyl-2-(2-formylethyl)-6-acetyloxychromane (VII). Its IR spectrum (1755 cm^{-1}, CH_3COO–; 1720 cm^{-1}, –CHO), its NMR spectrum (δ 9.61, triplet, 1H, –$\underline{CHO}$; 2.21, singlet, 3H, $\underline{CH_3}$COO–; 2.03, 1.95 and 1.95, singlets, 9H, $\underline{CH_3}$–Ar; 1.14, singlet, $\underline{CH_3}$–C–O), and the results of elementary analysis were all consistent with the VII structure.

The oxidation of VII with potassium permanganate gave its corresponding carboxylic acid, 2,5,7,8-tetramethyl-2-(2-carboxyethyl)-6-acetyloxychromane.*2

Pseudoionone (VIII) was reduced with sodium borohydride in ethanol, treated with an aqueous solution of sodium hydroxide, and distilled. The oil thus obtained was consistent with pseudoionol (IX) (IR: ν_{OH} 3300 cm^{-1}, NMR in carbon tetrachloride: δ 1.19, doublet, J=6 cps, 3H, $\underline{CH_3}$–CH–OH; 1.72, 1.66 and 1.58, singlets, 9H, $\underline{CH_3}$–CH=C–; 2.12, 2.06 and 2.02, 4H, –$\underline{CH_2}$–CH=C; 3.26, 1H, singlet, –$\underline{OH}$; 4.30, 1H, multiplet, $CH_3\underline{CH}$(OH)–; 4.8—6.6, 4H, multiplet, –$\underline{CH}$=C–). When the reaction product was not treated with aqueous alkali, the product obtained by distillation occasionally had no hydroxyl group (judging from the IR spectrum), and its absorption maximum (λ_{max}^{EtOH} 270 mμ, ε 48000) was longer than that of VIII (λ_{max}^{EtOH} 241 mμ, ε 24000). Accordingly, the product may be deduced to be the dehydrated product of IX, namely, 2,6-dimethylundeca-2,5,7,9-tetraene XI. As its NMR spectrum is accompanied by a small signal at δ 0.88 (doublet, CH_3–C–H, J=6 cps), the isomerized conjugated tetraene (XII) might be present in the product.



As the product before distillation always exhibits an absorption maximum at 241 mμ, the dehydration apparently takes place during distillation by the boric acid produced from the borohydride. However, the similar reduction of mesityl oxide, as an example of α,β-unsaturated ketone, always gave 4-methylpent-3-en-2-ol as a normal product and dehydration never occurred.

A simplified method of Wittig reaction proposed by Pommer *et al.*[5] has been applied to the condensation of VII and IX. Triphenylphosphine hydrochloride was reacted with IX in acetonitrile to yield the corresponding phosphonium salt. After the solvent had been substituted by dimethylformamide, VII was added and ylid was formed by the gradual addition of sodium methoxide and reacted *in situ* with VII. The product had an absorption maximum at 280 mμ, which was close to the expected value (278 mμ) of all *trans*-2,5,7,8-tetramethyl-2-(4,-8,12-trimethyl-3,5,7,11-tridecatetraen-1-yl)-6-acetyloxychromane (X). It can not be purified by distillation because it is very unstable to heat. Its IR spectrum showed the presence of the ester group ($\nu_{C=O}$ 1760 cm^{-1}), but no aldehyde group around 1720 cm^{-1}. The NMR spectrum showed signals at δ 1.22 ($\underline{CH_3}$–C–O–); 2.22 ($\underline{CH_3}$COO–); 2.05, 1.94 and 1.90 ($\underline{CH_3}$–Ar); 1.5—1.58 (CH_3–C=C–); 4.5—6.5 (–$\underline{CH}$=C–), supporting the idea of the X structure.

The hydrogenation of crude X with Raney Nickel was not feasible, presumably due to the presence of triphenylphosphine remaining in the product, so repeated treatment with Raney Nickel was necessary

*2 Green *et al.*[4] reported a melting point of 154°C.

5) H. Pommer, *Ang. Chem.*, **72**, 816 (1960).

to remove the catalyst poison in advance of the reduction. Heating during the reduction must be avoided since the isomerization of the side chain has been found to occur very easily. Reduction at room temperature with high-pressure hydrogen gave α-tocopheryl acetate (I), the structure of which was confirmed by a comparison of its IR, UV, and NMR spectra with those of an authentic sample.

Experimental

2,5,7,8-Tetramethyl-2-(4-methyl-3-penten-1-yl)-6-hydroxychromane (IV). To a solution of 50 g of trimethylhydroquinone (II) and 4.16 m*l* of boron trifluoride etherate in 1300 m*l* of anhydrous benzene, there were added, drop by drop, 101.2 g of geraniol (III) under stirring and refluxing. After it had then been heated to reflux for 3 hr, the benzene solution was washed with water, a sodium bicarbonate solution, and water, dried with anhydrous magnesium sulfate, and distilled; bp 130—156°C/0.01 mmHg, 81 g. A gas liquid chromatogram of the acetylated product showed the IV content to be 73%. Accordingly, the yield of IV from II was 62%. Rectification gave a pale yellow oil; bp 154—154.5°C/0.01 mmHg, λ_{max}^{EtOH} 294 mμ.

Found: C, 79.44; H, 9.92%. Calcd for $C_{19}H_{28}O_2$: C, 79.12; H, 9.79%.

2,5,7,8-Tetramethyl-2-(4-methyl-3-penten-1-yl)-6-acetyloxychromane (VI) and 2,5,7,8-Tetramethyl-2,3-(4,4-dimethylbutano)-6-acetyloxychromane (Vb). A mixture of 54 g of IV (73% pure) and 52 m*l* of acetic anhydride was refluxed for 3 hr. Fractional distillation then gave an oil; bp 143—158°C/0.02 mmHg, 54 g. For analysis, a part of it was redistilled; bp 133—134°C/0.04 mmHg, λ_{max}^{EtOH} 285 mμ (ε 1920).

Found: C, 76.58; H, 9.40%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

A part of the product crystallized to give white crystals, which were then triturated with methanol and filtered. Recrystallization from methanol gave white needles of Vb; mp 138—139°C, λ_{max}^{EtOH} 285 mμ (ε 1970).

Found: C, 76.53; H, 9.27%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

2,5,7,8-Tetramethyl-2-(2-formylethyl)-6-acetyloxychromane (VII). A solution of 16.5 g of VI (70% pure) was dissolved in 200 m*l* of methylne chloride and then cooled to −50°C. Oxygen containing 2.7% of ozone was introduced into the solution for 1 hr (the total amount thus corresponded to 1.2 g of ozone). The reaction mixture was immediately stirred, drop by drop, into a mixture of 4.3 g of zinc dust and 170 m*l* of 50% aqueous acetic acid. After the addition, the mixture was stirred for an hour; then the methylene chloride was distilled out, and the remaining mixture was heated at 100°C for 1 hr. After cooling, the mixture was extracted three times with 80 m*l* portions of ether, and the ether extract was washed with water, a sodium carbonate solution, and water to remove acetic acid. The ether layer was dried and concentrated. The residue was shaken vigorously with a solution of 10 g of sodium bisulfite in 15 m*l* of water, and the white precipitate was filtered and washed with petroleum ether. The precipitate was dissolved in 400 m*l* of water, an aqueous solution of 11 g of sodium carbonate was added, and the mixture was extracted with ether. The ether extract was washed with water, dried, and concentrated. The residue was almost pure VII (7.0 g, 66%). Distillation *in vacuo* gave an oil, bp 145—146°C/0.005 mmHg; which crystallized on standing; mp 48—49°C, λ_{max}^{EtOH} 285 mμ (ε 1880).

Found: C, 70.92; H, 8.02%. Calcd for $C_{18}H_{24}O_4$: C, 71.02; H, 7.95%.

2,5,7,8-Tetramethyl-2-(2-carboxyethyl)-6-acetyloxychromane. To a solution of 3.04 g of VII in 30 m*l* of acetone, there was added, drop by drop, 0.53 g of potassium permanganate in 20 m*l* of acetone at 0—2°C. The mixture was then stirred at the same temperature for 1 hr and poured into 200 m*l* of water. The precipitate was filtered and washed with ether. The filtrate was acidified with hydrochloric acid and extracted with ether. The combined ether solution was washed with water, dried with magnesium sulfate, and concentrated. The residue was triturated with petroleum ether and filtered to give white crystals; 1.0 g, mp 159.5—160.5°C (recrystallized from ethyl acetate).

Found: C, 67.34; H, 7.68%. Calcd for $C_{18}H_{24}O_5$: C, 67.48; H, 7.55%.

Pseudoionol (IX). A solution of 9.6 g of pseudoionone (VIII) was dissolved in 100 m*l* of 95% ethanol; after 0.68 g of sodium borohydride in ethanol had been added at room temperature, the mixture was stirred for 2 hr and then left standing overnight. The mixture was added to a solution of 2 g of sodium hydroxide in 500 m*l* of water. The mixture was extracted with ether, and the ether extract was washed with water, dried, and concentrated. The distillation of the residual oil *in vacuo* gave a colorless oil; bp 112—120°C/5 mmHg, 7.7 g (80%).

Found: C, 80.03; H, 11.36%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

2,6-Dimethyl-2,5,7,9-undecatetraene (XI). A solution of 29 g of VIII was dissolved in 100 m*l* of 99.5% ethanol, 2.1 g of sodium borohydride in ethanol were added at room temperature, and the mixture was stirred for 2 hr and then left standing overnight. The mixture was added to 500 m*l* of water and extracted with ether. The ether layer was washed with water, dried, and concentrated. Distillation *in vacuo* gave an oil; bp 89—103°C/2.5 mmHg, 23.4 g. The IR spectrum showed that a small quantity of a hydroxyl group was present. A part of the distillate was treated overnight with *p*-nitrobenzoyl chloride in pyridine; the mixture was then poured into water and extracted with ether, and the ether extract was washed with water, dried, and concentrated. The residue was dissolved in petroleum ether and passed through an alumina column to remove *p*-nitrobenzoic acid and its ester. The concentration and distillation of the petroleum ether solution gave an oil, bp 93—94°C/4 mmHg, which showed no hydroxyl group upon IR analysis; n_D^{15} 1.5328, λ_{max}^{EtOH} 270 mμ (ε 48000).

Found: C, 88.25; H, 11.26%. Calcd for $C_{13}H_{20}$: C, 88.56; H, 11.44%.

2,5,7,8-Tetramethyl-2-(4,8,12-trimethyl-3,5,7,11-tridecatetraen-1-yl)-6-acetyloxychromane (X) and α-Tocopheryl Acetate (I). To a solution of 2.97 g of IX in 10 m*l* of acetonitrile, there were added, under stirring and while the temperature was kept below 30°C, 4.53 g of triphenylphosphine hydrochloride which had been obtained by passing dry hydrogen chloride into a solution of triphenylphosphine in dry ether. After the mixture had then been left standing overnight at room

temperature, the acetonitrile was removed under reduced pressure below 50°C. To the residue there were added 4.2 g of VII in 15 m*l* of dimethylformamide, and the mixture was stirred. When a clear solution was obtained, sodium methoxide prepared from 0.352 g of sodium and 7 m*l* of anhydrous methanol was stirred in, drop by drop, below 15°C. The reaction mixture was turned red by the ylid formed. After the addition was complete, stirring was continued for 30 min at 10°C; then the mixture was gradually heated to 80°C, when the red color disappeared. The product was poured into 200 m*l* of 50% aqueous methanol and extracted with petroleum ether. The petroleum ether extract was washed three times with 50% methanol, dried, and concentrated *in vacuo*. The residual oil was dissolved in 20 m*l* of ether, and an ethereal solution of mercuric chloride was added until no more precipitate formed. When the precipitate was filtered and the filtrate was washed with water, dried, and concentrated, 4.7 g of a yellow oil were obtained (λ_{max}^{EtOH} 280 mμ). The oil solidified at about 120°C *in vacuo*, which made distillation impossible. To a solution of 3.0 g of the above oil in 50 m*l* of ethanol, 2 g of Raney Nickel were added, and the mixture was shaken under 22 atm of hydrogen at room temperature. The catalyst was renewed 3 times, whereby the calculated amount of hydrogen had been absorbed. The catalyst was filtered, and the filtrate was concentrated and distilled *in vacuo* to give an oil; bp 180—185°C/0.05 mmHg, 2.0 g. Its IR and UV spectra were identical with those of an authentic sample of α-tocopheryl acetate. A part of it was hydrolyzed by methanolic potassium hydroxide and converted into allophanate; mp 165—166°C (recrystallized from methanol).

Found: C, 72.15; H, 10.01; N, 5.32%. Calcd for $C_{31}H_{52}N_2O_4$: C, 72.05; H, 10.14; N, 5.42%.

The authors wish to express their thanks to Professor Masanao Matsui of the University of Tokyo and Dr. Tadao Takenishi of the Ajinomoto Co., Inc., for their valuable suggestions and encouragement.

Synthetic Studies of α-Tocopherol. II.*1 Synthesis of Trimethylbenzoquinone

Takehiko ICHIKAWA, Hiroko OWATARI and Tetsuya KATO

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received December 4, 1967)

Trimethylbenzoquinone (XII), a raw material for the synthesis of trimethylhydroquinone (XIII), was synthesized from trimethylcyclohexenones and trimethylcyclohexene by oxidation. Ethyl α-propionylpropionate (II) prepared from ethyl propionate was condensed with methyl vinyl ketone to yield 4-methyl-4-ethoxycarbonylocta-3,7-dione (IV), which was then dehydrated with beryllium chloride to give 2,3,6-trimethyl-6-ethoxycarbonyl-2-cyclohexen-1-one (V). The product (V) was heated with alkali to give 2,3,6-trimethyl-2-cyclohexen-1-one (VI). The refluxing of a solution of IV in a mixture of acetic acid and hydrochloric acid also gave rise to VI. When II was condensed with crotonaldehyde, 2,5,6-trimethyl-2-cyclohexen-1-one (VIII) was obtained in a single step. 1,4(or 1,5)-Dimethyl-5-(or 4)-formyl-1-cyclohexene (IX), obtained by the Diels-Alder reaction of crotonaldehyde with isoprene, was reduced by hydrazine hydrate to give 1,4,5-trimethyl-1-cyclohexene (X). X was oxidized with *t*-butyl chromate and acetic anhydride to give 3,5,6-trimethyl-2-cyclohexen-1-one (XI). VI, VIII, XI, and X were oxidized with *t*-butyl chromate and acetic anhydride to give XII in 53, 52, 22, and 12% yields respectively. The oxidation of VIII by selenium dioxide gave XII in a 23% yield, but only a trace of XII was formed by the similar oxidation of X.

Numerous syntheses of trimethylhydroquinone (XIII), an indispensable raw material for the synthesis of α-tocopherol, have hitherto been reported, but the starting materials have been restricted to such aromatic compounds as pseudocumene, hydroquinone, *m*-xylenol[1]; no report of synthesis from trimethylcyclohexene nor trimethylcyclohexenones is known.

Oppenauer *et al.* have found that *t*-butyl chromate has oxidizing ability enough to convert 2-cyclohexen-1-one into benzoquinone.[2] This oxidation has now been applied to trimethylcyclohexene and

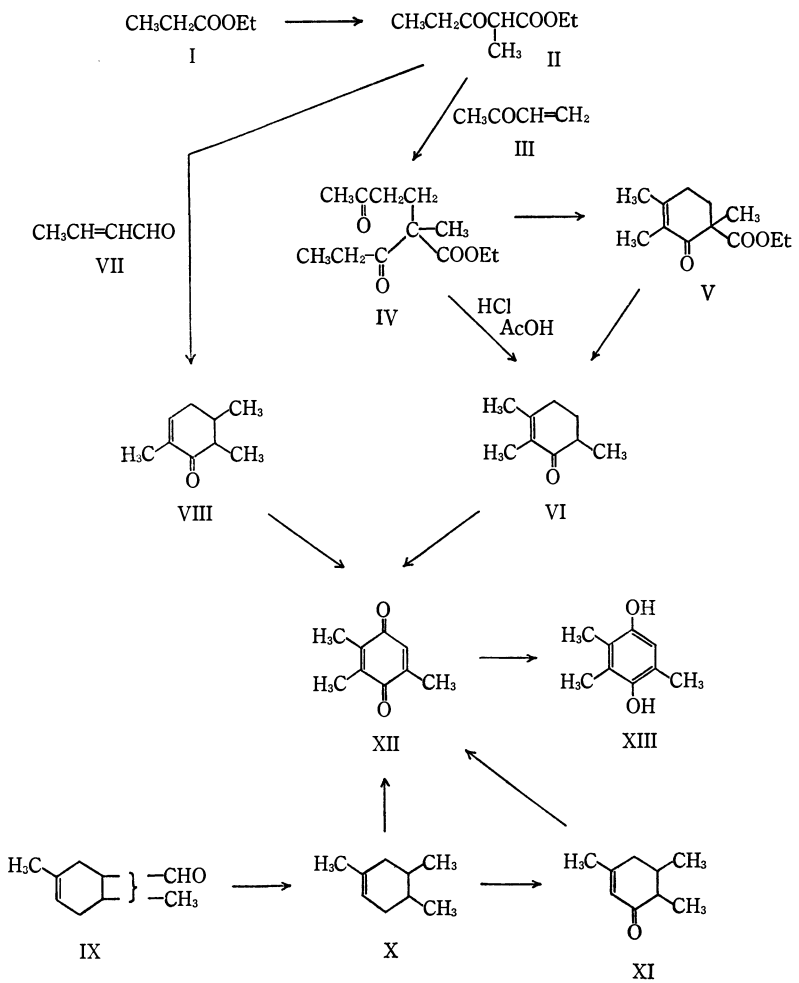

Scheme 1

trimethylcyclohexenones to obtain trimethylbenzoquinone (XII), which can then be easily reduced to give XIII. Three kinds of cyclohexenones and a cyclohexene were prepared, as shown in Scheme 1. Ethyl α-propionylpropionate (II)[3] prepared from ethyl propionate (I) was subjected to Michael condensation with methyl vinyl ketone (III) to yield 4-methyl-4-ethoxycarbonyloctane-3,7-dione (IV) (IR: $\nu_{C=O}$; 1715, 1725 (shoulder), and 1740 cm^{-1} (shoulder); NMR: δ 2.06, singlet, 3H, $\underline{CH_3}CO$; 1.25, singlet, 3H, $\underline{CH_3}$–C–; 4.15, quartet, $J=7$ cps, 2H, $CH_3\underline{CH_2}O$–). The dehydration of IV with beryllium chloride gave 2,3,6-trimethyl-6-ethoxycarbonyl-2-cyclohexen-1-one (V) (IR: $\nu_{C=O}$; 1733, 1665 and 1640 cm^{-1}; NMR: δ 1.25, singlet, 3H, $\underline{CH_3}$–C–COO–; 1.20, triplet, $J=7$ cps, 3H, $\underline{CH_3}$-CH_2O–; 1.71, 3H, $\underline{CH_3}C$=C–; 1.89, 3H, $\underline{CH_3}C$=C; 4.08, 2H, quartet, $CH_3\underline{CH_2}O$–), which was then converted to 2,3,6-trimethyl-2-cyclohexen-1-one(VI) by aqueous alkali. The refluxing of IV with hydrochloric acid and acetic acid gave VI directly. The absorption maximum of VI (244 mμ, ε 12400; 305 mμ, ε 90) is in good agreement with the expected value (242±5 mμ); the IR spectrum showed the presence of α,β-unsaturated ketone ($\nu_{C=O}$; 1670 cm^{-1}), while the NMR spectrum exhibited peaks at δ 1.68, 1.88 (singlets, 6H, $\underline{CH_3}$–C=C) and 1.05 (doublet, $\underline{CH_3}$–CH–, $J=7$ cps). All these facts sustain the VI structure.

When ethyl α-propionylpropionate (II) was condensed with crotonaldehyde (VII) in aqueous alkali, Michael addition, dehydration, saponification, and decarboxylation took place in succession to give directly 2,5,6-trimethyl-2-cyclohexen-1-one (VIII) (IR: $\nu_{C=O}$; 1680 cm^{-1}). The UV absorption maximum of VIII at 235 mμ ($\pi\rightarrow\pi^*$, ε 8900) was shorter than that of VI by 9 mμ, and the absorption

3) S. M. McElvain, *J. Am. Chem. Soc.*, **51**, 3124 (1929).

maximum at 318 mμ ($n\rightarrow\pi^*$, ε 80) was longer by 13 mμ (305 mμ); these facts are consistent with the idea of VIII being short of one olefin methyl group compared with VI.

An attempt to obtain 1,4,5-trimethyl-1-cyclohexene (X) by the direct Diels-Alder reaction between isoprene and 2-butene was a failure; the main product was the isoprene dimer, for it was identical with the product from isoprene alone under the same conditions. Therefore, 1,4(or 1,5)-dimethyl-5(or 4)-formyl-1-cyclohexene (IX), obtained by the Diels-Alder reaction of crotonaldehyde with isoprene,[4] was subjected to a Huang-Minlon reduction to give X. The IR spectrum showed a weak band at 1670 cm^{-1} ($\nu_{C=C-}$). The structure was further confirmed by ozonolysis and by converting the keto-aldehyde obtained into its disemicarbazone. When X was oxidized with *t*-butylchromate, an unsaturated ketone ($\nu_{C=O}$; 1670 cm^{-1}) with a small amount of trimethylbenzoquinone was obtained. The elementary analysis of its 2,4-dinitrophenylhydrazone is consistent with its being a trimethylcyclohexenone. The IR spectrum was quite different from the spectra of either VI or VIII, and the absorption maxima at 234 mμ (ε 12900) and 322 mμ (ε 70) coincided well with the expected value of 3,5,6-trimethyl-2-cyclohexen-1-one (XI). Each cyclohexenone can be distinguished from the others by gas liquid chromatography*2 and was gas chromatographically pure.

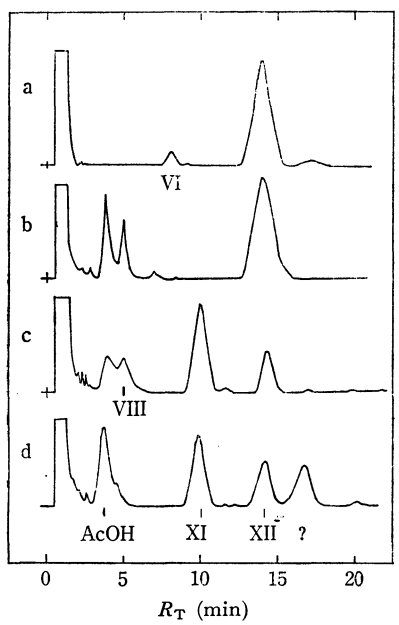

Fig. 1. Gas liquid chromatograms of oxidation products of VI(a), VIII(b), X(c) and XI(d) by *t*-butyl chromate.
Column: 5% PEG 6000 on Diasolid M, 4 mm ×3 m; carrier gas: helium; flow rate: 86 m*l*/min; temp: 205°C.

4) O. Diels and K. Alder, *Ann.*, **470**, 62 (1929).

It is reasonable that the less-hindered methylene group of X was selectively oxidized; the fact that the oxidation to XII can not proceed further easily is presumably due to the separation of the chromate complex during the reaction.

The three cyclohexenones (VI, VIII, XI) and one cyclohexene (X) thus obtained were then oxidized with *t*-butyl chromate in the presence of acetic anhydride. The chromatogram of the oxidation product of VI (Fig. 1a) showed the formation of benzoquinone (XII), accompanied by a small amount of the unreacted VI. Ten moles of the chromate to one mole of VI and refluxing for 12 hr in benzene were necessary to obtain the best yield of XII (53%). On long refluxing (24 hr), the yield of XII decreased to 38%. A similar oxidation of VIII gave 52% of XII (*t*-butyl chromate: 10 mol; refluxing time: 20 hr). The results (see Fig. 1b) were very similar to the case of VI, perhaps because of a similar steric hindrance at the C-4 positions. When XI was oxidized under similar conditions, an unknown side product (see Fig. 1d) was formed along with XII. The yield of XII was 22% (*t*-butyl chromate: 10 mol; refluxing time: 25 hr), which was rather low compared with those in the former cases. As the side product (R_t: 17 min, Fig. 1d) was not reduced by hydrosulfite, the olefinic methyl group might be oxidized in place of the sterically-hindered C-4 of XI.

As has been stated before, the oxidation of X gave XI as a major product, but small amounts of VIII and XII were also formed (see Fig. 1c). The employment of a small excess of the oxidizing agent and a long refluxing time gave a fair yield of XI, but that of XII did not exceed 12% even when an oxidizing agent was employed in a large excess (40 mol), under

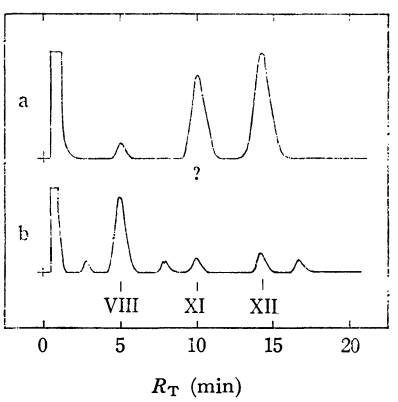

Fig. 2. Gas liquid chromatograms of oxidation products of VIII(a) and X(b) by selenium dioxide.
Column: 5% PEG 6000 on Diasolid M, 4 mm × 3 m; carrier gas: helium; flow rate: 86 m*l*/min; temp: 205°C.

*2 Column: PEG 6000, 5% on Diasolid M, 4 mm ×3 m; carrier gas: helium; flow rate: 86 m*l*/min; temp.: 134°C.

which conditions cyclohexenones completely vanished.

When VIII (1 mol) was oxidized with selenium dioxide (1.1 mol) in glacial acetic acid, XII was obtained in a 23% yield; this yield is considerably inferior to that obtained by the chromate oxidation. As can be seen from Fig. 2a, a side product was formed. This is probably an oxidized product of VIII at the olefinic methyl group. When one mole of X was oxidized with 1.5—2.0 mol of selenium dioxide, the major product was found to be VIII (5% from X), plus a trace of benzoquinone (see Fig. 2b). The yield of VIII was low, but it is interesting that this oxidation seems to have taken place at the more sterically-hindered methylene group.

When these oxidized products were reduced by sodium hydrosulfite, trimethylhydroquinone (XIII) was obtained in a quantitative yield.

Experimental

4-Methyl-4-ethoxycarbonyloctane-3,7-dione (IV). To 40 g of ethyl α-propionylpropionate (II) there was added a solution of sodium ethoxide prepared from 0.32 g of sodium and 20 m*l* of ethanol, with the temperature kept below 10°C. Freshly-distilled methyl vinyl ketone (19.6 g) was added, drop by drop, to the above solution under stirring at the same temperature. The reaction mixture was then stirred for 1 hr and left standing overnight at room temperature. The mixture was poured into 200 m*l* of water containing 1 m*l* of acetic acid, and then extracted with ether. The ether extract was washed with water, dried, and evaporated, and the residue was distilled under reduced pressure; bp 151—167°C/4 mmHg, 45 g (75%). Redistillation gave a colorless oil boiling at 123—124°C/3.5 mmHg.

Found: C, 63.32; H, 8.92%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

2,3,6-Trimethyl-6-ethoxycarbonyl-2-cyclohexen-1-one (V). A solution of IV (8.3 g) and beryllium chloride (2.9 g) in benzene (30 m*l*) was refluxed for 4 hr in a flask equipped with a calcium chloride tube. The reaction mixture was then poured into a mixture of 50 m*l* of 1 N hydrochloric acid and ice, extracted three times with benzene; the benzene extract was washed with a sodium bicarbonate solution and then with water, dried over calcium chloride, and distilled; bp 105—107°C/17 mmHg, 4.9 g (65%).

Found: C, 63.27; H, 8.41%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

2,3,6-Trimethyl-2-cyclohexen-1-one (VI). a) To a solution of potassium hydroxide (7 g) in 30 m*l* of water 3 g of V were added, and the mixture was refluxed for 2 hr. After cooling, the mixture was extracted with ether, and the ether extract was washed with water, dried, and distilled; bp 92—96°C/16 mmHg, 1.6 g (80%).

b) To 33.5 g of IV there were added 35 m*l* of concentrated hydrochloric acid and 70 m*l* of acetic acid, after which the mixture was refluxed for 6 hr. The mixture was concentrated under diminished pressure. The residue was added to water, neutralized with sodium bicarbonate, and extracted with ether. The ether extract was washed with water, dried, and distilled; bp 93—96°C/16 mmHg, 13.5 g (67%). The IR spectrum was identical with that of the product obtained by a).

Found: C, 78.48; H, 10.23%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

2,5,6-Trimethyl-2-cyclohexen-1-one (VIII). Into 21.3 g of ethyl α-propionylpropionate (II) there was stirred a solution of 0.3 g of sodium hydroxide in 50 m*l* of ethanol at 5—10°C. Crotonaldehyde (11.7 g) was stirred into the reaction mixture at the same temperature, and the solution was left standing overnight. It was then refluxed for 2 hr with a solution of 15 g of potassium hydroxide in 75 m*l* of water, poured into 300 m*l* of water, and neutralized with diluted hydrochloric acid. The mixture was extracted with ether, and the ether extract was washed with a 10% sodium bicarbonate solution and water, dried, and distilled; bp 92—100°C/24 mmHg, 8.9 g (48%). Semicarbazone; mp 230—231 °C.

Found: C, 61.01; H, 8.71; N, 22.00%. Calcd for $C_{10}H_{17}ON_3$: C, 61.51; H, 8.78; N, 21.52%.

1,4,5-Trimethyl-1-cyclohexene (X). A mixture of aldehydes prepared by the Diels-Alder reaction of isoprene and crotonaldehyde (IX, 40 g) and potassium hydroxide (50 g) was dissolved in 200 m*l* of diethylene glycol. Hydrazine hydrate (80%, 40.2 m*l*) was then added to the reaction mixture. On stirring, an exothermic reaction took place and the temperature of the reaction mixture rose to 80°C. The mixture was refluxed for 1 hr and then steam-distilled. The distillate was extracted with ether, and the ether extract was washed with water, dried, and distilled; bp 143—155°C, 22.5 g (63%). For analysis, a part was ozonized and reduced with zinc and acetic acid, and the product was precipitated as disemicarbazone, mp 176.5—178.5°C (decomp.).

Found: C, 49.34; H, 8.34; N, 30.83%. Calcd for $C_{11}H_{22}O_2N_6$: C, 48.87; H, 8.20; N, 31.09%.

3,5,6-Trimethyl-2-cyclohexen-1-one (XI). Fifteen grams of X were added to a mixture of 244 m*l* of the solution of *t*-butyl chromate (prepared from 185 g of chromic anhydride and 470 m*l* of *t*-butyl alcohol, diluted to 1.3 *l* with benzene, dried, and concentrated to 1 *l*) and 23 m*l* of acetic anhydride. The mixture was then refluxed for 22 hr under stirring and then steam-distilled. The distillate was extracted with ether, and the ether extract was washed with water, dried over magnesium sulfate, and distilled; bp 99—113°C/24 mmHg, 6.3 g (38%). Redistillation gave an oil; bp 104.5—106.5°C/21.5 mmHg. 2,4-Dinitrophenylhydrazone; mp 177—178°C (decomp.).

Found: C, 56.78; H, 5.93; N, 17.40%. Calcd for $C_{15}H_{18}O_4N_4$: C, 56.59; H, 5.70; N, 17.60%.

Oxidation by *t*-Butyl Chromate (General Procedure). To a trimethylcyclohexene or a cyclohexenone (1 g) dissolved in 10 m*l* of benzene, a solution of *t*-butyl chromate in benzene and acetic anhydride equimolar to the chromate were added and the mixture was heated to reflux under stirring. The reaction product was poured into water and steam-distilled until the distillate was no longer yellow. The distillate was then extracted with ether; the ether extract was washed with water, dried over sodium sulfate and concentrated to 10 m*l*, and the sample was submitted to gas chromatographic analysis.

Oxidation by Selenium Dioxide. To a trimethylcyclohexene or a cyclohexenone (2.8 g), 3 m*l* of glacial acetic acid were added. Selenium dioxide was then

stirred in, portion by portion. After the addition was complete, the temperature of the reaction mixture was gradually elevated until the mixture was finally heated to reflux. The product was steam-distilled as long as the distillate was yellow. The distillate was then extracted with ether, and the ether extract was washed with water, dried over sodium sulfate, concentrated to 20 m*l*, and submitted to gas chromatography.

Trimethyl Hydroquinone. The ethereal solution of trimethylbenzoquinone (XII) obtained by the oxidation described above was treated with an aqueous solution of sodium hydrosulfite until the yellow color vanished. The ether layer was then washed with water, dried, and concentrated. The residue was triturated with petroleum ether, and white crystals of trimethylhydroquinone were obtained. When the substance was recrystallized from water, its mp was 169—170°C; this mp was not depressed when it was admixed with an authentic sample, and its IR spectrum was identical with that of the authentic sample.

The authors wish to express their thanks to Professor Masanao Matsui of the University of Tokyo and to Dr. Tadao Takenishi of the Ajinomoto Co., Inc., for their valuable suggestions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1232—1236 (1968)

Synthetic Studies of α-Tocopherol. III.*1 Synthesis of Phytone

Takehiko ICHIKAWA and Tetsuya KATO

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received December 4, 1967)

Phytone (XI), an important intermediate in the preparation of α-tocopherol, was synthesized by a selective Wittig reaction between geranyltriphenylphosphonium halide (VII) and the aldehyde group of 2-methyl-6-oxoheptanal (VIII), followed by the hydrogenation of the product. VIII was prepared from 1,3-dimethyl-1-cyclohexene (V) by ozonolysis and reductive decomposition. V could not be obtained in a pure state by the dehydration of 2,6-dimethylcyclohexan-1-ol (II), presumably because of the isomerization of the intermediate carbonium ion. The pyrolysis of the acetate of II (III) was found to give pure V. That the hardly-pyrolizable stereoisomer of III was *cis,cis*-2,6-dimethylcyclohexyl-1-acetate (VI) is consistent with the *cis*-elimination mechanism.

Recent advances in biological study have revealed numerous biological activities of tocopherols, and their physiological significance has come to be increasingly recognized.[1] Phytone (XI), namely, 6,10,14-trimethyl-2-pentadecanone, serves as an important intermediate for the synthesis of α-tocopherol, and a large number of methods of synthesizing it have been described.[2] However, we have now attempted to develop the new, simple method of synthesis as indicated in Scheme 1.

2,6-Xylenol (I) was hydrogenated in the presence of Raney Nickel and sodium salt of 2,6-xylenol[3] to yield 2,6-dimethyl-1-cyclohexanol (II) in a nearly quantitative yield. The description of how Ruzicka *et al.*[4] obtained 1,3-dimethylcyclohexene (V) by the dehydration of II with potassium hydrogen sulfate has been found to be erroneous, for the NMR spectrum of the dehydrated product showed two olefinic protons of about the same intensities (δ 5.2 and 5.3), while that of the ketoaldehyde obtained by its ozonolysis and reductive decomposition showed two pairs of doublets of methyl groups of about equal intensities (δ 0.88 and 1.07, $C\underline{H}_3CH$–, doublets, $J=7$ cps) and two kinds of aldehyde groups (δ 9.55, –CH–C$\underline{H}$O, doublet, $J=2$ cps; 9.70, –$CH_2C\underline{H}O$, triplet, $J=2$ cps) (Fig. 1a). These results show that the dehydrated product is a 1 : 1 mixture of V and 2,4-dimethylcyclohexene (IV), and that the ketoaldehyde is a mixture of 2-methyl-6-oxoheptanal (VIII) and 4-methyl-6-ketoheptanal. Neither the 85% phosphoric acid[5] nor the aluminum oxide[6] employed in the dehydration has been found to be effective in obtaining V in a pure state, as can be seen from Figs. 1b and 1c, the isomerization of the carbon skelton has apparently occurred in the latter case. The bromination and dehydrobromination of II gave a very pure 1 : 1 mixture of V and IV (see Fig.

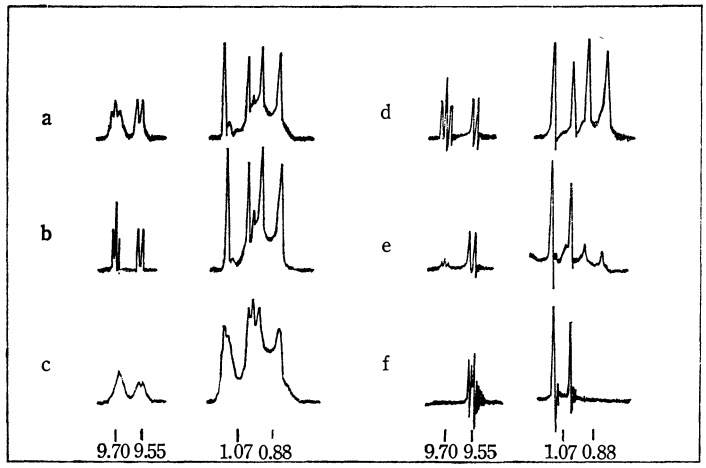

Fig. 1. NMR spectra of aldehyde and methyl groups of ketoaldehydes obtained from dehydrated products of 2,6-dimethylcyclohexan-1-ol (II) with potassium bisulfate (a), phosphoric acid (b), alumina (c), bromination and dehydrobromination (d), boric acid (e) and acetylation followed by pyrolysis (f), (in CCl_4).

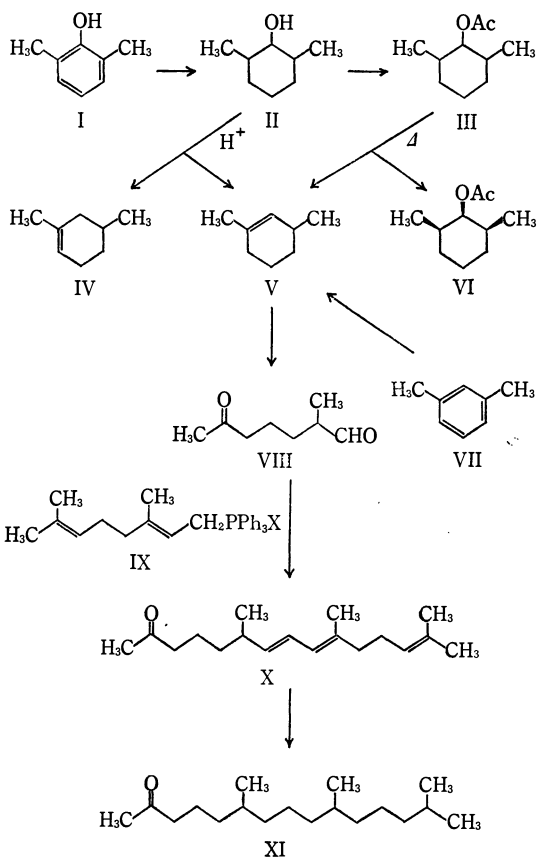
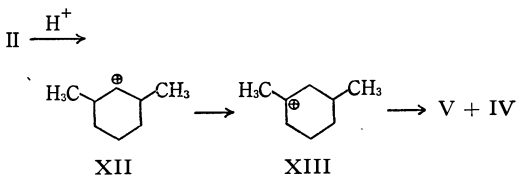
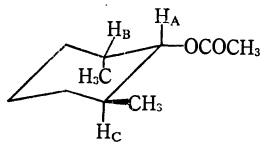


Scheme 1

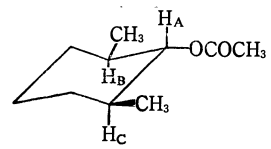
ld). These results seem to suggest that the secondary cation (XII) formed by the protonation of II rapidly isomerizes to the more stable tertiary cation (XIII), and that the subsequent abstraction of the proton from XIII gives rise to a 1 : 1 mixture of V and IV.



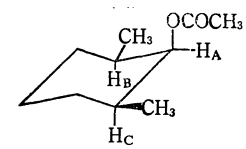
As no dehydrating process seems to serve in the present purpose, the pyrolysis of borate and acetate of II has been attempted. Boric acid and II were first reacted under mild conditions to give the borate of II; its following pyrolysis gave V as the major product (see Fig. 1e), but it was not free of IV. The dehydration of II seems to have taken place in part. The acetylation of II with acetic anhydride gave 2,6-dimethyl-1-cyclohexylacetate (III) in a quantitative yield. The pyrolysis of III was found to give pure V (δ 0.90, 3H, C<u>H</u>$_3$–CH–, doublet, J=7 cps; 1.60, 3H, C<u>H</u>$_3$–C=C, broad singlet, line width=4 cps; 5.21, 1H, <u>H</u>–C=C, broad singlet, line width=6 cps), and the ketoaldehyde obtained from it was naturally pure VIII (see Fig. 1f). The pyrolysis of the acetate (III) was achieved by passing vaporized III through a heated quartz column at 500—550°C, along with a flow of nitrogen. Considerable amounts of side products were formed at temperatures above 550°C, whereas the yields of V were low below 500°C. The yield was only slightly influenced by the flow rate of III at 500°C, but it decreased considerably when the velocity was decreased to below 0.4 g/min at 580°C. The highest yield (71%) was obtained at



XIV



XV



VI

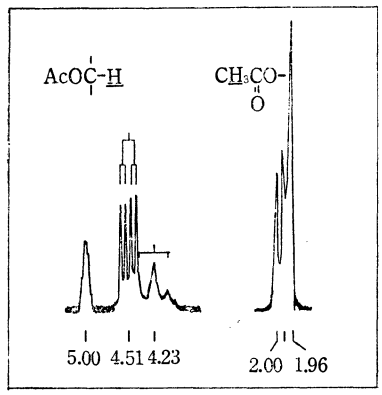


Fig. 2. NMR spectrum of 2,6-dimethylcyclohexyl-1-acetate (in CCl_4).

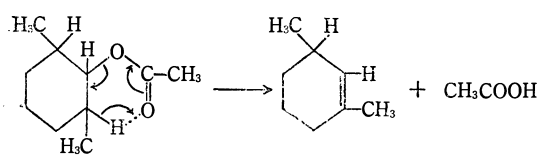
550°C with the flow rate of 1.5 g per minute. Although the recovered unreacted acetate was pyrolyzed under the same conditions, the yield of V amounted to only a few percent. A gas liquid chromatogram of III showed the presence of three stereoisomers (R_t: 11.6 (minor), 12.7 (minor), 13.8 (major) min); their ratio was slightly influenced by unknown factors during the hydrogenation of I. The recovered acetate was found to correspond to a minor component (R_t: 11.6 min). The NMR spectrum of III showed the presence of three kinds of -CH-OAc groups (δ 5.00, broad singlet, line width = 5 cps, 4.51, quartet, and 4.23, triplet) and three kinds of acetyloxy groups (δ 1.96, 1.97 and 2.00) (see Fig. 2), whereas the spectrum of the recovered acetate showed one -CH-OAc group, at δ 5.00, and one acetyloxy group, at δ 2.00. The possible conformations of V are XIV, XV, and VI. As J_{AB} ($\phi = 60°$) and J_{AC} ($\phi = 180°$) of XIV are expected to be about 2 cps and 9 cps respectively from the Karplus equation, the spectra of XIV, XV, and VI correspond to the signals at δ 4.51 and 1.96, at 4.23 and 1.97, and at 5.00 and 2.00 respectively. The pyrolysis of acetate is believed to feature intramolecular cis-elimination,[7] as is shown in XVI.



XVI

That VI is hard to pyrolyze is comprehensible from the fact that a conformation of sterically-hindered 1,3-diaxial methyl groups is inevitable when a cyclic transition state XVI is formed.

A recent method patented by Amagasa *et al.*[8] claims to be able to obtain V from *m*-xylene (VII) by reduction with sodium-water in liquid ammonia; this may offer a simpler way of obtaining V.

Geranyl triphenylphosphonium bromide (IX, X = Br) was prepared by the method of Isler *et al.*[9] from linalool or geraniol. The corresponding phosphonium chloride (IX, X = Cl) was prepared in a similar manner, but the yield was not satisfactory. The ylid from geranyl triphenylphosphonium halide has been prepared at first with phenyl lithium in ether, and the ketoaldehyde was added to the solutions of the ylid. The infrared spectra of the product showed an absorption band at 1715 cm^{-1}, while no absorption band of the unsaturated carbonyl group was found to be present, so the aldol condensation

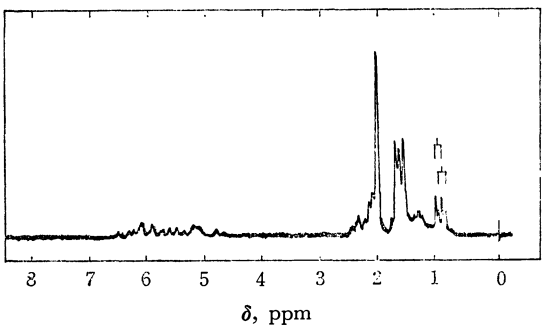


Fig. 3. NMR spectrum of 6,10,14-trimethylpentadeca-7,9,13-trien-2-one (X), (in CCl_4).

of aldehyde group seems not to have taken place. The Wittig reaction has been simplified in order to make it proceed in a better yield by adding sodium methoxide to a mixture of VIII and IX in an oxygen-containing solvent, such as ether, dioxane, tetrahydrofuran, dimethylformamide, or ethyl acetate. The yield was poor in a non-oxygen-containing solvent, such as chloroform or liquid ammonia. The NMR spectrum of the product shows an acetyl group (δ 2.00, 3H), three olefinic methyl groups (δ 1.58,

7) D. Y. Curtin and D. B. Kellom, *J. Am. Chem. Soc.*, **75**, 6011 (1953).

9) O. Isler, H. Gutman, H. Lindler, M. Montavon, R. Ruegg, G. Ryser and P. Zeller, *Helv. Chim. Acta*, **39**, 463 (1956).

1.66, 1.70, 9H), and two kinds of methyl groups (δ 0.92, doublet, 3H, $J=7$ cps; 0.96, doublet, 3H, $J=7$ cps) and supports the expected structure, 6,10,14-trimethyl-7,9,13-pentadecatrien-2-one (X) (see Fig. 3). That the two kinds of secondary methyl group are present shows that the product is a mixture of 7-*cis*- and 7-*trans*-isomers, one of which, presumably *trans*-, predominates. For the hydrogenation of X, it was necessary to treat X with Raney Nickel or with cationic exchange resin, for example, Amberlist 15 (H^+), to remove the catalyst poison, which is presumably a trace of triphenylphosphine. Palladium (5%) on active carbon was satisfactory for hydrogenating the double bonds of X selectively, yielding phytone (XI) in a nearly quantitative yield. Its IR spectrum ($\nu_{C=O}$, 1720 cm^{-1}) showed the presence of ketone and no hydroxyl group; its NMR spectrum (δ 2.01, singlet, $C\underline{H}_3CO-$; 1.23, $-C\underline{H}_2-$; 0.88, doublet, $C\underline{H}_3-CH-$, $J=6$ cps; 2.32, triplet, $-CH_2-C\underline{H}_2-CO-$) is consistent with XI, and the shapes of the signals of methyl and methylene groups resemble those of authentic phytol.

Experimental

2,6-Dimethylcyclohexan-1-ol (II). To 2.5 g of xylenol (I), 0.5 g of sodium metal was added, after which the mixture was heated at 100°C for 30 min. After cooling, absolute benzene was added and the reddish white mass was crushed and filtered to afford a green precipitate of phenolate of I.

The hydrogenation of I (52 g) with Raney Nickel in the presence of 0.2 g of the phenolate[3] gave 50.4 g (93%) of II; bp 77—82°C/21 mmHg. For analysis a part of it was refractionated; bp 66.5°C/5 mmHg. $n_D^{16.8}$ 1.4660.

Found: C, 74.80; H, 12.44%. Calcd for $C_8H_{16}O$: C, 74.94; H, 12.58%.

2,6-Dimethylcyclohexyl-1-acetate (III). To a mixture of 106 g of cyclohexanol (II) and 101 m*l* of acetic anhydride, three drops of concentrated sulfuric acid were added, and the mixture was shaken in a flask equipped with a calcium chloride tube. The temperature of the mixture was maintained below 100°C by cooling it with running water. After the vigorous reaction had subsided, the mixture was further heated at 100°C for 2 hr. The mixture was then poured into 300 m*l* of water, salt was added, and the mixture was shaken thoroughly. The aqueous layer was extracted with ether, and the extract was combined with an organic layer, washed with water, saturated sodium bicarbonate, and water, dried with anhydrous magnesium sulfate, and distilled; bp 87—92°C/24 mmHg, 130.6 g (93%). For analysis, a part of it was refractionated; n_D^{18} 1.4422, bp 72°C/4 mmHg.

Found: C, 70.62; H, 10.51%. Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%.

Dehydration of 2,6-Dimethyl-1-cyclohexanol (II).

a) Dehydration by Potassium Bisulfate.[2] A mixture of 12.8 g of II and 25.6 g of potassium bisulfate was heated in an oil bath kept at 180—190°C. The distillate was then freed from water and distilled; bp 115—130°C, 4.8 g (44%). Ozonolysis and reductive decomposition gave a mixture of ketoaldehydes (see Fig. 2a).

b) Dehydration with 85% Phosphoric Acid.[3] To 2 g of 85% phosphoric acid heated at 165—170°C in an oil bath, 12.8 g of II were added, drop by drop, and the distillate was dried, redistilled, and converted into a mixture of ketoaldehydes (see Fig. 2b).

c) Dehydration by Alumina. Through a 2 cm × 25 cm column packed with 10-mesh active alumina and heated at 360—380°C, there were passed 10 g of II in 20 min. The pyrolysate was dried, redistilled, and converted into a mixture of ketoaldehydes by ozonolysis (see Fig. 2c).

d) Bromination and Dehydrobromination. To a solution of 19 g of II in 20 m*l* of tetrachloromethane, there was added, drop by drop, 17.6 g of phosphorous tribromide in 17 m*l* of tetrachloromethane. The mixture was then stirred for 1 hr at room temperature, poured into water, and extracted with ether; the ether extract was washed, dried, and distilled; bp 82—83°C/25 mmHg, 20.5 g. Five grams of the oil thus obtained were added, drop by drop, to a solution of 4.5 g of potassium hydroxide in 9 m*l* of methanol at 100—105°C. The mixture was then heated further 30 min, poured into water, and extracted with ether; the ether extract was washed, dried, distilled, and converted into ketoaldehydes (see Fig. 2d).

e) Dehydration by Boric Acid. To a solution of 6 g of II in 20 m*l* of 1,2-dichloroethane, 2.9 g of boric acid were added; the mixture was then distilled slowly through 1 cm × 20 cm Vigreux column. Distillation was continued, with dichloroethane supplied occasionally, until water no longer distilled out and a clean solution was finally obtained. The supply of dichloroethane was then stopped, and distillation was continued further. When the temperature of the solution reached 240°C, decomposition began and the distillate was dried with magnesium sulfate and fractionated. Yield; 3.8 g (73%). The product was ozonolysed to give mainly 2-methyl-6-ketoheptanal (see Fig. 1e).

f) Pyrolysis of III, 1,3-Dimethyl-1-cyclohexene (V). 370 grams of acetate (III) were evaporated in a preheater (1 g/min) and passed through a quartz column (30 mm × 300 mm) heated at 550°C under a nitrogen stream of 60 m*l*/min. When the pyrolysate was then condensed with an efficient cooler, 306 g of the pyrolysate were recovered (97%). Water (800 m*l*) was added, and the mixture was neutralized carefully with 320 m*l* of 5 N sodium hydroxide (74% of acetic acid was assumed to be formed). The oily layer was separated and fractionated through a Widmer column; bp 119—125°C, 170 g (71%). n_D^{17} 1.4520.

Found: C, 87.41; H, 12.80%. Calcd for C_8H_{14}: C, 87.19; H, 12.81%.

The residue (89 g, 24%) was fractionated under a vacuum; bp 73—79°C/13 mmHg, 8.4 g. It was found to be *cis,cis*-2,6-dimethylcyclohexyl-1-acetate (VI), which gave only 5% of the cyclohexene under the above pyrolytic conditions.

Found: C, 70.62; H, 10.49%. Calcd for $C_{10}H_{18}O$: C, 70.54; H, 10.66%.

2-Methyl-6-ketoheptanal (VIII). A solution of 22 g of V in 200 m*l* of dichloromethane was cooled to −50—−60°C, and then oxygen gas (350 m*l*/min) containing ozone was introduced for 7 hr (0.03 mol/hr). The solution was immediately added, drop by drop, to a mixture of 15 g of zinc dust and 140 m*l* of 70% acetic acid. After the addition was complete, the mixture was refluxed for 2 hr and neutralized to pH 6 with sodium hydroxide. Care was taken to keep the pH of the solution below 6 and the temperature below 20°C. The mixture

was extracted with ether, dried, and distilled; bp 49—57°C/0.3 mmHg, 20.3 g (71%). A part of it was fractionated with efficient column for analysis; bp 67°C/0.5 mmHg, n_D^{14} 1.4376.

Found: C, 67.51; 9.80%. Calcd for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

Geranyltriphenylphosphonium Bromide (IX, X=Br). Geraniol (10 g) purified through a calcium chloride complex was converted into the phosphonium bromide IX (X=Br; 23 g) in a 73% yield by Isler's method[9]; mp 178—183°C. The product was used in the subsequent reaction without further purification. Geraniol can be successfully replaced by linalool.

6,10,14-Trimethyl-7,9,13-pentadecatriene-2-one (X). To 60 m*l* of anhydrous dioxane there were added 2 g of ketoaldehyde (VIII) and 6.6 g of IX (X=Br), and the mixture was stirred under an atmosphere of dry nitrogen. A methanolic solution of 2 N sodium methoxide (7 m*l*) was added, drop by drop, to the above mixture at 25°C over a 30-min period. After the addition was over, the mixture was heated at 55°C for 30 min under stirring. Then the mixture was poured into 50% aqueous methanol and extracted with petroleum ether. The petroleum ether extract was washed twice with 50% methanol and water, dried with anhydrous magnesium sulfate, and distilled; bp 113—119°C/0.1 mmHg, 2.44 g (66%). Redistillation for analysis gave an oil; bp 121—123°C/0.17 mmHg, n_D^{21} 1.4960. λ_{max}^{EtOH} 242 mμ (ε 2.98 $\times 10^4$).

Found: C, 82.18: H, 11.42%. Calcd for $C_{18}H_{30}O$: C, 82.38; H, 11.52%.

When geranyltriphenylphosphonium chloride was used in place of the bromide, the yield was 64%. When the reactions were carried out in methanol, X was not obtained.

Phytone (XI). To 38 g of X 4 m*l* of methanol and 4 g of Raney Nickel were added and the mixture was heated to reflux for 1 hr. The treatment with Raney Nickel can successfully be replaced by a treatment with a cationic resin such as Amberlist 15 (H^+) at room temperature. The catalyst was filtered off, 2 g of palladium charcoal (5%) were added, and the mixture was shaken at room temperature in an autoclave under the initial hydrogen pressure of 125 kg/cm^2. After the calculated amount of hydrogen had been absorbed, the catalyst was filtered and the filtrate was fractionated; bp 114—117°C/0.2—03 mmHg, 35. 3 g (91%). For analysis, a part of it was refractionated; bp 115°C/0.2 mmHg.

Found; C, 80.57; H, 13.51%. Calcd for $C_{18}H_{36}O$: C, 80.52; H, 13.52%.

The authors wish to express their heartfelt thanks to Professor Masanao Matsui of the University of Tokyo and to Dr. Tadao Takenishi of the Ajinomoto Co., Inc., for their valuable suggestions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1237—1240 (1968)

Synthesis of 4,5-Di- and 1,4,5-Trisubstituted Imidazole Derivatives from 4,5-Dicyanoimidazole

Yoshitaka YAMADA, Izumi KUMASHIRO and Tadao TAKENISHI

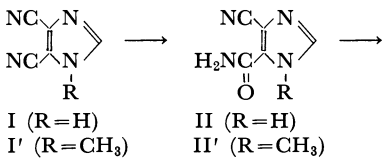
Central Research Laboratories Ajinomoto Co., Inc., Kawasaki

(Received December 13, 1967)

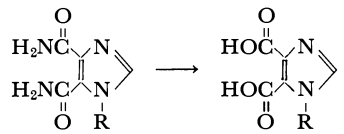
The chemical reactivities and the synthesis of various derivatives of 4,5-dicyanoimidazole formed by heating a solution of hydrogen cyanide in liquid ammonia were studied, as were the partial hydrolysis, hydrogenation, and addition reaction of cyano groups and the alkylation, cyanoethylation, and vinylation of the imidazole ring. From these experiments, a few new compounds were synthesized, which had been expected as intermediates of polymers containing imidazole rings.

In a previous paper,[1] the present authors have reported that adenine and 4,5-dicyanoimidazole were formed simultaneously by heating a solution of hydrogen cyanide in excess liquid ammonia. Though 4,5-dicyanoimidazole (I) has been already described in the literature,[2,3] the chemical properties of the compound have not yet been adequately described. This substance was recently found to be a valuable intermediate for the synthesis of various useful derivatives of imidazole and purine, *e.g.*, 4-amino-5-imidazolecarboxamide.[4] Furthermore, I may be expected to be a valuable intermediate for various polymers containing imidazole rings.

The present investigation was undertaken in order to clarify the reactivities of two cyano groups and one imino group of I and to prepare various imidazole derivatives.



I (R=H) I′ (R=CH_3) II (R=H) II′ (R=CH_3)



III (R=H) III′ (R=CH_3) IV (R=H) IV′ (R=CH_3)

The partial hydrolysis[4] of I to 4-cyano-5-imidazolecarboxamide (II) had been achieved in a 90% yield by treatment with a 1 N sodium hydroxide solution. Under more drastic conditions, however, the hydrolysis of I could not be stopped at the diamide (III) stage, and 4,5-imidazoledicarboxylic acid (IV) was obtained in a 88% yield. In contrast with these findings, the hydrolysis of 1-methyl-4,5-dicyanoimidazole (I′) was found to occur hundreds of times faster than that of I. Consequently, whereas 1-methyl-4,5-imidazoledicarboxamide (III′) was obtained in a 80% yield, it was difficult to isolate 1-methyl-4-cyano-5-imidazolecarboxamide (II′) in a high yield. Besides, far more reduction of cyano groups of I′ was achieved than in the case of the reduction of I by lithium aluminium hydride or by catalytic hydrogenation (Raney Cobalt). The increased reactivities of the cyano groups of I′ may be due to the electron-releasing effect of the methyl group in the position 1. Attempts to prepare amidine and orthoester derivatives *via* iminoether[3] of I were unsuccessful. These data on the addition reactions indicate that the cyano groups of I are extremely different from those of malononitrile and benzonitrile. Hydrogen sulfide, however, reacted

with I vigorously to form 4,5-imidazoledithiocarboxamide in a high yeild. I is a weakly acidic substance,[5] exhibiting different chemical reactivities than imidazole. Therefore, the imino group of I did not react with alkyl halide and dimethylsulfate, unless the basic substance was already present. The labile hydrogen atom of I was, however, readily added to acrylonitrile. In a similar fashion, I was converted to 1-vinyl-4-cyano-5-imidazolecarboxamide (XII) by the addition of ethylene oxide in the presence of sodium hydroxide as a catalyst. The imino group of I reacted with vinyl acetate in the presence of mercuric sulfate to form 1-vinyl-4,5-dicyanoimidazole (IX), though sodium salt of I did not react with vinyl halide in a nonaqueous solvent.

Experimental[6]

1-Methyl-4,5-dicyanoimidazole (I′). A) Into a solution of I (2.36 g, 20 mmol) in 0.2 N sodium hydroxide (100 m*l*), a 1 N silver nitrate solution (20 m*l*) was vigorously stirred. The precipitates were filtered, washed with water, and dried, and then treated with a solution of methyl iodide (1.25 m*l*, 20 mmol) in ether (50 m*l*) at 110°C for 2 hr in a sealed vessel. Silver iodide was then filtered out, and the clear etheral solution was evaporated to dryness. Crude I (1.68 g) was thus obtained. For further purification, the compound was recrystallized from hot water to give colorless crystals.

B) To a mixture of I (11.8 g, 0.1 mol) and sodium hydrogen carbonate (14.3 g, 0.17 mol) in 100 m*l* of water, dimethyl sulfate (14.3 m*l*, 0.15 mol) was added, drop by drop, over a 30-min period at 50—60°C. After the reaction mixture had been stirred at the same temperature for an additional hour, the product was extracted from the solution by ethyl acetate. The extract was washed with dilute aqueous sodium carbonate and water, and dried. The evaporation of the extract gave 12.5 g of I′.

1-Methyl-4-cyano-5-imidazolecarboxamide (II′). A solution of I′ (92 g) in 1.84 *l* of 0.5 N sodium hydroxide (as 50 v/v% aqueous ethanol) was allowed to stand at 24—25°C for 30 min. The solution was then neutralized with hydrochloric acid, and evaporated to 500 m*l*. The crystals formed were filtered off and washed with cold water. About five recrystallizations from ethanol gave an analytical sample of II′ (20 g).

4,5-Imidazoledicarboxamide (II). To a solution o I (2.36 g, 20 mmol) in 1.1 N sodium hydroxide (18 m*l*), 30% aqueous hydrogen peroxide (9.1 m*l*) was added, drop by drop, at 50—60°C over a 2-hr period. The solution was then neutralized with dilute hydrochloric acid, filtered, and the precipitates were washed with water and dried to give 1.66 g.

1-Methyl-4,5-imidazoledicarboxylic Acid (IV′). I′ (1.32 g, 10 mmol) was heated with a 6 N sodium

5) pK*a* 5.2 at 18°C.
6) The detailed data are listed in the table, in which the melting points and boiling point are uncorrected.

water; C, dilute hydrochloric acid; D, ethanol; E, methanol; F, dioxane.

hydroxide solution (10 m*l*) under refluxing for 1 hr and then neutralized with 3 N hydrochloric acid. The solution was cooled in an ice box. The precipitates were filtered, washed with cold water, and dried to give 1.19 g of the product.

4,5-Bis(aminomethyl)imidazole (V). A) To a suspension of lithium aluminum hydride (4.55 g, 0.12 mol) in tetrahydrofuran (400 m*l*), a solution of I (4.72 g, 40 mmol) in tetrahydrofuran (50 m*l*) was added, drop by drop, at 25—30°C. The mixture was stirred at 35—40°C for an additional 2 hr, and then water was added to the reaction mixture under cooling. Aluminum hydroxide was filtered out, and the filtrate was evaporated under reduced pressure. The brown residue was dissolved in water, and the aqueous solution was passed through a column of Amberite IR-120 (H^+ form). After washing with water, elution was effected with dilute aqueous ammonia. The eluate was evaporated to dryness under reduced pressure, and the residue was acidified with hydrochloric acid and decolorized. The solution was again evaporated to give crude 4,5-(bisaminomethyl)imidazole trihydrochloride (3.8 g), which showed a violet-red color when treated with ninhydrin.

B) To a solution of I (1.18 g, 10 mmol) in isoamyl alcohol (150 m*l*), sodium (11 g, 0.48 g atom) was added a little at a time under refluxing. When the metallic sodium had been dissolved completely, the solution was evaporated to dryness under reduced pressure. The isolation of V (0.47 g) was achieved in the way described in A.

C) A solution of I (0.5 g, 4.25 mmol) in methanol (20 m*l*) saturated with ammonia at 0°C was hydrogenated in the presence of Raney cobalt (0.7 g as alloy) under an initial hydrogen pressure of 110 kg/cm² and at a temperature in the range from 100 to 110°C. After the catalyst had been removed from the reaction mixture, the solution was evaporated to dryness under reduced pressure. V (0.12 g) was isolated in the way described in A.

4,5-Imidazoledithiocarboxamide (VIII). I (2.36 g, 20 mmol) and powdered sodium hydroxide as a catalyst (2 g) were added to liquid hydrogen sulfide (50 m*l* at −75°C), and the reaction mixture was heated at 70°C for 3 hr in a pressure vessel. The solution was then cooled and evaporated to dryness. Water (30 m*l*) was added and the pH adjusted to 2—3 with hydrochloric acid. A crude yellow product (2.79 g) was filtered out, washed, and recrystallized from hot water.

1-Allyl-4,5-dicyanoimidazole (IX). To a mixture of allyl bromide (18 g, 0.15 mol) and I (11.8 g, 0.1 mol) in 100 m*l* of water, sodium hydrogen carbonate (14.3 g, 0.17 mol) was added. The mixture was then heated at 80°C for 2 hr, and the cooled mixture was extracted with ether. The etheral solution was washed with dilute aqueous sodium carbonate and water, and then dried. After the evaporation of the etheral solution, the residual oil was distilled to give 13 g of IX.

1-(β-Cyanoethyl)-4,5-dicyanoimidazole (X). A mixture of I (1.18 g, 10 mmol) and powdered potassium hydroxide (100 mg) as a catalyst in acrylonitrile (20 m*l*) was heated at 120°C for 5 hr in a sealed tube, and then the solution was evaporated to dryness. Water (20 m*l*)

was added and the pH adjusted to 7 with hydrochloric acid. The cooled solution gave 1.53 g of the product.

1-Vinyl-4,5-dicyanoimidazole (XI). To a solution of I (35.4 g, 0.3 mol) and mercuric acetate (12 g) in vinyl acetate (618 g, 7.2 mol), concentrated sulfuric acid (1.5 m*l*) was added. After the solution had been heated at 40—45°C for 48 hr, the precipitates were filtered and the excess vinyl acetate was removed under reduced pressure. The recrystallization of the residue from methanol gave 14.3 g of the product (IX).

1-Vinyl-4-cyano-5-imidazolecarboxamide (XII). A mixture of I (2.36 g, 20 mmol) and sodium hydroxide (0.4 g) as a catalyst in liquid ethylene oxide (10 m*l*) was carefully heated at 100°C for 3 hr in a pressure vessel. After the evaporation of the excess ethylene oxide, 1.95 g of XII were obtained by the recrystallization of the residue from hot water. The infrared spectrum (KBr) showed strong absorptions at 3025 (vinyl hydrogen), 2275 (cyano group), and 1670 cm^{-1} (amido group).

1-Acetyl-4,5-dicyanoimidazole (XIII).[7] To a solution of I (2.36 g, 20 mmol) and sodium hydrogen carbonate (0.42 g, 5 mmol) in 0.5 N sodium hydroxide (20 m*l*), acetic anhydride (2.04 g, 20 mmol) was added at 0—5°C. After 5 min, the resulting white precipitates (3.0 g) were filtered and recrystallized from dioxane. The infrared absorption spectrum (KBr) showed strong absorptions at 2270 (cyano group) and 1775 cm^{-1} (acetyl group).

The authors wish to express their deep thanks to Mr. Shinichi Motozaki, Director of the Central Research Laboratories, for his kind encouragement. The assistance of Mr. Takashi Zama throughout this work is also gratefully acknowledged.

7) The authors wish to thank Dr. Yoshioki Komachiya for his helpful suggestions regarding the synthesis of XIII.

Reaction of Oxymercurials. Synthesis of 6,6-Dimethyl-spiro[2,5]octan-4,8-dione*1

Katsuhiko ICHIKAWA, Osamu ITOH and Takahisa KAWAMURA

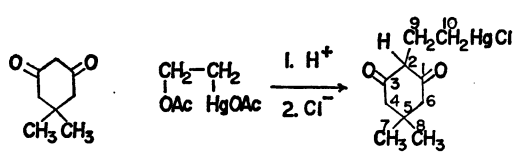
Department of Hydrocarbon Chemistry, Kyoto University, Yoshida, Kyoto

(Received December 14, 1967)

The reaction of oxymercurial of ethylene with dimedone in acetic acid containing perchloric acid, followed by treatment with sodium chloride, gave 2-(β-chloromercuriethyl)-5,5-dimethylcyclohexan-1,3-dione. Upon treating this mercurial with an equimolar amount of aqueous potassium hydroxide, 6,6-dimethyl-spiro[2,5]octan-4,8-dione was obtained. Oxymercurial of propylene reacted with dimedone to form a mixture of 4-oxo-2,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran and 4-oxo-3,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran under simultaneous demercuration; the mercurial corresponding to that in the case of ethylene could not be isolated.

In a previous paper,[1] it has been demonstrated that alkyl groups containing mercury can be introduced into active methylene by the reaction of acyclic β-diketones with oxymercurials of olefins. This paper will report that the same reaction takes place between dimedone (a cyclic β-diketone) and the oxymercurial of ethylene, and that the resulting mercurial, which is isolated as a chloromercury derivative, reacts with aqueous potassium hydroxide at room temperature to form 6,6-dimethyl-spiro[2,5]-octan-4,8-dione, which might be an interesting compound for UV absorption and NMR spectroscopy. The same attempt will also be applied to the oxymercurial of propylene.

Into a solution of β-acetoxyethylmercuric acetate (1,8 molar) which had been prepared by introducing ethylene to acetic acid containing mercuric acetate, perchloric acid (1 molar) and dimedone (a slight excess over the oxymercurial) were added.



(I)

The reaction product was isolated as a crystalline chloromercury derivative for experimental convenience. After a reaction at 10—20°C for one day, 2-(β-chloromercuriethyl)-5,5-dimethylcycohexane-1,3-dione (I), mp 199—201°C, was obtained in a 25%

*1 A part of this paper was presented at the 19th Annual Meeting of the Chemical Society of Japan, Yokohama, April, 1966.

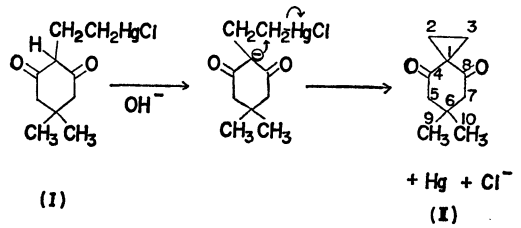
1) K. Ichikawa, O. Itoh, T. Kawamura, M. Fujiwara and T. Ueno, *J. Org. Chem.*, **31**, 447 (1966).

yield. By prolonging the reaction time to 7 days, the yield was increased to 35%. At temperatures above 25°C, metallic mercury was formed and the yield of I decreased. For example, the yields of I were 22% (accompanied by 11% demercuration) and 18% (accompanied by 22% demercuration) in the reactions at 25—30°C for 2 days and at 40°C for 5 hr respectively.

The results of the experiments with purified β-acetoxyethylmercuric acetate, which had been isolated and recrystallized, were the same as those with the oxymercurials prepared *in situ*.

The structure of I was assigned by analogy with the results obtained with acyclic β-diketones and on the basis of the spectral data. The UV spectra (λ_{max} 262 mμ, $\varepsilon=3600$ in chloroform and λ_{max} 269 mμ, $\varepsilon=12200$ with a shoulder at λ_{max} 300 mμ, $\varepsilon=5800$ in ethanol) showed the presence of an enolizable β-diketo group. The IR spectrum also supported this structure, since absorptions observed at 2300—2700 (w, broad), 1730 (w), 1700 (s), and 1630 (w) cm^{-1} can be assigned to $\nu_{O-H\cdots O=C}$, $\nu_{C=O}$, $\nu_{C=O}$, and $\nu_{C=C}$ respectively. The NMR spectrum obtained at 60 Mc, using tetramethylsilane as an internal standard, in pyridine can be explained reasonably in terms of the enol form of I. The signals observed at τ −1.43 (singlet), 6.84 (triplet), 7.57 (singlet) 7.75 (triplet), and 9.00 (singlet), with relative intensities of 1 : 2 : 4 : 2 : 6, can be assigned to those due to the protons at O, C_9, C_4 and C_6, C_{10}, and C_7 and C_8 respectively (Fig. 1).

When I was treated with an equimolar amount of potassium hydroxide (10% aqueous) at 40°C for 3 hr, demercuration proceeded and 6,6-dimethyl-spiro-[2,5]octan-4,8-dione (II), bp 86.2—86.5°C/3 mmHg, n_D^{25} 1.4808, was obtained in a 90% yield on the basis of demercuration (75%). The mechanism is considered to be the same as that of 1,1-diacetylcyclopropane formation from 3,3-diacetylpropylmercuric chloride,[1] since the reaction conditions and scheme are the same. In the latter case, it has been suggested that the demercuration was assisted by the chelation of the β-diketo group with mercury. However, this cannot be applied to the present case, since the diketo group of dimedone cannot form a chelate compound. This demercuration mechanism, however, appears to require further investigation, because the purification of the mercurials is a necessary condition for the demercuration. Unknown impurities appear to inhibit the reaction.

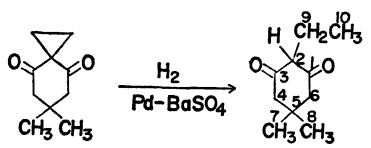


(I) (II)

The structure of II was identified on the basis of the results of elementary analysis and the spectral data. Analysis showed that II has a formula of $C_{10}H_{14}O_2$ (Found: C, 72.53; H, 8.74%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%). The IR spectrum showed absorptions at 1705 and 1678 cm^{-1} due to $\nu_{C=O}$, and at 3020 cm^{-1} due to the ν_{C-H} of the cyclopropane ring.

The NMR spectrum clearly proved that the assigned structure is correct. In deuterochloroform, using tetramethylsilane as an internal standard, signals were observed at τ 7.44, 8.25, and 8.87, with relative intensities of 4 : 4 : 6; these signals can be assigned to those due to the protons at C_5 and C_7, C_2 and C_3, and C_9 and C_{10} respectively (Fig. 2).

As further evidence, when II was hydrogenated over Pd-$BaSO_4$ catalyst in methanol at room temperature, the product was crystalline ethyldimedone.



Since this product is unstable, it was identified by means of the NMR spectrum. In a pyridine solvent, signals were observed at τ 7.18 (quartet, $J=$ 7.3 cps), 7.63 (singlet), 8.73 (triplet, $J=7.3$ cps) and 8.98 (singlet), with relative intensities of 2 : 4 : 3 : 6. These signals may be assigned to the protons at C_9, C_4 and C_6, C_{10}, and C_7 and C_8 (Fig. 3).

When the reaction mixture of oxymercurial of ethylene and dimedone mentioned above was kept at the higher temperature of 40°C for 10 hr, the formation of metallic mercury (29% of the total amount) was observed. A work-up of the mixture gave 0.7 g of a liquid product, bp 109—113°C/4 mmHg. Gas chromatographical analysis showed that this product consisted of II (2%) and another product (96%). Spectral data disclosed that the latter was 4-oxo-6,6-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (III). The infrared spectrum showd a characteristic absorption of the 3-acetyl-4,5-dihydrofuran skeleton at 1635 cm^{-1}.[2-4]

The NMR spectrum is also consistent with this structure. Two singlets at τ 8.90 and 7.75 and three triplets at 7.70 ($J=1.5$ cps), 7.15 (broad, $J=9.2$ cps), and 5.39 ($J=9.2$ cps), with relative intensities of 6 : 2 : 2 : 2 : 2, can be assigned to the protons at C_{10} and C_{11}, C_5, C_7, C_3, and C_2 respectively.[2,5] The broading of the triplet at τ 7.15 is due to a long-range

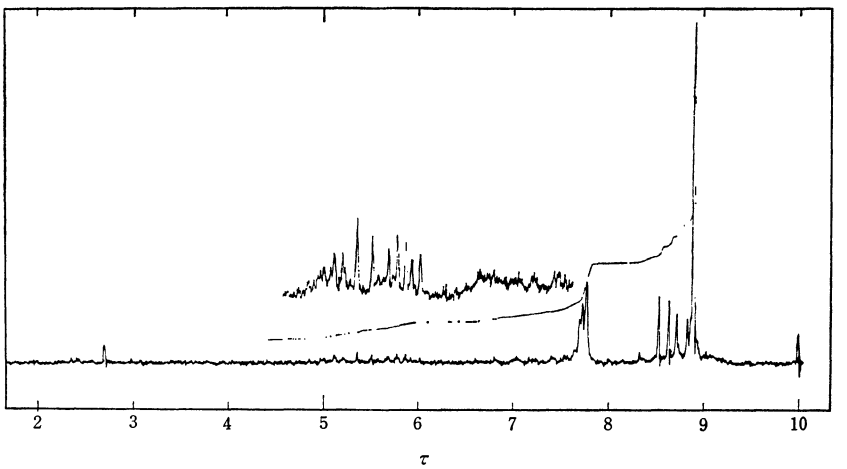

Fig. 5. NMR spectrum of a mixture of 4-oxo-2,6,6-trimethyl- (IV) and 4-oxo-3,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran (V) in $CDCl_3$ (60 Mc).

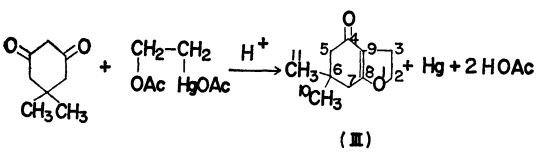


(III)

coupling ($J = 1.5$ cps) between 7-methylene and 3-methylene protons, this coupling is generally observed in this system and will be discussed in a separate paper.

This result of dihydrofuran formation is similar to those of the reactions between the oxythallate[3] and oxyplumbate[4] of ethylene and acetylacetone, and the mechanism also appears to be similar. However, the possibility of the formation of the same product through the isomerization of the cyclopropane (II) by acid cannot be excluded, because an attempt to obtain dinitrophenylhydrazone of II in ethanol containing sulfuric acid gave the hydrazone of III instead of II, and the same type of isomerization has been demonstrated to proceed in concentrated sulfuric acid.[6]

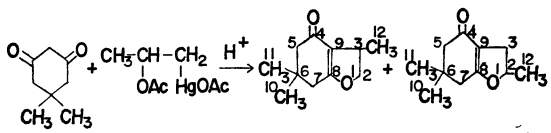
In the case of oxymercurial of propylene, 2-acetoxypropylmercuric acetate, the reaction with dimedone was slower than that of ethylene. Even after a reaction at 5—15°C for 5 days, the presence of unreacted oxymercurial was detected, and the formation of metallic mercury was also observed. The expected mercurial appears to be unstable and to be subject to demercuration under these conditions. Several attempts to isolate the mercurial corresponding to I in an earlier stage of the reaction were unsuccessful. After a reaction at 5—15°C for 5 days, 58% of the total mercury in the reaction mixture precipitated as metal.

Gas chromatographical analysis of the organic products showed that the main product (more than

6) O. Itoh, T. Kawamura and K. Ichikawa, *Bull. Inst. Chem. Res., Kyoto Univ.*, **44**, 207 (1966).

96%) is a mixture of two compounds (55 : 45), with close retention times. Because of the difficulty of purification and separation, the structures were estimated on the basis of the spectral data and the results of analogous reactions.[3,4]

The NMR spectrum was explained reasonably by assuming that the product is a mixture of 4-oxo-2,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran (IV) and 4-oxo-3,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran (V). The signals observed at τ 8.90 (singlet), 7.77 (singlet) and 7.71 (triplet), with relative intensities of 6 : 2 : 2, can be assigned to those due to the protons of the C_{10} and C_{11}, C_5, and C_7 of both IV and V. The broad complicated signals observed at τ 6.4—7.6 and 4.8—6.1, with relative intensities of *ca.* 1.5 : 1.5, are those due to protons of the C_2 and C_3 of IV and V respectively. The two doublets centered at τ 8.59 (J=6.2 cps) and 8.77 (J=6.8 cps) can be reasonably assigned to the protons of methyl groups attached to the C_2 of IV and the C_3 of V on the basis of the results observed in the NMR spectra of 3-acetyl-2,5-dimethyl-4,5-dihydrofuran[6] and 3-acetyl-2,4-dimethyl-4,5-dihydrofuran.[7]



(V) (IV)

Experimental

2-(β-Chloromercuriethyl)-5,5-dimethylcyclohexan-1,3-dione (I). The following is an example of a typical experimental procedure. Into an acetic acid solution of β-acetoxyethylmercuric acetate which had been prepared by introducing ethylene into a mixture of mercuric acetate (0.6 mol) and acetic acid (180 g), dimedone (100 g, 0.6 mol) was added. The reaction mixture (heterogeneous) was kept at 0°C, and then 70% perchloric acid (48 g) was slowly added. Throughout the procedure, the mixture was stirred mechanically; it became homogeneous after the addition of the acid. After the mixture had stood at 5—15°C for 24 hr, a grey slurry was formed. This reaction mixture was then added to an aqueous sodium chloride solution to precipitate white crystals, which were dried and recrystallized from ethanol. Seventy-three g of I (18% yield), mp 199—201°C, were thus obtained. The results of mercury content analysis (49.3%)[8] agreed with the calculated value (49.7%). IR (KBr): 3300 (w), 2930 (m), 2700—2300 (broad, w), 1730 (m), 1700 (m), 1630 (w). 1570 (m), 1547 (s), 1415 (m), 1377 (sh., w), 1366 (s), 1355 (s), 1311 (m), 1246 (s), 1136 (s), 1015 (w), 820 (w), 800 (w), 690 (w), 645 (w), 595 (m), 575 (w), 490 (w), 455 (w) cm^{-1}.

6,6-Dimethyl-spiro [2,5] octan-4,8-dione (II). Into 50 m*l* of a 10% aqueous solution of potassium hydroxide, 40.3 g of I was added, and the mixture was stirred at room temperature (15—20°C) for 3 hr. When the reaction temperature was raised to 25—30°C, the formation of metallic mercury was observed. After a reaction at 25—30°C for 3 hr, the metallic mercury (14 g, 70% of the theoretical amount) was removed, and the mixture was acidified with 1 m*l* of 1 N hydrochloric acid and extracted twice with 100 m*l* portions of ether. By evaporating the solvent, 11.5 g of II (90% yield, on the basis of demercuration) was obtained. Gas chromatographical analysis showed that the product consisted only of II, bp 86.2—86.5°C/3 mmHg, n_D^{25} 1.4804. UV: $\lambda_{max}^{n\text{-Hexane}}$ 196 mμ (ε=4700) and 267 mμ (ε=35); λ_{max}^{EtOH} 203 mμ (broad, ε=4050) and 276 mμ (ε=60). IR (liquid film): 3020 (w), 2960 (m), 2880 (w), 1705 (s), 1678 (s), 1465 (m), 1405 (m), 1390 (w), 1370 (m), 1335 (s), 1320 (s), 1290 (m), 1265 (w), 1175 (m), 1140 (m), 1120 (w), 1080 (m), 1035 (w), 1015 (w), 985 (m), 915 (m), 610 (w), 585 (w) cm^{-1}.

Found: C, 72.53; H, 8.74%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

II was added to an excess 2,4-dinitrophenylhydrazine solution (ethanol-sulfuric acid) to prepare the hydrazone in the usual way.[9] The red crystals thus obtained were recrystallized from ethanol, mp 165—168°C. This hydrazone was not of II, but of III. A mixed melting point determination with that of III showed no depression.

Found: C, 54.68; H, 5.20%. Calcd for $C_{16}H_{18}N_4O_5$; C, 55.48; H, 5.24%.

This shows that II was converted to III during the preparation of hydrazone.

Hydrogenation of II to Ethyldimedone. With a palladium-barium sulfate catalyst (1.0 g), II (0.213 g, 1.05 mmol) was hydrogenated in methanol (30 m*l*) at room temperature. In 5 min, 23 m*l* of hydrogen were absorbed. After filtering off the catalyst, the solvent was distilled to give crystalline ethyldimedone. The IR spectrum disclosed the presence of two carbonyls (1690 and 1665 cm^{-1}), a carbon-carbon double bond (1620 cm^{-1}) and intermolecular hydrogen-bonded carbonyl (1550 cm^{-1}).

4-Oxo-6,6-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (III). To an acetic acid (15 g) solution of β-acetoxyethylmercuric acetate prepared from 0.05 mol of mercuric acetate and ethylene, dimedone (0.05 mol) and then 70% perchloric acid (4 g) were added. The reaction was continued at 40°C for 10 hr under stirring. After the metallic mercury formed (2.9 g, 29%) had been removed, the reaction mixture was added to an aqueous sodium chloride solution. The crystals formed (3 g, 15% yield) were filtered off and the remaining solution was extracted three times with 100-m*l* portions of ether. The ether extract was washed with a 5% sodium bicarbonate solution and then with water. After drying over sodium sulfate, the solvent was distilled off. Distillation gave 0.7 g of III (29% yield on the basis of demercuration), bp 109—113°C/4 mmHg. 2,4-Dinitrophenylhydrazone melted at 167—169°C.

Found: C, 55.55; H, 5.40%. Calcd for $C_{16}H_{18}N_4O_5$: C, 55.48; H, 5.40%.

4-Oxo-2,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran (IV) and 4-Oxo-3,6,6-trimethyl-2,3,4,5,6,7-hexahydrobenzofuran (V). By the same method as has been described in the case of I, a reaction mixture of β-acetoxypropylmercuric acetate (0.5 mol), dimedone (0.68 mol), and perchloric acid (70%, 45 g) in acetic acid (150 g) was prepared. By a reaction at 5—15°C for 5 days, 58% of the total mercury was precipitated as metal. The reaction mixture was then filtered, water (twice the volume) was added, neutralized with a sodium hydroxide solution, and extracted with ether. After the ether had been removed, 80 g of an oily product were obtained. This contained unidentified mercury compounds, the oil was extracted with petroleum ether repeatedly (10 times with 100 m*l* portions). After the oil had been dried over anhydrous sodium sulfate and the solvent removed, a liquid product (15 g), bp 110—115°C/6 mmHg, was obtained. Gas chromatographic analysis showed that the main product (more than 96%) was a mixture of two components with close retention times. The two components could not be separated into pure components either by distillation or by column chromatography. IR (liquid film): 2950 (s), 2875 (s), 1718 (m), 1625 (s), 1460 (m), 1445 (m), 1398 (s), 1365 (m), 1335 (w), 1285 (w), 1240 (m), 1215 (s), 1165 (m), 1140 (m), 1100 (m), 1010 (m), 945 (m), 890 (m), 820 (w), 610 (m) cm^{-1}. UV: λ_{max}^{Hexane} 262 mμ ($\varepsilon=12500$), $\lambda_{max}^{Ethanol}$ 272 mμ ($\varepsilon=13300$).

Spectral Measurements. IR, UV, and NMR spectra were recorded by JASCO IR-S, Hitachi EPS 2, and Varian 60A apparatuses respectively.

Reagents. The commercial ethylene and propylene were used without further purification. The dimedone was also a commercial one, mp 144—146°C. All the other reagents were commercial products of an analytical grade.

Effect of Coexisting Minerals on Graphitization of Carbon. I. Heat Treatments of Carbon under 3 kbar in the Presence of Limestone

Tokiti NODA,*1 Michio INAGAKI, Shin-ichi HIRANO and Kiyoshi AMANUMA

Faculty of Engineering, Nagoya University, Nagoya

(Received November 24, 1967)

The effect of the presence of limestone on the graphitization of carbon was investigated by the heat treatments of the carbon sample under the quasi-hydrostatic pressure of 3.2 kbar. The carbon sample used was a coke (PV-7) prepared by carbonization of polyvinylchloride up to 680°C. It was placed between two disks of limestone so as to make a sandwich-type specimen. The heat treatments were performed in a simple piston-cylinder type vessel at various temperatures of 800—1300°C for 20—240 min. Above 1000°C, the carbon specimens were obtained as caked tablets. The profiles of (002) diffraction line of these carbon tablets were found to be composite, consisting of a sharp component profile at 26.5° and a broad one at lower angle than 26.2°. The component G_M corresponding to the sharp component profile seemed to have the graphite structure. The content of the component G_M increased very rapidly with the increase in heat treatment temperatures above 1000°C. Phenomenally, the developement of the graphite structure seemed to be closely related to the recrystallization and the melting of coexisting limestone, but some chemical effects should not be excluded.

In the nature, a good quality of graphite crystals has been found in beds of metamorphic rocks, such as limestone. The temperature-pressure condition of the graphite formation was estimated geologically as the temperature of several hundreds degrees and the pressure of several kilobars. On the other hand, it has been found in a laboratory that the carbon is graphitized very rapidly at around 1500°C under the pressure of 10 kbar[1] and even under 5 and 3 kbar.[2] However, any indication of the presence of graphite structure could not be found by X-ray diffraction at temperatures lower than 1300°C. Therefore, the limestone might have some effect on graphitization, like the pressure and the temperature have.

The purpose of the present work is to see the effect of the presence of limestone on the graphitization of carbon under the pressure.

Experimental and Results

The carbon sample used was a coke (PV-7) prepared by carbonization of polyvinylchloride and consequently heated up to 680°C. The grain size of the sample was limited in the range between 0.1 and

0.4 mm. Limestone disks of 3.5 mm thick and 8.0 mm in diameter were cut out from Fusulina limestone from Akasaka, Gifu-ken, Japan. The carbon sample of 180 mg was placed between two disks of limestone so as to make a sandwich-type specimen as shown in Fig. 1. A high pressure apparatus used was a simple piston-cylinder type one, which was made from a tool steel. The bore and outer diameter were 24 and 50 mm, respectively, and the cylinder was protected by a soft steel guard ring. The heat treatments were performed at various temperatures between 800 and 1300°C for 20—240 min under the quasi-hydrostatic pressure of 3.2 kbar. The heat treatment temperature (HTT) was estimated from input power using the relation between temperature and input power, which was determined beforehand using a chromel-alumel thermocouple inserted in the carbon specimen arranged in the same way as in the heat treatments. The temperature was controlled by adjusting the input power. The pressure was calibrated by using KNO_3 and AgI.[3]

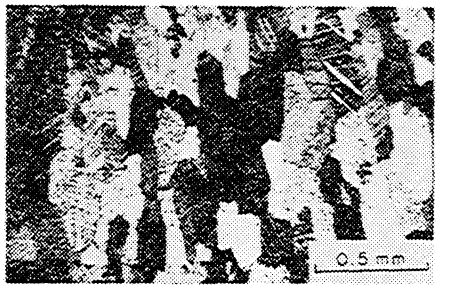
In comparison, the carbon sample was heat-treated under the same pressure without limestone, replacing limestone disks (in Fig. 1) by glassy carbon plates and pyrophyllite disks. Glassy carbon plates were used to prevent the direct contact of carbon specimen with pyrophyllite disks.

Profiles of (002) diffraction line of the heat-treated specimens were measured by a recording X-ray diffractometer using Ni-filtered Cu$K\alpha$ radiation. Specimens for X-ray diffraction were taken from the central part of heat-treated carbon tablets.

3) M. Inagaki, S. Hirano and H. Saito, to be published.

Above 1000°C, the carbon specimens heat-treated with limestone were obtained as caked tablets. In the tablets, appreciable amounts of calcium carbonate were detected by X-ray diffraction method and the amounts increased with HTT. Limestone disks themselves were found to have recrystallized above 1000°C. The thickness of recrystallized part of limestone increased with the increase in HTT and residence time. Grains of recrystallized limestone grew along the axial direction of the heater (Fig. 2), to which the temperature gradient was parallel. Limestone was found to have melted above 1250°C.

Higher temperature



Lower temperature side

Fig. 2. Growth of grain of recrystallized calcite in contact with carbon sample treated at 1120°C for 60 min under 3.2 kbar (under polarized light).

Profiles of (002) diffraction line of the carbon samples heat-treated with linestone above 1000°C were found to be composite, consisting of a relatively sharp profile at 26.5° in 2θ (6.72 Å in the c_0-spacing) overlapping on a broad profile at an angle lower than 26.2°. With the increase in HTT and residence time, the sharp profile at 26.5° became stronger and narrower, while the broad profile shifted to higher angles. The profile of (002) diffraction line of the carbon sample heat-treated without limestone had only a hump at about 26.5° above 1300°C. The representative changes of the profiles with HTT are shown in Fig. 3 a) and b).

The composite profiles were graphically separated into two component profiles. The schema of the separation is shown in Fig. 4: After the observed composite profile (1) is corrected for the Lorentz-polarization, atomic scattering and absorption factors by conventional methods[4] (the profile (2)), the high angle side of the sharp profile is folded to the low angle side and the profile (3) is obtained. Subtracting the profile (3) from the composite profile (2), the balance profile (4) is obtained. Since the profile (4) is not symmetrical usually, however, the profile (5) for the broad component is obtained by folding the low angle side of the profile (4) at the angle of the maximum intensity. Finally, the profile (6) for the sharp component is obtained by subtracting the profile (5) from the profile (2). Some trial and error

4) W. R. Ruston, *Fuel*, **32**, 53 (1953).

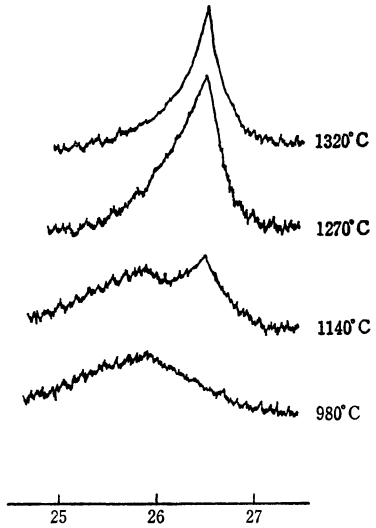


Fig. 3 (a).

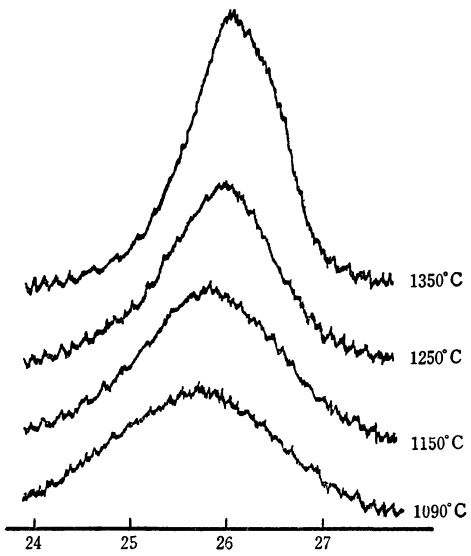

Fig. 3 (b).

Fig. 3. Changes of profiles of (002) diffraction line with HTT for 60 min.
a) treated in the presence of limestone
b) treated without any minerals

adjustments are needed in order to obtain the symmetrical component profiles and to fit the profile composed from the component profiles satisfactorily well with the original composite profile. The components which correspond to the sharp and broad component profiles are designated as G_M and A_M, respectively.*2

The c_0-spacing of the two components was measured from the separated profiles (5) and (6), and

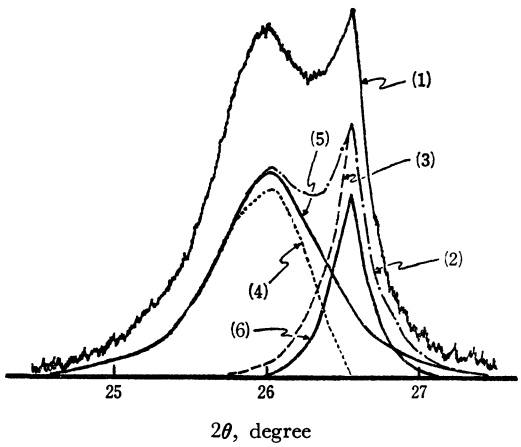

Fig. 4. Schema of separation of the composite profile.

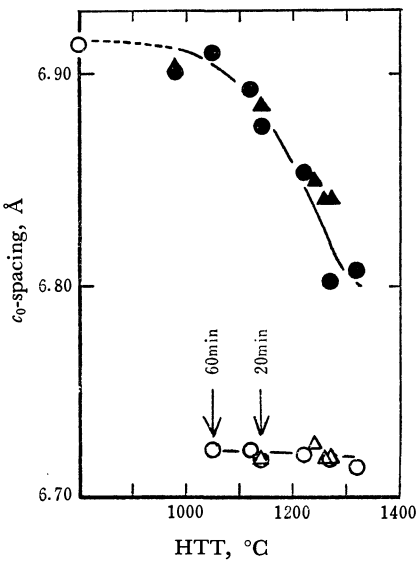

Fig. 5. Variation of c_0-spacing of two components, G_M and A_M, with HTT.
Above the temperature marked by the arrow, the component G_M could be observed on the diffraction profile.
G_M A_M
△ ▲: 20 min
○ ●: 60 min

the result is shown in Fig. 5. The c_0-spacing of the component G_M is almost constant and around 6.72 Å, while the c_0-spacing of the component A_M decreased

*2 For the soft and hard carbons heat-treated under pressure without any minerals, the composite profiles were observed and separated into two components G_S and A_S, and G_H and A_H, respectively. In the present work, the suffix " M " was used for each component in order to distinguish from the components reported previously.[2,5]

5) M. Inagaki, K. Kamiya, M. Mizutani and T. Noda, to be published.

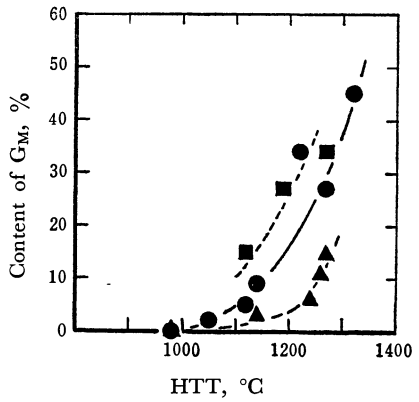

Fig. 6. Variation of content of the component G_M with HTT.
▲, 20 min ●, 60 min ■, 240 min

gradually from 6.91 to 6.80 Å. It is reasonable to take the component G_M as the graphitic component, because the component G_S having the c_0-spacing of 6.72 Å was reported to have the graphite structure.[2,6] Therefore, the content of the component G_M was used as a measure of graphitization of the sample. The content of the component G_M was obtained from the ratio of the area under the profile of the component G_M to the total area under the composite profile. The ratio of areas was corrected for the preferred orientation of crystallite in the specimens for X-ray diffraction, when the ratio was converted to the content of the component G_M. Changes of the content of the component G_M with HTT are shown in Fig. 6 for several residence times.

6) M. Inagaki, K. Kamiya and T. Noda, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind.Chem. Sect.*), **71**, 652, 812 (1968).

Discussion and Summary

The graphitization of carbon under pressure is evidently accelerated by limestone. Under 3 kbar in the presence of limestone, the component G_M, which seems to have the graphite structure, begins to appear just above 1000°C. This temperature is much lower than that in the case of the heat treatment of the same sample PV-7 under the same pressure without limestone.

The content of the component G_M increased very rapidly with the increase in HTT. The content was about 45% with the heat treatment at 1300°C for 60 min. However, with a longer treatment as 240 min, only a small increase in the content was observed.

Phenomenally, the developement of the graphite structure seems to be closely related to the recrystallization and the melting of the coexisting limestone, but some chemical effects should not be excluded. In order to know the mechanism of the effect of limestone on the graphitization of carbon under pressure, more precise experiments are needed.

The authors wish to thank Mr. Kan-ichi Kamiya in our laboratory for his kind coorperation and assistance, and also Tokai Electrode Mfg. Co. for supplying the graphite materials used.

NOTES

Photochemical Reduction of Nitrobenzene and Its Reduction Intermediates. III.[1] The Photochemical Reduction of Nitrobenzene*[1]

Shizunobu HASHIMOTO, Junzo SUNAMOTO,*[2] Hironori FUJII and Koji KANO

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received July 5, 1967)

Several studies of the photochemical reaction of nitrobenzene have been reported,[2-8] but no investigation of the photoreduction of nitrobenzene to anilines has been published.

Recently, Hurley and Testa[9] reported that the photoreduction of nitrobenzene in isopropyl alcohol gives phenylhydroxylamine as an initial product; this product is immediately oxidized by air to nitrosobenzene and coupled with the latter to give azoxybenzene. On the other hand, Kaneko and his co-workers[10] have shown that 4-nitropyridine-*N*-oxide undergoes a quantitative photoreduction to the corresponding hydroxylamino compound in ethanol.

In the present paper, the photoreductions of nitrobenzene to aniline in an isopropanoic hydrochloric acid solution with or without a photosensitizer will be described. In addition, the photoreduction of nitrosobenzene, phenylhydroxylamine, and azoxybenzene have been carried out in order to make the reduction process clear.

Experimental

Materials. Nitrobenzene and isopropyl alcohol commercially obtained were further purified by distillation prior to use. Nitrosobenzene,[11] phenylhydroxylamine,[11] and azoxybenzene[12] were prepared and recrystallized according to the procedures described in the literature. Disodium 2,6-anthraquinone disulfonate (=AQ) was prepared by the usual disulfonation of anthraquinone and was purified by recrystallization from methanol.

Photochemical Reduction Procedures. A typical method of photochemical reduction was as follows. A mixture of 5×10^{-4} mol of nitrobenzene (nitrosobenzene, phenylhydroxylamine, or azoxybenzene), 5 m*l* of concentrated hydrochloric acid, and 10 mg of AQ was placed in a 250 m*l* volumetric flask and diluted to exactly 250 m*l* by isopropyl alcohol. This isopropanolic solution was then placed in an inside-irradiation-type reaction flask equipped with a 130 W-pressure mercury lamp. The reaction was commenced by irradiation under a nitrogen atmosphere at the boiling point of the solvent used.

Rate Measurements. Nitrobenzene, nitrosobenzene, and phenylhydroxylamine were determined by polarography. The ionic strength and pH were adjusted by using a potassium biphthalate - sodium hydroxide buffer solution (pH=6.0) or a sodium boronate - sodium hydroxide buffer solution (pH=12.0); for nitrobenzene, pH=6.0 and μ=0.12; for nitrosobenzene and phenylhydroxylamine, pH=12.0 and μ=0.21.

The aniline produced during the course of the reaction was followed by the following method. Samples drawn out of the reaction flask at appropriate time intervals were diazotized and coupled with NW acid (1-naphthol-4-sulfonate) by the usual method. The resulting azo dye solution was paper chromatographed by a 2% aqueous ammonium solution, and then the dye spot corresponding to the aniline dye was separated and extracted by a 20% aqueous pyridine solution. The absorbance of the extract was measured at 490 mμ on a Shimadzu Bausch & Lomb Spectronic 20 photometer.

Identification of Products. In our present experiments, aminophenols, *p*-chloroaniline, benzidine, and diphenyline were produced simultaneously with aniline, as shown in Table 1. They were, therefore, identified

a) Concentration of the starting materials was 2×10^{-3} mol/*l* in isopropyl alcohol. (at boiling point of isopropyl alcohol under nitrogen atmosphere)
Maximum yields of aniline were b) 36%, c) 25%, d) 23%, e) 38% and f) 65% respectively.

with authentic samples by paper chromatography (solvent: 4 : 1 = *n*-butanol : concentrated hydrochloric acid, cyclohexane, or a 2% aqueous hydrochloric acid solution; detection : diazotization and coupling with NW acid, or Schiff base formation with *p*-dimethylaminobenzaldehyde). Furthermore, all of the dyes separated from paper chromatograms were independently extracted by suitable solvents and their visible absorption spectra were examined.

The other photoreduction products were identified by spectrophotometry and/or polarography. The acetone generated during the course of the reaction was derived to 2,4-dinitrophenylhydrazone and identified by means of its melting point.

Results and Discussion

The disappearance of nitrobenzene and the formation of aniline are shown in Fig. 1. Much as in the case of Hurley and Testa,[9] in our photochemical reduction of nitrobenzene the formation of phenylhydroxylamine was obviously detected on the polarogram and by means of the UV spectra upon the disappearance of nitrobenzene. When hydrochloric acid was added to this system, the rate of the disappearance of nitrobenzene became fast and the phenylhydroxylamine intermediately produced was immediately changed to aniline, *p*-chloroaniline, and *p*-aminophenol. Figure 2 shows that, when hydrochloric acid is present, phenylhydroxylamine converts to the primary amines even in the dark.

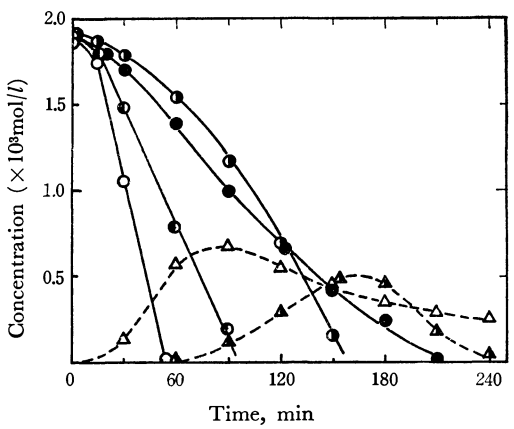

Fig. 1. Photochemical reduction of nitrobenzene.
—— Disappearance of nitrobenzene
○ No. 1, ◑ No. 2, ◐ No. 3, ● No. 4
--- Formation of aniline
△ No. 1, ◭ No. 2

In Bamberger's well-known reaction,[13] phenylhydroxylamine converts to *p*-anisidine, *p*-chloroaniline, and *p*-aminophenol in an acidic methanol solution. However, in our experiment aniline was given in a rather good yield (*ca.* 40%), and no alkoxyaniline was detected.

On the other hand, when AQ was added to this reaction system, the rate of the disappearance of nitrobenzene also became fast. Dependent upon the disappearance of nitrobenzene, the phosphorescence of excited AQ decreased in intensity. When the photoreduction of nitrobenzene was carried out in the presence of hydrochloric acid and AQ under an oxygen atmosphere, the same kinds of amines were produced as those under a nitrogen atmosphere.

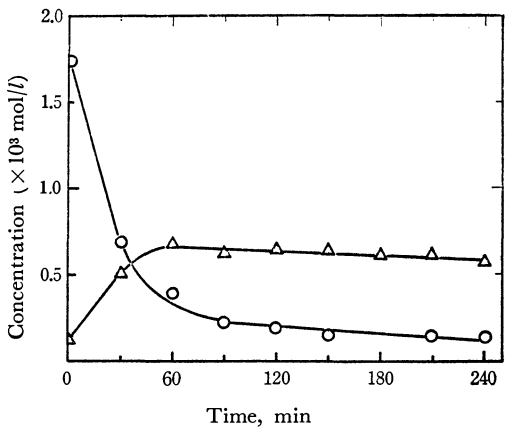

Fig. 2. Redution of phenylhydroxylamine in isopropyl alcohol in the dark; under nitrogen atmosphere, boiling point of isopropyl alcohol, conc. HCl=5 m*l*, AQ=10mg.

○ Phenylhydroxylamine, △ Aniline

However, the rate of the disappearance of nitrobenzene and the yields of amines became less than those under a nitrogen atmosphere. Comparing with AQ, benzophenone was not a useful catalyst in these photoreductions. From these results obtained above, it seems that the AQ used in the present photoreduction is useful as a reducing agent as well as a photosensitizer, because AQ can be easily photoreduced to give the semiquinone radical or the hydroquinone in a hydrogen-donating solvent.[14]

The light of 330—340 mμ, which are effective for the n–π^* transition of nitrobenzene, are also absorbed by phenylhydroxylamine. Therefore, it may be reasonable to suppose that the reaction rate of nitrobenzene will become slower if hydrochloric acid is absent, because of the inner-filter effect of the phenylhydroxylamine produced.

It was clarified that, in the photoreduction of nitrobenzene in the presence of hydrochloric acid, the primary product was phenylhydroxylamine, not nitrosobenzene; that the final products were aniline, *p*-aminophenol, and *p*-chloroaniline, and that hydrochloric acid and AQ were effective as the catalysts for this photoreduction. On the other hand, in the photochemical reduction of nitrosobenzene in the presence of hydrochloric acid and AQ, the detectable primary product was azoxybenzene, and the final reduction products were aniline, *o*-aminophenol, benzidine, and diphenyline. From these results obtained, it may be most reasonable to assume that the corresponding hydrazo compound may be produced as an intermediate in the photoreduction of nitrosobenzene, unlike as in that of nitrobenzene. Bamberger[15] and Cumming and Ferrier[16] have suggested that azoxybenzene and nitrobenzene are produced in the photodisproportionation of nitrosobenzene. In our present experiment, however, no nitrobenzene could be detected in the photoreduction of nitrosobenzene.

In the oxidation of phenylhydroxylamine to nitrosobenzene by *t*-butylhydroperoxide, $C_6H_5\dot{N}OH$ has been detected by ESR spectroscopy.[17] Therefore, it may be reasonable to assume that this radical will be produced as an intermediate of the photochemical reduction of nitrosobenzene to phenylhydroxylamine, which may then couple immediately with nitrosobenzene to form azoxybenzene.[18]

A Modified Wittig Synthesis of 6,10-Dimethyl-3,9-undecadien-2-one, Ethyl 5,9-Dimethyl-2,8-decadienonate, and Their α-Alkyl Homologs: Stereochemistry of the Reaction and Conformation of the Products

Kazuhiro SASAKI

Ichikawa Works, Kobayashi Perfumery Co., Ltd., Ichikawa, Chiba

(Received October 16, 1967)

In previous papers,[1-3] the modified Wittig reaction of citrals with diethyl 2-oxophosphonates was described. When the substituent on the α-carbon atom of the phosphonate was methyl group or hydrogen, the resultant C=C double bond of the condensation product had only *trans* configuration.

On the other hand, when the substituent was ethyl group, the formation of small amounts of *cis* isomers was observed together with the major formation of *trans* isomers.

It was of interest to investigate whether the saturation of the α,β-unsaturated linkage to the aldehydic group in citrals affects the stereochemistry of the reaction. I the present report, β-citronellal (I) was condensed with various diethyl 1-alkyl-2-oxoalkylphosphonates (II) or diethyl 1-ethoxycarbonylalkylphosphonates (III) under usual reaction conditions.

$$(EtO)_2P(O)\underset{\displaystyle R}{\underset{|}{C}}HCOR' \xrightarrow[\beta\text{-Citronellal (I)}]{NaNH_2}$$

II: R′=Alkyl
III: R′=OEt

$$CH_3\underset{\displaystyle CH_3}{\underset{|}{C}}=CHCH_2CH_2\underset{\displaystyle CH_3}{\underset{|}{C}}HCH_2CH=\underset{\displaystyle R}{\underset{|}{C}}COR'$$

IV:	R=H, R′=CH_3	VIII:	R=H, R′=OEt
V:	R=CH_3	IX:	R=CH_3
VI:	R=C_2H_5	X:	R=C_2H_5
VII:	R=H, R′=C_2H_5		

The results are summarized in Table 1. From these data the following points were notable: i) The relative amounts of the *cis* isomers in the products augmented with increasing size of the alkyl substituent on the α-carbon atom of the phosphonates. ii) The ethoxycarbonyl group on the α-carbon atom of a phosphonate was advantageous over the alkyl group in increasing the *cis-trans* ratio of the resulted olefins. iii) Saturation of the α,β-unsaturated linkage in citrals increased the proportion of a *cis* isomer in the product, although the dominance of a *trans* isomer over a *cis* isomer was unchanged.

The infrared and ultraviolet absorption data of the products are given in Table 2. It is well known that the α,β-unsaturated carbonyl compounds may exist in two possible conformations, *i.e.*, *s-trans-* and *s-cis-*forms. In the case of 3-*trans*-V and 3-*trans*-VI, the difference of wave numbers between the C=O and the C=C stretching vibration is less than 30 cm^{-1} and the intensity of the K-band at 232—233 mμ is very strong. These spectral properties are probably ascribed to the *s-trans* conformation. On the other hand, 3-*cis*-V and 3-*cis*-VI appear to have the *s-cis* conformation, since the difference of the wave numbers between the C=O and the C=C stretching vibration is more than 60 cm^{-1} and the K-band is rather shifted bathochromically and is remarkably weakened in intensity.*1 The splitting of the C=O stretching infrared absorption bands of 3-*trans*-IV and 4-*trans*-VII may be ascribed to an equilibrium between the *s-trans-* and *s-cis-*conformations as demonstrated in the case of *trans*-3-penten-2-one and its analogs.[1,5] The ascription seems to be supported by the fact that each of the splitting carbonyl bands of 3-*trans*-IV and 4-*trans*-VII apparently corresponds in its position to the carbonyl bands of 3-*trans*-V and 3-*trans*-VI, and 3-*cis*-V and 3-*cis*-VI, respectively.

Examination of scale models reveals that 3-*trans*-IV and 4-*trans*-VII can exist as two hindrance-free conformers. In the case of 3-*trans*-V and 3-*trans*-VI, the *s-trans* conformation is less-hindered, while the steric hindrance of 3-*cis*-V and 3-*cis*-VI is apparently stronger in the *s-trans*-conformation than in the *s-cis*-. These considerations also substantiate the above conclusions.

Analogous considerations with scale models of the α,β-unsaturated carboxylates disclosed that either of the two possible conformations is substantially hindrance-free and therefore energetically more favored *s-trans* form is the preferred conformation.

In summary, apparent difference in a steric hindrance between an α,β-unsaturated ketone and the relevant carboxylate is probably one of the cause for the different *cis-trans* ratio in these compounds obtained by means of the modified Wittig reaction.

Diethyl 2-Oxoalkyl- and 1-Ethoxycarbonylalkylphosphonates. These phosphonates were prepared from triethylphosphite and appropriate α-bromocarbonyl compounds by means of Michaelis-Arbuzov reaction.[1,3]

3,6,10-Trimethyl-3,9-undecadien-2-ones (V). (*A typical Example of the General Procedure*). *Method A.* To a suspension of 1.56 g (0.04 mol) of sodium amide in 30 m*l* of dry dimethylformamide (DMF), there was added a solution of 8.33 g (0.04 mol) of diethyl 1-methyl-2-oxopropylphosphonate in 20 m*l* of dry DMF with stirring and cooling in an ice-salt bath. Stirring and cooling were continued and dry nitrogen gas was passed into the mixture until the evolution of ammonia had ceased. The resultant solution was cooled below −10°C and

treated dropwise with 6.17 g (0.04 mol) of β-citronellal in 20 m*l* of dry DMF. After the solution had stood overnight, the solvent was removed under vacuum and the residue was poured into water and extracted with ether. The ethereal extract was washed with water and dried over sodium sulfate. The solvent being evaporated, the residue was distilled under reduced pressure to yield V as a colorless oil.

Method B. To the carbanion of diethyl 2-oxopropylphosphonate, prepared from 7.77 g (0.04 mol) of the phosphonate in a manner similar to the Method A, there was added dropwise 5.96 g (0.042 mol) of methyl iodide with stirring and cooling in an ice-water bath and the mixture was allowed to stand overnight. After the mixture was cooled below −10°C, 1.56 g (0.04 mol) of sodium amide was added all at once and the mixture was stirred under a slow stream of dry nitrogen gas. The resultant carbanion of diethyl 1-methyl-2-oxopropylphosphonate was treated with β-citronellal in an analogous manner to the Method A to give V as a colorless oil.

Procedures similar to those described above gave the ketones IV, VI, and VII. A minor modification of the condensation conditions was required for the preparation of the carboxylates VIII, IX, and X; at 75°C for 3 hr (for the preparation of X, Method A) to 24 hr (for the preparation of IX, Method A).

The author is indebted to Professor Masaki Ohta and Assistant Professor Rokuro Sudo of the Tokyo Institute of Technology for their encouragement and support; to Mr. Kenjiro Kobayashi, President of Kobayashi Perfumery Co., Ltd., and Mr. Mitsuhiro Takahashi, Director of the same company, for their permission to publish this paper.

Determination of Complex Species by the Method of Continuous Variation Using Infrared Spectroscopy

Keikichi NAKAMURA

National Research Institute For Metals, 2-3-12, Naka-meguro, Meguro-ku, Tokyo

(Received August 19, 1967)

The method of continuous variations has been widely used to determine the composition of complex species using such intensive properties of the systems as visible and ultraviolet absorption[1,2] and conductivity.[3] Few studies, however, have used infrared absorption as a basis for this method, apart from those studies where hydrogen bonded systems arise,[4] in which case large shifts are usually found.

In the case of lanthanide salts-TBP(tributyl phosphate) systems, the stoichiometry of the solvates formed have thus far been determined only by liquid-liquid partition methods and solubility methods.[5,6]

Since the organic diluents employed in the above studies dissolve the lanthanide thiocyanates only sparingly or not at all, the method of continuous variations could not be employed. However, such diluents as acetonitrile appear to be compatible with the use of the continuous variation method, provided that an absorption change due to complex formation takes place.

This paper will report the results obtained by the method of continuous variations from an infrared spectroscopic study of the $Ln(SCN)_3$-TBP and -TPPO(triphenyl phosphine oxide) systems using acetonitrile as the diluent.

Experimental

The lanthanide thiocyanates were prepared by dissolving the appropriate oxides in warm, freshly prepared hydrogen thiocyanate and the free water was removed by vacuum evaporation. The TBP was purified by the method of Alcock *et al.*[7] The acetonitrile was purified by distilling it several times from P_2O_5. The TPPO was prepared by the Grignard reaction between phenylmagnesium bromide and phosphorous oxychloride. The resulting product was recrystallized several times from a mixture of ethanol and water. The infrared spectroscopic data were recorded as previously described. Procedure: 0.1 M (0.02 M) of TBP (TPPO) and equimolar lanthanide thiocyanate solutions were equilibrated in varying proportions according to the expression:

$$x = \frac{[\mathrm{Ln}]}{[\mathrm{Ln}] + [\mathrm{TBP(TPPO)}]}$$

Thus, the total concentration was kept at 0.1 M (0.02 M). It was assumed that no appreciable volume change took place on the equilibration.

Results and Discussion

The effect on the infrared spectra of representative lanthanide thiocyanate-TBP(TPPO)-acetonitrile solutions by varying the x parameter is shown in Fig. 1.

In the erbium thiocyanate-TPPO-acetonitrile system, as x increased, the free TPPO absorption band at 1192 cm^{-1} became increasingly weaker, while new absorption bands, which appeared at lower frequencies, became increasingly stronger. The examination of these new bands suggested that at least three species were present, represented by the absorption bands at 1142 cm^{-1}, 1157 cm^{-1} and 1169 cm^{-1}. A continuous variation analysis of these bands, shown in Fig. 2, indicates that the band at 1142 cm^{-1} represents the tri-solvated species, while the bands at 1157 cm^{-1} and 1169 cm^{-1} may be assigned to the mono- and di-solvated species respectively. The same assignment was found to be applicable for the yttrium and dysprosium systems as well.

In the case of the lighter lanthanide thiocyanate-TPPO complexes (*i.e.*, La and Ce), no distinct absorption bands could be distinguished, indicating that with them complex formation did not occur in distinct steps. For the lighter lanthanide thiocyanates, therefore, the strongest absorption, that at 1140 cm^{-1}, may be attributed to a tri- or tetra-solvated species.

As for the dysprosium thiocyanate-TBP-acetonitrile system, Fig. 1(b) will show that two distinct absorption bands appeared, one at 1216 cm^{-1} and the other at 1195 cm^{-1}, under the experi-

mental conditions of $0.05 \leqq x \leqq 0.15$. This result indicates the coexistence of two species, with the species absorbing at 1216 cm^{-1} predominantly. Under the conditions of $0.20 \leqq x \leqq 0.35$, the band at 1195 cm^{-1} became increasingly stronger, and when $x \geqq 4$, an absorption band appeared at 1212 cm^{-1} and increased in intensity as x increased. Thus, the results demonstrate the formation of at least three species, whose solvation number increases with respect to the observed absorption wavelength in the order: 1216 cm^{-1} > 1195 cm^{-1} > 1212 cm^{-1}.

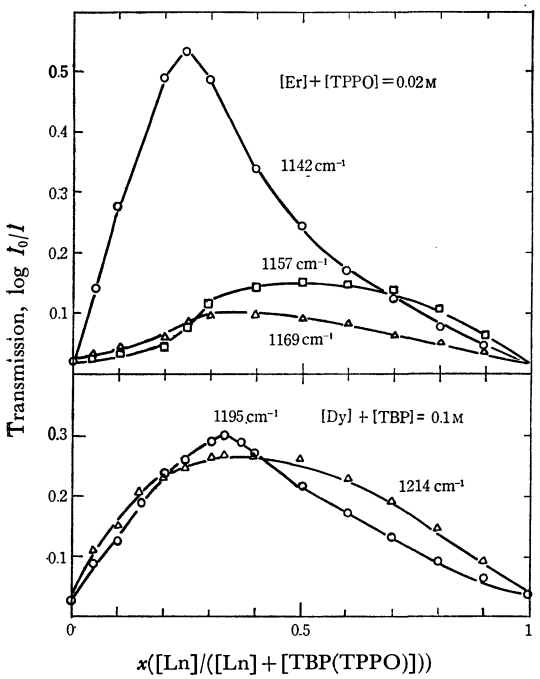

Fig. 2. Continuous variations for acetonitrile solutions of $Er(SCN)_3$-TPPO and $Dy(SCN)_3$-TBP.

A continuous variation analysis in this spectral region is shown in Fig. 2. An examination of Fig. 2 will show that the band at 1195 cm^{-1} may be assigned to the di-solvated species. The band at 1216 cm^{-1} and 1212 cm^{-1} overlap, which makes resolution very difficult. However, in view of the experimental conditions under which these two bands appeared, it is reasonable to assign the band at 1216 cm^{-1} to the tri- or tetra-solvated species, and the band at 1212 cm^{-1} to the mono-solvated species.

This study has revealed many difficulties in connection with the use of infrared spectroscopy on such systems. These difficulties may be listed as below:

1) The absorption shift due to complex formation is small.

2) Because of the strong absorption of the diluents the absorption frequency range for the detection of complex formation and the concentration range available are severely restricted.

3) The NaCl and KCl cells tend to dissolve slightly in polar diluents, and trace amounts of water cause frosting of the optical surface of the cell.

In spite of the above difficulties, however, infrared spectroscopy can be used for the determination of complex species provided that, with the above qualifications in mind, a suitable choice is made of the diluent, the material of construction of the cell, and the range of absorption frequency used for detection.

The author wishes to express his thanks to Dr. Kazutaka Kawamura and Dr. Akira Kawase for their encouragement and discussions. He also wishes to express his thanks to Dr. D. S. Flett of the Warren Spring Laboratory for his helpful discussions.

Comparison of Metal Bath Techniques in Vacuum Fusion Analysis by an Isotope Dilution Method

Hitoshi KAMADA and Keiichi FURUYA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received September 19, 1967)

Many applications of metal bath techniques to vacuum fusion analysis have been reported. In these reports, metal bath techniques are used to promote a reaction between carbon and oxygen in a flux and/or to eliminate a gettering action by the adsorptive elements evaporated from the samples. Beach and Guldner[1] measured the effect of evaporated films of carbon, nickel, iron, germanium, platinum, aluminum, manganese and titanium on the recovery of carbon monoxide, nitrogen and hydrogen at a crucible temperature of 1650°C.

Sloman[2] pointed out that carbon in the iron bath is very reactive, and the iron metal depresses the vaporization of adsorptive elements. McDonald,[3] and Smith,[4] on the other hand, showed that carbon

2) H. A. Sloman, *J. Inst. Metals*, **71**, 391 (1945).

3) R. S. McDonald, J. E. Fagel and E. W. Balis, *Anal. Chem.*, **27**, 1632 (1955).

4) W. H. Smith, *ibid.*, **27**, 1636 (1955).

becomes easily oversaturated in an iron flux at high temperature and the bath becomes very viscous, which gives erroneous low results. Smiley,[5] and Gregory[6] used platinum metal as a metal bath for the determination of oxygen in titanium, and Ogahara[7] used it for oxygen analysis in stainless steels. Platinum metal has a low vapor pressure, which minimizes the amount of metal evaporating to the furnace walls, and does not become viscous. Wilkins[8] reported that the platinum bath does not adsorb the extracted gases. Tin has been used by many investigators as a metal bath in order to eliminate the adsorption of the extracted carbon monoxide by manganese evaporated from a flux. Guldner[9] pointed out that the function of the tin in the case of addition of both iron and tin to the crucible is two-fold: first, to increase the fluidity of the bath, and second, to act as a mechanical stirrer.

A method of isotope dilution employed in the determination of gases in metals has been reported by Kirshenbaum and Grosse,[10] Pearce,[11] and Burden.[12]

An isotope dilution method using ^{18}O-labelled carbon monoxide was employed in the present paper for the determination of oxygen in a high manganese steel without the bath technique, and with iron, platinum and tin bath techniques. When isotopic equilibrium is established only in the gas phase, this method gives results in which gas adsorption errors have been eliminated.

Experimental

The apparatus used is identical to that reported previously.[13,14]

NBS standard steel 1041 containing 1.2% manganese was used as a sample. Specimens for each metal bath were neighboring sections cut out parallel to the aixs in order to avoid the effect of sedimentation. They were then polished with carborundum paper, rinsed in petroleum benzene, and dried in air.

^{18}O-labeled carbon monoxide was prepared from $Hg^{18}O$ (about 90 atom%^{18}O), produced by the BIO-RAD Laboratory, Richmond, California, U.S.A.

Carbon Monoxide Adsorption Curves. After outgassing the graphite crucible, 10 g of the bath metal listed above was added and fused to be degassed at 1850°C, while metal vapor deposited continuously on the surface of the walls. A measured quantity of carbon monoxide was admitted from a storage bottle and circulated in the system. The recovery of carbon monoxide was measured. Figure 1 shows the carbon monoxide adsorption curves.

When 5 g of the sample was added to the fused metal, the carbon monoxide adsorption rate increased in platinum and in iron, while it did not change in tin. These phenomena may be related to the magnitude of the chemical affinity between the metal and carbon monoxide.

Determination of Oxygen in NBS 1041. The methods of isotope dilution and vacuum fusion were applied to the determination of oxygen in a sample of NBS standard steel 1041 using the above mentioned metal baths. The procedures employed were identical to those reported previously.[14]

In Table 1 are summarized these data, which are the arithmetic means of three or four determinations from outer portions of every sample rod.

When no metal bath was used, the oxygen content of the initial six specimens could not be determined owing to the large adsorption of carbon monoxide in the furnace. During 3 min of gas circulation, carbon monoxide in the system was completely adsorbed, so their isotope concentrations could not be measured. However, in the case of the final three specimens, the gas adsorption became rather small, and the isotope concentrations could be measured.

In the platinum bath method, the isotope concentration of residual gas extracted from the furnace after gas circulation was close to that of the collected gas sample. This indicates that almost all of the oxygen in the sample was already extracted from the crucible. However, there were marked differences between the results of the isotope dilution method and the vacuum fusion method caused by gas adsorption in the furnace.

In the iron bath method, the results were close to those in the case of the platinum bath in the isotope dilution method, while the results in the vacuum fusion method were lower than those in the platinum bath method. This is related both to the gas adsorption property of iron, and to the fatigue of bath action caused by carbonization viscousness. The isotope concentration of the residual gas was close to that of the collected gas sample.

In the tin bath method there were no differences between results of the isotope dilution and the vacuum fusion method. This shows that there is no gas adsorption lowering the vacuum fusion results in the tin bath method. The isotope concentration in a small quantity of the residual gas was about 90 atom% ^{16}O, and this shows that the oxygen in the sample was incompletely decomposed and remained in the crucible.

In argon fusion analysis using no metal bath,[15] the results agreed well with those obtained by the isotope dilution method with the tin bath.

The results of the isotope dilution method and the data obtained for the ^{18}O concentration of the residual gas indicate that the platinum and iron baths can promote reaction between carbon and oxygen in a melt. That these metal baths can partly suppress carbon monoxide adsorption is shown by a comparison of their data with the data in which no metal bath was used. The tin bath can effectively prevent the adsorption of carbon monoxide in the furnace, and does not promote the reaction in a flux.

From this consideration, though the vacuum fusion results for the platinum and tin baths are apparently in agreement, the processes of the extraction of oxygen were different from each other. In the platinum bath, part of the extracted carbon monoxide, after the promotion of the reaction by platinum, was adsorbed by the adsorptive elements such as manganese, while in the tin bath all of the incompletely extracted carbon monoxide was collected. When the metal bath technique was not used, extraction of oxygen was also incomplete.

According to the above consideration, it is desirable to use a combination bath, one containing a metal which promotes reaction in the flux, and also a metal which prevents the adsorption of carbon monoxide in the furnace. From this point of view, the mechanism of the iron-tin bath method, and the platinum-tin bath method can both be well explained.

Studies on Heteroaromaticity. XIV.[1] Ring-opening Reaction of *N*-[β-(5-Nitro-2-furyl)vinyl]- and *N*-(2-Furyl)-*N'*-ethyleneurea

Tadashi SASAKI and Yoshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received October 25, 1967)

In the previous paper[2] we reported the ring-opening reaction of β-(5-nitro-2-furyl)acryloyl- and furoyl aziridine. In this paper the similar ring-opening reaction and nucleophilic rearrangement reaction of *N*-[β-(5-nitro-2-furyl)vinyl]- and *N*-(2-furyl)-*N'*-ethyleneurea will be described.

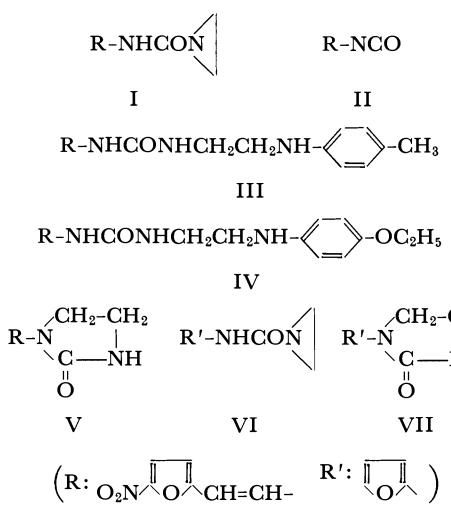
N-[β-(5-Nitro-2-furyl)vinyl]-*N'*-ethyleneurea (I) was easily prepared in 90% yield by the Curtius rearrangement of β-(5-nitro-2-furyl)acryloyl azide[3] in boiling benzene, followed by treatment with aziridine. β-(5-Nitro-2-furyl)vinyl isocyanate (II), the Curtius rearrangement product, could be isolated in quantitative yield by removing benzene prior to addition of aziridine in the former reaction. Compound I was treated with *p*-toluidine or *p*-phenetidine at room temperature for one month to give the corresponding ring-opened compounds, III or IV, in yields of 18% or 12% respectively. Compound I was refluxed in acetone or acetonitrile in the presence of sodium iodide to afford the rearranged imidazolidine-2-one (V) in 85% or 90% yield. The structure of V was confirmed by the following spectral data: the IR spectrum showed characteristic absorptions at 3420 (ν_{NH}) and 1730 cm^{-1} (ν_{CO} of five-membered ureide[3]), the UV spectrum showed λ_{max}^{DMSO} 440 mμ ($\varepsilon = 13800$), somewhat shifted bathochromically

1) Part XIII of this series: T. Sasaki and K. Shoji, *Yuki Gosei Kagaku Kyokai-shi* (*J. Soc. Org. Synth. Chem. Japan.*), **26**, 432 (1968).
2) T. Sasaki and T. Yoshioka, *ibid.*, **25**, 658 (1967).
3) A. Sugihara and M. Ito, *Yakugaku Zasshi* (*J. Pharm. Soc. Japan*), **86**, 269 (1966).

compared with that of I, and the NMR spectrum in DMSO-d_6 showed singals at 6.04 τ (multiplet, 4 H, methylene protons) and at 2.20 and 4.31 τ (each doublet, 1 H, $J=14.5$ cps, methine protons in a trans-configuration) and at 2.40 τ (broad, 1 H, N*H*, disappeared by deuteration) besides those due to furan ring protons.

Similarly, *N*-furyl-*N'*-ethyleneurea (VI) was prepared in 60% yield from furoyl azide.[4] This somewhat lower yield compared with that of I may be explained by the different stability of the intermediate isocyanates.[4] Compound VI was refluxed in acetone with sodium iodide to give 1-(2'-furyl)imidazolidine-2-one (VII) in 50% yield.

The mechanism of these rearrangements of I and VI to the corresponding imidazolidine-2-ones, V and VII, will be explained by Heine's theory about the rearrangement of the corresponding phenyl derivatives.[5] All attempts to isomerize I or VI with hydrochloric acid, hydrobromic acid and acetic acid failed and resulted in the formation of intractable tars.



Experimental

***N*-[β-(5-Nitro-2-furyl)vinyl]-*N'*-ethyleneurea (I).** A solution of 5.0 g (0.025 mol) of β-(5-nitro-2-furyl) acryloyl azide[3] in 40 m*l* of dry benzene was refluxed in an oil bath at 105°C for 7 hr until the evolution of nitrogen had perfectly ceased. After filtering off a small amount of an insoluble material, the filtrate was cooled to 10°C and a solution of 2.0 m*l* of aziridine in 10 m*l* of dry benzene was added dropwise to the cooled solution and the resulting reaction mixture was stirred at 10°C for 1 hr and then, at room temperature for 1 day. Precipitated crystals were collected and washed with a small amount of benzene to afford I as red crystals, mp 181—182°C (EtOH–C_6H_6).

Found: C, 48.06; H, 3.96; N, 18.66%. Calcd for $C_9H_9O_4N_3$: C, 48.43; H, 4.06; N, 18.85%.

UV: λ_{max}^{DMF} mμ (ε) 421 (17900). IR: (KBr) cm^{-1} 3350 (ν_{NH}), 1678 (ν_{CO}).

β-(5-Nitro-2-furyl)vinyl Isocyanate (II). The above experiment was repeated and after filtering off a small amount of an insoluble material, benzene used as a solvent was removed under reduced pressure at room temperature and the residual yellow crystals were recrystallized from a small amount of benzene to give II of mp 88—89°C, indicating a characteristic IR absorption at 2260 cm^{-1} (ν_{NCO}).

Found: C, 46.58; H, 2.19; N, 15.63%. Calcd for $C_7H_4O_4N_2$: C, 46.67; H, 2.24; N, 15.55%.

Reaction of I with *p*-Toluidine. I, 0.5 g (0.002 mol), was melted with 0.5 g (0.004 mol) of *p*-toluidine at 50°C and the mixture was kept standing at room temperature for 1 month. Solidified masses were dissolved in chloroform and chromatographed on a silica gel column, using chloroform as an eluent. From the first and second fractions of the chromatography there obtained a small amount of intractable red oils, which were not further investigated and discarded; from the third fraction there obtained 0.15 g of purple-red crystals of mp 179—180°C (EtOH), the structure of which was confirmed as III by the following spectral data: IR spectrum (KBr disk), 3380 (ν_{NH}), 1687 (ν_{CO}) cm^{-1} and UV spectrum, λ_{max}^{EtOH} 412 ($\varepsilon=13400$) and 253 ($\varepsilon=17200$) mμ, shifting hypsochromically compared with **I**.

Found: C, 58.38; H, 5.39%. Calcd for $C_{16}H_{18}O_4N_4$: C, 58.17; H, 5.49%.

Reaction of I with *p*-Phenetidine. Similarly, red crystals of mp 194—195°C were obtained in 12% yield. The structure was confirmed as IV, considering from the similar spectral patterns as III.

Found: C, 56.34; H, 5.73%. Calcd for $C_{17}H_{20}O_5N_4$: C, 56.66; H, 5.59%.

1-(5'-Nitro-2'-furyl)vinylimidazolidine-2-one (V). I, 0.38 g (0.0015 mol), was dissolved in 20 m*l* of acetone and 0.22 g (0.0014 mol) of sodium iodide was added to this solution. The mixture was refluxed for 17 hr. During this period of time a crystalline substance was separated. After cooling, it was collected and recrystallized from a mixture of DMF and EtOH to give V as red crystals, mp 237—239°C (decomp).

Found: 48.41; H, 4.22; N, 18.58%. Calcd for $C_9H_9O_4N_3$: C, 48.43; H, 4.06; N, 18.83%.

***N*-Furyl-*N'*-ethyleneurea (VI).** Similarly as for the preparation of I, from furyl isocyanate, which was prepared in 70% yield from furoyl azide by the known procedure,[4] bp 111°C, and aziridine there obtained VI as white needles (petroleum ether + benzene), mp 98—99°C.

Found: C, 55.26; H, 5.16; N, 18.00%. Calcd for $C_7H_8O_2N_2$: C, 55.25; H, 5.30; N, 18.41%.

UV: λ_{max}^{EtOH} mμ (ε) 250 (13300). IR: (KBr) cm^{-1} 3200 (ν_{NH}), 1700 (ν_{CO}).

1-(2'-Furyl)imidazolidine-2-one (VII). VI, 0.4 g (0.0034 mol), was dissolved in 20 m*l* of dry acetone and 0.32 g (0.002 mol) of sodium iodide was added to this solution. After refluxing the reaction mixture for 11 hr, the solvent was removed under reduced pressure, 50 m*l* of water was added to the residue and the solution was extracted with ether. The ether extract was dried over anhydrous sodium sulfate and the ether was removed. The residue was recrystallized from benzene - petroleum ether to give VII as colorless crystals, mp 124—126°C.

5) H. W. Heine, *Angew. Chem.*, **60**, 540 (1962).

Found: C, 55.08; H, 4.96; N, 18.20%. Calcd for $C_7H_8O_2N_2$: C, 55.25; H, 5.30; N, 18.41%.

UV: λ_{max}^{EtOH} mμ (ε) 253 (13500). IR: (KBr) cm^{-1} 3230 (ν_{NH}), 1710 (ν_{CO}).

The authors wish to thank Mr. Akiho Ishihara at their laboratories for microanalyses and the Ueno Pharmaceutical Co. for kind supply of some starting materials. For the NMR spectral measurements the authors are much indebted to the Dainippon Pharmaceutical Co.

The Dipole Moment and Polarizability in the Excited State of *p*-Nitroaniline from Spectral Solvent Shifts

Takehiro ABE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received November 2, 1967)

The absorption spectrum of *p*-nitroaniline in vapor has not yet been reported on, although there have been many data on the solvent effects. This paper will aim to estimate the dipole moment and polarizability in the π-π^* excited state of *p*-nitroaniline by a method similar to that used in previous papers[1,2] without a spectral datum on the absorption transition of *p*-nitroaniline in vapor.

Considering an unperturbed solute molecule and the solvent molecules already interacting with one another in the zeroth-order approximation, one may write an absorption frequency in cm^{-1} in a transition from the ground state to the *i*th excited state of the solute molecule in the solution as follows by the same procedure as was used in Ref. 1 :

$$\begin{aligned}\nu_{i0} = {} & \nu_{i0}^0 - 1.007\times10^{65}(\mathrm{erg^{-1}cm^{-1}})\times(d^v/M^v)^{2/3} \\ & \times[\{(M^u/d^u)^{1/3}+(M^v/d^v)^{1/3}\}^{-4}+\{(M^u/d^u)^{1/3} \\ & +3(M^v/d^v)^{1/3}\}^{-4}+\{(M^u/d^u)^{1/3} \\ & +5(M^v/d^v)^{1/3}\}^{-4}]\times[(2/3\boldsymbol{kT}) \\ & \times(\mu_1^v)^2\{(\mu_i^u)^2-(\mu_0^u)^2\}+3.963\times10^{-25} \\ & \times(M^v/d^v)\times\{(n^v)^2-1\}/\{(n^v)^2+2\} \\ & \times\{(\mu_i^u)^2-(\mu_0^u)^2\}+(\mu_1^v)^2\{(\alpha_i^u)-(\alpha_0^u)\} \\ & +5.945\times10^{-25}\times(M^v/d^v) \\ & \times\{(n^v)^2-1\}/\{(n^v)^2+2\}\times I_0^v \\ & \times\{(I_0^u-\boldsymbol{hc}\nu_{i0}^0)/(I_0^v+I_0^u-\boldsymbol{hc}\nu_{i0}^0)\times(\alpha_i^u) \\ & -I_0^u/(I_0^v+I_0^u)\times(\alpha_0^u)\}] \qquad (1)\end{aligned}$$

where M is the molecular weight, d is the liquid density, n is the refractive index, I is the ionization potential, μ is the permanent dipole moment, α is the isotropic polarizability, and $\boldsymbol{k}$, $\boldsymbol{c}$, and T have the usual meanings. Here ν_{i0}^0 is the frequency in the vapor, and μ_1 is the liquid dipole moment. The notations u and v refer to the solute and the solvent respectively. The subscript zero indicates the ground electronic state.

The procedure of calculation is as follows : Taking the value of $(I_0^u-\boldsymbol{hc}\nu_{i0}^0)$ which has been calculated with an arbitrary value for ν_{i0}^0, one applies Eq. (1) to the observed frequencies for various solvents and estimates the values of ν_{i0}^0, μ_i^u, and α_i^u by the least-squares method. Next, using the new value of ν_{i0}^0 estimated above, one recalculates the value of $(I_0^u-\boldsymbol{hc}\nu_{i0}^0)$ and continues the iterative process until the value of ν_{i0}^0 no longer changes.

In applying Eq. (1), the temperature was assumed to be 20°C. The values of d and n were taken from tables.[3,4] The value of 6.13 *D*[5] was used for μ_0^u (gas). The value of α_0^u was calculated as 157×10^{-25} cm^3 from a combination of the bond refractions and the value[5] observed for a deformation polarization of nitrobenzene. Neglecting α_0^u and α_i^u in Eq. (1), the author preliminarily obtained 33420 cm^{-1} and 20.9 *D* for ν_{i0}^0 and μ_i^u respcctively. Starting with these values, the author has finally estimated as follows; $\nu_{i0}^0=33740$ cm^{-1}, $\mu_i^u=10.26$ *D*, and $\alpha_i^u=729.8\times10^{-25}$ cm^3. By putting the above values into Eq. (1), the author has calculated the frequencies for the solutions listed in Table 1.

The ν_{i0}^0 value of 33740cm^{-1} is larger than the value of 32300 cm^{-1} calculated by Tanaka.[7] According to Tanaka,[7] the absorption band is a charge-transfer one and is polarized along the two-fold symmetry axis of the molecule. The large dipole moment in the excited state may be due to the charge transfer. The μ_i^u value of 10.26 *D* is smaller than

Experimental

p-Nitroaniline was recrystallized twice from water. All the solvents used were of a spectroscopic grade. The absorption spectra were obtained at room temperature by means of a Hitachi 139 spectrophotometer.

The Estimation of Free Ion Life Time by Pulse Electrical Conductivity Measurement

Kanae HAYASHI, Torao TAKAGAKI, Kiyoshi TAKADA, Koichiro HAYASHI and Seizo OKAMURA

Osaka Laboratories for Radiation Chemistry, Japan Atomic Energy Research Institute, 508 Mii, Neyagawa, Osaka

(Received November 13, 1967)

Hitherto the electrical conductivity measurements of liquid under the ionizing radiation have been reported in many compounds[1-5] to investigate the mechanism of free ion generation, however less attention had been paid for their life times.[2a,4] Nevertheless, the determination of free ion life time seems to be required in relation to active species of radiation-induced ionic reaction, especially polymerization.[6]

The life time of free ion, τ, was proved to be given by following equation,

$$\tau = \frac{\varepsilon}{4\pi\sigma} = 2.8\times10^{-13}\frac{\varepsilon}{\pi\sigma} \qquad (1)$$

and to depend only on the steady state specific conductance, σ,[4] where ε represents a dielectric constant. The measured life times are known to be fairly long for radiation-induced intermediates at room temperatures,[2a,4] for instance in *n*-hexane, 120 msec at the dose rate of 10^{14} eVcm^{-3}sec^{-1} or 2.6 R sec^{-1},[5] though such a long life time may be understood in terms of extremely diluted steady state concentration of free ions (in above instance, roughly 10^{-11} M). In order to confirm the previously reported free ion life times,an estimation was made by a completely different method from the steady state conductance method using Eq. (1).

When reaction intermediates generated by photoillumination disappear through bimolecular reaction, it is widely known that its steady state life time is estimated by the method of "intermittent illumination" or "rotating sector."[7] On the other hand, in our systems under investigation, a bimolecular decay of charged species through a neutralization between positive and negative ions has been established by the square root dependence of specific

conductance on dose rate[1a,1b,2a,4,5] and decay behavior of cell current after an interruption of irradiation.[1a,1b,4] So as to apply the "intermittent illumination" method into the life time determination of free ion, Van de Graaf electron accerelator was modified for a repeated pulse irradiation and measurements of time-averaged ion currents were carried out.

Experimental

Distilled cyclohexane (Merk, spectrograde) was degassed in a vacuum line and dried through repeated contacts with sodium-potassium alloy. Then it was vacuum-distilled into a glass cell with stainless steel parallel plate electrodes of 30 mm diameter situated in a distance of 5 or 9 mm and sealed off under 10^{-5} mmHg. The details of electrical conductivity measurement were described elsewhere.[4] For the direct reading of average iron current under pulse irradiation, digital electrometer was connected to the output of vibrating reed electrometer. Measurements were carried out at room temperatures (15 ± 1°C).

Van de Graaf electron accerelator(High Voltage Corp.) was modified for the pulse irradiation applying pulsed negative voltage to a plate which is located just outside of filament. Only four kinds of pulses were available. Their repetition times are 10, 31, 120 and 250 msec. Synchroscopic traces of each pulse pattern were shown in Fig. 1. Except for superimposed a.c. signals on each top of pulses, which seems to give no influence on ion current on average, they all are consisted of rectangular wave. Irradiation ratio, a ratio of an irradiation interval of one pulse to the pulse repetition time, β, was maintained in all pulses to be 0.42, which is determined by the limitation of pulser.

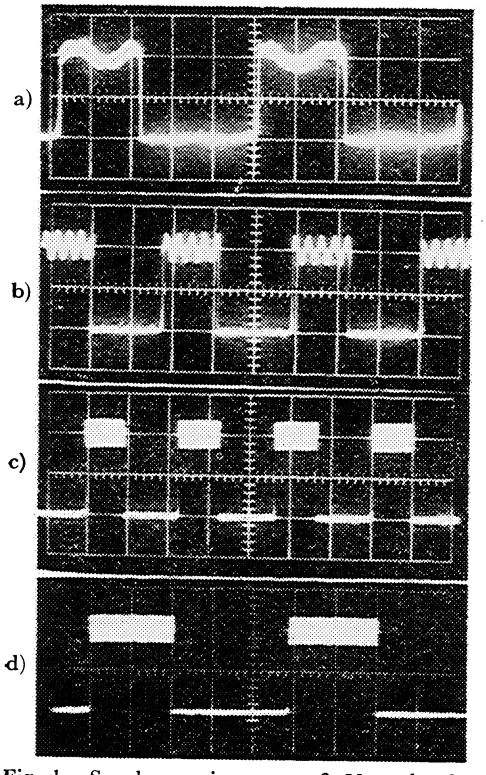

Fig. 1. Synchroscopic traces of Van de Graaf electron pulses ($\beta=0.42$).
Repetition times are; a) 10 msec (2 msec/div.), b) 31 msec (10 msec/div.), c) 120 msec (50 msec/div.), d) 250 msec (50 msec/div.).

Results

Cell current ratios, $i/\sqrt{\beta i_s}$, are shown in Fig. 2 for four kinds of pulses keeping the dose rate of each series invariable. Here, i and i_s represent an average cell current under pulse irradiation and that under the steady irradiation operated to have the same peak beam current as the corresponding pulses, respectively. It is valid that the cell current ratios gradually decrease at longer pulse repetition time and the three curves corresponding to the different dose rates are similar in their shape; at lower dose rate, the curve moves to the direction of slower pulse. These results qualitatively agree with the expected consequence from the ordinary kinetics of intermittent illumination,[7] indicating a bimolecular disappearence of charge carriers.

However, at the pulses of 120 and 250 msec, all the experimental curves show negative deviations from the kinetically calculated curve for $\beta=0.42$, given with a broken line in Fig. 2, and consequently considerable amounts of errors on the free ion life times are introduced since life times are determined through appropriate overlapping of experimental curves onto the kinetically calculated one. Such a negative deviation was always observed irrespective to the electrode distance, applied voltage or the effect of electrodes irradiation.

With no regard for such deviations, the free ion life times are roughly estimated at several dose rates and at various field strengths as shown in Fig. 3. Vertical lines above and below the each point show a

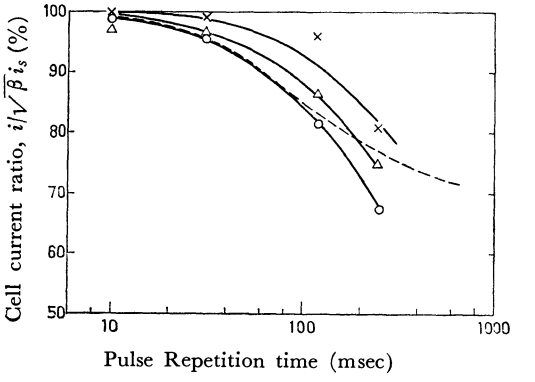

Fig. 2. Pulse repetition time *vs.* cell current ratio in cyclohexane at several dose rates; ○ 3.7×10^{14}, △ 1.5×10^{14}, × 3.7×10^{13}, eV cm^{-3} sec^{-1}. Applied voltage; 400 V. The distance between electrodes, 0.89 ± 0.05 cm. Broken line denotes the theoretical curve for $\beta=0.42$ drawn to fit lowest experimental curve.

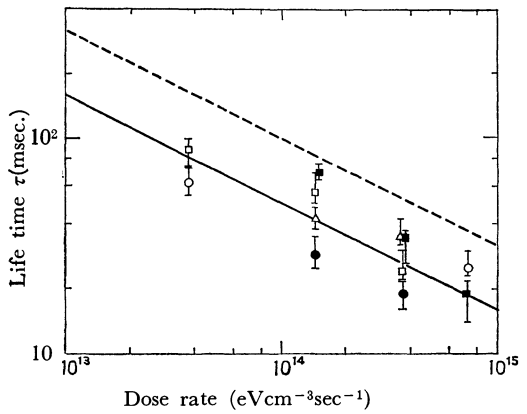

Fig. 3. Dose rate *vs.* estimated life time in cyclohexane at various field strength; ○; 800; ●; 440, □; 400, ■; 165, △; 40 Vcm^{-1}. Broken line denotes the life time calculated by steady state conductivity.

probable limit of error which may be introduced by the overlapping procedure of curves. Though the estimated life times scatter so much at a fixed dose rate, no systematic variation due to the field strength can be recognized. Thus estimated life time, as shown with solid line in Fig. 3 agreed with the calculated one by steady state conductance, dotted line, within a factor of two. The difference between the life times obtained through two independent methods may be attributed to the incompletion of both methods as the life time determination method. Even in steady state conductance measurements, the results from three independent experiments do not show so good agreements each other.[1a,2b,5]

Discussion

As reasons for the deviation of experimental curves from the kinetically calculated one, at first a deformity of pulse shape, an inhomogenity of ionic concentration to the direction perpendicular to the electric field attributed to an insufficient penetration of radiation and a competitive unimolecular decay of ions due to discharge at the electrodes are considered. However, corrections to the ordinary kinetics of intermittent illumination[7] indicate that such effects cannot account for the negative deviation at long repetition time pulses. If there were to be a distribution in the free ion life time, the observed deviation would be positive. Another possibility is an inhomogenity of ionic concentration to the direction of the electric field, which arises from a translational motion of ions along the field.

In the dark period between the pulses, there appear space-charge regions where positive or negative ions are exclusively present in neighborhood of anode and cathode respectively, since ions move toward the oppositely charged electrode all the time when a diffusional motion of charges is disregarded. Namely, the influence of the space-charge region on an average cell current should be considered from the both points of view *i.e.* the decrease of the space-averaged ionic concentration and the decrease of field strength in bulk region. A modified kinetics of intermittent illumination taking account of the space-charge regions under the assumption of the uniform field strength along the electrode distance[8] indicates that the deviation from the ordinary kinetics in cell current ratio-repetition time curve is negative and is proportional to the dark period or repetition time. Moreover, in the dark time, the observed cell current is expected to become smaller because of the decreasing field strength of bulk regions with time. In consequence, the deviation from the ordinary kinetics is negative and proportional to several powers of the pulse repetition time, which is consistent with our results; negative deviation at longer repetition time pulses, especially at the longest repetition time pulse.

At all events, pulse irradiation effect on cell current ratio was observed at the repetition time between 10 and 250 msec, the same range as the free ion life times estimated by steady state conductivity measurement. It confirms the validity of the free ion life time estimation method by steady state conductivity measurement.

Correction of the Absolute Configuration of Nuphar Alkaloids

Ichiro KAWASAKI, Isao KUSUMOTO and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

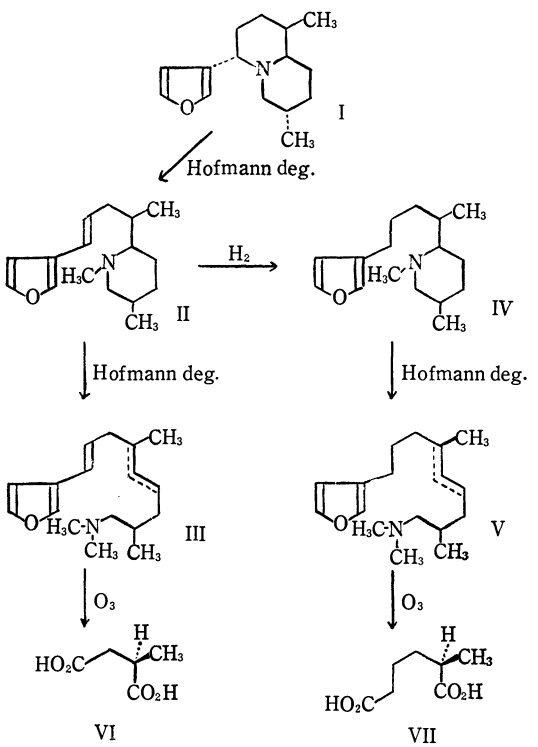
(Received December 5, 1967)

Previously, we reported the determination of the absolute configuration of *Nuphar* alkaloids[1] on the basis of (−)-α-methyladipic acid (VII), an oxidation product from anhydrodihydrodes-*N*-methyldeoxynupharidine (V), having the S-configuration. This configurational assignment of (−)-α-methyladipic acid was derived from the basis of its synthesis from (−)-α-methyl-γ-butyrolactone which was correlated with S(−)-methylsuccinic acid.[2],*1

Recently Turner *et al.* obtained R(−)-α-methylglutaric acid, R(+)-β-methyladipic acid and (−)-α-methyladipic acid from the oxidation of cytochalasins A and B,[3] metabolites of *Helminthosporium dematioideum*, and they suggested that (−)-α-methyladipic acid is shown to have the R-configuration.[4]

Now we reinvestigated the oxidation of the second Hofmann degradation product of deoxynupharidine (I) and found that the oxidation of anhydrodes-*N*-methyldeoxynupharidine (III) gave R(+)-methylsuccinic acid (VI).

Therefore (−)-α-methyladipic acid should have R-confuguration as was suggested by Turner and the stereostructures of nuphar alkaloids are shown to have the antipodal configuration of the previously presented formulae[5-7] (*e.g.* formula I is given to the stereostructure of the main alkaloid deoxynupharidine.).



Experimental

Anhydrodes-*N*-methyldeoxynupharidine (III). Deoxynupharidine (I) methoiodide (40 g) was dissolved in methanol (300 m*l*) and shaken with silver oxide (prepared from 50 g of silver nitrate) for 1 hr and then filtered. The filtrate was evaporated and heated on the water bath for 2 hr. The reaction mixture was extracted with ether and the ethereal solution was washed with water. The solvent was evaporated and the residue was distilled at 113—115°C/10^{-3} mmHg to give 20.5 g of des-*N*-methyldeoxynupharidine.

To the above oil (20.5 g) was added methyl iodide (25 g) and then the methoiodide obtained was subjected to Hofmann degradation in the same manner mentioned above to give 14.6 g of anhydro base, bp 125°C/10^{-3} mmHg.

Oxidation of the Anhydro Base. The above anhydro base was dissolved in chloroform (200 m*l*) and treated with a stream of oxygen containing ozone under ice-salt cooling. To the reaction mixture was added water (600 m*l*) and heated on the water bath under removing the chloroform by evaporation, then 30% hydrogen peroxide (600 m*l*) was added to the solution and heated for an additional 4 hr. The resulting mixture was extracted continuously with ether for 36 hr and water was added to the ether extract, then the solvent removed. The residual aqueous solution, after decomposition of a remaining hydrogen peroxide by the addition of sodium bisulfite, was reextracted with ether and the dried ether extract was methylated with ethereal diazomethane. The obtained methyl esters were separated by fractional distillation. An ester distilled at 100—103°C/21 mmHg gave dimethyl methylsuccinate which was identical with an authentic specimen in IR spectra. The ester was boiled

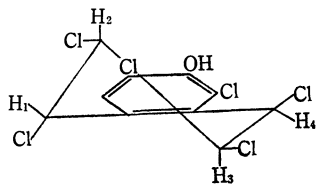
Additive Chlorination of 1-Iodonaphth-2-ol

Hitomi SUZUKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 9, 1967)

Naphth-2-ols with a substituent at the 1-position usually react with chlorine in an additive way to yield, depending on the amount of chlorine consumed, derivatives of either 2-keto-1,2-dihydronaphthalene or 2-keto-1,2,3,4-tetrahydronaphthalene.[1] An exception is 1-iodonaphth-2-ol. The conventional procedure involving chlorination in acetic acid has been found to result in the displacement of the iodine atom by chlorine, giving 2-keto-1, 1, 3, 4-tetrachloro-1, 2, 3, 4-tetrahydronaphthalene (mp 100—102°C)[1] as the final product. It had strong infrared absorptions in Nujol at 722, 760, 847, 1153, and 1751 cm^{-1}. Its PMR spectrum in carbon tetrachloride at 60 Mc/sec showed two doublets, due to aliphatic protons, at 4.67 and 5.11 τ (J—4.8 cps) and two aromatic multiplets, at 1.70—1.95 and 2.20—2.65 τ. The formation of remarkable amounts of polymeric substances accompanied the reaction. The use of an aprotic solvent such as chloroform, however, showed another mode of chlorine addition to the naphth-2-ol system. The saturation of the solution with chlorine also led to a considerable formation of resinous by-products, and the removal of the solvent together with the iodine liberated gave a light brown syrup which, on standing, slowly separated pale yellow fine needles (mp 149—150°C after recrystallization from hot ligroin (bp 80—100°C)). Analysis showed this substance to fit the formula $C_{10}H_6Cl_6O$ (Found: C, 33.99; H, 1.72; Cl, 59.88; O, 4.72%. Calcd for $C_{10}H_6Cl_6O$: C, 33.84; H, 1.70; Cl, 59.94; O, 4.53%), and its infrared spectrum in Nujol had prominent peaks due to the -C-OH group at 1192, 1416 and 3460 cm^{-1}, but no carbonyl absorption. Its PMR spectrum run in deuterochloroform at 60 Mc/sec revealed the presence of four aliphatic protons (two doublets at 4.60 τ (H^1) and 4.38 τ (H^4), two quartets at 5.57 τ (H^2) and 4.84 τ (H^3); $J_{1,2}=3.1$ cps, $J_{2,3}=10.1$ cps, and $J_{3,4}=4.4$ cps), one aromatic proton (singlet at 2.43 τ), and a hydroxylic proton (somewhat broad) at 3.6 τ. Therefore, this adduct is a tetrachloride of a dichloronaphth-2-ol, in which two chlorine atoms belong to an aromatic ring and four to an aliphatic ring. The high value of the coupling constant, $J_{2,3}$, shows that the 2,3-pair of C–H bonds are trans-diaxially disposed; the low values of $J_{1,2}$ and $J_{3,4}$ shows, then, that the 1- and 2-hydrogen atoms are *cis*, and that the 3- and 4-hydrogen atoms are *cis* to each other. The sharp appearance of the OH stretching absorption indicates that the hydroxyl group is blocked on both sides by chlorine atoms and is prevented from polymeric association. Thus, the α-hydrogen atom with signals in the low field is probably at the 4-position, near the chlorine atom. By analogy with the well-established α-naphthalene tetrachloride,[2] the stereochemistry may be formulated as below;



Considering the great tendency of naphth-2-ols to undergo additive chlorination to form ketopolychlorides, this is an unusual result. One possible explanation for such an anomaly may be that chlorine first reacts with the iodine substituent to form an unstable naphthyliododichloride, and that the strong electron-withdrawing effect of the dichloroiodo group directs further chlorine addition in the opposite ring. Decomposition of the tetrachloride thus formed would lead to the above addition product. A similar case has earlier been reported in the spontaneous decomposition of naphth-1-yliododichloride to 1,1,2,3,4-pentachloro-1,2,3,4,-tetrahydronaphthalene and 1-chloro-4-iodonaphthalene.[3]

The author wishes to thank Dr. M. D. Johnson for determining the PMR spectra and Dr. A. Bernhardt for his analysis.

Synthesis of DL-α-Aminosuberic Acid and Its Optical Resolution

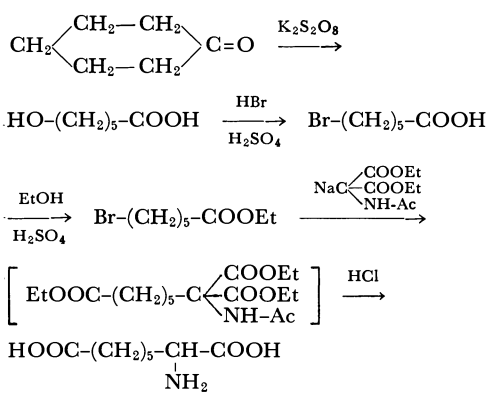
Satoe HASE, Reiko KIYOI and Shumpei SAKAKIBARA

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received December 14, 1967)

α-Aminosuberic acid is a key substance in synthesizing an analogue of deamino-oxytocin which has an ethylene linkage in place of the disulfide bond of oxytocin. DL-α-Aminosuberic acid (I) was first synthesized in 1956 by the hydrogenation of α-oximinosuberic acid, but the procedure was not practical and the optical resolution of the racemate has not yet been achieved.[1] Farkašová and Rudinger[2] derived L-α-aminosuberic acid from L-glutamic acid by the step-by-step addition of methylene groups to the side chain.

In the present study, the racemic compound I was synthesized by the acetaminomalonate procedure using ethyl ε-bromocaproate. The latter had been obtained from cyclohexanone following the procedure of Brown and Partridge.[3] The optical resolution of



the racemate was carried out by two different procedures. One route was the enzymic digestion of *N*-chloroacetyl-DL-α-aminosuberic acid (II) at pH 7.2 with Taka-acylase. The other route was the fractional crystallization of *N*-carbobenzoxy-DL-α-aminosuberic acid (III) with D-tyrosine hydrazide according to the procedure of Vogler *et al.*[4] In the former case, it took about ten days at 37°C to complete the digestion, and L-α-aminosuberic acid (IV) was obtained in about an 80% yield; the all-around efficiency was found to be lower than in the latter method. The fractional crystallization procedure afforded carbobenzoxy-L-α-aminosuberic acid (V) in a good yield, and this was immediately available for the synthesis of its peptides; the recovery of the D-form from the mother liquor was also easy in this case. The same optical rotation value was obtained for the free L-amino acids prepared by the two methods, and this value was identical with that reported previously.[2]

Experimental

Materials. Ethyl ε-bromocaproate (bp 116—120°C/14 mmHg) was synthesized following the procedure of Brown and Partridge.[3] DL-Tyrosine was prepared from L-tyrosine by racemization with acetic anhydride.[5] DL-Tyrosine was converted to the ethyl ester and then to the hydrazide as has been described in the literature;[6,7] the over-all yield from L-tyrosine was 57%, mp 171—173°C. The optical resolution of DL-tyrosine hydrazide was carried out with carbobenzoxy-L-proline as has been described by Vogler and Lanz.[4] The Takadiastase was obtained from the Sankyo Co., Ltd.*1

DL-α-Aminosuberic Acid (I). Ethyl acetaminomalonate (183 g, 0.84 mol) was added to a solution of sodium ethoxide in absolute ethanol (18.4 g sodium in 800 m*l* of ethanol), and the mixture was refluxed gently. Ethyl ε-bromocaproate (183 g, 0.82 mol) was then stirred slowly in over a period of 80 min; refluxing and stirring were continued for a further 7.5 hr, and then the whole mixture was kept overnight at room temperature. The precipitate formed was removed, the ethanol solution was concentrated under reduced pressure, and the residual oil was taken up in ether. The ether solution was washed with water, and the solvent was removed by evaporation. The oily residue was refluxed with conc. hydrochloric acid (1.2 *l*) for 6 hr, and then concentrated to dryness. The final residue was dissolved in water (350 m*l*), the pH of the solution was adjusted to 3 with aqueous ammonia, and the mixture was kept overnight in a refrigerator. The crystals which appeared were collected by filtration, washed with water and with methanol, and dried in a desiccator over sulfuric acid; crude yield, 133 g (80%). The crude product was dissolved in boiling water, and the solution was decolorized with active charcoal; on cooling compound I crystallized as the monohydrate; yeild, 127 g (77%), mp 240—241°C (decomp.). Reported, mp 233°C (decomp.).[1] For analysis, this material was dried over phosphorus pentoxide *in vacuo* for 10 hr at 90°C.

***N*-Chloroacetyl-DL-α-aminosuberic Acid (II).** Compound II was obtained from I (151 g, 0.73 mol as the monohydrate) by a normal Schotten-Baumann reaction with chloroacetyl chloride (100 g, 0.88 mol) and 4N sodium hydroxide. The crude product was recrystallized from ethyl acetate and petroleum ether; yield, 149 g (77%), mp 116—118°C.

Found: C, 44.97; H, 6.02; N, 5.22; Cl, 13.61%. Calcd for $C_{10}H_{16}O_5NCl$: C, 45.20; H, 6.07; N, 5.27; Cl, 13.34%.

***N*-Carbobenzoxy-DL-α-aminosuberic Acid (III).** Compound I (41.5 g, 0.2 mol as monohydrate) was treated with carbobenzoxy chloride (40.8 g, 0.24 mol) and with 2N sodium hydroxide under the normal conditions of a Schotten-Baumann reaction; crude yield, 58.5 g (90%), mp 123—125°C. Recrystallization from ethyl acetate afforded needles; yield, 54.3 g (84%), mp 124—125°C.

Found: C, 59.50; H, 6.52; N, 4.31%. Calcd for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55; N, 4.33%.

Isolation of L-α-Aminosuberic Acid (IV) and of Its D-Isomer by Enzymic Digestion of II. A solution of Takadiastase (250 g) made by extraction with ice water (1.8 *l*) was added to a mixture of II (266 g, 1 mol) and cobaltous chloride (460 mg) in 4N sodium hydroxide; the pH of the solution was adjusted to 7.2 with acetic acid and with sodium hydroxide before and after the addition of the enzyme solution respectively. During the incubation at 37°C the solution was frequently adjusted to pH 7.2 with 4N sodium hydroxide. After 8 days the mixture was boiled for 10 min to precipitate proteins, which were then removed by filtration with Hyflo Supercel. The unchanged chloroacetyl derivative (mainly the D-form) was extracted with ethyl acetate at pH 1.7, and then the water layer was adjusted to pH 3 and stored overnight in a refrigerator. The crude IV was collected by filtration and recrystallized from hot water after decolorization with active charcoal; yeild, 80 g (84%), mp 243—245°C (decomp.), $[\alpha]_D^{17}$ +20.1° (*c* 1.9, 5N hydrochloric acid), $[\alpha]_D^{26}$ +19.6° (*c* 1.4, 6N hydrochloric acid). Reported, $[\alpha]_D^{25}$ +20.2° (*c* 0.1, 5N hydrochloric acid).[2)]

Found: C, 50.73; H, 8.35; N, 7.64%. Calcd for $C_8H_{15}O_4N$: C, 50.78; H, 7.99; N, 7.40%.

The ethyl acetate extract, which was rich in the D-form, was dried over sodium sulfate and concentrated *in vacuo*. The oily residue was refluxed with concentrated hydrochloric acid for 5 hr, and then the solution was concentrated to dryness. The residue was dissolved in water, the pH of the solution was adjusted to 3, and the D-α-aminosuberic acid which precipitated was collected by filtration. The crude crystals were recrystallized from hot water, as in the case of the L-form; yield, 42.5 g (45%), mp 243—245°C (decomp.), $[\alpha]_D^{15}$ −19.9° (*c* 2.1, 6N hydrochloric acid).

***N*-Carbobenzoxy-L-α-aminosuberic Acid (V).** D-Tyrosine hydrazide (29.3 g, 0.15 mol) and III (32.3 g, 0.1 mol) were dissolved in boiling methanol (600 m*l*), and a small amount of an insoluble material was filtered off. The resulting clear solution was concentrated to about 300 m*l*, and V was precipitated as the salt of D-tyrosine hydrazide by the careful addition of ethyl acetate (about 350 m*l*). When oily material appeared during the precipitation procedure, the addition of ethyl acetate was stopped and the oil was rubbed vigorously with a glass rod until it changed to crystals. After the solution had stood overnight at room temperature, the crystals were collected by filtration, washed with a mixture of methanol and ethyl acetat , and dried; yeild, 32.3 g (90%), mp 151—153°C. (The mother liquor was used later for the isolation of VI.). This material, which represented the salt of D-tyrosine hydrazide and V (2: 1 mol/mol), was recrystallized from ethanol (800 m*l*) for purification; yeild, 25.8 g (72%), mp 153—154°C, $[\alpha]_D^{24}$ −56.0° (*c* 1.8, water). A second crop of crystals was recovered from the mother liquor; weight, 2.7 g (7.4%), mp 153—154°C, $[\alpha]_D^{25}$ −56.1° (*c* 2, water).

Found: C, 57.20; H, 6.94; N, 13.66%. Calcd for $C_{34}H_{47}O_{10}N_7$: C, 57.21; H, 6.64; N, 13.73%. This salt (25.6 g, 0.036 mol) was suspended in ethyl acetate (120 m*l*), and the mixture was shaken with 4N hydrochloric acid (30 m*l*). The ethyl acetate layer was separated, washed with water, dried over sodium sulfate, and concentrated to a residue, which was then recrystallized from ethyl acetate and petroleum ether; yield of V, 10.8 g (93%), mp 119—121°C, $[\alpha]_D^{26}$ −3.3° (*c* 7.7, acetic acid), $[\alpha]_D^{25}$ −9.1° (*c* 4, dimethylformamide).

Found: C, 59.39; H, 6.56; N, 4.29%. Calcd for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55; N, 4.33%. The optical purity of this compound was confirmed after the removal of the protective group by catalytic hydrogenolysis; the compound IV thus obtained showed a mp of 246—248°C (decomp.), $[\alpha]_D^{28}$ +20.0° (*c* 2, 5N hydrochloric acid).

***N*-Carbobenzoxy-D-α-aminosuberic Acid (VI).** The mother liquor mentioned above was concentrated, and crude VI was extracted from the residue with ethyl acetate in the presence of hydrochloric acid. On the concentration of the extract, a residue of crystals was obtained; yield, 17.3 g, $[\alpha]_D^{25}$ +6.3° (*c* 4, dimethylformamide). A part of this material (3.23 g, 0.01 mol) was dissolved in boiling methanol, together with L-tyrosine hydrazide (3.90 g, 0.02 mol), and the mixture was treated as in the case of V. The yield of the salt of L-tyrosine hydrazide and VI was 4.86 g (73%); mp 153—154°C, $[\alpha]_D^{27}$ +56.1° (*c* 2, water). Compound VI was isolated from the salt as has been described previously; yield, 97%, mp 119—121°C, $[\alpha]_D^{28}$ +9.1°(*c* 4, dimethylformamide). D-α-Aminosuberic acid was obtained from VI by the removal of the protecting group; mp 246—248°C (decomp.), $[\alpha]_D^{28}$ −20.1° (*c* 2, 5N hydrochloric acid).

Investigations on Polymolybdates of Rare Earths. Electrometric Studies on the Compositions of Samarium Polymolybdate

C. M. GUPTA and M. P. JOSHI

Department of Chemistry, Universty of Rajasthan, Jaipur, India

(Received March 24, 1967)

A survey of the literature reveals that the composition of samarium molybdate, which may be of great significance in the geochemistry of both elements, has not been studied so far by electrometric techniques. The only available reference is that of Cleve,[1] who has thrown some light on the composition of samarium molybdate by adopting analytical means. His results, however, could not be confirmed later. The present investigation has, therefore, been initiated with a view to study the reaction equilibria between $Sm(NO_3)_3$ and various molybdate polyanions by means of amperometic and conductometric titrations. The results have also been substantiated by gravimetric analysis of the compounds formed. These interesting results are a continuation of our similar type of studies.[2,3]

Appratus and Procedure

Anal. R. (B. D. H.) reagents sodium molybdate Na_2MoO_4, lithium chloride LiCl, samarium nitrate $Sm(NO_3)_3$ (Atomic Energy Establishment, Trombay) and gelatine were used. A manual polarograph with a spot galvanometer was used for polarographic and amperometric work. A dropping mercury electrode with the characteristics $m^{2/3}t^{1/6}=4.58$ mg$^{2/3}$ sec$^{-1/2}$, where m is the weight of mercury in a closed circuit= 7.166 mg/sec, and t is the drop time of the capillary at -1.0 V (*vs.* SCE)$=3.50$ sec, in Na_2MoO_4 solution, was used in conjunction with SCE and the proportionality of i_d with respect to concentration was observed. Conductance was measured with the help of a Tesla conductivity bridge, and the procedure adopted was the same as described earlier.[4] Amperometric titrations were carried out between $Sm(NO_3)_3$ and various alkali di, para, tri and meta molybdates at an applied potential of -1.7 V (*vs.* SCE) in the presence of 0.1 M LiCl as supporting electrolyte, and 0.005% gelatine as maxima supressor. The end points were located graphically with plots of diffusion current values and conductance drawn as a function of milliliters of titrant added.

Discussion

The addition of acid to alkalimolybdate causes the formation of various polyanions with regard to the changes occurring in H^+ ion concentration. It was considered of importance to ascertain electrometrically whether similar samarium salts can be obtained as a result of reaction between samarium nitrate and various alkali molybdates solutions.

Normal Molybdate Titration. Using different concentrations of $Sm(NO_3)_3$ and Na_2MoO_4, a series of amperometric titrations were carried out and the well defined breaks in curves (a) and (b) (Fig. 1) at the end points suggested the formation and precipitation of normal samarium molybdate $Sm_2O_3\cdot 3MoO_3$ at a pH range of 5.5—6.0 where the atomic ratio of Sm : Mo is 2 : 3. The reaction proceeds as follows:

$$2Sm(NO_3)_3 + 3Na_2O\cdot MoO_3 \rightarrow Sm_2O_3\cdot 3MoO_3 + 6NaNO_3.$$

Conductometric titration using similar solutions substantiated the formation of the above compound.

Para-Molybdate Titrations. The solution of sodium para-molybdate was prepared by adding 1.14 mol of HCl per mole of normal molybdate (Na_2MoO_4) at 100°C, and its reaction with $Sm(NO_3)_3$ was studied amperometrically and conductometrically. The well defined breaks obtained in the titration curves (Fig. 2) reveal the formation and precipitation of smarium para-molybdate with the molecular composition $Sm_2O_3\cdot 7MoO_3$ in the pH range 3.5—4.5. The formation can be described as follows:

$$7\,Na_2O\cdot MoO_3 + 8\,HCl \rightarrow 3\,(Na_2O\cdot 2.33\,MoO_3) + 8\,NaCl + 4\,H_2O$$

$$2\,Sm(NO_3)_3 + 3\,(Na_2O\cdot 2.33\,MoO_3) \rightarrow Sm_2O_3\cdot 7\,MoO_3 + 6\,NaNO_3.$$

Similar titrations were also performed with a view to study the reaction between Sm^{3+} and tri and meta alkali molybdates but they could not throw any light on the formation of tri and meta molybdates of samarium. The compositions of the compounds formed were also checked by analyzing the precipitate obtained at the end point gravimetrically, whose results were found to confirm those obtained by electrometric techniques.

ΔH for the formation of normal and para-molybdates of samrium has also been determined

SHORT COMMUNICATIONS

A Coordination Compound between Vanadium Oxytrichloride and Triphenyl Phosphine

Kimio TARAMA, Satohiro YOSHIDA, Hiroyoshi KANAI and Shozo OSAKA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 19, 1968)

While various kinds of coordination compounds of vanadium oxytrichloride ($VOCl_3$) have been reported,[1] any compound between $VOCl_3$ and triphenyl phosphine (Pph_3) has not been synthesised. The authors found the formation of this compound in the course of a study on the catalytic action of $VOCl_3$.[2] When $VOCl_3$ was added to petroleum ether solution of Pph_3, red brown powders precipitated at room temperature. The elemental analysis of this precipitate after purification showed that the composition of this compound was VOC_3lPph_3 (Found: V, 11.81; Cl, 23.66; C, 49.75; H, 4.24%. Calcd: V, 11.91; Cl, 24.43; C, 49.52; H, 3.45%).

This compound melts with partial decomposition at a temperature higher than 210°C. At room temperature it is decomposed by moisture, but is stable in dry oxygen. It is soluble in tetrahydrofuran, but is insoluble in carbon tetrachloride and *n*-hexane.

Infrared spectrum of $VOCl_3$ has a sharp absorption at 1035 cm^{-1} due to the stretching vibration of $(V{=}O)^{3+}$ [3] and the center of this peak shifts to 1000 cm^{-1} in the case of $VOCl_3Pph_3$ as shown in Fig. 1. This red shift reveals that an increase of electron density on vanadium ion is caused by coordination of Pph_3. This increase of electron density on vanadium ion is ascertained also by the ESR measurement.

Vanadium oxytrichloride does not show any ESR signal, but $VOCl_3Pph_3$ shows an ESR spectrum with h.f.s. similar to that of $(V{=}O)^{2+}$ in vanadium oxysulfate supported on γ-alumina[4] (Fig. 2). When triphenylphosphine was added to $VOCl_3Pph_3$ suspended in carbon tetrachloride at 10—25°C, oxygen was rapidly absorbed and triphenyl phosphine oxide was catalytically produced. Further kinetic studies for this oxidation reaction are in progress.

δ-Bonded 2-Phenylpyridine Palladium Complex

Akira KASAHARA

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received January 16, 1968)

In general, heterocyclic amines such as pyridine react with palladium(II) dichloride to give a square-planar complex such as $Pd(pyridine)_2Cl_2$. However, the observation[1] that azobenzenes and *N,N*-dimethylbenzylamine react with palladium(II) halides and platinum(II) halides in alcoholic solutions to give complexes (1) and (2) with carbon-metal σ-bonds has led to an examination of a similar reaction between palladium(II) dichloride and heterocyclic amines. We have found that, in alcoholic media, 2-phenylpyridine undergoes a similar unusual reaction with sodium chloropalladate.

2-Phenylpyridine and sodium chloropalladate were dissolved in alcohol and allowed to stand at room temperature for two days. A pale yellow material believed to have the structure (3) was isolated in about a 70% yield. The compound (3) is insoluble in all common organic solvents and does not melt before decomposition, which occurs at about 270°C. The structure of the complex (3) was established by the results of the elementary analysis (Found: C, 44.38; H, 2.56; N, 4.57%. Calcd for $C_{22}H_{16}N_2Pd_2Cl_2$: C, 44.82; H, 2.72; N, 4.14%) and the following data.

In the infrared spectrum of the compound (3), the characteristic C–H out-of-plane deformation modes of a mono-substituted benzene at 770—730 and 690 cm^{-1} are absent and are replaced by one at 737 cm^{-1}, which can be assigned to a C–H deformation mode of an ortho-disubstituted benzene.[2] The lithium aluminum hydride reduction of the compound (3) gave 2-phenylpyridine (4a), whose mass spectrum, picrate, and hydrochloride were identical with those of an authentic sample. On the other hand, the lithium aluminum deuteride reduction of the compound (3) gave 2-phenylpyridine-d_1 (4b). The position of the deuterium and, therefore, the site of the carbon-to-palladium σ-bond, were established by a comparison of the mass spectrum of (4b) with that of the undeuterated (4a). The compound (4a) gave peaks at *m/e* 155 (100%, parent ion), 128 (12%, loss of HCN), and 52 (21%, loss of PhCN). The mass spectrum of the compound (4b) showed peaks at *m/e* 156 (100%, parent ion), 129 (13%, loss of HCN), and 52 (21%, loss of PhCN-d_1).

2-Phenylquinoline also reacted with sodium chloropalladate in alcohol to give a yellow compound believed to have the structure (5) (dec. p. 270°C; Found: C, 51.72 H, 2.68; N, 3.87%. Calcd for $C_{30}H_{20}N_2Pd_2Cl_2$: C, 52.05; H, 2.91; N, 4.04%). In the infrared spectrum of the compound (5), the characteristic C–H deformation mode of a mono-substituted benzene is absent, but an intense band at 738 cm^{-1} can be assigned to the C–H deformation mode of an ortho-disubstituted benzene. This behavior is analogous to that of the spectra of the 2-phenylpyridine palladium complex (3). The presence of a bond between the metal atom and a carbon atom of the phenyl group in the 2-phenylquinoline molecule was also established by mass spectrometric analysis. The compound (5) was reduced with lithium aluminum hydride to 2-phenylquinoline (6a), whereas with lithium aluminum deuteride it was reduced to 2-phenylquinoline-d_1 (6b). The mass spectrum of the compound (6a) gave peaks at *m/e* 205 (100%, parent ion) and 102 (13%, loss of PhCN). The mass spectrum of 6b showed peaks at *m/e* 206 (100%, parent ion) and 102 (12%, loss of PhCN-d_1).

Synthesis of Poly-(L-prolyl-L-prolylglycyl) of Defined Molecular Weights

Shumpei SAKAKIBARA, Yasuo KISHIDA, Yasuo KIKUCHI, Rume SAKAI and Kinji KAKIUCHI

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received February 3, 1968)

A major problem in polypeptide synthesis is the formation of products with a wide range of molecular weights. As a step toward the total synthesis of natural protein, an attempt was made to synthesize a sequential polypeptide with a defined molecular weight. Thus, poly-(L-prolyl-L-prolylglycyl) with ten or twenty repeating units was synthesized by the step-by-step addition of AOC-L-prolyl-L-prolylglycine (I)[1] using the solid-phase procedure.[2] The synthesis was started from glycine-anchored polystyrene (100—200 mesh, copolymerized with 2% divinylbenzene; 14 g, 0.1 mmol/g), to which AOC-L-prolyl-L-proline (1.4 g)[1] was coupled in methylene chloride with dicyclohexylcarbodiimide. The AOC-group was then removed with 2N hydrogen chloride in acetic acid, and the tripeptide-cycle was extended with I (1.7 g per cycle) and dicyclohexylcarbodiimide (0.9 g per cycle); each coupling reaction was carried out in methylene chloride for 3 hr at room temperature. After nine reaction cycles, when ten repeating units were expected to have been formed, a part of the resin was dried (wt 7 g) and placed in an HF-reaction cylinder;[3] anisole (7 ml) was added, and then anhydrous hydrogen fluoride (HF, 60—70 ml) was introduced over the resin by means of the HF-reaction apparatus.[3] After one hour at 0°C, the excess HF was removed, and the peptide liberated was extracted with water. The water extract was treated with IR-45 (OH^- form), and then dialyzed against distilled water for 3 days. The final solution was lyophilized (II, wt 0.74 g). Found: C, 53.49; H, 6.96; N, 15.54%. Calcd for $(C_{12}H_{17}O_3N_3)_{10}\cdot 10H_2O$: C, 53.52; H, 7.11; N, 15.60%.

The polypeptide-resin, which was expected to include the eicosamer (wt 6g), was also synthesized from the rest of the decamer-resin by ten more reaction cycles, and the resin was treated as has been described above. The lyophilizate (III, wt 0.67 g) thus obtained dissolved poorly in water, in contrast to the reported findings of Engel *et al.*,[4] but it was soluble in dilute aqueous acetic acid or 50% ethanol. Found: C, 53.40; H, 7.01; N, 15.62%. Calcd for $(C_{12}H_{17}O_3N_3)_{20}\cdot 20H_2O$: C, 53.52; H, 7.11; N, 15.60%.

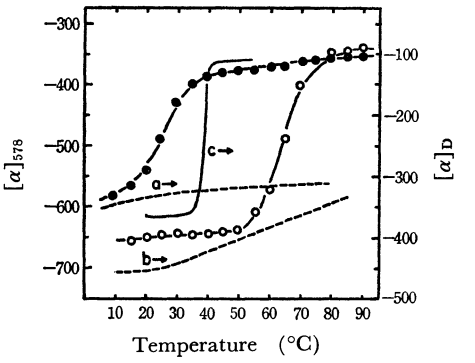

Fig. 1. Temperature dependence of specific optical rotation of (Pro-Pro-Gly)$_n$; (—●—), II, $n=10$, $c=0.187$ in 0.1 M NaCl solution; (—○—), III, $n=20$, $c=0.183$ in 10% acetic acid solution. The broken lines are cited from the data published by Engel *et al.*[4] for (Pro-Gly-Pro)$_n$, which were plotted by corrected data; a, mol wt 2950; b, mol wt 6900. The continuous line (c) is cited from the data published by Sakai *et al.*[5] for natural collagen.

The weight-average molecular weight of each polymer was determined by the sedimentation-equilibrium technique in the presence of 5M guanidine hydrochloride (0.73 was assumed for the partial specific volume). Found: 2300 (calcd for II: 2531). Found: 5300 (calcd for III: 5044). In these cases, plots for the logarithm of the concentration of the solute against the square of the radial distance, which was measured from the axis of the rotor, were completely linear. This indicates that the distribution of molecular weights was practically monodispersed in each case. The temperature-dependence of the optical rotation change was measured with the samples II and III. As is shown in Fig. 1, the behavior was much more similar to that of natural collagen[5] than those of the same type of polypeptides with a random molecular weight, (L-prolylglycyl-L-prolyl)$_n$.[4] Furthermore, it was found that the two regular polypeptides, II and III, each showed a different transition temperature, depending on their molecular weight.

Thus, a new route for the synthesis of regular polypeptides has been developed.

Triplet-Triplet Absorption Spectrum of *N,N*-Dimethylaniline (DMA) measured by the Flash Photolysis Technique

Katsumi KIMURA*[1], Satoshi ARIMITSU, Naoto YAMAMOTO and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 19, 1968)

Land and Porter[1] have studied the photolysis of DMA in liquid paraffin at room temperature by the flash-photolysis technique, and assigned a transient absorption spectrum whose maxima are at 3140 and 4000 Å tentatively to the anilino radical ($C_6H_5\dot{N}CH_3$). In our previous work,[2] the flash photolysis of TMPD[3] in solution has been studied in detail and it has been shown that a transient spectrum obtained in liquid paraffin, which is similar to the absorption of $TMPD^+$, is due to the triplet-triplet (T-T) absorption. Except TMPD, so far, no T-T absorption spectra have been reported for benzene derivatives having electron donating groups such as the amino group.

A liquid-paraffin solution of DMA (about 10^{-4} mol/*l*) was deoxygenated by purging with dry nitrogen. The electronic absorption spectra of transient species formed by the flash illumination at room temperature were measured for various delay times by using the flash-photolysis apparatus in our laboratory.[2] The transient spectrum obtained with a delay time of 5 μsec, as shown in Fig. 1, consists of a fairly sharp band whose maximum is at 3400 Å and a broad band whose maximum is at 4800 Å. It was also found that the absorption at 4800 Å decays with a half-decay time of about 100 μsec. The spectrum shown in Fig. 1 may be assigned to the T-T transitions of DMA from the following reasons:

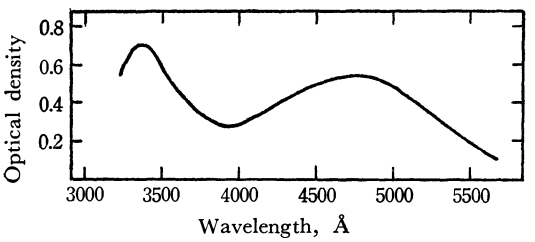

Fig. 1. A transient absorption spectrum obtained with a delay time of 5 μsec by the flash photolysis of DMA in liquid paraffin at room temperature.

1) The life time of the absorption measured at 4800 Å is comparable to that reported for the T-T spectrum of TMPD.[2]

2) In the present work, in order to confirm that the spectrum shown in Fig. 1 is attributable to T-T transitions, we also employed the steady-cross-illumination method with an EPA rigid glass of DMA at 77°K, and it was found that almost the same absorption spectrum is obtained as that by the flash illumination and its decay time is almost identical to that of the phosphorescence.[4]

3) The energy levels of triplet states of DMA have recently been calculated theoretically, by taking into account the configurational interactions between the locally-excited triplet configurations of benzene and the intramolecular charge-transfer (CT) configurations.[5] One of the present authors recalculated the triplet energy levels of DMA by selecting energy values of the CT configurations so as to reproduce the energy of the lowest triplet level estimated from the phosphorescence spectrum.[6] From this calculation, it has been confirmed that the band at about 4800 Å (2.58 eV) is due to a transition to the intramolecular CT state, its calculated energy being 3.10 eV ($f_{calc.}=0.05$), and the band at 3400 Å is concluded to correspond to a transition to one of the split states of $^3E_{2g}{}^+$ states of benzene ($f_{calc.}=0.03$), and furthermore a weak absorption ($f_{calc.}=0.01$) should exist at around 5500 Å due to a transition characteristic of one of the split states of the $^3E_{2g}{}^-$ states of benzene. It may be considered that the observed broad band probably includes this weak absorption in the longer wavelength side.

4) From our recent studies of the low temperature photolysis of DMA,[7] it has been found that the spectrum shown in Fig. 1 does not coincide with that of DMA^+ nor the anilino radical.

Absorption Spectra of Erbium TTA-TOPO Complexes Extracted from Aqueous Perchlorate Solutions

Tomitsugu TAKETATSU and Nobuyo TORIUMI

College of General Education, Kyushu University, Fukuoka

(Received March 2, 1968)

It has been reported that the absorption spectra of neodymium, holmium and erbium complexes extracted into toluene containing 2-thenoyltrifluoroacetone (TTA) and tri-*n*-octyl phosphine oxide (TOPO) from an aqueous acetate solution had a strong band in the visible region with a maximum of 584, 452 and 520 mμ, respectively, and the formulae of these complexes were estimated to be $Ln(TTA)_3 2TOPO$.[1]

In the present paper, we will describe the preliminary results of a spectrophotometric study of erbium TTA-TOPO complexes extracted into organic solvents with a series of various dielectric constants (ε) from aqueous solutions containing various amounts of perchlorate ions.

Figure 1 shows the absorption spectra for erbium complexes extracted into cyclohexane (ε: 2.02), isopropyl ether (ε: 3.88), chlorobenzene (ε: 5.62), dichloromethane (ε: 9.08) and 1,2-dichloroethane (ε: 10.36) from aqueous solutions containing a slight excess of perchlorate ion with respect to erbium ion. With increase in the dielectric constant of the organic solvents, a new sharp band appeared and grew regularly at 518 mμ. Moreover, even in the case of cyclohexane, a similar variation of the absorption band at 518 mμ was observed with increase in the concentration of perchlorate ion in an aqueous solution. The intensity at 518 mμ almost linearly increased with increase in $[ClO^-_4/Er^{3+}]_{org}$, which represented the mole ratio of perchlorate and erbium ions extracted into various organic solvents, and became constant in the region above a 1 : 1 ratio of $[ClO^-_4/Er^{3+}]_{org}$. When the intensity at 518 mμ was studied using 1,2-dichloroethane as a function of the mole ratio of TTA to erbium in the presence of excess TOPO, the break occurred at a mole ratio of TTA : Er = 2 : 1. On the other hand, in the case of mixtures containing excess TTA and various amounts of TOPO, the break was observed at a mole ratio of TOPO : Er = 5 : 1. Both intensities were almost constant with concentration of TTA and TOPO above these breaks. From these results and considering the coordination number of heavy lanthanide, it is felt that the complex in 1,2-dichloroethane prefers the formula $[Er(TTA)_2 5TOPO]^+ClO^-_4$ to $[Er(TTA)_2ClO_4 5TOPO]$.

Since the absorption spectrum obtained using cyclohexane coincides with that of the $Er(TTA)_3$-2TOPO complex in a previous paper,[1] it is supposed that the following equilibria may exist as a function of dielectric constant of the organic solvents and concentration of perchlorate ion in an aqueous solution.

$$Er^{3+} + 2HTTA_{(o)} + 5TOPO_{(o)} + ClO_4^- \rightleftarrows [Er(TTA)_2 5TOPO]^+ClO_4^-{}_{(o)} + 2H^+$$

An investigation using other lanthanide is in progress. Further discussion of the results and details of this study will be published later.

On the Yield of Hydrogen Atoms in the Vapor Phase Radiolysis of Ammonia

Masaru NISHIKAWA, Kazufumi KURODA and Niro MATSUURA

Department of Pure and Applied Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received March 4, 1968)

Recently, two different values were reported for the yield of hydrogen atoms in the radiolysis of ammonia vapor ; $G_H = 12.5 \pm 1$ by Jones and Sworski from their study on NH_3+D_2 and $NH_3+N_2H_4$ system,[1] and $G_H \gtrsim 7.2$ by Johnson and Simic on $NH_3+C_3H_8$ system.[2] In this communication, we wish to report some of the results of our study on the γ-radiolysis of $NH_3 + C_3H_8$ system which indicate still lower G_H from ammonia.

Purification of ammonia (99.9%, Matheson) and propane (>99.8%) and the method of irradiation were described.[3] Gas chromatographic analysis of propane indicated that no organic impurities were present at levels exceeding 10^{-3} mol%. The amount of energy absorbed in ammonia fraction (E_a) and in propane fraction (E_p) were calculated from that in a nitrous oxide dosimeter, assuming $G(N_2) = 10.0$,[4] for the runs at near-atmospheric pressure, and a Fricke dosimeter at higher densities, using the relative stopping powers obtained by Meisels.[5] The non-condensable products H_2 and N_2 were analyzed by combustion in a cupric oxide furnace.

The total hydrogen yield calculated for energy absorbed in ammonia fraction increased from $G(H_2) = 4.1$ to 7.8 at the propane concentration of 8.6 mol% in agreement with Johnson's value.[2] However, in contrast to their observation, no plateau was reached up to this concentration, suggesting hydrogen formation from the direct radiolysis of propane fraction. Therefore, in order to estimate the contribution of propane fraction for the observed yield of hydrogen, G-values of total hydrogen yields (G_t) were calculated for the total energy absorbed by the system ($E_t = E_a + E_p$) and are plotted against the fraction of energy absorbed in propane ($f_p = E_p/E_t$) in Fig. 1. A good straight-line relationship is demonstrated for f_p below 0.13 regardless of density and/or temperature and extrapolation to $f_p = 0$ yields $G(H_2)^\circ = 5.84$.

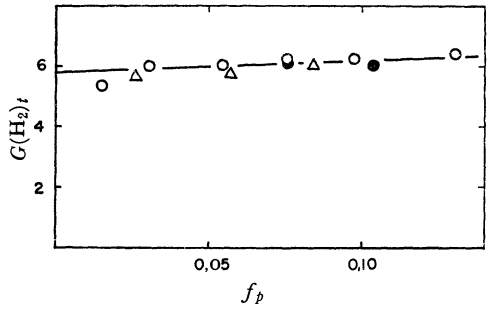

Fig. 1. Dependence of $G(H_2)_t$ on the fraction of energy absorbed by C_3H_8.
○, d~5.0×10^{-4} g/cc, 22°C
△, d~0.065 g/cc, 140°C
●, d~0.13 g/cc, 140°C

Hydrogen atoms react with propane by $H+C_3H_8 \rightarrow H_2+C_3H_7$. The yield of hydrogen at $f_p = 0$, $G(H_2)^\circ = 5.84$, is therefore a measure of the total yield of hydrogen atoms and the molecular hydrogen from the radiolysis of ammonia vapor. The latter has been determined to be 0.74,[3] hence $G_H = 5.84 - 0.74 = 5.10$.

The value of G_H thus obtained is significantly lower than those reported by Jones and Sworski[1] and by Johnson and Simic.[2] The disagreement with Johnson's value may be probably due to their neglect of hydrogen produced from propane radiolysis. It seems inconceivable in view of the large value of the relative stopping power of propane, $s_p/s_a = 2.65$,[5] that no hydrogen is produced from propane, for example, at 6 mol% where they observed the plateau in $G(H_2)$. The more serious disagreement with Sworski's value might be inherent in the system they used. For NH_3+D_2 system, they also noted that G_H as high as 90 ± 66 was obtained from their proposed mechanism at the total pressure of 600 mmHg, suggesting some kind of chain mechanism is operating. For $NH_3+N_2H_4$ system, their mechanism does not include reactions such as $NH_2+N_2H_3 \rightarrow NH_3+N_2+H_2$ ($\Delta H = -99$ kcal/mol) proposed by Dainton *et al.*,[6] the inclusion of which should lower the estimate of G_H. The use of $NH_3+C_3H_8$ system with proper corrections for hydrogen produced from propane appears more straight-forward and less ambiguous for the estimate of G_H from ammonia radiolysis.

The Synthesis of 3-Carboxyalkyl-salicylaldehyde Derivatives and Application of Their Chelate Forming Properties to the Analysis of Copper and Nickel[1]

Tsuguo TANAKA

Department of Science and Technology, Saga University, Honjo, Saga

(Received March 7, 1968)

In connection with the previous report on the ethylenediamine conjugate of bis-*O*-carboxymethyl-salicylaldehyde-alkylenediimine-copper,[2] Reimer-Tiemann synthesis of the following three 3-carboxy-alkylsalicylaldehydes IIa, b, c and the synthesis of their derivatives were made with hydroxyacid Ia, b, c as the starting material.

Ia (mp 151°C, Found: C, 41.62; H, 3.19%. Calcd for $C_8H_7O_3Br$: C, 42.01; H, 3.05%) was prepared by the bromination of 2-hydroxyphenyl-acetic acid[3] in carbon disulfide solution. IIIa, b, c were obtained by the reaction of two moles of IIa,b,c, with one mole of ethylenediamine in ethanolic solutions and IVa, b were obtained by the reduction of IIIa, b with sodium borohydride in methanolic solutions.[4] The results are summarised in Table 1.

TABLE 1

Starting material	React. prod.		Yield %	Mp °C	Found (Calcd) C	H	N
Ia	IIa	PY	12.30	204	42.01 (41.72)	3.00 (2.72)	
Ib	IIb	PY	0.65	95	63.71 (63.45)	5.84 (5.81)	
Ic	IIc	Y	6.30	118	52.70 (52.53)	4.02 (3.97)	
IIa	IIIa	Y	92.23	242	44.69 (44.30)	3.16 (3.35)	4.94 (5.17)
IIb	IIIb	Y	83.63	195	64.19 (65.44)	6.46 (6.41)	7.09 (6.36)
IIc	IIIc	Y	46.98	204	54.89 (54.74)	4.61 (5.03)	5.82 (5.55)
IIIa	IVa	G	50.32	300*	43.37 (43.98)	4.32 (4.06)	5.41 (5.13)
IIIb	IVb-$2H_2O$	W	51.53	285	59.54 (59.98)	7.23 (7.55)	5.99 (5.83)

P=pale, Y=yellow, G=gray, W=white; * decomposition

Disodium salt of IVb works as a hexadentate ligand and forms a green copper(II) chelate but does not form any stable nickel chelate in aqueous solutions of pH 10 (it does not reveal any purple color of Murexide when added into an aqueous solution of nickel-Murexide complex), and was satisfactorily used in the spectrophotometric determination of copper(II) ions out of the mixed solutions of copper(II) and nickel(II) ions as illustrated in Fig. 2 and Table 2.

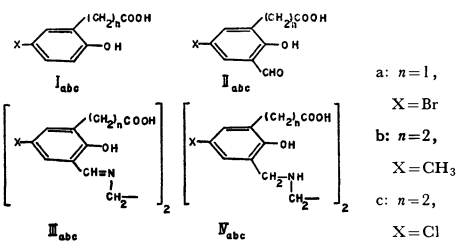

Fig. 1.

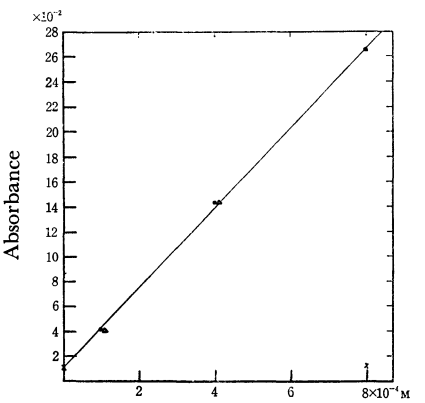

Fig. 2. Measurements were made of 5 m*l* of aqueous solutions containing 0.5 m*l* of 1/100 mol solution of disodium salt of IVb, 0.1 m*l* of pH 10 buffer solution[6] and; ○, moles of copper (II) acetate; ×, moles of nickel acetate; △, each moles of copper (II) acetate and nickel acetate, respectively. Cell depth 1 cm and pure water as reference.

TABLE 2

Sample		Found (as Cu)	Sample		Found (as Cu)
Cu	0.798 mg	0.798 mg	Cu	0.399 mg	0.411 mg
Ni	0.780 mg	0.001 mg	Cu	0.099 mg	0.094 mg
Cu	{0.399 mg}	0.411 mg	Cu	{0.099 mg}	0.091 mg
Ni	{0.390 mg}		Ni	{0.097 mg}	

In aqueous solutions of pH 10 containing Murexide indicator, IVa (Ni taken 1.76 mg, found 1.87 mg) and IVb (Cu taken 0.636 mg, found 0.699 mg) can be used as the reagent of chelatometric titration of nickel and copper respectively in place of EDTA.[5]

The Behavior of Hydrogen Chemisorbed over the Electron Donor-Acceptor Complexes of Aromatic Hydrocarbons with Sodium in the Hydrogen Exchange and Hydrogenation Reactions

Sadao TANAKA, Masaru ICHIKAWA, Shuichi NAITO, Mitsuyuki SOMA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

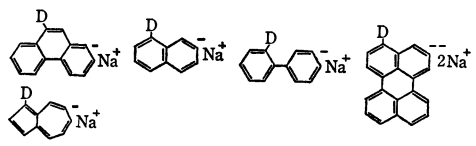
(Received March 22, 1968)

In a previous paper[1] it was demonstrated that the hydrogen molecule is activated at room temperature over the electron donor-acceptor (EDA) complexes of various organic compounds with metals such as sodium, whereas no activations took place over the organic molecules or over such metals alone.

In this experiment anthracene-Na (1 : 1 and 1 : 2) films were prepared over the glass wall of a reaction vessel in an ordinary manner.[2] The reactions were carried out over the films after evacuation had been carried out for several hours at 100°C.

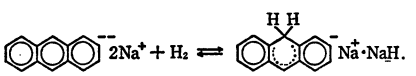
When 15 cmHg of D_2 gas was introduced onto the 1 : 1 and 1 : 2 complex films in the temperature range between 25 and 90°C, a considerable amount of HD was formed reversibly; the apparent activation energies for the reactions were approximately 16 and 12 kcal/mol respectively. The film of the anthracene-Na (1 : 2) complex was approximately ten times as active as that of the 1 : 1 complex for the hydrogen exchange. The rates of the H_2–D_2 (1 : 1) exchange reaction were of the same order of the magnitude as those of the D_2–HZ exchange reaction under similar conditions, where HZ represents the EDA complexes.

After the exchangeable hydrogens in these complexes had been replaced with deuterium to a considerable extent by treating the complexes with deuterium gas at 80°C, the deuterated positions in these complexes were studied by means of the ESR and NMR techniques, which revealed that the hydrogen at the 9 or 10 position of and  was only exchanged with deuterium. The deuterated position of similar EDA complexes was also studied in a similar manner. It was consequently found that the exchange reaction took place at the following positions:



The positions where the exchange reaction took place were those with the lowest localization energy in the mononegative or dinegative ions, except for the case of azulene.

By admitting the hydrogen gas onto the thin films of 1 : 1 and 1 : 2 anthracene-Na complexes, which had been prepared on the wall of a quartz cell, a new peak appeared at 432 mμ, while the peaks due to the dinegative anion and to the mononegative radical anthracene in the complexes decreased correspondingly. The new peak is seemingly due to the 9-monohydroanthracenium anion; it disappeared after evacuation had been carried out at 100° C for several hours. The ESR measurements of the complexes indicated that the total spin concentration of the 1 : 1 complex film diminished considerably upon the introduction of hydrogen onto the complex. The free spins were restored almost completely by evacuation at 100°C. When 1 : 2 complex films were treated with hydrogen gas at 90°C and were then dissolved in THF at 25°C, the resulting solutions showed a new NMR signal, at $\tau = 8.73$, corresponding to H–Na.*1 The results suggest that the hydrogen molecule attacks the 9-position of the anthracene-dinegative anion and is dissociated heterolytically in the following manner:



In this case the ambient hydrogen gas was replaced by deuterium, and the formation of hydrogen deuteride was followed with the time. It was accordingly found that almost all the hydrogens chemisorbed over the complex films participate in the exchange reaction with the ambient deuterium molecules, and the exchange rate was proportional to the amount of hydrogen adsorbed.

Monodeuteroanthracene of the 1 : 2 complex was prepared by treating the film with excess D_2 at 90°C for 2 days; subsequently the ambient hydrogen gas was replaced with dimethylacetylene, butadiene, or methylacetylene. As a consequence, a small amount of deuterated 2-butenes was selectively produced, while the peak at 432 mμ of 9-monohydroanthracene slowly decreased.

*1 The signal was the same as that of a THF solution of sodium hydride.

Measurement of Adsorbed Amount of Sodium Dodecylsulfate at Gas-Solution Interface by Radiotracer Method Using Tritium-Labeled Compounds

Mitsuo MURAMATSU, Kazuo TAJIMA and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 13, 1967)

Sodium dodecyl-2,3-^{3}H,^{3}Hsulfate (SDS) was synthesized from non-radioactive dodecanol, and the adsorbed amount of SDS at the gas-water interface, Γ, was directly measured by the radiotracer method with the use of 2π gas-flow windowless counter and humidified propane as a flow-gas. Because of a very soft nature of tritium β-rays, surface radioactivity is exclusively due to the solute adsorption compared with the large contribution from the bulk of the solution as in the case of ^{14}C or ^{35}S labeled detergents. Therefore the use of ^{3}H labeled compounds enables the determination of the amount of adsorption in high accuracy, even in the region of high concentration beyond the critical micelle concentration (CMC) of SDS solution. However, no reliable reports have appeared as yet on the studies of adsorption of surfactant at gas-solution interface using ^{3}H labeled compounds. Our measurement was carried out under exactly specified conditions, namely using chemically and radiochemically pure sample and under the condition free from evaporation. It was confirmed that Γ increased with the increase of SDS concentration and approached the saturation value of 5.9×10^{-10} mol/cm^2 or 28.2 Å^2/molecule at the concentration higher than 6×10^{-3} mol/1000 g solution and beyond CMC. Furthermore, Γ proved to be independent of the acidity of solution above pH 4, while it increased with increasing acidity below pH 4. The phenomenon is explained by the presence of hydrolytically formed dodecylsulfuric acid whose surface activity is higher than that of SDS.

Recently, much experiment has been carried out in an effort of determining the adsorbed amounts of surface-active substances at gas-solution interfaces by the radiotracer technique using soft β-emitters, such as ^{35}S[1-3] or ^{14}C.[3,4] Though these isotopes enable us to make a direct and hitherto difficult measurement of adsorption for compact aqueous surfaces, the results obtained are not satisfactory in the accuracy especially in the region of concentrated solution and in the case of weak adsorption. In this connection, it is particularly recommended to use a compound labeled with tritium which emits an extremely soft β-radiation. This is best explained by the following equation:

$$\frac{A_1-A_2}{A_1}=\frac{1}{1+C/(1000\Gamma\mu)}, \qquad (1)$$

where A_1 denotes the total radioactivity in cpm measured over the solution surface and A_2 that due to the bulk of the solution, C the concentration (mol/1000 g solution), Γ the adsorbed amount (mol/cm^2) and μ the mass-absorption coefficient (cm^2/g) for β-rays in the solution. The higher accuracy can thus be expected either for small value of C/Γ, or for large μ value. The value for C/Γ, however, is inherent to the surfactant chosen as a sample. Therefore, in order to obtain a high accuracy for a relatively large value of C/Γ as in the case of SDS, a radioisotope of sufficiently small μ is required to use as a tracer. For this reason, ^{14}C or ^{35}S is not satisfactory, and the use of ^{3}H is recommended since μ value of ^{3}H is about 50 times as large as that of ^{14}C or ^{35}S. Also, the use of ^{3}H is favorable because hydrogen is a common constituent of organic compounds.

However, no reliable reports have appeared as yet on the studies of adsorption of surfactant at gas-solution interface using ^{3}H labeled compounds. It appears that the tentative experiments by Nilsson[5] on adsorption of tritiated sodium dodecylsulfate (TSDS) have involved some uncertainty as to his synthetic processes leading to the tritiated sample, as pointed out previously.[6]

We have obtained the radiochemically and surface-chemically pure surfactants,[6,7] and developed the 2π windowless gas-flow counting for determining tritium radioactivity over solution surfaces.[8] In the present paper an attempt is made to determine the adsorbed amount of TSDS at gas-solution interface by means of 2π windowless counter under the flow of humidified propane.

Experimental

Reagents. TSDS was prepared by the method formerly reported,[6] the process of which is shown as follows:

$$C_{12}H_{25}OH\ (I) \rightarrow C_{11}H_{23}COOH\ (II) \rightarrow$$
$$C_{10}H_{21}CHBrCOOH\ (III) \rightarrow$$
$$C_9H_{19}CH{=}CHCOOH\ (IV) \rightarrow$$
$$C_9H_{19}CH^3HCH^3HCOOH\ (V) \rightarrow$$
$$C_9H_{19}CH^3HCH^3HCH_2OH\ (TDOH) \rightarrow$$
$$C_9H_{19}CH^3HCH^3HCH_2OSO_3Na\ (TSDS).$$

Normal-dodecanol-1 (I) purified by fractional distillation (bp 141—142°C/11 mmHg) was oxidized by sulfuric acid and potassium dichromate mixture to II. For the bromination of the compound II it was mixed with phosphorus trichloride and bromine was added to the mixture gradually at 85—90°C. The compound III thus obtained was dehydrogenated by potassium iodide and potassium hydroxide. A resulting compound IV was tritiated to V with tritium gas using Urushibara nickel (U-N-A)[9] as a catalyst. The reduction of V to TDOH was carried out using lithium aluminum hydride with good yield. TDOH thus obtained was carefully purified by means of preparative gas chromatography to remove homologue impurities. TDOH thus purified was treated with chlorosulfonic acid to obtain TSDS. Purification of TSDS was performed in a usual manner.[10] In addition to the usual chemical purification, a radiochemical purification was worked out to remove radioactive TDOH by the isotopic dilution method, that is, by repeating the addition of non-radioactive dodecanol to the alcoholic solution of TSDS and subsequent precipitation of TSDS from the solution. TSDS was finally purified by the Soxhlet extraction using ether followed by a recrystallization from ethanol. The TSDS thus obtained was sufficiently pure both chemically and radiochemically showing neither minimum in surface tension *versus* concentration curve nor the trace of volatile radioactive impurities presumably due to TDOH. Specific activity was 720 mCi/mol both for TDOH and TSDS.

Other reagents used in the present experiment were purified thoroughly by pertinent procedures. Samples of propane (98—99% pure) and methane (99.6%) used as flow gases were kindly supplied from Toa Nenryo Kogyo K. K.

Apparatus. Figure 1 illustrates schematically the apparatus which consists of the flow-gas preheater C, humidifier D, and the counting probe F of 2π windowless gas-flow counter (Aloka DC-1001). A solution of TSDS or TDOH for counting was contained in the planchette G, covered with the concentric mask H, which eliminates radioactivity from the periphery of G. The planchette and the mask made of stainless steel were polished and cleaned electrolytically with 1.2 A/cm² d. c. current in a solution of phosphoric acid prior to the experiments. The whole system was thermostatted to 20±0.5°C.

It has been pointed out in the previous paper[8] that the flow gas for counting the radioactivity over a solution surface should be moistened moderately to keep humidity neither so high as to permit multiple discharge, nor so low to enhance evaporation, since evaporation sometimes causes the concentration of solute at gas-solution interface. The optimum conditions for the least evaporation without multiple discharge were examined by changing the type of flow gas, its humidity and flow rate. The humidity was controlled by changing the length of preheater C, and the number of humidifier tubes D (2.0 cm diameter and 55 cm length each), which were packed with pieces of filter paper soaked with distilled water. The best condition was found to use propane of 82.6% humidity and 9.7 ml/min gas flow rate, and a voltage from 4600 to 4900 V applied to the counter. Under this condition, the rate of water evaporation from SDS solution in the planchette G, was less than 0.10 mg/cm²/hr. This amount corresponds approximately to a surface deposition of SDS of 6×10^{-10} mol/cm²/hr at the surface of 6×10^{-3} mol/1000 g solution, if we assume the deposit to remain undisturbed. However, the surface cooling involved in the actual system causes a convection current which results in a retardation of surface enrichment

of solute.[11] Therefore, it seems possible that the surface enrichment of the actual system is much less than the above value, as has been suggested in the experiments using $^{35}SO_4^{2-}$ in aqueous solution under the flow of dry nitrogen.[12]

Procedures. A portion of 0.80 m*l* of TSDS solution which had been aged in the thermostat for more than 15 min was brought by a syringe into the planchette G. The turn table, I, was revolved to get it into the counting chamber, in which humidified propane had been flowed previously for 5 hr to make its humidity and temperature constant. Surface radioactivity, A_1, of the solution was then determined as a function of time which elapsed from the revolving of the table.

The bulk radioactivity, A_2, of aqueous TSDS solution was estimated by converting the radioactivity (bulk) A_2', obtained with TDOH solution of the same radioactive concentration in non-radioactive dodecanol under the same geometrical conditions in the flow counter. For the same radioactive concentration C_r (dpm/g solution), these quantities are expressed by

$$A_2 = G\eta C_r \frac{f}{\mu}(1 - e^{-\mu R}), \quad (2)$$

$$A_2' = G\eta C_r \frac{f'}{\mu'}(1 - e^{-\mu' R'}), \quad (3)$$

where G is the geometrical factor, η the counting efficiency, f the back- and self-scattering factor, and R the maximum range (g/cm^2) of medium for β-particles. The prime denotes the TDOH-dodecanol system. Combining the Eqs. (2) and (3), we have

$$A_2 = \frac{f}{f'}\frac{\mu'}{\mu}\frac{1 - e^{-\mu R}}{1 - e^{-\mu' R'}} A_2' = kA_2'. \quad (4)$$

The proportionality factor, k, was determined by evaluating the individual terms in Eq. (4).

The adsorption amount of surfactant Γ (mol/cm^2) was calculated by the following equation,

$$\Gamma = \frac{A_1 - A_2}{S\sigma D}, \quad (5)$$

where S denotes the surface area (cm^2), σ the specific activity of the radioisotope used (dpm/mol) and D the detection coefficient (cpm/dpm). The term $S\sigma D$ was determined separately by the method to be described in the following section.

Radioactivity was measured under the condition that the counting rate lies within a 1—1.5% standard deviation. The background radioactivity was about 30 cpm throughout the experiments.

Results and Discussion

Determination of A_1 and A_2. In Fig. 2 are shown the values of surface radioactivity of TSDS solutions as a function of time elapsed from revolving the turn table. Neither acid nor alkali was added to these solutions. Therefore pH values were in a range of 5.8 to 6.1, depending on concentration. It can be seen in this figure that the

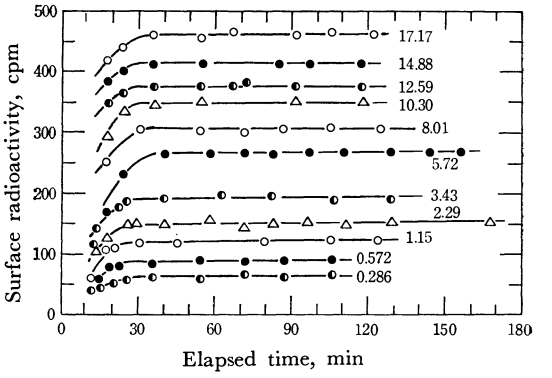

Fig. 2. Surface radioactivity for various TSDS solutions as a function of elapsed time.
The figures by the curves indicate concentration of the solutions in 10^{-3} mol/1000 g.

radioactivity increases with time and reaches a constant value in 30—40 min, depending on concentration. The initial increase with rather steep slope seems to indicate the dynamic processes of adsorption and the removal from flow gas of air which has been mixed by revolving the turn table. In fact, *ca.* 15 min was required for obtaining the stationary value of counting rate for a sample of stearic-9,10-^{3}H,^{3}H acid[7] spread over the same planchette. Thus, in Fig. 2, the linear portion of the curve after at least 40 min was extrapolated to time zero and the corresponding surface radioactivity was taken as A_1, for each solution.

Similar experiments were carried out for determining the radioactivity, A_2', over the surfaces of TDOH solutions in non-radioactive dodecanol-1 at 30—60 min after the initial revolving. To convert A_2' into A_2, reasonable approximations have been made for the propotionality factors in Eq. (4). First, the ratio, f/f' is estimated to be approximately unity, because the scattering power of aqueous TSDS solution is not much different from that of dodecanol-1. It is well known[13] that the scattering power for β-rays can be expressed as a function of the average atomic number

$$Z_{av} = \sum x_i m_i Z_i / \sum x_i m_i, \quad (6)$$

where x_i is fractional number of ith constituent atom of mass number m_i and atomic number Z_i. In the second line of Table 1 are shown the Z_{av} values calculated for the solutions of SDS in water and of TDOH in dodecanol-1. Putting these values into the empirical relationship between Z_{av} and the scattering factor[14] gives f/f'. Secondly, the mass-absorption coefficient, μ or μ', of a medium for given β-particles is determined by the

average ratio of atomic number to mass number,

$$(Z/m)_{av} = \sum x_i Z_i/m_i \,. \tag{7}$$

As a first approximation,

$$\mu = \alpha(Z/m)_{av}, \tag{8}$$

where α denotes the proportionality constant, which depends only on the energy of β-particles. Equation (8) which has been verified with rather hard β-rays[15] seems to be applicable to the tritium β-rays, as shown in Table 2 from which one obtains 23.3 cm²/mg for average α value. Combining the value with individual $(Z/m)_{av}$ values, which are given in the third line of Table 1, one can estimate the mass-absorption coefficient, values

of which are shown in fourth line of Table 1. Thirdly, $R=R'=0.55$ mg/cm² was obtained by interpolation of the energy-range relationship for various β-particles.[18] Putting these values into Eq. (4), we have

$$A_2 = \frac{19.4}{19.4} \cdot \frac{1-\exp(-19.4\times 0.55)}{1-\exp(-19.0\times 0.55)} A_2' = 1.00\, A_2' \,. \tag{9}$$

The amounts of A_1, A_2 and A_1-A_2 thus obtained are plotted in Fig. 3 against the radioactive concentration, C_r, for each solution.

Determination of $S\sigma D$. The value of $S\sigma D$ in Eq. (5) was determined by counting the surface radioactivity for known amounts of TSDS film spread over the nearly saturated solution of ammonium sulfate. A mixture of ethanol and benzene (1 : 40 in volume) containing TSDS was applied to the surface of 0.80 m*l* of the solution in planchette G in Fig. 1 and, after evaporating the solvent, turn table I was revolved to count the surface radioactivity. Exactly same conditions on S, σ and D were employed in the experiments as in determination of A_1 for aqueous TSDS solution. Also, it has been assumed tacitly in the experiments that the value of D and so the back- and self-scattering factor of nearly saturated solution (75.4 g/100 g solvent) of ammonium sulfate is the same as that of TSDS solutions. The assumption seems to be valied, as Z_{av} values are 7.4 for the former and 7.2 for the latter throughout the concentration range from 0 to 2×10^{-2} mol/1000 g solution. The difference in back- and self-scattering factor between the above two solutions could thus be much less than 1%.[14] Consequently, the value of $S\sigma D$ measured on saturated solution of ammonium sulfate can be used for the calculation of Γ using Eq. (5).

Figure 4 shows the dependence of surface radioactivity upon the amount of TSDS, assuming

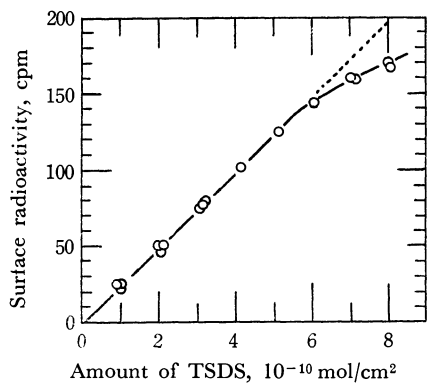

Fig. 4. Surface radioactivity as a function of TSDS applied to the surface of saturated solution of ammonium sulfate.

18) G. Friedlander and J. W. Kennedy, *loc. cit.*, p. 202.

that the molecules are all retained in the surface under the present experimental condition.[19] It can be seen in Fig. 4 that the radioactivity increases proportionally to the amount of TSDS up to *ca.* 5.5×10^{-10} mol/cm^2 or 30 Å^2/molecule; the value agreeing approximately with the limiting area of docosanylsulfate in insoluble monolayer at air-water interface.[20] Beyond this value, the curve tends to decrease in its slope, showing possible dissolution of the surfactant molecules into subphase. Similar phenomenon was observed by Brady[21] who employed surface tension and microtome methods for determining the nature of SDS films spread on various salt solutions. Therefore, the inclination of the linear portion in Fig. 4 is considered to give the value of $S\sigma D$ and we have empirically

$$\Gamma = 4.03\times10^{-12}(A_1-A_2) \qquad (10)$$

with A_1 and A_2 in cpm and Γ in mol/cm^2.

Adsorption Isotherm of SDS at about pH 6. Inserting the A_1-A_2 values shown in Fig. 3 into Eq. (10), we obtain Γ values as a function of TSDS concentration. The results are shown as the open circles in Fig. 5. The adsorbed amount increases with the increase of C and gives the saturation value of 5.9×10^{-10} mol/cm^2 or 28.2 Å^2/molecule beyond the concentration of 6×10^{-3} mol/1000 g solution, the value being in good accord with the value for alkylsulfates in the state of insoluble monolayers at air-water interfaces.[20,21]

In Fig. 5 the semi-closed and closed circles are those reproduced from the papers by Matuura *et al.*[2] and Nilsson,[5] respectively. These data are not in accord with our results. The former investigators used SDS-^{35}S which suffers from an inevitable errors, especially in large concentration; while in the study of the latter author, tritiated SDS contains surface-active impurities whose specific activity might be much high in comparison with that of the main component, as has been pointed out previously.[6] In fact, Nilsson's synthetic product, according to experience, was much complicated in its chemical and radiochemical composition, since he paid no attention to the separation of undesirable impurities in the intermediate and final products formed in his synthetic procedure.

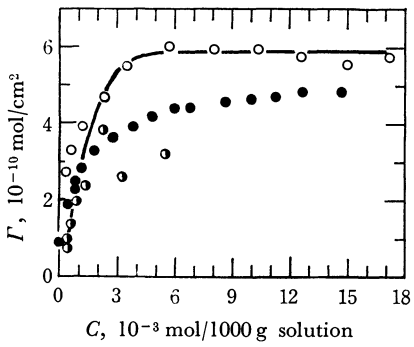

Fig. 5. Adsorption isotherm of SDS solution.

●, by Nilsson,[5] using ^{3}H as a tracer;
◑, Matuura *et al.*,[2] ^{35}S as a tracer.

pH Dependence of Γ. Similar experiments were carried out with TSDS solutions below and above CMC at various pH values. It can be seen in Fig. 6 that Γ is almost constant throughout the range of pH beyond 4, while it increases markedly with decreasing pH below 4. This suggests at least the enhanced formation of dodecylsulfuric acid which might correspond with the lowering of surface tension at pH lower than 4.[22] The total increase of dodecylsulfate radicals as shown in Fig. 6 may be explained by taking account of the decrease in electrostatic repulsion between charged radicals in adsorbed layer, caused by introduction of free acid.

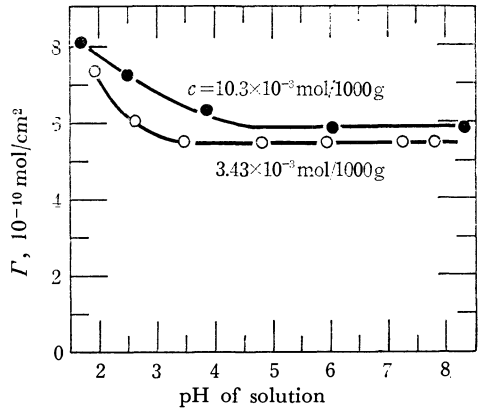

Fig. 6. Effect of solution pH upon the adsorbed amounts of SDS solution below (○) and above (●) CMC.

It might seem evident that the measured value of Γ, especially in acid region, is mainly attributable to TDOH formed by the hydrolytic reaction,

$$C_9H_{19}CH^3H\cdot CH^3H\cdot CH_2O\cdot SO_3^- + H_2O \rightarrow$$
$$C_9H_{19}CH^3H\cdot CH^3H\cdot CH_2OH + HSO_4^-,$$

which is more enhanced in acidic medium. However, a recent radiotracer study on the reaction rate[23] suggests that the dodecanol formation is too small to explain the enhanced adsorption. For 3.43×10^{-3} mol/1000 g SDS solution at 20°C,

23) M. Muramatsu, M. Inoue and T. Sasaki, "Proc. 7th Japan Conf. on Radioisotopes," Japan Atomic Energy Ind. Forum, Tokyo (1966), p. 240.

as an example, the reaction rate was estimated to be 3.7×10^{-6} and 1.5×10^{-8} mol dodecanol/1000 g solution/day at pH 1 and 5, respectively. The figures correspond to at most 6.1×10^{-11} and 2.5×10^{-13} mol dodecanol/cm^2 respectively, for the "surface density" of dodecanol, even though we assume the exhaustive adsorption of dodecanol molecules from the bulk phase of 0.8 m*l* solution which has been contained in the planchette of 2.5 cm in diameter for 2 hr. Therefore, it is considered that the pH dependence observed may be mainly explained by the bulk and surface hydrolysis resulting in dodecylsulfuric acid which is more surface active than dodecylsulfate ion. Further studies along this line are desired.

Remarks on the Present Method. In general, 2π windowless gas-flow counting is one of the easiest, simplest and inexpensive methods for determining the radioactivity of tritiated specimen. It has been pointed out previously[8] that the method involves the advantage that the counting rate is not much influenced by the geometric position of the specimen, so far as it is contained in the metallic planchette. Thus, the method seems to be suited for counting the surface radioactivity of relatively small amount of solution containing tritiated specimen.

On the other hand, the windowless gas-flow counting inevitably encounters difficulties arising from the fact that the solution surface is always exposed to flowing gas, which should be humidified moderately so as to minimize the surface enrichment of solute due to the evaporation of the solvent, as mentioned in the former section. In the present experiment, the above mentioned rate and humidity of flowing gas proved to be sufficient to eliminate such a disturbance, since we could hardly detect the additional surface enrichment due to the evaporation. This results can reasonably be expected from the result of a similar evaporation experiment for $^{35}SO_4^{2-}$ solution in which even a flowing of dried nitrogen did not cause a measurable amount of a change in surface concentration.[8]

It must be noted that the results hereby obtained are concerned with the adsorption at the interface between "*humidified propane*" and SDS solution saturated with propane. Such an interface might be different in its nature from SDS solution-air interface, which would best be studied by an end-window counter specially designed for tritium radioactivity measurements.

Radiolysis of Co^{III}-EDTA in Aqueous Solution; The Effect of pH

Niro MATSUURA, Nobuyoshi SHINOHARA and Masaru NISHIKAWA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

and Masao TAKIZAWA

Radiation Chemistry Laboratory, Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received October 13, 1967)

The hydrogen and hydrogen peroxide produced in the radiolysis of Co^{III}-EDTA ($Co^{III}Y^-$) in various pH's have been measured. $G_\infty(H_2)$ in the deaerated system sharply dropped from the value of 3.2 at pH$<$1 to the value of 0.8 at pH$>$4 where G_∞ denotes a limiting value which is reached with increasing solute concentration. $G_\infty(H_2O_2)$ in the aerated system was found to be 2.5—2.0. $G_\infty(-Co^{III}Y^-)$ ($=4.4$) was not affected by the addition of N_2O. $G_\infty(N_2)$ and $G_\infty(H_2)$ were found to be 2.6 and 0.8 respectively. From the results, it is concluded that H atoms and OH radicals reduce Co(III) to Co(II) through the dehydrogenation from the ligand, while e_{aq}^- reduce the complex without any degradation of the ligand.

In the previous papers of the series of study on the radiolysis of Co^{III}-EDTA, we reported that OH radicals and H atoms abstract hydrogen from α-carbon position of EDTA molecule of the complex and that the free radical $Co^{III}Y\cdot^-$ formed by hydrogen abstraction is reduced to $Co^{II}Y'$ by

intramolecular electron transfer from ligand to central cobalt(III) ion where Y′ denotes a degraded EDTA.[1-4]

In this paper the study of radiolysis of Co^{III}-EDTA in dilute solution was extended to higher pH region where hydrated electrons are the predominant reducing species.[5,6] We are particularly interested to see whether hydrated electrons react with Co^{III}-EDTA in a similar way as H atoms do in the acidic medium. Following reactions (1) and (2) are conceivable for e_{aq}^- and Co^{III}-EDTA.

$$Co^{III}Y^- + e_{aq}^- \xrightarrow{H_2O} Co^{III}Y^{\cdot -} + H_2 + OH^- \quad (1)$$

$$Co^{III}Y^- + e_{aq}^- \longrightarrow Co^{III}Y^{2-} \quad (2)$$

By the determination of the hydrogen yields, one can select one of the alternatives as the plausible reaction for e_{aq}^-. Some of the experiment was carried out in the presence of N_2O as the electron scavenger.[7]

Experimental

Material. Triply distilled water was used throughout the study. Ethylenediaminetetraacetatocobaltate(III) salt (KCo^{III}-EDTA·$2H_2O$) was prepared by the method, described previously[1] and then twice recrystallized. The other material used were of reagent grade.

Preparation of Samples and Their Irradiation. Sample solutions were prepared by dissolving the complex salt in 0.4 M sulfate solutions whose pH has been adjusted by adding the required amounts of sulfuric acid and potassium sulfate. The experiment was carried out in the range of pH 0.4—5.0. The irradiation vessel used was the same as that reported previously.[1] Deaerated solutions were prepared by bubbling nitrogen washed with alkaline pyrogarol solution or by thoroughly degassing by repeated freezing-pumping-thawing. The irradiation vessel for solution containing N_2O was cylindrical one of the capacity of 45 m*l*. The vessel containing 15 m*l* of the solution was thoroughly degassed and N_2O was introduced to various pressure. After being sealed off, the vessel was shaken and then irradiated with ^{60}Co γ-rays at the dose rate of 7.2×10^{18}—8.1×10^{18} eV·ml^{-1}hr^{-1} determined by the Fricke dosimeter, taking $G(Fe^{3+})=15.5$.

Analysis of Products. Hydrogen peroxide was determined polarographically.[4] The gases produced by irradiation were pumped from the solution by the freeze-thaw technique, passed thorugh traps at −196°C in order to condense N_2O, and collected in a gas burette. The amount of hydrogen was determined either by passing the gases over heated cupric oxide, or by the gas chromatographic method described previously[4]; these results agreed within experimental error.

Results

Hydrogen Peroxide. Hydrogen peroxide from irradiated solution of Co^{III}-EDTA in the presence of oxygen were determined at various values of pH. The yields of hydrogen peroxide were found to depend on the dose absorved but little on the solute concentration and initial pH of the solution. The good straight lines were obtained between the yield and the dose absorbed up to 4×10^{18} eV·ml^{-1}. Figure 1 shows the hydrogen peroxide yields as the function of solute concentration at a given pH, which shows that the yield is virtually constant except in the lower concentration region. The curve in Fig. 1 approaches to a limiting G value $G_\infty(H_2O_2)$ with increasing solute concentration. By the inverse plot method described in previous paper[1,3] the limiting G value can be calculated and plotted as function of pH in Fig. 2.

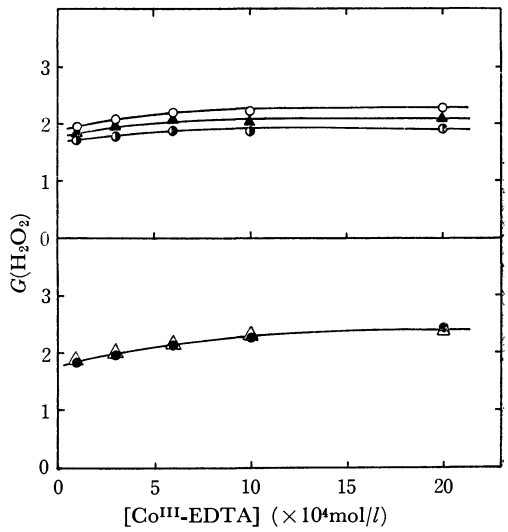

Fig. 1. Hydrogen peroxide yields in aerated Co^{III}-EDTA solution at various pH's.
Initial pH: ● 1.0, △ 2.0, ○ 3.0, ▲ 4.0, ◑ 5.0

Hydrogen peroxide could not be detected from the irradiated Co^{III}-EDTA solution, if oxygen is removed.

Hydrogen Yields. Hydrogen formed in the irradiated solution of Co^{III}-EDTA in the presence and absence of oxygen was measured. The amount depends both on the dose absorbed and initial pH of the irradiated solution. Straight lines were obtained between the yield and the dose absorbed

Effect of N_2O. Figure 5 illustrates the effect of N_2O on $G(H_2)$ together with $G(N_2)$ at the fixed concentration of Co^{III}-EDTA 10^{-3} mol/l (pH= 4.0) in the absence of oxygen. $G(H_2)$ decreases and $G(N_2)$ increases with N_2O concentration until they reach constant values of 2.6 and 0.8 at the concentration of $\sim10^{-2}$ mol/l, indicating the complete scavenging of e_{aq}^-. Effect of variation of Co^{III}-EDTA concentration upon $G(H_2)$ and $G(N_2)$ in deaerated Co^{III}-EDTA solution containing N_2O in sufficiently high concentration to scavenge e_{aq}^- (2.5×10^{-2} mol/l) is shown in Fig. 6. It is readily seen that both $G(N_2)$ and $G(H_2)$ depend on Co^{III}-EDTA concentration up to $\sim10^{-3}$ mol/l, beyond which $G(N_2)$ and $G(H_2)$ were 2.6 and 0.8, respectively.

$G(-Co^{III}Y^-)$ in the presence of 2.5×10^{-2} mol/l of N_2O increases with Co^{III}-EDTA concentration,

○ Co^{III}-EDTA
● Co^{III}-EDTA+2.4×10^{-2}mol/l N_2O

as shown in Fig. 7 together with the result of the system in the absence of N_2O. Each curve in Fig. 7 approaches to a limiting G value with increasing Co^{III}-EDTA concentration. By the inverse plot method, $G_\infty(-Co^{III}Y^-)$ was determined to be 4.5 for Co^{III}-EDTA system and 4.4 for Co^{III}-EDTA-N_2O system. The various limiting G values obtained were summarized in Table 1.

Discussion

Decomposition Mechanism in Deaerated System. Co^{III}-EDTA is reduced to Co(II) state in aqueous medium under the effect of irradiation and the decomposition mechanism of Co^{III}-EDTA in the 0.8 N sulfuric acid solution was explained in terms of a series of the processes of (3), (4), (5), (6), (7) and (8) as described in the previous papers,[1,2,4] where Y and Y′ denoted EDTA and a degraded form of EDTA, respectively.*1

$$Co^{III}Y^- + H \longrightarrow Co^{III}Y\cdot^- + H_2 \quad (3)$$

$$Co^{III}Y\cdot^- \longrightarrow Co^{II}Y' + H^+ \quad (4)$$

*1 Concievable forms of the species of Y· and Y′ were shown in Ref. 4.

$$Co^{III}Y^- + OH \longrightarrow Co^{III}Y\cdot^- + H_2O \quad (5)$$

$$H + O_2 \longrightarrow HO_2 \quad (6)$$

$$HO_2 + HO_2 \longrightarrow H_2O_2 + O_2 \quad (7)$$

$$H + H_2O_2 \longrightarrow OH + H_2O \quad (8)$$

In the present discussion we attempt to explain stoichiometrically the G values observed in higher pH solution. It seems reasonable to assume that oxidizing radicals OH, whose $pK_a=11.2$,[8] react as such with Co^{III}-EDTA by reaction (5) also at pH$\simeq$5 as in 0.8 N sulfuric acid, while it is expected that reactions of the reducing radicals in higher pH range are different. In the radiolysis of deaerated Co^{III}-EDTA solution, $G_\infty(H_2)$ sharply dropped from the value of 3.2 in the acidic medium to the value of 0.8 at pH=4 as shown in Fig. 4. $G(H_2)=0.8$ in the deaerated system is larger than the primary hydrogen yield $G_{H_2}=0.4$ from water. This suggests that H atoms ($G_H=0.55$)[9] are produced in higher pH region besides hydrated electrons, and it is only H atom that abstracts hydrogen from ligand EDTA of the complex by reaction (3) as in 0.8 N sulfuric acid medium. The facts that $G(H_2)\fallingdotseq G_H+G_{H_2}$ appears to indicate the absence of the reaction (1).

We found that the reduction yield of the complex was almost independent of pH as shown in Table 1. This may be interpreted as the result of the direct attack of e_{aq}^- to the central cobalt(III) ion of the complex *via* reaction (2).

$$Co^{III}Y^- + e_{aq}^- \longrightarrow Co^{II}Y^{2-} \quad (2)$$

The evidence for the participation of the hydrated electrons in the reduction of the complex is provided by $G_\infty(N_2)$ and $G_\infty(-Co^{III}Y^-)$ from the irradiated Co^{III}-EDTA in deaerated solution at pH=4 in the presence of N_2O which is believed to convert the hydrated electron to radical OH by reaction (9).

$$N_2O + e_{aq}^- \xrightarrow{H_2O} N_2 + OH + OH^- \quad (9)$$

TABLE 2. COMPARISON BETWEEN THE OBSERVED G VALUES AND THE CALCULATED G VALUES FROM POSTULATED MECHANISM AT pH=4.0

System	$G(-Co^{III}Y^-)$	$G(H_2)$
Co^{III}-EDTA	$G_{e_{aq}^-} + G_H + G_{OH} = 5.10$ (4.5)	$G_H + G_{H_2} = 1.00$ (0.8)
Co^{III}-EDTA + O_2	$G_{OH} = 2.25$ (1.8)	$G_{H_2} = 0.45$ (0.4)
Co^{III}-EDTA + N_2O	$G_{e_{aq}^-} + G_H + G_{OH} = 5.10$ (4.4)	$G_H + G_{H_2} = 1.00$ (0.8)

System	$G(H_2O_2)$	$G(N_2)$
Co^{III}-DTA	(0)	—
Co^{III}-EDTA + O_2	$G_{OH} + (G_{e_{aq}^-} + G_H)/2 = 2.14$ (2.1)	—
Co^{III}-EDTA + N_2O	—	$G_{e_{aq}^-} = 2.3$ (2.6)

( ) denotes the observed G values.

As shown in Table 1 $G_\infty(N_2)$ and $G_\infty(-Co^{III}Y^-)$ were 2.6 and 4.4, respectively and $G(-Co^{III}Y^-)$ was almost the same value regardless of the presence or absence of N_2O. This observation may be explained by the reduction of $Co^{III}Y^-$ to $Co^{II}Y'$ *via* reactions (5) and (4) by OH radicals from reaction (9), which supplements the decreases of the reaction (2).

In the radiolysis of Co^{III}-EDTA in deaerated 0.8 N sulfuric acid solution, hydrogen peroxide was not detected, probably because it is destroyed by H atoms through reaction (8).[4] The fact that hydrogen peroxide can neither be detected in higher pH region may be explained by invoking a similar reaction of hydrated electron with hydrogen peroxide (reaction (10)).[9,10]

$$H_2O_2 + e_{aq}^- \longrightarrow OH + OH^- \qquad (10)$$

If H atoms react quantitatively with hydrogen peroxide (reaction (8)) $G(H_2)$ observed should be equal to the primary hydrogen yield ($G_{H_2}=0.45$) from water.

From the above consideration, it may be concluded that all the reacting species (H, e_{aq}^- and OH) from water radiolysis contribute to the reduction of the complex. H atoms and OH radicals reduce the complex through the hydrogen abstraction from the ligand, while e_{aq}^- reduced the complex by direct attack of the central cobalt(III) ion.

Decomposition Mechanism in Aerated System. As seen in the radiolysis in the 0.8 N sulfuric acid medium not only H atoms but also hydrated electrons are scavenged by oxygen to form anion O_2^- by the reaction (11).

$$e_{aq}^- + H^+ + O_2 \longrightarrow HO_2 \rightleftarrows H^+ + O_2^- \qquad (11)$$

The anion O_2^- does not usually participate in the reduction of complex, because the radiolysis of the aerated solution gives much smaller $G_\infty(-Co^{III}Y^-)$ than in the deaerated one as shown in Table 1. The $G_\infty(H_2O_2)$ in the aerated solution is 2.1 as shown in Fig. 2, which may be explained if we assume one equivalent of O_2^- is consumed for producing half equivalent of hydrogen peroxide by reaction (12) without any reaction with Co^{III}-EDTA.[1]

$$O_2^- + O_2^- \longrightarrow H_2O_2 + 2OH^- \qquad (12)$$

It implies that in the aerated system only OH radicals decompose the complex by reactions (5) and (4) as in 0.8 N sulfuric acid.

The decomposition mechanism of Co^{III}-EDTA invoking the reactions described above are consistent with the obtained results in that it satisfies the stoichiometric relationship between observed G values and the primary radical and molecular yields (taking $G_H=0.55$, $G_{e_{aq}^-}=2.30$, $G_{OH}=2.25$, $G_{H_2O_2}=0.71$, $G_{H_2}=0.45$).[11] As shown in Table 2, our observed G value can be explained quantitatively using the primary radical and molecular yields from water, except $G(-Co^{III}Y^-)$ where small discrepancy between calculated G values from the mechanism and observed G values exists. Nevertheless the discrepancy would not affect greatly the essential part of the decomposition mechanism.

The authors express thanks to Professor Y. Yoshino and his co-workers for many useful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1289—1295 (1968)

The Electronic and Vibrational Spectra of Oxalyl Bromide*[1]

Hiroko SHIMADA, Ryoichi SHIMADA and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received December 15, 1967)

The infrared and Raman spectra of oxalyl bromide have been observed. The spectral features suggest that this molecule is planar and *trans* at room temperature. An assignment has been given for all the fundamental vibrational frequencies. The ultraviolet absorption spectrum of oxalyl bromide has been studied in cyclohexane and in the vapor. The spectrum consists of four absorption systems. These were ascribed to a $^3A_u(n, \pi^*)\leftarrow{}^1A_g$, a $^1A_u(n, \pi^*)\leftarrow{}^1A_g$, the second $^1A_u(n, \pi^*)\leftarrow{}^1A_g$ and a $^1B_u(\pi, \pi^*)\leftarrow{}^1A_g$ transitions, respectively. Vibrational analyses have been made for the $^3A_u(n, \pi^*)\leftarrow{}^1A_g$ and the first $^1A_u(n, \pi^*)\leftarrow{}^1A_g$ systems.

The infrared and Raman spectra of oxalyl chloride have been investigated by several workers.[1-4] Recently, Hencher and King[5] have shown that only the *trans*-form contributes to the observed spectra and given assignments for all the fundamental vibrational frequencies.

Saksena and Kagarise[6] have studied the near ultraviolet absorption spectrum of oxalyl chloride and found two $n\rightarrow\pi^*$ absorption systems in the 3800—2400 Å region. Sidman,[7] and Saksena and Jauhri[8] have also observed the absorption spectrum of the oxalyl chloride vapor and carried out a vibrational analysis for the first $n\rightarrow\pi^*$ system. Shimada and Kanda[9] have studied the T–S emission and absorption spectra of oxalyl chloride and ascribed these spectra to a $^3A_u(n, \pi^*)$–^1A_g transition.

Very few spectroscopic works have been reported for oxalyl bromide, although its molecular stucture is quite similar to that of oxalyl chloride. A weak absorption spectrum of oxalyl bromide in the 4300 Å region has been observed by Shimada and Kanda and it was ascribed to a $T(n, \pi^*)\leftarrow S$ transition.[10] This assigmnent was confirmed by Borkman and Kearns.[11] In the present investigation, the electronic and vibrational spectra of this molecule have been studied in continuation of a previous work.

Experimental

Oxalyl bromide was synthesized with oxalyl chloride and gaseous HBr, which was produced by dropping bromine on a mixture of red phosphorus, sand and water. The crude product was distilled and a fraction which boiled at 103°C was collected. The collected distillate, which still contained free bromine, was shaken with a small quantity of mercury. After the red color of bromine disappeared, the transparent liquid was decanted and fractionally distilled repeatedly. The purified oxalyl bromide was stored in an evacuated cell. The sample was prepared in a dry room just before the measurement, because oxalyl bromide reacts quite easily with water and decomposes into CO, CO_2 and HBr.[12]

The Raman spectrum of oxalyl bromide was studied at 20°C, 77°K and 4.2°K with a two-prism spectrograph described previously.[13] An aqueous solution of $K_2Cr_2O_7$ was used as a filter in order to eliminate exciting light shorter in wavelength than 5460 Å (Hg-c line). Concentration of the filter solution was 0.2% and the optical path was 1 cm. Exposure time ranged from 12 to 48 hr with a slit-width of 50μ and Eastman Kodak 103a-F plates. The slit was widened up to 300 μ for the low temperature measurement. The liquid sample was replaced with new one for every three hours, since prolonged strong irradiation decomposes oxalyl bromide[12] and turns the sample reddish brown. A Wollaston prism was used for the study of the depolarization factor.

The infrared spectrum of oxalyl bromide was studied in the crystal at 77°K, in the liquid at 20°C, in CCl_4 and CS_2 solutions at 20°C and in the vapor at various temperatures ranging from 20 to 200°C without

altering the total number of molecules in the vapor cell with a Hitachi Infrared Spectrophotometer, type EPI-2. Since oxalyl bromide is not stable at high temperature,[12] the vapor cell was heated rapidly up to an appropriate temperature and the spectrum was scanned very quickly. The sample was replaced with new one for every run. The cell thickness was 10 cm for the vapor and 0.1 cm for solutions. A thin layer sample was used for studying the liquid phase. The spectrum of the crystal at 77°K was observed in the same way as described previously.[14]

The ultraviolet absorption spectrum was observed in cyclohexane solution at 20°C with a Hitachi Recording Spectrophotometer, type EPS-3, and in the vapor with a Shimadzu Large Quartz Spectrograph, type QL-170. Vapor pressure of oxalyl bromide in a vapor cell of 40 cm in length was controlled by changing the temperature of the cell from −20 to 50°C. A 1 m vapor cell was used for the observation of the T←S absorption. The vapor spectrum was also studied at various temperatures ranging from 20 to 200°C with keeping the total number of molecules constant in the cell. The same care was taken to prevent the sample from decomposition by heating as that taken for the infrared spectrum.

Upper half: in various phases.
Lower half: at various temperatures in the vapor phase.

Results and Discussion

Rotational Isomerism. Since oxalyl bromide contains two CoBr groups connected with a C–C bond, one can expect the existence of rotational isomers, that is, *trans*-, *cis*- and *staggered*-isomers. Among them, the first isomer is expected to be most stable, because (1) the resonance energy of π-electrons is greater in the *trans*- and *cis*-isomers than in the *staggered*-isomer, (2) the electrostatic potential is lower in the *trans*-isomer than in the *cis*-isomer, and

(3) the steric repulsion between the Br and O atoms is smaller than that between the two Br atoms.

In order to seek the possible evidences for the existence of rotational isomers in oxalyl bromide, we studied the temperature dependences of the Raman, infrared and ultraviolet absorption spectra of this molecule. The infrared spectra observed in various phases and at various temperatures are shown in Fig. 1 and the spectral data are given in Table 1. The Raman spectral datum observed in the liquid is given in Table 2. The observation of the Raman spectrum of the oxalyl bromide crystal was unsuccessful owing to quite weak scattering from the crystal and only a few bands were obtained. These are given in Table 2. The temperature dependence of the ultraviolet absorption spectrum is shown in the upper right of Fig. 3. It can be seen from these figures and tables that:

(1) Each band in the infrared spectrum observed in the vapor becomes broader with increasing temperature but the essential spectral structure remains unchanged except for a few bands which increase in intensity at high temperature and become quite prominent in the spectrum at 200°C. The infrared spectrum of the "oxalyl bromide"

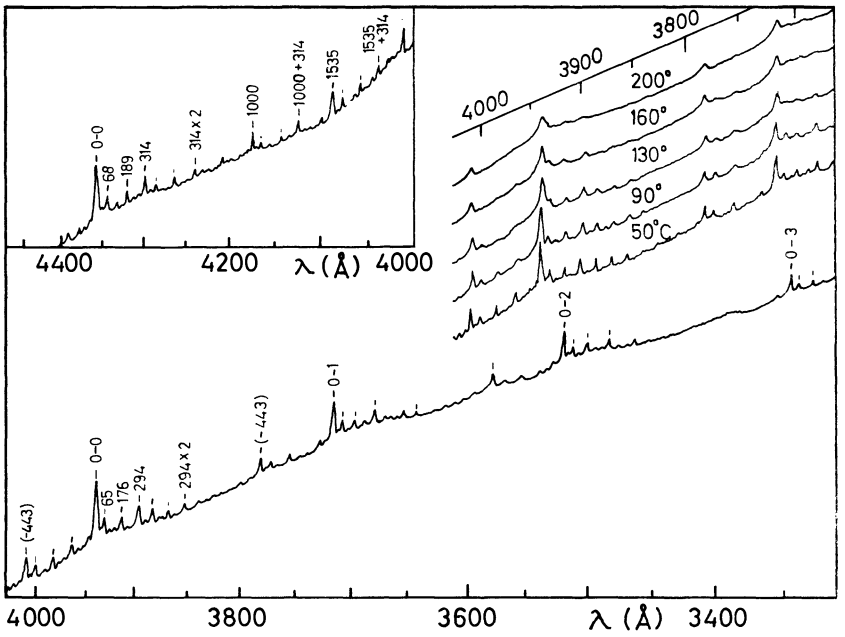

Fig. 3. Near ultraviolet absorption spectrum of the oxalyl bromide vapor.

vapor which was kept at about 220°C for about one hour and then cooled at room temperature is given in the bottom of Fig. 1. This spectrum consists of a few bands which coincide with the unusual bands observed in the high temperature spectrum. These frequencies are 2350, 2155, 2080, 720, 668 and 616 cm^{-1}. The 2155 cm^{-1} band is ascribed to the CO gas[15] and the others to the CO_2 gas.[16]

(2) There are no essential structural differences in the infrared spectra observed in various phases except for the bands at about 540, 660, 714, 975 and 1780 cm^{-1}. The 540 cm^{-1} band is assigned to a difference band and this must be diminished at low temperature. The 660 cm^{-1} band, whose intensity is fairly strong in the condensed phases, is ascribed to an unresolved band of 662 and 667 cm^{-1}. The 667 cm^{-1} band and the 714 cm^{-1} band, which is observed in the crystal, are ascribed to CO_2, because slight bubbling of oxalyl bromide was inevitable during the preparation of the sample. The weak 975 cm^{-1} band, which is not observed in the vapor, is assigned to an infrared inactive band which appears in the spectrum through perturbation by the medium.

(3) A mutual exclusion relationship is found between the infrared and Raman spectra except for the strongest Raman band at 1784 cm^{-1}. The same vibrational frequency was also observed in the infrared spectrum as a shoulder of the strongest band at 1807 cm^{-1} in the liquid and solutions, but this was not observed in the crystal nor in the vapor even at high temperature. This band is assigned to an infrared active band and will be discussed in the next section.

(4) The behavior of the temperature dependence of the ultraviolet absorption spectrum of the oxalyl bromide vapor is the same as that observed in the oxalyl chloride vapor by Sidman.[7] Although the spectral structure remains unchanged, the absorption bands, which are very sharp at room temperature, become broader and decrease in intensity with increasing temperature. At higher temperature, the discrete bands are superimposed on a continuous background and this background increases in intensity with increasing temperature. This phenomenon is reversible if heating does not exceed 130°C. Heating of the oxalyl bromide vapor above 130°C does not change the spectral structure when the sample is cooled at room temperature again, but the absorption decreases in intensity owing to the decomposition of the sample.

These experimental facts indicate that only one isomer contributes to the observed discrete spectral bands and thus it can immediately be concluded that the discrete band spectra are due to the *trans*-isomer of oxalyl bromide. A careful observation of the ultraviolet absorption spectrum of the oxalyl bromide vapor showed that the continuous background, which was assigned to the *cis*-form by Sidman,[7] was hardly detectable at room temperature. This indicates that the oxalyl bromide molecule is planar and *trans* at room temperature.

16) G. Herzberg, "Molecular Spectra and Molecular Structure. II. Infrared and Raman Spectra of Polyatomic Molecules," D. Van Nostrand Company, New York (1949), p. 272.

Vibrational Spectrum and Assignments. For the *trans*-form of oxalyl bromide (C_{2h} point group), the twelve fundamental vibrations are classified into four symmetry species, that is, 5 vibrations into a_g species, 1 into b_g, 2 into a_u and 4 into b_u. The first six fundamentals are Raman active and the last six are infrared active.

The observed strong and polarized Raman bands of 191, 415, 600, 1032 and 1784 cm^{-1}*2 are straightforwardly assigned to totally symmetric COBr rocking ν_5, COBr scissoring ν_4, C–Br stretching ν_3, C–C stretching ν_2 and C=O stretching ν_1 vibrations, respectively and the strong and depolarized Raman band of 376 cm^{-1} to a COBr wagging vibration ν_8 of b_g species.

The strong infrared bands of 728 and 1807 cm^{-1} are assigned to a C–Br stretching vibration ν_{10} and a C=O stretching vibration ν_9, both are of b_u species, respectively. A weak infrared band around 405 cm^{-1}, whose intensity could not precisely be measured because of poor reliability of our spectrophotometer in this region, can be assigned to a COBr scissoring vibration ν_{11} of b_u species. The medium strong Raman band of 808 cm^{-1}, which seems to be polarized, and the medium infrared bands of 592 and 1004 cm^{-1} can be interpreted as an overtone vibration of ν_{11} and combination vibrations of $\nu_5+\nu_{11}$ and $\nu_3+\nu_{11}$, respectively.

The remaining three fundamentals, that is, a COBr rocking vibration ν_{12} of b_u species, a COBr wagging vibration ν_6 of a_u species and a COBr twisting vibration ν_7 of a_u species are expected to appear in the lower frequency region than 400 cm^{-1}, which is the limit of measurement with our spectrophotometer. The weak Raman bands of 246, 342 and 494 cm^{-1} were presumed to be assigned to overtone vibrations of ν_7, ν_{12}, and ν_6, respectively. The medium infrared bands of 662 (a component of the unresolved 660 cm^{-1} band), 690 and 772 cm^{-1} could be interpreted as combination vibrations of $\nu_4+\nu_6$, $\nu_5+\nu_7+\nu_8$ (or $\nu_7+\nu_{11}+\nu_{12}$) and $\nu_3+\nu_{12}$, respectively.

The weak but distinct infrared band of 1780 cm^{-1} is rather puzzling. This band was assigned to a combination vibration of $\nu_2+\nu_{10}$, but it cannot be understood why this band is not observed in the crystal nor in the vapor. Detailed analyses of the infrared and Raman spectra are given in Tables 1 and 2.

Ultraviolet Absorption Spectrum. *Assignment of the Electronic Transitions.* The ultraviolet absorption spectrum of oxalyl bromide in cyclohexane is given in Fig. 2 together with that of oxalyl chloride. The spectrum consists of four absorption systems, which will be called here system I, II, III and IV.

The system I appears in the longest wavelength region and its absorption maximum is located at 4276 Å with $\varepsilon=2.0$ in cyclohexane. We observed the corresponding absorption system of oxalyl chloride in the 4100 Å region with $\varepsilon_{max}=0.07$ and ascribed it to a $^3A_u(n, \pi^*)\leftarrow{}^1A_g$ transition on the basis of a vibrational analysis and the lifetime of the corresponding emission spectrum.[9] Comparing these two absorption spectra with one another, the system I has to be assigned to the same T←S transition as that of oxalyl chloride. A vibrational analysis of this system in the vapor spectrum, which will be described later, indicates that the transition has an allowed $n\rightarrow\pi^*$ character. This fact also supports the $^3A_u\leftarrow{}^1A_g$ assignment given to this system.

We tried to observe the T→S emission of oxalyl bromide but it was too weak to be measured in any solvent. Recently, Borkman and Kearns[11] studied the phosphorescence excitation spectrum of oxalyl bromide in rigid glass solutions containing naphthalene or phenanthrene and confirmed this assignment.

The $f_{T\leftarrow S}$-value observed in cyclohexane solution is 3.0×10^{-6}. This is unusually large for a multiplicity forbidden transition.[17]

The system II which appears in the 4000—3200 Å region with $\varepsilon_{max}=50$ is ascribed to a $^1A_u(n, \pi^*)\leftarrow{}^1A_g$ transition on the analogy of the corresponding absorption system of oxalyl chloride.[6] We observed the rotational spectrum of the 0–0 band of this system under high resolution condition and found that this band has a typical parallel type structure. This fact indicates that the transition moment of the 0–0 band is perpendicular to the molecular plane and this definitely confirms the above assignment. A detailed report on the rotational spectrum will be given elsewhere. The f-value observed in cyclohexane is 7×10^{-4}.

The system III which appears in the 3000—2500 Å region with $\varepsilon\approx500$ is very diffuse and was attributed to the second $^1A_u(n, \pi^*)\leftarrow{}^1A_g$ transition by analogy with the assignment given for the corresponding absorption system of oxalyl chloride.[6]

The onset of the system IV overlaps on a tail of the system III and a broad absorption appears to the shorter wavelengths with increasing intensity. Although the exact absorption maximum was not determined because of poor reliability of our spectrophotometer in this region, the apparent maximum is located around 1900 Å with $\varepsilon\approx10^4$. Sidman[18] calculated the energy of the first $^1B_u(\pi, \pi^*)\leftarrow{}^1A_g$ transition in glyoxal and obtained 7.4 eV for this energy, which corresponds to about 1680 Å. From the very strong intensity of this system and the general prediction that a bromine substitution causes a red shift for a $\pi\rightarrow\pi^*$ transition, we ascribed this system to a $^1B_u(\pi, \pi^*)\leftarrow{}^1A_g$

*2 The Raman and infrared frequencies observed in the liquid at room temperature are used in this discussion.

transition.

Vibrational Analysis of the Absorption Spectrum. The absorption spectrum of the oxalyl bormide vapor due to the first $^1A_u(n, \pi^*) \leftarrow {}^1A_g$ transition consists of a number of sharp bands and its spectral structure quite resembles to that of oxalyl chloride.[7] The spectrum and the spectral data for this system are shown in Fig. 3 and Table 3, respectively.

The strongest band at 25373 cm^{-1} was taken as the 0–0 band of this system. The prominent feature of the spectrum is the interval of 1537 cm^{-1}, which produces a main progression starting from the 0–0 band. This frequency can be assigned to the totally symmetric C–O stretching vibration ν_1 in the excited state.

The next prominent feature is the interval of 443 cm^{-1} which appears in the longer wavelength side of the individual bands of the main progression. Temperature dependence of the 24930 cm^{-1} band, which is separated by 443 cm^{-1} from the 0–0 band, clearly shows a characteristic behavior of a hot band (see Fig. 3). We therefore, assigned the interval of 443 cm^{-1} to the ground state frequency of ν_4. The corresponding Raman frequency observed in the liquid is 415 cm^{-1}. The discrepancy between two frequencies is fairly large. The similar frequency shifts were also observed in the Raman spectrum by changing the phase from the liquid to the crystal (see Table 2). These observations may suggest that the modes of these vibrations are sensitive to a change of the phase in this molecule. The band at 26,465 cm^{-1} is separated by 445 cm^{-1} from the 0–1 band and by 1092 cm^{-1} from the 0–0 band. Although the interval of 1092 cm^{-1} might be assigned to the excited state frequency of the totally symmetric C–C stretching vibration ν_2, the behavior of the temperature dependence of the 26465 cm^{-1} band is the same as that of the 24930 cm^{-1} band. This fact denies the ν_2 assignment.

There are another prominent interval of 294 cm^{-1} which appears in the shorter wavelength side of the individual bands of the main progression. This interval very probably corresponds to the excited state frequency of ν_4, because the band structure of the 294 cm^{-1} band resembles to that of the 443 cm^{-1} band and the overtone of this frequency is also observed in the spectrum. Other intervals of 65 and 176 cm^{-1} are also quite prominent. All strong bands mentioned above are accompanied by these two subbands in their shorter wavelength side.

The absorption spectrum of the oxalyl bromide vapor due to the $^3A_u(n, \pi^*) \leftarrow {}^1A_g$ transition consists of a number of sharp bands. A microphotometer tracing of the spectrum and the spectral data are presented in the upper left of Fig. 3 and Table 3, respectively. The spectral structure is quite similar to that of the $^1A_u(n, \pi^*) \leftarrow {}^1A_g$ absorption system.

The strongest band at 22943 cm^{-1} was taken as the 0–0 band of this system. The totally symmetric C–O stretching vibration seems to constitute a main progression, but the tail of this system overlaps on the onset of the strong S′←S absorption system and, therefore, only one quantum of this vibration could be observed. A strong band at 24478 cm^{-1}, which is separated by 1535 cm^{-1} from the 0–0 band, is the first member of this progression. There is a sharp and distinct band at 23943 cm^{-1}, which is separated by 1000 cm^{-1} from the 0–0 band and by 535 cm^{-1} from the 0–1 band. The interval of 1000 cm^{-1} was assigned to the triplet state frequency of the C–C stretching vibration ν_2, because the interval of 535 cm^{-1} is too large to be assigned to the ground state frequency of ν_4. There are prominent intervals of 68, 189 and 314 cm^{-1} which appear in the shorter wavelength side of three strong bands mentioned above. The interval of 314 cm^{-1} very probably corresponds to the triplet state frequency of ν_4.

The fact that the spectral structure of this system quite resembles to that of the first $^1A_u(n, \pi^*) \leftarrow {}^1A_g$ absorption system (see Fig. 3) suggests that the system I is caused by an $n \rightarrow \pi^*$ promotion. The allowed $n \rightarrow \pi^*$ character of this transition definitely indicates that the triplet state involved in this transition is a $^3A_u(n, \pi^*)$ state.

Detailed vibrational analyses of both the systems I and II are given in Table 3.

Studies of Poly-2-vinylpyridine. VI. Thermodynamic Data on Solutions of Poly-2-vinylpyridine in Various Solvents

Shizuo ARICHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

and Yoshio TANIMOTO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 18, 1967)

The viscosities of dilute solutions of several fractions of poly-2-vinylpyridine have been measured in methanol, isopropanol, chloroform, benzene, dioxane, and methyl ethyl ketone at different temperatures, ranging from 15 to 65°C. The osmotic pressures of dilute solutions of fractions of the polymer have been measured in dioxane at 10, 25, 40, and 65°C. The data have then been analysed using the theories of Flory and Fox and of Kurata and Stockmayer. The results obtained are as follows: (1) the entropy parameters, ψ_1, for the solutions of poly-2-vinylpyridine in methanol and isopropanol are negative, while the critical miscibility temperatures, θ, are positive and extraordinary high; (2) ψ_1 is positive and θ is negative in chloroform; (3) These parameters behave regularly in benzene and dioxane. Qualitatively the same results have also been obtained with the poly-4-vinylpyridine fraction in several solvents, including methanol and chloroform. These results show that in alcohols and chloroform the temperature coefficient of the solubility of polyvinylpyridines is negative, and indicate the presence of strong interaction between segments and solvents, probably due to hydrogen-bond formation.

In the preceding paper[1] some properties of poly-2-vinylpyridine solution in ethanol have been described: the entropy parameter, ψ_1, from the viscosity data is negative; the critical consolute temperature, θ, from the same data is extraordinary high, and both the heat and the entropy of dilution obtained from the data of osmotic pressure are negative. It has been concluded that these peculiarities may be the result of the strong interaction between the segment and solvent itself, probably because of the hydrogen-bond formation between the nitrogen atom in the pyridine ring and the hydroxyl group in the solvent molecule.

The same results have been reported for the poly-4-vinylpyridine-*t*-butanol-benzene system[2] and the polyacrylic acid - dioxane system.[3] The negative value of ψ_1 has also been reported for the polymethacrylonitril - methyl ethyl ketone system.[4] However, the reports on such peculiar properties are very limited, and it is considered to be important to confirm the conclusions of the preceding paper by performing similar experiments in other acidic solvents which are capable of hydrogen-bond formation, and also in neutral or basic solvents which are not. In this report, thermodynamic data on poly-2-vinylpyridine solutions in methanol, isopropanol, and chloroform, and on such solutions in benzene, dioxane and methyl ethyl ketone as slovents of the latter category are presented. The results of complementary experiments on poly-4-vinylpyridine in several solvents will also be described.

Experimental

The fractions of poly-2-vinylpyridine, E-2, K-2, and C-1, were the same as those used in a previous study.[5] The unfractionated poly-2-vinylpyridine, $2U_0$, was obtained by block polymerization in a sealed tube at 60°C, and was purified by repeated precipitations in methyl ethyl ketone by addition of ligroin.

Poly-4-vinylpyridine was prepared by the suspension method.[6] Thirty-five grams of the polymer were fractionated into 8 fractions by the column-elusion method. The fourth fraction, 4F-4, was used in this study.

The intrinsic viscosity and osmotic pressure were measured by the methods described in a previous paper.[1] The solvents were dried and fractionally distilled according to usual methods.[7]

Results

Temperature Variation of the Intrinsic Viscosity. The intrinsic viscosities of the solutions of the poly-2-vinylpyridine fraction, E-2, in methanol, isopropanol, and chloroform; those of the K-2 fraction in benzene, dioxane, and methyl ethyl ketone, and those of $2U_0$ in methanol at various temperatures are shown in Table 1. The experimental results for the poly-4-vinylpyridine fraction, 4F-4, in methanol, isopropanol, chloroform, and pyridine are summarized in Table 2.

The relations between the intrinsic viscosities and the temperature for poly-2-vinylpyridine fractions in various solvents are shown in Fig. 1, and those for the poly-4-vinylpyridine fractions, in Fig. 2.

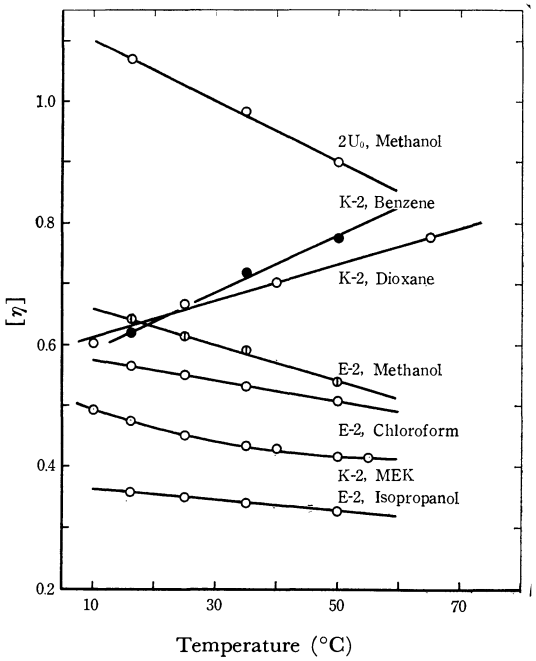

Fig. 1. Plots of the intrinsic viscosities of poly-2-vinylpyridine fractions in various solvents *vs.* temperature.

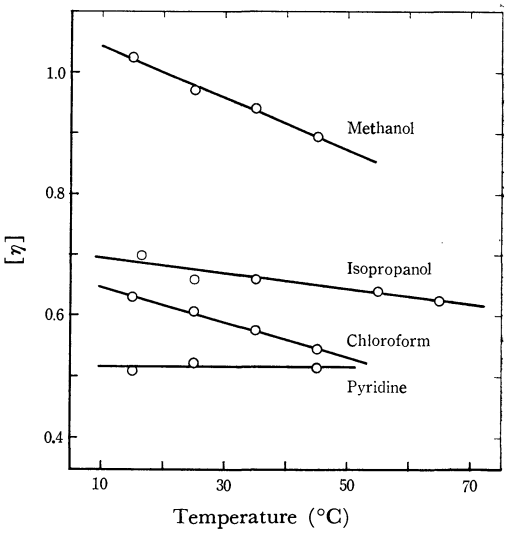

Fig. 2. Plots of the intrinsic viscosities of poly-4-vinylpyridine fractions *vs.* temperature.

Table 1. The intrinsic viscosities of poly-2-vinylpyridine fractions in various solvents at different temperatures

Fraction	Solvent	[η] Temperature (°C)						
		10	16.2	25	35	40	50	65
E-2	Methanol		0.640	0.614	0.583		0.540	
$2U_0$	Methanol		1.068		0.982		0.901	
E-2	Chloroform		0.566	0.549	0.531		0.510	
E-2	Isopropanol		0.358	0.349	0.344		0.328	
K-2	Benzene		0.620		0.719		0.775	
K-2	Dioxane	0.601		0.668		0.701		0.701
K-2	MEK	0.495	0.479	0.452	0.434	0.430	0.415	

Table 2. The intrinsic viscosities of poly-4-vinylpyridine fractions in various solvents at different temperatures

Fraction	Solvent	[η] Temperature (°C)						
		15	16.5	25	35	45	50	65
4F-4	Methanol	1.025		0.970	0.942	0.895		
4F-4	Chloroform	0.630		0.606	0.575	0.545		
4F-4	Isopropanol		0.700	0.660	0.660		0.640	0.625
4F-4	Pyridine	0.510		0.522		0.515		

As may be seen in these figures, the temperature coefficients of the intrinsic viscosities of both poly-2-vinylpyridine and poly-4-vinylpyridine fractions in methanol, isopropanol and chloroform are negative, as are those of poly-2-vinylpyridine[1] and poly-4-vinylpyridine[6] in ethanol. On the contrary, the coefficients are positive or almost zero in the case of neutral or basic solvents, such as benzene and pyridine, as is usual in a nonpolar polymer - nonpolar solvent system. Methyl ethyl ketone is a typical basic solvent,[8] but the temperature coefficient for the system of poly-2-vinylpyridine-methyl ethyl ketone is rather negative.

Although the results shown in Figs. 1 and 2 seem to support our previous conclusion[1,8] that, for polyvinylpyridine, acidic solvents are good solvents and neutral or basic solvents, poor solvents, further examinations were made by analysing the data using the Flory-Fox[9] and Kurata-Stockmayer[10] theories.

As is well known, the thermodynamic interactions between polymer segments and solvent molecules are represented by the following equations, (1) and (2), given by Flory and Fox[9] and by Kurata and Stockmayer[10] respectively:

$$(K_T/K_0)(\alpha_\eta^5-\alpha_\eta^3)/M^{1/2} = 2C_M\psi_1(1-\theta/T) \quad (1)$$

$$(K_T/K_0)(1-\alpha_\eta^{-2})(\alpha_\eta^2+1/3)^{3/2}/M^{1/2} = (3^5/2^3)1.10C_M\psi_1(1-\theta/T) \quad (2)$$

where the symbols are the same as those used in the previous paper.[1]

It has been reported[1] that the value of the Flory constant, K, for poly-2-vinylpyridine, as estimated from the intrinsic viscosity data in ethanol, is considerably larger than those in the neutral or basic solvents. Now, let us suppose that the values of the Flory constant, K_i, for the samples of poly-2-vinylpyridine with a homogeneous molecular weight in methanol and chloroform are the same as those in ethanol at a certain temperature,[1] and that those in neutral or basic solvents are all equal to the value[11] of 8.2×10^{-4}, regardless of the temperature and the kind of solvent. As for isopropanol, it has already been pointed out that, because of the steric hindrance, the interaction between this solvent and the nitrogen atom in the pyridine ring of poly-2-vinylpyridine is relatively small compared with that in other primary alcohols.[8] In fact, the values of the intrinsic viscosity in isopropanol in this study are very small. Consequently, it was supposed that the value of K_i for this solvent is nearly equal to that of the neutral solvent: 8.2×10^{-4}.

Using the following equations,[10] the values of K_w were calculated, assuming that the molecular-weight distribution for each polymer fraction is represented by the exponential-type molecular-weight distribution function:[12]

$$K_w = K_i q_w \quad (3)$$

$$q_w = \Gamma(h+1.5)/(h+1)^{1/2}\Gamma(h+1) \quad (4)$$

where h is the parameter of the molecular-weight inhomogeneity and is defined by the following equation:

$$M_w/M_n = (h+1)/h \quad (5)$$

The values of K_w thus calculated are shown in Table 3.

TABLE 3. THE VALUES OF K USED FOR CALCULATION OF EQS. (1) AND (2)

Fraction	$M_w\times10^{-4}$	$M_n\times10^{-4}$	M_w/M_n	q_w
E-2	12.01	7.42	1.62	0.955
K-2	52.06	18.07	2.88	0.924

For methanol and chloroform solutions

Temp. (°C)	$K_i\times10^4$ a)	$K_w\times10^4$	
		E-2	K-2

25	13.0	12.4	12.0
40	12.2	11.7	11.3
65	11.5	11.0	10.6

For benzene, dioxane, methyl ethyl ketone and isopropanol solutions

Temp. (°C)	$K_i\times10^4$ b)	$K_w\times10^4$	
		E-2	K-2
10—65	8.20	7.83	7.58

a) The values from Ref. 1.
b) The value from Ref. 2.

The values of α_η were calculated by inserting the values of $[\eta]$, K_w, and M_w into the following equation:[9]

$$\alpha_\eta^3 = [\eta]/K_w M_w^{1/2} \quad (6)$$

Plots of the left-hand side of Eq. (1) for data of the intrinsic viscosity of poly-2-vinylpyridine in various solvents against the reciprocal temperature, $1/T$, are shown in Fig. 3, and those for Eq. (2) are shown in Fig. 4. These figures show the relation to be linear for all the solvents used. The slopes of the lines for benzene and dioxane are normal, while those for the other solvents are negative, in contrast to the case with ordinary polymer-solvent systems.

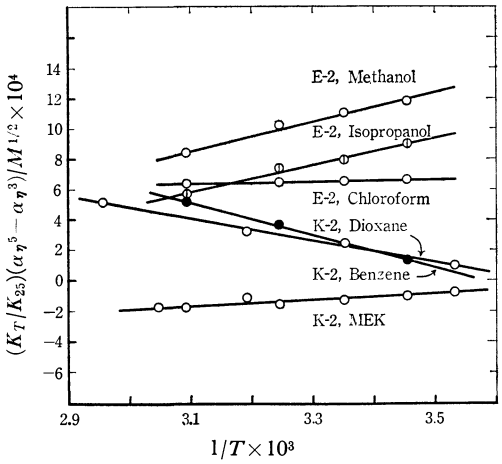

Fig. 3. Plots of the left hand side of Flory-Fox equation, Eq. (1), *vs.* the reciprocal temperature.

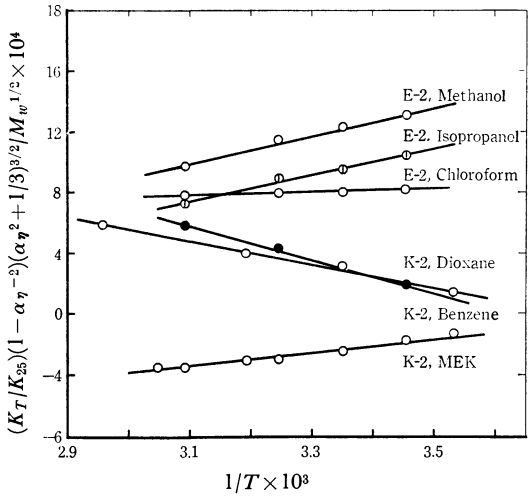

Fig. 4. Plots of the left hand side of Kurata-Stockmayer equation, Eq. (2), *vs.* the reciprocal temperature.

The equations of the linear lines in Figs. 3 and 4 were obtained by the least-square method; the values of the thermodynamic parameters, ψ_1 and θ, were calculated to be as shown in Table 4.

Thermodynamic Interaction Parameters Obtained from the Temperature Dependence of the Osmotic Pressure. The thermodynamic interaction parameters were estimated from the measurement of the temperature variation of the osmotic second virial coefficient, A_2. According to the Flory theory,[13] the relation between A_2 and T is shown by the following equation:

$$A_2 = (\bar{v}^2/V_1)\psi_1(1-\theta/T)F(X) \qquad (7)$$

where $\bar{v}$ is the specific volume of the polymer, and V_1, the molar volume of the solvent; $F(X)$ depends mainly on the thermodynamic interaction parameters but also partly on the molecular weight of the polymer and on the temperature, but at the temperature of θ, $F(X)$ takes a definite value of 1.

In order to compare the data on the intrinsic viscosity with those on osmotic pressure, measurements were carried out for solutions of the C-1 fraction in methanol, chloroform, and dioxane and for a solution of the F-2-3 fraction in methyl ethyl ketone. Unfortunately, the experiments succeeded only in the dioxane solution. In the other solutions the temperature variations of the second virial coefficient were very small, and, in addition, the leak of solute molecules from the membrane at relatively high temperatures could not be avoided. Thus, experimental accuracy was not good enough for the data to serve as the basis of further discussion.

Plots of the reduced osmotic pressure, π/c, against the concentration, c, at each temperature are shown in Fig. 5 for the solution of the poly-2-vinylpyridine fraction, C-1, in dioxane. As may be seen in this figure, the points lie on linear lines, so the osmotic third virial coefficient was neglected. In Fig. 6 the values of A_2 obtained by the least-square method are plotted against T. These plots are also represented by a linear line, whose equation was calculated by the least-square method; the value of θ was determined to be 268.9°K. This value of θ was then inserted into Eq. (7). Plots of $\psi_1 F(X)$ against T are shown in Fig. 7,

from which the value of ψ_1 is obtained as 0.28 for the system of poly-2-vinylpyridine - dioxane.

Discussion

As may be seen in Table 4, the estimated values of θ for benzene, dioxane, and methyl ethyl ketone are somewhat lower than room temperature and seem probable. The value of θ for chloroform is negative, while those for methanol and isopropanol are positive and extraordinary high. On the other hand, the value of ψ_1 for chloroform is positive, while those for methanol and isopropanol are negative. The heat of dilution for chloroform is, therefore, negative, indicating that chloroform is a very good solvent for this polymer. For the solutions of methanol and iospropanol, both the heat and the entropy of dilution are negative, as in the results for the poly-2-vinylpyridine - ethanol system.[1]

The hydrogen-bond formation, as described in a previous paper,[1] is considered to be the main reason for the peculiar findings on the thermodynamic interaction parameters in poly-2-vinylpyridine solutions in alcohols and chloroform. Nevertheless, it seemed useful to confirm that the peculiarity is not due to the presence of some impurities in the polymer. With this object, measurements of the temperature variation of the intrinsic viscosity in methanol with the $2U_0$ polymer and those of several solvents for poly-4-vinylpyridine were carried out; the results are shown in Table 1 and Fig. 1 for the former, and in Table 2 and Fig. 2 for the latter respectively. In order to avoid any possibility of contamination, the poly-2-vinylpyridine sample, $2U_0$, was thermally polymerized in a sealed tube without any initiator or solvent, and was carefully purified by reprecipitation. As may be seen in Fig. 1, the behavior of the intrinsic viscosity of $2U_0$ in methanol is just the same as that of K-2 in the same solvent. The behavior of the intrinsic viscosity of poly-4-vinylpyridine, fraction 4F-4, in pyridine is not so peculiar, while those in alcohols and chloroform are just the same as those of poly-2-vinylpyridine in the same solvents. From these results, it may be concluded that the peculiar behavior of the intrinsic viscosity is not due merely to the presence of some impurities in the samples.

The value of θ for the solution of poly-2-vinylpyridine in a neutral solvent, benzene, as estimated from the data on the intrinsic viscosity, seems appropriate, though the value is rather lower than the value obtained from the dependence of the consolute temperature on the polymer-chain length.[5]

The value of θ for the solution of poly-2-vinylpyridine in dioxane agrees well with that obtained from the osmotic second virial coefficient. It is noteworthy that the value of ψ_1 obtained from the osmotic pressure data is larger than that obtained from the intrinsic viscosity data.

As for the solution of poly-2-vinylpyridine in methyl ethyl ketone, various parameters which indicate that the θ temperatures lie near room temperature were described in a previous paper.[11] For example, at 25°C the long-range interaction

parameter, B, obtained from Fixman's plots is negative; the osmotic second virial coefficient, A_2, is negative, and the exponent, ν, in the Mark-Houwink-Sakurada equation is smaller than 0.5, which is theoretically the smallest value.[10]

The values of α_η obtained from the viscosity data in methyl ethyl ketone in this study are again smaller than 1 in the temperature range of 10—45°C. The osmotic second virial coefficients, A_2, were almost zero throughout the 10—40°C temperature range measured in steps of 5°C. The application of the viscoisity data to Eq. (2) gives 249.3°K and -0.01 for θ and ψ_1 respectively. In fact, the phaseseparation experiments showed that the critical temperature for the poly-2-vinylpyridine fraction, H-3 ($M_w = 14.9 \times 10^4$), is about 247°K.

These results show that the dilution of the solution is exothermic and that methyl ethyl ketone brings poly-2-vinylpyridine to the suspected θ state over a very wide range of temperature. Similar results have been reported by Fujita and others[14] for the polychloroprene - methyl ethyl ketone system. It is not yet clear what kind of chemical interaction is the source of the solution properties in the poly-2-vinylpyridine - methyl ethyl ketone system, but it is possible that the alcoholic –OH group produced by keto-enol tautomerism in methyl ethyl ketone[15] plays some role.

One of the authors (S. A.) wishes to thank Professor Masaji Miura of Hiroshima University and Professor Daisei Yamamoto of Kumamoto University for their kind encouragement and helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1301—1307 (1968)

The H/D Isotope Effect in the Conversion of the Electron into a Hydrogen Atom in Aqueous Acid Solutions at 300 and 77°K[1]

Shin-ichi OHNO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received December 18, 1967)

The isotope effect in the formation of hydrogen atoms as a result of the reaction of the photochemically-produced electron in an acidified solution of hexacyanoferrate(II) has been investigated in both the liquid and solid phases. The magnitude of the effect (H/D) in the liquid phase, determined by a mass-spectrometric analysis of the hydrogen gas evolved from CH_3OH-containing solution, ranges from 3 to 4, and it depends on the temperature. The corresponding H/D ratio in acidic ices (at 77°K), determined by comparing the relative intensities of the ESR signals of the H and D atoms, is rather low (~1.5). Possible mechanisms by which the electron is converted into a hydrogen atom in aqueous acid solutions in both phases are discussed.

Electrons which are generated either by the ionization of water molecules (in radiation chemistry) or by photo-detachment from the solute (in photochemistry) have been shown to react with a variety of substances.[2,3] Many of these reactions in an aqueous solution are diffusion-controlled and may, therefore, be expected to occur even at low temperatures, provided that the reactants can encounter each other. The reaction:

$$e_{aq}^- + H_3O^+ \rightarrow H + H_2O \qquad (1)$$

is one such fast reaction.

The H/D isotope effect in the formation of hydrogen atoms as a result of the reaction of the photochemically-produced electron in an acidified solution of $[Fe(CN)_6]^{4-}$ by way of Reaction (1) has previously been reported;[4] the magnitude of the effect depends slightly on the temperature. Although, these experiments might be helpful in the understanding of the above reaction, no

details of the experimental results were given, nor was there any detailed discussion of them. The present author has since measured the ratio of the H/D atoms produced in UV-irradiated acidic ices (at 77°K) containing $[Fe(CN)_6]^{4-}$ by comparing the relative intensities of the ESR signals of the H and D atoms. The H/D ratio observed in an equi-molar mixture of H_2O-D_2O ice is rather low ($\sim$1.5) as compared with the corresponding value ($\sim$3.5) in the fluid phase. This paper will present these results and will consider the reaction mechanism of the electron in both phases.

Experimental

A low-pressure mercury lamp of the spiral type was used as the light source.[5] The light of wavelengths below 2000 Å was eliminated using a 0.1 M NaCl solution as a filter. Solutions were prepared from laboratory-distilled water. The heavy water (99.7%) was from Showa Denko Co., Ltd. The other chemicals used were of the purest grade available.

Liquid-phase Experiments. Irradiations were carried out in a quartz cylindrical vessel 3 cm in diameter employing 30 or 50 m*l* of the solution. The vessel immersed in a thermostat was connected to a vacuum system. The solution was evacuated as has been previously described.[5] The solution was irradiated for 30 min, during which period it was stirred by a magnetic stirrer. After irradiation, the evolved gas ($\sim$0.7 cm^3) was analysed by a CEC 103 mass spectrometer after having passed through a trap cooled to −196°C. The peak heights were determined in the order of *m/e*: 2, 3, 2, in order to take into account pressure changes in the mass spectrometer. The D_2 (*m/e*=4) was not observed at any time during the experiment. No correction for the fractionation in the mass spectrometer was made, as this is identical for all the samples and was found to be small (an absolute error <10%).[6]

Solid-phase Experiments (ESR Measurements). The electron spin resonance spectra were obtained with a JEP-1 spectrometer operating at 9.4 kMc and with 100 kc/s field modulation. The spectra recorded, after phase-sensitive detection, form the first derivative of the absorption curves.

Sample solutions, after having been flushed with argon, were rapidly frozen in 0.4-cm-diam. quartz tubes in liquid nitrogen. All the frozen samples appeared opaque, except for the 10 N NaOH-solutions, which appeared glassy. The samples weighed about 0.1 g; freezing was complete in about 10 sec. The quartz tube was then placed inside a quartz Dewar flask filled with liquid nitrogen and positioned in the center of the spiral lamp. After irradiation the specimens were transferred, without having been allowed to warm up, into liquid nitrogen in a quartz tipped-Dewar flask, which fits into the ESR cavity. A stream of nirogen gas was passed through the cavity in order to prevent condensation of moisture on the tip of the dewar.

Results

H/D Isotope Effects in the Liquid Phase. When an aqueous acidic solution of potassium hexacyanoferrate(II) containing 1 M CH_3OH is irradiated by light with a wavelength of 2537 Å, the following reactions occur:[5]

$$[Fe(CN)_6]^{4-} + h\nu \rightarrow [Fe(CN)_6]^{3-} + e_{aq}^- \quad (2)$$

$$e_{aq}^- + H_3O^+ \rightarrow H + H_2O \quad (1)$$

$$H + CH_3OH \rightarrow H_2 + CH_2OH \quad (3)$$

$$CH_2OH + [Fe(CN)_6]^{3-} \rightarrow H^+ + HCHO + [Fe(CN)_6]^{4-} \quad (4)$$

In an H_2O-D_2O mixture where the hydrogen ion exists as H_3O^+, H_2DO^+, HD_2O^+ and D_3O^+, both H and D atoms are formed in Reaction (1). Its isotope effect may be measured from the evolved H_2/HD ratio, as the hydrogen atoms thus produced, H and D, react with CH_3OH by Reaction (3) to yield H_2 and HD respectively. The results obtained at a constant temperature (*ca.* 27°C) using various sulfuric acid concentrations are presented in Table 1. In this table, $(H/D)_{water}$ means the H *vs.* D atom ratio in the solution; $(H/D)_{atom}$ means that of the hydrogen atom produced, which is measured as the observed H_2/HD ratio; *S* is the $(H/D)_{atom}/(H/D)_{water}$ ratio, and is commonly called the separation factor.[7] Table 2 presents the results obtained at $[H_2SO_4]$=0.1 N and $(H/D)_{water}$ =1.1, but at various temperatures of irradiation.

It should be noted that the interaction of H and D atoms with the solvent does not contribute to the isotope effect in the present case, since the exchange reaction:

$$D + H_2O \rightarrow H + HDO \quad (5)$$

was found to be slow (k=2 sec^{-1} at pH 2).[8] Formaldehyde, which is produced by Reaction (4),

Table 2. H/D isotope effects as a function of the temperature, observed at $[H_2SO_4]=0.1$ N and $(H/D)_{water}=1.1$

Temp., °C	L	$K(=L^{1/6})$	S	$S_{ion}(=S/K)$
2.0	9.43	1.45	4.35	3.00
10.4	8.94	1.44	4.16	2.89
21.6	8.36	1.42	3.80	2.68
25	8.20	1.42	—	—
30.2	7.97	1.41	3.64	2.58
40.8	7.54	1.40	3.61	2.58

shows a rather low reactivity toward e_{aq}^- and H atoms.[9]

In a solvent composed of light and heavy water, the isotopic composition of the hydrogen ion differs from that of the solvent.[10-12] These two quantities are related by the equilibrium constant;

$$K = (H/D)_{\text{hydrogen ion}}/(H/D)_{\text{water}} \quad (6)$$

which determines the fractionation effect. The K constant corresponds[13] to $L^{1/6}$, L being the equilibrium constant for the reaction:

$$2\,D_3O^+ + 3\,H_2O = 2\,H_3O^+ + 3\,D_2O,\ L \quad (7)$$

if one assumes that the proton is solvated in the H_3O^+ form.[14] The value of L has been evaluated by different methods; these have been reviewed and discussed by Heinzinger and Weston[10] and by Schaleger, Salomaa and Long.[11] Following these authors, here we take the value of 8.2 for L at 25°C. The values at other temperatures can be calculated using an approximate value of -1000 cal mol^{-1} for ΔH[10] for Reaction (7). The results of these calculations are included in Table 2. Fortunately, the uncertainty of this temperature coefficient is not at all serious when $K(=L^{1/6})$ is considered. The last coulmn of Table 2 refers to the isotopic fractionation (S_{ion}) due to the production of hydrogen atoms from the hydrogen ion (in Reaction (1)), calculated from the relation:

$$S = (H/D)_{atom}/(H/D)_{water} = \left[\frac{(H/D)_{atom}}{(H/D)_{\text{hydrogen ion}}}\right] \times \left[\frac{(H/D)_{\text{hydrogen ion}}}{(H/D)_{water}}\right] = S_{ion} \times K \quad (8)$$

ESR Measurements of Frozen Alkaline and Neutral Solutions. The irradiation of the $[Fe(CN)_6]^{4-}$ ions (10^{-2}—10^{-3} M) in 10 N NaOH at 77°K with a light with a wavelength of 2537 Å gave an intense blue-violet color and an ESR signal consisting of a single narrow line at $g=2.00$ and with a maximum slope-linewidth of 17 gauss (Fig. 1, (a)). On exposure to visible light, both the blue-violet color and the ESR signal are lost (Fig. 1, (a), dotted curve); this ESR line is identical with the well-known signal of the trapped electron, e_t^-.[15-19]

The same solution, however, if irradiated with light of 3660 Å, gave no blue-violet color and no ESR signal attributable to e_t^-. Instead, there appeared an unidentified signal (Fig. 1, (b));

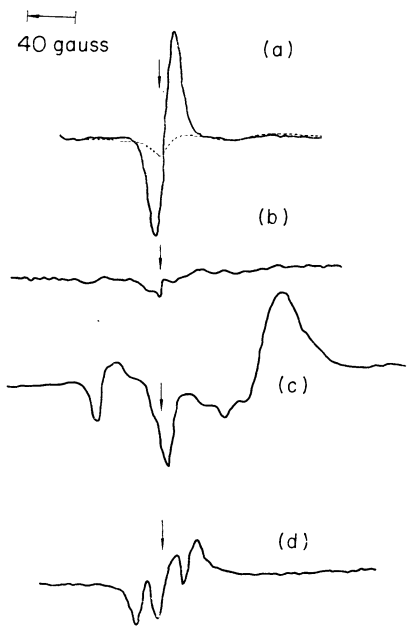

Fig. 1. ESR spectra of UV-irradiated frozen solutions of 10^{-2} M $[Fe(CN)_6]^{4-}$ at 77°K. Arrows show the field value of the DPPH signal. (a) 2537 Å, 10 N NaOH; (b) 3660 Å, 10 N NaOH; (c) 2537 Å, 10 N NaOH containing 10^{-2} M NO_3^-; (d) 2537 Å, neutral ice containing 10^{-2} M $ClCH_2COOH$

this is a strong confirmation of the previous findings that the d-d excitation of $[Fe(CN)_6]^{4-}$ does not lead to an electron-detachment,[5,20] while the charge-transfer excitation results in an electron release.

It should be noted that the presence of 10^{-2} M NO_3^- in an UV(2537 Å)-irradiated 10 N NaOH solution of $[Fe(CN)_6]^{4-}$ reduced completely the signal due to the e_t^-; instead, there appeared a more complex signal (Fig. 1, (c)), with the specimen turning yellow. The presence of 10^{-2} M N_2O in the same system, on the other hand, caused no significant change.

Moreover, in an UV(2537 Å)-irradiated neutral ice containing 10^{-2}—10^{-3} M $[Fe(CN)_6]^{4-}$ and $ClCH_2COOH$, the signal attributable to the radical, CH_2COOH,[18] is observed (Fig. 1, (d)):

$$e + ClCH_2COOH \rightarrow Cl^- + CH_2COOH \quad (9)$$

H/D Isotope Effects in Frozen Solutions. The electron is converted to the hydrogen atom in frozen aqueous acid solutions.[16,21-23] Figure 2 shows the ESR signals of the H and D atoms thus produced in an H_2O—D_2O mixture at 77°K. A doublet of 509 gauss and a triplet of 153 gauss (end-to-end) are due to the H and D atoms respectively. The origin of the small signal in the center portion of the spectrum is not known. In both the H and D atom spectra, the low-field lines are somewhat more intense than the high-field lines.

The relative concentrations of H and D atoms can be determined by calculating the sums of the hw^2 values of the H and D lines respectively, where h is the height of the line and w, its width at a maximum slope of the first derivative curve. In effect, the signal intensities were calculated simply from the heights of the lines, as the linewidths and shapes for the H and D lines in the H_2O-D_2O (50% D) system were nearly identical (the linewidth: about 4 gauss). The satellite lines appeared in some cases (Fig. 3), as is often observed in γ-irradiated ice,[16,23b,24] but this, too, was identical in both the H and D spectra.

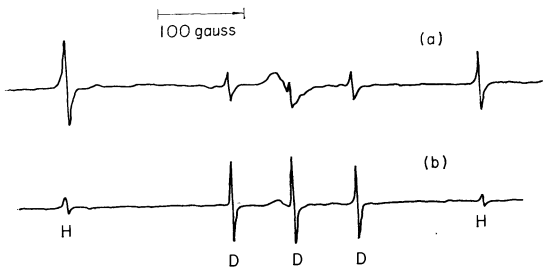

Fig. 2. ESR spectra of UV(2537 Å)-irradiated acid solutions (H_2O-D_2O) of 10^{-3} M $[Fe(CN)_6]^{4-}$ at 77°K.

were found to be nearly in the region of power saturation, even at the lowest crystal current employed. However, the signal heights for the H and D lines relative to each other are constant within the limits of experimental error at crystal currents below 0.2 mA. The actual measurements were made within this range.

No decay in the H and D signals was seen over a period of several days at the temperature of liquid nitrogen.

In all the systems examined, the signal intensities increased with the irradiation time, reaching a more or less steady value upon prolonged irradiation (Fig. 4). The signal intensities, resulting from irradiation for 15 min, on the linear part of the yield-time curve were used to calculate the relative yields of H and D atoms.

The results obtained with photolysed H_2O-D_2O mixtures containing 10^{-3} M $[Fe(CN)_6]^{4-}$ and varying amounts of sulfuric or perchloric acid are shown in Table 3. The error included may be small (±10%), as the conditions under which the spectra were obtained were exactly identical with those for the H and D atoms in each measurement.

Discussion

Possible Mechanisms for Observed Isotopic Effects in the Liquid Phase. In a previous communication,[4] the relative rates of O–H and O–D breakages, k_H/k_D, from the isotopic hydronium ion were computed on the simple assumptions that the $H_nD_{3-n}O^+$ species ($n=0$, 1, 2, or 3) gives the H or D atom in the $H/D = nk_H/(3-n)k_D$ ratio, and that the reactivity of $H_nD_{3-n}O^+$ with e_{aq}^- does not depend on the value of n. There, however, the implausibly high k_H/k_D value of 4—5 was obtained, in comparison with the low value observed ($S=1.2$)[26] for the isotope effects in the vapor-phase radiolysis of water, where monomolecular decompositions of the excited H_2O or the neutralization of the H_3O^+ ion are probably involved,[26,27] according to the following reactions:

$$H_2O^* \rightarrow H + OH \quad (10)$$

$$H_2O \rightarrow H_2O^+ + e \quad (11)$$

$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH \quad (12)$$

$$H_3O^+ + e \rightarrow H + H_2O \quad (13)$$

In the condensed medium, where interaction with another water molecule can easily occur, the mode of H-atom production may be very complex.

The rate constant of Reaction (1)[28,29] is 2—2.3 $\times 10^{10}$ $M^{-1}sec^{-1}$; its activation energy is 3.2 kcal/mol.[30] This latter value is nearly identical with that of the diffusion-controlled neutralization reaction (14), namely, 3.5 kcal/mol:[31]

$$H_3O^+_{aq} + OH^-_{aq} \rightarrow 2\,H_2O \quad (14)$$

Yet Reaction (1) proceeds 6—7 times less rapidly than Reaction (14) ($k_{14} = 1.4 \times 10^{11}$ $M^{-1}sec^{-1}$ [32]). The most rapidly diffusing species in both of these reactions is likely to be $H_3O^+_{aq}$ presumably by a mechanism of H transfer along the chain of hydrogen-bonded waters,[33] since the diffusion coefficient of the e_{aq}^- (4.7×10^{-5} cm^2sec^{-1} at 25°C[34]) is rather low compared with that of $H_3O^+_{aq}$ (9.5×10^{-5} cm^2sec^{-1}).

It may be speculated that the proton interacting with the negative charge due to the e_{aq}^- forms an intermediate complex, *i. e.*, $(H_3O^+ \cdot e^-)_{aq}$, which then decomposes either to give the H atom or to regenerate e_{aq}^-:[35]

$$H_3O^+_{aq} + e_{aq}^- \rightarrow (H_3O^+ \cdot e^-)_{aq} \quad (1a)$$

$$(H_3O^+ \cdot e^-)_{aq} \rightarrow e_{aq}^- + H_3O^+ \quad (1b)$$

$$\searrow\ H + H_2O \quad (1c)$$

35) Melton and Joy has recently reported the existence of H_3O in the gas phase evidenced by a mass-spectrometric study. If such a species exists in an aqueous solution, then one might consider the H_3O in place of $(H_3O^+ \cdot e^-)_{aq}$ in the present argument. See C. E. Melton and H. W. Joy, *J. Chem. Phys.*, **46**, 4275 (1967). The theoretical calculation of Bishop does not predict the existence of H_3O, however; D. M. Bishop, *J. Chem. Phys.*, **45**, 2474 (1966).

Reaction (1a) is expected to proceed at a diffusion-controlled rate (the same as Reaction (14); thus, $k_{1a}=1.4\times10^{11}$ M^{-1}sec^{-1}).[36] In this scheme, the observed rate of Reaction (1), k_1, is expressed by:

$$k_1 = \frac{k_{1a}k_{1c}}{k_{1b}+k_{1c}} \qquad (15)$$

Using the reported value for k_1[28,29] and the assumed value for k_{1a} as above, one gets $k_{1b}/k_{1c}=5$. The value of k_{1b}/k_{1c} might be different for each isotopic hydronium ion, $H_nD_{3-n}O^+$, where $n=0$—3, thus causing some part of the isotopic effects observed.

The results shown in Table 2 would indicate that the isotope effect for H-atom *vs.* D-atom production by way of Reaction (1c) ranges from 2.6 to 3, and that it depends slightly on the temperature. Even if the highest possible value for the ΔH of Reaction (7), namely, $\Delta H=-2000$ cal/mol,[10] is adopted, this causes only slight changes (1% or less) in the value of K and, thus, in the value of S_{ion}. Other systematic errors in obtaining S_{ion} are all identical for all the results. One may thus conclude that decreasing the temperature results in an enhancement of the isotope effect.

The isotope effect found here is too large to be attributed to a diffusion isotope effect. It can not be due to a difference in the vibrational frequencies of O–H and O–D bonds, either, since this would cause an isotope effect of only 1.4 or so and since this should be independent of the temperature. On the other hand, the large H/D isotope effect can be explained in terms of a difference in the activation energy for the O–H and O–D bond dissociations in the $(H_3O^+\cdot e^-)_{aq}$. As a result of the difference in zero-point energies,[37] more energy should be required to remove the D than the H. This would also account for the slight temperature dependence of the isotope effects seen in Table 2.

A similar intermediate, $(H_3O^+\cdot e^-)_{aq}$, has been considered by Hart[38] in a different connection. In the $(H_3O^+\cdot e^-)_{aq}$ complex, one of the water molecules in the hydration structure of the e^- may be incorporated in the outer shell of H_3O^+. This complex, which can be regarded as a closely-coupled unit, could either produce a hydrogen atom (Reaction (1c)) or decompose into H_3O^+ and e_{aq}^- (Reaction (1b)). These processes are caused by either a proton movement toward an adjacent hydrogen-bonded water molecule or rotations of the water molecules in the hydration sphere of the electron.

It should be emphasized here that, in the vapor-phase radiolysis, the H_3O-radical, if formed by the $(H_3O^+ + e^-)$ reaction, decomposes probably in the first vibration, and that, therefore, the relative probability of the dissociation of O–H and O–D bonds is closely related to the relative bond-stretching vibrational frequency, that is, 1.4.

Possible Reaction Mechanisms and Isotope Effects in the Solid State. The isotope separation factor which we have obtained for the frozen acid solution containing $[Fe(CN)_6]^{4-}$ and illuminated with ultraviolet light at 77°K (Table 3) is much smaller than the corresponding values of 3—4 obtained in the liquid phase. The present author considers this to be evidence that different mechanisms of the production of hydrogen atoms are operative for the two phases.

Dainton and Jones[22] have reported that the photo-detached electron, though differring from the radiolytically-formed electron in having much less kinetic energy, becomes a mobile electron in a frozen system. In a rigid medium, where the relaxation time for the orientation of the water dipoles is much longer than in a fluid medium, the electron could not easily polarize the surrounding medium; this would cause the electron to move larger distances from its point of origin. Moreover, the Coulombic repulsion between the ejected electron and the remaining species in the present case, namely $[Fe(CN)_6]^{3-}$, may be more effective than in a liquid phase, since the Coulomb interactions in a frozen solution at 77°K are, in an extreme case, mainly governed, not by the static dielectric constant (~80), but by the optical dielectric constant (~1.7).

The mobile electron moves through the medium until it finds a suitable site at which to be trapped (*e. g.*, a hydroxide anion vacancy[19,39]) or a species with which to react. The reaction of the electron in γ-irradiated frozen solutions has been studied in many works.[19,21,22,40,41] The trend in the rate-constant ratios at 77°K of the solutes, NO_3^-, NO_2^-, and acetone, with respect to $H_2PO_4^-$ was found to be the same as in an aqueous solution at 300°K.[40,41] More recently, the quantitative correlation of the rates in both phases for the electron reaction with Cd^{2+}, Cu^{2+}, CrO_4^{3-}, Zn^{2+}, and $ClCH_2COO^-$ ions has been verified further.[42] Unfortunately, no data on the H_3O^+ as well as on O_2 and N_2O have yet been given.

From the known values of the rate constants at *ca.* 25°C of Reactions (1) and (9), namely, $k_1=2.3\times10^{10}$ and $k_9=6.5\times10^9$ M^{-1}sec^{-1},[7] one may

36) Schwarz estimated the value of k_{1a} as 10.4×10^{10} M^{-1} sec^{-1} on the basis of a simple model of the diffusion-controlled reaction developed by Debye; H. A. Schwarz, *Radiation Res. Suppl.*, **4**, 89 (1964).

37) The difference in zero-point energy between O–H and O–D bonds in the $(H_3O^+\cdot e^-)_{aq}$ complex may not be largely different from that in the hydronium ion, namely 1.2 kcal/mol (see Ref. 4); a value of this order of magnitude is responsable to the temperature dependence shown in Table 2.

expect that, in a frozen solution containing equal amounts of $ClCH_2COOH$ and H_3O^+, Reaction (1) occurs predominantly over Reaction (9). However, the results shown in Table 4 indicate

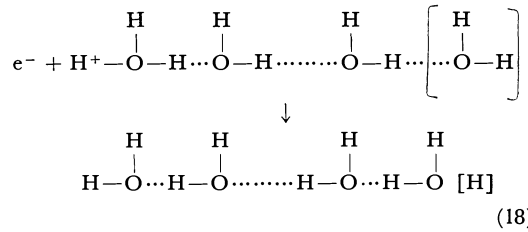
that considerably high concentrations of the sulfuric acid are needed to suppress Reaction (9). An apparent unreactivity of the hydrogen ion toward the electron in an ice has been previously reported by Weiss *et al.*[40,41] In order to explain the marked differences in the H atom yields in 1 M solutions of $HClO_4$, H_2SO_4, H_3PO_4, and HCl, these authors suggested[41] that Reaction (1) is rather insignificant compared with the reactions of the electron with the anions (HX^-) and with the undissociated acid molecules (H_2X):

$$e^- + HX^- \rightarrow H + H_2O + X^{2-} \quad (16)$$

$$e^- + H_2X \rightarrow H + H_2O + HX \quad (17)$$

The isotope effect of the production of H atoms *vs.* D atoms in this model must be governed by the isotopic fractionation between the solvent and the reacting species, HSO_4^-, H_2SO_4, or $HClO_4$. However, the reason for the relative insignificance of Reaction (1) compared with Reactions (16) and (17) at 77°K is not clear.

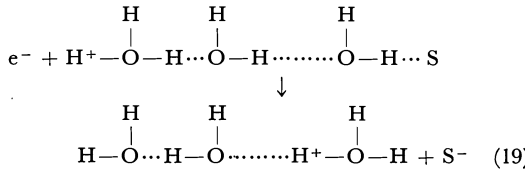
An alternative model for the production of hydrogen atoms as a result of the reaction of electrons in an acidic ice may be as follows: the electron reacts with the hydrogen ion, but in the hydrogen-bonded network, through which the hydrogen atom is transferred according to:



(18)

in which [ ] represents the site in the solid which can stabilize the hydrogen atom. The thermal vibrations of the lattice may be sufficient for such an H-atom transfer.[43] The hydrogen isotope separation factor by this model would be governed by the isotopic effect in the formation of the H atom from a water molecule at the trapping site. It is, thus, not surprising that a marked difference in the magnitude of the isotope effect is found between the solid and liquid phases.

Morevoer, it may be possible, by the mechanism of Eq. (18), for an electron transfer to a solute to take place easily if the solute is involved in the same hydrogen-bonded chain as the hydrogen ion initially reacting the electron:



(19)

where S denotes the solute. Reactions (18) and (19) would compete with each other. Thus, one might expect that, in an acidic ice ($H_3O^+ >$ 1 M), competition between the solute and the H-atom-trapping site for the electron (or the H-atom moving by the above mechanism) occurs. This mechanism would predict the relative ineffectiveness as an electron scavenger of the solute which does not couple with the H-bonded unit. Such electron scavengers as O_2 or N_2O might be such cases.

The author is greatly indebted to Professor Shizuo Fujiwara, the University of Tokyo, for his useful suggestions and kind guidance throughout this work. The stimulating discussions of Dr. Kenji Ishida are also acknowledged.

43) A similar mechanism of H-transfer was suggested in Ref. 40 for a possibility that two hydrogen atoms form a molecule of hydrogen in an ice at 77°K without the diffusion of the two H-atoms.

An X-Ray Determination of the Structure of Motiol Iodoacetate*1

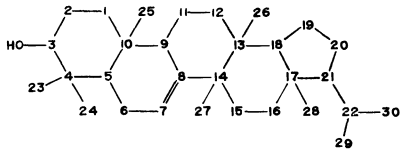
Yoriko NISHI, Tamaichi ASHIDA, Yoshio SASADA*2 and Masao KAKUDO

Institute for Protein Research, Osaka University, Joancho, Kita-ku, Osaka

(Received December 22, 1967)

The molecular configuration of motiol has been determined by the X-ray crystal analysis. The crystal of motiol iodoacetate, $C_{32}H_{52}O_2I$, is monoclinic with two molecules in a unit cell of dimensions; $a=17.37$, $b=6.78$, $c=13.04$ Å and $\beta=99.6°$, the space group being $P2_1$. The crystal structure was solved by the heavy atom method. The atomic coordinates and anisotropic temperature factors were refined by block-diagonal matrix least-squares method. The structure determined is, in general, compatible with that derived chemically. The rings A and D are of a chair form, and the rings B and C are of a semi-chair. The molecule bends at the rings B and C to make a bow as a whole. All but one of the methyl groups are in axial junction.

In 1965 Nakamura, Yamada, Wada, Inoue, Goto and Hirata have determined the stuctures of motiol, $C_{30}H_{50}O$, and four related compounds.[1] These triterpene alcohols are obtained from a viscous substance of *Rhododendoron Linearifolium*, from which motiol itself has been isolated by Kariyone, Hashimoto and Tobinaga early in 1952.[2]



Before completing chemical studies, Professors Hirata and Goto of Nagoya University supplied us the crystals of motiol iodoacetate for an X-ray analysis. The present paper describes the three-dimensional structure determination of motiol iodoacetate.

Experimental

The crystals of motiol iodoacetate, $C_{32}H_{52}O_2I$, are colourless and of mica-like form. Cleavage is observed along the (001) plane.

Unit cell dimensions were obtained by the photographic method; the values of a and c were derived from the ($h0l$) Weissenberg photographs on which aluminum powder diffraction lines were superposed for calibration, while that of b was determined from the ($hk0$) and ($0kl$) precession photographs.

Equi-inclination Weissenberg photographs were taken up to the 5th layer along the b axis using multiple-film technique. With Cu$K\alpha$ radiation of 30 kV and 18 exposure time was about 70 hr for each layer. The size of crystal used was about $0.1\times0.3\times1.5$ mm. After X-ray exposure of about 200 hr the crystal was coloured brown and the shape of the diffraction spots became blurred foggy. Therefore, two crystals of about the same size were needed for collection of the complete intensity data.

Intensities of 2511 reflexions were measured by visual comparison with a standard intensity scale, the relative intensity being ranged between 23000 and 1. Some reflexions which were not accessible by the b axis Weissenberg photographs were supplemented from the precession photographs.

Corrections for Lorentz and polarization factors were made in the usual way, while that for absorption was neglected.

Crystallographic Data

Crystallographic and physical data obtained are: Motiol iodoacetate, $C_{32}H_{52}O_2I$. Monoclinic,

$a=17.37\pm0.04$, $b=6.78\pm0.02$, $c=13.04\pm0.03$ Å,

$\beta=99.6\pm0.5°$.

Volume of the unit cell, 1514.2 Å.

Systematic absence, ($0k0$) when k is odd. Space group, $P2_1$. Two molecules per unit cell. Density observed (by floatation), 1.32 g·cm^{-3}. Density calculated, 1.30 g·cm^{-3}. Total number of electrons per unit cell, $F(000)=626$. Linear abosrption coefficient for Cu$K\alpha$ radiation, $\mu=93.87$ cm^{-1}.

Structure Determination

Patterson projection on (010) showed clearly a peak corresponding to the iodine-iodine interaction, which gave the coordinates of the iodine as

*1 Read before the 19th Annual Meeting of the Chemical Society of Japan, April, 1966, Yokohama.

*2 Present address: Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo.

1) S. Nakamura, T. Yamada, H. Wada, Y. Inoue, T. Goto and Y. Hirata, *Tetrahedron Letters*, **24**, 2017 (1965).

$x=-0.025$ and $z=0.195$. On the other hand, the y coordinate of the iodine may be assigned arbitrarily as -0.25 in this space group.

A Fourier synthesis was carried out using phases based on the coordinates of the iodine atom. It was very easy to find a general lay-out of the molecule from the resulting electron density distribution; in the section $y=0.25$ where the equivalent iodine atom appeared, there were twelve high peaks which built up major part of the rings A, D and E. The atoms in iodoacetyl group and those in the rings B and C were also recognized as resolved peaks, although there is a pseudo mirror plane at $y=0.25$. Therefore, it was possible to construct two models of the main skeleton; in one model iodoacetyl group and the rings B and C are on the same side of the pseudo mirror plane and in another they are on the opposite. In the former model, the conformation of the cyclohexane ring A is of a boat form, while in the latter it is of a chair.

Since chemical studies supported the latter model, we proceeded at first the refinement of the structure based on it. Even if the general conformation of the molecule had been selected, it was still difficult to decide to which side the y coordinates deviate from the mirror if the deviations are small. For such atoms we gave appropriate y coordinates by inspection. Fourier synthesis was evaluated with phases based on all the atoms. In the resulting electron density distribution, all the peaks corresponding to the light atoms showed very reasonable height and there were found only a few ghost peaks whose heights were not over a half of those of the carbon.

Three cycles of a least-squares refinement were carried out with isotropic temperature factors, initial B being 5.2 Å. The iodine atom was treated as anisotropic (two cycles) and then all the atoms were taken as anisotropic (two cycles). The R factor decreased to 0.177.

In these processes, the y coordinate of C(7) moved from 0.24 to 0.285 across the pseudo mirror plane, and that of C(6) decreased from 0.22 to 0.194 and then increased gradually. Their standard deviations were larger than those of the others. Since it seemed likely that the anomaly should be due to the mislocation of C(6), its y coordinate was changed artificially to be 0.28 across the pseudo mirror. Two cycles of the refinement were conducted so that the R factor dropped from 0.178 to 0.172 and the standard deviations of all the atoms did not differ to much extent.

It is known that the effect of anomalous dispersion of the iodine could not be neglected. Two enantiomorphous structures with the parameters at this stage were examined for 165 sampled reflections. Difference between these enantiomorphs was not quite definite, but one of them seemed to be more favourable. With this model, the least-squares refinement including anomalous dispersion effect was made (one cycle). It gave a slightly lower R factor of 0.169 ($R=0.148$ for non-zero reflexions) and better bond lengths.

The final atomic coordinates and anisotropic temperature factors are listed in Tables 1 and 2 respectively. The composite diagram of the final electron density distribution viewed along the b axis is shown in Fig. 1.

Throughout the refinement process, 2051 reflexions with $\sin\theta/\lambda$ less than 0.550 were used and the atomic scattering factors were taken from the International Tables for X-ray Crystallography. Programme for the least-squares method was written by one of us (T. A.) with block-diagonal matrix approximation. The weights in the least-squares were 1.0 for $F_o>1.0$ and 0.5 for $F_o\leqslant 1.0$, and fudge factors were 0.7 for the scale and positional parameters and 0.5 for the thermal parameters.

For iodine atom, contours are drawn at intervals of 5 e.Å^{-3}, beginning with 5 e.Å^{-3}.

Examination of the Alternative Structure

From the crystallographic point of view, the other model in which the ring A has a boat form was also possible as stated in the previous paragraph. This alternative model was subjected to the Fourier and least-squares refinement. Several abnormal figures were obtained in the course of refinement; for example, the bond length C(18)–C(19) became too longe, 1.99 Å, C(19)–C(20)rem arkably short, 1.19 Å and the isotropic temperature factor of C(19) was very large, 16.4 Å^2. The R factor did not go down less than 0.227. Therefore, it was concluded that this structure is not correct.

Some Remarks on Reliability of the Analysis

As mentioned in the previous paragraph, we changed artificially the y coordinate of C(6) at a certain stage. It may be of some interest whether this atom moves to the correct position in the other side of the pseudo mirror plane by continuing the least-squares process. We examined this, and found that it needed eight cycles to get the final result from the stage just before the artificial change. One of the reasons why the rate of convergence is so slow is that almost all the atoms in the principal skeleton of the molecule lie near the special plane and that since intensity data were collected from Weissenberg photographs about the b axis only the largest k reached to about a half of the possible maximum k within the copper sphere.

This crystal analysis met another serious difficulty. The crystal sufferred heavy degradation during the X-ray exposure. It was naturally supposed that reflexions on each layer might correspond to different stages of degradation. To examine this possibility the parameters except those related to the y direction were refined by the least-squares using several sets of the intensity data which were sampled from the individual layers. Intensity data of ($h0l$) and ($h3l$) were supposed to be those of rather fresh crystal. Corresponding bond lengths derived from the refinement of each layer are in good agreement, considering the fact that limited number of data makes standard deviations large; mean deviation being 0.054 Å and the maximum 0.17 Å. On the other hand ($h2l$) and ($h5l$) were taken from the heavily sufferred crystal. Corresponding lengths from these layer data fluctuated to much extent; mean deviation being 0.17 Å and the maximum 0.48 Å. Difference in bond lengths between the new and damaged crystals averages 0.08 Å. Therefore, it may be concluded that the error of the bond lengths due to such a systematic error in intensity data is about 0.1 Å, which is of about the same magnitude as the standard deviation derived formally from the least-squares calculation.

Description of the Structure and Discussion

The structure determined here is compatible, in general, with that derived from chemical studies. The rings A and D have a chair form. Owing to the existence of the double bond, the rings B and C have a half-chair form. All the neighboring rings are trans-fused. The molecule bends at the rings B and C, so that it is bow as a whole. Configurations of O(1) and seven methyl groups (C(22) to C(28)) are also in agreement with chemical argument. Figure 2 shows the perpendicular displacements of the atoms from the mean plane of each ring.

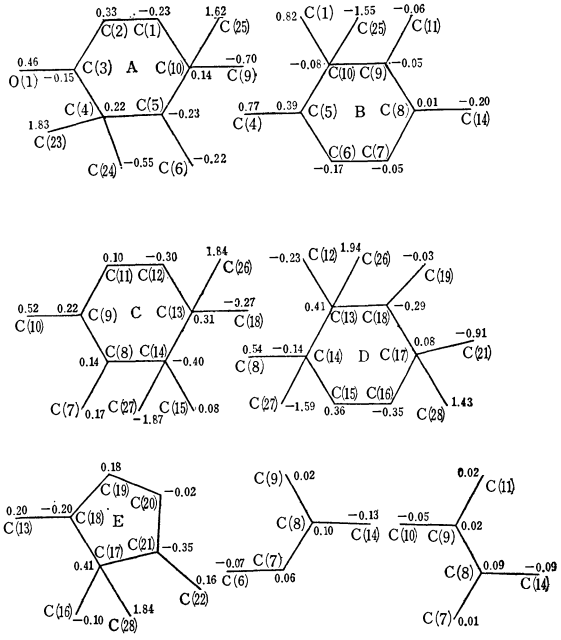

Fig. 2. The deviations of the atoms from the mean plane of each ring.

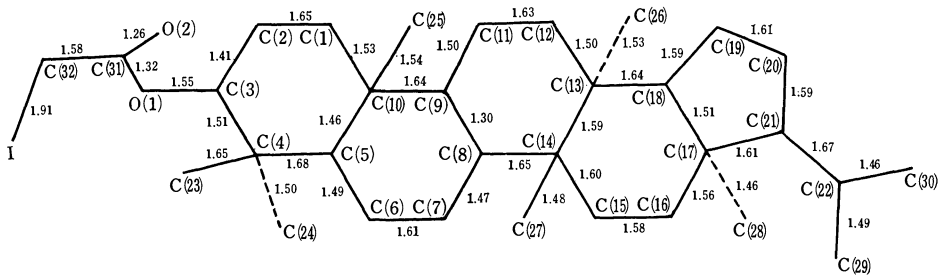
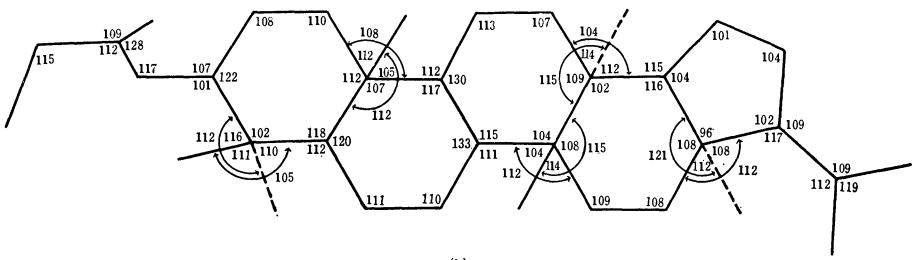
The bond lengths and angles are given in Fig. 3. Several interesting features are observed in the molecular dimensions, although their physical significance could not be insisted from the view of rather large errors.

(1) While the average bond length of all the C–C is 1.56 Å, the average of C–C bonds which are nearly parallel to the a axis is 1.62 Å. As the long axis of the molecule lies in the direction nearly parallel to the a axis, this elongation of the C–C may be interpreted as a result of long range intramolecular steric hindrance. The related nonbonded intramolecular distances are listed in Table 3.



(a)



(b)

Fig. 3. (a) Bond longths (Å) and (b) bond angles (°) in the molecule of motiol iodoacetate.

TABLE 3. NON-BONDED DISTANCES IN THE MOLECULE (Å)

C(1) -C(11)	2.84	C(27)-C(12)	2.87

C(23)-C(25)	3.20	C(27)-C(18)	3.03
C(24)-C(6)	2.97	C(28)-C(15)	3.15
C(25)-C(11)	3.18	C(28)-C(19)	2.99
C(26)-C(8)	3.02	C(28)-C(20)	2.98
C(26)-C(9)	3.16	C(28)-C(22)	3.02
C(26)-C(28)	3.20	C(30)-C(20)	2.93
C(27)-C(7)	3.20		

(2) Chemical studies assigned C(7)–C(8) as a double bond. In the present analysis, the average deviation from the mean plane consisting of C(6), C(7), C(8), C(9) and C(14) is 0.079 Å, while that of the mean plane of C(7), C(8), C(9), C(10), C(11) and C(14) is 0.057 Å (Fig. 2). The difference might not be significant, however,

C(2)	C(32)	IV	3.98
C(31)	C(32)	IV	3.66
C(31)	I	IV	3.91
C(32)	C(32)	IV	3.82
C(32)	C(2)	IV	3.62
O(1)	C(32)	IV	3.45

Molecule	I	$1-x$,	$\frac{1}{2}+y$,	$1-z$
	II	$1-x$,	$\frac{1}{2}+y$,	$-z$
	III	x,	$1+y$,	z
	IV	$-x$,	$\frac{1}{2}+y$,	$-z$

C(7)–C(8) is 1.47 Å, while C(8)–C(9) is 1.30 Å. From these figures, it seems likely that the double bond is C(8)–C(9). According to Hirata, there is a possibility of the transfer of the double bond of C(7)–C(8) to C(8)–C(9) at the reaction of iodoacetylation of motiol.[5] If C(8)–C(9) is the double bond, the compound may be called as iso-motiol iodoacetate.

(3) There are observed very similar aspects of

molecular structures to those in the related compounds such as epilimonol iodoacetate[3] and methyl melaleucate iodoacetate.[4]

The arrangement of the molecules in the crystal is shown in Fig. 4. All the intermolecular distances shorter than 4.0 Å are listed in Table 4, which are equal or longer than the normal van der Waals contacts.

The authors would like to express their deep thanks to Professors Yoshimasa Hirata and Toshio Goto of Nagoya University for supplying the material and valuable discussions. All numerical computation were done on the NEAC 2101 of this Institute, NEAC 2206 of the Computing Centre of Osaka University and HITAC 5020 of the University of Tokyo.

Thermodynamic Properties of Solutions of *m*-Terphenyl in Benzene. I. The Vapor Pressures and the Related Thermodynamic Functions at 30 and 50°C*[1]

Sadao TAKAGI, the late Katsuya FURUKAWA and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 31, 1967)

Vapor pressures of solutions of *m*-terphenyl in benzene were measured for the concentration less than 0.23 in mole fraction x of terphenyl at 30 and 50°C. Vapor pressures P mmHg obtained are represented by $\log_{10} P(30°)=2.076970-0.4343x-0.06569x^2-0.4340x^3$ and $\log_{10} P(50°)=2.432100-0.4343x-0.14654x^2-0.3412x^3$. Chemical potentials observed were reproduced by the quasi-lattice theory for mixtures of molecules of different sizes. The Miller-Guggenheim expression ($r=3$, $z=6$—8) gives $w/\boldsymbol{k}=100\pm5°$, and the Flory-Huggins expression (r=molecular volume ratio) gives $\chi=0.272\pm0.004$ (30°) and $\chi=0.243\pm0.006$(50°). Partial molar heats of mixing are rather fitted by the regular solution theory similarly to the case for benzene+biphenyl, and the Flory-Huggins expression gives a concentration-dependent enthalpy parameter, $\chi_H=(0.77_2+1.7_{16}\phi)\times10^2/T$, where ϕ means a volume fraction of terphenyl. The average value of χ_H, 0.39 agreed with a theoretical estimate from solubility parameters.

It is well known that the thermodynamic study of the monomer+oligomer solutions is quite significant for the investigation of the molecular size effect in the solutions of small molecules as well as in the polymer solutions. In these monomer+oligomer mixtures, the monomer+dimer mixtures have been thermodynamically studied by many authors. Of those the benzene+biphenyl system has been most extensively studied, and has shown that the results of both vapor-pressure and heat of dilution measurements behave like those predicted for mixtures of molecules of different sizes.[1-6] Kortüm, *et al.* have shown, however, that the heats of mixing over the whole range of compositions at 71.6°C can not be fitted by the quasi-lattice model[7] for mixtures of molecules of different sizes but can only be fitted using the model for mixtures of molecules of the same size, and that the experimental values of the excess partial molar entropy of mixing are strongly temperature-dependent and cannot be fitted by the formulae for athermal mixtures of molecules of

different sizes.[8,9] In order to obtain further information about size effect, thermodynamic properties of benzene+terphenyl system were begun to measure.

Experimental

Materials. Commercial *m*-terphenyl (chemical grade, Tokyo Kasei Kogyo K. K.) was purified carefully by repeating fractional recrystallizations from the solutions first with trichlorobenzene and thereafter with ethanol.[10] The *m*-terphenyl obtained was further purified by chromatography on silica gel (for chromatography, E. Merck) with benzene as an elutant. Finally occluded benzene was removed by vacuum sublimation. Mp 86.5°C.*2 An ultraviolet absorption spectrum of the purified *m*-terphenyl in alcohol showed no trace of the isomeric impurities.

Benzene was purified by an ordinary method with concentrated sulfuric acid, and then fractionally distilled twice over phosphorus pentoxide through a 1-m column packed with helices of stainless steel. After having been passed through silica gel, benzene was fractionally distilled once again, and finally submitted to repeated fractional crystallization. The boiling point sample used was 80.1°C.

Apparatus. The measurements of vapor pressures were carried out by using a liquid-vapor equilibrium still of recirculation type which was appropriate for small sample size.*3 Auxiliary equipments for the control and measurement of pressure were essentially the same as those described by Scatchard *et al.*,[11] and dry nitrogen was used as confining gas. The heights of mercury in a precision manometer which was immersed in a water thermostat were read to 0.05 mm by means of a 1-m cathetometer. Equilibrium temperatures were measured with a Beckmann thermometer which was calibrated against a standard thermometer certified by National Research Laboratory of Metrology, Tokyo. The error in the temperature measurements was within 0.003°C relatively, and within 0.03°C absolutely.

Procedures. The vapor pressures of the *m*-terphenyl solutions were measured over the concentration range less than 0.23 in mole fraction of terphenyl at 30 and 50°C. After about three or four hour's recirculation, both the equilibrium pressure and temperature were measured thrice. In order to obtain the equilibrium pressure at the precisely definite temperature as a function of composition, the interpolation of the points of three sets of measurements were carried out. The interpolation was made by first plotting the values of $\log P$ against reciprocals of temperature, and next reading a value from the smoothed curve at a desired temperature. This procedure is illustrated in Fig. 1. As the differences in temperatures were very small, each equilibrium composition was thought to be unchanged. An equilibrium liquid sample was withdrawn into a weighing bottle from the liquid trap of the still. The weight of this solution and that of *m*-terphenyl crystal which was produced by slow evaporation*4 of benzene from this solution were measured. The composition of the solution was determined by these weights. In the range of dilute concentration, *i. e.*, less than 0.1 in mole fraction, the composition was also determined by the measurement

*4 Evaporation of benzene from the solution was carefully carried out in a hot atmosphere at the temperature not higher than 55°C.

of the density with the aid of a calibration curve shown in Fig. 2. The values of the composition obtained by both methods agreed within the experimental error.

Experimental Results

The values of vapor pressures obtained are summarized in Table 1 where P is in standard mm of mercury and x is the mole fraction of terphenyl in the solution. The vapor pressure of pure *m*-terphenyl melt has been measured by Mandel *et al.*[12] in the high temperature range. These data are represented by the following expression*5

$$\log_{10}P(\text{mmHg}) = 7.68211 - 2814.37/(207.79 + t) \quad (1)$$

where t is temperature expressed in degree Celcius. By assuming that this expression holds at temperature below the melting point, the values of the vapor pressure of the super-cooled pure *m*-terphenyl melt at 30 and 50°C are estimated to be 7.0×10^{-5} and 5.8×10^{-4} mmHg, respectively. The partial pressures of terphenyl in the solutions investigated were thus quite negligible, compared with the values of the vapor pressures of benzene over the solutions.*5

Usually, for a solution composed of a solvent and a non-volatile solute whose molecular sizes are not so different each other, the vapor pressure of the solvent can be expressed as

$$P=P^\circ(1-x)\exp(\alpha x^2+\beta x^3+\cdots)$$

or

$$\log_{10}P=\log_{10}P^\circ-0.4343x+cx^2+dx^3+\cdots \quad (2)$$

where x is the mole fraction of the solute, P° the vapor pressure of the pure solvent at the same temperature with the solution, and $\alpha, \beta, \cdots$, or $c, d, \cdots$, adjustable parameters. A least-squares treatment of our data according to Eq. (2), neglecting higher terms than the fourth power of x, gave

$$\log_{10}P = 2.076970 - 0.4343x - 0.06569x^2 - 0.4340x^3 \text{ at } 30^\circ\text{C}$$

and

$$\log_{10}P = 2.432100 - 0.4343x - 0.14654x^2 - 0.3412x^3 \text{ at } 50^\circ\text{C} \quad (3)$$

The calculated values of vapor pressure by using Eq. (3) are seen to be in good agreement with the observed ones, as shown in the last column of Table 1, suggesting that Eqs. (3) are adequate expressions for representing the vapor pressure of the benzene solutions of *m*-terphenyl at both temperatures.

Then the activity coefficients of the solvent were obtained at every 3 mol per cent for each temperature by making use of Eq. (3) and the following equation including the correction due to the gas imperfection,

$$\log_{10}\gamma_1 = \log_{10}\frac{P}{P^\circ(1-x)} - \frac{B(P^\circ-P)}{2.3026RT} + \frac{V_1^\circ(P^\circ-P)}{2.3026RT} \quad (4)$$

where B is the second virial coefficient of pure benzene in the gaseous state and V_1° the molar volume of pure benzene. Values used for B's are evaluated from the expression given by Allen *et al.*,[13] which are tabulated in Table 2 as well as the values of V_1° used. The molar volume of benzene at t°C are calculated from the density,[14]

$$d = 0.90005 - 1.0636\times10^{-3}t - 0.0376\times10^{-6}t^2 - 2.213\times10^{-9}t^3, \quad (\pm2\times10^{-4}). \quad (5)$$

Numerical values of $\log_{10}\gamma_1$ thus obtained are listed in Table 3. The deviations from the ideal solutions are positive. The relative contribution of each of the terms in Eq. (4) to the total $\log_{10}\gamma_1$ is illustrated in Table 4 which shows the importance of the term involving the second virial coefficient B.

From $\log_{10}\gamma_1$'s, the excess partial molar enthalpy and entropy of benzene are derived by the following thermodynamic relationships;

$$\overline{H}_1^E = \partial(\overline{G}_1^E/T)/\partial(1/T) = 2.3026R[\Delta\log_{10}\gamma_1/\Delta(1/T)] \quad (6)$$

$$\bar{S}_1^E = \bar{H}_1^E/T - 2.3026\boldsymbol{R}\log_{10}\gamma_1 \quad (7)$$

and are also summarized in Table 3.

Discussion

For a solution which consists of N_1 monomers and N_2 r-mers, Guggenheim[16] has derived the theoretical formula, according to which the activity coefficient of solvent (monomer) is written in the zeroth approximation as follows:

$$\log_{10}\gamma_1 = -\log_{10}(1-x) + \log_{10}[N_1/(N_1+rN_2)] + (z/2)\log_{10}[(N_1+rN_2)/(N_1+qN_2)] + (1/2.3026)[qN_2/(N_1+qN_2)]^2 w/\boldsymbol{k}T \quad (8)$$

where z is the co-ordination number, $zq(=rz-2r+2)$ is the number of the nearest neighbor contacts around a r-mer molecule, w is the free energy parameter of interaction between monomer and r-mer molecules, and $\boldsymbol{k}$ is the Boltzmann constant. Assuming that terphenyl is a trimer of benzene ($r=3$), and z lies between 6 and 8,*6 one can calculate the values of $w/\boldsymbol{k}$ by substitution of the observed values of $\log_{10}\gamma_1$ into the Miller-Guggenheim expression, Eq. (8), as shown in Table 5.

Table 5. Values of interaction parameter obtained with the zeroth approximation of Guggenheim

x	$10^{-2}w/\boldsymbol{k}$,[deg^{-1}]			
	$z=8$		$z=6$	
	30°C	50°C	30°C	50°C
0.06	1.0_3	1.03	0.97	0.96
0.09	1.02	1.03	0.98	0.99
0.12	1.02	1.02	0.99	0.98
0.15	1.03	1.02	1.00	0.98
0.18	1.04	1.02	1.01	0.99
0.21	1.05	1.02	1.02	0.99

The constancy in the values of $w/\boldsymbol{k}$ irrespective of the mole fraction of terphenyl in the solution seems to suggest that Eq. (8) is adequate to the system such as benzene+*m*-terphenyl solution. The constant value of about 100° for $w/\boldsymbol{k}$ may be reasonable, compared with 76° or 77° found for the benzene solution of biphenyl which is regarded as a dimer ($z=6$).[3,4b]

It is well known that the Miller-Guggenheim formula becomes the Flory-Huggins expression when the co-ordination number z reaches infinity. The Flory-Huggins expression for activity coefficient of a solvent (monomer) is

$$\log_{10}\gamma_1 = \log_{10}[(1-\phi)/(1-x)] + (1/2.3026)(1-1/r) + (1/2.3026)\chi\phi^2 \quad (9)$$

where ϕ is the volume fraction of solute (r-mer), r the volume ratio of r-mer to monomer, and χ the free energy parameter of interaction between solvent and solute. By using Eq. (9), the free energy parameters χ were evaluated and values obtained are summarized in Table 6 where the

corresponding value for the case of benzene+biphenyl is cited from the literature for comparison, and are plotted in Fig. 3. The numerical values of volume ratios r used are shown in Table 2. Figure 3 shows a slight tendency of the concentration-dependence of the parameters, which decrease with the volume fraction of terphenyl at 50°C and increase with the concentration at 30°C. The reasons for these behaviors, however, have not been discussed here, because there is no information about the excess volumes at those temperatures. The average values of χ at 30 and 50°C, $\chi=0.272_3$ and 0.243_1, correspond to $w/\boldsymbol{k}=83$ and 79°, respectively when r is chosen to be the volume ratio. The corresponding value for benzene+biphenyl mixture is $w/\boldsymbol{k}=63°$. Figure 4 shows that the Flory-Huggins expression, as well as the Miller-Guggenheim expression, represents the experimental values of free energy of mixing.

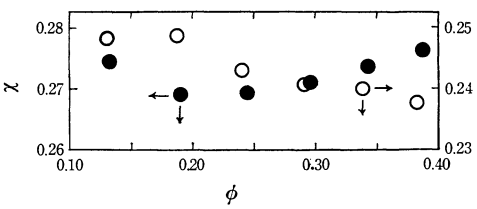

Fig. 3. Concentration-dependence of free energy parameters at 30°C (filled circles) and 50°C (open circles).

*6 For the sake of comparison with the case of benzene+biphenyl, 6 and 8 are used as z after Everett and McGlashan.[3] If $z=10$ are used, a little larger values of $w/\boldsymbol{k}$ will be obtained.

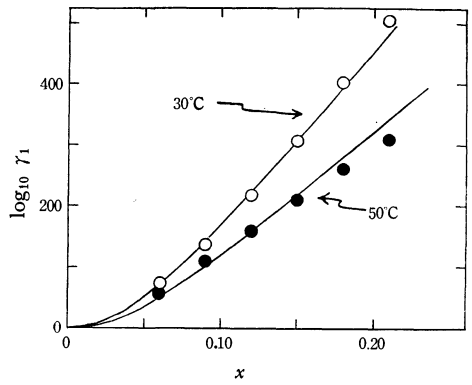

Fig. 4. $\log_{10}\gamma_1$ as a function of x.
○ or ● Experimental
—— Thpeoretical curves calculated by the Flory-Huggins expression by using $\chi = 0.272_3$ (at 30°C) and 0.243_1 (at 50°C).

The enthalpy parameter χ_H calculated through Eq. (10) at each temperature are also given in

$$\chi_H = H_1^E/\boldsymbol{R}T\phi^2 \tag{10}$$

Table 6. Their composition dependence at 30 and 50°C is given as a linear function of the volume fraction of terphenyl, Eq. (11), by a least-squares calculation.

$$10^{-2}T\chi_H = 0.77_2 + 1.7_{16}\phi \tag{11}$$

In the case of benzene+biphenyl mixtures heat of dilution measured are compatible to both the quasi-lattice theory for mixtures of molecules of different sizes and the regular solution theory with the same degree of accuracy within the experimental error,[4b,9] and the heat of mixing of benzene and molten biphenyl can not be expressed by other than the regular solution theory.[8] In our case of *m*-terphenyl also the regular solution theory can reproduce the partial molar heats of mixing of benzene as shown in Fig. 5. Figure 6 shows the systematic deviation of the experimental

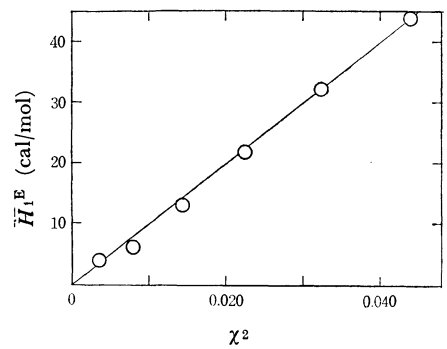

Fig. 5. Regular solution plot of the partial molar heat of mixing of benzene at 40°C.
○ Experimental

—— $\boldsymbol{R}T\chi_H\phi^2$ when $\chi_H=0.39$.

points from the Flory-Huggins equation. If the Flory-Huggins equation holds, the experimental points would lie on a straight line through the origin. The quasi-lattice theory which contains the molecular size effect reproduces the experimental values only when the composition dependence of the parameter χ_H is considered. The average value of the parameter is $\chi_H=0.39$ (at 40°) which corresponds to $zu/\boldsymbol{k}=122°$ and $\boldsymbol{N}zu=242._7$ cal/mol, on the other hand those reported[4b] for benzene+biphenyl mixture are $zu/\boldsymbol{k}=58°$ and $\boldsymbol{N}zu=114._9$ cal/mol at 25°C and $zu/\boldsymbol{k}=51°$ and $\boldsymbol{N}zu=101._5$ cal/mol at 50°C.

The χ_H parameter can be estimated by using Eq. (12) based on the zeroth approximation of mixtures of molecules of different sizes,

$$\chi_H = (\bar{V}_1/\boldsymbol{R}T)(\delta_1 - \delta_2)^2 \tag{12}$$

where $\bar{V}_1$ is the partial molar volume of benzene and δ's are the solubility parameters which are defined by

$$\delta^2 = (\Delta H^v - \boldsymbol{R}T)/V \tag{13}$$

$$= n^{-1}(\partial E/\partial V)_T \tag{14}$$

where ΔH^v is the heat of vaporization, V the molar volume, $(\partial E/\partial V)_T$ the internal pressure, and n the parameter which is slightly greater than 1.0 for non-polar liquids.[17] The internal pressure can be computed directly from the thermal pressure coefficient or from the coefficient of expansion α and the isothermal compressibility β_T. The external pressure P is negligibly small, compared to the thermal pressure term in a condensed phase under atmospheric pressure.

$$(\partial E/\partial V)_T = T(\partial P/\partial T)_V - P$$
$$\simeq T(\partial P/\partial T)_V = T(\alpha/\beta_T) = T\gamma \tag{15}$$

17) J. H. Hildebrand and R. L. Scott, "The Solubility of Noneletrolytes," 3rd Edition, Dover Publications, Inc., New York, N. Y. (1964), p. 97.

Since there is the experimental evidence of constancy of the quantity $TV^2\gamma$ over a range of temperature,[18-20] once it is known at an appropriate temperature it is possible to deduce the internal pressure at any desired temperature by using only the knowledge of the molar volume at that temperature.

The internal pressures of benzene were calculated from the data given by Stavely *et al.*[18] The comparison with the cohesive energy density[21] gave 1.06 as a numerical value of n at 25°C which agreed very well with the value obtained at 20°C ($n=1.06$).[22] Thus, $n=1.06$ has been used for both components at 30 and 50°C. The internal pressures of *m*-terphenyl were estimated from the solubility parameter at 90°C given by Clark and Schmidt,[23] under the assumption that $TV^2\gamma$ is constant over the range of temperature. The solubility parameters obtained are given in Table 7. The values of χ_H calculated through Eq. (12) are 0.3_9 and 0.3_2 at 50 and 30°C, respectively, on the assumption that the partial molar volume of benzene is approximately equal to the molar volume in pure state, $V_1°$. Taking account of the assumptions made in the calculation, agreement between the values of χ_H obtained by the experiment and those calculated by using Eq. (12) is satisfactory as shown in Table 7. After the present measurements had been completed, the studies of this system by gas-liquid partition chromatography were presented by Clark and Schmidt.[23] They reported that the heat of solution at infinite dilution for benzene in *m*-terphenyl ($x\rightarrow 1$) at 90°C is 180±50 cal/mol. It corresponds to 0.25±0.07 as χ_H which is consistent with the present experimental values obtained at 50 and 30°C.

Table 7. Prediction of χ_H from the solubility parameters

t °C	δ_1	δ_2	χ_H Eq. (12)	χ_H Expt.
50	8.8_5	10.5_0	0.3_9	0.38
30	9.0_8	10.5_4	0.3_2	0.40

The partial molar excess entropies of mixing of benzene are described by the Flory-Huggins formula as follows,

$$\overline{S}_1^E = \overline{S}_1^E(\mathrm{I}) + \overline{S}_1^E(\mathrm{II}) \quad (16)$$

$$\overline{S}_1^E(\mathrm{I}) = -R\{\ln[(1-\phi)/(1-x)] + (1-1/r)\phi\} \quad (17)$$

$$\overline{S}_1^E(\mathrm{II}) = -R\chi_S\phi^2 \quad (18)$$

where $\chi_S=\chi-\chi_H$. In Fig. 7 the experimental partial molar excess entropies and the athermal contributions for those, given by Eq. (17), are plotted against the volume fraction of terphenyl, where the curves have been drawn by hand through the origin of the co-ordinate. Figure 7 shows that the contribution for the excess entropy from the non-athermal term, Eq. (18), seems to be significant,*7 although the detailed studies on the physical meanings of the χ_S must be postponed until the excess volumes and compressibilities at the temperatures where present experiments were undertaken become available.

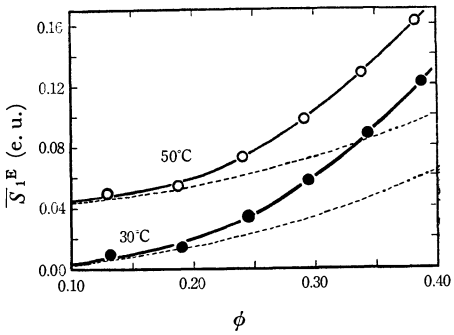

Fig. 7. Excess partial molar entropies of benzene (plots for 50°C is shifted upwards by 0.04 in e. u.).
——: $\overline{S}_1^E$, Experimental
- - -: $\overline{S}_1^E(\mathrm{I})$, Calculated

Since calculations of the excess thermodynamic functions in terms of the average potential, corresponding states theory of polymer mixtures extended by Prigogine implicitly, include the effects of volume changes on mixing,[24] the experimental results have been compared with the predictions by this theory. Explicit expression derived for excess Gibbs energy of mixing at vanishing pressure agreed with that given by Clark *et al.*[23] In this case, however, it was not able to predict the thermodynamic properties obtained by the measurements.

Finally we conclude that the thermodynamic behavior of benzene+*m*-terphenyl solution is similar to that of benzene+biphenyl solution.

We thank Mr. M. Matsumoto, of Kayagaki Irikakikai-Kogyo K. K. for the measurement of mp of *m*-terphenyl.

*7 If we evaluate $\overline{S}_1^E(\mathrm{I})$ by using the Miller-Guggenheim formula, difference of $\overline{S}_1^E$ and $\overline{S}_1^E(\mathrm{I})$ becomes larger, because the Flory-Huggins formula ($z=\infty$) gives the largest athermal entropy of mixing.

Electron Spin Resonance Study of the Radiolysis of Monocarboxylic Acids Adsorbed on Silica Gel

Masaji MIURA, Akinori HASEGAWA and Yoshio YAMADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 12, 1968)

Electron spin resonance measurements were carried out on γ-irradiated monocarboxylic acids (formic, acetic, and propionic acids) adsorbed on silica gel. In the case of formic acid, the spectrum assigned to the CO_2^- radical was mainly observed, but also observed was the signal caused by the defects of γ-irradiated silica gel, whereas for the acetic acid a quartet due to the methyl radical was obtained. These spectra, however, were not found in the frozen acids alone. As regards propionic acid, ethyl radicals were produced in both the adsorbed and frozen states. It was concluded from these results that the characteristic radiolysis of monocarboxylic acids on the adsorbed state is to be attributed to interaction between the acids adsorbed on silica gel as monomers and the surface. On the basis of these spectra, the adsorbed state of the acids and the stability of the radicals have been discussed.

The investigation of radicals adsorbed on solid surfaces seems to be of interest not only in the field of catalysis, but also in connection with the behavior of radicals on the surfaces.[1-4] Recent studies of the radiolysis of substances adsorbed on insulators with high surface areas have indicated that the radiolysis yield is higher on the adsorbed state than on the homogeneous state as a result of the energy migration from the solid surface to the adsorbate.[5-7] The behavior of hydrogen atoms and of methyl and ethyl radicals on silica gel has been studied by the ESR technique by Kazanskii *et al.*[8] They have determined the state of the adsorbed radicals by an analysis of the hyperfine structure and the coupling constant; they have found that these radicals are much stabilized on silica gel in comparison with those in a solid matrix.

In connection with their reports, we have attempted a study of the radicals formed by the radiolysis of monocarboxylic acids adsorbed on silica gel. For the adsorbate which interacts with the surface by means of the hydrogen bond, the characteristic radiolysis due to the change in the electronic state can be expected, among other things, when the coverage is less than unity. For this purpose, the ESR technique was used to obtain information on the radicals of the adsorbed state and on the nature of their thermal motion.

Experimental

The silica gel was prepared from water glass and sulfuric acid. It was purified by washing and electrodialysis, and was then calcinated in the air for 10 hr at about 450°C. Its surface area was measured by the BET method (S=790 m^2/g). The formic, acetic, and propionic acids used as adsorbates were dehydrated and distilled by the ordinary method.

The silica gel was outgassed in a vacuum of 10^{-5} mmHg for 5 hr at 450°C. The adsorption isotherms of these three acids on the silica gel were then measured by using a thermo-balance. The amounts of these acids adsorbed in a complete monolayer film were determined from these isotherms. The gel in a sample tube was exposed to the vapor of acid in a vacuum. When the desired coverage was attained, the tube was sealed off. In such a way samples with various coverages were obtained. The γ-irradiation was carried out by exposure to a ^{60}Co source at −196°C. The sample tubes used here were of quartz glass for acid on silica gel and of spectrosil for acid alone. The ESR spectra were obtained by using a Japan Electron Optics Laboratory JES-3BS-X type ESR spectrometer. The magnetic field was modulated at 100 kc/sec, and the g-value was determined by comparison with the value for DPPH.

Results and Discussion

γ-Irradiated Silica Gel. The spectra of the silica gel irradiated at −196°C and at room temperature are illustrated in Figs. 1a and 1b respectively. The spectrum shown in Fig. 1a

consists of a doublet with the coupling constant of 506.5 gauss and broad lines. This is in good agreement with the spectrum reported by Kazanskii *et al.*[1] The doublet is due to hydrogen atoms formed by the cleavage of hydroxyl groups on the surface, while the broad lines are caused by residual oxygen radicals and by radiation defects in the irradiated silica gel.[9] The hydrogen atoms and residual oxygen radicals gradually decreased with a rise in the temperature and disappeared at a high temperature, while the defects were still present at room temperature. When the silica gel was irradiated at room temperature, only one singlet spectrum coincident with that of the defects appeared at $g=2.0009$, as is seen in Fig. 1b.

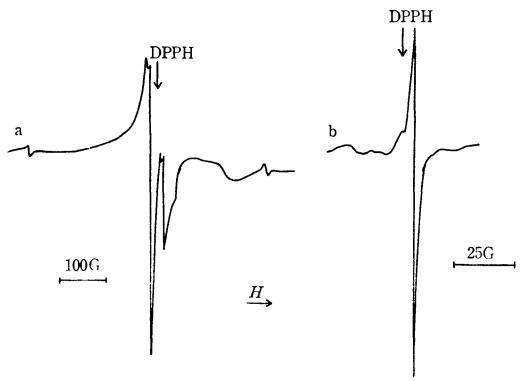

Fig. 1. ESR spectra of γ-irradiated silica gel (a) at liquid nitrogen temperature and (b) at room temperature.

γ-Irradiated Formic Acid Adsorbed on Silica Gel. The spectrum of the radicals which are produced by the radiolysis of the formic acid adsorbed on silica gel is different from that of formic acid alone (Fig. 2a, 2b). It has been reported regarding the X-irradiated formic acid that the radical, $H-\dot{C}(\diagup OH\cdots)(\diagdown O^-\cdots)$ or $H-\dot{C}(\diagup OH\cdots)(\diagdown OH\cdots)$, is formed by the radiation-induced reaction of the formic acid dimer.[10] The dotted lines indicate the hydrogen bond with the other molecule. From the close similarity of the spectrum obtained here to that previously reported, the spectrum shown in Fig. 2a can be assigned to the radical described above.

In the case of the adsorbed state, besides the defects of the γ-irradiated silica gel, another radical was formed, as is seen in Fig. 2b. In addition to these signal, a weak signal due to the radical, $H-\dot{C}(\diagup OH\cdots)(\diagdown O^-\cdots)$ or $H-\dot{C}(\diagup OH\cdots)(\diagdown OH\cdots)$, also appeared; this became still weaker with a decrease in the coverage.

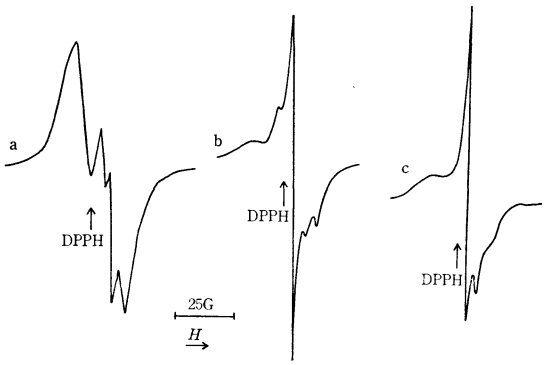

Fig. 2. (a) Spectrum of γ-irradiated formic acid, (b) spectra of γ-irradiated formic acid on silica gel at -196°C and (c) at -140°C.

The new signal became distinct at elevated temperatures as is seen in Fig. 2c. This radical may be assigned to the CO_2^- by a comparison of its g-value with the literature values.[3,11] The formation of carbon dioxide from the decomposition of formic acid was confirmed by gas chromatography. In view of the strong interaction of the formic acid monomer with the surface by means of the hydrogen bond,[12] it may be said that both the C–H bond and the O–H bond of the adsorbed acid were ruptured by γ-irradiation.

The formation of the CO_2^- radical was further studied as follows. Carbon dioxide was introduced to γ-irradiated silica gel. The ESR measurement was done while the sample was being irradiated with UV light.*1 The spectrum was in complete agreement with that shown in Fig. 2c. Our results on the g-value for CO_2^- radical are summarized in Table 1, along with those obtained by other authors.[3,11]

*1 The details of this study will be reported later.

been assigned by them to the radical, $CH_3\dot{C}(OH\cdots)(OH\cdots)$ or $CH_3\dot{C}(OH\cdots)(O^-\cdots)$. The change in the spectrum may be due to the rotational motion of the methyl group of the radical at higher temperatures.

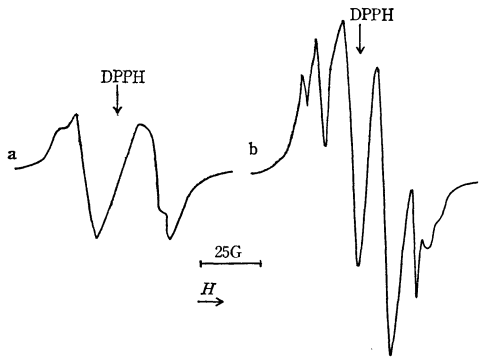

Fig. 3. Spectra of γ-irradiated acetic acid (a) at -196°C and (b) at -160°C.

The spectrum of the irradiated acetic acid on silica gel (Fig. 4a) consists of a quartet superimposed on a broad doublet. Since the quartet has the coupling constant of *ca.* 23 gauss, it is assigned to the methyl radical. The formation of the methyl radical indicates that the cleavage of the C–C bond occurred on the adsorbed acetic acid. The intensity ratio of the methyl radical spectrum at the coverage $\theta=1$ was 1 : 4.3 : 4.7 : 1.3, where θ is the fraction of the surface covered by the adsorbate. In comparison with the usual binominal coefficient ratio, the intensities of the central two components are too large. The central two components became sharp with a decrease in the coverage (Fig. 4b). The intensity ratios were 1 : 5.1 : 5.9 : 1.7 at $\theta=0.15$ and 1 : 6.0 : 6.2 : 2.0 at $\theta=0.04$. The abnormality in the intensity ratio suggests that the methyl radical interacts with the silica gel surface.

In addition to the quartet and doublet, a signal due to the defects in the silica gel begins to appear with a decrease in the coverage. The spectrum of the ·COOH radical was not observed. The difference between the spectra in the frozen and adsorbed states might be explained as follows. It is well-known that acetic acid forms a dimer by means of the hydrogen bond. However, when the acetic acid was adsorbed on silica gel, the three hydrogens of the methyl group as well as the carboxylic hydrogen may interact considerably with the surface.[13] According to this view, the transfer of the electron from the carboxyl group to the surface and the reduction of the inductive effect of the methyl group due to the interaction with the surface would lead to the weakness of the C–C bond. If this effect is taken into account, the breakage of the C–C bond can be understood. The appearance of the quartet and doublet shows that the acetic acid adsorbed on the silica gel decomposes through the following two simultaneous processes:

Fig. 4. Spectra of γ-irradiated acetic acid on silica gel (a) at $\theta=1$ and (b) at $\theta=0.15$.

$$CH_3COOH \rightarrow \cdot CH_3 + \cdot COOH \quad (1)$$

$$CH_3COOH \rightarrow CH_3\dot{C}(OH\cdots)(OH\cdots) \text{ or } CH_3\dot{C}(OH\cdots)(O^-\cdots) \quad (2)$$

The process (2) is considered to arise from the acetic acid, which interacts weakly with the surface.

In order to investigate the stability of the methyl radical, ESR measurements were made at various temperature. As the temperature was raised from -196°C, the intensity ratio of the quartet approached the binominal ratio. The radical continued to be present up to about -60°C. From these results it can be concluded that the methyl radical is initially fairly-well stabilized on the surface of silica gel but becomes mobile with a rise in the temperature.

γ-Irradiated Propionic Acid on Silica Gel. In the spectrum observed from the γ-irradiated

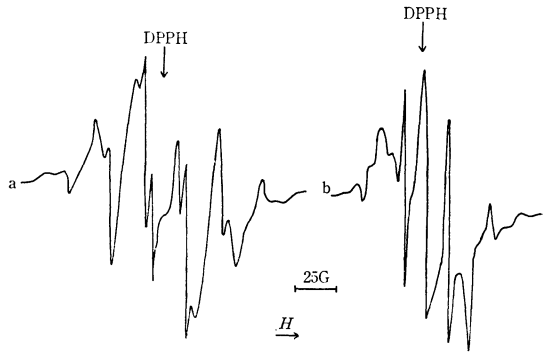

Fig. 5. (a) Spectrum of γ-irradiated propionic acid, (b) spectrum of γ-irradiated propionic acid on silica gel.

13) M. Shimizu and I. Higuchi, *Nippon Kagaku Zasshi (J. Chem. Soc. Japan, Pure Chem. Sect.)*, **81**, 1501 (1960).

propionic acid on silica gel (Fig. 5b), the singlet signal in the center seems to be due to the defects. With the exception of this singlet, this spectrum has a close resemblance to that of γ-irradiated propionic acid alone (Fig. 5a). The formation of the ethyl radical on the adsorbed state may be explained in the same way as in the case of acetic acid. However, because of the disappearance of the outer two components of the spectrum due to the ethyl radical on silica gel and the superposition of other radicals, it is impossible to discuss the adsorbed state of the ethyl radical.

The authors wish to express their hearty thanks to Assistant Professor Keiji Kuwata of Osaka University for his valuable discussions. Special thanks are also extended to Professor Satoru Tsuda, Mr. Akira Yokohata, and Mr. Osamu Yamamoto of Hiroshima University for kindly offering facilities for the γ-irradiation.

Microwave Spectrum of Cyclohexanone*[1]

Yoshitake OHNISHI and Kunio KOZIMA

Laboratory of Chemical Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 16, 1968)

The microwave spectrum of cyclohexanone has been investigated in the frequency region from 7.7 to 23.4 Gc/sec. The R- and Q-branches for both the a- and the c-type have been assigned for the vibrationally ground state. The rotational constants obtained are $A=4195.30$ Mc/sec, $B=2502.57$ Mc/sec, and $C=1754.49$ Mc/sec. From these values it can be concluded that the molecules have the chair form. The value of the component of the dipole moment $|\mu_a|$ is 2.74 ± 0.03 D, and that of $|\mu_c|$ is 0.86 ± 0.03 D. The value of the total dipole moment is 2.87 ± 0.04 D, a value which is in agreement with that obtained by Debye's method. For the structural parameters Romers' data obtained by the electron diffraction seems to be nearly correct.

An electron diffraction investigation of cyclohexanone has been reported by Romers.[1] By assuming the chair form for this molecule, the structural parameters obtained in his investigation were as follows: the bond distances were 1.54 ± 0.01 Å, 1.24 ± 0.02 Å, and 1.09 ± 0.02 Å for C–C, C=O, and C–H respectively, and all the carbon bond angles were $109.5°\pm2.5°$, with the exception of the valency angle of the carbonyl carbon atom, which was $117°\pm3°$ for the C–C–C angle. By the study of the microwave spectrum of acetone,[2] the ∠C–C–C valency angle has been estimated to be $117°12'\pm20'$. This value is essentially the same as that obtained by Romers. However, no structural investigation of cyclohexanone by microwave spectroscopy has yet been reported. The present work has been carried out in the hope of determining the special ring structure of this molecule.

Experimental

The spectrum was measured over the frequency range from 7700 to 23400 Mc/sec with a conventional Stark modulation microwave spectrometer, employing 100 kc/sec square-wave or sine-wave modulation. All the measurements were made at about −15°C. The frequencies were measured by the method reported in a previous paper.[3]

The sample of cyclohexanone, obtained from a commercial source, was distilled twice before use.

Results and Discussion

Microwave Spectrum and Rotational Constants. To obtain an idea of how the spectrum would appear, preliminary rotational constants were calculated by use of the structural parameters obtained by Romers[1] for three possible structures, *i. e.*, the chair form, the boat form, and the skew-boat form, as shown in Fig. 1.

It was difficult to assign the spectrum because of its richness, but almost all of the low J transitions for the a-type and some of the low J, c-type transitions were identified by their characteristic Stark effects; these assignments were confirmed by fitting them with rigid-rotor rotational constants. The measured frequencies and the transitions for both a- and c-type are listed in Table 1, together with the rotational constants obtained. In view

	$2_{12} \rightarrow 3_{22}$	20093.6	0.0
	$2_{21} \rightarrow 3_{31}$	23215.8	−0.3
	$4_{22} \rightarrow 4_{32}$	8532.4	−0.9
Rotational constants:		$A=4195.30$ Mc/sec	
		$B=2502.57$ Mc/sec	
		$C=1754.49$ Mc/sec	

* Maximum uncertainty of the observed values is ±0.2 Mc/sec.

** Uncertainty of the observed value is ±0.5 Mc/sec, because of an overlap with other line.

of the relative intensities of the spectrum, it is sure that the frequencies listed in Table 1 are those for the vibrationally ground state. No b-type transitions could be found.

Because the rotational constants thus obtained almost agreed with the preliminary constants of the chair form and differed markedly from the preliminary constants of both the boat and skew-boat forms, it can be concluded that the molecules of cyclohexanone have the chair form, with C_h symmetry.

Dipole Moment. The Stark displacements of the $M=1$ component of the $1_{11} \rightarrow 2_{12}$ transition and of the $M=2$ and M=3 components of the $3_{13} \rightarrow 4_{14}$ transition were measured in order to determine the a and c components, μ_a and μ_c, of the electric dipole moment. These lines were nicely fitted to quadratic Stark displacements. The absorption cell was calibrated using the $J=0 \rightarrow 1$ transition of OCS, taking the dipole moment of OCS as 0.7124 D.[4] The observed and calculated Stark coefficients are given in Table 2.

TABLE 2. STARK COEFFICIENTS AND DIPOLE MOMENT

		$\Delta\nu/E^2$ (Mc/sec)/(kV/cm)^2	
Transition,	M	Obsd	Calcd
$1_{11} \rightarrow 2_{12}$	1	645 ±10	640.3
$3_{13} \rightarrow 4_{14}$	2	42.3± 1.0	42.4
	3	96.2± 2.5	98.6
$\lvert\mu_a\rvert=2.74\pm0.03$ D			
$\lvert\mu_c\rvert=0.86\pm0.03$ D			
$\mu=2.87\pm0.04$ D			

The subscripts a and c refer to principal inertial axes of cyclohexanone.

An analysis of these data yields $\lvert\mu_a\rvert=2.74\pm0.03$ D, $\lvert\mu_c\rvert=0.86\pm0.03$ D, and a total dipole moment of 2.87±0.04 D. This value agrees with that of 2.90 D[5] obtained in a 1,4-dioxane solution by Debye's method.

By taking into account the fact that the vector of the dipole moment should be nearly parallel to the C=O bond, the directions of the vectors of μ_a and μ_c can be determined; from this, the angle, α, made by the vector of the total dipole moment and the a axis can then be determined to be 17.5°±1°.

Structural Calculations. Since the experimental results provide only three moments of inertia and the orientation of the dipole moment vector, a number of assumptions are required in order to extract any structural information. It may be assumed that (i) all C–H bonds are of equal length; (ii) the oxygen atom is coplanar with the three

4) S. A. Marshall and J. Weber, *Phys. Rev.*, **105**, 1502 (1957).

carbon atoms of C_6, C_1, and C_2; (iii) the internuclear distance, r_{2-3}, between C_2 and C_3 is equal to that, r_{3-4}, between C_3 and C_4; (iv) the HC_iH angle bisector is located along the $C_{i-1}C_iC_{i+1}$ angle bisector; (v) the HC_iH plane is perpendicular to the $C_{i-1}C_iC_{i+1}$ plane, and (vi) all of the HCH angles are the same. We then find that there are still nine undetermined structural parameters: r_{1-2}, r_{2-3}, r_{C-H}, $r_{C=O}$, $\angle C_1C_2C_3$, $\angle C_2C_3C_4$, $\angle C_3C_4C_5$, $\angle C_6C_1C_2$, and $\angle HCH$, where the numbers denote the positions of the carbon atoms in the ring, as shown in Fig. 1, and where r denotes the internuclear distance between the atoms shown in the subscripts. Therefore, we have to make six additional assumptions.

In our calculations the four internuclear distances and the two angles of $\angle C_6C_1C_2$ and $\angle HCH$ were assumed, and the remaining three angles were determined so as to get agreement between the observed and the calculated rotational constants. For the set I of the structural parameters, the assumed values are those[1] obtained by the electron diffraction. For the set II, the assumed values are those found in the microwave studies of acetone[2] and propane,[6] except that $\angle HCH$ is assumed to be a tetrahedral angle. The values of $r_{C=O}$, r_{1-2}, and $\angle C_6C_1C_2$ are those of acetone, and the values of r_{2-3} and r_{C-H} are those of propane. The angles of the ring obtained are listed in Table 3. Since, for the set II, the angle, β, made by the C=O bond and the a axis is considerably larger than the value of α, the set II seems to be inadequate. With an increase in the values of r_{2-3} or r_{1-2}, or with a decrease in the value of $C_6C_1C_2$, the value of β decreases. By the use of these facts, the sets III and IV, shown in Table 3, are tentatively calculated.

The agreement between the angle of α and that of β is satisfactory in the case of the set I; this favors Romers' data.

Table 3. Structural parameters of cyclohexanone

	Set I	Set II	Set III	Set IV
r_{1-2}*	1.54	1.507	1.507	1.516 Å

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1325—1329 (1968)

Anticatalytic Effect of Mn(II) in the Silver Catalyzed Oxidations by Peroxydisulphate

H. G. S. SENGAR and Y. K. GUPTA

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received July 25, 1967)

Mn(II) has been found to be an anticatalyst in the silver catalyzed oxidations of oxalate, citrate, tartrate, malonate and arsenious acid and the limiting value of the rate constants in each case is about 0.4 *l*/mol·min at 35°C which is very much comparable to the rate constant for the separate silver catalyzed oxidation of Mn(II), H_2O, Ce(III), N_2H_4 and vanadyl ion. A mechanism has been proposed in which the simultaneous oxidation of Mn(II) and the organic substrate or arsenious acid takes place and when sufficiently large concentration of Mn(II) is present, the latter oxidation is almost completely suppressed. The oxidations of citrate and tartrate are consecutive reactions. The first faster reaction is followed by the second slower reaction.

Mn(II) has been reported to be an anticatalyst in the silver catalyzed oxidations of As(III)[1] and oxalate[2] by peroxydisulphate, but no mechanism to explain its action has been proposed so far. We have made a systematic relevant study in the oxidations of arsenious, malonic, oxalic, tartaric,

citric, acetic and formic acids. The kinetics have been followed by estimating peroxydisulphate iodometrically by the method of Szabo, Csanyi and Galiba.[3] The detailed kinetic study of the oxidation of malonic, tartaric and citric acids has not been made in the past and nor we intend to report such results in the present paper. We have considered their oxidations only with reference to the effect of Mn(II).

Experimental

All chemicals used were either B. D. H. Analar or E. Merck G. R. quality. Manganous sulphate was used for Mn(II). Water used was doubly distilled in pyrex glass vessels. Potassium peroxydisulphate was freshly prepared by direct weighing and its concentration checked by any known method.

Calculated quantities of perchloric acid, substrate (arsenious, malonic, citric, tartaric, acetic, oxalic or formic acid), silver nitrate, manganous sulphate and water were taken in the reaction vessel placed in a thermostat at 35°C. Peroxydisulphate solution was separately thermostated. Calculated quantity of peroxydisulphate was then added to the reaction vessel to initiate the reaction. Total reaction mixture was 100 m*l*. After suitable intervals 5 m*l* of the reaction mixture was pipetted out and determined for peroxydisulphate.[4] For this aliquots were transferred to a beaker containing 2.5 m*l* of 60% KI (added in the last), 2.5 m*l* of conc. HCl, 5 m*l* of water and 1 m*l* of the catalyst. The catalyst was prepared by dissolving 2.59 g of ferrous ammonium sulphate and 9.52 g of copper sulphate in 500 m*l* of water. A drop or two of conc. H_2SO_4 was added to make the solution clear.

The liberated iodine was titrated against a standard solution of thiosulphate from a burette using starch as indicator. A blank was also run with the catalyst and all other reactants except the peroxydisulphate and this was subtracted from all observed readings of the burette.

The results of experiments referred to Fig. 1 were also obtained in a similar way. The fortunate circumstance is that in any run Mn(II) and the substrate are not oxidized simultaneously, at least apparently. In case of oxalate, citrate, tartarate, malonate, As(III), *etc.*, these are first oxidized and no Mn(III) or MnO_2 is seen or found in the system. Mn(III) or MnO_2 could be found only when the substrate was completely oxidized. In case of acetate Mn(II) is first oxidized to MnO_2, and when this is complete, only then acetate is oxidized. It was possible to make a check on this conclusion in case of acetate. MnO_2 formed was separated by centrifuging the reaction mixture, and the precipitate and the liquid were separately analyzed for MnO_2 and peroxydisulphate respectively iodometrically. It was found that the decrease in peroxydisulphate was exactly equal to MnO_2 formed and hence it was concluded that acetate was not oxidized till there was any Mn(II) in the system. In other cases (oxalic, citric acid, *etc.*) there appeared no MnO_2 in the system till there was any substrate. The reduction of peroxydisulphate, therefore, takes palce in two parts with two different rates as shown in Fig. 1.

Results and Discussion

All the reactions are first order with respect to peroxydisulphate and the first order catalytic constants, k were calculated[5] from the following equation:

$$k = \frac{2.303 \times \text{slope}}{[Ag^+]}$$

where the slope refers to that of the straight line obtained by plotting the logarithm of the concentration of peroxydisulphate at different intervals of time, against time. The effect of Mn(II) on all these acids is shown in Figs. 2, 3 and 4 and a comparison of the rate for one concentration of Mn(II) has been made in Table 1.

A particular function of the concentration of

Mn(II) has been selected for a graphical plot to obtain a limiting value of k in presence of infinite amount of Mn(II). The dependency of the pseudo-first order rate constants upon Mn(II) concentration is of varying nature in different cases. Only complete kinetic studies of the oxidation of organic acids by Mn(III) can give an explanation for this curious behaviour. However, we are concerned here only with the mechanism of the reduction of peroxydisulphate in presence of Mn(II) and the limiting value of the rate constant and not with the mechanism of the oxidation of the organic acids by Mn(III) or MnO_2. Nevertheless, this curious dependency on Mn(II) appears to be connected in some way with the complex formation of Mn(III) with the organic acids.

A look at the figures of Table 1 will indicate that in all cases except one, the limiting value of k is about 0.4—0.5 l/mol-min which is the same as for the oxidations of Mn(II),[7,8] Tl(I),[5] Ce(III),[9] H_2O,[10] *etc.* These results can be explained on the basis of the following general mechanism which has already been advanced by the previous workers.

$$S_2O_8^{2-} \rightleftharpoons 2SO_4^- \qquad \text{(i)}$$

$$2SO_4^- + Ag^+ \rightarrow 2SO_4^{2-} + Ag^{3+} \qquad \text{(ii)}$$

(1)

$$Ag^{3+} + IS \rightarrow \text{Products}$$

$$Ag^{3+} + Mn(II) \rightarrow Ag^+ + Mn(III) \text{ or } MnO_2 \qquad \text{(iiia)}$$

(2)

$$Ag^{3+} + S \rightarrow Ag^+ + R_1 \qquad \text{(iiib)}$$

$$S_2O_8^{2-} + R_1 \rightarrow SO_4^- + SO_4^{2-} + \text{products}$$

$$SO_4^- + R_1 \rightarrow SO_4^{=} + \text{products}$$

$$2R_1 \rightarrow \text{products}$$

Steps (iiia) and (iiib) are faster than (ii). Mechanism (I) refers to the oxidation of inorganic substrate (IS) and hence, is independent of the concentration of the latter giving overall catalytic rate constant of 0.4—0.5 l/mol-min (or the observed rate constant of $8—10\times10^{-4}$/min). Mechanism (2) involving the organic substrate is a chain mechanism. This mechanism and hence the overall rate constant would slightly change (the chain breaking step in particular) depending on the species being oxidized.

It appears that in presence of Mn(II), both mechanisms (I) and (2) occur simultaneously. Mn(II) competes with S in reaction with Ag^{3+}. Mn(II) is oxidized to Mn(III) or MnO_2 and the latter in acid medium quickly reacts with S. In previous studies of oxidations of tartarate,[11] citrate,[12] malonate[13] and oxalate[14] by MnO_2, the first order rate constants were found to be of the order of $5\times10^{-2}—1\times10^{-1}$/min which are about a hundred times higher than the observed rate constant of the present study. Hence the reaction of MnO_2 with S is fast, but this process may not be an efficient chain mechanism. Although S is oxidized by both mechanisms, the chain process becomes less significant in competition with the reaction with MnO_2 and the rate decreases. In the limit when sufficient Mn(II) is present, the chain mechanism (2) may not work at all and S is oxidized only through mechanism (1). The rate, therefore, falls to the limiting value of 0.4—0.5 l/mol-min. The limiting value in case of oxalate is slightly higher, but is by no means very different than 0.5. The probable reason for this higher value is that the reaction of Mn(III) with oxalate itself is a free radical reaction involving chains as reported by Taube[15] and Alder and Noyes[16].

The results with acetate are a little different. The catalytic rate constant was found to be about 1.1 to 1.5 l/mol-min depending on the ionic strength, and in absence of Mn(II). In presence of any concentration of Mn(II), the rate constant was 0.44 l/mol-min. Mn(II) is oxidized to MnO_2, but the latter does not react with acetate and hence accumulates in the system. (The peroxydisulphate was estimated after separating MnO_2 by centrifuging the reaction mixture.) Acetate, however, was not oxidized by the independent path (mechanism (2)) also and it was oxidized only when the oxidation of Mn(II) was complete. There are two distinct oxidations as is apparent from Fig. 1. This was proved by the fact that the rate of decrease of peroxydisulphate was exactly equal to the rate of formation of MnO_2, and acetate had absolutely no effect, *i. e.*, it was neither oxidized nor it affected the oxidation of Mn(II). This may indicate that the step (iiib) is too slow as compared to step (iiia), although the former is quite fast as compared to step (i) or step (ii). The situation is similar to the oxidation of water[10] in absence of any reducing substance, which takes place at the same rate at which Mn(II), if present, is oxidized and in that case water is not at all oxidized so long any Mn(II) is present. Another point of mechanistic interest

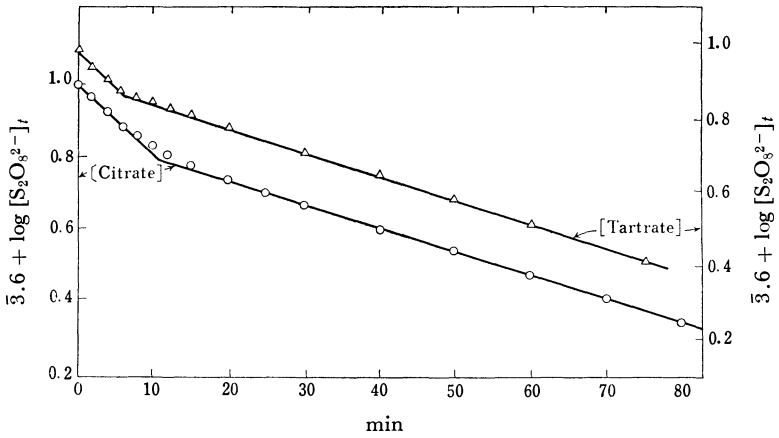

Fig. 5. First order plots for the oxidation of citrate and tartrate by peroxydisulphate, each one of them showing two reactions, one after the other.
$[S_2O_8^{2-}]=0.02$ M; [citrate]=[tartrate]$=0.02$ M; $[Ag^+]=0.005$ M; $[HClO_4]=0.182$ M; $[NaClO_4]=0.50$ M

found was that the rate of decrease of peroxydisulphate or the rate of oxidation of acetate (in absence of Mn(II)) was always about three times that of the oxidation of Mn(II).

A reverse behaviour is seen with the pair oxalate-Mn(II) or As(III)-Mn(II). So long any oxalate or arsenious acid is present in the system, Mn(II) is apparently not oxidized, and MnO_2 begins to form only after the oxidation of oxalate or arsenious acid is complete. Figure 1 shows these results. In fact Mn(II) is definitely oxidized as stated earlier, but Mn(III) formed reacts with oxalate or arsenious acid. The reaction is almost instantaneous in high acid medium.

In the oxidation of formic acid in presence of Mn(II), MnO_2 is formed as in the case of acetate, but the results show that the formic acid is also oxidized because the rate of decrease of peroxydisulphate is more than the rate of formation of MnO_2. In fact the rate of formation of MnO_2 is less than even the value of 0.4—0.5. A plot of log[MnO_2] *vs.* time also does not give a straight line. It appears that MnO_2 is further oxidized to permanganate which then slowly reacts with the formic acid. In this process more of peroxydisulphate is used up and some quantity of MnO_2 is also consumed. The overall observed first order rate constant, therefore, is more (0.51) than 0.4 (for Mn(II) alone). However, this constant is much less than the rate constant for the oxidation of formic acid alone in absence of Mn(II) which was found[17] to be 8—10 *l*/mol-min. The reaction mixtures were found to turn pink, obviously due to the formation of permanganate which subsequently slowly reacted with the formic acid forming back Mn(II). Mn(II), therefore, is never completely oxidized to MnO_2 in such a case till any formic acid is present. However, in case of acetate, permanganate even if formed does not react with the acetate.

We thus find that Mn(II) retards the rate in the silver catalyzed peroxydisulphate oxidations which go by a chain mechanism and this it does by reacting with the chain propagating free radical in competition with the substance being oxidized.

Oxidation studies of citrate and tartrate revealed another interesting fact though not relevant to the present paper. Both reactions seem to involve two consecutive reactions and that the first faster reaction is followed by the second slower reaction almost after when the former is complete (Fig. 5). First and second of Fig. 4 refer to these first and second reactions. In case of tartarate the first reaction is retarded and the second accelerated in presence of Mn(II). A detailed study of this reaction is being made to explain such behaviour of Mn(II). In case of citrate both the reactions are retarded in presence of Mn(II) and the limiting value in each case is 0.4 *l*/mol-min.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1330—1333 (1968)

Stability Constants of Some Uranyl Complexes

S. RAMAMOORTHY and M. SANTAPPA

Department of Physical Chemistry, University of Madras, Madras-25, India

(Received August 1, 1967)

Complexes of uranyl ion with benzoic, phenylacetic, phenoxy-acetic, thiomalic and itaconic acids were studied by pH titration method at 31 ±0.1°C. A 1 : 1 complex is formed in all the cases in the pH range 2.5—3.5 and their stability constants are reported.

In a potentiometric study of chelates of Uranyl nitrate with hydroxy, mercapto and amino acids, Cefola and coworkers[1] reported the first and second formation constants of uranyl-thiomalate complex in the pH range 2—4, neglecting the hydrolysis of uranyl ion till pH 4.00. Later, Mathur, Nigam and Srivastava[2] in a spectrophotometric study (Job's method) of the uranyl-thiomalic acid system reported the formation constants of the 1 : 1 complex in the pH range 3—7, neglecting again the hydrolysis of uranyl ions. It may be mentioned here that extensive investigations by Sutton,[3] Ahrland[4] and recently by Sommer[5] revealed that hydrolytic species of the type $U_2O_5^{2+}$, $U_3O_8^{2+}$, $U_3O_8(OH)$, $(UO_2)_2(OH)_2$, $(UO_2)_2OH$, *etc.*, at pH >3.5 were present. As a part of our studies on complexes, systems of uranyl ion with benzoic, phenyl acetic, phenoxy acetic, thiomalic and itaconic acids were studied by pH titration method at 31 ±0.1°C with a view to determine the composition(s) and formation constant(s) of the complex(es) and to detect possible formation of polymeric species especially in the systems of uranyl ion with thiomalic and itaconic acids in the pH range 1.5—3.5 in which hydrolysis of uranyl ion may be completely neglected.

From the results of our studies, it is concluded that a 1 : 1 complex is formed in all the systems. The stability constants of all the complexes were evaluated at 31±0.1°C.

Experimental

Materials. The uranyl perchlorate prepared from uranyl nitrate (BDH, AnalaR) by the standard procedure[6] was assayed by the Jone's reductor method[7] for uranyl content and by cation resin exchange method[8] for free acid. A stock solution (0.26 M in uranyl and 0.09 M in hydrogen ion) was prepared. Carbonate free sodium hydroxide (1.0 M) was used in all the titrations, the former after dilution to ten times was standardized against potassium hydrogen phthalate (0.1 M). The ligand acids (A. R.; all correct M. ps) were standardized with sodium hydroxide solution (0.2 M). Deionised water free from carbonate was used in all the titrations. Sodium perchlorate (2.008 M) prepared from perchloric acid (60% G. R., E. Merck) and AnalaR sodium hydroxide was used for constancy of ionic strength at 0.1.

Procedure. A pH meter (Cat. No. 7666, Leeds and Northrup) with glass and calomel electrodes standardized with potassium hydrogen phthalate buffer (0.05 M; pH 4.01 at 31°C) was used for measurements of pH during titrations of the system, ligand - perchloric acid - sodium perchlorate with or without uranyl perchlorate against standard alkali (1.0 M). All titrations were carried out in a double walled glass titration vessel provided with inlet and outlet tubes for circulating water at constant temperature (31°C or 45°C). The cell was covered with black cloth during titrations. Nitrogen freed from carbon dioxide was continually passed through the system under study in the titration cell. After each addition of the alkali titrant (0.05 m*l*), solutions were allowed to stand for 10—15 min for attainment of equilibrium. The titrations were carried out from an initial pH 1.5 to 11.0 and for ratios of [Ligand/Uranyl]≡1 to 10.

Results and Discussion

pH Titrations. Acid dissociation constants of the ligand acids were determined by titrating systems of ligand - perchloric acid - sodium perchlorate against standard sodium hydroxide solution (1.0 M). The initial volume of the solution was 100 m*l* and the ionic strength was kept at 0.1. pHs of the solution were recorded after each addition of

0.05 m*l* of sodium hydroxide solution. Acid dissociation constants of benzoic, phenyl acetic and phenoxy acetic acids were calculated by the algebraic method and those of thiomalic and itaconic acids (first, K_1 and second, K_2) were determined conveniently by the method of slope and intercept due to Irving and Rossotti[9] because the two inflexions in the titration curves overlapped to give single inflexion points in the latter two cases. The following equation[9] due to Irving and Rossotti was used:

$$\frac{\bar{n}_H}{(1-\bar{n}_H)\,[H]} = \frac{1}{K_2} + \frac{1}{K_1K_2}\,\frac{(2-\bar{n}_H)\,[H]}{(1-\bar{n}_H)} \qquad (1)$$

$$K_1=[HA][H]/[H_2A] \text{ and } K_2=[H][A]/[HA]$$

$\bar{n}_H$, the average number of hydrogen ions bound to a ligand anion and corresponds to the Bjerrum's formation function[10]; charged species H^+ are written as H for simplicity. The pK_1 and pK_2 values for all acids are given in Table 1. A value of 0.83 for activity coefficient for H^+ (0.1 N) was used[11] for computing the concentration of the latter. p*K* values for various acids with those reported in literature[12-14] are given (Table 1).

* Concentration constants
** Temperature: 28°C

Stability Constants K_{ML}. A known concentration, C_L, of the ligand was titrated without and with a known concentration, C_M, or uranyl ion, so that $[C_L/C_M]=1$ or 2 to facilitate formation of complexes 1 : 1 (ML_1) and 1 : 2 (ML_2) respectively. Titrations were also carried out for $[C_L/C_M]=10$ to allow the formation of higher complexes, if any. The degrees of formation of the metal complexes, $\bar{n}$, were calculated from the titration curves by Irving and Rossotti's difference method.[15] Values for the log of free ligand concentration, p*L* were obtained from the equation:

$$pL = \log_{10}\frac{\{1+([H]/K_2)+([H]^2/K_1K_2)\}}{(C_L-\bar{n}C_M)} \qquad (2)$$

Values of $\bar{n}$ and p*L* were used to draw the formation curves for the systems and $\log K_{ML}$ of the complex was evaluated from the value of p*L* at $\bar{n}=0.5$ (Fig. 1a). The stability constants were also determined graphically using Eq. (3), also due to Irving and Rossotti.[9]

$$\frac{\bar{n}}{(1-\bar{n})[L]} = K_{ML} + K_{ML}K_{ML_2}\frac{(2-\bar{n})[L]}{(1-\bar{n})} + \sum_{n=3}^{N} K_{ML}K_{ML_2}\cdots K_{ML_n}\frac{(n-\bar{n})[L]^{n-1}}{(1-\bar{n})} \qquad (3)$$

K_{ML}, $K_{ML_2},\cdots,K_{ML_n}$=successive formation constants and [L]=free ligand concentration. The formation of only 1 : 1 complex was also obvious from the plots $\bar{n}/(1-\bar{n})[L]$ *vs.* $(2-\bar{n})[L]/(1-\bar{n})$ being parallel to the abscissa (Fig. 1b). The stability constants calculated from $\bar{n}$ *vs.* p*L* curve agreed very well with those calculated from Eq. (3). It may be mentioned that $\bar{n}$ did not go beyond unity even when $[C_L/C_M]\geqq 1$ up to 10. From the order of stability constants (Table 1) for phenoxy acetic acid and benzoic acid being similar it appears that a chelate ring involving phenoxy oxygen atom is not formed for UO_2^{2+}-phenoxy acetic acid complex. The difference in the stability constant values between phenyl acetic acid and phenoxy acetic acids may be due to the respective p*K* values being different and therefore affecting considerably the stabilities of the complexes formed.[16,17] No data for stability constants for UO_2^{2+}-monobasic acid complexes (studied by us) are available in literature for comparison.

Thiomalic and Itaconic Acids. The formation curves of these systems showed the formation of only 1 : 1 complex in the pH range (1.5—3.5) (Fig. 1a and 1b). In order to detect the possible polymerization of the UO_2^{2+}-thiomalate and UO_2^{2+}-itaconate complexes, the pH titrations of the 1 : 1 uranyl-thiomalate and uranyl-itaconate systems were carried out for $[UO_2^{2+}]=[\text{Ligand}]=0.02$ M, 0.008 M, 0.005 M, 0.0025 M and 0.001 M for the former and 0.02 M, 0.0032 M, and 0.0016 M for the latter system which amounts to variation in

the total ligand and total metal concentrations by factors of 20 and 12 respectively. The data (Table 2) show that the log K_{ML} values for the uranyl-thiomalate and uranyl-itaconate systems increase slightly with decreasing concentration of the metal chelates and therefore polymeric complexes may be assumed to be absent in these systems.[18] We restricted our studies to pH<3.5 so that hydrolytic equilibria did not interfere with the systems under consideration.

pH titrations of the thiomalic acid against sodium hydroxide with and without uranyl ion were also carried out by us at 45°C. The stability constants for uranyl - thiomalic acid system at 31°C and 45°C (Table 2) did not vary very much within the limits of experimental errors and therefore calculation of thermodynamic parameters ΔH and ΔS under these circumstances would be futile according to Rossotti[19] and therefore no attempts for calculation of these parameters were made by us. Values of stability constants for uranyl-itaconic acid complex are not available in literature for comparison. Our value for the stability constant for UO_2^{2+}-thiomalic acid complex has been calculated under conditions of negligible hydrolysis and least complexing medium and therefore represents an improvement over the values already reported.[1,2]

Conclusion

From our results, it is evident that uranyl ion forms a 1 : 1 complex with all the ligands under study in the pH range, (1.5—3.5). This is the case even when the ratio [Ligand/Uranyl] = 1 to 10.

It is probable that itaconic acid may coordinate through two COO^- groups to uranyl ion, forming a chelate ring. But in the case of thiomalic acid, a consideration of magnetic susceptibility data of uranyl-thiomalate complex by Mathur *et al.*,[2] and comparison of the log K_{ML} (3.75) for the latter with that for uranyl-malate complex (log K_{ML} = 1.66)[18] under more or less identical conditions indicate the possible involvement of neutral sulfur atom in coordination to uranyl forming a chelate ring, similar to coordination of neutral oxygen in hydroxy acids to metal ions.[20,21] The possibility of coordination of S^- to UO_2^{2+} cannot be discounted. The coordination of –SH group to metal ion even in the acidic region resulting in the deprotonation of the former is possible; however, we were unable to detect the release of the third proton in the pH range 2.0 to 5.0 of our studies. (Absence of inflexion corresponding to the release of third proton in our plots of pH *vs.* "moles of base"/"mole of ligand" added.)

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1333—1339 (1968)

Kinetics of Multidentate Ligand Substitution Reactions. II. Substitution Reactions of BT with Nitrilotriacetato Nickelate(II) Chelate and with Ethylenediaminetetraacetato Nickelate(II) Chelate

Mutsuo KODAMA, Chifumi SASAKI and Mitsuko MURATA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received October 4, 1967)

This paper reports a spectrophotometric study of the solution equilibria and the kinetics of the substitution reaction of Eriochrom Black T (BT) with nickel(II)-NTA and with nickel(II)-EDTA chelates. In solutions of pH 8.50—9.50 containing a large excess of uncomplexed NTA over BT and nickel(II)-NTA chelate, BT forms only 1-to-1 normal chelate, NiD^-, with the nickel(II) ion, the stability constant of which is $10^{20.8}$ ($\mu=0.30$). Kinetically, the ligand-exchange reaction of BT with the nickel(II)-NTA chelate was found to proceed through the following two simultaneous reaction paths and to be much faster than that with the nickel(II)-EDTA chelate,

i) $NiX^- + HD^{2-} \rightleftharpoons NiD^- + HX^{2-}$ (rapid $\updownarrow$ NiX_2^{4-})

ii) $HD^{2-} \overset{\text{rapid}}{\rightleftharpoons} D^{3-} + H^+$; $NiX^- + D^{3-} \rightleftharpoons NiD^- + X^{3-}$ (rapid $\updownarrow$ NiX_2^{4-}) rate-determining step

where NiX^-, NiX_2^{4-}, HD^{2-}, and D^{3-} represent Ni(II)-NTA chelate of 1-to-1 composition, Ni(II)-NTA chelate of 1-to-2 composition, doubly deprotonated BT anion and completely deprotonated BT anion, respectively. The substitution reaction of BT with nickel(II)-EDTA chelate was found to proceed mainly through the following reaction path,

$$HD^{2-} \overset{\text{rapid}}{\rightleftharpoons} D^{3-} + H^+ \qquad NiY^{2-} + D^{3-} \rightleftharpoons NiD^- + Y^{4-}$$

rate-determining step

and the contribution of the following reaction to the whole reaction is negligible at pH 9.00—10.50.

$$NiY^{2-} + HD^{2-} \rightleftharpoons NiD^- + HY^{3-}$$

In a previous paper,[1] the kinetics of the substitution reaction of Eriochrom Black T (BT, H_3D) and ethylenediaminetetraacetato cobaltate(II) were studied spectrophotometrically. The substitution

1) M. Kodama, This Bulletin, **40**, 2575 (1967).

reaction was found to proceed through doubly dissociated and completely dissociated BT ions, but contribution of the reaction path where the dissociation of Co(II)-EDTA chelate is rate-determining is negligible.

In this paper, we report the kinetics of the substitution reactions of BT with nitrilotriacetato nickelate(II) chelate (Ni(II)-NTA) and with ethylenediaminetetraacetato nickelate (II) chelate (Ni-(II)-EDTA).

Experimental

Reagents. NTA and EDTA were recrystallized as free acids, and their solutions were standardized by the methods described previously.[1,2] Nickel(II) perchlorate solution was prepared by the following procedure. A known amount of metallic nickel of 99.99% purity was dissolved in dilute HNO_3 solution (1+1), and the nickel(II) was precipitated as hydroxide. The nickel(II) hydroxide was washed thoroughly with redistilled water and dissolved in diluted perchloric acid solution (0.25 M). The concentration of nickel(II) perchlorate solution was standardized against a standard EDTA solution using Murexide as indicator.[3] The purification of BT and the test of its purity are also described in an earlier paper.[2]

Apparatus and Procedure. The apparatus and the experimental procedures were the same as described previously.[1] In this study no buffer reagent was used because uncomplexed EDTA and NTA are considered to have enough buffer capacity to maintain pH values constnat.

Results and Discussion

The Substitution Reaction of BT with Nickel(II)-NTA Chelate. First, the composition and the stability constant of nickel(II)-BT chelate were determined by the same method as in the equilibrium study of the BT-cobalt(II)-EDTA system.[1] As shown in Fig. 1, the concentration ratio between uncomplexed BT and nickel(II)-BT chelate can be determined successfully by measuring the absorbance at 640 mμ. Under the experimental conditions where free NTA is present in a large excess over BT and nickel(II)-NTA chelate, by the analogy to the equilibrium between BT and zinc(II)-NTA chelate,[2] the following relation can be derived when only 1-to-1 chelate, NiD^-, is formed between BT and the nickel(II) ion.

$$\log \frac{A_D-A}{A-A_{NiD}} \cdot \frac{1}{m-\dfrac{A_D-A}{A_D-A_{NiD}}} \cdot [BT]_0 = \log \frac{K_{NiD}}{K_{NiX}} \frac{(\alpha_H)_x}{(\alpha_H)_{BT}} + \log \frac{1}{[X]_f \cdot \left\{1+\dfrac{K_{NiX_2}\cdot[X]_f}{(\alpha_H)_x}\right\}} \quad (1)$$

where symbols, A_D, A, $(\alpha_H)_{BT}$ and $[X]_f$, have the same meanings as were used in the previous paper[2] and other notation definitions used are as follows. A_{NiD}: Absorbance of the solution where all the BT ions are considered to form complex with nickel(II) ion, m: The ratio of the total concentration of nickel(II) to that of BT, $[BT]_0$: The total concentration of BT, K_{NiX}: Stability constant of Ni(II)-NTA chelate of 1-to-1 composition, K_{NiX_2}: Equilibrium constant defined as $K_{NiX_2}=[NiX_2^{4-}]/[NiX^-]\cdot[X^{3-}]$, K_{NiD}: Stability constant of Ni(II)-BT chelate, $(\alpha_H)_x$: (α_H) value of NTA.

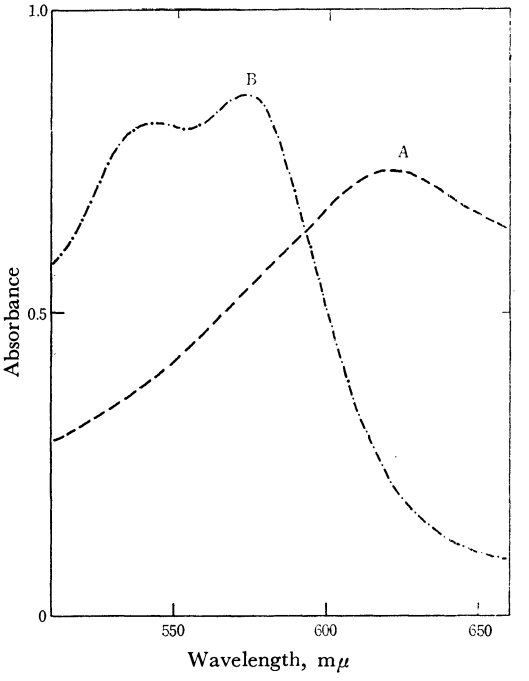

Fig. 1. Absorption curves.
$\mu=0.30$, pH=9.45
The concentration of uncomplexed NTA=27.0 mM
The concentration of BT=2.26×10^{-5} M
A. No nickel(II)-NTA chelate
B. 9.0 mM nickel(II)-NTA chelate

The ratio of the total concentration of nickel-(II) to that of BT m, was made 1.50 and all measurements were conducted in solutions at constant pH 9.54. A straight line with a slope of unity was obtained by plotting

$$\log \frac{A_D-A}{A-A_{NiD}} \cdot \frac{1}{m-\dfrac{A_D-A}{A_D-A_{NiD}}} \cdot [BT]_0 \text{ vs. } \log \frac{1}{[X]_f \cdot \left\{1+\dfrac{K_{NiX_2}\cdot[X]_f}{(\alpha_H)_x}\right\}}$$

2) M. Kodama and H. Ebine, *ibid.*, **40**, 1857 (1967).
3) H. Flaschka and H. Abdie, *Chemist-Analyst*, **44**, 30 (1955).

showing a confirmatory evidence that under the present experimental conditions only normal chelate NiD^- is formed (Fig. 2). From the intercept, K_{NiX} value[4] and pK values[5] in Table 1, the K_{NiD} value was determined to be $10^{20.8}$ (μ= 0.30, 25°C). This value can satisfactorily account for the well-known interference of nickel(II) ions in the EDTA titration of Mg(II) using BT as indicator.

As described previously,[2] the numerical values used in the above calculation were estimated from the related stability and the dissociation constants.[4] The concentration of free NTA $[X]_f$ was calculated by using the following relation.

$$[X]_f = \frac{-\left\{1-\frac{K_{NiX_2}}{(\alpha_H)_x}([X]_t-2[Ni(II)]_t)\right\}+\sqrt{1+\frac{2\cdot K_{NiX_2}\cdot[X]_t}{(\alpha_H)_x}+\frac{K^2_{NiX_2}}{(\alpha_H)_x{}^2}([X]_t-2\cdot[Ni(II)]_t)^2}}{\frac{2\cdot K_{NiX_2}}{(\alpha_H)_x}} \quad (2)$$

where $[X]_t$ and $[Ni(II)]_t$ refer to the total concentrations of NTA and nickel(II), respectively.

The kinetics of the substitution reaction of BT with Ni(II)-NTA chelates was studied at 16°C in the presence of a large excess of NTA and its nickel(II) chelate at a pH range 8.50—9.50. Therefore, the reaction can be treated as a pseudo first-order reaction, and simplified to,

$$\left\{\begin{array}{l} HD^{2-} \\ \uparrow\downarrow \\ D^{3-} \end{array}\right. \overset{\overset{k^+}{\rightleftharpoons}}{\underset{k^-}{}} NiD^- \quad (3)$$

The reaction gave invariably the linear relation between $\log(A_D/(A-A_{NiD}))$ and time, t, with the intercept identical with $\log(\varepsilon_{BT}/(\varepsilon_{BT}-\varepsilon_{NiD}))$

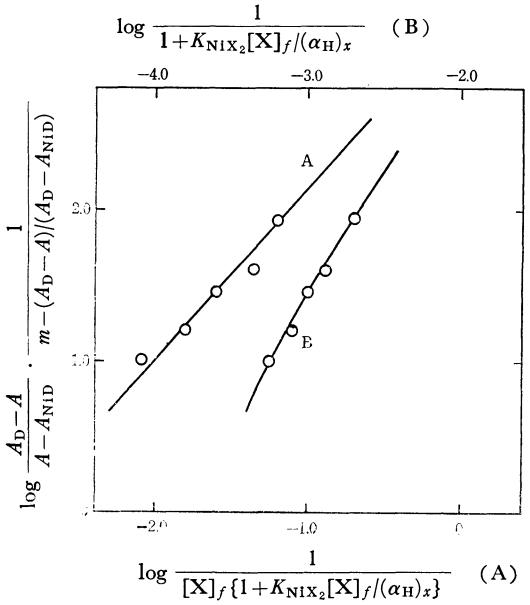

Fig. 2. The plot of $\log[X]_f(1+K_{NiX_2}[X]_f/(\alpha_H)_x)$ against $\log\frac{A_D-A}{A-A_{NiD}}\cdot\frac{1}{m-\frac{A_D-A}{A_D-A_{NiD}}}$.
μ=0.30, pH=9.54, λ=640 mμ

5) G. Schwarzenbach and R. Gut, *ibid.*, **39**, 1589 (1956).

when the pH value of the solution is kept constant, because it can be thermodynamically equated as $(\varepsilon_{H_2D}[H^+]^2/k_1 \cdot k_2 + \varepsilon_{HD} \cdot [H^+]/k_2 + \varepsilon_D)/(\alpha_H)_{BT}$. Therefore, in this study, ε_{BT} value observed at the pH, where the kinetic measurement was conducted, was used in the analysis of experimental data. Here, ε_{H_2D}, ε_{HD} and ε_D mean true molar extinction coefficients of singly deprotonated, doubly deprotonated and completely deprotonated BT anion respectively, and k's are dissociation constants of BT.[9] Strictly k_1 should refer to the dissociation of sulfonic acid, but Schwarzenbach's notation was followed here, k_1 and k_2 referring to the dissociation of the phenolic hydrogen atoms. Considering that the stability constants of Ni(II)-BT chelate is much greater than that of nickel(II)-NTA chelate, under the present experimental conditions where the concentration of free NTA (the sum of concentrations of free singly deprotonated, doubly deprotonated and completely deprotonated NTA anions and of free NTA) is comparable with that of nickel(II)-NTA chelate, the concentration of free BT (the sum of concentrations of free singly deprotonated, doubly deprotonated and completely deprotonated BT anion and of free BT) at equilibrium, $[BT]_e$, is negligibly small as compared with its initial concentration, $[BT]_0$, and the free BT concentration at t, [BT], at an early stage of the reaction. Therefore, the slope of the linear relation between $\log(A_D/(A-A_{NID}))$ and t should correspond to the apparent rate constant, k^+, of the reaction (3) as was discussed in the substitution reaction of BT with cobalt(II)-EDTA chelate.[1]

The following facts were also found in the preliminary experiments where free NTA ranged from 10 mM to 40 mM and nickel(II)-NTA chelate, from 2.0 mM to 9.0 mM.

i) The slope of the linear relation between $\log(A_D/(A-A_{NID}))$ and t was independent of the initial concentration of BT, $[BT]_0$, in solutions of a given pH, a given concentration of free NTA and a given total concentration of nickel(II)-NTA chelate (Table 2).

TABLE 2. DEPENDENCE OF THE SLOPE ON THE INITIAL CONCENTRATION OF BT

pH=9.25, μ=0.30
Concentration of uncomplexed NTA=27.0 mM
Total concentration of Ni(II)-NTA chelate=6.50 mM

Concentration of BT, 10^{-5} M	Slope, sec^{-1}
0.90	3.33×10^{-3}
1.50	3.47×10^{-3}
2.00	3.50×10^{-3}
3.00	3.40×10^{-3}

ii) In solutions of a given pH and given initial concentrations of BT and of uncomplexed NTA, the slope of the above linear relation was proportional to the total concentration of Ni(II)-NTA chelate, $[NiX]_t$ (Table 3).

TABLE 3. DEPENDENCE OF THE SLOPE ON THE TOTAL CONCENTRATION OF Ni(II)-NTA CHELATES

pH=9.40, μ=0.30
Initial concentration of BT=2.00×10^{-5} M
Concentration of uncomplexed NTA=12.0 mM

Concentration of Ni(II)-NTA chelate, mM	Concentration ratio	Slope, sec^{-1}	Slope ratio
2.60	1.00	3.33×10^{-3}	1.00
3.90	1.50	5.20×10^{-3}	1.56
6.50	2.50	8.66×10^{-3}	2.60
9.10	3.50	1.18×10^{-2}	3.53

iii) In solutions of a given pH, a given initial concentration of BT and a given total concentration of Ni(II)-NTA chelate, the slope of the linear relation was inversely proportional to $1+K_{NiX_2}\cdot[X]_f/(\alpha_H)_x$ value (Table 4).

TABLE 4. DEPENDENCE OF THE SLOPE ON THE CONCENTRATION OF UNCOMPLEXED NTA

17.0	171	5.73×10^{-3}	9.80×10^{-1}
27.0	271	3.50×10^{-3}	9.50×10^{-1}

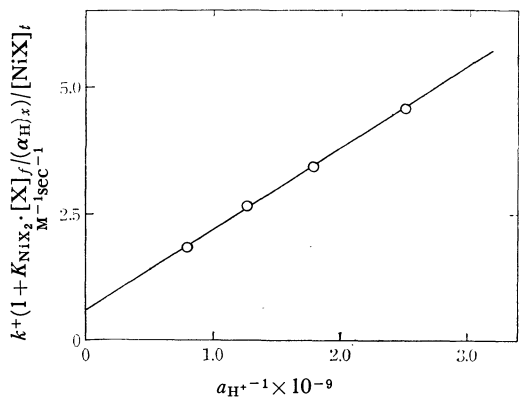

Fig. 4. Relation between $k^+(1+K_{NiX_2}\cdot[X]_f/(\alpha_H)_x)/[NiX]_t$ and the concentration of hydrogen ion.
μ=0.30
Initial concentration of BT=2.00×10^{-5} M
The concentration of uncomplexed NTA=12.0 mM
The concentration of Ni(II)-NTA chelate=6.50 mM

iv) In solutions of a given initial concentration of BT and given concentrations of free NTA and Ni(II)-NTA chelates, the slope of the linear relation was a linear function of the reciprocal of the hydrogen ion concentration and given by the Eq. (4) (Fig. 4).

$$\text{slope} = k_a + k_b/[H^+] \quad (4)$$

The nickel(II) ion can form chelates of 1-to-1 as well as 1-to-2 composition and the concentration of the former is given by $[NiX]_t/(1+K_{NiX_2}\cdot[X]_f/(\alpha_H)_x)$. Thus, the above experimental results clearly suggest that the substitution reaction of BT and nickel(II)-NTA chelates has the following reaction mechanism.

$$\text{i}_a)\quad NiX^- + HD^{2-} \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} NiD^- + HD^{2-}$$

$$\text{rapid}\ \uparrow\downarrow$$

$$NiX_2^{4-}$$

$$\text{ii}_a)\quad HD^{2-} \overset{\text{rapid}}{\rightleftharpoons} H^+ + D^{3-}$$

$$NiX^- + D^{3-} \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} NiD^+ + D^{3+}$$

$$\text{rapid}\ \uparrow\downarrow$$

$$NiX_2^{4-}$$

(rate-determining step)

The following relation can be derived, as was proposed for the substitution reaction of BT and Co(II)-EDTA chelate.[1]

$$\text{slope} = (k_1^+ + k_2^+\cdot k_2^{0})/[H^+])\ \frac{[NiX]_t}{1+\dfrac{K_{NiX_2}\cdot[X]_f}{(\alpha_H)_x}} \quad (5)$$

From the linear relation between the slope $\times(1+K_{NiX_2}\cdot[X]_f/(\alpha_H)_x)/[NiX]_t$ and $1/[H^+]$ (Fig. 4), k_1^+ and k_2^+ were determined to be 5.8×10^1 $M^{-1}\,sec^{-1}$ and 3.27×10^4 $M^{-1}\,sec^{-1}$, respectively.

Similar results were also obtained in the experiments at 24.5°C and 30°C and given in Table 5 along with the results at 16°C. Linear relation was found between $\log k^+$ and $1/T$ for those two elementary reactions, which made it possible to calculate the heat and the entropy of activation. The results for k_2^+ are shown in Table 5. Values for the elementary reaction (i_a) are considered less accurate as compared with the other data and not given here.

Table 5. Rate constants, k_2^+, for BT reaction with Ni(II)-NTA at various temperatures, and heat of activation and entropy of activation for reaction (iia)

Temperature °C	Rate constant $M^{-1}\,sec^{-1}$	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.
16	3.27×10^4		
24.5	1.15×10^5	11.5	37.6
30	2.51×10^5		

During the course of the exchange reaction, BT is considered to hold its planar configuration. Therefore, less conformational freedom would be lost in the substitution reaction. On the basis of this fact, as far as the conformational freedom is concerned, the great gain in the conformational freedom in the leaving NTA or EDTA ion may contribute to the positive entropy of activation. This expectation was satisfied by the results listed in Table 5.

The Substitution Reaction of BT with Nickel(II)-EDTA Chelate. The substitution reaction of BT with Ni(II)-EDTA chelate was also studied in the presence of a large excess of free EDTA and its nickel(II) chelate ions over BT in the pH range 9.00—10.50 at 15°C. The reaction gave the linear relation between $\log(A_D/(A-A_{NiD}))$ and time, t, whose intercept was identical with $\log(\varepsilon_{BT}/(\varepsilon_{BT}-\varepsilon_{NiD}))$ (Fig. 5). An analogous relation among $[BT]_0$, $[BT]$ and $[BT]_e$ also holds for the present system, and this fact clearly indicates that the slope of the linear relation can exactly correspond to the apparent rate constant, k^+, of the pseudo first-order reaction (3).

In addition to the above fact, the following experimental facts were also found under the present experimental conditions (free EDTA ranged from

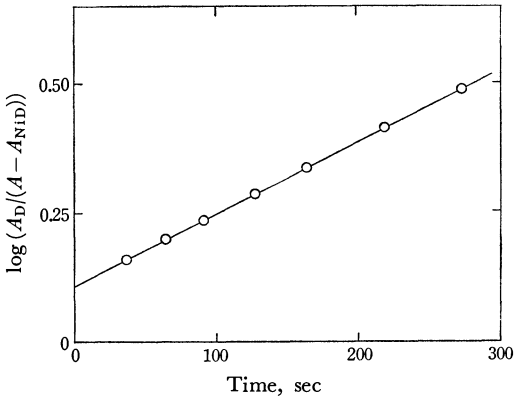

Fig. 5. The plot of $\log(A_D/(A-A_{NiD}))$ against t.
$\mu=0.30$, pH=10.25, $\lambda=630$ mμ

15	3.22×10^{-4}
25	3.18×10^{-4}

10 to 40 mM and Ni(II)-EDTA, from 8.0 mM to 25.0 mM).

i) The slope of the plot of $\log(A_D/(A-A_{NID}))$ against t was independent of the concentration of uncomplexed EDTA in solutions of a given pH and the given concentrations of BT, $[BT]_0$, and nickel(II)-EDTA chelate (Table 6).

ii) The slope of the plot of $\log(A_D/(A-A_{NID}))$ against t was independent of the initial concentration of BT in solutions of a given pH and given concentrations of free EDTA and its nickel(II) chelate (Table 7).

TABLE 7. DEPENDENCE OF THE SLOPE ON THE INITIAL CONCENTRATION OF BT

pH=10.0, μ=0.30
Concentration of uncomplexed EDTA=10.0 mM
Concentration of Ni(II)-EDTA=8.25_5 mM

Concentration of BT, 10^{-5} M	Slope, sec^{-1}
1.61	3.18×10^{-4}
2.25	3.20×10^{-4}
3.21	3.15×10^{-4}

iii) The slope of the above linear relation was proportional to the concentration of nickel(II)-EDTA chelate, [NiY], in solutions of a given pH and the given concentrations of BT, $[BT]_0$ and of free EDTA (Table 8).

TABLE 8. DEPENDENCE OF THE SLOPE ON THE CONCENTRATION OF Ni(II)-EDTA CHELATE

pH=10.25, μ=0.30
Concentration of uncomplexed EDTA=10.0 mM
Initial concentration of BT=2.25×10^{-5} M

Concentration of Ni(II)-EDTA, mM	Concentration ratio	Slope, sec^{-1}	Slope ratio
8.25_5	1.00	5.62×10^{-4}	1.00
16.51	2.00	1.12×10^{-3}	2.00
24.77	3.00	1.70×10^{-3}	3.03

iv) The slope for the linear relation was found to be a linear function of the reciprocal of the hydrogen ion concentration and given by Eq. (6) (Fig. 6).

$$\text{slope} = k_I + k_{II}/[H^+] \qquad (6)$$

where k_i is almost zero.

Since Ni(II)-EDTA chelate behaves in an identical manner with Co(II)-EDTA chelate, it can be concluded that the substitution reaction of BT with Ni(II)-EDTA chelate proceeds mainly through the reaction path (ii_b), and the percentage of the contribution of the reaction path (i_b) is practically zero.

$$i_b) \quad HD^{2-} + NiY^{2-} \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} NiD^- + HY^{3-}$$

$$ii_b) \quad HD^{2-} \overset{\text{rapid}}{\rightleftharpoons} H^+ + D^{3-}$$

$$D^{3-} + NiY^{2-} \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} NiD^- + Y^{4-}$$

(rate-determining step)

where NiY^{2-}, HY^{3-} and Y^{4-} mean Ni(II)-EDTA chelate, triply deprotonated EDTA anion and completely deprotonated EDTA anion, respectively.

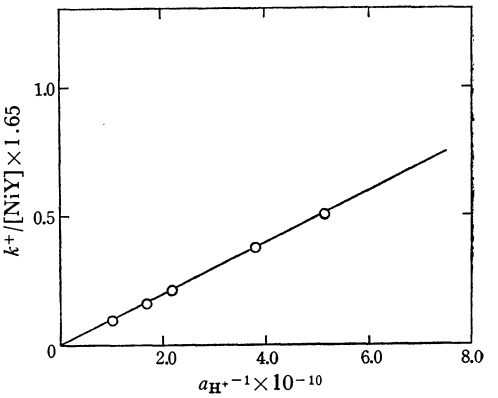

Fig. 6. Relation between $k^+/[NiY]$ and the concentration of hydrogen ion.
μ=0.30
Initial concentration of BT=2.25×10^{-5} M
The concentration of uncomplexed EDTA=10.0 mM
The concentration of Ni(II)-EDTA chelate=8.25_5 mM

On these assumptions, the following relation can be obtained.

$$k^+ = \frac{k_2^+ \cdot k_2^{9)}}{[H^+]} \cdot [NiY^{2-}] \qquad (7)$$

From the linear relationship between $k^+/[NiY]$ and $1/[H^+]$ (Fig. 6), k_2^+ value was determined to be 1.25 $M^{-1}\,sec^{-1}$.

The above reaction mechanism proposed for the substitution reactions of BT clearly involves the formation of mixed ligand intermediate complexes between BT and nickel(II) chelate of NTA or EDTA. By forming coordinate bonds with a nickel(II) ion prior to the complete dissociation to give X^{3-} or Y^{4-} from the nickel(II) ion, BT is considered to block the reformation of the nickel-(II)-NTA or nickel(II)-EDTA bonds and to help the dissociation of NTA or EDTA anion. Thus, rate constants of the substitution reactions of metal-(II)-NTA and EDTA chelates with BT are expected to be much greater than those of the dissociation of metal(II)-NTA and -EDTA chelates. A comparison of the rate constant of the dissociation reaction of cobalt(II)-EDTA chelate reported by Tanaka *et al.*[6] with that of the substitution reaction of BT

6) N. Tanaka, H. Osawa and M. Kamada, This Bulletin, **36**, 68 (1963).

with cobalt(II)-EDTA chelate[1] clearly confirms this explanation. Since the protonation of chelate is responsible to the rapid dissociation of metal chelate, the finding that k_2^+ value for the reaction of BT with nickel(II)-EDTA chelate is much greater than the rate constant for the dissociation of protonated nickel(II)-EDTA chelate, $NiHY^-$ [10],*1 is also an evidence for the above expectation. As in the case of the exchange reaction of EDTA with nickel(II)-polyamine,[8] the protonation of the incoming ligand (Strictly, in the substitution reaction of BT, incompletely dissociation of BT, HD^{2-}) tends to slow the reaction (k_2^+ is much greater than k_1^+).

Generally, for the reaction mechanism involving the formation of mixed ligand intermdiate complexes, the reaction rate is expected to be sensitive to the steric effect. The kinetic studies of the substitution reaction of BT with cobalt(II) and nickel(II) chelates of other chelons (EDTA-OH, GEDTA, CyDTA and DTPA) are now in progress. The importance of the steric effect on the rate of the substitution reaction of BT and the assignment of the reaction mechanism will be discussed in some detail in the subsequent paper.

*1 The rate constant was calculated from the reverse rate constant and appropriate stability constant to be 2.8×10^{-6} M^{-1} sec^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1339—1343 (1968)

Studies on Photo-polarography. I. Polarographic Behavior of Trioxalatoferrate(III) Ion under Ultraviolet Irradiation

Kazuo YAMASHITA and Hideo IMAI

Department of Chemistry, Faculty of General Education, Hiroshima University, Hiroshima

(Received December 2, 1967)

The polarographic behavior of trioxalatoferrate(III) ion under irradiation of ultraviolet light was studied. Trioxalatoferrate(III) was photo-chemically reduced in the bulk and the polarographic reduction current changed into the oxidation one, which showed a highly kinetic characteristic. The current-time curve during one drop growth of the dropping mercury electrode under irradiation was analyzed, and the rate constant of the photo-chemical reaction (k_ν) was evaluated. The apparent value given as $k_\nu' = I_0 \varepsilon k_\nu$ was 0.35 cm^{-1}, where I_0 being the intensity of the incident light and ε the extinction coefficient. The time dependence of the photopotential was elucidated on the basis of the Nernst equation. The possible photonometric determination of dissolved oxygen was suggested from the effect of dissolved oxygen on the half-life of the photo-chemical reaction.

The redox behavior of ferri- and ferro-oxalate complexes has been studied by von Stackelberg and von Freyhold,[1] Lingane,[2] and Randles and Somerton.[3] In their early work, the chemical constitution of ferrooxalate complex, which depends on the concentration of excess oxalate, was determined.

On the other hand, Rao and Aravamudan[4] have shown that iron(III) is photo-chemically reduced in the presence of excess citric acid, and that it can then be titrated with a standard solution of sodium vanadate. Thus, they proposed a photonometric determination of oxalic acid in the presence of excess ferric sulfate. Bricker and Schonberg[5] reported a new photonometric method for the separatory determination of vanadium and chromium by using the photo-chemical reduction of ferrioxalate.

Recently, Berg and his coworkers have investigated the effect of continuous or flash irradiation on the current-potential characteristics of ketyl radicals,[6] hydroquinones,[7,8] benzophenone,[6] and

other organic compounds.[6] As a result of their studies they have suggested four groups of photopolarographic reaction.

The present authors have investigated the photopolarographic behavior of trioxalatoferrate(III) ion in 0.5 M potassium oxalate with the continuous ultraviolet irradiation. The results and the apparent rate constant of the photo-chemical reaction evaluated are presented in this paper.

Experimental

Apparatus. The current-voltage curves were recorded with Yanagimoto Polarograph Model PA-102 and Shimadzu Polarograph Model RP-2.

The characteristics of the dropping mercury electrode (DME) were as follows: $m=1.30$ mg/sec, $t=4.5$ sec with the open circuit in an air-free 0.5 M potassium oxalate solution. A hammer with 4.0 sec interval was used to give the constant life-time of the DME.

For recording the current-time curve during one drop of the DME under a given voltage, Iwasaki Model 5155 cathode-ray oscilloscope with a plug-in amplifier Model SP-30H-A were used. The constant applied voltage was supplied from Yokogawa Model P-1 precision potentiometer through series 1 kΩ resistor, which is used to give the current signal.

The experimental arrangement is shown in Fig. 1. The light beam was emitted from Ushio Type UXL 500 DV xenon lamp (A in Fig. 1). The light was passed through a focusing lens, B, and was focused on a side of the DME. A quartz cell, C, (a conventional 10 mm quartz cell for the UV spectrophotometer) was used and the optical path of the incident light through the solution to the DME was about 3 mm. The geometry was kept constant throughout the measurements.

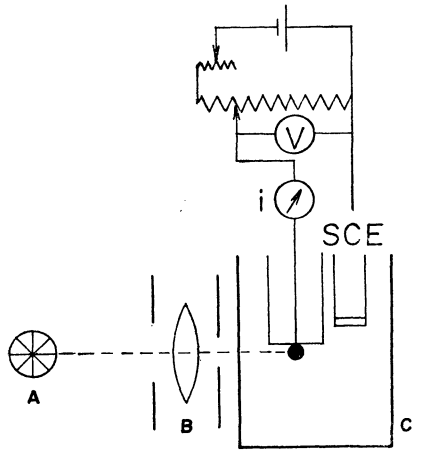

Fig. 1. The irradiation system.

The variation of the room temperature was about ±2°C. The temperature rise by the continuous irradiation is shown in Fig. 2. It is concluded that the temperature rise of the solution by the continuous irradiation during 5 min is as small as 1.8°C.

Reagents. The trioxalatoferrate(III) solution was prepared by dissolving metallic iron in dilute sulfuric acid, evaporating the excess acid, and then diluting to be 1.0×10^{-2} M in its concentration (pH=9.5) with aqueous 0.5 M potassium oxalate solution. Purified nitrogen was used to remove dissolved oxygen in the solutions.

All other chemicals were of analytical reagent grade, and they were purified by the conventional methods.

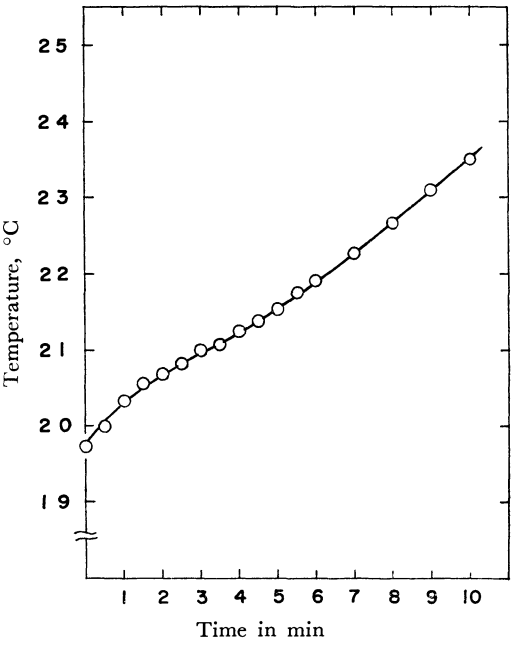

Fig. 2. Variation of temperature with the irradiation time in 0.5 M potassium oxalate solution.

Results and Discussion

D. C. Polarography. Trioxalatoferrate(III) developed a well-defined polarographic reduction wave, of which the half-wave potential was −0.26

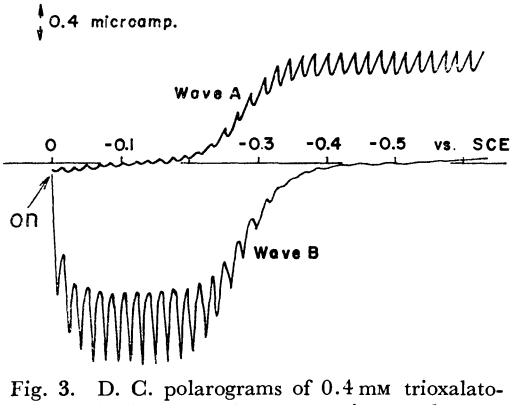

Fig. 3. D. C. polarograms of 0.4 mM trioxalatoferrate(III) ion in 0.5 M potassium oxalate solution.
Wave A: the reduction wave of trioxalatoferrate(III).
Wave B: the anodic wave appeared by the irradiation.

V *vs.* SCE (Wave A in Fig. 3). During the ultraviolet irradiation, the cathodic wave disappeared rapidly and a new anodic wave (Wave B in Fig. 3) appeared at almost the same potential as the cathodic wave. It is noteworthy that the anodic limiting current was about 1.6 times greater than the cathodic limiting current.

The dependence of the photo-polarographic limiting current at −0.15 V (the potential to give the limiting anodic current) on the height of mercury reservoir was examined. The result is shown in Fig. 4. It is seen in Fig. 4 that the photo-polarographic limiting current is actually unchanged by the mercury head, while the cathodic current without irradiation shows a trend to increase with increase of the mercury head.

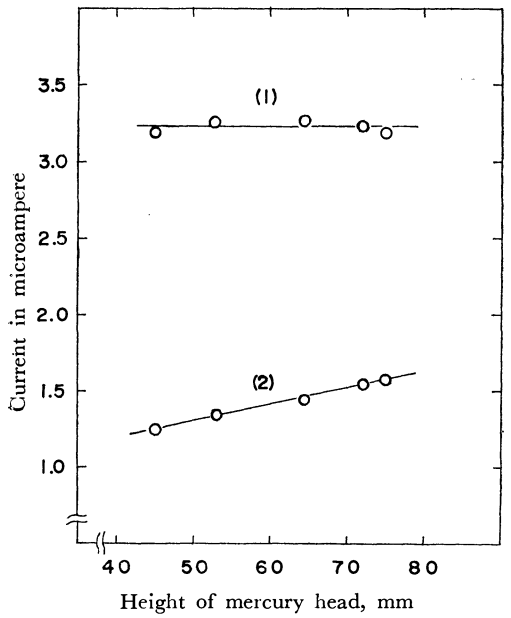

Fig. 4. Dependence of limiting current of (1) wave B and (2) wave A on the height of mercury head.

Figure 5 shows the plot of log *i versus* log *t* during one drop growth of the DME at −0.15 V after the continuous irradiation for 200 sec. From the inclination of the plot it was found that the photo-polarographic current varied with time to the power of 0.59. This result coupled with the above mentioned result in relation to the effect of the mercury head suggests the kinetically controlled feature of the photo-polarographic current. Thus, the following scheme of the parallel reactions is assumed at −0.15 V under continuous irradiation.

$$\text{Electrode Reaction:} \quad R - e = O \qquad (1')$$

$$\text{Photo-chemical Reaction:} \quad O + h\nu = R \qquad (2')$$

The reaction scheme shown in Eqs. (1') and (2') involves the regeneration of the reductant at the vicinity of the electrode surface by the photo-chemical reaction. Thus, the flux of the reductant toward the electrode surface is increased by the ultraviolet irradiation. This seems to elucidate the above-mentioned fact that the anodic limiting current under irradiation is about 1.6 times greater than the cathodic limiting current, which is observed without irradiation.

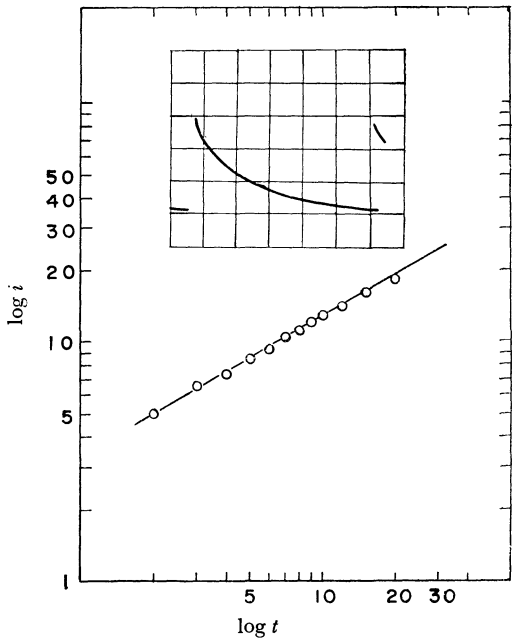

Fig. 5. log *i* - log *t* plots for the curve shown above, which was recorded during one drop growth of the DME after irradiation for 200 sec at −0.15 V.

Polarographic Current-Time Curve during One Drop Growth of DME. The parallel reactions occurring at −0.5 V and in the bulk are expressed as Eqs. (1) and (2), *i. e.*,

$$Fe(ox)_3^{3-} + e^- \rightleftarrows Fe(ox)_3^{4-} \qquad (1)$$

$$Fe(ox)_3^{3-} + \tfrac{1}{2}C_2O_4^{2-} + h\nu \rightleftarrows Fe(ox)_3^{4-} + CO_2 \qquad (2)$$

The variation of the concentration of the trioxalatoferrate(III) ion by the reaction given in Eqs. (1) and (2) is expressed by the following differential equation, *i. e.*,

$$\frac{\partial C}{\partial t} = D\left(\frac{\partial^2 C}{\partial x^2}\right) + \left(\frac{2x}{3t}\right)\left(\frac{\partial C}{\partial x}\right) - k_\nu\left(\frac{I_0}{l}\right)\left(1 - e^{-\varepsilon lC}\right) \qquad (3)$$

In the right hand side of Eq. (3) the first term represents Fick's 2nd. law, the second term represents the convection due to the growth of the mercury drop, and the third term represents the effect of the coupled photo-chemical reaction, where the absorption of the incident light is obeyed by Beer's law.

The magnitude of the photo-kinetic current for Eq. (3) can then be evaluated for the initial and boundary conditions given as follows:

$$\left.\begin{array}{lll} C=C_i^* & \text{for } x\geqq 0, & t=0 \\ C=0 & \text{for } x=0, & t>0 \\ C=C_i^* e^{-k_\nu' t} & \text{for } x\to\infty, & t\geqq 0 \\ \text{with } k_\nu'=k_\nu \varepsilon I_0 & & \end{array}\right\} \quad (4)$$

where C_i^* is the initial bulk concentration of the trioxalatoferrate(III) ion, and t the reaction time from the irradiation.

Reinert derived an explicit equation for this boundary value problem,[9] and Berg and Schwiess applied the Reinert's equation to a similar problem.[7,8] The explicit equation for the photopolarographic current (i_{rd}) during the growth of one mercury drop is then expressed as,

$$i_{rd} = KC_i^* e^{-k_\nu'(t+t'-u\tau)\bar{\alpha}} \quad (5)$$

where t is the reaction time from the irradiation, t' the time difference between the start of the drop growth of the DME and the start of the reaction, τ the life-time of the DME, $u=0, 1, 2, \cdots$ for the first, second, third, — drop, $\bar{\alpha}$ the average exponent for i_d-t curve, K the Ilkovic constant, I_0 the intensity of the incident light, ε the extinction coefficient, and l the length of the layer.

In Eq. (5) the plot of $\log(i_{rd}/(t+t'-u\tau)^{\bar{\alpha}})$ *versus* t yields a straight line and the value of k_ν' can be computed from the inclination. On the other hand, Eq. (6) can be derived from Koutecky's theory,[10] *i. e.*,

$$i_{rd}/i_d = F(y_t) \quad \text{with } y_t = k_\nu \varepsilon I_0 t = k_\nu' t \quad (6)$$

where $F(y_t)$ is an exponential function of y_t.[9] From Eq. (6) the plot of $\log(i_{rd}/i_d)$ *versus* t also yields a straight line, of which the inclination gives the value of k_ν'. These two plots are shown in Fig. 6, and the value of k_ν' is computed to be 0.35 cm^{-1} from the slopes of two plots, the slopes being agreed well with each other as is seen in Fig. 6. This value of k_ν' is the apparent rate constant of the photo-chemical reaction, and it involves the terms, the intensity of the incident light (I_0), the extinction coefficient (ε), and the net rate constant of the photo-chemical reaction (k_ν). Among these terms the absolute intensity of the incident light was difficult to measure at this stage, so that only the total dosage of light was determined under the same geometry. The experiment was carried out for 0.6 mM trioxalatoferrate(III) solution by irradiation during 150—200 sec, followed by stirring of the solution and polarographic determination of the concentration of trioxalatoferrate(III) remaining unreduced in the solution. The total dosage evaluated was 1.8×10^{15} molecules/sec. Only this rather relative datum is available at this stage. Since the photo-chemical reaction proceeds in the bulk of the solution, but only the reaction proceeded in the reaction zone at the vicinity of the electrode surface pertains to the electrode reaction, it seems to be very complicated to confer an absolute physical significance on the apparent value of k_ν', and further investigation is required before the physical meaning of k_ν' will be embodied.

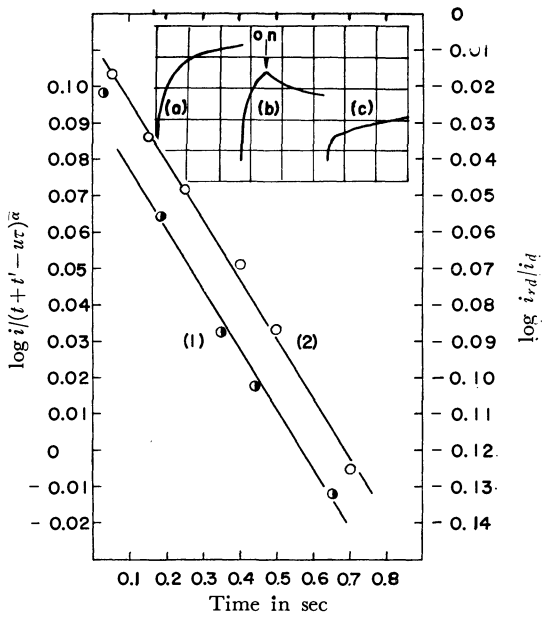

Fig. 6. log-plots plotted from the current-time curve (b) which shows the current during the drop growth of the DME. In curve (b) the continuous irradiation was started on the way of the second drop and the time of irradiation is denoted by ↓.

Photopotential. A typical photopotential-time curve for ferri-oxalate/ferro-oxalate system is shown in Fig. 7. It is evident that the potential rapidly shifts toward more negative potentials during irradiation and finally it attains to a plateau. When the irradiation was extinguished, the electrode potential slowly returned to the value near the initial potential. Similar trend has been observed for a variety of organic compounds,[11-13] and this trend can be attributed to the mixing of the irradiated part and unirradiated part of the solutions. The shift of the electrode potential by irradiation can simply by elucidated by the Nernst equation, *i. e.*,

$$E = E^\circ + \left(\frac{RT}{nF}\right)\ln\frac{[Fe(ox)_3^{3-}]}{[Fe(ox)_3^{4-}]} \quad (7)$$

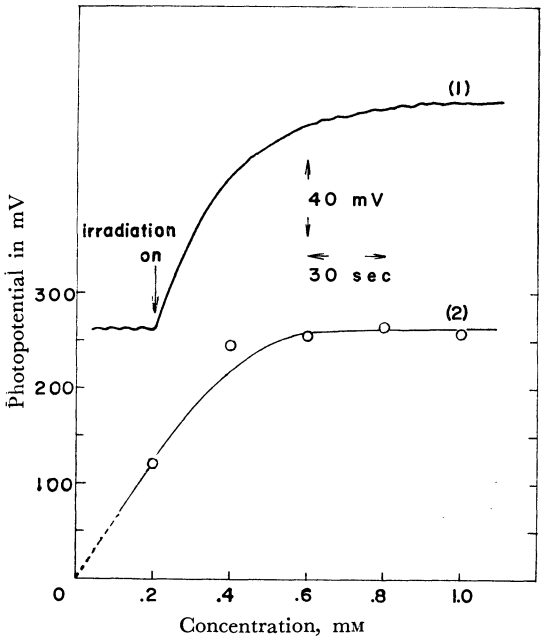

Fig. 7. (1) Photopotential-time curve of 0.2 mM trioxalatoferrate(III) in 0.5 M potassium oxalate solution.
(2) Dependence of photopotential on the concentration of trioxalatoferrate(III).

During the course of irradiation $Fe(ox)_3^{3-}$ is gradually converted into $Fe(ox)_3^{4-}$, and then the ratio of $Fe(ox)_3^{3-}/Fe(ox)_3^{4-}$ becomes smaller as a function of time. Such a behavior will tend to produce a negative-going potential according to Eq. (7). After the sufficient irradiation a steady state of the ferro-oxalate concentration is reached at the electrode surface, and a plateau is observed as is seen in curve (1) of Fig. 7. The photo-potential at the concentrations higher than 0.6 mM trioxalatoferrate (III) was evaluated as great as 258 mV.

Effect of Oxygen. Figure 8 shows the dependence of half-life time, which means the time required to attain the half-wave height of the anodic wave since the time of irradiation, on the concentration of dissolved oxygen. The measurement was carried out at the constant applied voltage of +0.05 V *vs.* SCE, where trioxalatoferrate(III) and oxygen are not electrolytically reduced.

When oxygen is present in the solution containing trioxalatoferrate(III), the decay time of trioxalatoferrate(III) by irradiation is elongated by the regeneration of the oxidant due to the chemical reaction of oxygen with the reductant formed during the course of irradiation. The reaction scheme will be expressed as follows;

$$\begin{aligned} &Fe(ox)_3^{3-} + (1/2)C_2O_4^{2-} + h\nu \rightleftarrows Fe(ox)_3^{4-} + CO_2 \\ &Fe(ox)_3^{4-} + O_2 \rightleftarrows Fe(ox)_3^{3-} + O_2^- \\ &Fe(ox)_3^{4-} \rightleftarrows Fe(ox)_3^{3-} + e^- \\ &\cdots\cdots\cdots\cdots\cdots\cdots \end{aligned} \quad (8)$$

In Fig. 8 an induction period is seen at the very low concentration of dissolved oxygen. This effect can often be seen in the usual redox reactions. Then, the variation of the half-life is apparently linear with increase of the oxygen concentrations covered in this experiment. This effect can be used for the photonometrical determination of dissolved oxygen.[14]

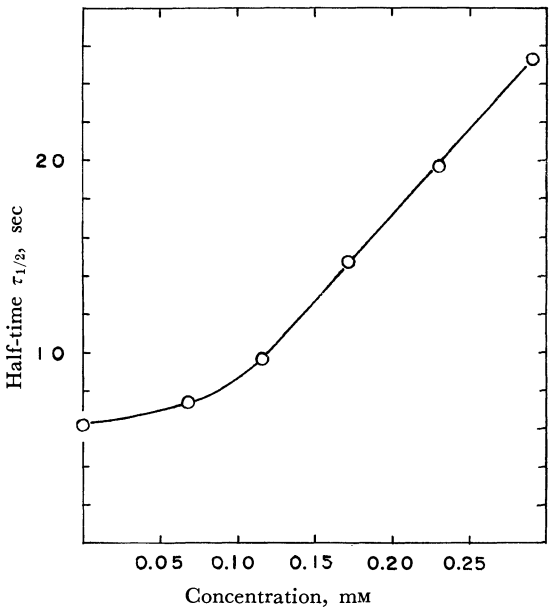

Fig. 8. Dependence of half-life of the photochemical reaction on the concentration of dissolved oxygen in 0.5 M potassium oxalate solution containing 0.6 mM trioxalatoferrate(III) ion.

The authors wish to express their hearty gratitude to Professor Mutsuaki Shinagawa of Osaka University and Professor Niro Matsuura of University of Tokyo for their valuable suggestions, especially for their discussion on this investigation in relation to γ-ray dosimetry. The financial support by the Scientific Research Fund from the Ministry of Education is gladly acknowledged.

Synthesis of Chelating Agents. VI.*1 Chelating Behavior of 1,2,3-Triaminopropanehexaacetic Acid with Divalent Metal Ions*2

Yoshiki MORIGUCHI, Mitsumasa MIYAZAKI*3 and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received December 6, 1967)

The chelate stability constants of 1,2,3-triaminopropanehexaacetic acid (TAPHA) with alkaline earth metals, cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) were determined at 25°C and an ionic strength of 0.1 (KNO_3). The stability constants of monoprotonated mono nuclear-, dinuclear- and mixed metal dinuclear chelates as well as normal mononuclear chelate were determined. The structure and chelating behavior of TAPHA in an aqueous solution were discussed by refering to those of the other complexanes of related structure. The crystalline metal chelates of TAPHA were also prepared and their structures were proposed on basis of the results of elementary analyses and infrared spectra.

1,2,3-Triaminopropane-*N,N,N',N',N'',N''*-hexaacetic acid (TAPHA) is a nonadentate ligand, having three nitrilodiacetic acid groups pending from each carbon atom of propane. As easily understood from the structure, these three nitrilodiacetate groups can not coordinate to a metal ion simultaneously. If the neighboring two nitrilodiacetate groups coordinate to a metal ion, leaving the remaining nitrilodiacetate group uncoordianted, then the coordinating structure of TAPHA resembles EDTA chelate. If the terminal two nitrilodiacetate groups coordinate to a metal ion, leaving the central nitrilodiacetate group uncoordinated, then the structure of TAPHA chelate resembles TMDTA (trimethylenediamine-*N,N,N',N'*-tetraacetic acid) chelate. It is of great interest to investigate the structure of TAPHA metal chelate from this standpoint of view.

Following to the previous paper,[1] in which the acid dissociation scheme of TAPHA was investigated, this paper is to report on the chelating behavior of TAPHA with divalent cations, such as magnesium(II), calcium(II), strontium(II), barium(II), cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) in an aqueous solution as well as in a solid state.

The stability constants of normal mononuclear chelates, monoprotonated mononuclear chelates, diprotonated mononucelar chelates, dinuclear chelates and mixed dinuclear chelates have been determined. By comparing their values with those of other complexanes of related structure, a possible structure of TAPHA chelates in aqueous solution is proposed.

Experimental

The pH measurement was carried out at 25±0.1°C. in aqueous solution of ionic strength with $\mu=0.1$ by KNO_3. The same apparatus as described in our previous paper was employed.[2] The procedure for the determination of chelate stability constants with

a) Metal content was determined by EDTA titration after wet digestion of the metal chelate with nitric acid and hydrogen peroxide. Y. Tsuchitani, Y. Tomita and K. Ueno, *Talanta*, **9**, 1023 (1962).

b) Sodium was determined by precipitating as zinc sodium uranyl acetate from acid digested solution, followed by EDTA titration of zinc in the precipitate.

alkaline earth metals involved the direct pH titration of 200 m*l* of 5×10^{-4} M ligand solution in 1 : 1 and 10—24 : 1 molar ratios of metal nitrate to ligand. The typical pH titration curves are shown in Figs. 1 and 2.

As for transition metal ions, the chelate stability constants were determined by the competitive reaction using triaminotriethylamine (tren)*4 and calcium ion as an auxiliary ligand and a metal ion respectively.[3] The measurements were carried out on the five solutions containing equimolar amounts of TAPHA (4×10^{-4} M), tren and metal ion, ten fold excess of calcium ion to TAPHA and different amounts of 1×10^{-1} N potassium hydroxide solution. The pH values of each soluiotn were measured until constant readings were obtained. They were usually attained within a week.

The acid dissociation constants of monoprotonated mononuclear chelates and the stability constants of dinuclear chelates were determined by the direct pH titration method as described above in the presence of equimolar amounts of TAPHA and metal ion and in the presence of 10—24 fold excess of metal ion to TAPHA respectively. The pH meter used and the method of calibration were those reported previously.[2]

Preparation of Crystalline Metal Chelates. TAPHA chelates of selected divalent metal ions were prepared in crystalline form by the procedures described below. Of the possible compositions of the chelates from the nonadentate hexa-basic ligand (H_6L) and divalent cations (M), three types of the chelates, $Na_4ML\cdot xH_2O$, $H_4ML\cdot xH_2O$ and $H_2M_2L\cdot xH_2O$, were isolated as well difined crystalline materials. The compositions of the chelates were determined by elementary analyses (C, H and N) as well as metal determinations. Hydrated water was determined from the weight loss after drying the sample in vacuum over phosphorus pentoxide at 100°C until it became constant weight. The results are summarized in Table 1.

$Na_4M^{II}L\cdot xH_2O$. Two millimoles (911 mg) of TAPHA ($H_6L\cdot H_2O$) and equimolar amount of metal carbonate in 80 m*l* of hot water was heated on a water bath. After complete dissolution, twice equivalent amounts of sodium carbonate (424 mg) were added, and the total volume of the solution was concentrated to 15 m*l*, to which 200—250 m*l* of ethanol was added to precipitate the sirupy product. After washing the precipitate by decantation with ethanol for several times, the crude chelate was dissolved into a small amount of water, and reprecipitated by adding a large amount of ethanol. The chelate was dried in vacuum over silica gel overnight at room temperature.

$H_2M_2^{II}L\cdot xH_2O$. An equimolar mixture of TAPHA and metal carbonate in hot water was heated on a water bath in a same scale as described above, and the solution was concentrated to 10—15 m*l*. To this solution, ethanol was added until the solution became slightly cloudy, and the mixture was kept in a refrigerator to precipitate the chelate. The crude chelate was recrystallized several times from 70—80% aqueous ethanol. The chelate was dried by the same fashion as described above.

$H_2M_2^{II}L\cdot xH_2O$. The chelate was prepared by the similar procedure as in the case of 1 : 1 hydrogen chelates, but twice molar equivalent of metal carbonate was used.

Besides the chelates listed in Table 1, which were obtained as well defined crystalline product, the chelates of manganese (II), cadmium(II) and lead(II) were prepared. However, manganese gave a sirupy chelate and cadmium and lead gave no products with consistent analytical results, so that the further purifications of these chelates were given up.

Infrared Spectra. The measurements were made with a Nippon Bunko Model DS 301 double-beam infrared spectrophotometer equipped with sodium chloride optics. The spectra were studied in Nujol mull.

Calculation of Chelate Stability Constants

Equilibrium Constants Involving Alkaline Earth Metal Ions. Definitions of equilibrium constants discussed in this paper, are summarized in Table 2.

TABLE 2. DEFINITIONS OF EQUILIBRIUM CONSTANTS

1) Acid dissociation constants of TAPHA

$K_1=[H_5L^{1-}][H^+]/[H_6L]$

$K_2=[H_4L^{2-}][H^+]/[H_5L^{1-}]$

$K_3=[H_3L^{3-}][H^+]/[H_4L^{2-}]$

$K_4=[H_2L^{4-}][H^+]/[H_3L^{3-}]$

$K_5=[HL^{5-}][H^+]/[H_2L^{4-}]$

$K_6=[L^{6-}][H^+]/[HL^{5-}]$

2) Composite acid dissociation constants[4,5]

$K_4'=[H^+]([H_2L^{4-}]+[MH_2L^{2-}])/[H_3L^{3-}]$

$K_5'=[H^+]([HL^{5-}]+[MHL^{3-}])/([H_2L^{4-}]+[MH_2L^{2-}])$

$K_6'=[H^+]([L^{6-}]+[ML^{4-}]+[M_2L^{2-}])/([HL^{5-}]+[MHL^{3-}])$

3) Acid dissociation constants of triaminotriethylamine trihydrochloride (H_3 tren)

${}^tK_1=[H_2\ tren^{2+}][H^+]/[H_3\ tren^{3+}]$

${}^tK_2=[H\ tren^{1+}][H^+]/[H_2\ tren^{2+}]$

${}^tK_3=[tren][H^+]/[H\ tren^{1+}]$

4) Acid dissociation constant of monoprotonated mononuclear chelate

$K^H_{MHL}=[H^+][ML^{4-}]/[MHL^{3-}]$

5) Chelate stability constants of TAPHA

$K_{MH_2L}=[MH_2L^{2-}]/[M^{2+}][H_2L^{4-}]$

$K_{MHL}=[MHL^{3-}]/[M^{2+}][HL^{5-}]$

$K_{ML}=[ML^{4-}]/[M^{2+}][L^{6-}]$

$K^M_{M_2L}=[M_2L^{2-}]/[M^{2+}][ML^{4-}]$

$K^{M'}_{MM'L}=[MM'L^{2-}]/[M'^{2+}][ML^{4-}]$

6) Chelate stability constant of tren

$K_{Mtren}=[Mtren^{2+}]/[M^{2+}][tren]$

In the following discussion, however, the charges on the ions, such as those in Eqs. (5)—(12) and (14)—(19), were omitted for the purpose of simplicity. The procedure of Schwarzenbach modified by Grims[4]

*4 Triaminotriethylamine trihydrochloride was synthesized by Mr. Y. Toyota in our laboratory.

3) G. Schwarzenbach and E. Freitag, *Helv. Chim. Acta*, **34**, 1492, 1503 (1951).

4) J. H. Grimes, A. J. Huggard and S. P. Wilford, *J. Inorg. Nucl. Chem.*, **25**, 1225 (1963).

was followed to determine the chelate stability constants of alkaline earth metals. The outline of this procedure is as follows. By an analogus treatment to the determination of acid dissociation constants of the free ligand,[1] the composite acid dissociation constants, K'_4, K'_5, K'_6 are obtained by the direct pH titration method in the presence of excess metal ions to ligand.[5] Then, the stability constants of mono- and diprotonated mononuclear chelates, K_{MH_2L}, K_{MHL}, can be calculated from the composite and the simple acid dissociation constants with an aid of Eqs. (1) and (2).

The acid dissociation constants of monoprotonated mononuclear chelates, K^{H}_{MHL}, can be determined by the direct pH titration method in the presence of equimolar amounts of metal and ligand, in a similar manner to the determination of simple acid dissociation constants.

Now, the stability constants of mononuclear chelates, K_{ML} and that of dinuclear chelates, $K^{M}_{M_2L}$ can be obtained from Eqs. (3) and (4) respectively, as the equilibrium constants on the right hand side are known, and [M] can be approximated as M_t, a total concentration of the metal ion, if a large excess of metal ions to ligand is present.

$$K_{MH_2L} = \frac{K'_4}{K_4[M]} - \frac{1}{[M]} \tag{1}$$

$$K_{MHL} = \frac{K'_4K'_5}{K_4K_5[M]} - \frac{1}{[M]} \tag{2}$$

$$K_{ML} = \frac{K^{H}_{MHL}K_{MHL}}{K_6} \tag{3}$$

$$K^{M}_{M_2L} = \frac{1}{K_{ML}[M]}\left(\frac{K_4'K'_5K'_6}{[M]K_4K_5K_6} - \frac{1}{[M]} - K_{ML}\right) \tag{4}$$

Equilibrium Constants Involving Transition Metal Ions. The stability constants of mononuclear chelates of nickel(II), cobalt(II), copper(II), zinc(II) and cadmium(II) were determined by extending Schwarzenbach's procedure[3] using the competitive reaction with an auxiliary ligand (tren) and a metal ion (calcium). In the case of thorium(IV) ion, the stability constant K_{ML} could not be obtained because of the precipitate formation. The final equations for the transition metal chelates are as follows:

$$M_t = c = [ML]\cdot(1 + [H]/K^{H}_{MHL}) + [Mtren] \tag{5}$$

$$tren_t = c = [Mtren] + \beta[H_3tren] \tag{6}$$

$$L_t = c = [ML]\cdot(1 + [H]/K^{H}_{MHL}) + [CaL]\cdot(1 + [H]/K^{H}_{CaHL}) \tag{7}$$

$$9c - [KOH] = [H] - [OH] + [ML][H]/K^{H}_{MHL} + [CaL][H]/K^{H}_{CaHL} + \gamma[H_3tren] \tag{8}$$

$$\beta = 1 + \frac{{}^tK_1}{[H]} + \frac{{}^tK_1{}^tK_2}{[H]^2} + \frac{{}^tK_1{}^tK_2{}^tK_3}{[H]^3} \tag{9}$$

$$\gamma = 3 + \frac{2{}^tK_1}{[H]} + \frac{{}^tK_1{}^tK_2}{[H]^2} \tag{10}$$

$$K_{ML} = \frac{{}^tK_1{}^tK_2{}^tK_3K_{CaL}K_{Mtren}}{K_C} \tag{11}$$

$$K_C = \frac{[H]^3[CaL][Mtren]}{[ML][H_3tren][Ca]} \tag{12}$$

The acid dissociation constants, K^{H}_{MHL}, of monoprotonated mononuclear chelates of transition metals and thorium(IV) were determined according to Anderegg[6] by the direct pH titration in the presence of equimolar amounts of metal and ligand. Then, the stability constants of monoprotonated mononuclear chelates, K_{MHL}, can be calculated from the known values, K_6, K^{H}_{MHL} and K_{ML}*5.

Mixed Metal Dinuclear Chelates.[6] The formation of dinuclear chelate could be considered by the two step process. The first step is the formation of 1 : 1 mononuclear chelate. The second step is the formation of 1 : 2 dinuclear chelate from mononuclear chelate and the second metal ion. When the first and the second metal ions are same, a homo-dinuclear chelate is formed. When these two metal ions are different, and the stability constant with the first metal ion (K_{ML}) is considerablly larger than that with the second metal ($K_{M'L}$), the stability constants of the mixed metal dinuclear chelates ($K^{M'}_{MM'L}$) could be obtained from Eq. (14) by the direct pH titration in the presence of an equimolar amount of the first metal ion (M) to the ligand, and in the presence of large excess of the second metal ion (M') to the first metal ion.

$$MHL^{3-} + M'^{2+} \overset{K_m}{\rightleftharpoons} MM'L^{2-} + H^+ \tag{13}$$

$$K^{M'}_{MM'L} = \frac{[H][MM'L]}{[M'][MHL]}\cdot\frac{[MHL]}{[H][ML]} = \frac{K_m}{K^{H}_{MHL}} \tag{14}$$

$$[MHL] = p\cdot L_t \tag{15}$$

$$[MM'L] = L_t(1 - \alpha p) \tag{16}$$

$$[M'] = M_t' - L_t(2 - \alpha p) \tag{17}$$

$$\alpha = 1 + K^{H}_{MHL}/[H] \tag{18}$$

$$p = 6 - \frac{[KOH] - [H] - [OH]}{L_t} \tag{19}$$

In the treatment of the mixed metal dinuclear chelates, it is assumed that a mononuclear chelate with the first metal ion is formed in the first step ($a \leqq 5$), then it reacts with a second metal ion to form a mixed metal dinuclear chelate in the second step ($5 < a \leqq 6$).

In the case of alkaline earth meatl ions, the stability constants of homo-dinuclear chelates were obtained as described previously. However, in the cases where the second metal ions are transition metals, the stability constants of homo-dinuclear or mixed metal dinuclear chelates could not be obtained, because the formation of precipitate was observed even at the earlier stage of pH titration in the presence of excess amount of transition metal ion to the ligand.

However, the pH titration was carried out successfully when the transition metals and calcium were chosen as the first and the second metal ions respectively, and the stability constants for the transition metal-calcium TAPHA chelates (K^{Ca}_{MCaL}) were obtained from Eq. (14).

The various equilibrium constants thus obtained are summarized in Tables 3—8.

Results and Discussion

Crystalline Chelates. The infrared spectra of alkaline earth metal chelates and some transition metal chelates are shown in Fig. 3. These spectra were interpreted with an aid of our knowledge on nitrilotriacetate chelates.[7] As for sodium salt of alkaline earth metal chelates ($Na_4ML \cdot xH_2O$), the absorption peak of -COOM and that of $\overset{+}{\rangle}NHCH_2COO^-$ appear in a similar region and become a single peak at around 1600 cm^{-1}. This peak shifts to lower frequency with the increase of ionic radius of metal ion. On the other hand, in the case of protonated chelate ($MH_4L \cdot xH_2O$), the two absorption peaks appear at around 1600 cm^{-1} and 1720 cm^{-1} respectively, and they are assigned to -COOM and -COOH groups respectively.[7] Therefore, if the ratio of -COOM to -COOH is estimated from the relative intensity of the two peaks, it is possible to presume the structure of $MH_4L \cdot xH_2O$. In order to make this estimation, the peak intensities were measured by the base-line method[8] and it is assumed that the values of molar extinction coefficient on EDTA chelates in aqueous solution can be adopted to TAPHA chelates, that is the molar extinction coefficient of -COOM is nearly equal to that of $-COO^-$, and the values for -COOH and -COOM are 240 and 705 $mol \cdot cm^{-1}$ respectively.[9] The latter assumption seems to be rather critical, since the absorption data in solution are employed in the interpretation of solid state spectra. However, the result may be still useful for the meaningful discussion of the structure, because the ratio of the band intensities of -COOM to -COOH will not differ appreciablly between the states in solid and in solution. The result shows that the ratio of -COOM to -COOH is approximately 1 : 1 in the case of protonated chelate ($MH_4L \cdot xH_2O$), and the structure of these chelates is presumed as shown in Fig. 4A or 4B.

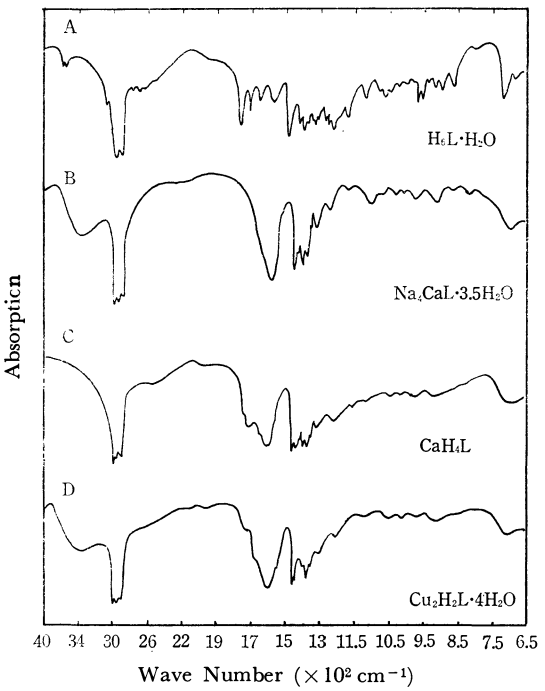

Fig. 3. Infrared spectra of crystalline TAPHA chelates in Nujol mull.

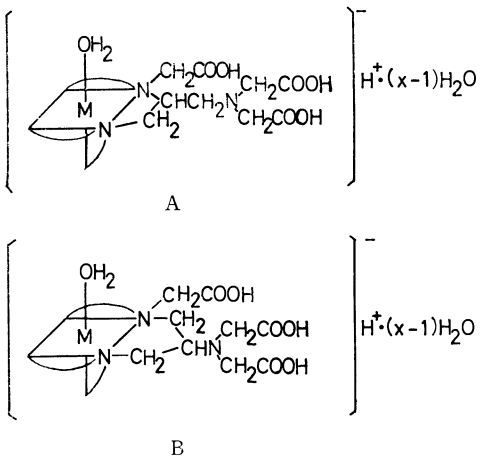

Fig. 4. Proposed structure of $MH_4L \cdot xH_2O$.

As for copper(II) dinuclear chelate ($Cu_2H_2L \cdot 4H_2O$), a peak at 1578 cm^{-1} and a shoulder at 1728 cm^{-1} are assigned to -COOM and -COOH groups respectively. The presence of two protons which is supported by the elementary analysis, suggests the existence of two uncoordinated carboxylic acid groups. Although the structures proposed in Fig. 5A or 5B may satisfy such requirment,

DTPA: diethylenetriaminepentaacetic acid, TTHA: triethylenetetraminehexaacetic acid

the relative absorption intensity of –COOH group against that of –COOM group is too weak to support the proposed structures, and more experimental results are needed to conclude the structure of this chelate.

Solution Equilibria. Mononuclear Chelates (ML). As shown in Table 3, the chelate stability order of TAPHA for alkaline earth and transition metal ions is same as that of other complexanes. In the case of alkaline earth metal chelates, it is noticed that the stability constants of TAPHA chelates are very close to those of EDTA chelates, but not to those of TMDTA chelates. This results may suggest that the ligand of mononuclear chelate (ML) will take a EDTA type coordination, but not a TMDTA type coordination, as far as the effect of uncoordinated nitrilodiacetate group on the chelate stability is assumed to be same order in either case.

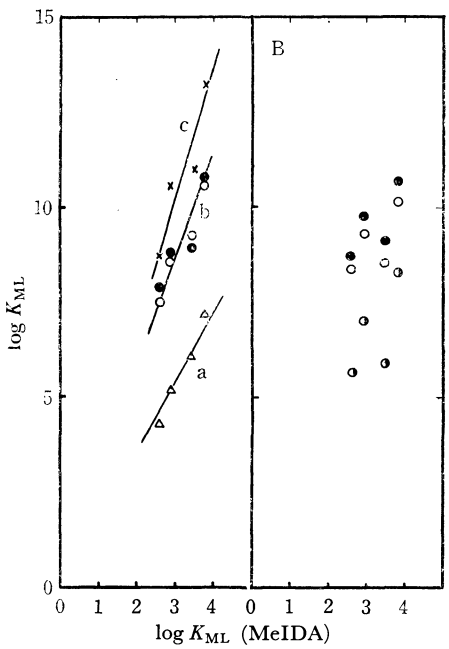

Fig. 6. Relationship between stability constant of alkaline earth metals - methyliminodiacetic acid chelates and stability constant of its related complexane chelates.
A ×: CyDTA, ○: EDTA, ●: TAPHA, △: TMDTA
B ●: DTPA, ⊙: TTHA, ◑: HEDTA

Now, if one looks into the structure of complexanes under consideration, the coordinating groups of these ligands can be divided into two classes, *i. e.*, *N*-methyliminodiacetic acid (MeIDA) and *N,N*-dimethylglycine. Figure 6 shows a plot of the chelate stability constants of various complexanes for alkaline earth metals versus those of *N*-methyliminodiacetic acid. The plots for TMDTA, EDTA, CyDTA and TAPHA give straight lines which pass through the origin (Fig. 6A), but those for HEDTA, DTPA and TTHA do not give straight lines (Fig. 6B). The complexanes of the first family have only *N*-methyliminodiacetic acid groups as coordinating group, but those of the second family have both *N*-methyliminodiacetic acid groups and *N,N*-dimethylglycine groups within a ligand molecule. The fact that the plots for TAPHA fit on the same line as those of EDTA, is indicative that the chelating behavior of TAPHA for alkaline earth metal ions is very similar to that of EDTA, since the slope of straight lines in Fig. 6A seems to be related with the nature and size of the chelate ring.

In the case of transition metal chelates, the stabilities of EDTA and TMDTA chelates are so close to those of TAPHA chelates that it is not so easy to discuss the coordinating structure of the chelates by comparing stability data of mononuclear chelate alone. In spite of the general concept that the chelate stability increases with increasing number of coordinating groups in the ligand, a nonadentate TAPHA chelate is less stable than an octadentate DTPA chelate. The result may be explained by the number of nitrogen

atoms which are involved in the coordination. In the case of DTPA chelate, all three nitrogens can coordinate to a metal ion, whereas, in the case of TAPHA, only two of three nitrogens can coordinate to a metal ion. Since the nitrogen atom has a larger affinity with transition metals than with alkaline earth metals, the number of coordinating nitrogens mainly affects the stability of transition metal chelates. Therefore, the values of the stability constant among EDTA, TMDTA and TAPHA chelates resemble each other.

An availability of only two nitrilodiacetate groups in the chelate formation of TAPHA, may also be proved by the following discussion. The dependence of the chelate stability of complexanes on the number of coordinating sites of the ligands can be clearly shown in Fig. 7, in which $\log K_{ML}$ values for selected metal ions are plotted against number of coordinating sites of the ligands form unidentate ammonia to multidentate complexanes.

TTHA	9.25	8.34	7.78	7.66	4[c]	7.97	9.11	7.96				12[a]

a) 25°C, μ=0.1. b) 20°C, μ=0.1. c) 30°C, μ=0.1

It is noticed that the chelate stability increases linearly with increasing number of coordinating sites until the coordination number of metal ion is filled up. However, the values for the chelates of TAPHA which is a nonadentate ligand, is almost same as those of EDTA which is a sexadentate ligand. This result is indicative that only six of nine coordinating site of TAPHA, or in other word, two of three nitrilodiacetate groups, are involved in the formation of mononuclear chelate.

Protonated Chelates (MHL and MH_2L). As TAPHA is a hexabasic acid, protonated chelates are formed more easily than in the case of tetrabasic EDTA. The stability constants of monoprotonated mononuclear chelates (MHL) and diprotonated mononuclear chelates (MH_2L) of TAPHA are shown in Tables 4 and 5 along with the corresponding values of other complexanes of related structure. It is seen from Table 4 that, in the case of transition metal ions, the values of stability constant of TAPHA lie in between those of EDTA and of DTPA, while, in the case of alkaline earth metal ions, the values of stability constant of TAPHA are comparable with those of TTHA which is a decadentate hexabasic ligand. It is also noticed that the stability constants of diprotonated TAPHA chelates for alkaline earth metal ions are comparable with those of TTHA chelates.

The acid dissociation constants of monoprotonated TAPHA chelates were also determined and their values are listed in Table 6 along with the corresponding values of other complexanes. The acidity of protonated chelate is found to decrease with increasing the number of coordination sites in the ligands.

In contrast with the stability constants of normal chelates as well as protonated chelates which are very much dependent upon the kind of metal ions, the difference of acid dissociation constants of protonated chelates among alkaline earth metal ions as well as transition metal ions is very small in TAPHA chelates. The average value of pK^{H}_{MHL} is 7.52±0.25 for alkaline earth metal ions and 6.54±0.14 for transition metal ions. Thus, although the acidity of free monoprotonated ligand

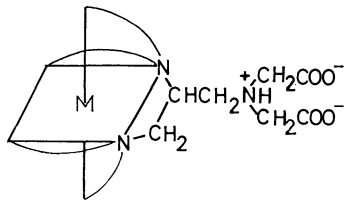

Fig. 8. Monohydrogen mononuclear chelate, MHL^{3-}.

(HL) is increased by metal chelation, the influence of the kind of metal ion on the acid dissociation constant of protonated chelate is found to be not so significant. The result may suggest that the bonding site of proton is so remote from the site of metal coordination, that the acidity is not so sensitive with the kind of metal ion within each group of metals. Therefore, the most reasonable structure for monoprotonated TAPHA chelate may be an EDTA type chelate in which a terminal uncoordinated group is protonated (Fig. 8). This coordination structure, in its deprotonated form, may also be true in the case of normal mononuclear chelate of transition metal ions, whose coordination structure was not concluded in the foregoing discussion.

Dinuclear Chelates (M_2L and $MM'L$). The formation of polynuclear chelates becomes easier when the number of coordination sites of the ligand is increased beyond the coordination number of the metal ion to be complexed. Thus, the formation of dinuclear chelates and di- and trinuclear chelates have been reported for DTPA and TTHA respectively.[6,12] The stability constants of polynuclear chelates have to be determined in the presence of large excess of metal ion. In the case of TAPHA, the formation of dinuclear chelate was observed for alkaline earth metals except magnesium. However, in the case of transition metals and magnesium, no satisfiable result could be obtained because of the formation of precipitation as the pH titration proceeded.

The stability constants of the dinuclear TAPHA chelate (M_2L) are shown in Table 7, together with those of TTHA. The values of $\log M^{M}_{M_2L}$ are

TABLE 7. STABILITY CONSTANTS ($\log K^{M}_{M_2L}$) OF ALKALINE EARTH METAL-DINUCLEAR CHELATES OF TAPHA AND TTHA

	Mg	Ca	Sr	Ba	Ref.
TAPHA		2.3	1.4	1.6	
TTHA	5.94	4.10	3.44	3.41	4c)

c) 30°C, $\mu=0.1$

considerably lower than those of $\log K_{ML}$ and are same order as those of 1 : 1 iminodiacetic acid chelates. This result suggests that the second metal ion may be chelated by the uncoordinated terminal nitrilodiacetate group of normal mononuclear TAPHA chelate. The structure of dinuclear chelate is proposed in Fig. 9.

It is also noticed that the values of the stability constant of dinuclear TAPHA chelate are apparently lower than those of TTHA. The magnitude of $\log K^{M}_{M_2L}$ for TTHA is comparable with those of quadridentate or quinquedentate complexanes, and this result can easily be understood if one consider the structure of mononuclear TTHA chelate, which can chelate the second metal ion by more coordination sites than does TAPHA.

As described in the experimental part, the stability

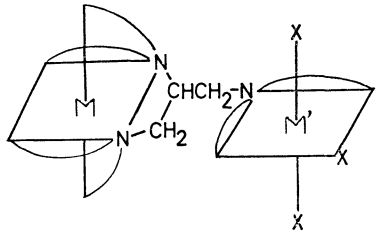

Fig. 9. Dinuclear chelate, $MM'L^{2-}$.

TABLE 8. STABILITY CONSTANTS ($\log K^{Ca}_{MCaL}$) OF MIXED METAL DINUCLEAR CHELATE OF TAPHA

Co	Ni	Cu	Zn	Cd
2.05 ±0.01	2.08 ±0.01	2.08 ±0.03	2.62 ±0.01	2.19 ±0.01

constants of mixed dinuclear chelate (MM'L) were also determined by choosing transition metals and calcium as the first and the second metal ions respectively. The values of $\log K^{Ca}_{MCaL}$ can be understood as the dinuclear chelate formation constants when calcium ion is bound by a mononuclear TAPHA chelate of transition metal. The observed values are listed in Table 8. It is seen from the table that the stability constants of MCaL chelates are same order as that of Ca_2L chelate and that the values of $\log K^{Ca}_{MCaL}$ are not sensitive to the kind of the first metal ions as in the case of pK^{H}_{MHL}. These results may also support the structure of dinuclear TAPHA chelate which is shown in Fig. 9.

Th(IV)-TAPHA System. Titration of TAPHA in the presence of excess of thorium to ligand could not be carried out because of the precipitate formation. Titration of 1 : 1 mixture was successful only in the lower pH region, where no precipitate was formed and no pH drift was observed. From the data of pH titration, the acid dissociation constant of monoprotonated chelate (ThHL) was calculated as shown in Table 6. In the higher pH region, however, the hydrolyses of aquo and chelated species as well as the polymerization through olation may take place to result in a complicated system.

Studies on Hydroxy Amino Acids. I. A New Synthesis of Aziridine Derivative from β-Hydroxy α-Amino Acid

Kenji OKAWA, Teiji KINUTANI and Katsunobu SAKAI

Department of Chemistry, Faculty of Science, Kwansei-Gakuin University, Nishinomiya

(Received August 16, 1967)

N-Tosyl-3-methyl-2-aziridinecarboxylic acid anilide was obtained by the β-elimination reaction of *N,O*-ditosyl-L-threonine anilide. The ethyleneimine ring of this compound was readily cleaved by acetic acid in the presence of boron trifluoride and *N*-tosyl-*O*-acetyl-L-threonine anilide was obtained. Formaldehyde also reacted with this compound in the presence of the same catalyst and gave 1,3-oxazolidine and 1,3-oxazine derivatives.

We have been studying the synthesis of α,β-unsaturated α-amino acid derivatives by dehydration of β-hydroxy-α-amino acid derivatives and have observed the formation of *N*-acyl-α,β-unsaturated amino acid esters from the corresponding *N*-acyl-β-hydroxyamino acid esters as described by Photaki.[1]

However, in the case of *N,O*-ditosyl-L-threonine anilide, an unexpected product, *N*-tosyl-3-methyl-2-aziridinecarboxylic acid anilide, was obtained in good yield.

Among the reports concerning the synthesis of aziridinecarboxylic acid derivatives,[2-6] only Smrt[7] has reported findings similar to the above. In his study he asserted that the aziridinecarboxylic acid ester was produced when *N*-trityl-*O*-mesyl-serine methyl ester in the benzene solution was treated with *N*-ethyl-piperidine.

We have also found that the ethyleneimine ring of our aziridine derivative is readily cleaved by acetic acid or formaldehyde in the presence of boron trifluoride. Acetic acid gave *N*-tosyl-*O*-acetyl-L-threonine anilide and formaldehyde gave 3-tosyl-5-methyl-1,3-oxazolidine-4-carboxylic acid anilide (IVA) and 3- phenyl-4-oxo-5-tosylamino-6-methyl-1,3-tetrahydro-oxazine (IVB) as shown in Fig. 1.

The compound II in dry tetrahydrofurane was treated with an equivalent amount of diethylamine to produce III. The elemental analysis and the molecular weight of III showed the molecular formula $C_{17}H_{18}O_3N_2S$. From this results, it was suggested that the compound is a dehydration product of I and has a structure of either III or III'. But III was confirmed by the spectral data.

The infrared spectrum indicated the presence of secondary amide bands at 1675 cm^{-1} and 1523 cm^{-1} respectively. But the characteristic absorption of a trisubstituted vinyl double bond was not detected. However, a new absorption band appeared at 885 cm^{-1}, this may be attributed to the aziridine ring deformation.

The NMR spectrum also supported the structure III. The vinyl proton and tosylated amide proton were not detected in the corresponding regions. The NMR spectrum of III showed one-proton octet at δ 3.12 ppm with J=7.7 cps for the C_3-proton, one-proton doublet at δ 3.47 ppm with J=7.7 cps for the C_2-proton, $J_{2,3}$=7.7 cps (*cis*-position).[8]

The ethyleneimine ring of III is readily cleaved by hydrochloric acid or toluenesulfonic acid, and V and II were obtained respectively. However, acetic acid cannot react with III but reacted with it in the presence of boron trifluoride - etherate and IV was obtained.

In the presence of the same catalyst, III also reacted with paraformaldehyde at 45°C and the products, IVA and IVB were separated by silica gel chromatography in the yield of 45% and 5% respectively. From the elemental analyses and the molecular weights, IVA and IVB were shown to have the same molecular formula of $C_{18}H_{20}O_4N_2S$ which indicated just one formaldehyde molecule combined with III.

Proof for the structure IVA was obtained by the spectral data and the direct synthesis of IVA from I and formaldehyde.

The infrared absorption spectrum of IVA shows secondary amide bands at 1685 cm^{-1} and 1525 cm^{-1} respectively and the characteristic strong bands of –N–C–O– group in a ring structure at 1155, 1110, 1087 and 1073 cm^{-1}.[9]

The NMR spectrum of IVA showed a three-proton doublet at δ 1.05 ppm with J=5.8 cps for the C_5-methyl protons, one-proton doublet at δ 3.64 ppm with J=6.8 cps for the C_4-proton, one-proton octet at δ 4.17 ppm with J=5.8 and 6.8 cps for the C_5-proton, two one-proton doublets at δ 4.62 and 5.34 ppm for the AB type C_2-methylene protons, and no tosylated amide proton was detected in the corresponding region.

The final structure IVB was determined by the spectral data.

The infrared absorption spectrum of IVB indicated the presence of a carbonyl group in tertiary amide bond at 1695 cm^{-1} and also showed a –N–C–O– group in a ring structure at 1145, 1112, 1087 and 1050 cm^{-1}.[9]

The NMR spectrum of IVB showed a three-proton doublet at δ 1.19 ppm with J=6.8 cps for the C_6-methyl protons, one-proton quartet at δ 4.20 ppm with J=2.0 and 3.3 cps for the C_5-proton, one proton octet at δ 3.86 ppm with J=3.3 and 6.8 cps for the C_6-proton, two-proton doublet at δ 5.39 ppm for the C_2-methylene protons and one proton doublet at δ 5.58 ppm with J=2.0 cps for the tosylated amide proton. The monosubstituted amide proton was not detected in the corresponding region.

Experimental

All melting points are uncorrected. NMR spectra were obtained with a Varian A-60 spectrometer in $CDCl_3$ solution and chemical shifts are given from TMS as an internal reference. Infrared spectra were recorded with a JASCO-DS-402G (Japan Spectroscopic Co., Ltd.).

***N*-Tosyl-L-threonine Anilide (I).** Dicyclohexylcarbodiimide (30.9 g, 0.15 mol) in methylene chloride (80 m*l*) was added drop by drop to the mixture of *N*-tosyl-L-threonine (30.9 g, 0.1 mol) and aniline (9.3 g, 0.1 mol) in methylene chloride (800 m*l*) with stirring at 0°C. After adding the solution, the stirring was continued for one hour at 0°C and the reaction mixture was allowed to stand at room temperature for 4 hr. The urea produced was filtered off and the filtrate was allowed to stand in a refrigerator. The separated crystals were collected and recrystallized from tetrahydrofuran - *n*-hexane. The total yield was 26.9 g (70%), mp 145—146°C; $[\alpha]_D^{24}$ −37.21° (*c* 1.13, dioxane).

Found: C, 58.48; H, 5.77; N, 8.10%. Calcd for $C_{17}H_{20}O_4N_2S$: C, 58.60; H, 5.79; N, 8.04%.

***N,O*-Ditosyl-L-threonine Anilide (II).** *p*-Toluenesulfonyl chloride (38.0 g, 0.2 mol) in pyridine (60 m*l*) was added drop by drop to a solution of I (38.4 g, 0.1 mol) in pyridine (200 m*l*) with stirring at 0°C. After stirring for thirty minutes, the reaction mixture was allowed to stand at room temperature for 4 hr.

Ice water was added to the reaction mixture until it became turbid and the mixture was kept in a refrigerator overnight. The separated crystals were filtered and washed with ethanol. Recrystallization from tetrahydrofuran - *n*-hexane gave fine crystals. The total yield was 29.6 g (65%), mp 186—188°C; $[\alpha]_D^{24}$ −16.11° (*c* 1.21, CH_2Cl_2).

Found: C, 57.70; H, 5.27; N, 5.63; S, 12.32%. Calcd for $C_{24}H_{26}O_6N_2S_2$: C, 57.35; H, 5.21; N, 5.57; S, 12.73%.

***N*-Tosyl-3-methyl-2-aziridinecarboxylic Acid Anilide (III).** Diethylamine (1.02 m*l*, 0.01 mol) was added to a solution of II (5.02 g, 0.01 mol) in tetrahydrofuran (50 m*l*). After incubation at 37°C for 5 hr, the reaction mixture was diluted with ether until it became turbid. The diethylamine *p*-toluenesulfonate produced was filtered off and from the filtrate solvent

was removed under reduced pressure. The resultant material was dissolved in ether under warming, insoluble material was filtered off and the filtrate was allowed to stand in a refrigerator. White needle crystals were obtained. The yield was 2.15 g (65%). The melting point was different depending upon the solvent of recrystallization: mp 50—56°C for ether, 90—91°C for ethanol-water. $[\alpha]_D^{20}$ −65.3° (*c* 1.08, EtOH), $\lambda_{max}^{MeOH\cdot H_2O}$ 246 mμ (ε=13000), ν_{max}^{KBr} 1675 (amide I), 1523 (amide II) and 885 cm^{-1} (aziridine ring).

Found: C, 61.97; H, 5.61; N, 8.21; S, 9.54%; mol wt (Rast), 315±15. Calcd for $C_{17}H_{18}O_3N_2S$: C, 61.80; H, 5.49; N, 8.48; S, 9.70%; mol wt, 330.4.

NMR: δ 1.33 ppm (3H (d), *J*=5.8 cps, C_3-methyl proton); 3.12 ppm (1H (d) *J*=5.8, *J*=7.7 cps, C_2-proton) 3.47 ppm (1H (d) *J*=7.7 cps, C_2-proton)

3-Tosyl-5-methyl-1,3-oxazolidine-4-carboxylic Acid Anilide (IVA).

3-Phenyl-4-oxo-5-tosylamino-6-methyl-1,3-tetrahydrooxazine (IVB). Paraformaldehyde (1.8 g, 0.02 mol) and ten drops of boron trifluoride etherate (47%) were added to the solution of III (6.60 g, 0.02 mol) in chloroform (50 m*l*) and stirred at 45°C for 50 hr.

Unreacted paraformaldehyde was filtered off and the solvent was removed. The oily residue (8.5 g) was chromatographed on silica gel (150 g) with benzene-ethyl acetate (10 : 1, v/v) to yield two reaction products.

From the fraction of R_f 0.74 on silica gel thin-layer chromatography with benzene - ethyl acetate (10 : 1, v/v) was obtained a product IVA yield 3.25 g (45%), mp 36—38°C from ether - petroleum ether; $[\alpha]_D^{20}$ −215.5° (*c* 1, EtOH), $\nu_{max}^{CCl_4}$ 1685 (amide I), 1525 (amide II), 1115, 1110, 1087 and 1073 cm^{-1} (–N–C–O– ring).

Found: C, 59.28; H. 5.79; N, 7.64; S, 9.27%; mol wt, 350±10,(Rast). Calcd for $C_{18}H_{20}O_4N_2S$: C, 59.98; H, 5.59; N, 7.77; S, 8.90%; mol wt, 360.

NMR: δ 1.05 ppm (3H (d) *J*=5.8 cps, C_5 methyl proton); 3.64 ppm (1H (d) *J*=6.8, C_4 proton); 4.17 ppm (1H (o) *J*=5.8, *J*=6.8, C_5 proton); 4.62, 5.34 ppm (2H (d) C_2 methylene proton)

From the fraction of R_f 0.44 (on the same silica gel thin-layer chromatography) was obtained a product IVB, 0.35 g (5%) mp 137—137.5°C (from ethyl acetate-ether); $[\alpha]_D^{20}$ +35.6° (*c* 1, EtOH), ν_{max}^{KBr} 1145, 1112, 1087 and 1060 (–N–C–O– ring), 3250 cm^{-1} (Tos-NH–).

Found: C, 60.04; H, 5.60; N, 7.71; S, 8.59%; mol wt, 355±10 (Rast). Calcd for $C_{18}H_{20}O_4N_2S$: C, 59.98; H, 5.59; N, 7.77 S, 8.90%; mol wt, 360.

NMR: 1.19 ppm (3H (d) *J*=6.8 cps, C_6 methyl proton); 3.86 ppm (1H (o) *J*=3.2, 6.8 cps, C_6 proton); 4.86 ppm (1H (q) *J*=2.0, 3.2 cps, C_5 proton); 5.39 ppm (2H (d) C_2 methylene proton); 5.58 ppm (1H (d) *J*=2.0 cps, tosylated amide proton)

From the fraction of R_f 0.66 on the same silica gel thin-layer chromatography 0.32 g of unreacted starting material was recovered.

3-Tosyl-5-methyl-1,3-oxazolidine-4-carboxylic Acid Anilide (IVA) from *N*-Tosyl-L-threonine Anilide (I). Five drops of boron trifluoride etherate (47%) were added to a mixture of I (1.74 g, 0.005 mol) and paraformaldehyde (0.9 g) in acetic acid (10 m*l*) and the mixture was stirred at 85°C for 20 min, and the solvent was evaporated under reduced pressure. The residual oily substance was dissolved in ether and was washed with 1 N sodium bicarbonate and water to remove a trace amount of acetic acid and aldehyde. The ether solution was dried over anhydrous sodium sulfate and the solvent was removed. Colorless oil (1.75 g) obtained gradually solidified to a glassy mass mp 36—38°C, R_f 0.74 (on silica gel thin-layer chromatography with benzene - ethyl acetate (10 : 1, v/v). This compound was identified with IVA by the IR spectrum and R_f value on silica gel thin-layer chromatography.

***N*-Tosyl-α-amino-β-chloro-*n*-butyric Acid Anilide (V).** Compound III (0.33 g, 1mmol) was warmed to be dissolved in 2 N hydrochloric acid (2 m*l*). The solution was kept at 40°C for 2 hr, and fine crystals gradually appeared during this period. The crystals were filtered and collected with theoretical yield. Recrystallization from methanol-water gave pure materials, mp 163—164°C, $[\alpha]_D^{24}$ −51.13° (*c* 1.02, MeOH).

Found: C, 55.70; H, 5.62; N, 7.63; S, 8.87; Cl, 9.66%. Calcd for $C_{17}H_{19}O_3N_2ClS$: C, 55.66; H, 5.22; N, 7.64; S, 8.74; Cl, 9.66%.

***N*-Tosyl-*O*-acetyl-L-threonine Anilide (VI).** A mixture of III (1.98 g, 0.006 mol), acetic acid (6 m*l*), and five drops of boron trifluoride etherate (47%) was stirred at 45°C for 4 hr. The reaction mixture was dissolved in ethyl acetate (100 m*l*) and was washed with 1 N sodium carbonate and then with 1 N sodium bicarbonate and water. The organic layer was dried over anhydrous sodium sulfate. After removal of the solvent, the crystalline residue was recrystallized from ethyl acetate - *n*-hexane to give a substance, mp 173—173.5°C in 88% yield. This substance was found to be identical with the authentic sample*1 (*N*-tosyl-*O*-acetyl-L-threonine anilide) by the IR spectrum and the mixed melting point test.

$[\alpha]_D^{20}$ −1.82° (*c* 1.92, dioxane), ν_{max}^{Nujol} 1736 (–OAc), 1661 (amide I) and 1534 cm^{-1} (amide II).

Found: C, 58.62; H, 5.78; N, 7.25; S, 8.23%. Calcd for $C_{19}H_{22}O_5N_2S$: C, 58.45; H, 5.68; N, 7.17; S, 8.21%.

The authors wish to express their hearty thanks to Fujisawa Pharmaceutical Company for the measurements of NMR spectra and for a grant-in-aid for fundamental scientific research.

Studies of the Pinacol Rearrangement. IV.*[1] The Kinetics and Mechanism of the Rearrangement of *meso*- and *dl*-2,2'-Dimethoxybenzopinacol

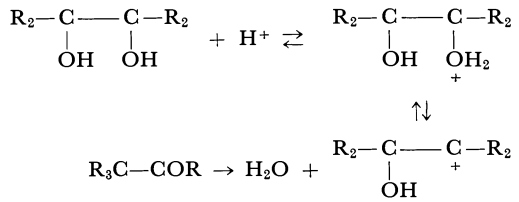
Kiyoshi MATSUMOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received October 6, 1967)

The first-order rate constants of the perchloric acid-catalyzed rearrangements of the *meso*- and *dl*-2,2'-dimethoxybenzopinacols were measured in anhydrous acetic acid. A linear correlation of the logarithm of the first-order rate constants ($\log k$) with Hammett acidity function (H_0) was obtained in each case. The large positive values of the entropy of activation support the A-1 mechanism, which is also supported by the linearities of $\log k$ with H_0, suggesting that the classical carbonium ion is an intermediate in these processes. The migration aptitude of the *meso*-isomer decreases with time, while that of *dl* increases. On the basis of this information, the mechanism of the rearrangement was discussed.

The pinacol rearrangement is one of the most classical reactions, therefore, a large amount of information about it and about related rearrangements has been reported.[1] Collins has reviewed the evidence on the mechanisms of the pinacol rearrangement and has concluded that it supports the general scheme:



However, there are numerous detailed aspects of these reactions which have been inadequately investigated.[2] The kinetics of the reactions of the tetraarylpinacols have received particularly little attention except for the rearrangement of the benzopinacol.[3]

The present communication will present our findings on the kinetics of the rearrangements of the *meso*- and *dl*-2,2'-dimethoxybenzopinacols (I) to the 2-methoxybenzoyl-2-methoxyphenyldiphenylmethane (II) and benzoyldi-2-methoxyphenylphenylmethane (III) in anhydrous acetic acid, with perchloric acid as the catalyst.

Experimental

Materials. *Anhydrous Acetic Acid.* Glacial acetic acid (commercial, extra pure) was refluxed with acetic anhydride and distilled through a 1-m column packed with glass tubes (1 cm long). The first 20% of the distillate was rejected, and the fraction of the 117.0—118.3°C boiling range was collected. This fraction was redistilled, after which the fraction of the 117.8—118.1°C boiling range was collected.

The methods of preparing and purifying *meso*- and *dl*-2,2'-dimethoxybenzopinacol have already been reported.[2c]

A standard stock solution of perchloric acid was prepared by the addition of 1.00 m*l* of a 70—72% reagent grade commercial product to approximately 200 m*l* of anhydrous acetic acid containing a stoichiometric amount of the redistilled acetic anhydride required to react with the water of the aqueous perchloric acid. The solution was then standardized by titration with a standard solution (0.0500 N) of sodium acetate in glacial acetic acid, using bromophenol blue as an indicator.[4]

Analytical Method. Since the oxidation method with lead tetraacetate is not accurate for 2,2'-disubstituted benzopinacol,[2c] the optical densities of the pinacolones were measured and the concentration of the pinacol remaining was calculated.

Reaction-rate Measurements. A reaction flask containing about 0.01 M of a pinacol solution was immersed in a thermostated oil bath. After half an hour, a measured volume of the catalyst was added to this solution. At appropirate times, 1-m*l* samples were removed and put into test tubes containing 0.0010 m*l* of a concentrated solution of potassium acetate. Each sample (0.20 m*l*) was treated by thin-layer chromatography.[2b] Each pinacolone fraction was extracted with chloroform to a 10.0-m*l* solution. Measurements of the optical densities of these solutions gave the concentrations of the pinacol remaining.*2 A straight line correlating the concentrations of the pinacolone, (II) or (III), with the optical densities at 2820 or 2765 Å was used to obtain the concentrations of the pinacolones. The reaction-rate constants were evaluated by the graphical method.

Results and Discussion

Products. The *meso*- and *dl*-2,2'-dimethoxybenzopinacols rearranged to produce *o*-anisoylanisyldiphenylmethane (II) and benzoyldi-*o*-anisylphenylmethane (III), which have absorption maxima at 282 mμ and 276 mμ respectively in chloroform. The thin-layer chromatography showed that the *meso*-isomer isomerizes to the *dl*, while neither pinacol forms a stable epoxide intermediate.[3,5]

Kinetics. We have much evidence that the pinacol rearrangement shows first-order kinetics, as was observed in the present case (*cf.* Fig. 1). The *dl*-isomer is rearranged about three times as fast as the *meso*. In the case of the *meso*-isomer, a slight curvature was evident. This curvature corresponded to acceleration as the reaction proceeded. This deviation may be due to the contribution of the isomerization of the *meso*-isomer to the *dl*, which was observed in the thin-layer chromatography of the reaction products. A similar phenomenon was observed in the rearrangements of the *cis*- and *trans*-1,2-diphenylacenaphthene-1,2-diol.[6]

Table 1. Summary of kinetic data for the perchloric acid-catalyzed rearrangement of 2,2'-dimethoxybenzopinacol in anhydrous acetic acid at 72°C

$HClO_4$ (mol×10⁴)	H_0	$k\times10^2$(min⁻¹)	log k	$k'\times10^{-2}$ (l/mol×min)
		(*meso*)		
0.518	−2.23	0.502	−2.30	0.969
0.857	−2.00	0.724	−2.14	0.845
1.36	−1.79	1.15	−1.96	0.846
2.60	−1.50	1.94	−1.72	0.746
3.98	−1.30	2.81	−1.55	0.706
		(*dl*)		
0.532	−2.22	1.38	−1.86	2.71
0.863	−2.00	1.99	−1.70	2.32
1.36	−1.79	3.12	−1.51	2.28
1.87	−1.65	4.14	−1.39	2.21
2.87	−1.45	6.03	−1.22	2.10

Table 1 summarizes the effects of the catalyst concentration upon the rate constant.[7] The plots of the Hammett acidity function values shown in Table 1 against log k are two straight lines with slopes of 0.90 and 0.85 for the *dl*- and *meso*-isomer respectively (Fig. 2). These correlations support the A-1 (acid-catalyzed first-order reaction) mechanism, according to the original form of the Zucker-Hammett hypothesis.[8]

The values of the experimental activation energy, E_a, and of the free energy, $\Delta F^{\neq}$, and entropy, $\Delta S^{\neq}$, of the activation were calculated from the specific rate constants, k' (Table 2).

Variation of Migration Aptitude with Time. Although the molecular rearrangements of tetraarylpinacols to pinacolones have been studied extensively with respect to the relative migration aptitudes of the aryl groups, most of the foregoing data were obtained without any knowledge of whether the configuration of the pinacols was *meso* or *dl*. In the rearrangement of *p,p'*-disubstituted benzopinacol, which probably rearranges *via* long-lived carbonium ion intermediates, the rate of the interconversion of the different rotational isomers is rapid in comparison with the rate of aryl-group migration, and a Hammett-type $\rho\sigma^+$ correlation is observed.[9] In the rearrangement of such sterically-condensed glycols as *o,o'*-disubstituted benzopinacols, however, the rate of the interconversion of the rotational isomers of the carbonium ions may be comparable with the rate of aryl-group migration. Thus, it is expected

9) J. E. Leffler and E. Grunwald, "Rate and Equilibria of Organic Reactions," John Wiley and Sons, New York and London (1963), p. 208.

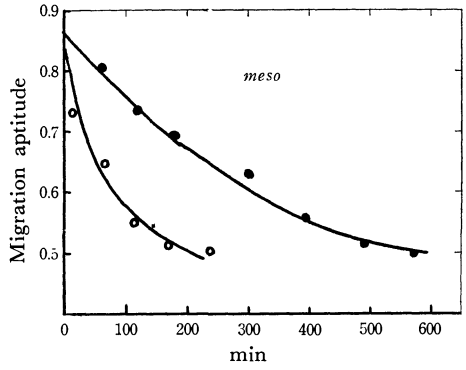

Fig. 3. Variation of migration aptitude with time (1.36×10^{-4} mol $HClO_4$).

● 62°C ○ 72°C

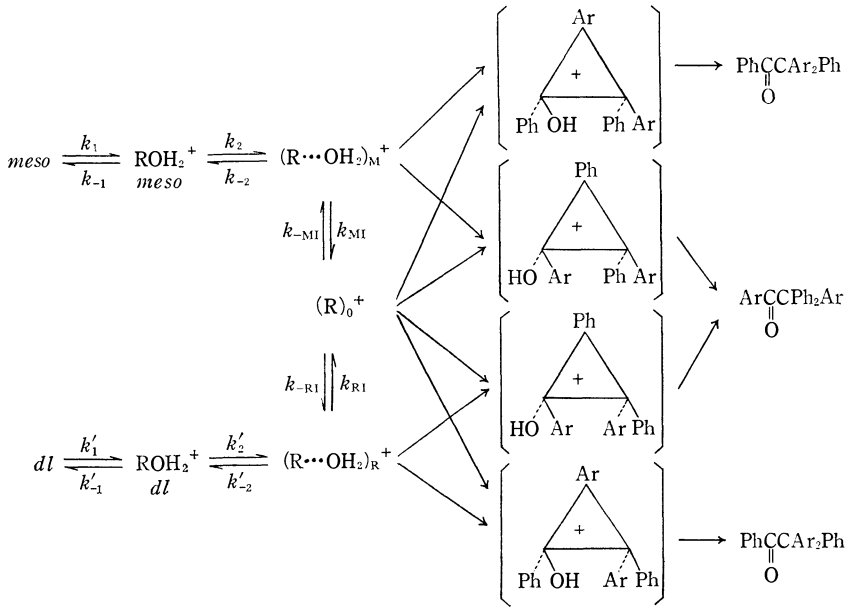
that the migration aptitude*3 would vary with time, as was observed in the present case (shown in Fig. 3). The implication of the variation of the migration aptitude of the *meso*-isomer with time is more complicated because of the isomerization of the *meso*-isomer to the *dl*. Figure 3 shows that the migration aptitude of the *meso*-isomer decreases with time, while that of the *dl* increases.

It seems that the isomerization of the *meso*-isomer to the *dl* and the change in the migration aptitude with time can reasonably be interpreted on the basis of the kinetic consideration, when the rate constants of the aryl-group migration are assumed to be roughly comparable with the rate constants, k_{-MI}, k_{MI}, k_{RI}, k_{-RI} and k'_{-2}, k_{-2} being much smaller in Scheme 1 (where $[R\cdots OH_2]^+_M$, $[R\cdots OH_2]^+_R$, and $[R]^+_O$ are two carbonium aggregate intermediates which retain *meso*(M) and *dl*(R) configurations, and an open carbonium ion (O) intermediate respectively). The decrease in the migration aptitude with time in the reaction of the *meso*-isomer may be interpreted by assuming the contribution of the aryl-group migration *via*

*3 Migration aptitude = Aryl/Phenyl.



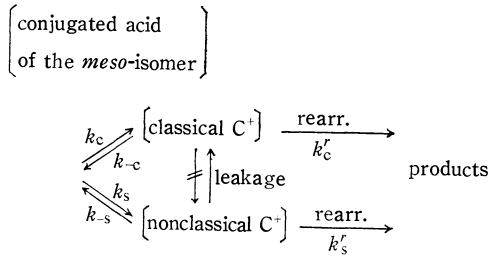
Scheme 1 { I ……Isomeisotion; R ……*dl*; M……*meso* }

intermediates without any configurational identities, such as $[R]^{+}_{O}$ and $[R\cdots OH_2]^{+}_{R}$, intervening through isomerization. The increase in the migration aptitude with time in the reaction of the *dl*-isomer can be explained in a similar way.

It is a sound assumption that the extrapolated value of the migration aptutude at time 0 (in Fig. 3) reflects the value of the intrinsic migration aptitude of $[R\cdots OH_2]^{+}_{M}$ or $[R\cdots OH_2]^{+}_{R}$. The difference between these two intrinsic migration aptitudes (0.3 and 0.85) may be explained in terms of the difference in the magnitude of the eclipsing effects in the transition states of the aryl-group migrations (see Scheme 1). An inspection of the model will reveal that the eclipsing effects in the transition states of the phenyl (*o*-anisyl)-group migration *via* the *dl*-aggregate intermediate, $[R\cdots OH_2]^{+}_{R}$ (*meso*-aggregate intermediate, $[R\cdots OH_2]^{+}_{M}$) is smaller in magnitude than that *via* the *meso*-aggregate intermediate, $[R\cdots OH_2]^{+}_{M}$ (*dl*-aggreagate intermediate, $[R\cdots OH_2]^{+}_{R}$), therefore, the phenyl-group migration *via* $[R\cdots OH_2]^{+}_{R}$ may be more probable than that *via* $[R\cdots OH_2]^{+}_{M}$. Thus, the diminished difference in the observed migration aptitudes of the *meso*- and *dl*-isomers may reasonably be interpreted in terms of the interconversion among the intermediates, $[R\cdots OH_2]^{+}_{M}$, $[R\cdots OH_2]^{+}_{R}$, and $[R]^{+}_{O}$.

Although the possibility of a contribution of the concerted mechanism and/or of the nonclassical carbonium ion mechanism*4 could not be excluded by the present results, the classical carbonium ion mechanism can be explained as follows:

(i) A considerable amount of the isomerization of the *meso*-isomer to the *dl* was observed.[2b] If $k_S > k_C$ (a rate enhancement is observed by neighboring-group participation) in the following chart,



$k_{-S} > k_{-C}$ would be valid on the basis of the principle of the microscopic reversibility. Since it is liekly that $rate_S^{rearr}$ and $rate_C^{rearr}$ are not very different, the return of the *meso*-isomer to the *meso*-isomer may be effected to be much more predominant than the return of the *meso*-isomer to the *dl*-isomer in addition to the *meso*-isomer. This is not, however, in accord with the observed results. Therefore, the case $k_S < k_C$ would be valid, showing a smaller contribution of nonclassical carbonium ions.

(ii) The large positive values of the entropy of activation is in accord with the classical carbonium ions if the contribution of the entropy of desolvation in the transition state is assumed to be small (Table 2).

*4 The concerted mechanism implies a two-step mechanism, while the nonclassical carbonium ion mechanism implies a three-step mechanism, $P \rightleftarrows PH^{+} \rightleftarrows C^{+}_{N} \rightarrow K$.

(iii) It is known that, in general, the neighboring group participation tends to decrease with an increase in the phenyl substitution of the carbon atom at which heterolysis occurs.[10]

(iv) In such a sterically-condensed system as 2,2'-dimethoxybenzopinacol, a classical carbonium ion would give more chances for a decrease in the steric interaction than would a nonclassical carbonium ion, as an inspection of molecular models suggests.

(v) If one assumes that either the concerted or nonclassical mechanism is exclusively operative, the extrapolated migration aptitude at time 0 in Fig. 3 would be observed, since the transition states or intermediates are considered to have structures similar to those of the transition states of aryl-group migration described in Scheme 1. The observed change in migration aptitude with time, therefore, seems to suggest that the classical carbonium ions are more favored as intermediates.

In conclusion, again, the contribution of the concerted mechanism and/or the nonclassical carbonium ion mechanism would be small, if not entirely absent.

The slightly larger rate constant (*ca.* three times) of the *dl*-isomer compared with the *meso* may be considered to be due to the conformational predominance of the *meso*-pinacol with a *trans* arrangement of the hydroxyl groups, while the *dl* has a *cis*.[2c]

Although the low migration aptitude (<1) of the *o*-anisyl group is usually ascribed to steric hindrance,[2b] it has been suggested by Pocker[11] that it could be due to the interaction of the *o*-anisyl oxygen with a developing carbonium ion.[12] However, this suggestion is not in accord with the large positive values of the entropy of activation which follow if the degree of desolvation in the transition state is assumed to be small. The abnormally low migration aptitude of the *o*-anisyl group may instead be ascribed to steric hindrance by the solvated methoxy group.[13]

Though the epoxide intermediates were not detected by thin-layer chromatography, the by-passed mechanism *via* unstable epoxide intermediates can not be excluded.

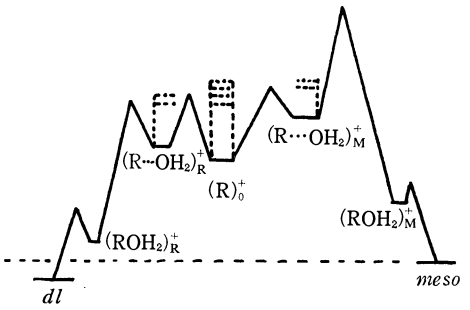


Fig. 4. Schematic energy diagram for interconversion of the diols (full line) and for formation of the products (broken line).

The conclusions as to the fates of the carbonium ions are summarized qualitatively in a plot of the free energy against the reaction co-ordinate (Fig. 4). From the evidence for the strong hydrogen bonding in the *dl*-isomer, it may be assumed that the *dl*-isomer is more stable than the *meso* in the ground state.[2c]

The author wishes to thank Professor Ryozo Goto for his helfpul discussions and encouragement, and Dr. Akira Sera and Dr. Jun'ichi Hayami for their kind and valuable advice and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1361—1367 (1968)

Some Reactions of *N*-Haloamidines*[1]

Eiichi HARUKI, Toshihiro INAIKE*[2] and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received October 25, 1967)

The reactions of a variety of *N*-haloamidines with silver oxide, sodium ethoxide, thiourea derivatives, and phenols are described. In these reactions, *N*-phenyl-*N'*-chlorobenzamidine gave diphenylcarbodiimide, benzimidazole, *N*-amidinobenzamidine and 2,4-diphenylthiadiazole respectively, while the other *N*-haloamidines afforded the corresponding products. The mechanistic implications of these reactions are discussed.

Although *N*-haloamidines had been prepared by Bougault and Robin early in the 1920's from amidine hydrochlorides and sodium hypochlorite,[1] the chemistry of the compounds has not been widely studied. The representative reactions of *N*-haloamidines were the nucleophilic replacement of the halogen atom with the cyanide or isothiocyanate ion,[2] and the oxidation of the iodide ion.[1] Recently, Grenda *et al.*[3] and we[4] have reported that the reaction of *N*-chlorobenzamidine with sodium ethoxide leads to the formation of benzimidazole, probably *via* a nitrene intermediate. These results indicate that the halogen atom of *N*-haloamidines could react in two different ways. In the first type of reaction, the halogen atom of *N*-haloamidines leaves as a halide ion, this reaction can be realized by treating the compounds with such reagents as (a) the silver ion, which has a strong affinity towards the halogen atom, (b) strong nucleophiles, such as cyanide or isothiocyanate ions, which replace the halogen atom directly, and (c) strong bases, such as the ethoxide ion, which takes up first a proton from the amino- or imino group and subsequently eliminates the halide ion. In the second type of reaction, the halogen atom of *N*-haloamidines leaves as a halogen cation, *i.e.*, a positive halogen; this reaction can be realized by the reaction with such reagents as (d) phenols, which readily undergo electrophilic substitution with a positive halogen, and (e) thioamides, which are oxidized with a positive halogen.

This paper will summarize the results obtained so far in our laboratory as to the reaction of *N*-haloamidines with the various kinds of reagents mentioned above.

Results and Discussion

Halogenation of Amidines. Haloamidines have been prepared from amidines and sodium hypochlorite or hypobromite in water.[1] However, the yield of this reaction was not always good, mainly because of the instability of *N*-haloamidines. The process of the separation of haloamidines from the reaction mixture also caused a marked drop of the yield. In this investigation, therefore, the halogenation of amidines was carried out using *t*-butyl hypohalite as a halogenation agent in such organic solvents as chloroform, benzene, or a benzene-ethanol mixture, and the resulting *N*-haloamidines were used for the subsequent reactions without separation. The yields of *N*-haloamidines varied with the structures of the amidines. Aromatic amidines usually gave *N*-haloamidines in good yields, but aliphatic amidines resulted in poor yields. *N*-Substitution with alkyl or aryl group did not affect the yield of the *N*-halogenation, but *N,N'*-disubstitution with two alkyl or two aryl groups completely inhibited the *N*-halogenation.

Formation of Carbodiimide. If the chlorine atom of *N*-haloamidine is removed as a chloride ion by the silver cation, the resulting nitrenium cation may react subsequently according to the following scheme to form carbodiimide:

$$R\text{-}C\begin{matrix}\diagup NX \\ \diagdown NH\text{-}R'\end{matrix} \rightarrow R\text{-}C\begin{matrix}\diagup N^{+} \\ \diagdown NH\text{-}R'\end{matrix} \rightarrow$$

$$R\text{-}N{=}\overset{+}{C}\text{-}NH\text{-}R' \rightarrow R\text{-}N{=}C{=}N\text{-}R'$$

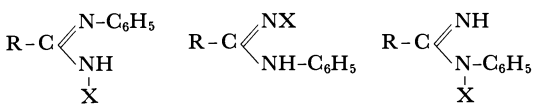
	Polymeric product	—	—	—	—	—

The figures in parentheses are calculated values for the corresponding benzimidazoles.

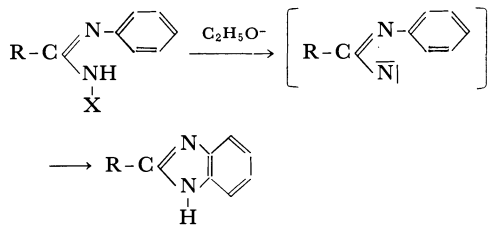
In accordance with this expectation, the reaction of *N*-chlorobenzamidine with silver oxide gave the corresponding diphenyl carbodiimide.

Formation of Benzimidazoles.[3] *N*-Phenylhaloamidines may exist in an equilibrium of three tautomeric forms, A, B and C:



(A) (B) (C)

When R is an aryl, the most favorable strcture is presumed to be A because of the great conjugation ability between the aryl and phenyl groups across the carbon nitrogen double bond. When R is an alkyl, however, the most of favorable structure could not be determined analogously. Furthermore, the hydrogen atom attached to the chloroimino group of the A structure is supposed to be fairly acidic, and it could be removed readily by a strong base. The resulting anion may spontaneously release a chloride ion to form a nitrene. The nitrene thus produced probably attacks the adjacent benzene nucleus to give a benzimidazole ring, as is illustrated in the following scheme. The same mechanism has been suggested by Grenda



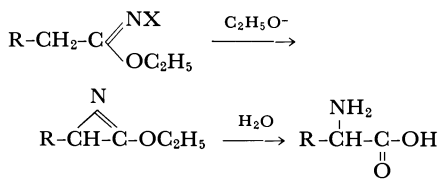
et al. in the benzimidazole formation from *N*-chloroamidines. Such a nitrene intermediate has also been proposed by Smith and Leon[5] in the pyrolysis of 1,5-diphenyltetrazole to give benzimidazole and *N,N'*-diphenylcarbodiimide.

When aromatic *N*-arylhaloamidines were treated with sodium ethoxide in ethanol, the expected benzimidazoles were obtained in good yields, as Table 1 shows. However, aliphatic *N*-arylhaloamidines such as *N*-phenyl-*N'*-chloroacetamidine did not form the expected 2-methylbenzimidazole, but only a resinous material.

The reaction of *N*-phenyl-*N*(or *N'*)-chlorophenylacetamidine with ethoxide ions was also investigated. If this haloamidine exists predominantly in the B structure, ethoxide ions may

5) P. A. S. Smith and E. Leon, *J. Am. Chem. Soc.*, **80**, 4647 (1958).

remove a proton from the α-methylene group rather than from the NH group. In such a case, an α-aminocarboxylic amide may be produced *via* the following processes, similar to the formation of the α-aminocarboxylic ester from imino ether[6]:



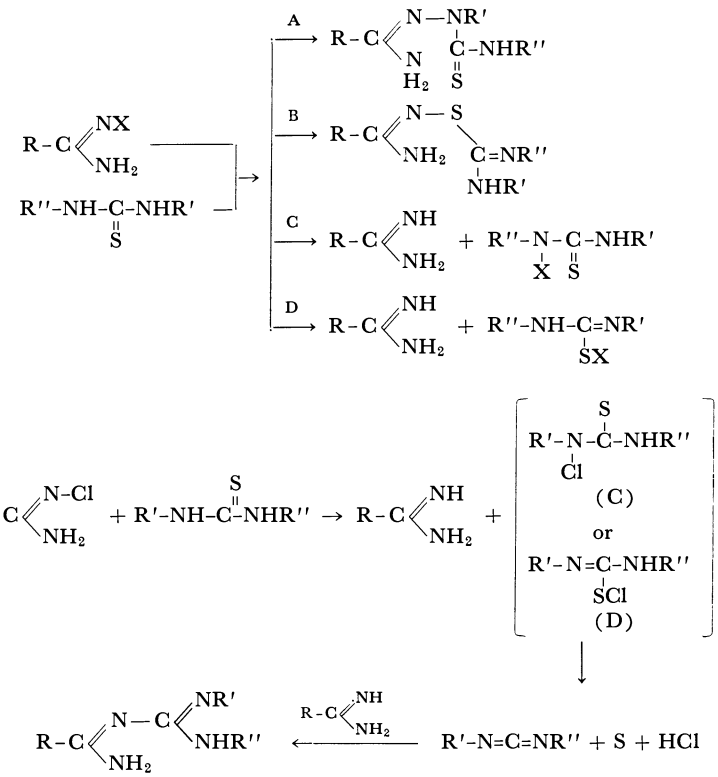
However, our expectation was pot realized; instead 2-benzylbenzimidazole was obtained in a 36% yield, as shown in Table 1. These results show that the hydrogen atom of the α-methylene group in *N*-phenyl-*N*(or *N'*)-chlorophenylacetamidine is not removed by ethoxide ions in ethanol; this amidine exists predominantly in the structure A.

Reaction of *N*-Bromobenzamidine with Phenol. *N*-Bromobenzamidine reacted with phenol in carbon tetrachloride to yield benzamidinium tribromophenolate. Similarly, *p*-hydroxybenzaldehyde yielded benzamidinium 2,6-dibromo-4-formylphenolate.

We also attempted a direct amination of phenol with *N*-haloamidines in the presence of aluminum chloride in nitrobenzene or carbon disulfide, and also in the presence of boron trifluoride etherate in ether. The direct amination of phenol was unsuccessful; only halophenol was obtained.

Reactions of Thioureas with Haloamidines. The reactions of *N*-haloamidines with thioureas are supposed to proceed though the following four processes. Routes A and B are a nucleophilic attack of the nitrogen or the sulfur atom of thioureas on the chloroamino (or chlorimino) group of haloamidines, followed by cyclization to give 1,2,4-thiadiazoles or 1,2,4-triazoles. On the other hand, routes C and D may result in the halogenation of the amino or sulfhydryl group of thiourea by the positive chlorine produced from *N*-haloamidines. Such halogenation has been proposed by Goerdeler *et al.*[7] as the first step in the formation of isothiazoles from β-iminothioamides and iodine in pyridine or in other solvents.

The experiments showed that the reaction of thiourea with *N*-chlorobenzamidine in ethanol or in water at room temperature affords *N*-amidinobenzamidine, which is then converted to *N*-cyanobenzamidine by treating it with sodium ethoxide in ethanol or to benzamide by refluxing it



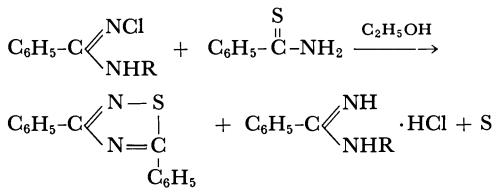
6) H. E. Baumgarten, J. E. Dirkes, J. M. Petersen and D. C. Wolf, *ibid.*, **82**, 4422 (1960); H. E. Baumgarten, J. E. Petersen and R. L. Zey, *J. Org. Chem.*, **31**, 3708 (1966).

7) J. Goerdeler and H. W. Phland, *Chem. Ber.*, **94**, 2950 (1961); *ibid.*, **96**, 596 (1963); J. Goerdeler and W. Miltler, *ibid.*, **96**, 944 (1963); J. Goerdeler and H. Horn, *ibid.*, **96**, 1551 (1963).

with sodium hydroxide in water for a long period of time. The *N*-cyanobenzamidine thus obtained was identical with that prepared from *N*-chlorobenzamidine and sodium cyanide in every respect. However, when the reaction between thiourea and *N*-chlorobenzamidine was carried out in the presence of sodium ethoxide in ethanol or of potassium hydroxide in water, *N*-cyanobenzamidine was obtained directly. These *N*-(*N'*-substituted amidine)benzamidines could not be converted to *N*-cyanobenzamidine by treating them with sodium ethoxide.

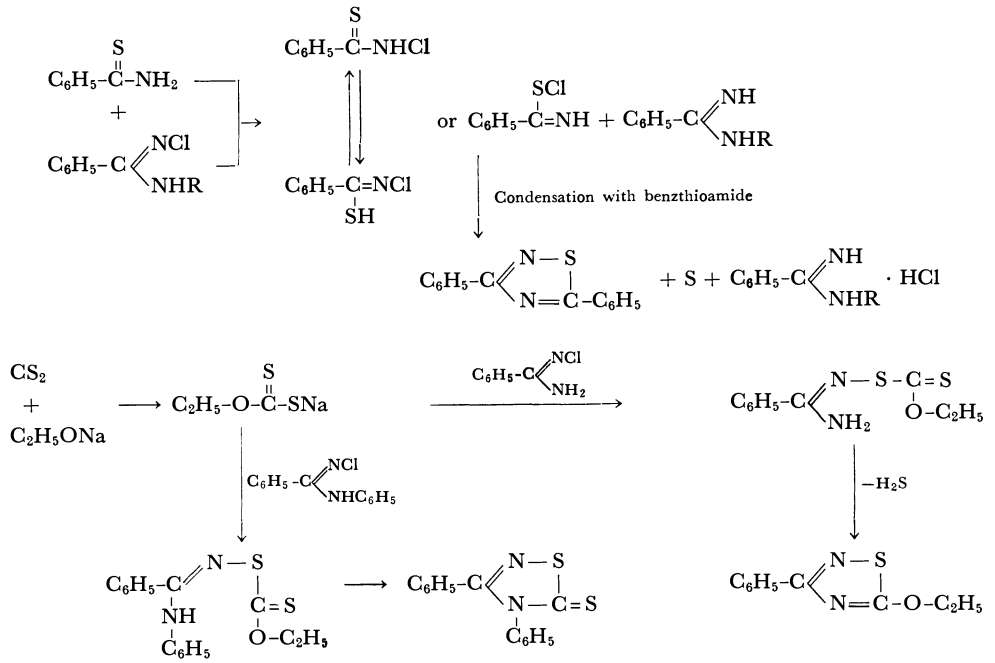
These results indicate that the process of the formation of *N*-amidinobenzamidines may proceed through the intermediate C or D, followed by the elimination of elemental sulfur and hydrogen chloride to form carbodiimide, to which the addition of amidine then takes place.

Formation of Thiadiazoles. The reaction of benzthioamide with *N*-chlorobenzamidine or *N*-chloro-*N'*-phenylbenzamidine in ethanol at room temperature for 5 hr afforded 3,5-diphenyl-1,2,4-thiadiazole, together with the amidine hydrochloride and elemental sulfur.



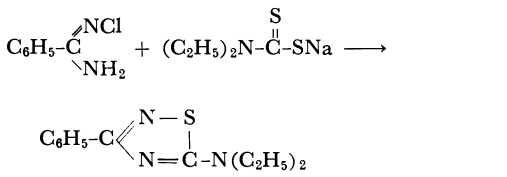
In this reaction *N*-haloamidines act as oxidizing agents on benzthioamide, as is shown in the following scheme. It is interesting to note that thiadiazoles have previously been obtained upon the oxidation of thioamides with halogen.[8]

Reaction of Carbon Disulfide with *N*-Haloamidines. The reaction of carbon disulfide with *N*-haloamidines was also investigated, although the structures of the products have not yet been completely determined. Carbon disulfide reacted with *N*-chlorobenzamidine in the presence of sodium ethoxide in an ethanol-benzene mixture at the reflux temperature to yield an oily material (bp 109—111°C/0.6 mmHg), while no reaction occurred in the absence of sodium ethoxide. The oily material obtained was assumed to be 3-phenyl-5-ethoxy-1,2,4-thiadiazole from the results of elemental analysis and from its absorption characteristics in the infrared spectrum (1520, 1430, 1330, 1300, and 1250 cm^{-1}). This compound may be formed from *N*-chlorobenzamidine and sodium ethyl xantate. That is, the reaction of *N*-chlorobenzamidine and sodium ethyl xantate may produce first an unstable intermediate, benzthioamidoxime ethyl thiocarbonate, and then this intermediate might cyclize, eliminating hydrogen sulfide, to produce the product. The eliminated hydrogen sulfide may be oxidized with *N*-chlorobenzamidine to sulfur. Carbon disulfide also reacted with *N*-chloro-*N'*-phenylbenzamidine to afford crystals with a mp of 146—156°C, the



8) A. W. Hoffmann and S. Gabriel, *Ber.*, **25**, 1586 (1892); S. Ishikawa, *Chem. Abstr.*, **22**, 1581 (1928); **19**, 3087 (1925); G. C. Charkravarti, *J. Chem. Soc.*, **123**, 964 (1923).

structure of which seemed to be 3,4-diphenyldihydro-1,2,4-thiadiazole-5-thione. When sodium *N*,*N'*-diethyl dithiocarbamate was used in the above reaction instead of sodium ethyl xantate, the product obtained seemed to be 3-phenyl-5-diethylamino-1,2,4-thiadiazole.



Reaction of *N*-Haloamidines with Acylating Agents. 1,2,4-Oxadiazoles have been prepared by the acylation of amidoxime, followed by a cyclization between the amino group and the ethoxycarbonyl carbon atom. Thus, it could be expected that 1,2,4-oxadiazole can also be produced from *N*-haloamidine and an acylating agent *via* the following processes.

However, even when a mixture of *N*-chlorobenzamidine and acetic anhydride was heated under reflux for 2 hr, the product was the unexpected 2-methyl-4,6-diphenyl-*s*-triazine, which was identified by a comparison of its mp and infrared spectrum with those of an authentic sample.[9] When a solution of *N*-chlorobenzamidine and benzoyl chloride in benzene was heated under reflux for 5 hr, the products were 2,4,6-triphenyl-*s*-triazine and *N*-benzoylbenzamide. In this case the expected 1,2,4-oxadiazole derivative was not obtained.

Experimental

Amidines. *N*-Phenylbenzamidine,[10] mp 110—112°C, *N*-phenylphenylacetamidine,[10] mp 137—139°C, *N*-(α-naphthyl)benzamidine,[11] mp 140—142°C, and *N*-(β-naphthyl)benzamidine,[12] mp 153—155°C, were prepared from the corresponding amine hydrochlorides and nitriles by a method similar to that described in the literature. *N*-Methyl-*N'*-phenylbenzamidine,[13] mp 126—130°C, was prepared from the *N*-phenylbenziminochloride and methyl amine hydrochloride. Benzamidine hydrochloride, mp 167—169°C, *N*-butylbenzamidine hydrochloride, mp 188—190°C, *N*, *N*-pentamethylenebenzamidine hydrochloride, mp 204—207°C, and *N*, *N*-pentamethylenephenylacetamidine hydrochloride, mp 218—220°C, were prepared from the corresponding iminoethers and amines by Pinner's method.[14]

Free amidines were obtained by extracting a solution of the respective amidine hydrochloride in 30% sodium hydroxide with chloroform and by then removing the solvent.

***N*-Haloamidines.** *N*-Bromobenzamidine was prepared from benzamidine hydrochloride and sodium hypobromite in water, according to the method reported in the literature;[15] it had a mp of 80—81°C after recrystallization from carbon tetrachloride.

N-Chloroamidines were prepared from amidines and *t*-butyl hypochlorite in organic solvents, such as chloroform, benzene, ligroin or a benzene-ethanol mixture, at 0—10°C. Among these solvents, chloroform gave the best results. The following is a typical experiment for the preparation of *N*-chloroamidines.

To a solution of *N*-phenylbenzamidine (78 g, 0.40 mol) in chloroform (300 ml) *t*-butyl hypochlorite (50 g, 0.46 mol) was added, drop by drop, at 0—10°C over

30 min; then the mixture was stirred at the same temperature for 3 hr. The solvent was removed by distillation under reduced pressure at room temperature, and the residue, a brown solid, was recrystallized from ligroin, mp 126—128°C. The yield of *N*-chloro-*N'*-phenylbenzamidine was 46 g (50%).

Found: C, 67.37; H, 4.88; N, 12.08%. Calcd for $C_{13}H_{12}N_2Cl$: C, 67.68; H, 4.81; N, 12.14%.

The other *N*-haloamidines were prepared by a method similar to that described above and were used for the subsequent reactions without separation.

Preparation of Carbodiimide. Diphenylcarbodiimide. A suspension of *N*-chloro-*N*(or *N'*)-phenylbenzamidine (2.3 g, 0.01 mol) and silver oxide (5.0 g, 0.02 mol) in ligroin was heated at reflux for 2 hr. After the precipitate had been removed by filtration, the filtrate was distilled under reduced pressure to give a fraction with a bp of 140—144°C (14 mmHg) (1.6 g), which was identified as diphenylcarbodiimide by a comparison of its infrared spectrum with that of an authentic sample prepared from *N,N'*-diphenylthiourea. The distillate (1.9 g) was dissolved in methanol (10 m*l*), mixed with 10 m*l* of 6 N hydrochloric acid, and then boiled for 30 min. After cooling, the solid which was precipitated, *N,N'*-diphenylurea showed no depression of its melting point (229—230°C) upon a mixed-melting-point determination with an authentic *N,N'*-diphenylurea.

2-Substituted Benzimidazoles and 2-Phenylnaphtho[1',2'-*d*]imidazole. To 3.9 g (0.02 mol) of *N*-phenylbenzamidine in 15 m*l* of dry benzene and 15 m*l* of absolute ethanol, 2.3 g of *t*-butyl hypochlorite were added at −5—0°C. After the mixture had been stirred at the same temperature for 2 hr, sodium (0.9 g, 0.039 mol) in 10 m*l* of absolute ethanol was added, and then the mixture was refluxed for 3 hr. When the mixture was cooled and poured into ice water, brown precipitates were obtained. Recrystallization from aqueous ethanol gave 3.1 g (80%) of a pure product, mp 289—290°C. This compound was identified with 2-phenylbenzimidazole by means of infrared and ultraviolet spectroscopic measurements, and by a mixed-melting-point test with an authentic sample which had been prepared according to the method described in the literature.[16] By the same procedure, *N*-(*o*-tolyl)-benzamidine was converted to 4-methyl-2-phenylbenzimidazole in a 76% yield, and *N*-phenylphenylacetamidine, to 2-benzylbenzimidazole in a 35% yield. However, an attempt to convert *N*-phenylacetamidine to 2-methylbenzimidazole was unsuccessful. Both *N*-(α-naphthyl)benzamidine and *N*-(β-naphthyl)benzamidine afforded the same product, 2-phenylnaphtho-[1',2'-*d*]-imidazole, in 24% and 64% yields respecti-vely.

Reaction with Thiourea and Thiourea Derivatives. *N*-Amidinobenzamidine. Thiourea (1.5 g, 0.020 mol) was added, portion by portion, to a solution of *N*-chlorobenzamidine (3.1 g, 0.020 mol) in 20 m*l* of absolute ethanol. An exothermic reaction started immediately, and sulfur soon began to precipitate. The reaction mixture was then kept overnight at room temperature. After separating the precipitated sulfur (0.38 g, 0.012 mol) by filtration, the filtrate was concentrated by distillation. The residual viscous liquid crystallized upon the addition of a small amount of ether. The *N*-amidinobenzamidine hydrochloride thus obtained 3.2 g (81%) was very hygroscopic and was used for the subsequent reactions without further purification.

***N*-Cyanobenzamidine.** A mixture of *N*-amidinobenzamidine hydrochloride (2.5 g, 0.013 mol) and metallic sodium (0.4 g, 0.017 mol) in 10 m*l* of absolute ethanol was kept overnight at room temperature. After the ethanol had then been removed from the reaction mixture by distillation, the addition of a small amount of water to the residue gave crude *N*-cyanobenzamidine, which was recrystallized from an ethanol-benzene mixture (4 : 1). The yield was 0.92 g (50%); mp 142—143°C. The *N*-cyanobenzamidine thus obtained was identified by a comparison of its infrared spectrum and melting point with those of an authentic sample which had been prepared by the method described in the literature.[14] A mixed-melting-point test with the authentic sample showed no depression.

Direct Preparation of *N*-Cyanobenzamidine from Thiourea and *N*-Chlorobenzamidine. To a suspension of thiourea (1.5 g, 0.02 mol) in 10 m*l* of ethanol, there was added, drop by drop, a solution of sodium (1.5 g, 0.065 mol) in 15 m*l* of ethanol, and then a solution of *N*-chlorobenzamidine (3.1 g, 0.02 mol) in 20 m*l* of ethanol. The reaction mixture immediately became turbid and sodium chloride precipitated out. After being allowed to stand overnight at room temperature, the reaction mixture was filtered and the precipitate was washed with water to give 0.47 g of sulfur. The filtrate was distilled under reduced pressure to remove the solvent. The viscous residue solidified upon the addition of a small amount of water. Recrystallization from a benzene-ethanol mixture, gave 1.8 g of *N*-cyanobenzamidine mp 142—143°C.

***N*-(*N,N'*-Diphenylamidino)benzamidine and *N*-(*N*-Phenylamidino)benzamidine.** A solution of *N*-chlorobenzamidine (3.1 g, 0.02 mol) in 20 m*l* of ethanol was added, drop by drop, to a solution of sodium (0.5 g, 0.022 mol) and *N,N'*-diphenylthiourea (4.0 g, 0.02 mol) in 20 m*l* of ethanol, after which the mixture was heated at reflux for 5 min. After it had been filtrated while hot to remove the sodium chloride, the filtrate gave, on cooling, crude *N*-(*N,N'*-diphenylamidino)-benzamidine which was recrystallized from ligroin, mp 134—135°C. The yield was 3.8 g (60%).

Found: C, 76.21; H, 5.44; N, 18.05%. Calcd for $C_{20}H_{18}N_4$: C, 76.40; H, 5.77; N, 17.82%.

N-(*N*-Phenylamidino)benzamidine was prepared by the same procedure as that of *N*-(*N,N'*-diphenylamidino)benzamidine.

Found: C, 70.37; H, 5.87; N, 23.83%. Calcd for $C_{14}H_{14}N_4$: C, 70.56; H, 5.92; N, 23.51%.

3,5-Diphenyl-1,2,4-thiadiazole. *N*-Chlorobenzamidine (3.1 g, 0.02 mol) was added in one portion to a solution of benzthioamide (2.7 g, 0.02 mol) in 20 m*l* of ethanol. The reaction mixture soon became turbid. When the exothermic reaction ceased and the reaction mixture was cooled to room temperature, colorless needle crystals gradually precipitate out. After standing for 5 hr, the precipitate was collected by filtration and recrystallized three times from an ethanol-water (4 : 1) mixture, mp 89—90°C. The 3,5-diphenyl-1,2,4-thiadiazole obtained was identified by a comparison of its infrared spectrum and melting point with those of an

16) B. A. Porai-Koshits, O. F. Ginzburg and L. S. Eflos, *J. Gen. Chem. (U. S. S. R.)*, **17**, 1768 (1947).

authentic sample synthesized from benzthioamide and benzthioperimidic acid by the method described in the literature.[17] A mixed-melting-point determination of the compound with the authentic sample showed no depression. The filtrate was concentrated under reduced pressure and the residual solid was washed with ether to obtain crude hydrated benzamidine hydrochloride with a mp of 75—85°C. The reaction between benzthioamide and *N*-chloro-*N'*-phenylbenzamidine was carried out as described above to give 3,5-diphenyl-1,2,4-thiadiazole, mp 87—89°C, after recrystallization from an ethanol-water mixture. The yield was 78%.

Reaction of Carbon Disulfide with *N*-Chlorobenzamidine. To a solution of carbon disulfide (1.5 g, 0.02 mol) and *N*-chlorobenzamidine (3.1 g, 0.02 mol) in 15 m*l* of ethanol, there was added a solution of sodium ethoxide prepared from sodium (0.46 g, 0.02 mol) and 10 m*l* of ethanol. The reaction mixture was heated gradually. An exothermic reaction occurred suddenly and the temperature rose to 60°C and boiled spontaneously. After having been heated for 1 hr, the reddish-colored reaction mixture was cooled and the precipitated crystals of sodium chloride were collected by filtration. The filtrate was concentrated under reduced pressure to remove the solvent and then distilled to give two fractions: (1) bp 95—109°C/0.6 mmHg, (0.4 g, n_D^{23} 1.5830), and (2) bp 109—111°C/0.6 mmHg (1.2 g, n_D^{23} 1.6042). The second fraction, the main product, was soluble in ether, ethanol, and glacial acetic acid, but was insoluble in water, 2 N hydrochloric acid, and 2 N sodium hydroxide.

Found: C, 58.12; H, 4.71; N, 13.67%. Calcd for $C_{10}H_{10}ON_2S$: C, 58.23; H, 4.89; N, 13.58%.

The structure of this compound was assumed to be 3-phenyl-5-ethoxy-1,2,4-thiadiazole on the basis of its infrared spectrum (1580, 1520, 1335, and 1300 cm^{-1}).

Reaction with Acetic Anhydride. A solution of *N*-chlorobenzamidine (3.1 g, 0.02 mol) in acetic anhydride (6.1 g, 0.06 mol) was refluxed for 2 hr. After cooling, the precipitate was collected by filtration, washed with a small amount of cold 95% aqueous ethanol, and then recrystallized three times from ethanol to give 1.4 g of 2-methyl-4,6-diphenyl-*s*-triazine, mp 108.5—109.5°C, which had the same melting point and infrared spectrum as an authentic sample; the melting point showed no depression upon a mixed-melting-point determination with an authentic sample.[9]

Reaction with Benzoyl Chloride. A solution of *N*-chlorobenzamidine (3.1 g, 0.02 mol) and benzoyl chloride (2.8 g, 0.02 mol) in 20 m*l* of benzene was refluxed for 5 hr. After the solution had been cooled and a small amount of the precipitates by removed filtration, the filtrate was evaporated and the residual solid was recrystallized from ethanol. The needles obtained were 2,4,6-triphenyltriazine (0.30 g, mp 225—230°C). The precipitates obtained upon the addition of water to the mother liquor were recrystallized from ligroin. The needles obtained were *N*-benzoylbenzamide (1.7 g, mp 145—146°C).

Bromination of Phenols with *N*-Bromobenzamidine. A solution of phenol (0.4 g, 0.004 mol) and *N*-bromobenzamidine (2.6 g, 0.013 mol) in carbon tetrachloride was refluxed for 10 min. Upon the cooling of the mixture, crystals (0.90 g, mp 116—122°C) were obtained. The same compound, benzamidinium tribromophenolate, was obtained by the addition of tribromophenol to a solution of benzamidine in ethanol, followed by the removal of the ethanol and washing with chloroform. The benzamidinium tribromophenolate thus obtained (0.9 g, 0.0027 mol) was heated for a little while together with 7 m*l* of 2 N hydrochloric acid, and cooled to give tribromophenol (0.4 g, 0.0012 mol).

p-Oxybenzaldehyde reacted similarly with *N*-bromobenzamidine in carbon tetrachloride to produce benzamidinium 2,6-dibromo-4-formylphenolate, mp 143—144°C. The salt obtained was treated with an acidic solution of 2,4-dinitrophenylhydrazine to yield 2,4-dinitrophenylhydrazone of 3,5-dibromo-4-hydroxybenzaldehyde, which was identified by a comparison of its melting point and infrared spectrum with those of an authentic sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1368—1371 (1968)

Syntheses of Heterocyclic Compounds from Benzamidine, Aldehydes, and Hydrogen Cyanide*1,*2,*3

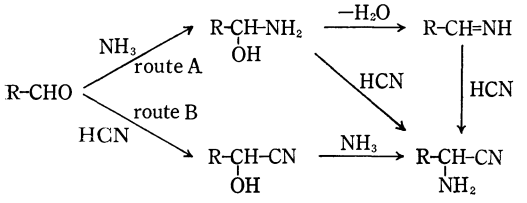
Eiichi HARUKI, Hiroshi IMANAKA and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received October 25, 1967)

The reactions of benzamidine with several aldehydes in the presence of hydrogen cyanide were studied, using an aqueous methanol as a solvent. When formaldehyde or acetaldehyde was used as an aldehyde component, α-hydroxyalkyldiphenyl-*s*-triazines were obtained, while when benzaldehyde, *p*-chlorobenzaldehyde, or furfural was used, the corresponding 4-arylmethylidenamino-2,5-diphenyloxazoles were obtained. However, under the same reaction conditions, *m*-nitrobenzaldehyde afforded dimethyl azoxybenzene-3,3'-dicarboxylate.

An α-aminonitrile, an intermediate of the Strecker synthesis of α-amino acid, can usually be prepared in a good yield from an aldehyde, hydrogen cyanide, and ammonia, though it is not obvious through which the following routes of the reaction proceeds:



If an amidine behaves similarly to ammonia in this reaction, Compound I may be formed and I may cyclize further to an imidazole derivative. Contrary to this expectation, however, when an aromatic aldehyde was used as an aldehyde component, an oxazole derivative VI was obtained, and when an aliphatic aldehyde was used, a triazine derivative, VII, was obtained, as is shown in the following chart.

The structures of VI and VII were confirmed from the following experimental evidence. Compound VIa ($C_{22}H_{16}ON_2$, mp 156—157°C) had no absorption band in the N–H region in its infrared spectrum and gave an equimolar amount of benzaldehyde 2,4-dinitrophenylhydrazone when it was treated with a solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid at room temperature for 24 hr. Furthermore, the steam distillation of VIa in the presence of concentrated hydrochloric acid gave benzaldehyde, benzoic acid, and mandelic acid as a result of hydrolysis. These facts exclude any structures other than VIc. Compound XI, which is an isomer of VIa and which was synthesized by Lichtenberger,[1] has, accidentally, the same melting point as VIa. However, the Compound XI prepared by the method described in the literature was found to be surely different from Compound VIa, for a mixed-melting-point determination showed a depression and the features of the infrared spectra were different.

Since Compounds VIb and VIc have infrared and ultraviolet spectra similar to those of VIa, and since they gave one mole of 2,4-dinitrophenylhydrazone of *p*-chlorobenzaldehyde and of furfural respectively, they must also be oxazole derivatives. Compounds VIIa and VIIb, which were obtained by the reaction with formaldehyde and acetaldehyde respectively, had ultraviolet spectra similar to that of methyl diphenyl-*s*-triazine, and their oxidation with potassium permanganate yielded the known diphenyl-*s*-triazine carboxylic acid. Hence, the presence of a triazine ring having two phenyl groups in VIIa and VIIb was established. The presence of the O–H group in VIIa and VIIb was confirmed by the absorption band at 3480 cm^{-1} in their infrared spectra and by the formation of the acetyl derivative, IX, from VIIa and of the phenylcarbamate, X, from VIIb, respectively.

The question now arises of why aromatic and aliphatic aldehydes yielded different products. The formations of VI and VII might indicate that the addition reaction of hydrogen cyanide to an aliphatic or aromatic aldehyde predominates over the addition of benzamidine to the aldehyde, and that the hydroxyl group of the cyanhydrine formed

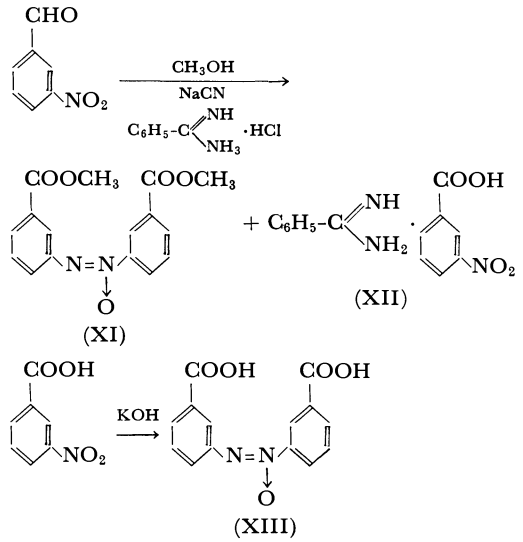
(XI)

was not replaced by the amino group of benzamidine, because of the lower nucleophilicity of benzamidine than that of ammonia. Under these conditions, benzamidine may be forced to react with the cyano group to form IVa. When R in IVa is aromatic, IVb would be more probable than IVa because of its larger degree of conjugation.

Since the carbon atom to which the hydroxyl group attaches in IV corresponds to the β-carbon atom of a vinylamine system, as in IVb, one of the tautomers of IV, this carbon atom may be attacked by a nucleophile only with great difficulty. For this reason, the nucleophilic attack of the hydroxyl group on the carbon atom of the amidino group would occur more easily to produce an oxazole ring. When R in IVa is aliphatic, the IVb tautomer is not always more favorable than IVa, and IVa may react with another molecule of benzamidine to form triazine derivatives, VIIa and VIIb.



m-Nitrobenzaldehyde in aqueous methanol reacted with sodium cyanide in the presence of an equimolar amount of benzamidine hydrochloride in a manner completely different from that in the reactions described above. In this case, dimethyl azoxybenzene-3, 3'-dicarboxylate (XI) and benzamidinium nitrobenzoate (XII) were produced. However, in this reaction benzamidine seems to act only as a base, because *m*-nitrobenzaldehyde and sodium cyanide in methanol without benzamidine hydrochloride also reacted to yield the same compound, XI. Compound XI was hydrolysed to azoxybenzene-3,3'-carboxylic acid (XII), which was identified by comparison with an authentic sample prepared from *m*-nitrobenzoic acid and potassium hydroxide.

Though the reaction of nitrobenzaldehyde with sodium cyanide seems to be very interesting, the details of this reaction will be reported elsewhere, for this reaction has no relation with the subject reported on this paper.

Experimental

General Method for the Preparating of Oxazole Derivatives. A solution of an aldehyde (0.02—0.04 mol) in methanol (10 m*l*) and a solution of sodium cyanide (0.01 mol) in water (20 m*l*) were mixed with a solution of benzamidine hydrochloride (0.1 mol) in methanol under ice-cooling, after which the reaction mixture was allowed to stand for few days. After about one day a small amount of crystals precipitated. After standing for three days, the crystals precipitated were collected by filtration and recrystallized from the solvents shown in Table 1. The melting points, the yields, and the results of the elemental analyses of the products obtained are shown in Table 1.

Hydrolysis of the Oxazole Derivatives. *a) Under Mild Conditions.* A solution of VIa (103.2 mg) in 50 m*l* of 2 N hydrochloric acid and a small amount of methanol was mixed with a saturated solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid. After the mixture has stood for 24 hr at room temperature while being stirred, benzaldehyde 2,4-dinitrophenylhydrazone was collected by filtration and weighed (94.6 mg, yield, 95%) after drying.

b) Under Severe Conditions. The steam distillation of a mixture consisting of 3.3 g (0.01 mol) of VIa and 20 m*l* of concentrated hydrochloric acid gave at first about 0.7 g (0.007 mol) of benzaldehyde. After the complete distillation of the benzaldehyde, benzoic acid was distilled out gradually; the total amount was 1.1 g (0.009 mol). The residue of distillation was evaporated to dryness, and the residue was extracted with ether to give 1.1 g (0.007 mol) of mandelic acid. The benzoic acid and mandelic acid obtained above were identified by comparison with respective authentic samples, while the benzaldehyde obtained was identified as its 2,4-dinitrophenylhydrazone.

c) Hydrolyses of VIb and VIc under Mild Conditions. Hydrolyses of VIb and VIc were performed similarly to that of VIa. *p*-Chlorobenzaldehyde 2,4-dinitrophenylhydrazone was obtained from VIb in a yield of 92%, while furfural 2,4-dinitrophenylhydrazone was obtained from VIc in a yield of 71%.

A General Method for the Preparation of *α*-Hydroxyalkyldiphenyl-*s*-triazine (VII). A solution of 0.04 mol of sodium cyanide (1.6 g) in 10 m*l* of water was added, portion by portion and under ice-cooling, to a solution of 0.07 mol of an aliphatic aldehyde in 10 m*l* of methanol. Into this mixture there was then stirred, drop by drop, under ice-cooling, a

TABLE 1

	Yield (%)	Mp °C	Solvent for recrystallization	Analysis C%	Analysis H%	Analysis N%	λ_{max}^{EtOH} (mμ)	ε_{max}
VIa (R=C_6H_5)	32	156—157	Ethanol-Benzene	81.65 (81.46)	5.15 (4.97)	8.99 (8.64)	334	5.7×10^4
VIb (R=C_6H_4Cl*p*)	35	189—190	Ethanol-Benzene	67.26 (67.21)	3.43 (3.59)	6.90 (7.12)	337	2.6×10^4

Values in parentheses are calculated for $C_{22}H_{16}ON$ (VIa), $C_{22}H_{14}ONCl_2$ (VIb) and $C_{18}H_{12}O_3N_2$ (VIc).

TABLE 2.

Product	Yield, g (%)	Mp, °C	Mol Wt	Analysis C%	Analysis H%	Analysis N%
VIIa (R=H)	1.5 (34)	122—124	250*	72.33 (72.98)	5.15 (4.98)	15.50 (15.50)
VIIb (R=CH_3)	1.4 (31)	114—115	280**	73.37 (73.63)	5.46 (5.45)	14.97 (15.15)

* This value was measured by the depression of melting point of nitrobenzene.

** This value was measured by the depression of the melting point of benzene. Analytical values in parentheses are calculated for $C_{16}H_{13}ON_3$ (VIIa) and $C_{17}H_{15}ON_3$ (VIIb).

solution of 5.0 g of benzamidine hydrochloride in 10 m*l* of methanol, and then 20 m*l* of water were added. The stirring was continued for 1 hr, after while the reaction mixture was allowed to stand at room temperature for three days. The crystals precipitated were collected by filtration. The concentration of the filtrate gave a further small amount of the same crystals. These crystals were combined and recrystallized from an ethanol-water.

Acetylation of VII. A solution of 1.0 g of VIIa in 10 m*l* of dry benzene was mixed with 5 m*l* of acetic anhydride and then refluxed for 3 hr. The evaporation of the solvents gave crystals, which were then recrystallized from ethanol; mp 112—114°C, yield 69%.

Found: C, 70.74; H, 4.86; N, 13.39%. Calcd for $C_{18}H_{15}O_2N_3$: C, 70.80; H, 4.95; N, 13.76%.

An attempt to prepare the acetyl derivative of VIIb was unsuccessful; only the starting material was recovered in a yield of 80%.

Preparation of Phenylurethane of VIIb. A mixture of VIIb (0.5 g), phenylisocyanate (0.3 m*l*), pyridine (one drop), and dioxane (5 m*l*) was warmed for 30 min. The solvent was evaporated to give colorless needles with a mp of 169—170°C. The yield was 0.5 g (70%).

Found: C, 72.46; H, 5.32; N, 14.02%. Calcd for $C_{24}H_{20}O_2N_4$: C, 72.71; H, 5.09; N, 14.13%.

Oxidation of VIIa and VIIb to VIII with Potassium Permanganate. A solution of potassium permanganate (0.5 g) and potassium hydroxide (0.5 g) in 20 m*l* of water was mixed with VIIa (0.1 g), and the resulting mixture was refluxed for 2 hr. The reaction mixture was filtered while hot. When the filtrate was cooled, potassium diphenyl-*s*-triazinecarboxylate was obtained as a precipitate. The acidification of the filtrate yielded a precipitate of diphenyl-*s*-triazinecarboxylic acid, which was identified by comparison with an authentic sample of this acid, which had been prepared by oxidation of methyldiphenyl-*s*-triazine[2] with potassium permanganate (which had in turn been prepared from benzamidine hydrochloride and acetic anhydride by the method described in the literature[2]).

Preparation of Dimethyl Azoxybenzene-3,3'-dicarboxylate (XI). *a) In the Presence of Benzamidine.* A solution of sodium cyanide (0.04 mol) in water (10 m*l*) was added, drop by drop, to a solution of *m*-nitrobenzaldehyde (4.53 g, 0.03 mol) in methanol (70 m*l*), and then to this mixture there was added a solution of benzamidine hydrochloride (5.0 g, 0.03 mol) in methanol (10 m*l*). The reaction mixture was stirred at 35—40°C for 4 hr. The crystals which precipitated on cooling were recrystallized from ethanol-benzene to produce 0.9 g of colorless needles with a mp of 132—133°C.

Found: C, 61.36; H, 4.47; N, 8.60%. Calcd for $C_{16}H_{14}O_5N_2$: C, 61.14; H, 4.49; N, 8.91%.

The filtrate was evaporated to dryness, and the solid obtained was recrystallized from ethanol to give benzamidinium *m*-nitrobenzoate with a mp of 237—239°C (yield 5.0 g, 60%).

Found: C, 58.54; H, 4.61; N, 14.85%. Calcd for $C_{14}H_{13}O_4N_3$: C, 58.53; H, 4.56; N, 14.63%.

b) In the Absence of Benzamidine. Sodium cyanide (1.0 g, 0.025 mol) was added to a solution of *m*-nitrobenzaldehyde (1.0 g, 0.007 mol) in methanol (20 m*l*). After the addition was complete, an exothermic reaction soon began to take place and a large amount of a pale yellow powder started to precipitate. After the heat evolution had ceased, the precipitates were collected by filtration, washed thoroughly with water, and recrystallized from an ethanol-benzene mixture to produce colorless needles with a mp of 132—133°C in a yield of 70%. The needles showed no depression upon a mixed-melting-point determination with Compound XI, obtained above. The aqueous solution which had been obtained by washing the precipitate was acidified with hydrochloric acid to give a small amount of *m*-nitrobenzoic acid (mp 140—141°C), which was identified by comparison with an authentic sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1372—1375 (1968)

Syntheses of Some Heterocyclic Compounds from α-Benzoyliminobenzyl Cyanide and Related Compounds*1,*2

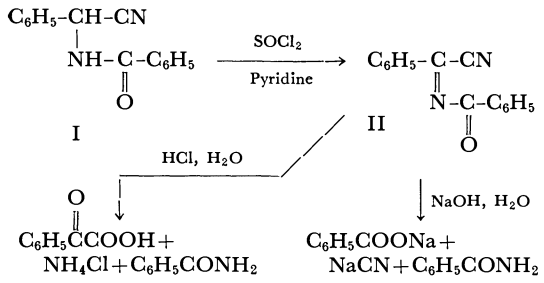
Masahiro FUJIMORI, Eiichi HARUKI and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received October 25, 1967)

The reaction of α-benzamidobenzyl cyanide (I) with thionyl chloride and pyridine in benzene gave α-benzoyliminobenzyl cyanide (II) in a 52% yield. II is a novel compound which can react readily with nucleophilic reagents, such as alcohols, mercaptans and amines. The reaction of II with ethyl-mercaptan and with alcohols gave α-ethylthio-α-benzamidobenzyl cyanide and α-alkoxy-α-benzamidobenzyl cyanide respectively. Furthermore, II reacts with bifunctional nucleophilic reagents to form heterocyclic compounds. The reaction of II with hydrazine and with hydroxylamine afforded 3,5-diphenyl-1,2,4-triazole and 3,5-diphenyl-1,2,4-oxadiazole respectively.

During the course of investigations concerning the reactions of α-aminonitriles, we happened to find a novel method for the preparation of α-benzoyliminobenzyl cyanide (II) from α-benzamidobenzyl cyanide (I) and thionyl chloride in pyridine. The structure of II was confirmed by the following experimental evidence: (i) The infrared spectrum shows the presence of C=N and C≡N bonds at 1620 and 2250 cm^{-1}, but shows no N–H bond near 3200 cm^{-1}. (ii) An acid hydrolysis of II with hydrochloric acid gave benzoylformic acid (62.5 mol%), benzamide (9.7 mol%), and a small amount of ammonium chloride. (iii) An alkaline hydrolysis of II gave benzoic acid (105.3 mol%) and benzamide (42.6 mol%), along with a small amount of sodium cyanide, as is shown below:



The formation of II is obviously due to the oxidation of I with thionyl chloride, even though the products derived from thionyl chloride could not be identified. Only a few reactions in which thionyl chloride acts as an oxidizing agent have been reported.[1-4] Hence, sulfuryl chloride, the oxidizing ability of which is usually stronger than that of thionyl chloride, was used for the above reaction instead of thionyl chloride. However, the yield of II was only 5%, and 70—75% of the starting material was recovered, as Table 1 shows. *N*-Bromosuccinimide (NBS) or *t*-butyl hypochlorite was also used as the oxidizing agent for the above reaction. As is shown in Table 1, *t*-butyl hypochlorite produced II in a yield of 51%, but NBS did not.

Table 1. Oxidation of α-benzamidobenzyl cyanide (I)

Oxidizing agent	Reaction temp (°C)	Yield of II (%)	I. Recovered (%)
Thionyl chloride	0—5	52	0
Thionyl chloride	Room temp.	2	0
Sulfuryl chloride	0—5	5	70
Sulfuryl chloride	Room temp.	5	70
Sulfuryl chloride	50—60	11	62
t-Butyl hypochlorite	Room temp.	51	0
NBS	Room temp.	0	55
NBS	50—60	0	52

It seems to be very strange that no α-acyliminobenzyl cyanide, represented by II, has ever been prepared in spite of the simplicity of its structure. Compound II has three carbon atoms, indicated by Gothic letters in Formula II, which a nucleophilic reagent may attack. We studied the reactions of II with several nucleophiles. The results

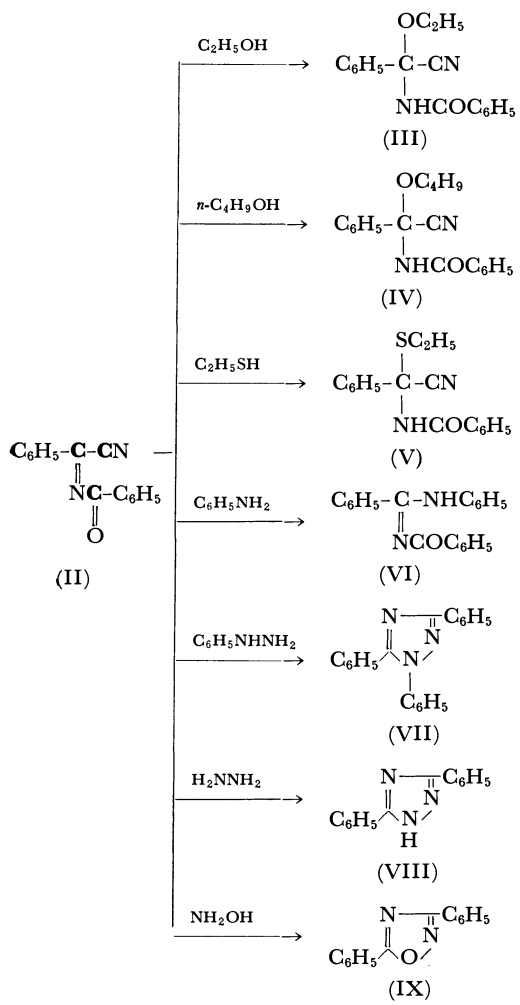
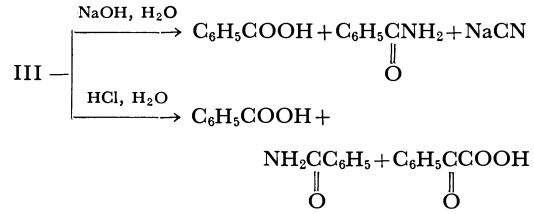
are shown in the following scheme:

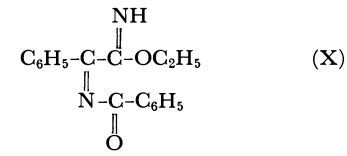


Alcohols and thioalcohols attacked the α-carbon atom of II and added to the C=N bond. Similarly, an amine attacked the cyano group, as aniline produced VI in a 65% yield as a result of the reaction with II. The bifunctional nucleophilic reagents, such as hydrazines and hydroxylamines, form 1,2,4-triazoles (VII) and (VIII) or oxadiazoles (IX) respectively. This reaction may be caused by a substitution of the cyano group with the amino group, followed by a cyclization between the carbonyl carbon and the amino or the hydroxyl group. All these cyclization reactions are, of course, novel reactions.

The structures of Compounds, VI, VII, VIII, and IX were confirmed by a comparison of their properties with those of authentic samples. The structures of Compounds, III, IV, and V were unknown. Hence, their structures were confirmed by elemental analyses, by a study of their infrared spectra, and by the results of the acid and alkaline hydrolysis described below:



If the reaction between ethanol and II does not form Compound III, but forms another compound such as Compound X, which is formed by the addition of ethanol to the cyano group, Compound X, an imino ether, must be very unstable toward water and must be hydrolyzed quickly.



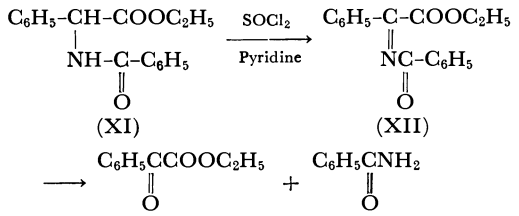
The actuality was opposite, in fact. The compound obtained from ethanol and II was not hydrolyzed at all but was recovered in a quantitative yield after having been treated with a water-ethanol mixture for 6 hr at 40—50°C. Therefore, Compound III does not have the structure of X. The structure of IV was also confirmed by methods similar to those used in the determination of III. The structure V was assumed on the basis of the data of elemental analyses, the presence of the N–H and C≡N groups in the infrared spectrum, and the similarity of the chemical behavior of thioalcohol to that of alcohol on a nucleophilic reaction.

The starting material for the above reaction, α-benzamidobenzyl cyanide, was prepared by the benzoylation[5] of α-aminobenzyl cyanide, which can be prepared easily from benzaldehyde, hydrogen cyanide, and ammonia. Another kind of α-(benzoylamino)-nitrile could be obtained by the *N*-benzoylation of the α-aminonitriles, when aldehydes other than benzaldehyde were used for the preparation of an α-aminonitrile. We tried to prepare α-benzamidopropionitrile from acetaldehyde, but this attempt failed.

Next, we prepared α-acetamidobenzyl cyanide and carried out its reaction with thionyl chloride in pyridine, but no crystalline product was obtained from the reaction mixture. Furthermore, we tried to react thionyl chloride with ethyl α-benzamidophenylacetate,[6] (XI), in which the cyano group is replaced by the ethoxycarbonyl group; we thus obtained ethyl α-benzoyliminophenyl acetate, (XII), in a yield of 18%, together with ethyl benzoylformate and benzamide. Ethyl benzoylformate and benzamide must be formed by the

5) R. Ruggeri and G. Rigoli, *Gazz. Chim. Ital.*, **54**, 555 (1924); *Chem. Abstr.*, **19**, 262 (1925).
6) A. Kossel, *Ber.*, **24**, 4151 (1901).

oxidation of XI with thionyl chloride, followed by the hydrolysis of the C=N bond:



From the above observations, it may be concluded that the oxidation with thionyl chloride would be facilitated by the benzoyl group attached to the amino group, and also be favored by the aryl group attached to the α-carbon atom in II. Furthermore, among the compounds of the II type, II was the only one which was accessible. It is, therefore, unlikely, in view of these limitations, that the reaction is of general utility for the synthesis of α-acyliminonitriles from α-acylamidonitriles.

However, the reactions are still of considerable interest in that thionyl chloride acts as an oxidizing reagent for the conversion of the acylamino group into the acylimino group in α-acylaminonitriles. The mechanism of this oxidation reaction is not at all clear. One can postulate that the active hydrogen atom attached to the α-carbon of Compound II is responsible in some manner for this oxidation. This postulation prompted us to examine the reaction of the three compounds, ethyl benzamidoacetate, diethyl acetamidomalonate, and, *N*-benzoylbenzylamine, all of which have an active hydrogen atom, with thionyl chloride. However, in no case was the expected reaction product obtained.

Experimental

The melting points and boiling points were not corrected. The molecular weights were measured with Hitachi Perkin-Elmer 115 Molecular Weight Apparatus, using benzene as the solvent.

α-Benzoyliminobenzyl Cyanide (II). To a solution of α-benzamidobenzyl cyanide (I) (5.0 g, 0.021 mol) in dry benzene (40 m*l*), there was added dry pyridine (3 m*l*) and then thionyl chloride (3.0 g, 0.026 mol), drop by drop, at 0—5°C. The mixture was stirred at this temperature for 3 hr and then left to stand overnight at room temperature. The precipitate pyridinium hydrochloride, was collected by filtration and washed with a small amount of dry benzene. After the combined filtrate had been concentrated under reduced pressure at 30—40°C, the solid residue obtained was recrystallized from ligroin to give α-benzoyliminobenzyl cyanide (II) (2.6 g, 52%), mp 80—82°C (decomp.).

Found: C, 76.93; H, 4.27; N, 11.80%; mol wt, 248. Calcd for $C_{15}H_{10}ON_2$: C, 76.91; H, 4.30; N. 11.96%; mol wt, 234.

Acid Hydrolysis of α-Benzoyliminobenzyl Cyanide (II). α-Benzoyliminobenzyl cyanide (1 g, 0.0043 mol) was dissolved in a mixture of 15 m*l* of 6 N hydrochloric acid and 15 m*l* of dioxane, and the solution was stirred at 45—50°C for 6 hr. After the reaction mixture had been concentrated *in vacuo* at 30—40°C, the viscous residue was mixed with 30 m*l* of water and extracted with ether. The ethereal extract was evaporated and treated with a solution of 2,4-dinitrophenylhydrazine in a dilute hydrochloric acid; benzoylformic acid 2,4-dinitrophenylhydrazone (0.85 g, 0.0027 mol) was thus obtained. The 2,4-dinitrophenylhydrazone obtained was recrystallized from ethanol, mp 180—185°C (decomp.). Its mixed melting point with an authentic sample showed no depression and its infrared spectrum coincided with that of the authentic sample. The aqueous layer was evaporated *in vacuo*, and the residue obtained was washed with a small amount of benzene to obtain ammonium chloride (0.12 g, 0.0024 mol). The evaporation of the benzene gave benzamide (0.05 g, 0.0004 mol).

Alkaline Hydrolysis of α-Benzoyliminobenzyl Cyanide (II). α-Benzoyliminobenzyl cyanide (1 g, 0.0043 mol) and sodium hydroxide (1 g, 0.025 mol) were dissolved together in a mixture of 15 m*l* of water and 15 m*l* of dioxane, and the solution was stirred at 45—60°C for 6 hr. After the evaporation of the solvent from the reaction mixture *in vacuo*, the solid residue was washed with 20 m*l* of water and separated by filtration, thus giving benzamide (0.22 g, 0.0018 mol). The acidification of the filtrate with 10 m*l* of 6 N hydrochloric acid gave benzoic acid (0.55 g, 0.0045 mol).

Hydrolysis of α-Benzoyliminobenzyl Cyanide (II) in a Neutral Medium. α-Benzoyliminobenzyl cyanide (0.5 g, 0.0021 mol) was dissolved in a mixture of 5.0 m*l* of water and 15 m*l* of dioxane, and the solution was stirred at 45—50°C for 6 hr. The reaction mixture was evaporated *in vacuo*, and the residue obtained was washed with 10 m*l* of a 10% aqueous solution of sodium carbonate. The insoluble crystals, benzamide (0.22 g, 0.0018 mol), were collected by filtration. The acidification of the filtrate with 6 N hydrochloric acid gave benzoic acid (0.25 g, 0.0020 mol).

α-Ethoxy-α-benzamidobenzyl Cyanide (III). α-Benzoyliminobenzyl cyanide (1.0 g, 0.0043 mol) was dissolved in absolute ethanol (20 m*l*), and the solution was refluxed for 3 hr. After the reaction mixture had been cooled in an ice bath, the precipitates were collected by filtration and recrystallized from 99% ethanol. Needle crystals of α-ethoxy-α-benzamidobenzyl cyanide melting at 153—154°C (decomp.) were thus obtained. Yield, 92%.

Found: C, 72.76; H, 5.67; N, 9.73%; mol wt, 291. Calcd for $C_{17}H_{16}O_2N_2$: C, 72.84; H, 5.75; N, 9.99%; mol wt, 280.

Acid Hydrolysis of α-Ethoxy-α-benzamidobenzyl Cyanide. α-Ethoxy-α-benzamidobenzyl cyanide (1 g, 0.0036 mol) was dissolved in a mixture of 15 m*l* of 6 N hydrochloric acid and 15 m*l* of dioxane, and the solution was stirred at 45—50°C for 6 hr. Benzoylformic acid 2,4-dinitrophenylhydrazone was obtained by treating a small portion of the reaction mixture with an acidic solution of 2,4-dinitrophenylhydrazine. Another portion of the reaction mixture was evaporated, and the residue obtained was washed with 20 m*l* of benzene to give ammonium chloride (0.15 g, 0.0028 mol). The benzene extract was washed with 10 m*l* of a 10% aqueous solution of sodium carbonate. The concentration of the benzene extract gave benzoic acid (0.4 g, 0.0033 mol).

Alkaline Hydrolysis of α-Ethoxy-α-benzamidobenzyl Cyanide. α-Ethoxy-α-benzamidobenzyl cyanide (1 g, 0.0036 mol) and sodium hydroxide (1 g, 0.025 mol) were disolved in a mixture of 15 m*l* of water and 15 m*l* of dioxane, and the solution was stirred at 45—50°C for 6 hr. After the reaction mixture had been evaporated *in vacuo*, the residue obtained was washed with 20 m*l* of water to give benzamide (0.22 g, 0.0018 mol). The acidification of the aqueous filtrate with 10 m*l* of 6 N hydrochloric acid evolved hydrocyanic acid, which was recognized by its characteristic odor and which gave benzoic acid (0.55 g, 0.0045 mol).

α-*n*-Butoxy-α-benzamidobenzyl Cyanide (IV). α-Benzoyliminobenzyl cyanide (0.5 g, 0.0021 mol) was dissolved in a 20 m*l* of *n*-butyl alcohol, and the mixture was stirred at 80—90°C for 3 hr. After standing in an ice-bath for 6 hr, the reaction mixture gave a precipitate of α-*n*-butoxy-α-benzamidobenzyl cyanide (0.12 g). The concentration of the filtrate *in vacuo* gave an addition 0.47 g of the same product. The total yield was 0.59 g (0.0019 mol, 90%). Recrystallization from carbon tetrachloride gave colorless needle crystals with a mp of 125—127°C.

Found: C, 73.68; H, 6.61; N, 9.07%. Calcd for $C_{19}H_{20}O_2N_2$: C, 74.00; H, 6.54; N, 9.09%.

α-Ethylthio-α-benzamidobenzyl Cyanide (V). A solution of α-benzoyliminobenzyl cyanide (1 g, 0.0043 mol) and ethyl mercaptan (1 g, 0.016 mol) in dioxane (15 m*l*) was stirred at 50—60°C for one hour. The subsequent concentration of the reaction mixture gave colorless needle crystals of α-ethylthio-α-benzamidobenzyl cyanide. Mp 159—161°C after recrystallization from benzene.

Found: C, 68.91; H, 5.48; N, 9.71%. Calcd for $C_{17}H_{16}ON_2S$: C, 68.90; H, 5.44; N, 9.45%.

***N*-Benzoyl-*N'*-phenylbenzamidine (VI).** After a solution of α-benzoyliminobenzyl cyanide (0.5 g, 0.0021 mol) and aniline (1 g, 0.011 mol) in 15 m*l* of dioxane had been stirred at 80—90°C for 3 hr, the reaction mixture was concentrated *in vacuo*. The recrystallization of the residue from ethanol gave *N*-benzoyl-*N'*-phenylbenzamidine (0.42 g, 0.0014 mol, 65%), mp 140—141°C (lit.,[7] 141°C). Admixture with an authentic sample[7] showed no depression of the melting point, and the infrared spectrum coincided with that of the authentic sample.

Found: C, 79.78; H, 5.47; N, 9.28%. Calcd for $C_{20}H_{16}ON_2$: C, 79.98; H, 5.37; N, 9.33%.

1,3,5-Triphenyl-1,2,4-triazole (VII). After a solution of α-benzoyliminobenzyl cyanide (2 g, 0.008 mol) and phenylhydrazine (2.0 g, 0.019 mol) in dioxane (40 m*l*) had been stirred at 70—80°C for 2.5 hr, the reaction mixture was concentrated *in vacuo*; the viscous residue thus obtained was recrystallized from ethanol to give 1,3,5-triphenyl-1,2,4-triazole (2.1 g, 0.0072 mol, 83.9%). Mp 103—104°C (lit.,[8] 104°C). No depression of melting point was observed on admixture with an authentic specimen, and the infrared spectrum of the compound obtained was identical with that of the authentic specimen.

Found: C, 80.54; H, 5.06; N, 13.67%. Calcd for $C_{20}H_{15}N_3$: C, 80.78; H, 5.09; N, 14.13%.

3,5-Diphenyl-1,2,4-triazole (VII). After a solution of α-benzoyliminobenzyl cyanide (2.0 g, 0.0086 mol) and hydrazine (1.0 g, 0.031 mol) in 40 m*l* of 99% ethanol had been stirred at 70—80°C for 2.5 hr, the reaction mixture was concentrated *in vacuo* to give a viscous residue. The residue was recrystallized from chloroform to produce 3,5-diphenyl-1,2,4-triazole (1.78 g, 0.0084 mol, 97.2%), mp 189—190°C (lit.,[9] 192°C). Admixture with an authentic sample showed no depression of the melting point, and the infrared spectrum was identical with that of the authentic sample.

Found: C, 75.85; H, 5.01; N, 18.69%. Calcd for $C_{14}H_{11}N_3$: C, 75.99; H, 5.01; N, 18.99%.

3,5-Diphenyl-1,2,4-oxadiazole (IX). A solution of hydroxylamine hydrochloride (1 g, 0.014 mol) in methanol (15 m*l*) was neutralized by a solution of sodium methoxide in methanol which had been prepared from sodium (0.33 g, 0.0014 gram atoms) and methanol (10 m*l*). The sodium chloride which precipitated was removed by filtration, and the filtrate was mixed with α-benzoyliminobenzyl cyanide (1 g, 0.0043 mol). The mixture was stirred at 50—60°C for 2 hr and then cooled to give precipitates. The precipitates were collected by filtration and recrystallized from ethanol. Mp 106—107°C (Needle crystals). A mixed-melting-point determination with an authentic sample[10] showed no depression and the infrared spectra was identical with that of the authentic sample.

Found: C, 75.70; H, 4.41; N, 12.41%. Calcd for $C_{14}H_{10}ON_2$: C, 75.65; H, 4.54; N, 12.61%.

Ethyl α-Benzoyliminophenylacetate (XII). To a solution of ethyl α-benzamidophenylacetate (XI) (25 g, 0.088 mol) in dry benzene (200 m*l*), there was added pyridine (40 m*l*) and then thionyl chloride (30 g, 0.25 mol), drop by drop, at room temperature. The mixture was stirred at 70—80°C for 6 hr. After the removal of the pyridinium hydrochloride by filtration, the filtrate was evaporated to afford a viscous residue. The distillation of the residue under a reduced pressure gave two fractions. The first fraction (bp 90—100°C/1.0 mmHg) consisted of ethyl benzoylformate, which showed the same infrared spectrum as that of an authentic sample. The second fraction (bp 165—180°C/1.0 mmHg) was a yellow oil, which solidified partly upon standing overnight. The filtration of the oily solid gave benzamide (2.0 g, 0.0165 mol). The distillation of the filtrate gave 4.5 g of pure ethyl α-benzoylimidophenyl acetate (X), which was hydrolyzed very quickly by moisture in air to ethyl benzoylformate and benzamide. The elemental analyses were carried out immediately after the distillation.

Found: C, 72.80; H, 5.45; N, 4.80%. Calcd for $C_{17}H_{15}O_3N$: C, 72.58; H, 5.37; N, 4.98%.

The Reaction between Hydrocarbon and Hydrogen Cyanide in Silent Electrical Discharge. I. The Formation of Cyclohexyl Cyanide from Cyclohexane and Hydrogen Cyanide*1

Kazuaki KAWAMOTO,*2 Noboru SONODA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received November 13, 1967)

In order to examine the possibility of the direct introduction of a cyano radical into cyclohexane by means of silent discharge, a mixture of cyclohexane and hydrogen cyanide was discharged in an ozonizer under various conditions. As a result, cyclohexyl cyanide was obtained. The yield of cyclohexyl cyanide depended upon the voltage of discharge, the residence time in the discharge tube, the temperature of the discharge tube, and the structual characteristics of the apparatus. In the refluxing method the maximum yield of cyclohexyl cyanide was obtained when the discharge was carried out at a low temperature. Besides cyclohexyl cyanide, the reaction products were confirmed to consist of bicyclohexyl, cyclohexene, methylcyclohexane, ethylcyclohexane, 3-cyclohexylcyclohexene, methylenecyclohexane, 1-hexene, *n*-hexane, *n*-pentane, methylcyclopentane, a solid brown deposit, and cracked gas. The principal reactions can be interpreted as being the formation of cyclohexyl and cyano radicals and the combination of these radicals, their dehydrogenation, their isomerization, their polymerization, and their decomposition.

In recent years, the oxidation of hydrocarbons by silent electrical discharge has been studied by Sugino *et al.*[1] However, no detailed study of the interaction of hydrocarbons and hydrogen cyanide under silent discharge has yet been reported. The synthesis of the cyano-compounds formed by the direct combination of these compounds in the silent discharge seems to be interesting and important from both the practical and the theoretical points of view.

The direct synthesis of cyclohexyl cyanide from cyclohexane and cyano-compounds has been attempted by several chemists: It was found by Müller and Huber[2] that cyclohexyl cyanide was obtained by the reaction of cyclohexane with cyanogen chloride upon irradiation with ultraviolet light. McKusick *et al.*[3] found that the irradiation of a mixture of cyclohexane and hydrogen cyanide with high-energy electrons led to cyclohexylnitriles. Grof[4] found that the reaction of cyclohexane with cyanogen chloride in the presence of peroxide ($C_6H_{11}SO_3OAc$) gave cyclohexyl cyanide. It was found by one of the present authors[5] that, when the irradiation of a solution of ethyl cyanoformate in cyclohexane by a 600 W high-pressure mercury arc lamp was carried out at room temperature, the direct-introducing reaction of cyano and ethoxycarbonyl radicals took place.

The present study was undertaken to find out whether or not the direct formation of cyclohexyl cyanide results from the reaction between cyclohexane and hydrogen cyanide occurring in the silent discharge; to determine, if possible, the optimum conditions for the preparation of cyclohexyl cyanide, and at the same time to ascertain the mechanism of this reaction. In this research, the silent discharge was carried out by three methods (passing, bubbling, and refluxing methods; see Experimental section) in a Siemen ozonizer for 5 hr, using voltages from about 12 to 15

kilovolts and frequency of 60 cycles per second. Furthermore, the effect of the temperature of the discharge tube was investigated, and a large number of reaction products were examined in detail.

Experimental

Materials. The cyclohexane used in this experiment was purified according to the procedure of Ho and Freeman:[6] bp 80—81°C, n_D^{25} 1.4226, d_4^{25} 0.7666. The hydrogen cyanide was prepared according to the procedure of Brauer.[7] Purification was carried out by passing the substance over calcium chloride (E) and phosphorus pentoxide (F), as in Fig. 1. In each experiment, about a 2-mol portion of hydrogen cyanide was used.

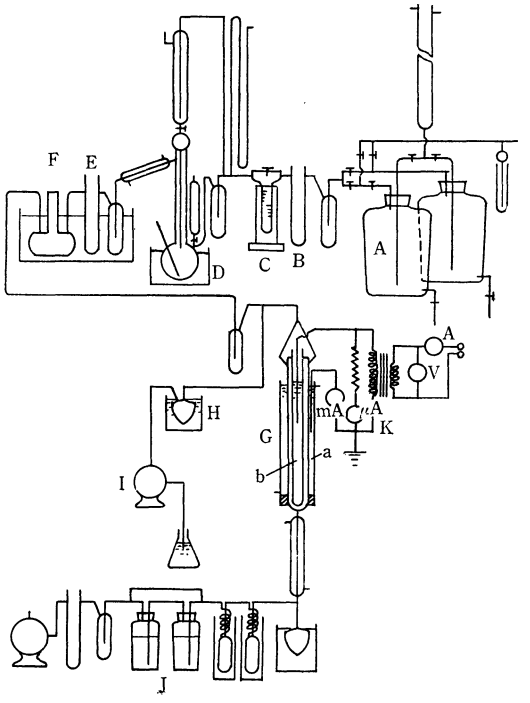

Fig. 1. Apparatus used in the passing method.

Apparatus. The apparatuses illustrated in Figs. 1, 2, and 3 were used. (1) Helium coming from a reservoir (A) was passed over calcium chloride (B), and the helium flow was measured by passing it through a calibrated flow meter (C). (2) The hydrogen cyanide was prepared in a flask (D) according to Brauer's method.[7] (3) The outside (a) of the discharge tube was filled with water, and the inner tube (b), with a 3% $CuSO_4$ solution. (4) In both the passing method and the refluxing method, the discharge tube (G) used was a Pyrex tube 40 cm in effective length, 4 cm in outside diameter, and with a space gap of 0.25 cm. In the case of the bubbling method, the central glass tube shown in Fig. 2 was 2.4 cm in diameter, and this tube was enclosed in a Pyrex tube 3.3 cm in diameter and 2 mm thick. A spiral glass stick was inserted in the space gap (0.25 cm). (5) Cyclohexane was vaporized through a vaporizer (H); the rate of the flow of the cyclohexane can be kept approximately constant by the use of a pump (I). (6) Unchanged hydrogen cyanide was absorbed in two bottles (J) (containing a mixture of NaOH and $Fe_2(SO_4)_3$). (7) The electrical energy was supplied by a 15-kV transformer (K).

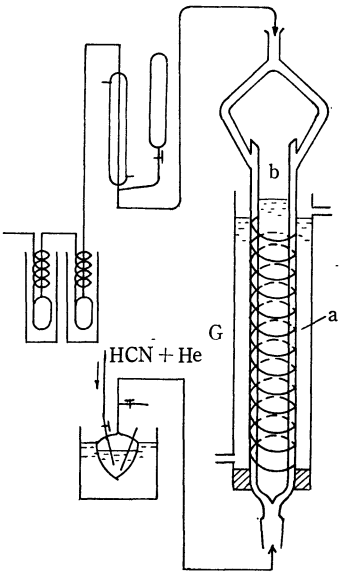

Fig. 2. Discharge tube used in the bubbling method.

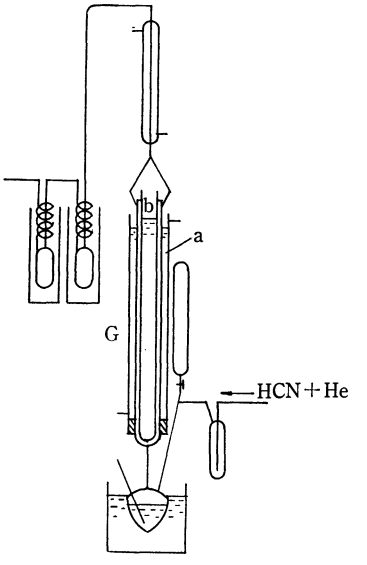

Fig. 3. Apparatus used in the refluxing method.

Procedure. In the passing method, helium, as the carrier gas, was passed through the discharge tube at a constant velocity, and the vaporizer (H) was heated at 150°C. The discharge tube was then heated to the

operating temperature. Cyclohexane and hydrogen cyanide were passed through the tube at a regular velocity for the period of the reaction. A current of 60 cycles was then sent through a voltage regulator, and the voltage was stepped up by a transformer in order to give it the necessary value. The products coming out of the discharge tube were condensed by passing them through a condenser, then they were cooled by being passed through two traps to 7°C, thus catching almost all of the unreacted cyclohexane, together with the reaction product. The liquid products were analyzed by the method described below, while the noncondensable gas was analyzed by gas chromatography at intervals of 30 min. In the bubbling method, the discharge tube and a round flask attached to it were filled with cyclohexane. A gas mixture of hydrogen cyanide and helium was bubbled into cyclohexane at a constant rate of flow. In the refluxing method, cyclohexane was boiled in a round flask attached to discharge tube. A gas mixture of hydrogen cyanide and helium was then flowed into the cyclohexane flask at a constant velocity. The discharge was carried out as in the case of the passing method.

Analysis of the Products. The reaction products were identified by comparing their retention times on gas chromatography with those of authentic samples.*3 (Columns of tricresyl phosphate, PEG 6000, and silicone DC 550 were used.) In addition, the reaction products were dried with anhydrous sodium sulfate and then fractionally distilled, and the constituents of the cut were identified b means of the derivatives formed.

Cyclohexyl cyanide was obtained in a fraction boiling at 180—188°C. From this fraction, the *p*-bromophenacyl ester of cyclohexanecarboxylic acid,*4 mp 92—93°C, and cyclohexanecarboxamide,*5 mp 184—185°C, were obtained. They showed no depression of their melting points when mixed with authentic synthesized specimens. The infrared spectrum of this fraction agreed with that of authentic cyclohexyl cyanide.

The quantitative analysis of the reaction products in this experiment was performed by gas chromatography. The gaseous products were also analyzed by gas chromatography. (Columns of activated charcoal, tricresyl phosphate, Molecular Sieve 13 X, and dimethyl sulfolane were used.) In both the passing method and the refluxing method, a solid brown deposit was formed on the glass wall of the ozonizer. This deposit dissolved in acetone, but its constitution was not determined.

Results and Discussion

The influence of the discharge conditions on the reaction between cyclohexane and hydrogen cyanide was examined. When the experiments were carried out under the conditions listed in Table 1, a large number of compounds were obtained as well as cyclohexyl cyanide, the object substance. Those of these compounds which have been identified are summarized in Table 2. The percentage of the compound shown in this table does not necessarily represent the maximum yield, but is an average of three experiments under constant operating conditions. However, the fluctuation in the yield of these compounds obtained in repeated experiments was less than 1 per cent. Since this discharge does not occur in the high temperature zone, the thermal pyrolysis of cyclohexane can not occur in this experiment. When the liquid products obtained by both the passing method and the refluxing method absorbed oxygen from the air, they were transformed into the solid products. The gaseous products given by the reaction of cyclohexane and hydrogen cyanide or cyclohexane alone consisted of hydrogen, methane, ethane, ethylene, acetylene, propane, propylene, *n*-butane, 1-butene, and 1,3-butadiene. The gaseous products could not be determined quantitatively. These hydrocarbons were considered to be decomposition products of activated cyclohexane. It has been found that a mixture of cyclohexane and hydrogen cyanide decomposes more violently than does cyclohexane alone, and that a portion of the energy is consumed, resulting in a rise in the temperature of the discharge wall.

Influences of the Discharge Temperatures and Voltages on the Reaction between Cyclohexane and Hydrogen Cyanide by Using the Passing Method. By running cyclohexane with hydrogen cyanide only one time in the ozonizer under the conditions described in Experiment Nos. 1, 2 and 4 of Table 1, these reactants were slightly converted to cyclohexyl cyanide, as is shown in Table 2. The yield of cyclohexyl cyanide depends upon the voltage and the temperature at which the discharge is carried out. It has been found that increasing the voltage increases the yield of cyclohexyl cyanide, and that cylohexyl cyanide is obtained when the ozonizer is kept "cold," while this compound is not formed when

*3 The authentic samples were prepared as follows: (1) Cyclohexyl cyanide was prepared according to the procedure of Tilford *et al.* (C. H. Tilford, M. G. Van Campen, Jr., and R. S. Shelton, *J. Am. Chem. Soc.*, **69**, 2902 (1947)). (2) Bicyclohexyl and 3-cyclohexylcyclohexene were prepared by Hickinbottom's method (W. J. Hickinbottom, "Reactions of Organic Compounds," Longmans, Green and Co., 3rd Ed., (1957), p. 56, 544). (3) Cyclohexene was prepared according to the procedure of Coleman and Johnstone (G. H. Coleman and H. F. Johnstone, "Organic Syntheses," Coll. Vol. I, 2nd Ed., p. 183 (1956)). (4) Methylenecyclohexane (bp 102—103°C, n_D^{20} 1.4494, d_4^{20} 0.8032) was given by the pyrolysis of cyclohexylmethyl acetate (bp 94—98°C/22 mmHg) prepared by refluxing cyclohexylcarbinol and acetic anhydride. The cyclohexylcarbinol (bp 91—96°C/22 mmHg) was prepared by the action of formaldehyde on cyclohexylmagnesium bromide. (5) The other authentic reagents used for the identification were commercial materials.

*4 The *p*-bromophenacyl ester of cyclohexanecarboxylic acid was prepared according to the procedure of Shriner *et al.* (R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," John Wiley & Sons, New York (1956), p. 200).

*5 Cyclohexanecarboxamide was prepared according to Radziszewski method (B. Radziszewski, *Ber.*, **18**, 355 (1885)).

*4 The unidentified product contained a brown solid.
T Trace

the ozonizer is kept "warm." Further, the liquid product obtained at a high-temperature discharge absorbed oxygen from the air quite readily and it was polymerized upon standing at room temperature. When materials were passed through at a high flow rate in the discharge tube, only a very small quantity of a solid was deposited.

The Reaction between Cyclohexane and Hydrogen Cyanide by Using the Bubbling Method. In the passing method, the solid brown deposit was alway formed on the glass wall; this seems to be the main reason for the decrease in the conversion of cyclohexane to cyclohexyl cyanide. Therefore, the glass wall of the discharge tube was covered with liquid cyclohexane and a gas mixture of hydrogen cyanide and helium was bubbled at a constant rate of flow into the liquid cyclohexane. A spiral glass stick was inserted in order to extend the residence time of the hydrogen cyanide vapor. In this case, a small amount of cyclohexyl cyanide was obtained, while little or no solid was formed.

Influence of the Discharge Temperatures on the Reaction between Cyclohexane and Hydrogen Cyanide by Using the Refluxing Method. As may be seen from Experiment Nos. 7 and 8 in Table 2, when the refluxing method

was used the yield of solid product increased with the rise in the discharge temperature. Thus, it may be said that a low temperature favors the formation of cyclohexyl cyanide.

There are differences between the refluxing method and the passing method. For instance, in the refluxing method, when the discharge was carried out at a low temperature, the maximum yield of cyclohexyl cyanide was obtained.

From the facts described above, the important variables may be said to be the voltage and the temperature of discharge, the residence time in the discharge tube, and the structual characteristics of the apparatus. By controlling these variables, the yield and the composition of the reaction product can be controlled to some extent.

The Mechanism of the Formation of Cyclohexyl Cyanide. It has been reported by Egloff *et al.*[8] that there are essential differences between thermal activation and electronic activation: In thermal activation energy must be put into the entire aggregation of molecules, but in electronic activation the electron collides with the electron which forms a part of the chemical bond. Devins and Burton[9] found that, in the decomposition of ammonia in an electric discharge at a pressure of 0.6 to 11mm, hydrazine and nitrogen (as well as hydrogen) were produced. In this reaction, they reported that, relative to the number of chemically important excited entities, the number of ionized molecules was very low. The formation of cyclohexyl cyanide by the reaction of cyclohexane with hydrogen cyanide in a silent discharge may be described as follows. The most striking characteristic of the action of the silent discharge on a mixture of cyclohexane and hydrogen cyanide seems to be the attack of the electron on the C–H linkage of cyclohexane and hydrogen cyanide molecules; that is to say, the electron collides with these materials and the activated molecules thus formed change into a cyclohexyl radical and a cyano radical. Cyclohexyl cyanide may be formed by a combination of these radicals. In addition, when cyclohexane alone was passed through the discharge tube, as is shown in Experiment No. 9 of Table 1, bicyclohexyl was obtained in poor yields. Accordingly, a part of the cyclohexyl radical seems to be formed by hydrogen abstraction from cyclohexane with a cyano-radical.

It is assumed that the cyclohexyl radical is the major active particle formed in this discharge; the formations of cyclohexyl cyanide, bicyclohexyl, methylcyclohexane, and ethylcyclohexane seem to be due to the greater stability of this radical.

The Reaction Occurring in the Silent Discharge. Although the reaction between cyclohexane and hydrogen cyanide in an ozonizer is somewhat complicated by secondary reactions, the principal reactions seem to be as follows: (1) The formation of radicals to give cyclohexyl cyanide and bicyclohexyl. (2) The dehydrogenation of a portion of the cyclohexane to produce cyclohexene. (3) Decomposition to give methane, ethane, ethylene, acetylene, *etc.* (4) Polymerization to give a brown solid. (5) Isomerization to give methylcyclopentane and 1-hexene. Lind and Schultze[10] found that, when *n*-butane was treated in an ozonizer, isobutane was formed in the reaction products. In the present research, isomerization seems to occur. Further, a secondary reaction gave alicyclic hydrocarbons with a side chain, such as methylcyclohexane, ethylcyclohexane, and methylenecyclohexane. From the retention time of its gas chromatogram, vinylcyclohexane seems to be present in the unidentified products listed in Table 2.

Compared with olefines*6 (ethylene and propylene), cyclohexane is less reactive and therefore requires a more intense discharge to make it react at a usable rate. The reaction of cyclohexane alone in the silent discharge resembles the reaction by irradiation with ^{60}Co γ-rays.[6]

It is of interest that cyclohexyl cyanide can be prepared in one step from cyclohexane and hydrogen cyanide using the silent discharge at a low temperature.

(Received November 15, 1967)

An acidic part obtained from cow's urine was examined by gas-liquid chromatography. As the major components of the acidic part, benzoic acid, phenylacetic acid, β-phenylpropionic acid, and derivatives in which hydroxyl or methoxyl groups are attached to, respectively, *para*-, *ortho*-, and 3,4-positions of the aromatic ring were identified. It is conceivable that these compounds were mainly metabolic products of the phenylalanine, tyrosine, and 3,4-dihydroxyphenylalanine (DOPA). Moreover, a new metabolic pathway of phenylalanine and its derivatives was tentatively represented.

Urine contains a vast number of substances as intermediates and end-products in the metabolic pathways of both endogenous and exogenous compounds. Many of these compounds are of great interest in the metabolism of amino acids.

In previous papers,[1,2] the phenolic part obtained from Holstein urine has been examined. In this paper, an acidic part from the urine of Nihon-ushi (*Bos taurus* Linneaus) will be examined by gas-liquid chromatography.

Experimental

The gas-liquid chromatography were performed on a Yanagimoto type GCG-3 Gas Chromatograph, equipped with a thermal-conductivity detector. Column; Silicone SE-30 (25%) on 80—100 mesh Celite 545, 2 m×5

mmϕ: temperature 170°C; flow rate of hydrogen, 80 ml/min. The retention times were measured from the time of the injection to the initial emergence of the peaks.

Extraction of Urinary Compounds. Sodium chloride (200 g) was added to one liter of the fresh urine (pH 8.6) of a Nihon-ushi, and the pH was adjusted to 2.0 with 10% hydrochloric acid. The urine was extracted three times with 100 ml portions of ethyl acetate, and the extracts, containing acids, phenols, and neutral compounds, were washed three times with 100 ml portions of a saturated sodium bicarbonate solution. The sodium bicarbonate solution was then acidified with 10% hydrochloric acid and extracted with ethyl acetate. After drying over anhydrous sodium sulfate, the solution was evaporated to a brown solid with acidic compounds (6.8 g), which was then separated into an ethyl ether - soluble part (2.9 g) and

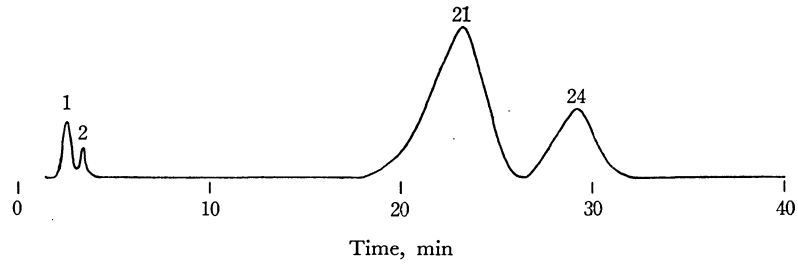

Fig. 4. Gas chromatogram of the methylesters of acidic part insoluble in ethyl ether.

an insoluble part (3.9 g). The fractionation of acidic, phenolic, and neutral part is shown in Fig. 1.

Determination of the Acidic Part Soluble in Ethyl Ether. The methylation of urinary carboxylic acids was carried out according to the following two methods: (1) The acidic part was refluxed with methanol in the presence of concentrated sulfulic acid, and (2) the acidic part was treated with ethereal diazomethane and methanol by the ordinary method. Both carboxylic groups and hydroxyl groups were also methylated by the latter method. Gas chromatograms of methylesters of the acidic part soluble in ethyl ether are presented in Fig. 2 (method 1) and Fig. 3 (method 2) respectively. The quantitative determination was carried out by measuring the peaks of Fig. 2 (triangulation method). When the peaks of Fig. 3 were compared with those of Fig. 2, it was found that there were clear differences between them. As is shown in Fig. 3, the 3, 9, 11, 13, 15, and 22 peaks decreased in area, while the 6, 6_1, 8, 10, 14, and 23 peaks increased; on the other hand, the 1, 2, 4, 5, 7, 12, 16, 17, 18, 19, 20, 21, 24, 25, 26, 27, and 28 peaks gave the same areas. These facts show that decreases in the areas in peaks are due to the presence of hydroxyl groups in urinary carboxylic acids.

The components were identified by comparing their retention times with those of authentic samples under the same conditions. The components of the acidic part obtained from cow's urine are shown in Table 1.

Determination of the Acidic Part Insoluble in Ethyl Ether. A gas chromatogram of the methyl esters of urinary acids insoluble in ethyl ether is shown in Fig. 4. The acidic part insoluble in ethyl ether was recrystallized from water, resulting in colorless needles with a mp of 186°C, and its infrared spectrum was perfectly identical with that of hippuric acid. Then the 21 peak was proved to be hippuric acid by comparing its gas chromatogram with that of an authentic sample.

On the hydrolysis of the same acidic part with 10% sodium hydroxide, followed by the identification of the components of the hydrolyzed products by the gas-liquid chromatographic method, benzoic acid and phenylacetic acid were proved to be the components. On the other hand, only glycine was proved to be present in the amino acid part by paper chromatography. Consequently, the 24 peak may be said to be due to phenacetyl glycine, which was proved to be another component of the acidic part.

Determination of the Phenolic Part Obtained from Cow's Urine. The determination of the phenolic part was carried out by means of a method previously reported.[1] The gas chromatogram and the components of the phenolic part are shown in Fig. 5 and Table 2 respectively.

Discussion

The following compounds were found in the acidic and phenolic parts of the cow's urine. The acidic components were benzoic acid, phenylacetic acid, β-phenylpropionic acid, *o*-hydroxybenzoic acid, *o*-methoxybenzoic acid, *p*-methoxybenzoic acid, *m*-methoxybenzoic acid, *p*-methoxyphenylacetic acid, *p*-hydroxybenzoic acid, *p*-hydroxyphenylacetic acid, *p*-methoxyphenylpropionic acid, *p*-hydroxyphenylpropionic acid, 3,4-dimethoxybenzoic acid, 3,4-dimethoxyphenylacetic acid, 3,4-dimethoxyphenylpropionic acid, *o*-hydroxyphenylpropionic acid, *o*-methoxyphenylpropionic acid, 3-indoleacetic acid (?), β-3-indolepropionic acid (?), hippuric acid, and phenacetyl glycine. As the phenolic components, we found phenol, guaiacol, *p*-cresol and *p*-ethylphenol.

It is well known that phenylalanine is easily converted to tyrosine, which is then further oxidized to 3,4-dihydroxy phenylalanine (DOPA); on the other hand, a part of the phenylalanine is

converted to *o*-hydroxyphenylalanine (*o*-tyrosine) *in vivo*.[3] It has also been reported that phenylalanine is converted metabolically to phenylacetic acid through phenylpyruvic acid.[4] However, the presence of the acidic and phenolic components mentioned above suggests the new metabolic pathways of phenylalanine, tyrosine, DOPA, and *o*-tyrosine shown in Fig. 6. As the pathways show, amino groups of the aromatic amino acids are deaminated to the corresponding phenylpropionic acids, which are then further converted to benzene or phenols by decarboxylation and ω-oxidation. Parentheses show the components which were not detected in this experiment, but which are very probably present. We are now trying to verify these routes; we will report on our studies in the near future.

The authors are grateful to Dr. R. Kawashima of Kyoto University for supplying the cow's urine. They wish also to thank Dr. K. A. Watanabe of the Sloan-Kettering Institute for his helpful suggestions regarding the preparation of this report.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1385—1387 (1968)

Total Synthesis of Nepseudin*[1]

Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received December 1, 1967)

The Hoesch reaction of 6-hydroxy-2,3-dihydrobenzo[b]furan with 2,3,4-trimethoxyphenylacetonitrile yielded 6-hydroxy-5-(2,3,4-trimethoxyphenylacetyl)-2,3-dihydrobenzo[b]furan. The cyclization of the dihydrobenzofuran with ethyl orthoformate-pyridine-piperidine gave dihydrodehydronepseudin, an isoflavone. The dehydrogenation of the above isoflavone with N.B.S. or Pd-C yielded dehydronepseudin. Nepseudin was derived by the reduction of dehydronepseudin with sodium borohydride and by subsequent oxidation with the chromium trioxide-pyridine complex.

Nepseudin was isolated as colorless needles, along with neotenone, dolineone and pachyrrhizin, from the roots of *Neorautanenia pseudopachyrrhiza (Leguminosae)* by Crombie and Whiting.[1] On the basis of degradation experiments and spectral examinations, its structure was shown to be furano-(3'',2'' : 6,7)-2',3',4'-trimethoxyisoflavanone (I), which is very similar to that of neotenone (II).[1] However, the oxygenation pattern, 2',3',4', instead of the usual 2',4',5', is unique in the A ring of the isoflavonoid and rotenoid series. On dehydrogenation with manganese dioxide, I has been converted[1] into dehydronepseudin (III), a furanoisoflavone. In a previous paper,[2] the authors reported the synthesis of 7-hydroxy-2',3',4'-tritrimethoxyisoflavone (IV), which has the same oxygenation pattern as I and III. The present paper will describe the total synthesis of I *via* III, thus confirming the proposed structure.

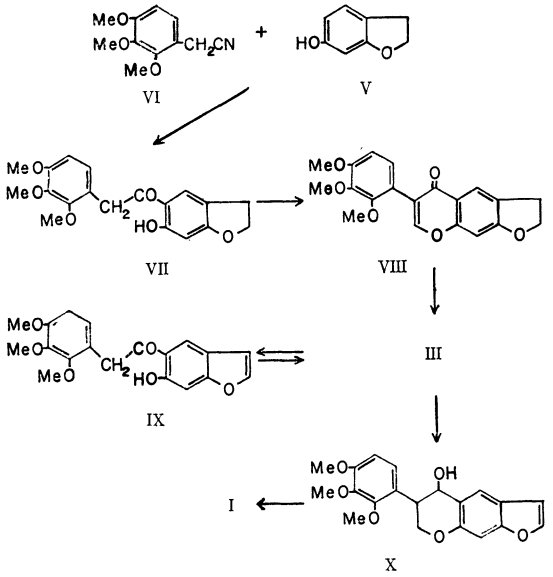
(VII) (mp 129—130°C). The cyclization of dihydrobenzofuran VII with ethyl orthoformate-pyridine-piperidine gave dihydrodehydronepseudin (VIII) (mp 143—144°C). By dehydrogenation either with *N*-bromosuccinimide in carbon tetrachloride or with 10% palladium on a carbon catalyst in diphenyl ether, the dihydrocompound VIII was converted into dehydronepseudin (III) (mp 164—165°C). III was identical with the isoflavone obtained from natural nepseudin by Crombie and Whiting.[1] On alkaline hydrolysis, III gave 6-hydroxy-5-(2,3,4-trimethoxyphenylacetyl)benzo[b]-furan (IX) (mp 118°C). III was resynthesized from IX with ethyl orthoformate-pyridine-piperidine. The isoflavone III, when reduced with sodium borohydride, gave furano-(3'',2'' : 6,7)-2',3',4'-trimethoxyisoflavan-4-ol (X) (mp 161—



162°C), presumably a product of 1,4-addition to the γ-pyrone system, followed by further reduction.[1,4]

On oxidation with the chromium trioxide-pyridine complex, isoflavanol X gave the desired isoflavanone I (mp 114—115°C); its identity

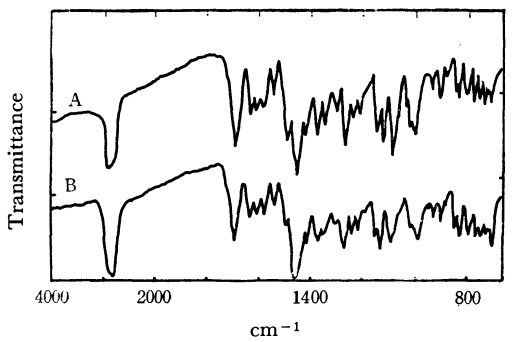


Fig. 1. IR spectra of synthetic (A) and natural (B) nepseudin in Nujol.

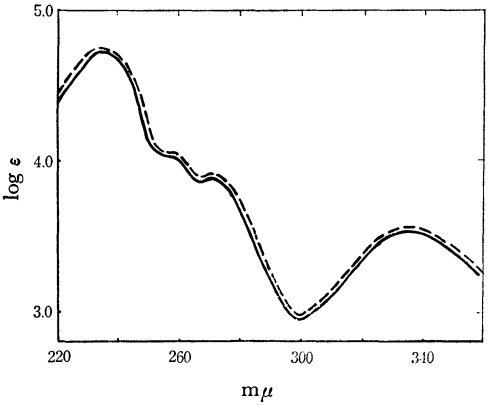

Fig. 2. UV spectra of synthetic (——) and natural (----) nepseudin in ethanol.

with natural nepseudin was confirmed by mixed-melting-point, infrared, and ultraviolet spectral comparisons (Figs. 1 and 2).

Experimental*2

6-Hydroxy-5-(2,3,4-trimethoxyphenylacetyl)-2,3-dihydrobenzo[b]furan (VII). A mixture of 6-hydroxy-2,3-dihydrobenzo[b]furan (V)[3] (5.0 g), 2,3,4-trimethoxyphenylacetonitrile (VI)[2] (5.0 g), and fused zinc chloride (4.0 g) in dry ether (150 m*l*) was saturated with dried hydrogen chloride for 4 hr at 0°C and then allowed to stand 2 days. The ethereal solution was decanted from the ketimine hydrochloride which had separated. The residue was washed twice with dry ether, and then heated on a steam bath with water (100 m*l*) for an hour. The resulting precipitates were collected and recrystallized from ethanol to give VII as colorless needles, mp 129—130°C, which gave a dark-brown ferric chloride reaction in ethanol; yield, 4.6 g (55%). IR: 1637 (C=O) cm^{-1}. UV: λ_{max} mμ (log ε); 281 (4.11), 330 (4.02).

Found: C, 66.37; H, 5.99%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

Dihydrodehydronepseudin (4'',5''-Dihydrofurano(3'',2'' : 6,7)-2',3',4'-trimethoxyisoflavone) (VIII). To a solution of VII (1.8 g) and ethyl orthoformate (8 m*l*) in pyridine (30 m*l*), piperidine (2 m*l*) was added; the mixture was then refluxed for 24 hr. The cooled reaction mixture was poured into ice-cooled dilute hydrochloric acid, and the resulting precipitates were colected. After being washed with water, the residue was recrystallized from ethanol to give VIII as colorless needles, mp 143—144°C; yield, 1.4 g (76%). IR: 1628 (γ-pyrone) cm^{-1}. UV: λ_{max} mμ (log ε); 240.5 (4.42), 310 (4.11).

Found: C, 67.87; H, 5.22%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%.

*2 All melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

Dehydronepseudin (Furano(3'',2'' : 6,7)-2',3',4'-trimethoxyisoflavone) (III). *a) N. B. S.* A mixture of VIII (1.0 g), *N*-bromosuccinimide (500 mg), and benzoyl peroxide (50 mg) in dry carbon tetrachloride (60 m*l*) was refluxed gently for an hour. The precipitates which separated on cooling were filtered off. The resulting filtrate was washed with a 5% sodium bisulfite solution and dried with anhydrous calcium chloride. The evaporation of the solvent under reduced pressure left a light yellow residue. After the addition of acetic acid (30 m*l*) and potassium acetate (5.0 g), the mixture was refluxed for an hour and then poured into water (300 m*l*). The resulting precipitates were collected and recrystallized from methanol to give III as colorless prisms, mp 164—165°C; yield, 550 mg (55%) (lit.[1] mp 158—160°C). IR: 1649 (γ-pyrone) cm^{-1} (lit.[1] 1647). UV: λ_{max} mμ (log ε); 244 (4.59), 324 (3.86) (lit.[1] λ_{max} mμ (log ε); 245 (4.64), 325 (3.92)).

Found: C, 67.96; H, 4.61%. Calcd for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58%.

b) 10% *Pd-C.* A mixture of VIII (1.0 g), 10% palladium on a carbon catalyst (700 mg), and diphenyl ether (20 m*l*) was refluxed for 10 hr. The catalyst was then filtered off, and the solvent removed by steam distillation. The resulting precipitates were collected and recrystallized from methanol to give III (mp 164—165°C), which was identical with the above sample; yield, 740 mg (74%).

6-Hydroxy-5-(2,3,4-trimethoxyphenylacetyl)benzo[b]furan (IX). A mixture of III (300 mg), a 5% aqueous sodium hydroxide solution (15 m*l*), and ethanol (20 m*l*) was refluxed for 3 hr on a steam bath. After the solvent had been evaporated, the residue was extracted with ethyl acetate. The resulting precipitates were recrystallized from methanol to give IX as pale yellow plates, mp 118°C, which gave a dark-green ferric chloride reaction; yield, 200 mg (69%) (lit.[1] mp 118—119°C). IR: 1639 (C=O) cm^{-1} (lit.[1] 1645). UV: λ_{max} mμ (log ε); 236 (4.76), 258.5 (4.07), 272.5 (3.97), 345 (3.71); (lit.[1] 235 (4.66), 258 (4.00), 270 (3.86), 345 (3.60)).

Found: C, 66.69; H, 5.40%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

The Cyclization of IX to III. By a reaction similar to that used for VII, III was prepared from IX (70 mg), ethyl orthoformate (3 m*l*), pyridine (10 m*l*), and piperidine (5 drops). Recrystallization from methanol gave III (mp 163—164°C), which was identical with the above sample; yield, 50 mg (69%).

Furano(3'',2'' : 6,7)-2',3',4'-trimethoxyisoflavan-4-ol (X). III (400 mg) in tetrahydrofuran (30 m*l*) was treated at 60°C for 90 min with sodium borohydride (300 mg) in 70% aqueous ethanol (30 m*l*) containing potassium hydroxide (30 mg). The mixture was kept at 20°C for 30 min and then diluted with a saturated ammonium chloride solution and extracted with ether. After the solvent had been evaporated, the residue was recrystallized from methanol to give X as colorless prisms, mp 161—162°C; yield, 200 mg (50%). IR: 3400 (broad) (OH) cm^{-1}.

Found: C, 67.23; H, 5.47%. Calcd for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%.

Nepseudin (I). Chromium trioxide (300 mg) was added to dry pyridine (3 m*l*); the mixture was swirled until it turned to an orange paste, and then X (100 mg) was added. The mixture was allowed to stand overnight at room temperature. After the addition of water, the resulting mixture was extracted with ether. The ether layer was washed with dilute hydrochloric acid, water, and a dilute sodium hydroxide solution, and finally dried over anhydrous potassium carbonate. After the solvent had been evaporated, the residue was recrystallized from methanol to give I as colorless prisms, mp 114—115°C; yield, 300 mg (75%) (lit. mp 115—116°C[1]; mp 115°C*[3]). IR: 1688, 1630, 1603, 1581, 1544, 1502 cm^{-1} (lit. 1686, 1631, 1605, 1585, 1541, 1490[1]; 1688, 1630, 1602, 1580, 1544, 1500*[3] cm^{-1}). UV: λ_{max} mμ (log ε); 235 (4.73), 257_i*[4] (4.03), 272.5 (3.88), 336 (3.56) (lit. 235 (4.74), 257_i (4.08), 272 (3.94), 335 (3.61)[1]; 235 (4.78), 257_i (4.06), 272.5 (3.91), 336 (3.60)*[3]). It was found, by mixed-melting-point measurement and by infrared and ultraviolet spectral comparisons, to be identical with the natural nepseudin supplied by Crombie.

Found: C, 67.94; H, 5.41%. Calcd for $C_{20}H_{18}O_6$: C, 67.79; H, 5.12%.

The authors are grateful to Professor L. Crombie, King's College, University of London, for his gift of natural nepseudin. Grateful acknowledgement is also made to Professor Tetsuo Mitsui, Kyoto University, for his microanalyses. This work was supported by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1388—1394 (1968)

The Thermal Decompositions and Mass Spectral Studies of the Cyclic Anhydrides of Some β-Sulfocarboxylic Acids

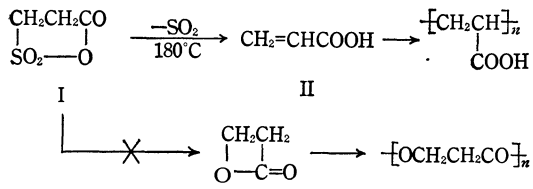
Katsuhiko NISHITOMI, Toshikazu NAGAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received December 5, 1967)

The thermal decompositions of the cyclic anhydrides of β-sulfopivalic acid (III) and β-sulfoisobutyric acid (IV) have been studied. The pyrolysis of III without a solvent gave pivalic acid, isobutene, isobutane, water, and a mixture of trimers of isobutene, while the pyrolysis of IV resulted in the formation of methacrylic acid and acetone. In the case of III, the evolution of sulfur dioxide and carbon dioxide occurred mainly. On the contrary, in the case of IV, the carboxylic acid derivative was the predominant product. These results might be interpreted in terms of a decomposition mechanism in which the compound (IV) having α-hydrogen to a carbonyl group undergoes thermal decomposition *via* a concerted mechanism. In the case of IV, it should be noted that acetone was formed. This paper will also be concerned with the mass spectra of III and IV and with the cyclic anhydride of β-sulfopropionic acid.

In a previous paper,[1] we reported the formation and decomposition mechanisms of cyclic anhydride of β-sulfopropionic acid (I); we found that acrylic acid (II) was formed intramolecularly in a 30.2% yield, and that the evolution of carbon dioxide was not detected, when I was heated at 180°C without a solvent.



No such a sterically unfavorable, intramolecular 1,3 hydrogen shift to oxygen as is described above has yet been reported so far as we know, while the 1,5 hydrogen transfer to oxygen[2-4] and the 1,3 hydrogen shift to carbon[5-7] have been reported. Thus, it was inferred that such a cyclic anhydride as I, with α-hydrogens to a carbonyl group, should exhibit interesting behavior upon thermal decomposition. Moreover, there have not yet been any reports about the 1,3 methyl shifts to oxygen in pyrolyses of saturated hydrocarbon systems. Therefore, we have examined the behavior of compounds similar to I upon heating. In the present paper, we wish to report on the behavior in thermal decomposition of the cyclic anhydrides of β-sulfopivalic acid (III) and β-sulfoisobutyric acid (IV). In these two systems, no 1,3 methyl shifts to oxygen were observed, through hydrogen shifts did occur in the case of IV. It was also found that the reaction courses of the pyrolyses were considerably affected with presence of the α-hydrogen to the carbonyl group; a possible mechanisms for this will be presented.

We will then deal further with the mass spectra of these three cyclic anhydrides (I, III and IV) in connection with pyrolysis studies of them.

Results and Discussion

Thermal Decompositions. When cyclic anhydride of β-sulfopivalic acid (III) was heated at 230°C without a solvent, there were obtained pivalic acid (V, in a 1.4% yield*1), isobutene (VI, in a 17.7% yield), isobutane (VII, in a 20.0% yield), water (VIII, in a 69.0% yield), and some bad-smelling, dark yellow liquid (IX, in a 6.1% yield as isobutene trimer); at the same time, sulfur dioxide and carbon dioxide were evolved. The residue was a black and spongy material which was insoluble and non-melting.

The sulfur dioxide, isobutene, and isobutane were identified by comparing their retention times in vapor-phase chromatography with those of authentic samples. No *n*-butane or propylene was

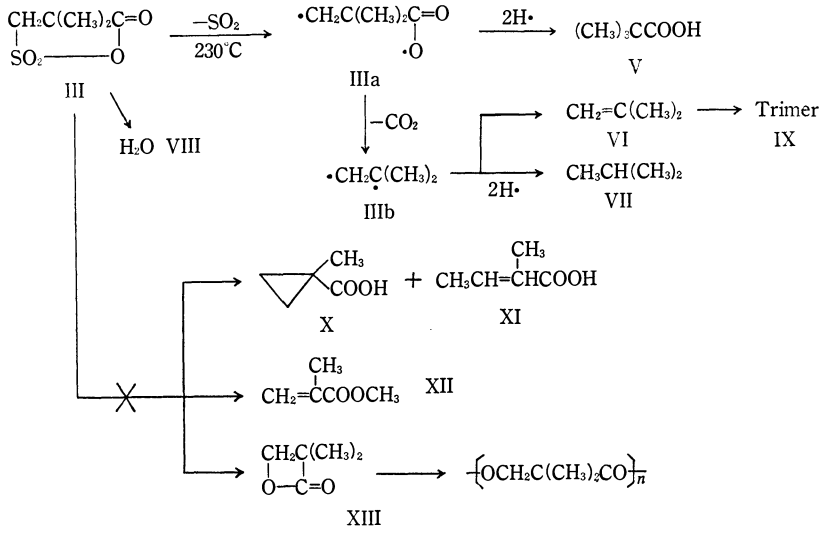

Scheme I

detected.

The pivalic acid (V) was identified by comparing its IR and NMR spectra with those of an authentic sample. The dark yellow liquid was confirmed to be a mixture of trimers of isobutene (IX) on the basis of the IR, UV, and NMR spectra, the boiling point, and chemical evidence. The IR spectrum showed absorptions at 2900 (methyl), 1365, 1380 (geminal dimethyl), and 800 cm^{-1}(C=C), among others. It also exhibited a moderate absorption at 1700 cm^{-1}, but this was not due to the carbonyl group, since authentic di-isobutylene showed a similar absorption at 1700 cm^{-1}. The NMR spectrum of IX showed multiplet peaks centered at τ 8.9, 7.9 and 3.4, the area ratio being 9 : 10 : 3. The UV spectrum of IX exhibited a very broad absorption at around 230 mμ ($\varepsilon = 3.0 \times 10^4$), with tailing up to 350 mμ. The multiplet at τ 3.4 and the broad absorption at near 230 mμ suggest the presence of a conjugated double bond in the IX molecule. The color of bromine in a carbon tetrachloride solution disappeared upon the addition of IX. The boiling point of IX was determined to be about 180°C. This boiling point coincided with that of the isobutene trimer which is obtainable from isobutene in the presence of sulfuric acid or by heating.[8] No further studies of the isomers or the structures of IX were carried out.

1-Methyl-1-carboxylcyclopropane (X) and its isomer, α-methylcrotonic acid (XI), were prepared by ordinary methods.[9] A comparison of their NMR spectra with that of the mixture of liquid products obtained in the present study showed that X and XI were not the products in the present case. Neither methyl methacrylate (XII), which should be formed if a 1,3 methyl shift to oxygen occurred, nor β-lactone (XIII), which might be obtained from IIIa, was detected in NMR analyses. From these results, it seems that the reaction products might be formed through a pathway such as that described in Scheme I. In this case, the fact that V and VII, which should be formed by intermolecular hydrogen abstraction, were obtained suggests that III undergoes thermal decomposition *via* a radical mechanism rather than *via* a concerted one.

Sulfur dioxide evolves first; the resulting diradical (IIIa) partly abstracts hydrogens intermolecularly to form V, and then mostly loses carbon dioxide to give another diradical (IIIb). Thus, IIIb, in one part, abstracts hydrogens intermolecularly to form VII and, in another part, converts to VI. Further, VI may be changed to IX. The formation of IX may be caused by heating under the experimental conditions or by the action of sulfuric acid, for the system evolves sulfur dioxide and water, and contains oxygen under an atmosphere. These results obviously indicate that no 1,4 hydrogen shift or 1,3 methyl shift occurs under these conditions. The formation of VIII should be noted, although the pathway to VIII is not clear.

Next, we examined the behavior of the cyclic anhydride of β-sulfoisobutyric acid (VI), with one α-hydrogen to a carbonyl group. When IV was heated at 220°C without a solvent, there were obtained methacrylic acid (XIV, in a 66.9% yield) and acetone (XV, in a 6.1% yield); at the same time sulfur dioxide and a small amount of carbon dioxide were evolved. In this case no gaseous compounds other than sulfur dioxide and carbon dioxide were detected by vapor-phase chromatography. The residue was a black and

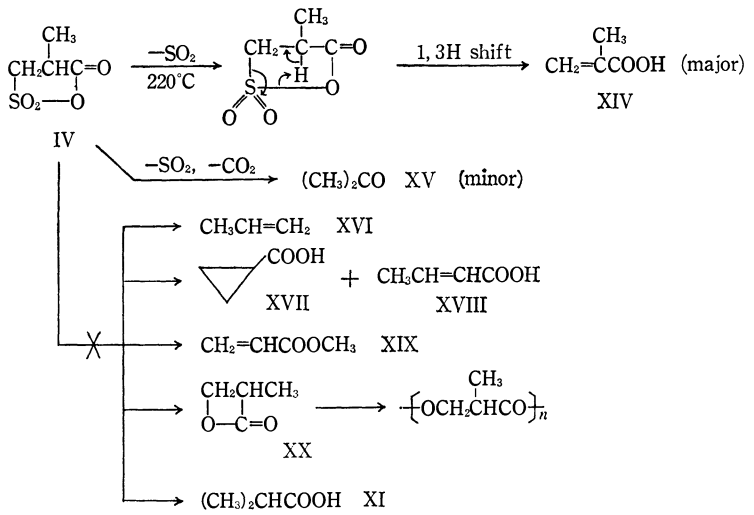


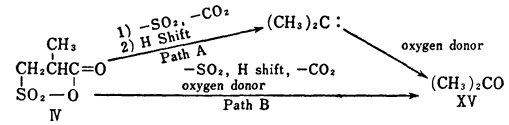
Scheme II

spongy material which was insoluble and non-melting.

Methacrylic acid (XIV) was identified by comparing its IR and NMR spectra with those of an authentic sample. Acetone (XV) was identified by comparing its NMR spectrum and the melting point of its 2,4-dinitrophenylhydrazone (mp 123.5—124°C) with those of an authentic sample. Propylene (XVI) was not detected by vapor-phase chromatography. There were none of the peaks at fields higher than 9.0 τ in the NMR spectrum which are characteristic of the methylene protons of 1-carboxylcyclopropane (XVII). Moreover, there were no peaks assignable to crotonic acid (XVIII), the isomer of XVII.[10] Neither methyl acrylate (XIX) nor β-lactone (XX) was detected in NMR analyses. Moreover, isobutyric acid (XXI), which should be formed by intermolecular hydrogen abstraction if the thermal decomposition proceeds, *via* such a radical mechanism as was observed in the case of III, was not detected in NMR analyses of the reaction mixture.

These results are presented in Scheme II. In this case, the fact that XXI, which should be formed by intermolecular hydrogen abstraction in a radical mechanism, was not obtained suggests that XIV is formed *via* a concerted mechanism rather than *via* a radical one. Moreover, no 1,4 hydrogen shift or 1,3 methyl shift occurred under these conditions, either.

It is very interesting that XV was formed in a 6.1% yield in this system, for the formation of XV involves the possibility of a 1,2 hydrogen shift in the thermal process, though there have hitherto been few examples of 1,2 hydrogen shifts in pyrolyses[11-15] (below 300°C). The fact that carbon dioxide was detected must be related to the formation of XV. In this case, it seems that XV is not formed *via* a free dimethylcarbene, for if this were the case, propylene (XVI) should be formed,[16] while XVI was not detected by vapor-phase chromatography. Also, it may be very difficult to consider the intermolecular hydrogen shift upon the formation of XV. Thus, Path B below may be more plausible than Path A, although the details of the process are obscure:



Sheme III

There exist two possibilities in this system as to the oxygen donor. One is atmospheric oxygen, and the other is sulfur dioxide. The former can be neglected from the fact that, in the experiment on the thermal decomposition of IV under a nitrogen stream, the yield of XV was essentially

10) Crotonic acid, $\begin{matrix} CH_3^a \\ \diagdown \\ H_b \end{matrix}\!\!>C=C<\!\!\begin{matrix} H^c \\ \diagup \\ COOH \end{matrix}$, exhibited peaks at τ 8.10 (a), 2.90 (b), and 4.17 (c), while methacrylic acid, $\begin{matrix} H^b \\ \diagdown \\ H_c \end{matrix}\!\!>C=C<\!\!\begin{matrix} CH_3^a \\ \diagup \\ COOH \end{matrix}$, showed peaks at τ 8.03 (a), 4.28 (b), and 3.70 (c).

the same as that in the experiment under an atmosphere (see Experimental Section). Sulfur dioxide can be used as the source of oxygen at a high temperature,[17] so the oxygen donor to XXII seems to be sulfur dioxide.

Mass Spectral Studies. There have been no reports on mass spectral studies of such compounds as cyclic anhydrides of β-sulfocarboxylic acids (I, III and IV) except that by Meyerson *et al.*[18] about benzyne formation. In the present work, we are going to compare the behavior of the compounds under electron impact with those under thermal decomposition. The mass spectra of I, III, and IV are shown in Figs. 1, 2, and 3 respectively. They display different features, although the parent peaks are all very weak. The intense peak at *m/e* 78 in Fig. 1 may be assigned as $CH_2SO_2^+$. The other peaks may be understood

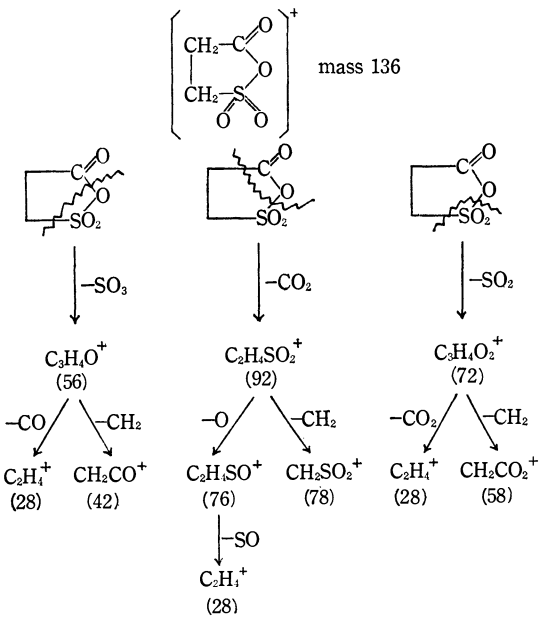

Scheme IV

in such a manner as in Scheme IV. The peak at *m/e* 28, which may be assigned to $C_2H_4^+$ (=I–SO_2–CO_2) and CO^+, is not so intense. This tendency is similar to that in thermal decomposition. The intense peaks at *m/e* 28, 41, 56 and 121 in Fig. 2 may be assigned to $C_2H_4^+$, $C_3H_5^+$, $C_4H_8^+$, and $C_4H_8SO_2^+ + 1$ (=III–CO_2+1) respectively. The other peaks may be understood in such a manner as in Scheme V. The intense peaks at *m/e* 28, 41, and 56 may correspond to olefins; this tendency is similar to that in thermal decomposition. The intense peaks at *m/e* 27, 42, and 70 in Fig. 3 may be assigned to $C_2H_3^+$, $C_3H_6^+$, and $C_4H_6^+$ (=IV–SO_3) respectively. The other peaks may be understood in such a manner as in Scheme VI. The intense peaks near *m/e* 42 may correspond to propylene or dimethylcarbene; this tendency is different from that in the thermal decomposition.

Experimental

Cyclic Anhydride of β-Sulfopivalic Acid (III). This was prepared by the photosulfonation of pivalic acid, which had been synthesized in the same manner as has been described in the literature,[19] with sulfuryl chloride in a manner similar to that described by Kharasch *et al.*[20] In this case, we added one or two drops of pyridine as a catalyst. The product was separated as a white solid. It was dried *in vacuo* in a desiccator containing phosphorus pentoxide and paraffin wax. The yield was about 17%. The melting point of this material (III) was 62—63°C (lit.[21,22] 62—64°C), which did not change upon crystallization from thionyl chloride. The NMR spectrum of III in water (10 wt%) showed two singlets at δ(ppm) 3.30 (β-methylene, 2H) and 1.40 (α-methyl, 6H), where water was used as the internal reference (its chemical shift relative to TMS was assumed to be δ=5.05 (ppm)).

Cyclic Anhydride of β-Sulfoisobutyric Acid (IV). This was prepared by the photosulfonation of isobutyric acid with sulfuryl chloride in the same manner as was described by Kharasch *et al.*[20] The boiling point of IV was 134—135°C/3 mmHg. The NMR spectrum

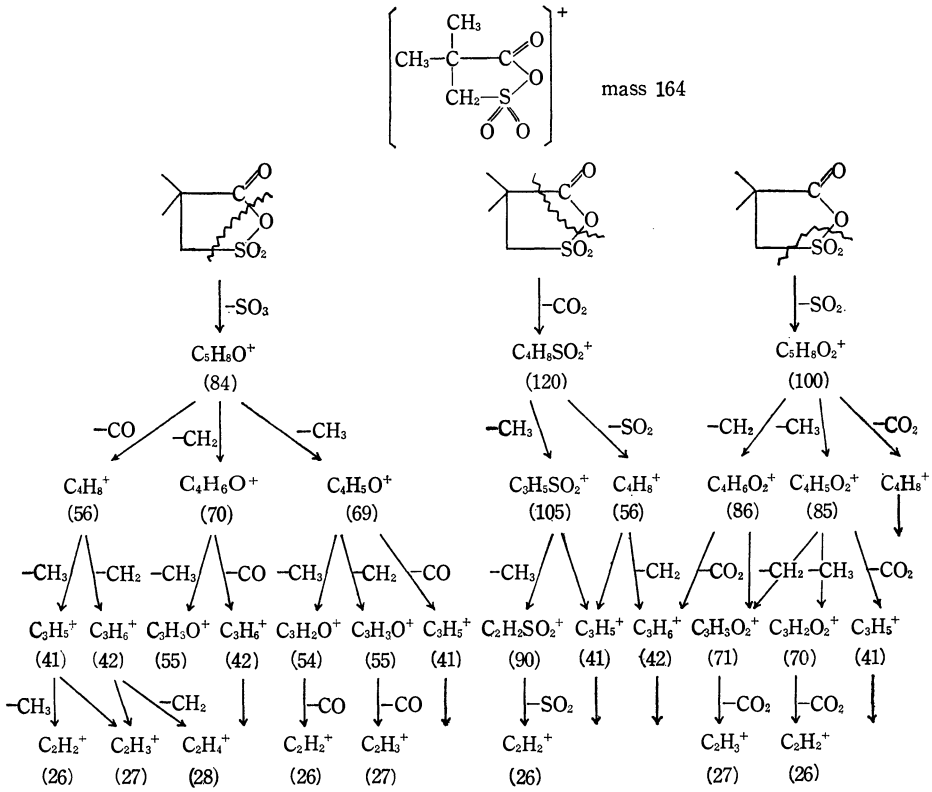
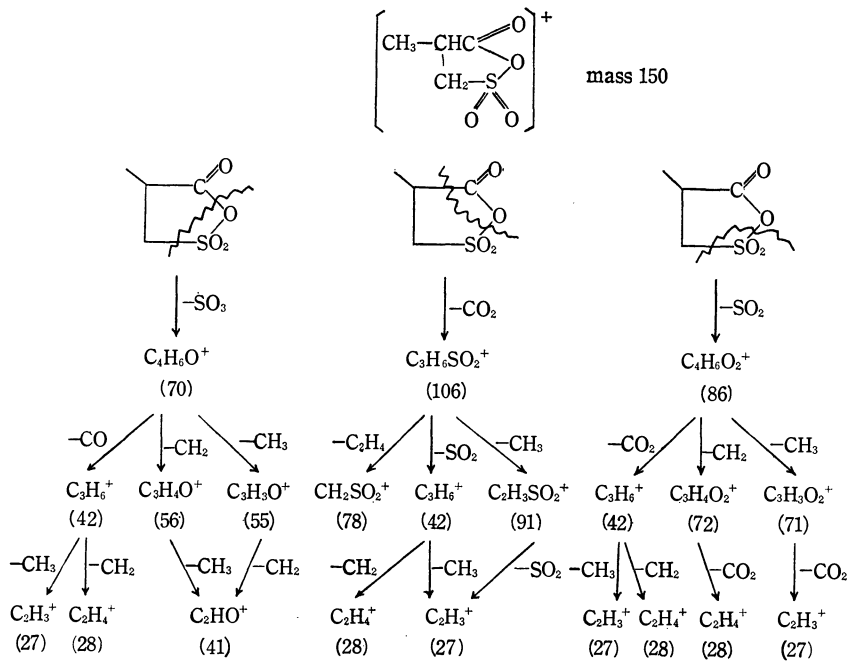


Scheme V



Scheme VI

of IV in water (11.76 wt%) showed a doublet at δ (ppm) 1.07 (α-methyl, 3H), and a doublet and a multiplet centered at δ 2.90 (β-methylene, 2H and α-methyne, 1H), where 1,4-dioxane was used as the internal reference (its chemical shift relative to TMS was assumed to be δ=3.57 (ppm)).

Thermal Decomposition of III. *A Typical Experiment.* In a 50 m*l*, round-bottomed flask fitted with an outlet tube leading to a cooler equipped with a receiving vessel and a calcium chloride tube, 10.6 g of III without a solvent were placed. The calcium chloride tube led to a trap dipped in dry ice and trichloroethylene bath equipped with a rubber tube. The trap further led to a 100 m*l* flask in which an aqueous calcium hydroxide solution was placed in order to remove carbon dioxide; the outlet gas was collected on the water. The round-bottomed flask was placed in an oil bath equipped with a thermometer, and heated gradually. When the temperature reached 65°C, the solid in the flask melted; upon further heating, to 220°C, sulfur dioxide gas evolved. The temperature was maintained at about 230°C for 3 hr, until the liquid in the flask changed to a black, spongy matter. During the heating, a mixture of a dark yellow liquid (IX) and a colorless liquid (VIII) was distilled out, and another mixture of sulfur dioxide and VI was trapped, while VII was collected on the water. Further calcium carbonate was also found to be deposited. The gaseous products were analysed by vapor-phase chromatography. As a result, VI and VII were identified by comparing their retention times with those of authentic samples. *n*-Butane and propylene were not detected.

The mixture of IX and VIII was treated as follows. It was mixed with anhydrous ether in a separate funnel, and the lower layer was removed. This lower layer was identified as water (0.802 g). The upper layer was further extracted with an alkali solution. The extract was acidified with hydrochloric acid and extracted with ether. The ether extract was dried over anhydrous sodium sulfate, and then the ether was distilled out. The resulting solid was identified as pivalic acid (V) by comparing its IR and NMR spectra with those of an authentic sample (0.124 g). The other ether extract, which was not extracted with the alkali solution, was dried over anhydrous sodium sulfate. Then the ether was distilled out. The resulting dark yellow liquid was confirmed to be isobutene trimer (0.591 g) by comparing its boiling point with that reported in the literature[8] and its IR spectrum with that of authentic di-isobutylene, and by considering the NMR spectrum and chemical evidence. The yield of VII was calculated from the volume of the collected gas by considering the dead volume. The yield of VII was 20.0%. The yield of VI was calculated from the weight of the mixture of sulfur dioxide and VI, and from their relative areas in vapor-phase chromatography. The yield of VI was 17.7%. The black, spongy residue was treated with anhydrous ether, and then the ether was distilled out from the ether extract. The resulting material was dissolved in chloroform, and the undissolved part was treated with aniline in a benzene solution. A white solid, which was supposed to be a monoaniline salt of β-sulfopivalic acid, was deposited, although it was only a trace. The dissolved part in chloroform was chromatographed over alumina. The resulting material (0.094 g) was identified as IX by its IR spectrum.

Thermal Decomposition of IV. *A Typical Experiment.* In a 50 m*l*, round-bottomed flask fitted with equipment in the same manner as has been described above in the case of III, 7.25 g of IV without a solvent were placed. The flask was placed in an oil bath equipped with a thermometer, and heated gradually. When the temperature reached 215—220°C, sulfur dioxide gas evolved. The temperature was maintained at about 220°C for 3 hr, by which time the liquid in the flask had changed to a black, spongy matter. During the heating, a colorless liquid (2.95 g) was distilled out. Most of it was identified as XIV by comparing its NMR and IR spectra with those of an authentic sample; the rest was identified as XV by comparing its NMR spectrum and the melting point of its 2,4-dinitrophenylhydrazone with those of an authentic sample. The yields of XIV and XV were caluclated from the total weight of the mixture and from their relative NMR areas. The yields were thus determined to be 66.9% (XIV) and 6.1% (XV). In this system no gaseous products except sulfur dioxide were detected by vapor-phase chromatography analyses. Calcium carbonate was also deposited, but its quantity was small. The black, spongy residue was treated in the same manner as has been described above in the case of III. The resulting liquid was identified as XIV (0.05 g) by means of its IR spectrum. In an experiment under a nitrogen stream, the yields of XIV and XV were 66.1% and 6.9% respectively.

IR Spectra. The infrared spectra were recorded on an EPI-S2-TYPE Hitachi spectrometer.

NMR Spectra. The proton resonance spectra were run on a Nihondenshi spectrometer at 60 Mc.

Vapor-phase Chromatography. Routine separations were carried out on a Yanagimoto Model GCS-100 gas chromatograph. A 3 m×0.25 in. stainless steel column packed with liquid paraffin (Column A) and a 4 m×0.25 in. stainless steel column packed with silicone hivac grease (Column B) were used. The column temperature was room temperature (31—33°C) for all fractions. Hydrogen (48 m*l*/min in Column A and 50 m*l*/min in Column B) was used as the carrier gas. The retention times in minutes were as follows: 1.4 (sulfur dioxide), 2.85 (VII), 3.45 (VI), 1.45 (propylene) and 3.75 (*n*-butane) in Column A; 3.0 (sulfur dioxide), 2.5 (VII), 3.15 (VI), 1.85 (propylene) and 3.2 (*n*-butane) in Column B.

Mass Spectra. The mass spectra were run on a VD-10001-A Hitachi spectrometer.

Reactions of Transition-Metal-Olefin Complexes. III. Kinetics of the Oxidation of Substituted Styrenes Catalyzed by Palladium Salts in an Aqueous Tetrahydrofuran Solution*[1]

Hiroyoshi OKADA, Takashi NOMA, Yoshihisa KATSUYAMA*[2] and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 7, 1967)

The kinetics of the oxidation of ring-substituted styrenes catalyzed by palladium(II) salts in a homogeneous aqueous tetrahydrofuran solution containing *p*-benzoquinone have been investigated at 30°C under a nitrogen atmosphere. The rate equation was found to be identical with the one previously found for styrene, *i. e.*, $-d[olefin]/dt = (k_I+k_{II})[Pd^{2+}][olefin]$, where k_I is the rate constant for ketone-formation and k_{II} is the rate constant for aldehyde-formation. It was found that both the proton and the chloride ion affect the rate inhibition at high concentrations and the rate acceleration at low concentrations. The product ratio of the ketone to the aldehyde decreased monotonously with the increase in proton concentration and with the increase in chloride ion concentration. An increase in the ionic strength from 0.052 to 0.787 increased the rate constants, but the ratio of the products scarcely changed at all. The substituent effects for the sites of nucleophilic attack were specific; *i. e.*, the electron-releasing substituents facilitated the formation of substituted acetophenone and diminished the formation of substituted phenylacetaldehyde. The reverse trend was found for the electron-withdrawing substituents. From these results, there is proposed a mechanism in which two active species, $[ArCH{=}CH_2Pd(H_2O)(OH)Cl]$ and $[ArCH{=}CH_2Pd(H_2O)(OH)Cl_2]^-$, are involved and in which the rate-determining step is the decomposition of the σ-complexes with the hydride shift to the carbonyl products.

Since the report of the palladium(II) ion oxidation of olefins by Smidt *et al.*,[1] many kinetic studies of the oxidation of ethylene and some olefins by palladium salts in aqueous solutions have been reported.[2] However, few kinetic studies concerning the sites of nucleophilic attack in the above oxidation of substituted olefins have been reported.[3] This study was undertaken to clarify the influences of such factors as proton concentration, chloride ion concentration, ionic strength, and the substituents on the sites of nucleophilic attack in the oxidation of ring-substituted styrenes by palladium salts in a homogeneous aqueous tetrahydrofuran (THF) solution at 30°C.

Results and Discussion

The oxidations of the substituted styrenes proceeded as is shown by the following equation;

$$X\text{-}C_6H_4CH{=}CH_2 + H_2O + Q \xrightarrow[THF\text{-}H_2O]{Pd^{2+}} \underset{I}{X\text{-}C_6H_4COCH_3} + \underset{II}{X\text{-}C_6H_4CH_2CHO} + H_2Q \quad (1)$$

(X: *p*-CH_3, *p*-Cl, *m*-CH_3, *m*-Cl and H)

where Q indicates the *p*-benzoquinone used as an oxidizing agent for palladium in the system and where H_2Q indicates hydroquinone. The reaction rates were followed by the gas chromatography of the unreacted styrenes and of the produced substituted acetophenone (I) and substituted phenylacetaldehyde (II). The reaction was first order in styrene and in palladium salts, and the ratio of acetophenone to phenylacetaldehyde was almost constant throughout the reaction.[3] For substituted styrenes, the kinetic relationships were identical with that of styrene. Thus, the rate expression is:

$[Cl^-]/[Pd^{2+}]=2.00$

When the perchloric acid concentration was changed from 0.03 M to 0.25 M in the oxidation of *p*-chlorostyrene by palladium chloride in THF-water (60 : 40 vol/vol) in the absence of added salts, the values of k_I and k_{II} reached their maxima, as shown in Table 1. The effect of the proton concentration on the rate constants in the oxidation of *m*-methylstyrene at a constant ionic strength of 0.44 and a constant chloride ion concentration (Cl/Pd=2) in the same solvent system is shown in Fig. 1. The rate constants, k_I and k_{II}, had their

△: *m*-chlorophenylacetaldehyde

maximum values in a proton concentration of about 0.02 M. Therefore, it appears that k_I and k_{II} generally have their maximum values at low proton concentrations in these systems.

Figures 2 and 3 show the effect of the chloride ion concentration on the rate constants in the oxidation of *m*-methylstyrene and *m*-chlorostyrene at a constant ionic strength (μ=0.44 and 0.90 respectively) and at a constant proton concentration (0.038 M and 0.0074 M respectively). It is obvious that, in these cases, the maximum points appear in the curves of k_I and k_{II} at low chloride ion concentrations, when the ratio of chloride ions to palladium ions is 2 : 1 or less.

In the oxidations of ethylene and propylene by palladium chloride in aqueous solutions in the presence of excess chloride ions, the first-order proton inhibition and the second-order chloride inhibition have been established.[4] Also, in the oxidation of styrene by palladium chloride in aqueous tetrahydrofuran, the logarithm of the rate constants of acetophenone-formation is approximately proportional to the values of the acidity function, H_0, of the system in high proton concentrations,[3] showing a first-order proton inhibition similar to that of ethylene. However, Smidt *et al.*[5] has recently reported, regarding the aqueous palladium chloride oxidation of ethylene in the presence of *p*-benzoquinone, that the rate constants have maximum values both in low proton concentrations and in low chloride concentrations; they obtained the experimental rate expression of Eq. (3):

$$-\frac{d[CH_2=CH_2]}{dt}=\frac{a[H^+][Cl^-]}{b+[H^+]^2[Cl^-]^3} \qquad (3)$$

Although the influences of the acid concentration and the anion concentration on the rate were not independently analyzed, similar results were obtained in the oxidation of carbon monoxide by palladium chloride in aqueous dioxane in the presence of *p*-benzoquinone,[6] and in the acetoxylation of ethylene by palladium chloride or palladium acetate in acetic acid containing sodium acetate and *p*-benzoquinone.[7] Therefore, it may be concluded to be generally true in these reactions that protons and chloride ions have both effects of the rate inhibition and acceleration. These facts suggest that, under the conditions of low proton concentrations and of limited amounts of chloride ions, the mechanisms of these oxidation processes or the reaction species may differ from those proposed previously.[3,8]

In all the experiments, the ratio of the acetophenone (I) to the products, *i. e.*, $k_I/(k_I+k_{II})$, decreased monotonously with any increase in either the proton or chloride ion concentration, independently of the maximum values of k_I and k_{II}, for example, from 0.86 to 0.63 in Fig. 1, from 1.00 to 0.57 in Fig. 2, and from 0.59 to 0.25 in Fig. 3. With palladium perchlorate in the absence of chloride ions, no oxidation of styrenes occurred in very low proton concentrations. While higher proton concentrations generally caused side reactions to produce ring-substituted benzaldehydes (substituents: *p*-CH_3, *m*-CH_3, *p*-Cl and *m*-Cl)

in the oxidation of the corresponding substituted styrenes, their amounts were no more than 5%.

Table 2 shows the effect of the ionic strength in the oxidation of *m*-chlorostyrene under comparable conditions. The results indicate that an increase in ionic strength considerably increases the values of both k_I and k_{II}, whereas it has little effect on the ratio of the products, that is to say, the value of $k_I/(k_I+k_{II})$.

In order to obtain further information regarding the mechanism of the reaction, we have investigated the effects of the ring-substituents on the oxidation rates. One example of the Hammett plots of the rate constants under typical experimental conditions is shown in Fig. 4. The rates roughly follow the Hammett $\rho\sigma$ equation. However, the sign of ρ is opposite for the α- and β-positions; that is, it is negative for the substituted acetophenone-formation and positive for the substituted phenylacetaldehyde-formation. This shows that electron-releasing substituents accelerate the reaction at the α-position and diminish the rate at the β-position. The reverse relationship holds for electron-withdrawing substituents. When the reaction conditions, especially the proton concentration and the chloride ion concentration were varied, the ρ-values changed somewhat, but the general tendency was the same. The reverse signs of ρ-values for the α- and β-positions have also been found in the hydroboration of substituted styrenes.[9,10]

The following reaction scheme is proposed to explain all of the results obtained: 1) the effects of both rate acceleration and retardation by protons and chloride ions; 2) the influence of the proton and chloride ion concentrations on the product ratio and 3) the opposite effects of the substituents on the reaction sites. In this scheme some assumptions are involved because of the complexity of the chemical species concerned.

In the above scheme, the A, B, C, D, E and F π-complexes are in a state of equilibrium. Both

10) H. C. Brown and G. Zweifel, *J. Am. Chem. Soc.*, **82**, 4708 (1960).

the A and D complexes may be considered to be inactive species, for at a very high chloride ion concentration the reaction almost stopped, and in the complete absence of chloride ions, *i. e.*, in a palladium perchlorate or palladium hydroxide solution, the reaction scarcely proceeded at all. The specific effects of the protons and chloride ions on the rate and on the product distribution described above suggest that at least two active species participate in the reaction, because it is difficult to explain those effects in terms of only one reactive species. We propose that the E and F π-complexes are active species, with E more reactive than F. Although a five-coordinated species such as F could not be isolated, it seems reasonable to assume its existence, as has been proposed by Khan *et al.*[11] for the stereospecific hydrogenation of benzyl derivatives.*3 At lower proton and chloride ion concentrations, the reaction path through the E complex is predominant. The higher the chloride ion concentration, the more does the reaction proceed through the F complex. The net effects will result the maximum of the rate constant at a given proton concentration and at a given chloride ion concentration respectively.

From the observed substituent effects, it is reasonable to consider that the transformation of the π-complex to the σ-complex is probably a reversible step and that the decomposition of the σ-complex to carbonyl compounds, involving a hydride shift, is the rate-determining step. If the conversion of the π-complex to the σ-complex were rate-determining, the electron-withdrawing substituents would facilitate this transformation and the same sign of the ρ-value would be observed in the Hammett plots regardless of the reaction sites.

In the σ-complexes the effects of the ring-substituents may be stronger at the α-carbon than at the β-carbon. Thus, the electron-releasing groups increase the electron density at the α-carbon in the G and G' σ-complexes and facilitate the hydride transfer from the α-carbon to the β-carbon atom and interrupt the hydride transfer from the β-carbon to the α-carbon in the H and H' σ-complexes. The tendency is the reverse in the case of the electron-withdrawing groups.

The ratio of the ketone to the aldehyde produced is determined by the ratio of the product of the rate constant and the equilibrium constant, for example, k_1K_1 to k_2K_2 and k_3K_3 to k_4K_4. The monotonous decrease in the ratio of $k_I/(k_I+k_{II})$ with increases in both the proton and chloride ion concentrations means that, in the reaction path through the F π-complex, k_3K_3 may be considered to be nearly equal to k_4K_4. The reason for this may be as follows. When the coordinated substituted styrene molecule of E rotates from a position nearly vertical to the palladium coordination plane to a coplanar orientation,*4 the d_{xy} metal orbital is used for π-bonding in place of the d_{xz} metal orbital, and there arises an opportunity to rearrange to the G or H σ-complex. In the coplanar orientation, if the α-carbon atom lies near the *cis*-Cl ligand (III), the overlap between the d_{xy} metal orbital and the π-antibonding orbital of substituted styrene will be prevented by the steric hindrance resulting from the interaction between the aryl group and chloride ions. Moreover, since the β-carbon atom lies far from the *cis*-OH ligand,*5 the conversion from the E π-complex to the H σ-complex, which is preferable for aldehyde formation, would be difficult. On the contrary, if the β-carbon atom lies near the *cis*-Cl ligand (IV), the p_π*-d_{xy} overlap will not be prevented and then the α-carbon atom will lie near the *cis*-OH ligand.*5 Thus, transformation to the G σ-complex, which is preferable for ketone formation, would be predominant.

20) P. D. Kaplan and M. Orchin, *Inorg. Chem.*, **6**, 1096 (1967).

In a vertical orientation such as in the F complex, the overlap between the p_π* orbital of olefin and the d_{xz} palladium orbital is at a maximum and an interaction with a fifth hydroxide ligand above or below the square plane of the four-coordinated planar complex may be expected. Because of the rapid rotation of olefin and/or the two coordination sites for the hydroxide ligand, the probability of an attack of the hydroxide ion on either the α-position or the β-position will be nearly equal. This may decrease the selective formation of either carbonyl compound from F. The transformation of the E π-complex to the G or H σ-complex may involve a four-center-type transition state. The four-center-type transition state has also been proposed for the rearrangement of the hydrido-π-olefin complex to a σ-alkyl complex in the hydrogenation of fumaric acid by ruthenium(II) chloride.[21]

Experimental

Materials. In the oxidation of *p*-chlorostyrene, *p*-dibromobenzene was used as an internal reference in the gas chromatographic quantitative analysis. It was the same material as was employed in the oxidation of styrene.[3] Bromomesitylene was used as an internal reference in the oxidations of the other three substituted styrenes; it was prepared by the bromination of mesitylene,[22] bp: 136—137°C/50 mmHg. Ring-substituted styrenes were prepared by the dehydration of the alcohols which were formed by the action of the corresponding ring-substituted phenylmagnesium bromide and acetaldehyde[23]; *p*-methylstyrene, bp: 61.5—62.5°C/13 mmHg; *m*-methylstyrene, bp: 61.0—62.0°C/13 mmHg; *p*-chlorostyrene, bp: 90.5—91.3°C/30 mmHg; *m*-chlorostyrene, bp: 62.0—63.0°C/7—8 mmHg. All the substituted styrenes described above were confirmed to be pure by means of g.l.c. and by means of their NMR spectra.

Kinetic Runs. The unreacted styrenes and reaction products were analyzed by means of g.l.c., using a 3-m copper column packed with 20% silicon DC 550 on Diasolid, at a hydrogen gas flow rate of 80 ml/min at 130°C. The other experimental techniques used in this study have been described previously.[3]

Identification of the Products. The ring-substituted acetophenones, phenylacetaldehydes, and benzaldehydes were identified by means of g.l.c. and their IR and/or NMR spectra in comparison with those of the authentic samples synthesized by the methods cited below or by similar methods. The boiling points of the authentic samples are also given below. The IR spectra were taken on neat liquid or on KBr tablets. The NMR spectra were measured by a Japan Electron Optics C-60 chemical analyzer at 60 Mc in carbon tetrachloride, containing tetramethylsilane as an internal reference.

Compounds Obtained in the Oxidation of p-Methylstyrene.
p-Methylacetophenone.[24] bp: 225—226.5°C/760 mmHg. IR: 1184, 1285, 1385 and 1677 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1401—1404 (1968)

Cleavage Reactions of Alkoxy Radicals Produced by Anodic Oxidation of *t*-Alcohols

Kazuhiro MARUYAMA and Katsuya MURAKAMI*1

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received December 7, 1967)

The anodic oxidation of *t*-alcohols in water - dioxane - sodium hydroxide system has been examined. The possibility of production of *t*-alkoxy radicals by anodic oxidation of *t*-alcohols in the electrolytic system was found. The relative ease of bond scission of the intermediate *t*-alkoxy radical was determined by quantitative analysis of the mixture of ketones produced. The relative rates of cleavage decrease in the order: allyl>*sec*-butyl>isopropyl>ethyl>*n*-propyl>*n*-butyl>*n*-pentyl>isobutyl>methyl. The hyperconjugative effect of β-hydrogen and effect of double bond at β-position to the rate enhancement of cleavage reaction was confirmed.

The two typical reactions of *t*-alkoxy radicals are, in general, i) hydrogen abstraction to form alcohols and ii) fragmentation to ketone and alkyl radical.[1,2] The cleavage reaction of *t*-alkoxy radical to form ketone and alkyl radical has been extensively investigated.[3-9] There are three ways of bond scission for an *t*-alkoxy radical theoretically (Eq. (1)).

$$R_1R_2R_3CO\cdot \longrightarrow \left\{ \begin{array}{l} \rightarrow R_1\cdot + R_2COR_3 \\ \rightarrow R_2\cdot + R_1COR_3 \\ \rightarrow R_3\cdot + R_1COR_2 \end{array} \right\} \quad (1)$$

The relative rates of formation of alkyl radicals can be determined if one can estimate quantitatively the amount of ketones and of alkyl radicals which are produced from the fragmentation of *t*-alkoxy radical. By such an idea the relative ease of cleavage reactions has been determined from 1) the redox reaction between alkyl hydroperoxides and reducing metal ion,[4] 2) the thermolysis of dialkyl peroxides,[4] 3) the oxidation of alcohols with Co(III),[5] and 4) the photolytic decomposition of alkyl hypochlorites.[6,8,9]

In this study we examined the possibility of production of *t*-alkoxy radicals by anodic oxidation of *t*-alcohols and intended to obtain a quantitative measure of the relative ease of cleavage reaction in the absence of the oxidising metallic cation or halogen radical, especially at low temperature. Using platinum electrodes the electrolytic oxidation of *t*-alcohols were conducted in a solvent system: dioxane - water - sodium hydroxide.

Results and Discussion

The synthetic methods of *t*-alcohols: R_1R_2PhCOH (R_1, R_2=alkyl, Ph=phenyl) used in this study and their physical constants are described in experimental part (Table 4). The reaction mixture resulted from electrolysis of *t*-alcohols in the dioxane-water - sodium hydroxide system, was extracted by ether and analysed by g.l.p.c. technique. Since it was confirmed by preliminary experiments that the expected ketones were produced efficiently at anode by electrolysis of *t*-alcohols if one used the dioxane - water - sodium hydroxide system as a solvent (80—90% of theoretical yields for ketones in 10—15 hr) and no successive reaction of the ketones was observed in this electrolytic system, the further reactions were conducted as it was described in experimental part. The yields of ketones obtained from the anodic oxidations of *t*-alcohols are given in Table 1. The values given in Table 1 are average of the values obtained by several runs (3—5 times) for an *t*-alcohol. The probable error was lower than 5%. Gaseous products corresponding to the respective runs are given in Table 2.

** J. K. Kochi, *J. Am. Chem. Soc.*, **84**, 1193 (1962).
*** D. G. Hoare and W. A. Waters, *J. Chem. Soc.*, **1964**, 2552.

The components of gaseous products could be identified by g.l.p.c. technique, but the amounts of each component could not be determined quantitatively, because the gaseous products produced at electrodes contained a large amount of hydrogen and oxygen which were the invariable products of electrolysis in an aqueous solvent.

Although an ambiguity remains in the anodic oxidation of *t*-alcohols, generation of *t*-alkoxy radical at anode and consequently the ejection of an alkyl radical from *t*-alkoxy radical can be deduced from the results given in Table 1 and Table 2; the high yields of ketones and generation of dimerization product of the ejected alkyl radical are indicative for the generation of *t*-alkoxy radical at anode (Eq. (2)).*2

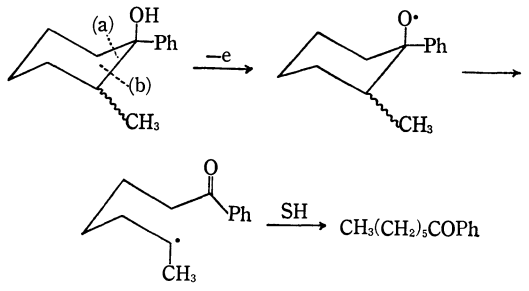
*2 There is a possibility of the anodic oxidation of *t*-alkoxy radical to *t*-alkoxy cation which produces ketone and alkyl cation. However, *t*-alkoxy cation which would be formed, should decompose to produce aliphatic ketone and phenol:

$$R_1R_2PhCO\cdot \xrightarrow{-e} R_1R_2PhCO^+ \xrightarrow[(H_2O)]{} R_1R_2CO + PhOH$$

because the alkoxy cation is a well established intermediate of the acid catalysed decomposition of aralkyl hydroperoxides. For example, α,α-dimethylbenzyl hydroperoxide decomposes to acetone and phenol (M. S. Kharasch, A. Fono and W. Nudenberg, *J. Org. Chem.*, **15**, 748 (1950)). Since none of phenolic product nor aliphatic ketone could be detected as the reaction product, such a possibility of the anoidic oxidation of *t*-alkoxy cation can be ignored.

$$\left.\begin{array}{l} R_1R_2PhCOH \xrightarrow{-e} R_1R_2PhCO\cdot + H^+ \\ R_1R_2PhCO\cdot \begin{cases} \xrightarrow{k_1} R_2COPh + R_1\cdot \\ \xrightarrow{k_2} R_1COPh + R_2\cdot \end{cases} \\ R_1\cdot + R_2\cdot \begin{cases} \longrightarrow R_1R_1 + R_2R_2 + R_1R_2 \\ \longrightarrow R_1H + R_2H + \text{olefins} \end{cases} \end{array}\right\} \quad (2)$$

Since the hydrogen abstraction from solvent by *t*-alkoxy radical which is another main reaction of it, produces the starting material in this reaction, such a way of stabilization of *t*-alkoxy radical can be neglected from the consideration. Assuming the relative amounts of ketones are equal to the relative ease of fragmentation of an alkyl moiety from *t*-alkoxy radical; $k_1/k_2 = R_2COPh/R_1COPh$, a trend of the relative ease of cleavage can be deduced, which is shown in Table 3 with the values obtained from the other reactions by several investigators. Thus, the trend of the relative ease of cleavage reaction deduced from the results of the anodic oxidation of *t*-alcohols coincides qualitatively with the results which are obtained from the other different type of reactions. It has been generally accepted that the predominant cleavage is that which forms the largest alkyl radical; qualitatively, the relative ease of ejection of an alkyl radical from *t*-alkoxy radical decreases in the order: *tertiary* > *secondary* > *primary*, but recently have presented the facts which are inconsistent with this conception from the study of dissociation energy of alkanes by electron impact[10] and from the study of photolytic decomposition of alkyl hypohalites.[9] Bacha and Kochi have shown that the relative rates of cleavage decreases in the order which is shown in Table 3; ethyl > γ,γ-dimethylbutyl > *n*-propyl, *n*-butyl > isobutyl > neopentyl ≫ methyl, from the study of photolytic decomposition of various *t*-alkyl hypochlorites, and have proposed that the most important factor which determines the relative rate of ejection of an alkyl radical from *t*-alkoxy radical is the hyperconjugative effect of β-hydrogen of a departing alkyl radical for the stabilization of transcient stage of bond scission.[9] Our results obtained from the anodic oxidation of *t*-alcohols seem to substantiate the conception presented by Bacha and Kochi. In order to examine further this problem, 1-phenyl-2-methyl-cyclohexanol which is considered to be relatively strain free compound, has electrolysed in the dioxane - water-sodium hydroxide system. If the bond scission occurred at (a), the number of β-hydrogen is two. If the bond scission occurred at (b), then the number of β-hydrogen is five. Actually, *n*-hexyl phenyl ketone which indicates the bond scission at (b), was the sole product as the ketonic product; this shows the importance of the hyperconjugative effect of β-hydrogen (Eq. (3)).



SH: solvent (3)

In addition to the effect of the number of β-hydrogen, a prominent rate enhancement for the bond scission by double bond at β-position can be found from the results of runs 10 and 11. Such an effect of double bond for the rate enhancement as well as the effect of β-hydrogen suggests that a stabilization of the polarized transcient stage for the bond scission is predominant factor (Eq. (4)).

$$R_2\text{-}\overset{\overset{R_1}{|}}{\underset{\underset{Ph}{|}}{C}}\text{-}O\cdot \rightarrow \left[R_2\cdot\overset{\overset{R_1}{|}}{\underset{\underset{Ph}{|}}{C}}{=}O \longleftrightarrow R_2{}^+\overset{\overset{R_1}{|}}{\underset{\underset{Ph}{|}}{C}}{=}O^- \right] \rightarrow R_2 + R_1COPh \quad (4)$$

The importance of the polarized transient stage has already pointed out by Bacha and Kochi as to the rate enhancement by β-hydrogen.[9] We can find ample evidences for such an importance of polar effects to the radical reactions.[11] Effects of ring size and ring strain are also shown to be a determining factor of the relative ease of ejection of an alkyl radical from the parent alkoxy radical.[8]

Experimental

Preparation of Alcohols. The tertiary alcohols were prepared by the Grignard procedure from phenyl bromide and corresponding ketones and were purified by vacuum distillation until to obtain materials giving a single spot *via* thin layer chromatography. Physical constants of *t*-alcohols found are shown in Table 4.

Anodic Oxidation and Quantitative Analysis of Reaction Mixtures. A typical anodic oxidation of *t*-alcohol was conducted as following; 1.00 g of an *t*-alcohol and 20 mg of sodium hydroxide were dissolved into a mixture of 10 m*l* of dioxane and 4 m*l* of water. The solution was electrolysed in a 100 cylindrical flask with two parallel platinum plates as electrodes (surface area: 2.0×1.5 cm^2, distance between electrodes: 0.2 cm, electric potential between electrodes: 10—20 V, current: 0.3—0.5 A). A violent evolution of gaseous product at anode could be observed. The temperature of the solution was held at 25—35°C by cooling with water. After electrolysis was continued for about ten

hours, the reaction mixture was treated with ether, dried with anhydrous sodium sulfate, and quantitatively analysed by g.l.p.c. techniques. Identifications of products were carried out by the comparison of the retention time of each component on chromatogram with authentic samples. The columns used for analyses of the ketones were calibrated with standard solutions at the same time under the same condition. Bromobenzene was used as an inner standard sample. From the ratio of peak areas (ketone to bromobenzene), the amount of each component could be determined. The gas chromatographic columns for the determination of ketonic components are following; (1) 200 cm Apiezon-L on Cerite (80—100 mesh), (2) 200 cm TG-3000 on Certie (80—100 mesh), (3) 300cm High Vacuum Grease on Cerite (80—100 mesh), Carrier gas: H_2 at 150—200°C. The gas chromatographic column for the identification of gaseous products was a 200 cm column of β,β'-oxydipropionitrile on Cerite, carrier gas: H_2 at 25°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1404—1413 (1968)

Perchloro-compounds. IV. *anti*-Perchloro-(3,4,7,8-tetramethylenetricyclo-[4.2.0.0^{2,5}]octane), a Dimer of Perchloro-(3,4-dimethylenecyclobutene)

Koichi MANO, Kousuke KUSUDA and Akira FUJINO

Organic Chemistry Division, Research Institute for Atomic Energy, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 16, 1967)

The structure of the first of the four thermolytic dimers of perchloro-(3,4-dimethylenecyclobutene) was characterized as *anti*-perchloro-(3,4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]octane) (II). This structure elucidation was principally based on: (a) the permanganate oxidation of II to perchloro-(dimethylenesuccinic) acid; (b) the two-step reduction of II to 1,2,3',4',5,6,7',8'-octachloro-3,4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]octane and 1,2,5,6-tetrachloro-3,4,7,8-tetramethyltricyclo[4.2.0.0^{2,5}]octa-3,7-diene (VII), and (c) the hydrogenation of the ozonized product from VII to two tetraacetylcyclobutanes (XVII and XVIII). The physical and chemical properties of II and of those substances derived from II and VII were discussed in detail. The stereochemical configurations of II and XVII were estimated to be *anti* and all-*trans* respectively.

It has already been briefly reported that the temperature-controlled thermolysis of perchloro-(3,4-dimethylenecyclobutene) (I)[1,2] affords, besides perchlorofulvene, perchloro-(4-methylenecyclopentene), and perchlorobenzene, at least four dimeric products, the first isomer of which is formed in the vicinity of 160°C and may be characterized as a cycloadduct, *anti*-perchloro-3,4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]octane) (mp 266°C) (II).[3,4] The differential thermal analysis data suggest that the successive transformation of II takes place, step by step as the thermolysis temperature rises, to

give the second isomer, labile perchloro-(3,4,7,8-tetramethylenecyclooctadiene) (mp 215°C) (III),[5] mixed with the third isomer (rigid form of III) (mp 262°C) (IV)[5] and the fourth isomer, perchloro-(4,8-dimethylenetricyclo[3.3.2.0^{1,5}]deca-2,6-diene) (mp 273°C) (V)[6] (Chart 1). The present paper will describe a detailed study of the structure elucidation of II as well as the physical and chemical properties of some related compounds obtained in the course of our investigation.

Results

The material necessary for the elucidation was best supplied by means of the ionic dimerization of I in dichloromethane with anhydrous aluminum chloride,[3] since the average yield of *ca.* 60% was much higher than that in thermolysis. It was observed that II is hardly soluble in ordinary nonpolar organic solvents (*e. g.*, approx. 2 g/1*l* carbon tetrachloride), is inert to acid or alkaline hydrolysis, and is stable against the UV-light irradiation in solution, in contrast to its remarkable thermal instability. The attempted chlorination of II in liquid chlorine or with chlorine gas in a heated solution was unsuccessful, only the unreacted substrate being recovered. The permanganate oxidation of II in acetone proceeded rapidly to give perchloro-(dimethylenesuccinic) acid in a yield as low as that in the similar oxidation of I.[1] The reduction of II with zinc in ethanol or acetic acid smoothly furnished 1,2,3′,4′,5,6,7′,8′-octachloro-3,4,7,8-tetramethylenetricyclo[4.2.2.0.0^{2,5}]octane (mp 223—225°C) (VI), which was then further hydrogenated over palladium charcoal at room temperature to give 1,2,5,6-tetrachloro-3,4,7,8-tetramethyltricyclo[4.2.2.0.0^{2,5}]octa-3,7-diene (mp 180°C, decomp.) (VII). The latter compound was also directly obtained in 77% yield from II by hydrogenation with the same catalyst. In this case there was isolated as a by-product a small amount of hydrocarbon (bp 80°C(bath)/20 mmHg) (VIII) to which the structure of 3,4,7,8-tetramethylbicyclo-

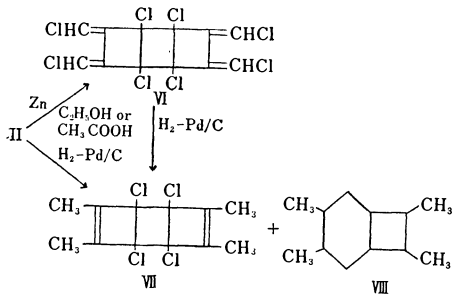

Chart 2

[4.2.0]octane was assigned. These reactions are illustrated in Chart 2.

The residual chlorine substituents in VII strongly resisted the attack of other reducing or basic reagents, such as lithium alanate-lithium hydride in ether, nickel carbonyl in benzene, Raney nickel in methanol, zinc-acetic acid, liquid ammonia, and alcoholic potassium hydroxide. So far as we have examined, only *n*-butyllithium in ether reacted with VII, but even if did so without any conclusive result. On the other hand, a variety of the ring-cleaved products were obtained when VII was subjected to ozonization. There was observed a marked dependence of the product on the solvent employed. Thus, in dichloromethane or carbon tetrachloride-chloroform at −20°C, VII was transformed by ozone to an unstable viscous oil which then gradually decomposes, liberating a gas with a phosgene-like odor. When this oil was treated with mineral acid, a crystalline compound, $C_{12}Cl_4H_{12}O_3$ (mp 125—127°C) (IX) was obtained. In ozonization in petroleum ether at room temperature, an isomer (mp 122—124°C) (X), possibly isoozonide of VII, and 5,6-diacetyl-1,4,5,6-tetrachloro-2,3-dimethylbicyclo[2.2.0]hexene-2 (mp 113—115°C) (XI) were the products, along with a small amount of IX. The low reactivity toward ozone of the remaining ring-double-bond in XI had already been briefly described.[3] Further careful work has revealed that the ozonization of VII in carbon tetrachloride-methanol at −20°C resulted in the production of a new crystalline isoozonide, $C_{12}Cl_4H_{12}O_5$ (mp 182°C, decomp.) (XII) (16% yield), in addition to X (4%) and XI (66%). A trend to form this extremely stable isoozonide was demonstrated in the experiment; the result of the ozonization of XI in ethyl acetate in the presence of tetracyanoethylene, a very effective oxygen-acceptor of ozonide,[7] was essentially the same as that in an experiment without such a special reagent. In a much higher yield (70—80%), XII was obtained by the ozonization of VII either in carbon tetrachloride or in acetic acid at room temperature, and later, quantitatively from XI under the same conditions.

Several attempts to synthesize a compound like XIIIa or XIIIb bearing a "Dewar-benzene" structure were made, since it appeared that the substituents on the ring were bulky enough to stabilize it rather than the benzene derivative.[8] However, the high cyclizing tendency between the vicinal acetyl groups in XI was a decisive disadvantage for any dechlorinating agent used; with zinc metal in ethanol or nickel carbonyl in benzene, the only product isolated was a ketol (XIV) (mp

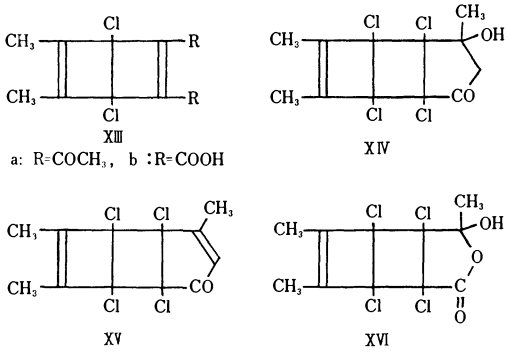
160°C, *ca.* a 50% yield in either case), while with a freshly-prepared nickel metal in benzene, the reaction again ended with the production of XIV (20% yield), along with the dehydrated dienone (mp 192—193°C) (XV). Contrary to our expectations, attempts at the degradation of XI by oxidation with sodium hypobromite or with nitric acid to dicarboxylic acid also resulted in cyclization to XIV or a lactol (mp 167—169°C) (XVI).



a: R=$COCH_3$, b: R=COOH

The isoozonide ring in XII was opened by catalytic hydrogenation over palladium charcoal in ethanol, giving all-*trans*-tetraacetylcyclobutane (mp 145°C) (XVII), identical with that reported by Griffin,[9] and the tetraketal (mp 282°C, decomp.) (XVIII) of its all-*cis*-isomer in a ratio of approximately 4 : 1. When a similar hydrogenation was carried out in the presence of sodium acetate, XVIII dominated XVII in the product yield. Chart 3 summarizes the results of the ozonization and hydrogenation of the compounds concerned.

Discussion

The reactivities of I toward various chemical reagents have been discussed in previous papers.[2,10,11] It can easily be inferred that II is a cycloaddition product, since the dimerization takes place in the thermal reaction at a high temperature, where the process is known to be essentially homolytic. The structural evidence for II and its degradation will be briefly discussed below.

Evidently, there is a close relationship between both the ultraviolet and the infrared spectral data of II and those of perchloro-(1,2-dimethylenecyclobutane) (XIX). The former gives rise to UV absorptions with the $\lambda_{max}^{n\text{-hexene}}$ of 287, 299, and 314 mμ (log ε 4.44, 4.65 and 4.43), which are, respectively, 8, 11 and 9 mμ shorter in their positions and 2—3 times more intense in their ε values than those described for the latter[1] (Fig. 1). The IR absorptions for the dichloromethylene groups of II ($\nu_{C=C}^{Nujol}$ 1610s, 1580s; $-C=CCl_2$ 910s[2] (cm^{-1})) consistently correspond to those (1605s, 1570s and 910s (cm^{-1}), Nujol mull) of XIX. The former compound resists chlorination under mild conditions, as, indeed, does the latter.

These data can reasonably be explained by assuming that II is composed of two units of the carbon skeleton of XIX. The permanganate oxidation of II to perchloro-(dimethylenesuccinic) acid has

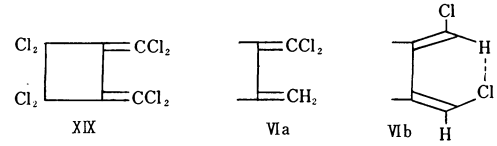
proved the presence of at least one vicinal dichloromethylene pair in the molecule. As for the position where the new bonding results, no other possibility than C_1 and C_2 in I can be considered in view of the relative reactivity of the double bonds.[2] The $\Delta\lambda_{max}$ (*ca.* 10 mμ) between II and XIX may well be interpreted by evaluating the hyperconjugative effect[12] of allylic chlorine substituents on both and a double bond-central ring interaction for the former. If the λ_{max} of 246 mμ for 1,2-dimethylenecyclobutane[13] is taken as a reference value, the substitution of its four exomethylene hydrogens by chlorines should cause a bathochromic shift of 32—34 mμ.[14] This is a common factor in both. The further increment of *ca.* 30 mμ for XIX was discussed by assigning it to the hyperconjugative effect of four allylic chloro-substitutions on the ring (7.5 mμ/Cl).[2] However, a similar interaction does not seem so effective in II, where the increment of 20 mμ is to be ascribed only to the paired angular chloro-substitution. On the contrary, X-ray crystallographic analysis[15] suggests that in II the angle, for instance, between the C_1–Cl bond and the p_z orbital of C_2 is near 42°, which is significantly wider than is the corresponding one in XIX (*cf.* near 35° in perchlorocyclobutane[16]). This relationship holds also in solutions (less than 7.5 mμ/Cl in II). Therefore, it may be speculated that there exists some interaction between the double bonds and the central cyclobutane ring in II. White and Dunathan[17] observed similar spectral evidence in a tricyclo[4.2.0.0^{2,5}]octa-3,7-diene system. A few additional pieces of evidence supporting this interpretation have been obtained in the course of our study and will be published later.

The assignment of the VI structure to the tetrahydro-compound rests on the following observation: (a) VI is further smoothly reduced to VII suggesting that no hydrogen atom is attached to the angular carbons; (b) the appearance of some new characteristic IR-absorptions, $\nu_{=CH}^{Nujol}$ 3060 and 3050 and $\delta_{=CH}$ 810 vs (cm^{-1}); (c) the value calculated (282 mμ) for the λ_{max} of the UV-absorption based on the reference hydrocarbon[13] is in good accordance with the observed value (278 mμ) if the same bathochromic displacement factor (20 mμ) as above is again taken into account. Unfortunately, it was impossible to examine the stereochemical configuration of the four hydrogens by means of NMR spectrometry because of the extremely low solubility of the sample. However, an alternative structure, partly shown by VIa, may be ruled out since only one strong singlet absorption is observed in the frequency range 970—830 cm^{-1} in IR, where VIa should give rise to at least two strong, distinguishable bands, corresponding to dimethylene and dichloromethylene groups. The band at 810 cm^{-1}, the most intense band over the whole range, could be due to the deformations of the four –C(Cl)=CHCl groups. The observed doublet due to $\nu_{=CH}$ absorption appears to indicate the non-equivalence of the hydrogens like VIb in each paired chloromethylene group, although the data of measurement in solution are lacking.



It is of interest to speculate on a possible course of the reduction of II to VI, in which the attack of the nascent hydrogen would first cause the replacement of one of the *endo*-chlorine atoms in each half of the molecule, resulting in some effective release of the Cl–Cl interaction. The distances in crystals[15] of Cl_2–$Cl_{3'(exo)}$ and $Cl_{4'(exo)}$–Cl_5 (both 3.32 Å), and of $Cl_{3'(endo)}$–$Cl_{4'(endo)}$ (3.28 Å), closer than twice the van der Waals radius of the chlorine atom, may reflect an interaction sufficient to make this stereospecificity possible.

Nenitzescu *et al.*[18] reported obtaining *syn*- and *anti*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene (XXa and XXb) from 3,4-dichlorocyclobutene by dechlorination. A more analogous pair (XXc and XXd) was synthesized by, respectively, the dechlorination of the suitable cyclobutene derivative (XXIb)[19] and by the thermal decomposition of tetramethylcyclobutadienenickel chloride.[20] Mechanistically, the formations of *syn*-stereomer involving those with other substituents[17,21] have been classified as by way of true cyclobutadiene intermediates.[22] Table 1 lists some physical properties of VII and XXa—XXd, along with those for cyclobutene (XXIa) and its derivatives (XXIb—XXId). The difference (0.45) in τ values between VII and XXc and XXd seems too large even if some difference in the shielding effect of the β-positioned angular

substituents is considered. The unusually low τ value of VII might be explained by assuming an especially sterically-enhanced shielding of the γ-positioned chlorine atoms which are, in the *anti*-form, on the same side of the paired methyl groups with respect to the central ring. Inasmuch as a value higher by far than 2.38 D (for XXIb) may be expected as the dipole moment for the *syn*-form, the ring configuration in VII may be ascribed to the *anti*-form.

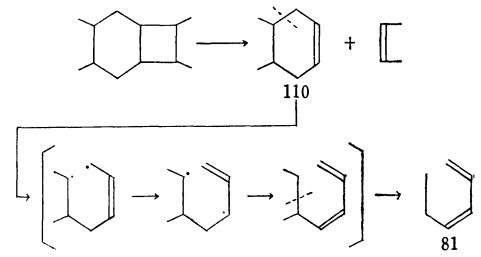
c: $R_1=CH_3$, R=H
d: $R_1=R_2=CH_3$

The extreme low reactivity of bridge-head chlorine substituents in compounds having a fused ring has been reported in many cases.[23] The four angular chlorines in VII were also very inert to reducing or hydrolyzing agents, even when the most drastic conditions were used.

Supporting evidence for the VIII structure was obtained in the mass spectrometric analysis as well as in the UV (no chromophore above 210 mμ) and the IR (no C=C band) spectra. The observed spectrum contains main peaks of $m/e=166$ (molecular ion), M−15, M−29, M−42, 110, 95 (base peak), 81, 69, and 55, and one metastable ion peak of m* 59.65 (110→81). These data are in accord with the bicyclic structure and the following degradation pattern.



The NMR spectrum also indicates the presence of ten and twelve protons in the ranges of, respectively, 7.70—9.00 τ and 9.00—9.45 τ; this is consistent with the formula shown above.

In co-operation with us, Furusaki *et al.*[15] have made a detailed X-ray analysis of II as well as a two-dimensional X-ray analysis of VII and have confirmed, in agreement with our estimation,[24] that the *anti*-form is referred to both the compounds.

Although the composition of IX corresponds to the ozonide of VII, its structure has remained uncertain. The isomeric product, X, may be presumed to be a stable isoozonide of VII on the

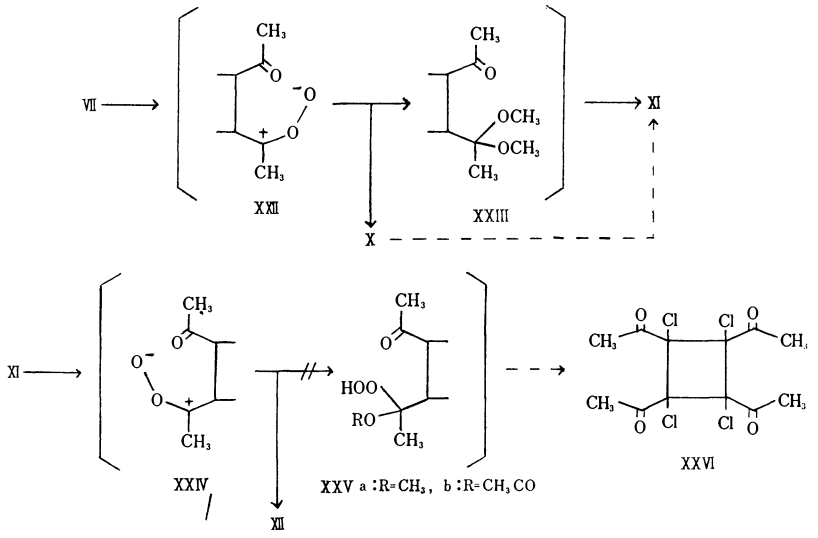
basis of its behavior toward a potassium iodide-starch solution being similar to that of XII (to be described below), as well as on the basis of the spectral data ($\nu_{C=C}$ 1680 m (cm^{-1}), 8.13 τ for $C{=}CCH_3$ and 8.13 τ for $\rangle CCH_3$). Compare these values with those of the related compounds, VII (Table 1), XI ($\nu_{C=C}$ 1680 w (cm^{-1}); 8.15 τ for $C{=}CCH_3$ and 7.63 τ for $COCH_3$), and XII (8.10 τ for $\rangle CCH_3$ and 7.70 τ for $COCH_3$). In X there is no λ_{max} in the UV spectrum observable above 215 mμ, but there are signals in NMR for the vinylic methyl groups coinciding with those for the saturated C-methyl groups. As expected from the least-satisfactory peroxide detection, X does not suffer any hydrolysis with mineral acid, reduction with zinc - acetic acid, or oxidation with permanganate.

The spectral data (UV: no λ_{max} with an ε value higher than 10^3 above 210 mμ; IR: $\nu_{C=O}^{CCl_4}$ 1720s, doublet; $\nu_{C=C}$ 1680 w, δ_{CH_3} 1380 m, 1360s (cm^{-1}); NMR: as above; two singlets equal in intensity) of XI support the diketone structure.

The observation that there is a complicated solvent- and temperature-dependency of the products in the ozonization of VII is noteworthy. Attention should also be paid to the fact that the exhaustive ozonization of VII, or the successive ozonization of XI, at room temperature affords a unique product, isoozonide XII, in good yields regardless of the type of solvent used. In our interpretation, it seems most possible that the ozone-adduct (XXII) first formed from VII is normally converted to the methoxy hydroperoxide (XXIII) according to the Criegee mechanism for the low-temperature reaction in a polar solvent (containing methanol),[25] and that hence XI is obtained as a preponderant product. Although the isolation of XXIII as substantial evidence has been unsuccessful, the alternate process through the X isoozonide does not seem to fit, particularly when the solvent contains methanol. Evidently, the ozonization of XI in such a solvent as carbon tetrachloride-methanol or acetic acid does not afford an analogous hydroperoxide (XXVa or XXVb) which, if produced, could eventually be converted to the isolable tetraacetyl-compound (XXVI). The difference in the ozonization modes shown above may be accounted for by the difference in the ease of isoozonide formation from the corresponding intermediate zwitter ions, XXII and XXIV, the former of which is bicyclic and the latter, monocyclic. The ring strain unfavorable for isoozonide formation would be significantly higher in the former than in the latter. The unexpected results of the ozonization of XI, even in the presence of tetracyanoethylene, indicate that the transfer of an oxygen atom from XXIV to the acceptor can not compete with the very smooth formation of the isoozonide ring.

Proofs for the structures of XIV and XV are as follows: (a) For XIV: IR: ν_{OH}^{Nujol} 3570s, 3490m, $\nu_{C=O}$ 1760s, $\nu_{C=C}$ 1680m, lack of a band at 1360 (cm^{-1}); NMR: 8.15 (6H, singlet, vinylic methyls), 8.72 (3H, singlet, saturated C-methyl), 6.80 (OH), and 6.50 and 7.27 (doublet, J=15.5 cps, methylene) (τ); (b) For XV: UV: λ_{max}^{EtOH} 225 mμ (log ε 3.97); IR: $\nu_{CH}^{CHCl_3}$ 3020w, $\nu_{C=O}$ 1740s, $\nu_{C=C}$ 1690w, 1625m (cm^{-1}); NMR: 3.90 (1H, quartet), 7.70 (3H, doublet, J=3 cps), 8.12 (6H, singlet) (τ).



24) Criegee *et al.*[20] describes an ozonization product of XXc, which can not be formulated as *syn*-5,6-diacetyl-1,2,3,4,5,6-hexamethylbicyclo[2.2.0]hexene-2 and probably be an unsaturated ketoether formed by a transannular reaction between the carbonyl groups and the sterically neighboring ring double bond in the expected bicyclohexene-2. If the *syn*-type is given to VII, the ozonolyzed product would be an analogous ketoether and not be diketone XI as is our case.

25) P. S. Bailey, *Chem. Revs.*, **58**, 925 (1958).

The easy occurrence of the intramolecular aldol-type cyclization from XI to XIV, followed by the dehydration to dienone XV, has indeed been a high barrier to approaching the "Dewar benzene." It has also made unsuccessful the attempted oxidation of XI with hypobromite - methanol, which would lead to another potential compound for the especially interesting benzene isomer. Contrary to the reported case with a permethyl analog,[26] the undesired XIV was obtained almost quantitatively. Nitric acid (sp. gr. 1.38) oxidizes one of the acetyl groups of XI to the carboxyl, which is then lactonized with the residual keto-group to form XVI. The structural evidence for XVI is: IR: ν_{OH}^{Nujol} 3320s, $\nu_{C=O}$ 1780s, $\nu_{C=C}$ 1690m (cm^{-1}); NMR: 7.99 (1.4H, singlet, $COCH_3$ due to partial dissociation), 8.13 (6H, singlet), 8.34 (1.6H, singlet) (τ) (in $CDCl_3$).

Practically, the hydrogenation was the only way achieved to cleave the isoozonide ring of XII, which strongly resists conversion to XXVI. Thus, the products were two isomeric chlorine-free compounds, XVII and XVIII. The spectral data for XVII (UV: λ_{max}^{EtOH} 283 mμ log ε 2.08; IR: $\nu_{OH}^{CHCl_3}$ 3400w, ν_{CH_3} 3030m, 3005m, ν_{CH} 2910w, $\nu_{C=O}$ 1715vs, $\nu_{C=C}$ 1675w, δ_{CH_3} 1425m, 1360s (cm^{-1}); NMR: 6.39 and 7.79 (both singlets, intensity ratio 1 : 3) (τ)) do not contradict the structure of all-*trans*-1,2,3,4-tetraacetylcyclobutane. The identification has been established by an IR spectra comparison between XVII and an authentic sample kindly offered by Professor Griffin. With both samples, the spectra in the solid state indicate weak absorptions for hydroxyl group and the C=C double bond absorptions, which become much weaker still when measured in chloroform. No OH-signal can be noticed in the NMR spectrum taken in D-chloroform. These facts suggest that at least one of the four acetyl groups in XVII exists in an enol-form in the solid; the equilibrium in solution between keto- and enol-forms is by far in favor of the former (more than 90% in the saturated solution). The production of the all-*trans*-isomer further suggests the inversion of at least two of the carbon moieties attached to the cyclobutane ring of XII.

Product XVIII shows much lower solubilities in alcohol, acetone, chloroform, carbon tetrachloride, *etc.*, than those for XVII, which is easily isolated by the recrystallization of the mixture. The IR (no carbonyl) and the NMR (6.76 and 8.47 (τ)) spectral data accord with the suggested structure. An analogous compound with the intramolecular tetraketal type has been reported by Criegee *et al.*;[20] *i. e.*, XXc was converted to the tetraketal of all-*cis*-1,2,3,4-tetraacetyl-1,2,3,4-tetramethylcyclobutane. Although a certain similarity was observed between the mass spectral data of XVII and XVIII, a significant difference was found in their base peaks (*m/e* 43 for acetyl and 18 for H_2O respectively), a difference which can reasonably be explained in terms of the proposed structures.

Experimental[27]

***anti*-Perchloro - (3,4,7,8 - tetramethylenetricyclo-[4.2.0.0^{2,5}]octane (II) from Perchloro-(3,4-dimethylenecylobutene) (I).** *a) By Pyrolysis.* In a sublimation apparatus, I (10 g, 35 mmol) was carefully heated at 155—165°C (oil bath temperature) for 3 hr without water in the cold finger. When the pyrolysis was over, water running was allowed to enter and there was collected a small amount of unreacted I by vacuum sublimation at 130—140°C/3 mmHg. The residue was refluxed with ligroin (300 m*l*) to remove the tarry by-product, and the insoluble fraction was, after filtration, recrystallized from carbon tetrachloride to give II (2.8 g, 5 mmol). Yield: 28%. Mp 266°C.

Found: C, 25.77; H, 0.90; Cl, 75.04%. Calcd for $C_{12}Cl_{12}$: C, 25.30; H, 0.00; Cl, 74.70%.

b) With Anhydrous Aluminum Chloride. To crystals of I (2.5 g, 8.8 mmol) well-mixed with anhydrous aluminum chloride (2.5 g, 19 mmol), dichloromethane (3 m*l*) was added while the moisture was shut off. The mixture immediately turned green, evolving hydrogen chloride. It was then allowed to stand at room temperature overnight. The reaction mixture was poured onto ice water, shaken with carbon tetrachloride (10 m*l*), and an insoluble fraction was separated by the decantation of the aqueous layer. Crude crystals (1.6 g, 2.8 mmol) of II were thus obtained. Yield: 64%.

Oxidation of II with Potassium Permanganate. A suspension of II (570 mg, 1.0 mmol) in acetone (100 m*l*) was vigorously stirred under refluxing, and then powdered potassium permanganate (1.4 g, 7.8 mmol) was added, portion by portion. After the complete consumption of the oxidizing agent, manganese dioxide was filtered off and washed with hot water. The filtrate was evaporated under reduced pressure to give the residue, which was, after being dissolved in ether, separated into acidic and neutral parts by the ordinary procedure. From the acidic fraction there was obtained a crystalline product (50 mg) which was recrystallized from water to furnish a pure sample (mp 215°C, decomp.) identical in all respects with authentic perchloro-(dimethylenesuccinic) acid.[2] The neutral fraction gave recovered II (26 mg).

Reduction of II with Zinc in Ethanol, *anti*-1,2,3',4',5,6,7',8'-Octachloro-3,4,7,8-tetramethylenetricyclo[4.2.0.0^{2,5}]octane (VI). Zinc powder freshly treated with dilute hydrochloric acid was added to a suspension of II (2.60 g, 4.5 mmol) in ethanol (280 m*l*), and the mixture was then heated under refluxing for 1.3 hr. The reaction mixture was centrifuged to separate

27) The differential thermal analysis data will be described in the succeeding paper. All melting points are measured under microscope and not corrected. Ultraviolet spectra are taken with Hitachi Ultraviolet Spectrophotometer EPS-2U, infrared spectra with Perkin-Elmer Infrared Spectrophotometer Model 337, and NMR spectra with Nuclear Magnetic Resonance Spectrometer JNM-C-60.

the insoluble material. The mud thus obtained was extracted with a large amount of boiling benzene to give the crude VI (1.20 g, 2.8 mmol) in a 62% yield. Recrystallization from carbon tetrachloride afforded a pure sample, mp 223—225°C.

Found: C, 32.96; H, 1.25; Cl, 66.03%. Calcd for $C_{12}Cl_8H_4$: C, 33.38; H, 0.93; Cl, 65.74%. λ_{max}^{EtOH} 278 (4.26), λ_{sh} 290 (4.04) mμ (log ε). ν_{CH}^{Nujol} 3060m, 3050m, $\nu_{C=C}$ 1650w, 1620s; $\delta_{=CH}$ 810vs (cm^{-1}).

Similarly, the reduction of II (570 mg) with zinc powder (5.0 g) in acetic acid (35 m*l*) at room temperature for 1 hr resulted in the isolation of VI (99 mg). Yield: 23%.

***anti*-1,2,5,6-Tetrachloro-3,4,7,8-tetramethyltricyclo[4.2.0.0^{2,5}]octa-3,7-diene (VII).** *a) Catalytic Hydrogenation of II.* In an autoclave (500 cc), a suspension of II (5.70 g, 10 mmol) in ethanol (300 m*l*) was, after the addition of 5% palladium-charcoal (5.0 g) and sodium acetate (12.0 g), stirred at room temperature under a compressed hydrogen atmosphere for 50 hr, during this period the initial pressure (60 atm) dropped to 32 atm. The product solution was filtered, concentrated, and extracted with petroleum ether, from which solution crude crystals (2.3 g, 7.7 mmol) of VII were isolated with a slight contamination of an oily material. Recrystallization from ethanol and subsequent sublimation at 100°C/3 mmHg afforded a pure sample. Mp 180°C, decomp.

Found: C, 48.35; H, 4.06; Cl, 47.43%. Calcd for $C_{12}Cl_4H_{12}$: C, 48.32; H, 4.02; Cl, 47.65%. No absorption maximum above 210 mμ (ethanol solution).

b) Catalytic Hydrogenation of VI. In an autoclave (50 cc), VI (650 mg, 1.5 mmol), 5% palladium-charcoal (800 mg), and sodium acetate (1.50 g) were suspended in methanol (300 m*l*), after which the whole mixture was shaken with an initial hydrogen pressure of 60 atm at room temperature for 77 hr. The final pressure was 30 atm. The same subsequent treatment as above gave VII (100 mg, 34% yield).

3,4,7,8-Tetramethylbicyclo[4.2.0]octane (VIII). The oily fraction separated in the recrystallization of VII in a) was vacuum-distilled; bp 80—100°C (bath)/20 mmHg. The gas chromatographic analysis of the colorless distillate showed a purity of approx. 98%.[28] No chlorine appeared in a Beilstein test.

Found: C, 86.80; H, 13.20%. Calcd for $C_{12}H_{22}$: C, 86.74; H, 13.25%. No absorption maximum above 210 mμ (ethanol solution). IR: 2950s, 2920s, 2860s, 1470s, 1460s, 1380s, 1010w (cm^{-1}) (liquid film). NMR: 7.70—9.00 (10H), 9.00—9.45 (multiplet, 12H) (τ) (CCl_4).

Ozonization of VII under Various Conditions. *a) In Carbon Tetrachloride-Methanol at a Low Temperature.* A stream of oxygen-ozone was passed into a suspension of VII (3.00 g, 10 mmol) in a mixture of carbon tetrachloride (220 m*l*)) and methanol (300 m*l*) which had been cooled at −20°C until the suspension disappeared and the solution VII became completely clear. On the evaporation of the solvent under diminished pressure at 0°C, white crystals (3.11 g) were obtained. The crude product was dissolved in carbon tetrachloride and chromatographed on silica gel (Mallinckrodt Chem. Works, 100 mesh,[29] 40 g) with the same developing solvent. From the No. 1 fraction (20 m*l*) unreacted VII (230 mg) was obtained. The No. 4, 5, and 6 fractions furnished, on the evaporation of the solvent, colorless crystals (130 mg in total, 4.0% yield), which were then recrystallized from ethanol to give a pure sample (mp 122—124°C) of X.

Found: C, 42.03; H, 3.56; Cl, 40.64%. Calcd for $C_{12}Cl_4H_{12}O_3$: C, 41.62; H, 3.47; Cl, 41.04%. No absorption maximum above 215 mμ (ethanol solution). $\nu_{C=C}^{Nujol}$ 1680 cm^{-1}. 8.13 τ (singlet, CCl_4).

The adsorbed product was further developed with carbon tetrachloride - chloroform (1 : 1 by vol.). The eluted crystals (2.04 g, 66% yield) were recrystallized from ethanol. The pure XI melted at 113—115°C.

Found: C, 43.75; H, 3.68; Cl, 42.78%. Calcd for $C_{12}Cl_4H_{12}O_2$: C, 43.64; H, 3.64; Cl, 43.03%. $\nu_{C=C}^{CCl_4}$ 1720s, 1710s, $\nu_{C=C}$ 1680w, δ_{CH_3} 1380m, 1360s (cm^{-1}); 7.63 (singlet, 6H), 8.15 (singlet, 6H) (τ) (CCl_4).

Finally, an ether - chloroform mixture (1 : 1) eluted the third fraction (549 mg) of crystals, which were purified to XII by recrystallization from ethanol. Mp 182°C (decomp.). Yield: 16%. Positive to a potassium iodide-starch test.

Found: C, 38.41; H, 3.24; Cl, 38.17%. Calcd for $C_{12}Cl_4H_{12}O_5$: C, 38.10; H, 3.17; Cl, 37.57%. $\nu_{C=C}^{CCl_4}$ 1750s, 1730s, δ_{CH_3} 1380s, 1360s (cm^{-1}); 7.70 (singlet, 6H), 8.10 (6H) (τ) ($CDCl_3$).

b) In Dichloromethane or Carbon Tetrachloride - Chloroform at a Low Temperature. By essentially the same procedure as above, a viscous oil (800 mg) was obtained from a solution of VII (600 mg, 2 mmol) in dichloromethane (100 m*l*) by ozonization, followed by solvent evaporation. Nitric acid (sp. gr. 1.38, 2 g) was then added to the oil, and the mixture was heated at 100°C on a water bath for 1 hr, during this time some crystals were sublimated on the wall of the cooler. Ether extraction from the aqueous solution and the subsequent fractionation of the neutral part furnished a crystal sludge (300 mg). The chromatography of the benzene solution on aluminum oxide (Woelm, neutral, activation grade 1, 6 g) gave a fraction of IX (180 mg, 26% yield), which was then eluted with acetone and further purified by recrystallization from benzene or by vacuum sublimation (100°C (bath)/3 mmHg). Mp 125—127°C. 25 mg.

Found: C, 41.75; H, 3.56; Cl, 40.51%. Calcd for $C_{12}Cl_4H_{12}O_3$: C, 41.62; H, 3.47; Cl, 41.04%. No absorption maximum above 215 mμ (ethanol solution). Starting with the same amount of VII, ozonization in carbon tetrachloride - chloroform at −20°C afforded the identical oily product (720 mg), from which IX (155 mg, crude) was isolated.

c) In Petroleum Ether at Room Temperature. After the ozonization of VII (600 mg, 2 mmol) in petroleum ether (boiling below 45°C, 70 m*l*) at room temperature, a crystal sludge (600 mg) was obtained. It was dissolved again in petroleum ether and chromatographed on silica gel much as in a). 1) Petroleum ether - carbon tetrachloride eluted first a crystalline material (mp 122—124°C, 59 mg) identical with X. Yield:

28) Hitachi Perkin-Elmer Gas Chromatography Model F6D; Carrier gas: nitrogen; Column: 3 mmOD × 1 m packed with SE-30 Silicon Oil on Chromosorb W. Programmed from 50°C to 150°C.

29) The same silica gel will be used hereinafter.

8%. 2) The next crop, eluted with carbon tetrachloride alone, was the crude XI (107 mg, 16% yield), melting at 113—115°C after recrystallization from methanol. 3) Finally, crystals (40 mg) identical with IX were eluted with chloroform. Yield: 6%. Mp 125—127°C.

d) In Carbon Tetrachloride or Acetic Acid at Room Temperature. From VII (300 mg, 1 mmol) dissolved in carbon tetrachloride (10 ml) and water (1 ml), a crystalline product (220 mg) identical with XII was obtained; it was then recrystallized from carbon tetrachloride. Mp 182°C (decomp.). The runs with acetic acid as a solvent resulted in a comparable yield of XII.

Ozonization of 5,6-Diacetyl-1,4,5,6-tetrachloro-2,3-dimethylbicyclo[2.2.0]hexene-2 (XI). *a) In Acetic Acid or Carbon Tetrachloride at Room Temperature.* At room temperature, XI (900 mg, 2.7 mmol) dissolved in acetic acid (40 ml) and water (10 ml) was ozonized for 3 hr after which period some solid material crystallized out. The ozone-passing was stopped after an additional hour, and the solvent was evaporated. The residue consisted of colorless prisms of XII melting at 182°C (1.00 g). When carbon tetrachloride (15 ml) was used as the ozonization solvent, the yield of XII was 72% from XI (750 mg, 2.1 mmol).

b) In Ethyl Acetate at Room Temperature in the Presence of Tetracyanoethylene (TCNE). From XI (330 mg, 1 mmol) dissolved in ethyl acetate (20 ml), after working up ozonization in the presence of TCNE (160 mg, 1.25 mmol) afforded XII (230 mg, 61% yield).

Attempted Dechlorinations of XII to a Dewar Benzene (XIII). *a) With Zinc Powder-Ethanol or Nickel Carbonyl in Benzene; 1,2,5,6-Tetrachloro-7-hydroxy-3,4,9-trimethyl-7-oxotricyclo[4.3.0.0^{2,5}]nonene-3 (XIV).* After XI (400 mg, 1.2 mmol) had been refluxed with zinc powder (250 mg) in ethanol (10 ml) for 3 hr the soluble material was filtered off. The evaporation of the solvent of the filtrate furnished a crystalline product, which was then purified by chromatography on silica gel (5 g). The fraction eluted with chloroform afforded, on solvent evaporation, white crystals (206 mg) of XIV. Mp 150—156°C. Recrystallization from carbon tetrachloride gave a pure sample melting at 160°C. Yield: 52%.

Found: C, 43.91; H, 3.95; Cl, 42.86%. Calcd for $C_{12}Cl_4H_{12}O_2$: C, 43.64; H, 3.64; Cl, 43.03%.

The run with XI (300 mg, 1 mmol) and nickel carbonyl (27% benzene solution, 2 ml) also resulted in the production of XIV (150 mg, 0.5 mmol).

b) With Freshly-Prepared Nickel Metal; 1,2,5,6-Tetrachloro-3,4,9-trimethyl-7-oxotricyclo[4.3.0.0^{2,5}]nona-3,7-diene (XV). Nickel formate (10.6 g, 71 mmol) was pyrolyzed under reduced pressure at 245°C. After complete decarboxylation and spontaneous cooling, a solution of XI (580 mg, 1.75 mmol) in anhydrous benzene (20 ml) was added under a nitrogen atmosphere and the suspension was refluxed for 2 hr. The reaction mixture was then cooled and filtered, and the solid residue was washed with benzene. On the evaporation of the solvent of the filtrate, a crystalline product (crude XV, 470 mg) was obtained. Chromatographical purification on silica gel (10 g) afforded a fraction (200 mg, 0.64 mmol) eluted with carbon tetrachloride. Further recrystallization from the same solvent gave colorless prisms melting at 192—193°C.

Found: C, 46.24; H, 3.37; Cl, 45.68%. Calcd for $C_{12}Cl_4H_{10}O$: C, 46.15; H, 3.21; Cl, 45.51%.

A second crop (116 mg), isolated by subsequent elution with chloroform, was identical with the XIV obtained in a). Mp 160°C. Yield 21%.

Oxidation of XI with Sodium Hypobromite; Conversion to XIV. A methanol solution (20 ml) of XI (100 mg) was added to a 10% aqueous solution (30 ml) of sodium hydroxide and bromine (0.2 ml), whereupon an exothermal reaction occurred, turning the solution dark yellow. After the solution had been allowed to stand overnight, the product was isolated according to the ordinary procedure. From the neutral fraction XIV was obtained in an almost quantitative yield. Mp 160°C. No detectable amount of the acidic fraction was found.

Nitric Acid Oxidation of XI; Lactol (XVI). A mixture of the crude XI (900 mg, 2.7 mmol) and nitric acid (sp. gr. 1.38, 50 ml) was kept at 80°C for 2.5 hr. From the bicarbonate-soluble fraction, the product (200 mg) was precipitated on acidification. It was purified by chromatography on silica gel. The fraction eluted with chloroform consisted of colorless crystals, which were then further recrystallized from the same solvent to give a pure sample. Mp 167—169°C.

Found: C, 39.74; H, 3.12; Cl, 42.29%. Calcd for $C_{11}Cl_4H_{10}O_3$: C, 39.76; H, 3.01; Cl, 42.77%. No 1360 cm^{-1} band originally observed in XI was found.

Catalytic Hydrogenation of XII; all-*trans*-Tetraacetylcyclobutane (XVII) and Tetraketal of all-*cis*-Tetraacetylcyclobutane (XVIII). *a) Without Sodium Acetate.* The solution of XII (1.00 g, 2.65 mmol) in ethanol (100 ml) was subjected to hydrogenation at an ordinary pressure over 5% palladium-charcoal (1.0 g). The absorption of hydrogen ceased when a 5.42 equimolar amount had been consumed. The catalyst was then filtered and washed. The filterate was concentrated by evaporation at reduced pressure to approx. one-third the original volume. During this process, the solution gradually turned dark brown. Complete evaporation resulted in a mixture of white crystals and a brown oil, the latter of which was removed by being dissolved in water. White crystals (250 mg), when showed no chlorine contamination when submitted to a Beilstein test, were recrystallized from methanol to give pure needle crystals of XVIII (50 mg) melting at 282°C under decomposition. No carbonyl band was observed in the IR spectrum. Yield: *ca.* 8%.

Found: C, 64.20; H, 7.37%. Calcd for $C_{12}H_{16}O_4$: C, 64.28; H, 7.14%. IR: 3020m, 2980s, 2940m, 1460m, 1380s (hexachlorobutadiene mull); 1330s, 1300s, 1260s, 1200—1130 (broad), 1000—880 (5 bands), 805—800 (doublet), 650—635 (doublet), 530s (Nujol mull) (cm^{-1}) NMR: 6.76 (singlet, 4H), and 8.47 (singlet, 12H) (τ) ($CDCl_3$).

The filtrate of the recrystallization of XVIII furnished on the evaporation of the methanol, crystals (mp 133—134°C) slightly contaminated by XVIII. Recrystallization from acetone gave pure needle crystals of XVII (mp 145°C), identical with an authentic sample of all-*trans*-tetraacetylcyclobutane[9] (reported melting point: 139—140°C) in a comparison of the IR spectra.

Found: C, 64.05; H, 7.20%. Calcd for $C_{12}H_{16}O_4$: C, 64.28; H, 7.14%.

b) With Sodium Acetate. In ethanol (80 ml), XII

917 mg, 2.42 mmol) was hydrogenated at ordinary pressure over 5% palladium-charcoal with sodium acetate (1.62 g). In all 5.04 equimolar hydrogen was absorbed. Treatment similar to that in a) gave a mixture of colorless oil and crystals. The mixture was washed with dilute hydrochloric acid to remove the sodium acetate recovered and the sodium chloride formed. The crystals thus obtained were almost XVII-free. Vacuum sublimation at 100°C (bath)/3 mmHg afforded pure needle crystals (mp 282°C, decomp.). Yield: *ca.* 20%.

We wish to express our deep thanks to Professor G. W. Griffin, Louisiana State University, New Orleans, Louisiana, U. S. A., for his kind gift of the sample for identification, and to Professor I. Nitta and Dr. A. Furusaki, Kwansei Gakuin University, for their X-ray analyses. Thanks are also due to Mr. Goda, Osaka City University for his elemental analyses.

Synthetic Studies of the Flavone Derivatives. VII.*1 The Synthesis of Jaceidin

Kenji FUKUI, Takashi MATSUMOTO, Shigehiro NAKAMURA and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

and Tokunaru HORIE

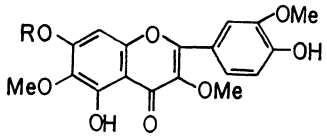
Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

(Received December 16, 1967)

The Hoesch reaction of iretol with methoxyacetonitrile yielded 2,4,6-trihydroxy-3,ω-dimethoxyacetophenone. According to the Allan-Robinson flavone synthesis with *O*-benzylvanillic anhydride, the acetophenone afforded 4'-benzyloxy-5,7-dihydroxy-3,3',6-trimethoxyflavone. The catalytic debenzylation of the flavone gave jaceidin, 4',5,7-trihydroxy-3,3',6-trimethoxyflavone, which had previously been isolated from Centaurea species. Its triethyl ether was prepared from 3,5-diethoxy-4-methoxyphenol *via* the corresponding acetophenone, followed by the above-mentioned flavone synthesis with *O*-ethylvanillic anhydride. The ultraviolet spectra of these flavones will also be reported.

Jaceidin (I) was isolated from the leaves and stems of *Centaurea jacea* L. by Farkas *et al.*[1] Their hydrolysis of I with hydrochloric acid afforded an aglycone, jaceidin. They established the structure of jaceidin to be 4',5,7-trihydroxy-3,3',6-trimethoxyflavone (II) on the basis of analytical data, the results of the degradation reaction, and a comparison of the triethyl ether (III) with a synthetic sample.

Recently, I and II have also been isolated from the Centaurea species by Bowie *et al.*[2] and by Bohlmann *et al.*[3]



I R=Glycosyl
II R=H

The present paper deals with the total synthesis of jaceidin (II) and confirms the proposed structure. The Hoesch reaction of iretol (IV) with methoxyacetonitrile yielded 2,4,6-trihydroxy-3,ω-dimethoxyacetophenone (V). According to Allan-Robinson's flavone synthesis, the condensation of V with *O*-benzylvanillic anhydride (VI) in the presence of triethylamine, followed by treatment with alcoholic potassium hydroxide, affords a hydroxyflavone, which then gives a diacetate. Two structures (VII and VIII) may be expected for this hydroxyflavone. In order to elucidate the structure of the flavone, a diethyl derivative, which was easily obtained with diethyl sulfate and anhydrous potassium carbonate in dry acetone, was synthesized by the following unambiguous method.

3,5-Diethoxy-4-methoxyphenol (IX) was converted to 4,6-diethoxy-2-hydroxy-5,ω-dimethoxyacetophenone (X) by a Hoesch condensation with methoxyacetonitrile or by a Friedel-Crafts reaction with methoxyacetyl chloride. The ketone (X),

when subjected to the Allan-Robinson flavone synthesis using VI, gave 4'-benzyloxy-5,7-diethoxy-3,3',6-trimethoxyflavone (XI), which was identified by a direct comparison with the diethyl derivative obtained by the ethylation of the hydroxyflavone. Furthermore, the partial methylation of the hydroxyflavone with diazomethane gave the monomethyl ether (XII), which was then debenzylated to give 4',5-dihydroxy-3,3',6,7-tetramethoxyflavone (XIII). This was also identified by direct comparison with an authentic sample, prepared by the method of

Hörhammer *et al.*[4] From these facts, the structure of the hydroxyflavone was established as 4'-benzyloxy-5,7-dihydroxy-3,3',6-trimethoxyflavone (VII).

The catalytic debenzylation of VII gave the desired flavone (II), which was shown to be identical with natural jaceidin by a mixed-melting-point determination, and by NMR, infrared, and ultraviolet spectral comparisons.

The infrared and ultraviolet spectra of synthetic and natural jaceidin are superimposable, as is shown in Figs. 1 and 2 and in Table 1. By the addition of fused sodium acetate,[5] the short-wavelength bands of jaceidin (II) and 4'-benzyl ether (VII) in ethanol undergo bathochromic shifts (18 mμ and 20.5 mμ), which show the presence of a free 7-hydroxyl group. The 5-hydroxyl group in II and VII is indicated by the bathochromic shifts (20 mμ and 19 mμ) of the

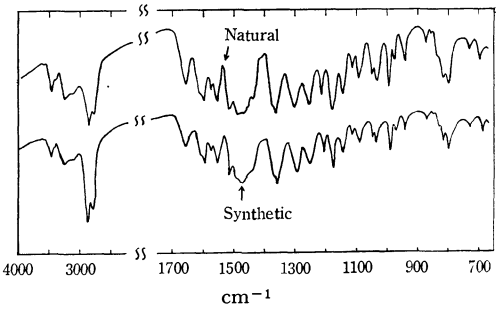

Fig. 1. Infrared spectra of natural and synthetic jaceidin in Nujol.

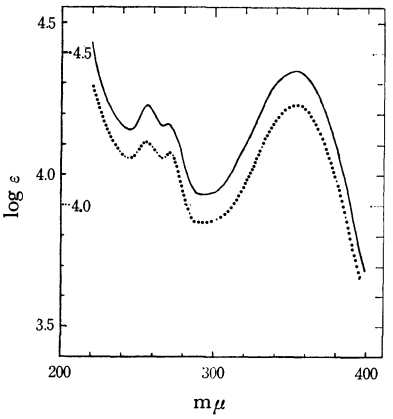

Fig. 2. Ultraviolet spectra of natural (·····) and synthetic jaceidin (——) in ethanol.

long-wavelength band in the presence of aluminum chloride.[6] The large bathochromic shift (64.5 mμ) of the long-wavelength band, without a decrease in its relative intensity, observed on making the ethanol solution of II alkaline indicates a 4'-hydroxyl group.[6] Both II and VII are stable in an alkaline solution, for when the alkaline solution is acidified, the spectra change to the parent respective spectrum in ethanol.

The synthetic jaceidin was converted to triacetate (XIV), trimethyl ether (XV), triethyl ether (III), and artemetin (XVI) by the usual method. The triethyl ether (III) was also synthesized by the

Allan-Robinson reaction of the ketone (X) with *O*-ethylvanillic anhydride.

Experimental*6

2, 4, 6-Trihydroxy-3, ω-dimethoxyacetophenone (V). A mixture of iretol (IV)[7] (5.0 g), methoxyacetonitrile (3.0 g), and anhydrous zinc chloride (8.2 g) in anhydrous ether (500 m*l*) was saturated with dried hydrogen chloride in an ice bath and then allowed to stand overnight. After the ether layer had been decanted, the ketimine hydrochloride was washed with anhydrous ether and then hydrolyzed with water (200 m*l*) on a steam-bath for 30 min. The mixture was evaporated under a vacuum, and the residue (*ca.* 50 m*l*) was extracted with ethyl acetate. The extract was washed with water, dried, and evaporated. The residue was recrystallized from water to give colorless needles, mp 79—80°C.

Found: C, 45.49; H, 5.96%. Calcd for $C_{10}H_{12}O_6 \cdot 2H_2O$: C, 45.45; H, 6.10%.

These needles were recrystallized from dry toluene to give colorless needles, mp 157—158°C; yield 4.3 g. They gave a dark green ferric chloride reaction in ethanol.

Found: C, 52.94; H, 5.31%. Calcd for $C_{10}H_{12}O_6$: C, 52.63; H, 5.30%.

4'-Benzyloxy-5, 7-dihydroxy-3, 3', 6-trimethoxyflavone (VII). A mixture of the ketone (V) (1.0 g), *O*-benzylvanillic anhydride (8.7 g), and triethylamine (2.2 g) was heated at 170°C for 5 hr under a stream of nitrogen. The reaction mixture was then cooled, powdered, and refluxed with a solution of potassium hydroxide (9.5 g) in aqueous ethanol (70%; 100 m*l*) for 20 min. After the evaporation of the solvent under a vacuum, the residue was dissolved in water (150 m*l*) and saturated with carbon dioxide. The precipitate was collected, washed with water, and recrystallized from aqueous acetone to give yellow needles, mp 181.5—183°C, which gave a dark green ferric chloride reaction in ethanol; yield 670 mg.

Found: C, 66.86; H, 5.06%. Calcd for $C_{25}H_{22}O_8$: C, 66.66; H, 4.92%.

Diacetate of VII: hot acetic anhydride-pyridine method; mp 161.5—162.5°C (colorless needles from ethanol). It gave a negative ferric chloride reaction.

Found: C, 65.30; H, 4.84%. Calcd for $C_{29}H_{26}O_{10}$: C, 65.16; H, 4.90%.

4,6-Diethoxy-2-hydroxy-5,ω-dimethoxyacetophenone (X). *a) Friedel-Crafts Reaction.* With stirring and cooling at 10°C, methoxyacetyl chloride (8 g) was added, drop by drop, to a solution of anhydrous aluminum chloride (12.5 g), 3,5-diethoxy-4-methoxyphenol (IX)[8] (10 g) and anhydrous ether (50 m*l*). After stirring below 20°C for 3 hr, the mixture was poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ether extract was washed successively with water, aqueous sodium carbonate, and water. After drying over sodium sulfate, the solvent was evaporated; the residue was distilled under a vacuum to give the ketone (X) as a pale yellow oil, bp 145—146°C/0.2 mmHg; yield 9.7 g.

Found: C, 59.24; H, 7.37%. Calcd for $C_{14}H_{20}O_6$: C, 59.14; H, 7.09%.

b) Hoesch Condensation. A mixture of IX (10 g), methoxyacetonitrile (7.1 g), anhydrous ether (300 m*l*), and anhydrous zinc chloride (10 g) was treated by a method similar to that used for V. The crude product was distilled under a vacuum to give X, bp 145—146°C/0.2 mmHg, which was proved identical with the sample of a) by infrared spectral comparison; yield 1.0 g.

4'-Benzyloxy-5, 7-diethoxy-3, 3', 6-trimethoxyflavone (XI). *a) From VII.* A mixture of VII (130 mg), diethyl sulfate (1.0 g), anhydrous potassium carbonate (2.5 g), and dry acetone (25 m*l*) was refluxed for 24 hr, then the acetone was, after addition of water, evaporated. The precipitate was collected, washed with water, and recrystallized from aqueous ethanol to give the diethyl ether (XI) as colorless needles, mp 116—117°C, which gave a negative ferric chloride reaction; yield 115 mg. UV: λ_{max}^{EtOH} mμ (log ε); 336 (4.27).

Found: C, 69.03; H, 6.04%. Calcd for $C_{29}H_{30}O_8$: C, 68.76; H, 5.97%.

b) From X. A mixture of the ketone (X) (1.0 g), *O*-benzylvanillic anhydride (3.5 g), and triethylamine (1.7 g) was treated by a method similar to that used for

*2 Inflection.
*3 Saturated with anhydrous sodium acetate.

VII. The crude product was recrystallized from ethanol to give XI; mp 117—118°C, which was undepressed on admixture with the sample of a); yield 400 mg.

Found: C, 68.50; H, 5.77%. Calcd for $C_{29}H_{30}O_8$: C, 68.76; H, 5.97%.

4'-Benzyloxy-5-hydroxy-3,3',6,7-tetramethoxyflavone (XII). To a solution of VII (1.2 g) in acetone (150 m*l*), an ethereal diazomethane solution was added, then the solution was allowed to stand at room temperature for 2 hr. After the evaporation of the solvent, the residue was recrystallized from ethyl acetate to give yellow needles, mp 167.5—168.5°C, which gave a dark green ferric chloride reaction in ethanol; yield 1.0 g.

Found: C, 67.23; H, 5.16%. Calcd for $C_{26}H_{24}O_8$: C, 67.23; H, 5.21%.

Monoacetate of XII: hot acetic anhydride - pyridine method; mp 222.5—223.5°C (almost colorless needles from ethyl acetate). It gave a negative ferric chloride reaction.

Found: C, 66.17; H, 5.11%. Calcd for $C_{28}H_{26}O_9$: C, 66.39; H, 5.17%.

4',5-Dihydroxy-3,3',6,7-tetramethoxyflavone (XIII). A solution of XII (750 mg) in ethyl acetate (250 m*l*) was submitted to catalytic reduction at room temperature in the presence of Pd-C (10%: 1.0 g). After the catalyst had been filtered, the filtrate was evaporated under a vacuum and the residue was recrystallized from methanol to give yellow needles, mp 181.5—182.5°C (reported[4] mp 181—182°C), which gave a dark green ferric chloride reaction in ethanol; yield 450 mg. The melting point was undepressed on admixture with a sample prepared by the method of Hörhammer *et al.*[4] UV: λ_{max}^{EtOH} mμ (log ε); 258.5 (4.33), 270*2 (4.28), 352 (4.42).

Found: C, 60.79; H, 4.80%. Calcd for $C_{19}H_{18}O_8$: C, 60.96; H, 4.85%.

Diacetate of XIII: hot acetic anhydride - pyridine method; mp 191—192°C (colorless needles from methanol), (reported[4] mp 191—192°C), undepressed on admixture with a sample prepared by the method of Hörhammer *et al.*[4] It gave a negative ferric chloride reaction.

Found: C, 60.11; H, 4.81%. Calcd for $C_{23}H_{22}O_{10}$: C, 60.26; H, 4.84%.

Jaceidin (4',5,7-Trihydroxy-3,3',6-trimethoxyflavone) (II). A mixture of VII (2.40 g,) Pd-C (10%: 2.0 g), and ethyl acetate (460 m*l*) was treated by the method described for XIII. The product was then recrystallized from aqueous methanol to give pale yellow needles, mp 130—135°C (reported[1,2] mp 127—133°C, 99—100°C, 111—112°C and 165—166°C),*7 which gave a green ferric chloride reaction in ethanol; yield 1.76 g. This was identified with natural jaceidin by a mixed-melting-point determination and by infrared and ultraviolet spectral comparisons. NMR*8 in $CDCl_3$: 3.88(s), 3.99(s), 4.06(s) (OMe), 6.03(s), 6.56(s) (C_7-OH, $C_{4'}$-OH), 6.61(s) (C_8-H), 7.09 (d: J_{ortho}=9.0 cps) ($C_{5'}$-H), 7.76 (dd: J_{ortho}=9.0 cps, J_{meta}=2.5 cps) ($C_{6'}$-H), 7.78 (d: J_{meta}=2.5 cps) ($C_{2'}$-H), 12.96(s) (C_5-OH). (Reported[2] NMR in $CDCl_3$: 3.86, 3.97, 4.04 (OMe), 6.59 (C_8-H), 7.05 ($C_{5'}$-H), 7.68 ($C_{6'}$-H), 7.70 ($C_{2'}$-H), 12.86 (C_5-OH); J_{ortho}=9.0 cps, J_{meta}=2.0 cps).

Found: C, 58.57; H, 4.82%. Calcd for $C_{18}H_{16}O_8 \cdot \frac{1}{2}H_2O$: C, 58.54; H, 4.61%.

After drying at 50—60°C/0.1 mmHg for 2 hr, it had a mp of 166—166.5°C (sintering at 127°C).

Found: C, 59.86; H, 4.48%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%.

Jaceidin Triacetate (XIV): hot acetic anhydride - pyridine method; mp 163—164°C (colorless needles from ethyl acetate) (reported[2] mp 159—160°C). It gave a negative ferric reaction. UV: λ_{max}^{EtOH} mμ (log ε); 248.5 (4.34), 326 (4.26) (reported[2] UV: λ_{max}^{EtOH} mμ (log ε); 248 (4.29), 325 (4.17)). NMR*8 in $CDCl_3$: 2.36(s), 2.38(s), 2.52(s) (OAc), 3.82(s), 3.89(s), 3.92(s) (OMe), 7.22 (d: J_{ortho}=9.0 cps) ($C_{5'}$-H), 7.30(s) (C_8-H), 7.72 (dd: J_{ortho}=9.0 cps, J_{meta}=2.5 cps) ($C_{6'}$-H), 7.78 (d: J_{meta}=2.5 cps) ($C_{2'}$-H). Reported[2] NMR in $CDCl_3$: 2.37, 2.39, 2.44 (OAc), 3.83, 3.89, 3.92 (OMe), 7.20 ($C_{5'}$-H), 7.29 (C_8-H), *ca.* 7.70 ($C_{2'}$-H, $C_{6'}$-H).

Found: C, 58.94; H, 4.42%. Calcd for $C_{24}H_{22}O_{11}$: C, 59.26; H, 4.56%.

Hydrolysis of Jaceidin Triacetate (XIV). A solution of XIV (400 mg) in ethanol (8 m*l*) was gently refluxed with aqueous potassium hydroxide (30%: 3 g) for 10 min. After the evaporation of the solvent under a vacuum, the residue was dissolved in water (20 m*l*) and filtered, and the filtrate was acidified. The precipitate was collected, washed with water, and recrystallized from ethanol to give yellow needles, mp 130—135°C, which gave a green ferric chloride reaction in ethanol; yield 250 mg. This yield was identical with that of natural jaceidin.

Jaceidin Triethyl Ether (4',5,7-Triethoxy-3,3',6-trimethoxyflavone) (III). *a) From Jaceidin (II).* A mixture of synthetic jaceidin (II) (150 mg), anhydrous potassium carbonate (4.0 g), diethyl sulfate (1.5 g), and dry acetone (15 m*l*) was treated by a usual method. The crude product was recrystallized from aqueous ethanol to give colorless needles, mp 118—119°C (reported[1] mp 118°C); yield 155 mg. UV: λ_{max}^{EtOH} mμ (log ε); 334 (4.31).

Found: C, 64.60; H, 6.32%. Calcd for $C_{24}H_{28}O_8$: C, 64.85; H, 6.35%.

b) From the Ketone (X). A mixture of X (1.0 g), *O*-ethylvanillic anhydride (2.7 g), and triethylamine (1.7 g) was treated by a method similar to that used for VII. The crude product was recrystallized from aqueous ethanol to give colorless needles, mp 118—119°C which was undepressed on admixture with the sample of a); yield 120 mg.

Found: C, 64.82; H, 6.27%. Calcd for $C_{24}H_{28}O_8$: C, 64.85; H, 6.35%.

Jaceidin Trimethyl Ether (3,3',4',5,6,7-Hexamethoxyflavone) (XV). A mixture of synthetic jaceidin (II) (500 mg), dimethyl sulfate (0.4 m*l*), anhydrous potassium carbonate (5.0 g) and dry acetone (50 m*l*) was treated by a method similar to that of Farkas *et al.*[1] The crude product was then recrystallized from aqueous ethanol to give colorless needles, mp 142—143°C (reported mp 142°C[1] and 142—

*7 Depend on the crystallization conditions. The same results were also obtained with a synthetic sample.

*8 The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 Mc/sec), using tetramethylsilane as an internal standard; their chemical shifts are presented in terms of δ values; s: singlet, d: doublet, dd: double doublet.

143°C[2]), which gave a negative ferric chloride reaction; yield 490 mg. UV: λ_{max}^{EtOH} mμ (log ε); 335 (4.29).

Found: C, 62.52; H, 5.45%. Calcd for $C_{21}H_{22}O_8$: C, 62.68; H, 5.51%.

Jaceidin Dimethyl Ether (5-Hydroxy-3,3',4',6,7-pentamethoxyflavone) (XVI). Synthetic jaceidin (II) (380 mg) in acetone (70 m*l*) was partially methylated with diazomethane, and the product was recrystallized from methanol to give yellow needles, mp 161—162°C (reported mp 161—162°C[4] and 158—159°C[2,9]), which gave a dark green ferric chloride reaction in ethanol; yield 380 mg. UV: λ_{max}^{EtOH} mμ (log ε); 257 (4.38), 274 (4.34), 348 (4.45).

Found: C, 61.58; H, 5.05%. Calcd for $C_{20}H_{20}O_8$: C, 61.85; H, 5.19%.

Monoacetate of XVI: hot acetic anhydride - pyridine method; mp 163—163.5°C (colorless needles from ethanol) (reported[9] mp 160.5—161.5°C). It gave a negative ferric chloride reaction.

Found: C, 59.84; H, 5.22%. Calcd for $C_{22}H_{22}O_9 \cdot \frac{1}{2}H_2O$: C, 60.13; H, 5.24%.

The Benzylation and Phenylation Reactions of Unsaturated Compounds Using Organo Monohalides and Polynuclear Iron Carbonyl

Ilsong RHEE, Norio MIZUTA, Membo RYANG and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima, Osaka

(Received December 23, 1967)

The reaction of iodobenzene and benzyl halides (Cl, Br and I) with $Fe_3(CO)_{12}$ (mole ratio; $Fe_3(CO)_{12}/R-X=1/3$) gave the corresponding symmetrical ketones (18—55.2%). The increasing order of the reactivity of the organo halides to $Fe_3(CO)_{12}$ was as follows: iodobenzene< benzyl chloride<benzyl bromide<benzyl iodide. In the reaction of benzyl chloride with $Fe_3(CO)_{12}$, when two-thirds of the $Fe_3(CO)_{12}$ had been used, or moles equal to benzyl chloride, the yields of the ketones were increased to 87% (total yield). The same reaction in the presence of olefin produced benzylation or phenylation products of the olefin; for example, the reaction of benzyl iodide with $Fe_3(CO)_{12}$ in the presence of acrylonitrile (in tetrahydrofuran) gave 4-phenylbutyronitrile (30.2%) and 4-cyano-6-phenylhexanonitrile (10.0%). When olefin with a higher coordinating ability to iron carbonyl was used, the yields of the benzylated adducts of the olefin decreased, while when the more reactive organo halide was used, the yields increassed. Thus, it was postulated that organo halide reacted with $Fe_3(CO)_{12}$ to form the σ-complex, benzyl(or phenyl)iron carbonyl halide, as an intermediate to the benzylation (or phenylation) products. The benzylation and phenylation reactions proceeded smoothly in a polar solvent (dimethylformamide or ethanol) to give high yields. The benzylation of phenylacetylene did not occur in benzene, but in a polar solvent it proceeded, giving 1,3-diphenylpropane and -propene. The mechanistic aspects of these reactions are discussed below.

In a previous paper,[1] we reported that organo monohalide (benzyl chloride and iodobenzene) reacted with polynuclear iron carbonyls, triiron dodecacarbonyl [$Fe_3(CO)_{12}$], and diiron nonacarbonyl [$Fe_2(CO)_9$], to form the σ-complex as an intermediate, from whose decomposition the corresponding symmetrical ketone was produced, while when olefin was present in the reaction, its benzylated adduct was obtained.

In this paper, we wish to report on our study of several factors which affect the above benzylation reaction; the reactivity of organo monohalide to $Fe_3(CO)_{12}$, the coordinating ability of olefin to $Fe_3(CO)_{12}$, the remarkable solvent effect, and the effect of the mole ratio between organo monohalide and $Fe_3(CO)_{12}$.

a) Theoretical yield, based on organo halide used.
b) Crude yield.
c) Based on moles of organo halide used.
d) In this reaction, polymerization of styrene proceeded predominantly and dimer and ketone were also produced (see experimental section).
e) Even in THF as solvent, the reaction did not occur.

(0.015 mol) in refluxing toluene gave benzophenone in a 20% yield. In the presence of acrylonitrile, however, iodobenzene did not react with $Fe_3(CO)_{12}$ in refluxing toluene and all the iodobenzene was recovered. The results are extremely interesting in contrast with those in the case of benzyl chloride, which reacted with $Fe_3(CO)_{12}$ in the presence of acrylonitrile [in tetrahydrofuran (THF)] at 67°C to give benzylated adducts of the olefin in a 22.7% yield.*1 Furthermore, when styrene was used as an olefin, iodobenzene reacted with $Fe_3(CO)_{12}$ to give *trans*-stilbene in a low yield.

These results stimulated us to study the reactions of iodobenzene and benzyl halides (Cl, Br and I) with $Fe_3(CO)_{12}$ in the presence of some olefins (styrene, ethyl acrylate, acrylonitrile and maleic anhydride). The coordinating ability of the above olefins decreases in the following order: maleic anhydride > acrylonitrile > ethyl acrylate > styrene.*2

*1 All yields in this paper are theoretical yields based on the organo halide used.

*2 The order was assumed by considering the ease of formation and the stability of the olefin-iron carbonyl π-complex; for example, maleic anhydride - iron tetracarbonyl[2] is produced in a 78% yield by the reaction of maleic anhydride with $Fe_2(CO)_9$, and it is relatively stable in air. Acrylonitrile - iron tetracarbonyl[3] is obtained in a 3% yield from the reaction of acrylonitrile with $Fe_2(CO)_9$, decomposes at 60°C, and is unstable at room temperature. However, the unstable π-complexes of ethyl acrylate and styrene are first obtained by a reaction between the olefins and iron pentacarbonyl under UV irradiation.[4]

Table 3. Effect of mole ratio of $Fe_3(CO)_{12}$ to organo halide

R-X	$Fe_3(CO)_{12}$/R-X[c]	Products, %[a]		
		R-R	RCOR	$RCOCH_2C_6H_4$-R[b]
PhI	1/3	Trace	20.0	—
PhI	2/3	Trace	53.3	—
$PhCH_2Cl$	1/3	Trace	18.0	11.1
$PhCH_2Cl$	2/3	5.4	45.1	25.0
$PhCH_2Cl$	1	5.4	52.0	35.0

a) Theoretical yield, based on organo halide used.
b) Crude yield.
c) Mole ratio.

First, the results of the reactions of iodobenzene and benzyl halides with $Fe_3(CO)_{12}$ are summarized in Table 1.

The reactivity of organo halide to $Fe_3(CO)_{12}$ increased in the following order: iodobenzene< benzyl chloride< benzyl bromide< benzyl iodide.

The results of the same reaction in the presence of olefin are summarized in Table 2.

As may be seen in Table 2, the yields of benzyl adducts of olefins increase in parallel with the increasing order of reactivity of the halide. By comparing Table 1 with Table 2, it can easily be found that the addition of olefin to the reaction system between halide and $Fe_3(CO)_{12}$ markedly affected the reactivity of the halide to $Fe_3(CO)_{12}$; for example, iodobenzene, which reacted with $Fe_3(CO)_{12}$ to give benzophenone in a 20% yield, did not react at all with $Fe_3(CO)_{12}$ in the presence of acrylonitrile. When olefin was present, each conversion of organo halides decreased; furthermore, when the coordinating ability of olefin became stronger, the conversion of the halide was suppressed more (Tables 1 and 2).

The Effect of the Solvent. As has been mentioned, iodobenzene did not react with $Fe_3(CO)_{12}$ in the presence of acrylonitrile or ethyl acrylate in toluene or THF, but when dimethylformamide (DMF) was used as a solvent at 100°C, the reaction proceeded well, giving phenylated products of the olefins: in the case of acrylonitrile, hydrocinnamonitrile (18%) and cinnamonitrile (5%), and in the case of ethyl acrylate, ethyl hydrocinnamate (22%) and ethyl cinnamate (9%). These results indicate that, in this reaction, the solvent plays a very important role. A similar tendency was also observed in the reaction of benzyl chloride. That is, when DMF was used as the solvent instead of THF, the reaction of benzyl chloride (0.05 mol) with $Fe_3(CO)_{12}$ (0.015 mol) at 80°C gave the increased yields of the dibenzyl ketone (40%) and the benzyl *p*-benzylbenzyl ketone (crude yield, 12%). When acrylonitrile was present in the above reaction, benzylated adducts, 4-phenylbutyronitrile and 4-cyano-6-phenylhexanonitrile, were obtained in yields of 35.8 and 12.1% (in THF, 18.7 and 4.0%) respectively.

When refluxing ethanol was the solvent, the reaction of benzyl chloride (0.05 mol) with $Fe_3(CO)_{12}$ (0.015 mol) gave ethyl benzyl ether (20%), ethyl phenylacetate (3.3%), and dibenzyl (8%). The same reaction in the presence of acrylonitrile produced ethyl benzyl ether (7.8%), ethyl phenylacetate (3.6%), dibenzyl (6.6%), and 4-phenylbutyronitrile (44.8%). Thus, the yields of the benzylation and phenylation products of olefins were much increased by using a polar solvent.

The Effect of the Mole Ratio of Organo Halide-Iron Carbonyl. In the reaction described above, $Fe_3(CO)_{12}$ has been used in the ratio of one-third of a mole to one of the organo halide, on the basis of the assumption that the halide reacts with each iron atom of $Fe_3(CO)_{12}$. On the other hand, when the ratio is two-thirds of a mole to one or when $Fe_3(CO)_{12}$ and the halide are equal, the yields of the products were markedly increased (Table 3).

Therefore, it was expected that if olefin were added to this reaction system, the yields of the adducts would increase. In truth, the reaction of benzyl chloride (0.05 mol) with $Fe_3(CO)_{12}$ (0.033 mol) in the presence of acrylontirile (0.05 mol) in THF at 67°C for 30 hr gave increased yields of 4-phenylbutyronitrile (26.2%) and 4-cyano-6-phenylhexanonitrile (crude yield, 10%).

B) The Reaction of Benzyl Chloride with $Fe_3(CO)_{12}$ in the Presence of the Acetylenic Compound. It is well-known[5] that the metal-carbon σ-bonding complex undergoes insertion reactions readily with a large variety of acetylenes; also, the σ-complex, derived from the reaction between benzyl chloride and $Fe_3(CO)_{12}$, may be assumed to react with an acetylenic compound. Thus, the reaction of benzyl chloride (0.067 mol) with $Fe_3(CO)_{12}$ (0.023 mol) in the presence of diphenylacetylene (0.056 mol) was carried out in refluxing benzene under argon for 30 hr. From the residual oil obtained after the removal of the solvent under reduced pressure, the following

5) R. F. Heck, "Advances in Chemistry Series 49, Am. Chem. Soc." Washington D. C. (1965), pp. 194—201 and references cited therein.

products were given: diphenylmethane*3 (8%), dibenzyl (3.3)%, dibenzyl ketone (12.1%), $Fe_2(CO)_6(PhC{\equiv}CPh)_2$ (43.3%, based on the diphenylacetylene used), and $Fe(CO)_4(PhC{\equiv}CPh)_2$ (6.8%). However, the expected benzylation product of diphenylacetylene was not isolated. Similarly, from the same reaction using phenylacetylene, the benzylated adduct was not obtained. On the other hand, when ethanol was used as the solvent, the same reaction gave 1,3-diphenylpropane and -propene in low yields (total yield, 2%). Furthermore, when DMF was the solvent, the former and the latter were produced in yields of 5.4 and 3.6% respectively. Thus, the insertion reaction of an acetylenic compound into a carbon-metal bond is markedly affected by the solvent polarity, although the reason for this is not yet clear.

C) Mechanistic Aspects. We have proposed that organo halide reacts with $Fe_3(CO)_{12}$ to yield the σ-complex, benzyliron carbonyl halide, as an intermediate, whose decomposition then produces the dibenzyl ketone, while when olefin is present, the σ-complex reacts with the olefin to give the benzylated products of olefin. Herein, the formation of the σ-complex was postulated as preceding the benzylation.

However, although iodobenzene reacted with $Fe_3(CO)_{12}$ in toluene to give benzophenone (20%), which was assumed to be produced by the decomposition of the σ-complex, iodobenzene did not react with $Fe_3(CO)_{12}$ in the presence of acrylonitrile and all the iodobenzene was recovered. Furthermore, in the case of benzyl halide, the presence of an olefin which has a strong coordinating ability resulted in a decreased conversion of benzyl halide. These results indicate that the olefin acts as an inhibitor of the reaction of halide with $Fe_3(CO)_{12}$. This inhibiting action may be interpreted in terms of the formation of an olefin-iron carbonyl π-complex prior to the formation of the σ-complex.

It is well known that π-complexes between iron carbonyl and acrylonitrile or maleic anhydride are easily formed under our reaction conditions.[2,3] Thus, the formations of the π-complex and the σ-complex are competitive with each other, and therefore, if a more reactive halide or a olefin of a lower coordinating ability is used, the conversion of the halide should be increased, and *vice versa*. For example, benzyl chloride reacted with $Fe_3(CO)_{12}$ in the presence of acrylonitrile to give benzylated adducts, and in the same reaction using maleic anhydride instead of acrylonitrile, all the benzyl chloride was recovered, while benzyl iodide reacted with $Fe_3(CO)_{12}$ not only in the presence of acrylonitrile, but also in the presence of maleic anhydride, to give benzylated adducts of the olefins.

The information reported about the reaction of the π-complex with organo halide is as follows; the reaction of bis-acrylonitrile nickel with allyl halide results in the formation of bis-(1-cyano-4-pentenyl)nickel, $(CH_2{=}CHCH_2CH_2CHCN)_2Ni$, while benzyl chloride or iodobenzene reacts a little with bis-acrylonitrile nickel,[6] but the reaction of π-allylnickel bromide with alkyl (aryl) halide does not occur in benzene or THF.[7]

The reaction of π-olefin - metal carbonyl with organo halide, however, has not yet been reported, and it was assumed that the π-complex was unreactive to halide in nonpolar solvents (THF, toluene, and benzene). Supporting evidence for our assumption was provided by the results of the reaction of benzyl chloride with a maleic anhydride-iron tetracarbonyl complex,*4 for the reaction did not proceed and all the benzyl chloride was recovered.

In the presence of an acetylenic compound, no benzylation product was yielded in a nonpolar solvent, so the iron carbonyl reacted predominantly with an acetylenic compound with a very strong coordinating ability, thus forming several previously-known iron complexes.[8] However, when ethanol or DMF was the solvent, benzyl chloride reacted with $Fe_3(CO)_{12}$ in the presence of phenylacetylene to give its benzylated adducts, 1,3-diphenylpropane and -propene.

Similarly, aroylnickel carbonyl halide does not react with acetylenic compound in benzene or THF,[9] but when water is the solvent, it reacts with acetylene to yield the adduct with acetylene, 3-benzoylpropionic acid.[10]

A similar interesting solvent effect was observed in the reaction between organo halide and $Fe_3(CO)_{12}$ in the presence of an olefin. In toluene iodobenzene did not react with $Fe_3(CO)_{12}$ in the presence of acrylonitrile, but when DMF was used as the solvent, it reacted well with $Fe_3(CO)_{12}$ to give phenylated adducts of the olefin. Hence, the insertion reaction of an unsaturated compound into a carbon-metal σ-bond is markedly affected by the solvent polarity. During the course of our study, Corey and Semmelhack reported that the π-allylnickel bromide complex, which did not

*3 It has been assumed that diphenylmethane was produced from a Friedel-Crafts type reaction between benzyl chloride and benzene by the action of iron carbonyl chloride, although it has not yet been isolated.

react with alkyl halide in benzene or THF, reacted smoothly in DMF to give coupling products in high yields.[7] As for the solvent effect of DMF, they suggested that dimeric π-allylnickel bromide became monomeric π-allylnickel bromide by the coordination of DMF, and that the latter reacted with alkyl halide. However, in our work, the olefin-iron carbonyl π-complex is monomeric.[2,3] Therefore, our results can evidently not be explained in terms of their explanation.

The solvent effect and the precise mechanism of these reactions are now under investigation; a detailed description of the mechanism and further applications of this reaction will be reported in due course.

Experimental

The Reaction of Organo Monohalide with $Fe_3(CO)_{12}$. The reaction and the identification of the product were carried out according to the method described in a previous paper.[1]

The Reaction of Organo Monohalide with $Fe_3(CO)_{12}$ in the Presence of Olefin. Most of these reactions were carried out in a method similar to that described in the previous paper. Only a typical reaction will be described here.

The reaction of iodobenzene (10.2 g, 0.05 mol) with $Fe_3(CO)_{12}$ (8.1 g, 0.015 mol) in the presence of styrene (5.2 g, 0.05 mol) was carried out in refluxing toluene for 30 hr under an atmosphere of argon. The resulting reaction mixture was filtered through magnesium sulfate under reduced pressure, and, after the removal of the solvent from the filtrate, the residual oil thus obtained was distilled to give a fraction (bp 45—172°C/0.7 mmHg, 0.7g) and a large quantity of a polymer. The fraction was then chromatographed on silica gel; the subsequent elution of the first band with petroleum ether gave white crystals after the removal of the solvent. This material was recrystallized from ethanol (mp 70.5°C) and confirmed to be biphenyl (3.5%) by a mixed-melting point determination with an authentic sample. The elution of the second band with petroleum ether gave *trans*-stilbene (3.0%) (mp 124°C, from petroleum ether). Elution with benzene showed the presence of a carbonyl group (ν_{CO} 1680 cm^{-1}); after the removal of the benzene, it was identified as benzophenone (8.4%) by a mixed-melting point determination of its 2,4-dinitrophenylhydrazone (mp 232°C, from ethyl acetate) with an authentic sample. The theoretical yields of the products were determined by vpc analysis. [Column, S.E. 30, 2.25 m; column temperature, 230°C; flow rate of carrier gas (helium), 7 m*l*/min; internal standard, dibenzyl; retention times, 2.8, 6.0 and 8.5 min respectively.] A large quantity of a polymeric material was assumed to be a polymer of styrene, but it was not examined.

The reaction of benzyl chloride (6.4 g, 0.05 mol) with $Fe_3(CO)_{12}$ (8.1 g, 0.015 mol) in the presence of styrene (5.2 g, 0.05 mol) was carried out at 67°C in THF (100 m*l*) for 30 hr. The residual oil obtained by a treatment similar to that described above was distilled under reduced pressure to give the following fractions: (1) bp 90—108°C/0.3 mmHg, 1.2 g, and (2) bp 150—190°C/0.3 mmHg, 0.8 g. The results of vpc analysis showed the fraction (1) to be a mixture of the following materials: dibenzyl (1.7%), 1,3-diphenylpropane (1.8%), 1, 3-diphenylpropene (2.2%), and dibenzyl ketone (17.0%) [Column, S. E. 30, 2.25 m; column temperature, 230°C; flow rate of carrier gas (helium), 7 m*l*/min; flame ionization detector; retention times, 4.8, 6.8, 8.2 and 9.7 min respectively]. The fraction (2) has not yet been identified.

The reaction of benzyl iodide (10.9 g, 0.05 mol) with $Fe_3(CO)_{12}$ (8.1 g, 0.015 mol) in the presence of maleic anhydride (4.7 g, 0.05 mol) was carried out at 40—45°C in THF for 30 hr. The residue after the removal of the THF *in vacuo* was dissolved in benzene and filtered through magnesium sulfate. The mother liquors were then chromatographed on silica gel after the benzene had been removed under reduced pressure. The product of elution with petroleum ether was confirmed by vpc to be unreacted benzyl iodide (7.6 g). The product of elution with benzene was hydrolyzed with 6 N hydrochloric acid and then extracted with benzene; the resulting free acid was recrystallized from water to give 1.0 g of white crystals (mp 161°C). This material was then assumed to be benzylsuccinic acid (9.6%). [Found: C, 62.97; H, 5.83%; mol wt (in the neutralization equivalent method), 209.8. Calcd for $C_{11}H_{12}O_4$: C, 63.10: H, 5.80%; mol wt, 208]. Therefore, the product of elution with benzene was mainly the anhydride of benzylsuccinic acid.

With DMF as the Solvent, the Reaction of Organo Halide with $Fe_3(CO)_{12}$ in the Presence of Olefin. The reaction of iodobenzene (9.6 g, 0.044 mol) with $Fe_3(CO)_{12}$ (7.4 g, 0.014 mol) in the presence of ethyl acrylate (5.0 g, 0.05 mol) was carried out at 100°C in DMF (100 m*l*). After the reaction had continued for 30 hr, the reaction mixture was hydrolyzed with 6 N hydrochloric acid and then extracted with diethyl ether. The residual oil obtained after the removal of the solvent was distilled under reduced pressure to give the following fractions: (1) bp 78—100°C/0.7 mmHg, 2.4 g, and (2) bp 150—220°C/0.6 mmHg, 1.9 g. The fraction (1) showed the presence of ester groups (1740, 1100—1300 cm^{-1}) and was found by vpc to be a mixture of ethyl hydrocinnamate (22%) and ethyl cinnamate (9%) [Column, S. E. 30 (5%), 2.25 m; column temperature, 180°C; flow rate of carrier gas (helium), 10 m*l*/min; flame ionization detector; retention times, 2.3 and 3.4 min]. The fraction (2) also showed the presence of an ester group, but has not yet been identified. The other reactions and the identification of the product were carried out according to the methods described above.

With Ethanol as the Solvent, the Reaction of Benzyl Chloride with $Fe_3(CO)_{12}$ in the Presence of Acrylonitrile. The reaction (at 80°C) and treatment were carried out by a method similar to that described in the case of DMF; the following fractions were thus obtained; (1) bp 60—70°C/25 mmHg, 1.2 g, and (2) bp 80—90°C/0.9 mmHg, 4.2 g. Vpc analysis showed 44% of the fraction (1) to be ethyl benzyl ether (7.8%), while the fraction (2) was found to be a mixture of ethyl phenylacetate (3.6%), dibenzyl (6.6%), and 4-phenylbutyronitrile (44.8%) [Column, S.E. 30 (5%); column temperature, 210°C; flow rate of carrier gas (helium), 10 m*l*/min; flame ionization detector; retention times, 1.6, 2.1, 4.2, and 3.0 min respectively].

The Reaction of Benzyl Chloride with $Fe_3(CO)_{12}$ in the Presence of an Acetylenic Compound. The reaction of benzyl chloride (8.6 g, 0.067 mol) with $Fe_3(CO)_{12}$ (11.6 g, 0.023 mol) in the presence of diphenylacetylene (10.0 g, 0.056 mol) was carried out for 30 hr in refluxing benzene. The residual oil obtained after the removal of the benzene *in vacuo* under an atmosphere of argon was dissolved in hot acetic acid (70 m*l*). The red crystals (6.7 g) crystallized from this solution were recrystallized from acetic acid (mp 197—199°C). This material was identified as a known π-complex, $Fe_2(CO)_6(PhC{\equiv}CPh)_2$ (IR: ν_{CO} 2020, 1993, 1969, 1950 and 1905 cm^{-1}; NMR: τ 3.2 ppm; Found: C, 63.85; H, 3.25%. Calcd for $Fe_2C_{34}H_{20}O_6$: C, 64.15; H, 3.14%), an identification which agreed with the data of Ref. 8 (43.2%). The residual oil remaining after the removal of acetic acid from the filtrate was chromatographed on silica gel. Orange crystals were obtained from elution with benzene; they were recrystallized from ethanol, mp 184—186°C (Found: C, 74.01; H, 3.59%. Calcd for $FeC_{32}H_{20}O_4$: C, 73.25; H, 3.81%). This material was identified as $Fe(CO)_4(PhC{\equiv}CPh)_2$ by the agreement with the data of Ref. 8 (6.8%). The products of all the other elutions were distilled together *in vacuo* under argon to give the following fractions: (1) bp 53—60°C/12 mmHg, 3.6 g, and (2) bp 100—130°C/3 mmHg, 4.0 g. The fraction (1) was confirmed to be unchanged benzyl chloride, while the fraction (2) was found by vpc to be a mixture of diphenylmethane (8%), dibenzyl (3.3%), and dibenzyl ketone (12.1%).

In the presence of phenylacetylene, the same reaction gave diphenylmethane (26%), dibenzyl (4.4%), dibenzyl ketone (5.5%), and $Fe_2(CO)_6(PhC{\equiv}CH)_2$, the data of all of which agreed with that in Ref. 8. The other complex was not examined.

With ethanol as the solvent, the same reaction was carried out and the residual oil obtained after the removal of the ethanol *in vacuo* was distilled under argon. From the fraction thus obtained, the following products were identified by vpc: ethyl benzyl ether (32.8%), ethyl phenylacetate (2%), dibenzyl (0.5%), ethyl cinnamate (6.6%, based on the phenylacetylene used), 1,3-diphenylpropane (1.5%), 1,3-diphenylpropene (0.5%), and the dibenzyl ketone (1%). [Column, S.E. 30; column temperature, 230°C; flow rate of carrier gas (helium), 5 m*l*/min; flame ionization detector; retention times, 4.1, 5.4, 11.5, 9.2, 16.5, 19.6 and 21.1 min]. No other complexes were examined.

From the same reaction with DMF as the solvent, dibenzyl (3.2%), 1,3-diphenylpropane (5.4%) and 1,3-diphenylpropene (3.6%) were obtained.

The Reaction of Benzyl Chloride with Maleic Anhydride-Iron Tetracarbonyl. The reaction of benzyl chloride (3.2 g, 0.025 mol) with maleic anhydride-iron tetracarbonyl (6.4 g, 0.025 mol), which had been obtained by the reaction[2] of maleic anhydride with $Fe_2(CO)_9$, was carried out for 30 hr in refluxing THF (60 m*l*). The resulting reaction mixture was filtered through magnesium sulfate *in vacuo*, and, after the removal of THF from the filtrate, unchanged benzyl chloride (2.9 g) was recovered by distillation under reduced pressure; the residue (6.0 g) was dried *in vacuo* and was confirmed from its IR to be the starting π-complex.

Authentic Samples. *Ethyl Cinnamate* was prepared from the reaction of cinnamic acid with ethanol, n_D^{20} 1.5597 (lit., n_D^{20} 1.55982).

Ethyl Hydrocinnamate was obtained from the reduction of ethyl cinnamate using a sodium amalgam, n_D^{20} 1.4955 (lit., n_D^{20} 1.49542).

1,3-Diphenylpropene was prepared by a Wittig reaction using benzyl iodide, triphenylphosphine, *n*-butyllithium, and phenylacetaldehyde (mp 56°C, from ethanol; lit., mp 57°C).

1,3-Diphenylpropane was afforded by the reduction of 1,3-diphenylpropene using palladium black, n_D^{20} 1.5697 (lit., n_D^{20} 1.5694).

Cinnamonitrile was prepared by the reaction of benzaldehyde with cyanoacetic acid in pyridine and piperidine (bp 89°C/1.8 mmHg).

Hydrocinnamonitrile was obtained by the reaction of β-phenethyl bromide with potassium cyanide (bp 114°C/8 mmHg).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1423—1426 (1968)

Nitration of Thenyl Derivatives. II. Preparation of Three Isomeric Mononitro Derivatives of 2-Thenyl Chloride and 2-Thenyl Acetate*1

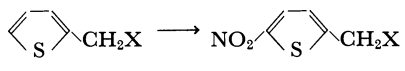
Tyo SONE*2 and Yasuo MATSUKI

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

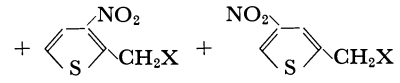
(Received December 26, 1967)

In connection with the investigation of the products of the nitration of 2-thenyl chloride (I) and 2-thenyl acetate (II), three isomeric mononitro derivatives of I and II were prepared, and it was shown by NMR spectral study that, as in the case of I, the product obtained in the nitration of II by nitric acid in acetic anhydride consisted of all three isomeric mononitro derivatives. The isomer distribution of the mononitro derivatives of II, as determined by infrared spectroscopy, indicated 77% of the 5-, 9% of the 4-, and 14% of the 3-nitro isomer.

In the previous communication[1] it was shown by NMR study that, in the nitration of 2-thenyl chloride (1) by the nitric acid-acetic anhydride procedure, the product consisted of all three isomeric mononitro derivatives of I. This seems to have been the first observation of the formation of the 4-substituted isomer in the electrophilic substitution of thiophene derivatives with an *o*-, *p*-directing group in the 2-position, though it had long been recognized that the substitution occurred predominantly at the 5-position and occurred at the 3-position, if at all, to only a minor extent. However, several attempts at the isolation of the isomers from the total product were all unsuccessful.



I: X=Cl III: X=Cl
II: X=OCOCH$_3$ VI: X=OCOCH$_3$



IV: X=Cl V: X=Cl
VII: X=OCOCH$_3$ VIII: X=OCOCH$_3$

The same is the case in the nitration of 2-thenyl acetate (II). Figure 1 shows the NMR spectrum of the nitration product[2] of II. The assignment of the peaks to each of the isomers is based on the ring-coupling constants[3] and on the coupling constants[4] between the methylene protons and the ring protons. The set of four strong peaks, two triplets at 5.59 ppm relative to cyclohexane as an internal standard and a doublet at 6.29 ppm (J= 4.0 cps, $J_{2CH_2\text{-ring H}}$=0.7 cps), is clearly due to 5-nitro-2-thenyl acetate (VI), while the two doublets at 5.81 ppm and 6.10 ppm (J=5.8 cps) are due to 3-nitro-2-thenyl acetate (VII). The doublet at the lowest field is due to the proton at the 5-position of 4-nitro-2-thenyl acetate (VIII), while the proton at the 3-position appears as a quintet with a relative intensity of 1 : 2 : 2 : 2 : 1 centered at 6.13 ppm; the proton at the 3-position is coupled with both the one at the 5-position and the methylene protons at the 2-position to form two triplets, the overlapping of which shows a quintet ($J_{3\text{-}5}$=1.6 cps, $J_{2CH_2\text{-}3}$=0.7 cps). Besides the peaks arising from the ring protons, there are four peaks in the higher field which are related to the methylene and the methyl protons, the shifts of these peaks being 4.16 ppm (VII CH_2), 3.76 ppm (VI CH_2, VIII CH_2), 0.72 ppm (VII CH_3), and 0.66 ppm (VI CH_3, VIII CH_3) respectively. The chemical shifts and the coupling constants are in accordance with those expected for the spectra of VI, VII, and VIII.

In order to confirm the facts shown by the NMR spectra, two sets of three isomeric mononitro derivatives of I and II were prepared.

VI was isolated as colorless needles, mp 36—37°C, from the nitration product of II. The acidic hydrolysis of VI gave the corresponding alcohol, IX, which was then converted into III, bp 112—114°C/4 mmHg, by being treated with a mixture of zinc chloride and hydrochloric acid.

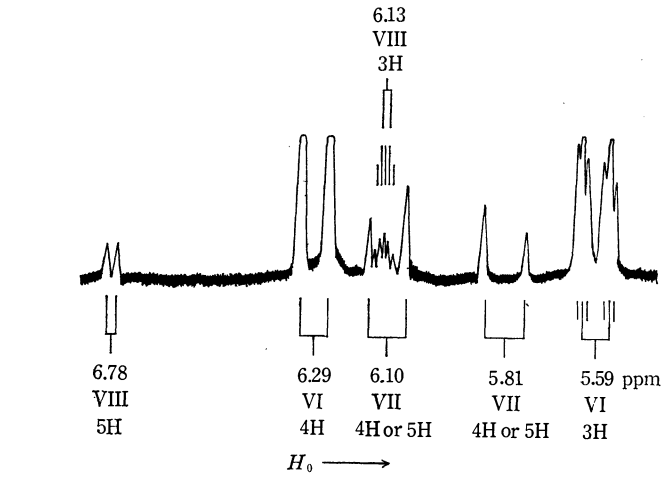

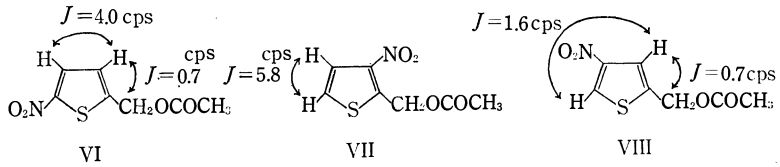

Fig. 1. NMR spectrum of the ring protons of the nitration product of 2-thenyl acetate (II) in carbon tetrachloride (60 Mc; Relative to cyclohexane as 0.00 ppm)

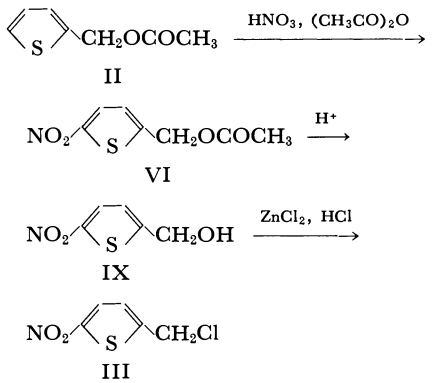
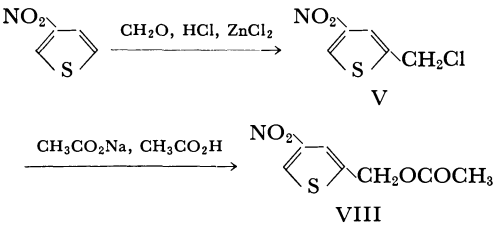
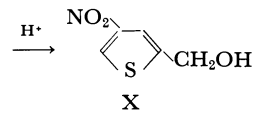
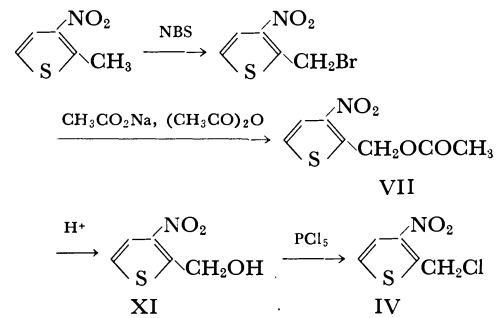


While 2-nitrothiophene, as well as nitrobenzene, is extremely difficult to be chloromethylated in the usual manner, 3-nitrothiophene is reactive enough for chloromethylation by a mixture of trioxane, hydrogen chloride, and zinc chloride; it gives V, bp 105—107°C/2 mmHg, which in turn is converted into VIII, mp 27—29°C.





VII,[6] mp 60—61°C, was prepared by treating 3-nitro-2-thenyl bromide with sodium acetate in acetic anhydride. The hydrolysis of VII, followed by the chlorination of the resultant alcohol by phosphorus pentachloride, gave IV, mp 49—50°C.



The signals in the NMR spectra of the nitration mixture of I and II correspond well with those of authentic samples.

The isomer distribution of the nitration product of II was determined by infrared spectroscopy using the absorption bands at 814 cm^{-1} for VI, at 1077 cm^{-1} for VIII, and at 705 cm^{-1} for VII, indicating 77% of VI, 9% of VIII, and 14% of VII

in the product. As the nitration was accompanied by the formation of a small amount of a resinous material, the results obtained by the determination of the isomer distribution should be considered with care, but they do clearly show that the 4-substitution occurs in a relatively higher proportion.

Experimental[5]

5-Nitro-2-thenyl Acetate (VI). 2-Thenyl acetate (31.2 g) was nitrated by nitric acid in acetic anhydride as has been described before[2] to give an oily mixture of nitro-2-thenyl acetates (25.2 g, 62.6%; bp 138—142°C/4 mmHg), a mixture which, on being left standing, partially solidified to colorless crystals. The crystals were collected by filtration and recrystallized from low-boiling petroleum ether to afford VI (9.0 g) as colorless needles, mp 36—37°C.

5-Nitro-2-thenyl Alcohol (IX). A mixture of VI (8.0 g) and 10% sulfuric acid (150 m*l*) was gently refluxed for 1 hr. The clear yellow solution was then cooled, and the resultant oily material was extracted with ether. The ether extract was dried (Na_2SO_4), and the ether was evaporated. The distillation of the residual oil gave IX (4.0 g, 63.0%) as a pale yellow oil, bp 148—150°C/3 mmHg, mp 20—21.5°C.

Found: C, 37.69; H, 2.71; N, 8.60%. Calcd for $C_5H_5NO_3S$: C, 37.73; H, 3.17; N, 8.80%.

5-Nitro-2-thenyl Chloride (III). A mixture of IX (5.0 g), zinc chloride (8.5 g), and hydrochloric acid (5.1 m*l*) was gently refluxed for 30 min, and then the reaction mixture was poured into water. The resultant oil was extracted with ether, and the ether extract was washed with water and dried (Na_2SO_4). After the evaporation of the solvent, the residue was distilled to give III (3.8 g, 68.2%) as a pale yellow oil, bp 112—114°C/4 mmHg, n_D^{20} 1.6213.

Found: C, 33.95; H, 2.08; N, 7.65%. Calcd for $C_5H_4ClNO_2S$: C, 33.81; H, 2.27; N, 7.88%.

3-Nitro-2-thenyl Alcohol (XI). A mixture of VII[6] (10 g) and 10% sulfuric acid (180 m*l*) was gently refluxed for 1 hr. The solution was then decolorized with charcoal and cooled to yield pale yellow needles (5.5 g, mp 71—72°C). Another crop of XI (1.6 g, mp 71—72°C) was obtained by extracting the filtrate by ether and by the subsequent evaporation of the solvent. The total yield of XI was 7.1 g (89.9%). The recrystallization of the crude XI from water gave pale yellow needles, mp 71—72°C.

Found: C, 37.73; H, 2.99; N, 8.56%. Calcd for $C_5H_5NO_3S$: C, 37.73; H, 3.17; N, 8.80%.

3-Nitro-2-thenyl Chloride (IV). To a mixture of XI (3.2 g) and chloroform (30 m*l*), phosphorus pentachloride (4.2 g) was added in small portions with shaking at room temperatre. After standing overnight, the reaction mixture was washed with water and dried ($CaCl_2$). The evaporation of the solvent and the recrystallization of the crude crystalline product from a mixture of ether and petroleum ether gave IV (2.1 g, 59.1%) as pale yellow prisms, mp 49—50°C.

Found: C, 33.81; H, 2.27; N, 7.88%. Calcd for $C_5H_4ClNO_2S$: C, 33.90; H, 2.30; N, 7.76%.

4-Nitro-2-thenyl Chloride (V). Into a mixture of 3-nitrothiophene (6.5 g), trioxane (2.4 g), zinc chloride (2.6 g), and carbon tetrachloride (50 m*l*), a stream of dry hydrogen chloride was stirred for 30 min. Then the mixture was gradually warmed to 50°C and stirred for 1 hr at that temperature, while the stream of hydrogen chloride continued to pass through. The resultant solution was poured into water, and the organic layer was separated, washed well with water, dilute sodium carbonate solution, and again with water, and dried. After the solvent had been removed, the residue was distilled under reduced pressure to yield V as a pale yellow oil, along with a small amount of a high-boiling material which was not examined further. Yield 4.1 g (46.1%). Bp 105—107°C/2 mmHg, n_D^{20} 1.6065, d_4^{20} 1.4825.

Found: C, 33.89; H, 2.02; N, 7.52%. Calcd for $C_5H_4ClNO_2S$: C, 33.81; H, 2.27; N, 7.88%.

4-Nitro-2-thenyl Acetate (VIII). A mixture of V (4.6 g), anhydrous sodium acetate (3.5 g) and acetic anhydride (20 m*l*) was heated for 6 hr at 60—70°C, and then gently refluxed for 4 hr. The mixture was cooled and poured into water. The resulting organic layer was extracted with ether, and the ether extract was washed with water and dried (Na_2SO_4). After the evaporation of the solvent, the residue was distilledunder reduced pressure to give crude VIII (3.3 g; bp 120—135°C/2—3 mmHg), which was found to contain a small amount of the starting chloride. The above distillate was then gently boiled for 5 hr with anhydrous sodium acetate (1 g) in acetic anhydride (5 m*l*), after which the reaction mixture was treated as before. The distillation of the product gave VIII (2.0 g, 38.4%) as a pale yellow oil, bp 129—131°C/3.5 mmHg, mp 27—29°C.

Found: C, 41.44; H, 3.42; N, 7.22%. Calcd for $C_7H_7NO_4S$: C, 41.78; H, 3.50; N, 6.90%.

4-Nitro-2-thenyl Alcohol (X). VIII (0.8 g) was treated with dilute sulfuric acid in the same way as has been described for VI. Crude alcohol (0.4 g, 63.4%; mp 52—54°C) was recrystallized from a mixture of ether and petroleum ether to yield colorless needles, mp 54—55°C.

Found: C, 37.81; H, 2.96; N, 8.47%. Calcd for $C_5H_5NO_3S$: C, 37.73; H, 3.17; N, 8.80%.

IR Spectrophotometric Determination of the Isomer Distribution of Nitro-2-thenyl Acetates. The quantitative analysis was carried out by a routine peak-intensity method based on the proportionality between the concentration and the absorption-peak height. The calibration spectra for the pure nitro-2-thenyl acetates were measured in a 0.5-mm cell in carbon disulfide solutions, the absorption bands chosen as key bands for the determination being 814 cm^{-1} for VI, 1077 cm^{-1} for VIII, and 705 cm^{-1} for VII. A linear relationship exists between the concentration of the isomers and the optical density within the concentration range examined. Known mixtures prepared from pure samples of each isomer were analyzed in order to determine the accuracy, and the results

5) All melting points and boiling points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-2A spectrophotometer. The NMR spectra were recorded with a Varian Associates Model V-4300B or A-60 spectrophotometer at 60 Mc, using cyclohexane as an internal reference. The microanalyses were carried out by Miss Yoko Endo and Miss Noriko Matsukawa of this Institute, to whom the authors are indebted.

Mechanism of Asymmetric Reactions. II.*[1] Kinetical Resolution of Racemic Primary Amines by Means of Sulfonylation with (+)-Camphor-10-sulfonyl Chloride—Preferential Conservation of an Absolute Configuration in the Asymmetric Sulfonylation of Racemic Amines

Kunio Okamoto, Etsuo Minami and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 26, 1967)

α-Phenylethylamine (I), α,β-diphenylethylamine (II), α-(β-naphthyl)-ethylamine (III) α-(α-naphthyl)-benzylamine (IV), α-pipecoline (V), 2-aminobicyclo[2.2.2]octane (VI), and methylamine (VII) have been partially sulfonylated by (+)-camphor-10-sulfonyl chloride in benzene (or toluene); the optical rotations for the unsulfonylated amines, partially resolved, have been measured. Examination of absolute configurations for the amines indicates that the (R) enantiomers of these amines (I, II, V and VII, including neomenthylamine (VIII)[3] and isomenthylamine (IX)[3]) react faster than the respective (S) enantiomers, with exception of III. The rate for the sulfonylation of (−)-menthylamine with (+)-camphor-10-sulfonyl chloride have been determined in toluene at the temperatures ranging from −20 to −40°C; the rate ratio of the (+)-menthylamine to the (−)-amine has been estimated from the extent of the kinetical resolution of the (±)-menthylamine. Kinetical implication of the coincidence of the preferred absolute configurations has been discussed.

A number of studies[1] concerned with the kinetic method of resolution have been reported since the beginning of this century. However, relatively few data[2] are available for a systematic scrutiny of the correlation between the structural factors of the racemic substrate and the extents or the directions of the resolution.

One of the purposes of this study was to provide additional examples of the kinetical resolution in the partial sulfonylation of a series of racemic primary amines (heretofore only three isomers of menthylamines[3] had been examined) by means of (+)-camphor-10-sulfonyl chloride as an asymmetric reagent.

Another purpose was to scrutinize steric factors which characterize the extent and the direction of such kinetical resolutions, and to discuss its mechanistic implication.

Results

The Partial Sulfonylation of Several Racemic Amines with (+)-Camphor-10-sulfonyl Chloride. Equal molar quantities of racemic amine and (+)-camphorsulfonyl chloride were allowed to react in benzene (or toluene). Since the reaction proceeds following the stoichiometric relation shown below, after the completion of this reaction the half of the starting amine was recovered as the hydrochloride. The amounts of one enantiomer enriched in

Table 1. Optical rotations and the extents of kinetical resolution (α%) for unsulfonylated amines[a]

Amine	Temp. °C	$[\alpha]_D$ (c, solvent, temp.) for unsulfonylated amine or derivatives of the amine	α%[b]
α-Phenylethylamine (I)	27—30	−0.057°[c] (29.0, water, 32°C)	0.69%
α, β-Diphenylethylamine (II)	25—30	−1.83°[c] (0.87, water, 31°C)	2.61%
α-(β-Naphthyl)-ethylamine (III)	28—30	+2.04°[d] (1.5, ethanol, 30°C)	3.0%
α-(α-Naphthyl)-benzylamine (IV)	25	−0.94° (9.68, benzene, 22°C)	1.48%
α-Pipecoline (V)	23—25	+0.43° (13.3, benzene, 24°C)	1.44%
2-Aminobicyclo[2.2.2]octane (VI)	15	0.00° (3.0, benzene, 15°C) 0.00°[c] (5.0, water, 15°C)	0.00%
Menthylamine (VII)[f]	−6.0	+7.27°[c] (1.0, water, 25°C)	19.9%
Menthylamine (VII)[f]	−40.0	+10.73°[c] (1.0, water, 25°C)	29.3%
Menthylamine (VII)	room temp.	+10.7°[c,e] (water)	29.2%[e]

a) All reactions were conducted in benzene except when otherwise noted.
b) The rotations, $[\alpha]_D$, of the optically pure materials are taken to be −8.27° (c 31.45, water)[4] for the hydrochloride of I, 70° (c 0.7, water, 15°C)[5] for the hydrochloride of II, +67.9° (c 1.12, water, 17°C)[6] for carbamide of III, +63.6° (p 4.76, benzene, 15°C)[7] for IV, +30.0° (c 20, benzene, 15°C)[8] for V, +36.6° (water, 15°C)[9] for the hydrochloride of VII, respectively.
c) For the hydrochloride. d) For the carbamide.
e) Data given by Read and Story.[3] f) In toluene.

the unsulfonylated amine were determined by the measurement of the optical rotation of the recovered amine.

$$2RNH_2 + (+)\text{-}RSO_2Cl = RNH_2\cdot HCl + (+)\text{-}RSO_2NHR$$

The extents (α%) of the resolution for the unsulfonylated amines were estimated by the comparison of their rotations with those of the optically pure amines (or hydrochlorides).[4-9] The reaction conditions, the otpical rotations and the extents of the resolution (α%) are listed in Table 1. Among several amines examined, menthylamine (VII), which seems to be the most dissymmetric with regards to the reaction center, has been resolved in the greatest extent, and, in contrast, for 2-aminobicyclo[2.2.2]octane (VI), which is relatively symmetric because of its ball-like structure, there is no rate difference between the (R)- and the (S)-enantiomer.

Rate Measurements for the Sulfonylation of (−)-Menthylamine with (+)-Camphor-10-sulfonyl Chloride in Toluene. In order to compare the activation parameters for the sulfonylation of (+)- and (−)-menthylamine, first, the rates of the reaction of (−)-menthylamine with (+)-camphor-10-sulfonyl chloride were measured at the temperatures ranging from −20 to −40°C. The reaction was started by a rapid mixing of the toluene solutions (0.1 M for each) of the (−)-amine and the (+)-sulfonyl chloride; after an appropriate reaction time the reaction was stopped by adding a cold toluene solution of formic acid. The liberated chloride ion was extracted with

water and titrimetrically determined. Since the reaction was started with the equimolar quantities of the substrate and the reagent, we interpreted the rate data by a modified second-order kinetic equation (Eq. (1)), which was derived on the basis of the stoichiometry of this reaction:

$$k_2 = \frac{1}{at} \ln \frac{a-x}{a-2x} \quad (1)$$

where a is the initial concentration of the amine or the sulfonyl chloride, and x is the instantaneous concentration of the chloride ion at time t. The rate constants were calculated graphically by plotting $\log (a-x)/(a-2x)$ against time, and the results are illustrated in Fig. 1.

Secondly, the rate ratio of (+)- to (−)-menthylamine was estimated from the extent of the kinetical resolution of the racemic menthylamine with the (+)-sulfonyl chloride in toluene, as is described in the following.

The reaction of the racemic menthylamine and (+)-camphor-10-sulfonyl chloride is expressed as a competitive reaction of the (+)- and (−)-amine toward the sulfonyl chloride. So that, we obtain the following rate expression.

$$\frac{d[(+)\text{-RNHSO}_2\text{R}']}{dt} = k_{(+)\text{-Amine}}[\text{R}'\text{SO}_2\text{Cl}][(+)\text{-RNH}_2]$$

$$\frac{d[(-)\text{-RNHSO}_2\text{R}']}{dt} = k_{(-)\text{-Amine}}[\text{R}'\text{SO}_2\text{Cl}][(-)\text{-RNH}_2]$$

or when the reaction is conducted with the equal molar quantities of the racemic amine and the chloride,

$$\frac{dx}{dt} = k_{(+)\text{-Amine}}(a-x-y) \times \left\{0.5a - x - (x+y)\frac{(0.5a-x)}{(a-x-y)}\right\} \quad (2)$$

$$\frac{dy}{dt} = k_{(-)\text{-Amine}}(a-x-y) \times \left\{0.5a - y - (x+y)\frac{(0.5a-y)}{(a-x-y)}\right\} \quad (3)$$

where $x = [(+)\text{-RNHSO}_2\text{R}']$,

$y = [(-)\text{-RNHSO}_2\text{R}']$, $a = [\text{R}'\text{SO}_2\text{Cl}]_0$,

$0.5a = [(+)\text{-RNH}_2]_0 \equiv [(-)\text{-RNH}_2]_0$,

$(x+y) = \{[(+)\text{-RNH}_2\cdot\text{HCl}] + [(-)\text{-RNH}_2\cdot\text{HCl}]\} \equiv \{[(+)\text{-RNHSO}_2\text{R}'] + [(-)\text{-RNHSO}_2\text{R}']\}$,

$(a-x-y) = [\text{R}'\text{SO}_2\text{Cl}] \equiv \{[(+)\text{-RNH}_2]_0 + [(-)\text{-RNH}_2]_0\} - \{[(+)\text{-RNHSO}_2\text{R}'] + [(-)\text{-RNHSO}_2\text{R}']\}$,

$(0.5a-x) = \{[(+)\text{-RNH}_2]_0 - [(+)\text{-RNHSO}_2\text{R}']\}$, and

$(0.5a-y) = \{[(-)\text{-RNH}_2]_0 - [(-)\text{-RNHSO}_2\text{R}']\}$.

From Eqs. (2) and (3), dx/dy is expressed as:

$$dx/dy = k_{(+)\text{-Amine}}(0.5-x)/k_{(-)\text{-Amine}}(0.5a-y) \quad (4)$$

The integration of Eq. (4) gives:

$$k_{(+)\text{-Amine}}/k_{(-)\text{-Amine}} = \log\left(\frac{0.5a-x}{0.5a}\right)\Big/\log\left(\frac{0.5a-y}{0.5a}\right) \quad (5)$$

Since $x_{t=\infty} = [(-)\text{-RNH}_2\cdot\text{HCl}]_\infty$ and $y_{t=\infty} = [(+)\text{-RNH}_2\cdot\text{HCl}]_\infty$, the Eq. (5) is expressed as:

$$\frac{k_{(+)\text{-Amine}}}{k_{(-)\text{-Amine}}} = \frac{\log\left\{\dfrac{[(-)\text{-RNH}_2]_0 - [(-)\text{-RNH}_2\cdot\text{HCl}]_\infty}{[(-)\text{-RNH}_2]_0}\right\}}{\log\left\{\dfrac{[(+)\text{-RNH}_2]_0 - [(+)\text{-RNH}_2\cdot\text{HCl}]_\infty}{[(+)\text{-RNH}_2]_0}\right\}} \quad (6)$$

When $[(-)\text{-RNH}_2\cdot\text{HCl}]_\infty > [(+)\text{-RNH}_2\cdot\text{HCl}]_\infty$, the Eq. (6) can be expressed as the Eq. (7), which indicates the relation between $k_{(+)\text{-Amine}}/k_{(-)\text{-Amine}}$ and α% of the unsulfonylated menthylamine.

$$\frac{k_{(+)\text{-Amine}}}{k_{(+)\text{-Amine}}} = \log\left(\frac{100-\alpha}{200}\right)\Big/\log\left(\frac{100+\alpha}{200}\right) \quad (7)$$

Using the rate ratio (Eq. (7)) and the rate constant observed for the (−)-amine, the rate constant for the (+)-menthylamine can be estimated.

Table 2. Rates and activation parameters for the sulfonylation of (−)- and (+)-menthylamine by (+)-camphor-10-sulfonyl chloride in toluene

Temp. °C	(−)-Menthylamine[a] 10^2k_2 ($\text{sec}^{-1}\,\text{M}^{-1}$)	(+)-Menthylamine 10^2k_2, calcd.[c] ($\text{sec}^{-1}\,\text{M}^{-1}$)
−6.0	3.20[b]	2.50[d]
−20.0	2.07	—
−30.0	1.44	—
−40.0	0.965	0.656[d]
E_A (kcal/mol)	4.40	4.84
$\Delta S^\ddagger$ (e.u.) at −40°C	−50.2	−49.1

a) The initial concentrations of the amine and the sulfochloride was 0.0500 M for each run.
b) Extrapolated from the data at other temperatures.
c) Calculated from the k_2 for the (−)-amine and the rate ratio, $k_{(+)\text{-Amine}}/k_{(-)\text{-Amine}}$ (*cf.* Eq. (7)).
d) $k_{(+)\text{-Amine}}/k_{(-)\text{-Amine}} = 0.78$ (at −6.0°C) and 0.68 (at −40°C).

In Table 2, the rate constants for the (−)- and the (+)-menthylamine are tabulated along with the respective activation parameters. In view of the observation that the reaction does not obey good second-order kinetics (*vide infra*), obviously the values for $k_{(+)\text{-Amine}}$ should be condisered as approximate ones.

As is shown in Table 2, (−)-menthylamine is sulfonylated 1.3 to 1.5 times as fast as (+)-menthylamine in the temperature range −6 — −40°C. The slower rate for the (+)-amine is attributed to the higher activation energy for the (+)-amine sulfonylation.

Discussion

The Mechanism of the Sulfonylation of the Primary Amines. The kinetics of the sulfonylation of the various amines have been studied by Litvinenko and his collaborators;[10] the second-order kinetics of an arylsulfonylation of a primary amine in nitrobenzene[10a] was interpreted by a two-step mechanism, which was composed of a rapid reversible formation of an adduct and a subsequent slow splitting of the adduct into *N*-alkylarylsulfonamide and hydrogen chloride; this is shown as in the following.

$$RNH_2 + ArSO_2Cl \overset{\text{rapid}}{\rightleftharpoons}$$

$$ArSO_2Cl\cdot NH_2R \overset{\text{slow}}{\longrightarrow} HCl + ArSO_2NHR$$

In benzene, however, they found the reaction of *n*-butylamine (R=*n*-Bu) and 2,4-dinitrobenzenesulfonyl chloride (Ar=2,4-$(NO_2)_2C_6H_3$) to be the 2.6 order,[10b] and explained this order assuming the parallel paths. Namely, for both paths an adduct was formed rapidly and reversibly; the adduct then splits into HCl and $ArSO_2NHR$ by the second-order path as is in nitrobenzene, but this decomposition (*i. e.*, dehydrochlorination) is accelerated by a second RNH_2 in the third-order path.

$$RNH_2 + ArSO_2Cl \rightleftharpoons$$

$$ArSO_2Cl\cdot NH_2R \rightarrow HCl + ArSO_2NHR \quad \text{(2nd-order path)}$$

$$\overset{+RNH_2}{\longrightarrow} RNH_2HCl + ArSO_2NHR \quad \text{(3rd-order path)}$$

In a similar fashion, Ebel[11] proposed a two-step mechanism for the sulfonylation of aniline with *p*-toluenesulfonyl chloride in ether. However, in this case the reaction was found to obey the fifth-order kinetics, and this was attributed to the formation of an intermediate between one mole of the sulfonyl chloride and three moles of aniline at the first step of this reaction, this being shown as follows:

$$3C_6H_5NH_2 + ArSO_2Cl \rightleftharpoons$$

$$ArSO_2Cl\cdot 3C_6H_5NH_2 \overset{+C_6H_5NH_2}{\longrightarrow}$$

$$ArSO_2NHC_6H_5 + C_6H_5NH_2HCl + 2C_6H_5NH_2$$

Such association of amines has been proposed in the case of the Menschutkin reaction of alkyl halides with diethylamine in cyclohexane.[12]

In our experiments carried out in toluene, the sulfonylation of (−)-menthylamine obeyed fairly good second-order kinetics, as is shown in Fig. 1. However, in view of a downward drift of the linear plot, the incursion of the third-order process (proposed by Litvinenko[10b]) or of the association of the amines might be considerable at least after the completion of 60% or more.

For the amines other than menthylamine we have not carried out kinetic measurements. However, it seems reasonable to consider that the reactions of these amines proceed through an amine-adduct to the sulfonyl chloride, as is considered in the case of sulfonylation with arylsulfonyl chloride.[10,11]

The Absolute Configuration of the Unsulfonylated Amines. In Table 3 the absolute

Table 3. Absolute configurations of unsulfonylated amines in the partial sulfonylation by (+)-camphor-10-sulfonyl chloride[a]

Amines	Signs of rotation[b] and absolute configurations[c] for unsulfonylated amines
α-Phenylethylamine (I)	(−)-S
α,β-Diphenylethylamine (II)	(−)-S
α-(β-Naphthyl)-ethylamine (III)	(+)-R
α-(α-Naphthyl)-benzylamine (IV)	(−)-?[g]
α-Pipecoline (V)	(−)-S
Menthylamine (VII)	(+)-S[d,f]
Neomenthylamine (VIII)	(+)-S[e,f]
Isomenthylamine (IX)	(+)-S[e,f]

a) In benzene.
b) The optically active hydrochlorides or carbamides possess the same signs of rotation as those for the respective amines of the same absolute configurations.
c) For the absolute configuration of I, III, V and methylamines (VII, VIII and IX), confer the Refs. 13, 2f, 14 and 15, respectively. The absolute configuration of II was deduced from the configuration of phenylbenzylcarbinol.[16]
d) The amines with the same configuration were obtained in toluene and in benzene (see Table 1).
e) The results obtained by Read and Story.[3]
f) The absolute configuration of the asymmetric carbon atom attached to the amino group.
g) The absolute configuration is not known.

a) Data were taken from the experimental results of Wegler.[2a)]

configurations[2f,13-15)] of unsulfonylated amines are listed along with the observed signs of rotation; the signs of rotation for neomenthylamine (VIII) and isomenthylamine (IX) were cited from the data reported by Read and Story.[3)]

It is immediately obvious from Table 3 that the amine, with (R)-carbon atom attached to the amino-group, reacts faster than the (S)-enantiomer, with exception of III.

In a similar fashion, we can point out that in the benzoylation or the acetylation of various secondary alcohols, which were conducted in the presence of brucine or strychinine by Wegler,[2a)] the (S)-alcohols react faster than the (R)-alcohols, This is illustrated in Table 4; among 27 examples of the alcohols with known configurations,[16)] four examples seem to be the exceptions.

Recently, the similar coincidence of preferred absolute configurations has been disclosed for the kinetical resolution in some amidation reactions. For example, in amidation with (S)-(+)-2-methylamino-1-phenylpropane in the presence of dicyclohexylcarbodiimide,[2d)] six (R)-alkylphenylacetic acids, with excption of two, were found to react faster than respective (S)-enantiomers. Furthermore, the *N*-substituted amides of (−)-hydratropic acid were found to be formed in the presence of ethyl carbonate preferentially from (R)-primary amines (ten examples with exception of one), in comparison with the respective (S)-amines.[2f)]

In general, the enantiomeric rate ratio in these kinetical resolutions depends on the free-energy difference between the diastereomeric intermediates. Therefore, the simple coincidence of the preferred absolute configurations may suggest that the free-energy difference in these cases may be controlled phenomenally by the combinations (*e. g.*, dextro+dextro and levo+dextro) of the arrangements of three (large-, medium- and small-sized) groups attached to the respective asymmetric carbons of the diastereomeric intermediates. This coincidence seems to be a general trend in the kinetical resolution, so far as it has been explored. However, we should find more examples available in order to confirm its conclusive generality.

In connection with an interpretation of the preference in configuration, examination of the most preferred constellation in the diastereomeric intermediates seems to be successful for several examples[2b,2d,17)] on the basis of a "rigid" model, which was proposed in the case of asymmetric "synthesis" of carbonyl-addition type.[18,19)] However, in the present case of asymmetric sulfonylation with (+)-camphor-10-sulfonyl chloride, in a

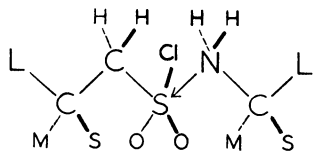
supposed intermediate (see below) the two asymmetric groups lie so remote from each other that it seems difficult to apply a "rigid" model similar to the one proposed by Cram[18] or Prelog.[19] A reasonable elucidation of the preferred configuration in these sulfonylations should be postponed in the future study.



With respect to the extent of these kinetic resolution, we can point out the following factors which may affect the extent of resolution. First, the more tightness of the bonds between the substrate and the reagent in the supposed intermediate may cause the greater degree of inhibition of the free rotation of the respective asymmetric groups, and result in the more extent of resolution. Secondly, the greater degree of the polymolecular association of amines may require their more specific orientation[12] in the intermediate, and cause an enlarged difference in the free energies of diastereomeric intermediates. Thirdly, the multiplicity of the reaction step may enlarge the extent of resolution, since in the multi-step reaction the substrate is kinetically resolved at least twice, or more, until it is converted to the product. The exderimental verification of these factors will be a subject of the future study.

Experimental

Materials. (+)-Camphor-10-sulfonyl chloride was prepared according to Smiles and Hilditch[20] from thionyl chloride and (+)-camphor-10-sulfonic acid, and recrystallized twice from ether; mp 67.0—68.0°C, corr.; $[\alpha]_D^{29}$ +36.5° (*c* 7.72, chloroform). (±)-α-Phenylethylamine (bp 74.0°C/15 mmHg) and (±)-α-pipecoline (bp 128°C) were purified by fractional distillation. (±)-α,β-Diphenylethylamine (bp 165—170°C/15 mmHg), (±)-α-(β-naphthyl)-ethylamine (bp 160°C/13 mmHg; mp 198—199°C, uncorr., for the hydrochloride), and (±)-α-(β-naphthyl)-benzylamine (bp 200—206°C/5 mmHg, mp 119—120°C) were prepared from the respective ketones by the method described by Ingersoll.[21] (±)-Menthylamine (bp 70.0°C/7 mmHg) and (−)-menthylamine (bp 80°C/12 mmHg) were prepared from the respective menthone oximes according to the method of Wallach.[22] (±)-2-Aminobicyclo[2.2.2]octane (mp 138—140°C, decomp.) was prepared by the method described by Seka and Tramposch.[23]

The Recovery of Unsulfonylated Amines from the Products of the Sulfonylation (General Procedure). The sulfonylation was carried out by mixing the sulfonyl chloride with the equal molar quantity of the racemic amine in dry benzene (or toluene). After standing overnight at room temperature, the hydrochloride of the unchanged amine was filtered, and its optical rotation was measured in aqueous solution, or else it was measured in an appropriate solvent after isolation as a free amine or a carbamide. No characterization of the sulfonamide so produced was carried out. The details of the isolation procedures for the respective sulfonylations are cited below.

Isolation of Unsulfonylated α-Phenylethylamine (I). To a solution of (+)-camphor-10-sulfonyl chloride (40.0 g, 0.155 mol) in benzene (50 cc), 20.0 g (0.164 mol) of (±)-I in 50 cc of benzene was added. After standing overnight at 27—30°C, α-phenylethylamine hydrochloride (9.0 g, mp 155—159°C, 34.7% of the starting amine), which separated from the reaction mixture, was filtered; a part of the hydrochloride was dissolved into an appropriate amount of water for the measurement of the optical rotation; $[\alpha]_D^{32}$ of the hydrochloride, −0.038±0.004° (*c* 20.0, water); lit.[4] $[\alpha]_D$ for the optically pure hydrochloride, −6.20° (*c* 20.0, water).

In a duplicate run, 15.2 g (0.125 mol) of (±)-I and 31.4 g (0.125 mol) of (+)-camphor-10-sulfonyl chloride afforded 6.0 g (30.5% of the starting amine) of (−)-phenylethylamine hydrochloride (mp 156—159°C; $[\alpha]_D^{32}$ −0.057°±0.005° (*c* 29.0, water); lit.[4] $[\alpha]_D$ for the optically pure hydrochloride, −8.27° (*c* 31.45, water)).

Isolation of Unsulfonylated α,β-Diphenylethylamine (II). A mixture of (±)-II (10.5 g, 0.0537 mol) and (+)-camphor-10-sulfonyl chloride (13.5 g, 0.0538 mol) in 100 cc of dry benzene was allowed to react overnight at 25—30°C. The crystals (15.0 g, 42.2% yield) of α,β-diphenylethylamine hydrochloride (mp 220—230°C), which precipitated in the reaction mixture, was filtered, and washed with 20 cc of benzene; $[\alpha]_D^{31}$ −1.83±0.15° (*c* 0.87, water); lit.[4] $[\alpha]_D^{15}$ for the optically pure hydrochloride, −70° (*c* 0.7, water). After evaporation of a part of the filtrate, the second crop (1.0 g) of the hydrochloride (total yield 50.7%) was obtained. No characterization of the product from the mother liquors was undertaken.

Isolation of Unsulfonylated α-(β-Naphthyl)-ethylamine (III). A mixture of (±)-III (10.0 g, 0.0588 mol) and (+)-camphor-10-sulfonyl chloride (14.8 g, 0.0588 mol) in benzene (100 cc) was allowed to stand overnight at 28—30°C. The crystals of α-(β-naphthyl)-ethylamine hydrochloride (5.5 g, 45.4% of the starting amine, mp 200—210°C), which precipitated during the reaction, was filtered. A part (2.7 g) of the hydrochloride was converted to its carbamide (2.5 g) by mixing aqueous potassium cyanate with the chloride. The carbamide was recrystallized from 95% ethanol giving 2.3 g of pure carbamide (mp 197—198°C; $[\alpha]_D^{30}$ +2.04±0.03° (*c* 1.5, ethanol), +2.03° (*c* 0.96, ethanol); lit.[6] $[\alpha]_D^{17}$ for the optically pure carbamide, +67.9° (*c* 1.12, ethanol).

Isolation of Unsulfonylated α-(α-Naphthyl)-benzylamine (IV). A mixture of (±)-IV (4.45 g. 0.0192 mol) and (+)-camphor-10-sulfonyl chloride (4.80 g, 0.0191 mol) in 130 cc of benzene was allowed to stand overnight at 25°C. The crystals (2.50 g) of α-(α-naphthyl)-benzylamine hydrochloride, which separated from the reaction mixture, was filtered, and shaken with 30% aqueous sodium hydroxide and ether. From the ethereal solution 2.0 g (45.0% of the starting amine) of the amine (IV) (mp 116—118°C) was recovered; $[\alpha]_D^{22}$ −0.94±0.04° (*c* 9.68, benzene); lit.[7] $[\alpha]_D^{15}$ for the optically pure IV, +63.6° (*c* 4.8, benzene).

Isolation of Unsulfonylated α-Pipecoline (V). A mixture of (±)-V (4.6 g, 0.0464 mol) and (+)-camphor-10-sulfonyl chloride (12.0 g, 0.0478 mol) in 100 cc of benzene was kept overnight at 23—25°C. The hydrochloride (3.0 g) of α-pipecoline, separated as a slightly hygroscopic crystals, was shaken with 20% aqueous sodium hydroxide and ether. The ethereal solution was dried with potassium hydroxide, and fractionated to give α-pipecoline (2.0 g; 43.4% of the starting amine; bp 110—120°C; $[\alpha]_D^{24}$ +0.43±0.01° (*c* 13.3, benzene); lit.[8] $[\alpha]_D^{15}$ for the optically pure V, 30.0° (*c* 20, benzene).

Isolation of Unsulfonylated 2-Aminobicyclo-[2.2.2]octane (VI). A mixture of (±)-VI (6.0 g, 0.0480 mol) and (+)-camphor-10-sulfonyl chloride (12.0 g, 0.0478 mol) in 110 cc of benzene was allowed to react for two days at 15°C. The hydrochloride (3.5 g; 45.7% of the starting amine) of VI was filtered, and showed no optical rotation within the experimental error ($[\alpha]_D^{15}$ 0.00+0.01° (*c* 5.0, water) for the hydrochloride, $[\alpha]_D^{15}$ 0.00±0.05° (*c* 3.0, benzene) for the free amine).

Isolation of Unsulfonylated Menthylamine (VII). A solution of (+)-camphor-10-sulfonyl chloride in toluene was prepared by dissolving about 6 g of the chloride into 100 cc of toluene; the concentration (0.213 M) was determined by the analysis of chloride ion liberated after 2 hr refluxing of an aliquot (1 cc) with 15 cc of 0.05 N ethanolic potassium hydroxide. The (±)-VII solution (100 cc) was prepared by dissolving 3.30 g of the amine into dry toluene (100 cc). The toluene solutions (80 cc for each) of the chloride and the amine were cooled at −40.0°C, and mixed with each other in one portion. After standing for 5 hr at −40.0°C, the unsulfonylated menthylamine was isolated following the method described by Read and Story.[3] The reaction mixture was made slightly alkaline with 5% sodium hydroxide and shaken until no further reaction occured. The toluene solution was washed with two 100-cc portions of water and extracted with two 100-cc portions of 10% aqueous hydrochloric acid. The hydrochloric acid solution of the amine was evaporated to afford 1.1 g (34.1%) of menthylamine hydrochloride ($[\alpha]_D^{25}$ +10.73±0.18° (*c* 1.0, water); lit.[9] $[\alpha]_D^{15}$ +36.6° (water)).

In the succeeding run carried out for 5 hr at −6.0°C, from a 0.23 M solution (80 cc) of (+)-camphor-10-sulfonyl chloride and a 0.23 M solution (80 cc) of (±)-menthylamine 1.8 g of menthylamine hydrochloride ($[\alpha]_D^{25}$ +7.27±0.10° (*c* 1.0, water)) was obtained.

Kinetic Measurements. A solution (0.1 M, 2.0 cc for each) of (+)-camphor-10-sulfonyl chloride and of (−)-menthylamine in toluene were placed in a Y-shaped tube, and kept at an appropriate reaction temperature in a thermostatted ethanol bath, which was cooled in another carbon dioxide - ethanol bath kept at about −45°C. The two 0.1 M solutions (2 cc for each) were mixed in one portion under nitrogen atmosphere; after appropriate reaction time, the reaction was stopped by adding 1 cc of cold toluene, saturated with formic acid; the solution was extracted with 10 cc of water. From the aqueous extracts 5 cc of an aliquot was titrated by the Volhard method. The rate data were treated graphically by the plot described in text; the results are shown in Table 2 and Fig. 1. In each case the reaction was followed to at least 60% completion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1433—1440 (1968)

Kinetic Studies of Solvolysis. XV.*1 Racemization Caused by the Molecular-Complex Formation in the Acetolysis of Optically Active 2,4,7-Trinitro-9-fluorenyl (+)-Camphor-10-sulfonate

Kunio OKAMOTO, Issei NITTA and Haruo SHINGU

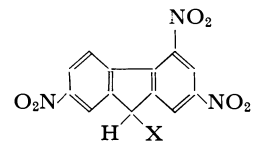
Department of Hydrocarbon Chemistry, Faculty of Enginering, Kyoto University, Sakyo-ku, Kyoto

(Received December 26, 1967)

Optically active 2,4,7-trinitro-9-fluorenyl (+)-camphor-10-sulfonate (II) has been synthesized by asymmetric attack of (+)-camphor-10-sulfonic acid to 9-diazo-2,4,7-trinitrofluorene. Acetolysis of II is accelerated by added phenanthrene, anthracene, and hexamethylbenzene at 116—120°C. This acceleration is attributed to molecular complex formation between II and these hydrocarbons. The complex formation has been examined by spectrophotometry or by the isolation of the crystalline complex of II. The acetolysis product, *i. e.*, optically active 2,4,7-trinitro-9-fluorenyl acetate (III), has been racemized in the greater degree in the presence of the more aromatic hydrocarbons. This racemization is ascribed to the prolonged life of the S_N1 ion-pair intermediate caused by the rapid equilibration between the uncomplexed and the complexed S_N1-intermediate; the kinetic nature of this interaction has been discussed.

In the previous papers of this series[1] we have reported on several examples of the solvolysis of α-phenylethyl chloride which proceeded with net retention of configuration. With regard to these retentive solvolyses, it was not clear whether the "back-side shielding"[2] of the S_N1 solvolysis intermediate by a molecule of such retentive solvents as phenol[1a-c] and acrylonitrile[1d] was responsible for those retentive courses or not. In connection with this problem, we undertook the examination of the steric course for the acetolysis of a molecular complex formed from an aromatic hydrocarbon and an optically active substrate, because this reaction might be a model solvolysis which proceeds with net retention of the configuration possibly due to "back-side" shielding of the S_N1 intermediate by such aromatic hydrocarbons.

As a solvolysis substrate which exhibits facile complexation with some aromatic hydrocarbons, we chose a 2,4,7-trinitro-9-fluorenyl system, since Colter and his collaborators[3] clearly established that 2,4,7-trinitro-9-fluorenyl *p*-toluenesulfonate (I) forms a molecular complex with such aromatic hydrocarbons as phenanthrene, anthracene and hexamethylbenzene, and that the rate of the acetolysis of I is enhanced by this molecular complexation.



I : X = *p*-toluenesulfoxy
II : X = (+)-camphor-10-sulfoxy
III : X = acetoxy

The 2,4,7-trinitro-9-fluorenyl system with optical activity, caused by an asymmetric carbon at the 9-position, was prepared by an asymmetric attack of (+)-camphor-10-sulfonic acid to 9-diazo-2,4,7-trinitrofluorene; the complexation of 2,4,7-trinitro-9-fluorenyl (+)-camphorsulfonate (II) so synthesized was examined by spectrophotometry and by the isolation of the molecular complexes in the cases of phenanthrene and anthracene; then the kinetic measurements and the product analyses were attempted of II in the presence of those aromatic hydrocarbons.

It is the purpose of the present report to show that the acetolysis of II is accelerated in the presence of the aromatic hydrocarbons as it was found in the case of the acetolysis of I,[3] and that, contrary to our anticipation, the acetolysis involves inversion

of configuration, accompanied by predominant racemization, in the presence of those hydrocarbons; the mechanistic implications of the kinetic and the steric characteristics of these acetolyses have been discussed.

Results and Discussion

Optically Active 2,4,7-Trinitro-9-fluorenyl (+)-Camphor-10-sulfonate (II). A mixture of 9-diazo-2,4,7-trinitrofluorene[4] and (+)-camphor-10-sulfonic acid in nitromethane was allowed to react for 2 hr at 40°C. The desired 2,4,7-trinitro 9-fluorenyl (+)-camphor-10-sulfonate (II), $[\alpha]_D^{16}$ +24.45°, was obtained in a fair yield. The sulfonate II was converted to the optically-active 2,4,7-trinitro-9-fluorenyl acetate (III), $[\alpha]_D^{20}$ −6.21°, in good yields after 20 hr of reflux in acetic acid. This indicates that the attack of (+)-camphor-10-sulfonic acid to the 9-diazofluorene had been made asymmetrically, namely, that the optical activity of the sulfonate II was originated partly from a carbon atom at 9-position of 2,4,7-trinitro-9-fluorenyl group, besides from the original (+)-camphor-10-sulfonyl group.

Since under a basic condition, *e. g.*, in pyridine, the sulfonate II and the acetate III were led to highly colored materials from which neither pure starting materials nor identifiable products could be obtained, the usual optical resolution through the hydrogen phthalate of 2,4,7-trinitro-9-fluorenol was not undertaken. Furthermore, in the S_N2 reaction with sodium acetate in nitromethane, the sulfonate II did not afford the acetate III, but colored materials. This made difficult to confirm the relationships between the optical rotations and the configurations with respect to II and III (*vide infra*).

Formation of Crystalline Molecular Complexes of the Sulfonate II. The formation of crystalline molecular complexes involving some aromatic hydrocarbons and 2,4,7-trinitro-9-fluorenyl *p*-toluene-sulfonate (I) has been reported by Colter and Wang.[4] According to their methods, the complex forming properties of the sulfonate II were investigated briefly in the present work. The crystalline molecular complexes between II and phenanthrene (or anthracene), which formed from the benzene or nitromethane solution, are described in Table 1. The isolation of the complex between II and hexamethylbenzene, using benzene or nitromethane as the solvent, was unsuccessful.

Table 1. Complexes of aromatic hydrocarbons with 2,4,7-trinitro-9-fluorenyl (+)-camphor-10-sulfonate (II)

Aromatic hydrocarbon	Melting point °C, corr.	Color	Analysis N% Found	Calcd
Phenanthrene	145.0—146.0	Yellow	5.73	5.92
Anthracene	149.0—149.5	Red	5.25	5.92

Spectrophotometric Studies of the Formation of Molecular Complexes of the Sulfonate II. On the assumption of 1 : 1 complex-formation in the solution, the complex-formation between the sulfonate II and aromatic hydrocarbons was investigated spectrophotometrically in glacial acetic acid at 24°C. The procedure of Colter and his collaborators[3b] was followed; optical densities of four to five mixtures of II ($18.4-8.84\times10^{-4}$ M) and various aromatic hydrocarbons (*i. e.*, hexamethylbenzene ($1.55-2.65\times10^{-2}$ M), phenanthrene ($1.25-5.00\times10^{-2}$ M)), and anthracene ($0.828-1.375\times10^{-3}$ M) were measured at 400 and 410 mμ (or at 450 and 475 mμ for anthracene). The data were treated using Eq. (1),[5,6]

$$\frac{[A]_0}{E_\lambda-\varepsilon_\lambda^A[A]_0}=\frac{1}{\varepsilon^{D\cdot A}-\varepsilon_\lambda^A}+\frac{1}{K_T[D]_0(\varepsilon_\lambda^{D\cdot A}-\varepsilon_\lambda^A)} \quad (1)$$

$[A]_0$ and $[D]_0$ are the stoichiometric concentrations of II and an aromatic donor hydrocarbon; ε_λ^A and $\varepsilon_\lambda^{D\cdot A}$ are the molar extinction coefficients of the sulfonate II and the 1 : 1 complex; E_λ is the measured optical density of the mixture, and K_T is the equilibrium constant for the reaction $A + D \rightleftarrows A\cdot D$.

From the plots of $[A]_0/(E_\lambda-\varepsilon_\lambda^A A)$ *vs.* 1/[D], the K_T's and $\varepsilon_\lambda^{D\cdot A}$'s were estimated. The results are listed in Table 2.

Table 2. The K_T and $\varepsilon_\lambda^{D\cdot A}$ values for 1 : 1 complex formation between II and aromatic hydrocarbons in acetic acid at 24.0°C

Aromatic hydrocarbon	Wavelength mμ	$\varepsilon_\lambda^{D\cdot A}$ $M^{-1}cm^{-1}$	K_T[a] M^{-1}	
Hexamethyl-benzene	400	1100	2.4	Av. 2.6
	410	873	2.8	
Phenanthrene	400	2040	2.5	Av. 2.7
	410	1320	2.9	
Anthracene	450	425	4.6	Av. 4.1
	475	547	3.6

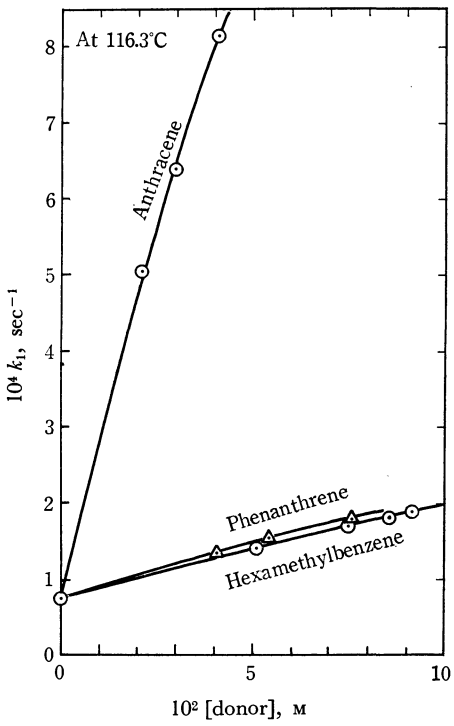

Fig. 1. Rates of acetolysis of II in the presence of aromatic hydrocarbons.

by following titrimetrically the liberated (+)-camphorsulfonic acid. The first-order rate constants, k_1's in the presence of the aromatic hydrocarbons are tabulated in Table 3 along with the rate constant in the absence of aromatic hydrocarbons. Plots of k_1 *vs.* the concentration of the added aromatic hydrocarbon are almost linear with gentle downward drift (see Fig. 1). This is a similar tendency to the observation made by Colter and Wang[3a)] on the acetolysis of the sulfonate I.

The product for the acetolysis of the sulfonate II, *i. e.*, the acetate III, was isolated in 85% yield after 20 hr of reflux of the reaction mixture. In the acetolyses in the presence of hexamethylbenzene, phenanthrene, or anthracene, were obtained some aromatic nitrohydrocarbons, along with the acetate III and unchanged aromatic hydrocarbons. Although the thorough characterization of these nitrohydrocarbons were not carried out, the hydrocarbons had rather high melting points and exhibited the infrared absorption bands characteristic for the nitro and the aromatic nucleus groups but no carbonyl absorption bands. From these facts the nitrohydrocarbons were assumed as the alkylated, *i. e.*, 2,4,7-trinitro-9-fluorenylated, products of the respective aromatic hydrocarbons.

The relation between the yields of the products and the initial concentrations of the added hydrocarbons is shown in Fig. 2 (see also Table 6). On the assumption mentioned above, the yields for nitrohydrocarbons were calculated as a monoalkylated product. The yields of the acetate III exhibit a decreasing tendency with increasing concentrations of added aromatic donor hydrocarbons, whereas the yields of monoalkylated aromatic hydrocarbons show an increasing tendency.

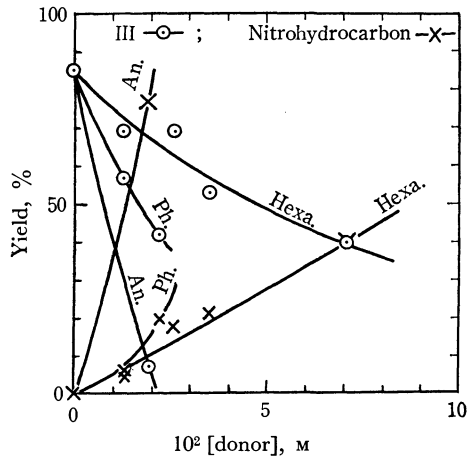

Fig. 2. Yields of III and nitrohydrocarbon in the acetolysis of II in the presence of aromatic hydrocarbons at a reflux temperature (Hexa. = hexamethylbenzene; Ph. = phenanthrene; An. = anthracene).

The latter tendency is enhanced in the case of the aromatic hydrocarbon with more facile complexing character (see the values of K_T's in Table 4).

Estimation of the Specific Rate for Complexed and Uncomplexed Sulfonate II. Among possible mechanisms for the rate enhancement by added hydrocarbons, as the simplest and the most probable one we chose the mechanism proposed by Colter and his collaborators.[3] According to the following reaction scheme A, in which a slight modification is introduced on the original mechanism[3] with respect to the nature of the reaction products,

$$\begin{array}{ccc} RX + D & \overset{K_T}{\rightleftharpoons} & RX\cdot D \\ {\scriptstyle HOAc}\downarrow{\scriptstyle k_u} & & {\scriptstyle HOAc}\downarrow{\scriptstyle k_c} \\ ROAc + D & \overset{K_A}{\rightleftharpoons} & ROAc\cdot D \\ + RD + HX & & + RD + HX \end{array}$$

Scheme A

(RX for II, ROAc for III, D for aromatic donor hydrocarbons, HX for (+)-camphorsulfonic acid, RD for alkylated hydrocarbons), the observed rate constant is given by the expression

$$k_{obsd} = k_u F_u + k_c F_c \qquad (2)$$

where F_u and F_c are fractions of II uncomplexed and complexed, respectively. Under experimental conditions where the hydrocarbon concentration $[D]_0$ is greater than the complex concentration $\{[RX\cdot D]+[ROAc\cdot D]\}$, we obtain the Colter's expression (Eq. (3)).

$$\frac{1}{(k_{obsd}-k_u)} = \frac{1}{(k_c-k_u)} + \frac{1}{K_T[D]_0(k_c-k_u)} \qquad (3)$$

A plot of $1/(k_{obsd}-k_u)$ *vs.* $1/[D]_0$ for the acetolysis in the presence of anthracene at 116.3°C is shown in Fig. 3, and the results of analysis of kinetic data for the respective aromatic hydrocarbons are tabulated in Table 4.

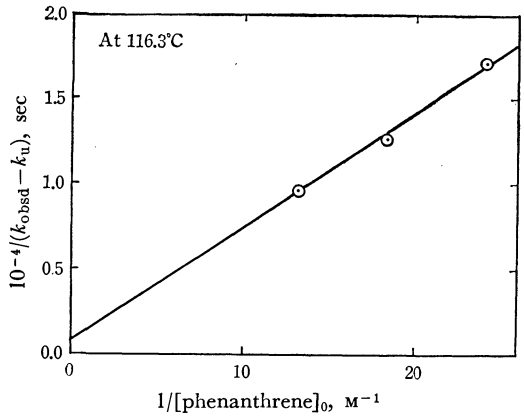

Fig. 3. Plot of $10^{-4}/(k_{obsd}-k_u)$ *vs.* 1/[phenanthrene].

Except the case of anthracene where only rough estimation of the K_T was made due to a large experimental error, the two sets of K_T's *i. e.*, K_T's from kinetic and spectrophotometric data, show a fair agreement with each other.

The values of the rate constant for the complexed substrate, k_c, are greater than those of the rate constant for the uncomplexed substrate, k_u (Table

Table 5. Estimation of the amounts of the products formed from the complexed and uncomplexed substrate in the acetolysis of II in the presence of hexamethylbenzene at 116.3°C[a]

10²[Hexa.] M	Equilibrium composition		Product[b] composition from	
	Complexed II	Uncomplexed II	Complexed II	Uncomplexed II
0.00	0.00%	100%	0.00%	100%
1.30	1.27	98.7	22.2	77.8
2.61	2.59	97.4	34.7	65.3
3.47	3.31	96.7	40.7	59.3
7.11	6.54	93.5	58.3	41.7

a) Initial concentration of II = 1.30×10^{-2} M; K_T = 1.0 (M^{-1}); k_c/k_u = 20.
b) III and nitrohydrocarbon (see text).

Table 6. Optical rotations of III and the yields of the products in the acetolysis of II in the presence of aromatic hydrocarbons at the reflux temperature (116—120°C)

Aromatic hydrocarbon	10^2 [Arom.] M	III		Nitrohydrocarbon % yield
		% yield	$[\alpha]_D$ in $MeNO_2$	
None	0.00	85	$-6.2\pm0.3°$	—
Hexamethylbenzene	1.30	69	$-1.6\pm0.3°$	6
	2.61	69	$-0.4\pm0.3°$	18
	3.47	53	$-0.8\pm0.7°$	21
	7.11	40	$-0.9\pm0.6°$	41
Phenathrene	1.30	57	$-4.4\pm0.5°$	4
	2.18	42	$-2.2\pm1.0°$	20
Anthracene	1.93	7	—	77

a) Initial concentration of II ($[\alpha]_D$ +24.45°) was 1.30×10^{-2} (M).
b) See text.

4); this rate increase for the complexed substrate is elucidated as due to the neutralization of the electron-withdrawing effect of the nitro substituents on the sulfonate II by complexation with the electron-donating aromatic hydrocarbon, since the nitro group on the substrate is known as a retarding substituent of the S_N1 solvolysis rate.

On the basis of the scheme A, we can calculate the respective amounts of the solvolysis products formed from the complexed substrate, RX·D, and the uncomplexed substrate, RX, using the estimated values for K_T, k_c and k_u. The results for the case of hexamethylbenzene are shown in Table 5, along with the equilibrium compositions for the complexed and uncomplexed substrate under the respective reaction conditions.

Optical Rotations of the Acetate III Obtained in the Presence of Aromatic Hydrocarbons. Figure 4 shows relationships between the optical rotations of the acetate III and the initial concentrations of aromatic hydrocarbons. The optical rotations of the acetate III decrease with an increase of the added hexamethylbenzene concentration; at the higher concentrations the optical rotations exhibit a tendency to a complete loss of the optical activity. In a similar fashion, optical rotations of the acetate III show a rapid decrease with an increase of the amounts of added phenanthrene (Fig. 4).

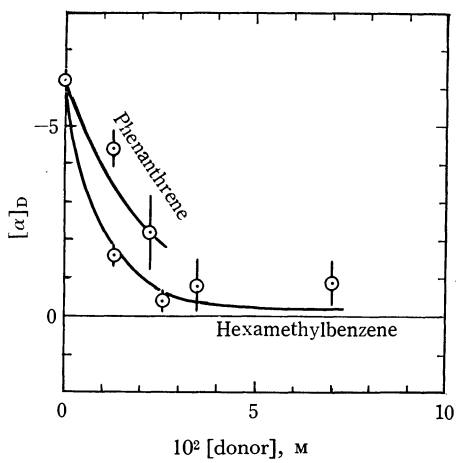

Fig. 4. Optical rotations of III formed in the acetolysis of II in the presence of aromatic hydrocarbons at reflux temperature.

As is mentioned above, an S_N2 reaction of the sulfonate II, which was carried out to determine the configurations of the sulfonate II or the acetate III, was unsuccessful owing to the unstability of II or III under the basic reaction condition. However, in acetolysis of a simple secondary alkyl substrate, the inversion of the configuration accompanying some racemization is usually observed, and this inversion is considered as a general character for the steric course of the solvolysis of simple alkyl compounds.[7] Accordingly, we may consider that the acetolysis of the sulfonate II also proceeds with net inversion of configuration.

If the greater S_N1 rate constant for the complexed substrate, as is compared with that for the uncomplexed sulfonate II, reflects on the prolonged life for the 2,4,7-trinitro-9-fluorenyl cation produced as the S_N1 intermediate, this longer life of the intermediate may cause the greater extent of racemization in the product III.

The Estimation of the Extents of Racemization of the Acetate III on the Basis of the Reaction Scheme A. In view of the complete racemization of III formed in the presence of added hexamethylbenzene, we may assume that the acetate III produced through the complexed substrate has no optical activity, and that, on the other hand, the uncomplexed substrate affords the acetate III with an optical rotation ($[\alpha]_D$ −6.2°) under the same reaction conditions.

On the basis of this assumption, the predicted values for the optical rotation of the acetate III can be calculated from the reaction scheme A, using the value for the product composition (*cf.*

7) See the footnote 1 of the Ref. 1b.

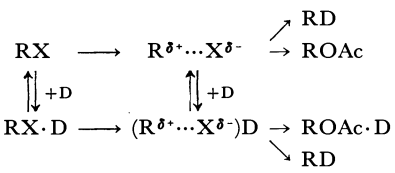
Table 7. Comparison of the optical rotations of III formed in the acetolysis of II in the presence of various amounts of hexamethylbenzene at the reflux temperature (116—120°C)[a]

10^2 [Hexa.]	$[\alpha]_D$ of III	
	Observed	Calculated, based on the reaction scheme A[b]
0.00	−6.2°	—
1.30	−1.6°	−4.8°
2.61	−0.4°	−4.0°
3.47	−0.8°	−3.7°
7.11	−0.9°	−2.6°

a) Initial concentration of II were 1.30×10^{-2} (M).
b) $[\alpha]_{D\,calcd} = -6.2°\times[\ \%$, Product from the uncomplexed II]/100.

Table 5). Since the actual products contain some nitrohydrocarbon, and since the S_N1 intermediate, which is formed from a complexed substrate, may afford much more nitrohydrocarbon than the uncomplexed intermediate, this prediction from the scheme A (Table 7) may be somewhat lower estimation.

Table 7 shows that the observed optical rotations for III are substantially lower than the values calculated on the basis of the scheme A. This gap clearly indicates that the aromatic hydrocarbon makes an additional contribution, other than the complexation of the substrate, to the loss of the optical activity of the acetate III. Therefore, we may add to the reaction scheme A an interconversion course between the complexed and uncomplexed S_N1 intermediate in order to explain this excess of racemization in the acetate. This is shown in the scheme B.



Scheme B

Kinetic Nature of the Interaction between the Aromatic Hydrocarbon and the S_N1 Intermediate. It may be difficult to find an unambiguous elucidation of the reason why the interconversion between the complexed and the uncomplexed intermediate causes the excess of the racemization for the acetate III. However, as one of the possible explanations, we may suggest the following mechanism.

The association and dissociation rates in the equilibrium between the complexed and the uncomplexed intermediate would be so frequent that the attack of the nucleophilies, *i. e.*, acetic acid or the acetate ion, would relatively be hindered. Consequently, the life of the ion-pair intermediate is prolonged and the cationic part of the intermediate rotates[8] more frequently until its asymmetric center is attacked by the nucleophile. This means that the intermediate would be racemized in greater extent in the presence of aromatic donor hydrocarbons.

Furthermore, the rate of the nucleophilic attack on the complexed intermediate would be lower than the rate for the uncomplexed intermediate, and accordingly the more acetate III (inverted) may be produced from uncomplexed intermediates than complexed ones. Thus, even if the nucleophilic attack on the complexed intermediate were made from the front-side, resulting in the retention of the configuration of the acetate, the predominance of the acetate produced from the inversive attack on the uncomplexed intermediate would lead to the over-all net inversion of configuration of the acetate. If this is the case in our experiments, it would be unable to verify whether the retentive attack is predominant for the complexed intermediate or not.

Experimental

Materials. Phenanthrene (mp 100.7—101.5°C, corr.) was purified according to the method of Phillips[9] by refluxing a mixture of phenanthrene, maleic anhydride, and xylene, and by succeeding recrystallization from ethanol; anthracene (mp 219.5—221.0°C, corr.) was recrystalized from acetic acid and then chromatographed over basic alumina, using benzene as an eluent. Hexamethylbenzene (mp 166.9—168.4°C, corr.) was used as received. Acetic acid (bp 118.0—118.5°C) was purified by refluxing with a small amount of acetic anhydride and by subsequent fractional distillation.

9-Diazo-2,4,7-trinitrofluorene (mp 204—205°C, decomp.) was prepared by the method described by Colter and Wang.[4] (+)-Camphor-10-sulfonic acid (mp 201°C, corr.; $[\alpha]_D^{20}$ +40.5° (*c* 3.16, ethanol)) was recrystallized from ethyl acetate.

The Asymmetric Synthesis of Optically Active 2,4,7-Trinitro-9-fluorenyl (+)-Camphor-10-sulfonate (II). A mixture of 9-diazo-2,4,7-trinitrofluorene (13.0 g, 0.0397 mol) and (+)-camphor-10-sulfonic acid (13.0 g, 0.0559 mol) in nitromethane (350 cc) was placed in a 500-cc three-necked flask equipped with a thermometer, a drying tube, and a magnetic stirrer. After 2 hr of stirring at 40°C, the reaction mixture was washed with two 100-cc portions of 10% aqueous sodium chloride and then with two 100-cc portions of water. Concentration of the nitromethane solution afforded bright yellow crystals (13.64 g). After recrystallization from 40 cc of nitromethane, 11.29 g (53.6%) of II (mp 192.0—193.0°C, decomp., corr.;

8) K. Okamoto, N. Uchida, S. Saitô and H. Shingu, This Bulletin, **39**, 307 (1966).
9) D. D. Phillips in "Organic Syntheses," Coll. Vol. IV, p. 313 (1963).

$[\alpha]_D^{16}$ $+24.45\pm0.4°$ (*c* 2.12, nitromethane)) was obtained.

Found: C, 51.78; H, 4.05%. Calcd for $C_{33}H_{21}O_{10}N_3S$: C, 51.98; H, 3.98%.

The Acetolysis of II in the Absence of Added Aromatic Hydrocarbons. A mixture of II (0.600 g, 0.00113 mol) and acetic acid (81 cc) was refluxed for 20 hr in a 200-cc round-bottomed flask equipped with a reflux condenser and a drying tube. After evaporation of acetic acid in vacuo, the residual yellow crystals were washed with water, ethanol, and ether, leaving 0.340 g (85%) of 2,4,7-trinitro-9-fluorenyl acetate (III) (mp 234—236°C, decomp. (lit.[4] mp 235°C, decomp.); $[\alpha]_D^{20}$ $-6.21\pm0.5°$ (*c* 2.13, nitromethane)).

The Acetolysis of II in the Presence of Added Aromatic Hydrocarbons. In a similar fashion to the acetolysis in the absence of added aromatic hydrocarbons, a mixture of II, an aromatic hydrocarbon and acetic acid was refluxed in a 200-cc three-necked flask equipped with a reflux condenser and a thermometer. After an appropriate reaction time, acetic acid was evaporated *in vacuo*, and the reaction products were isolated by extraction or by recrystallization. The details of the experimental procedures for some representative runs are cited below.

The Acetolysis of II in the Presence of Hexamethylbenzene. A mixture of II (1.00 g, 0.00188 mol), hexamethylbenzene (0.612 g, 0.0037 mol), and acetic acid (135 cc) was refluxed for 19 hr at 120°C. After evaporation of acetic acid *in vacuo* at 50—60°C, the residual yellow solid was washed with 80 cc of water and with 80 cc of ether to remove the remaining acetic acid and the unchanged hexamethylbenzene. The crude yellow crystals (0.551 g) was dissolved in 15 cc of hot nitromethane; after being kept at room temperature, the solution deposited bright yellow crystals (0.140 g; 18% yield, calculated as an alkylated hexamethylbenzene, *vide infra;* mp 279—280.5°C, decomp., corr.). After three recrystallizations of these crystals from nitromethane, 0.030 g of crystals (mp 293.7°C, decomp., corr.) were obtained (Found: C, 64.30; H, 4.98; N, 8.14%. Calcd for $C_{24}H_{21}O_6N_8$: C, 64.42; H, 4.73; N, 9.39%). These purified crystals exhibited infrared absorptions at 1520 and 1345 cm^{-1} (NO_2), at 2920 cm^{-1} (CH_3), at 3150 and 810 cm^{-1} (aromatic C–H). No carbonyl absorption was exhibited in the range 1650—1800 cm^{-1}. Although no further characterization was carried out, we assumed these crystals as an aromatic nitrohydrocarbon produced from hexamethylbenzene and II. The mother liquors obtained from the recrystallization of the above mentioned crude crystals were condensed to 5 cc, and 0.407 g (69%) of III (mp 231—234°C, uncorr.; the identical infrared spectrum with that of the authentic sample; $[\alpha]_D^{20}$ $-0.42\pm0.3°$ (*c* 1.79, nitromethane)) was obtained.

The Acetolysis of II in the Presence of Phenanthrene. A mixture of II (1.00 g, 0.00188 mol), phenanthrene (0.337 g, 0.001885 mol), and acetic acid (135 cc) was refluxed at 120°C for 17 hr. After evaporation of acetic acid *in vacuo* at 50—55°C, and washing with water, 0.739 g of yellow crystals were obtained. These crystals were refluxed with 15 cc of ether, leaving 0.49 g of a yellow solid; this was dissolved in 15 cc of nitromethane. After standing overnight in an ice-box, 0.033 g (4.2% yield, calculated as trinitrofluorenylphenanthrene, *vide infra*) of bright yellow crystals (mp 273.5—275.0°C, uncorr.) were obtained. Four recrystallizations of these crystals from nitromethane afforded 0.010 g of bright yellow needles (mp 297.5—298.5°C), which infrared spectra had characteristic bands at 3100 and 740 cm^{-1} (aromatic C–H) and at 1525 and 1345 cm^{-1} (NO_2). No carbonyl bands was found in the spectra (Found: C, 62.49; H, 3.29; N, 9.55%. Calcd for $C_{27}H_{15}O_6N_3$: C, 67.92; H, 3.17; N, 8.80%). Although results of elemental analysis were not satisfactory, we considered these crystals as trinitrofluorenylphenanthrene from the high melting point and the characteristic bands of the infrared spectra. After being condensed to 5 cc, the filtrate from the nitromethane solution of the crude reaction products afforded 0.399 g (57.2%) of III (mp 227—229°C, uncorr.; $[\alpha]_D^{22}$ $-4.37\pm0.44°$ (*c* 1.71, nitromethane); the same infrared spectrum as the authentic sample).

The Acetolysis of II in the Presence of Anthracene. A mixture of II (0.500 g, 0.000943 mol), anthracene (0.250 g, 0.00140 mol), and acetic acid (62.5 cc) was refluxed for 10.3 hr. After evaporation of acetic acid *in vacuo* at 50—60°C, the residual red-brown solid was washed with water. The dried solid was dissolved in 10 cc of acetone, leaving 0.240 g (53.4% yield, calculated as trinitrofluorenylanthracene) of insoluble crystals. After five recrystallizations from nitromethane, 0.050 g of orange needles (mp 294.0—294.5°C, uncorr.; Found: C, 67.09; H, 3.14; N, 8.19%. Calcd for $C_{27}H_{15}O_6N_3$: C, 67.92; H, 3.17; N, 8.80%). The infrared spectra had characteristic bands at 3110 and 730 cm^{-1} (aromatic C–H), 1520 and 1340 cm^{-1} (NO_2); No carbonyl bands were found. After condensation of the filtrate from the 10 cc of acetone solution, 0.105 g (23.4% yield, calculated as trinitrofluorenylanthracene) of the second crop (mp 305°C, corr., red-orange needle after four recrystallizations; the same infrared spectrum as the first crop) was obtained. From the mother liquors 0.165 g of a mixture of anthracene and III was obtained; the composition was determined by elution chromatography over acidic alumina. Anthracene (0.067 g) was eluted with benzene, and 0.025 g (7%) of III (mp 208—216°C, uncorr.; the same infrared spectrum as the authentic sample) was obtained from the succeeding fractions using ether as an eluent.

Isolation of Crystalline Molecular Complexes of II. To the solution of II (0.176 g, 0.000331 mol) in benzene (6 cc) was added anthracene (0.067 g, 0.000376 mol), resulting in a deep red solution. After standing overnight at room temperature, the red needles were collected by filtration, washed with small portions of ether. The dried complexes melted at 149.0—149.5°C (corr.) and weighed 0.11 g (0.000155 mol).

Found: C, 63.81; H, 4.96; N, 5.25%. Calcd for $C_{37}H_{31}O_{10}N_3S$: C, 62.62; H, 4.40; N, 5.92%.

From a mixture of II (0.305 g, 0.000575 mol) and phenanthrene (0.102 g, 0.000573 mol) in 3 cc of nitromethane, 0.120 g (0.000169 mol) of bright yellow complexes (mp 145.0—146.0°C, corr.) were obtained after standing overnight at room temperature.

Found: C, 62.64; H, 4.11; N, 5.73%. Calcd for $C_{37}H_{31}O_{10}N_3S$: C, 62.62; H, 4.40; N, 5.92%.

A trial to obtain the complexes between hexamethylbenzene and II from the benzene or nitromethane solution of a mixture (1 : 1 mol) of these components was unsuccessful.

Kinetic Measurements. All kinetics were measured at 116.4±0.5°C. The reaction vessels were 50-cc measuring flasks, and about 40 cc of the reaction mixture was placed. The first aliquot (3 cc) was removed 10 min after setting the flask in a thermostat. The subsequent aliquots (3 cc for each) were removed at intervals, added into 1 cc of cooled sodium acetate solution (0.01 N) in acetic acid, and titrated with 0.01 N perchloric acid in acetic acid, using crystal violet as an indicator. All the data were treated graphically by a plot of log $a/(a-x)$ against the time. In each run the reaction was followed to at least 80% conversion, and a smooth linear relationship was obtained for each run.

Spectrophotometric Determination of K_T. Optical density measurements were carried out with a double set of thermospacers connected to a circulating constant temperature bath. The temperature of the cell compartment was held in this way at 24.0±0.2°C. The measurements were carried out at the range of 390 to 600 mμ, using quartz cells with a path length of 10 mm. The data were treated in the manner described in text.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1440—1444 (1968)

Azirines. III. The Preparation of Azirine Derivatives by the Base-Catalyzed Rearrangement of Quaternary Hydrazones[1]

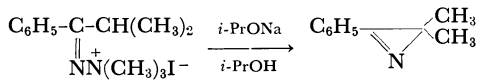
Shimao SATO

Kyorin Chemical Laboratory, Kyorin Pharmaceutical Co., Ltd., Ukima, Kita-ku, Tokyo

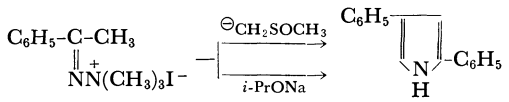
(Received December 27, 1967)

An attempt to prepare azirines by the base-catalyzed rearrangement of some quaternary hydrazones gave the corresponding azirine derivatives. Namely, 2-phenyl-3-methylazirine was obtained by the treatment of propiophenone dimethylhydrazone methiodide with potassium *t*-butoxide, but treatment with sodium isopropoxide gave 2,5-diphenyl-3,6-dimethylpyrazine or 2-phenyl-2-isopropoxy-3-methylaziridine, depending on the reaction conditions. 2-Phenyl-3,3-pentamethyleneazirine was obtained in a good yield by the treatment of cyclohexyl phenyl ketone dimethylhydrazone methiodide with sodium isopropoxide.

In 1957, Smith and Most[2] reported the rearrangement of quaternary hydrazones with a base to give aminoketones, but no intermediate azirine rings were isolated. Recently, Parcell[3] reported that 2-phenyl-3,3-dimethylazirine was isolated in a good yield by the treatment of isobutyrophenone dimethylhydrazone methiodide with sodium isopropoxide in isopropanol, but he did not describe the application of this reaction to other ketones or the effectiveness of other base-catalysts:



In a previous paper,[1] it was reported that 2,4-diphenylpyrrole, not 2-phenylazirine, was obtained by the treatment of acetophenone dimethylhydrazone methiodide (I) with methylsulfinyl carbanion as a base-catalyst:



I II

These results suggest that this rearrangement does not proceed along the same pathway for all ketones, and that the reaction is dependent upon the structures of the ketones or on the properties of the base-catalysts. Therefore, the object of the present study has been to examine the relationship between the azirine formation and the structures of the ketones or the properties of the base-catalysts.

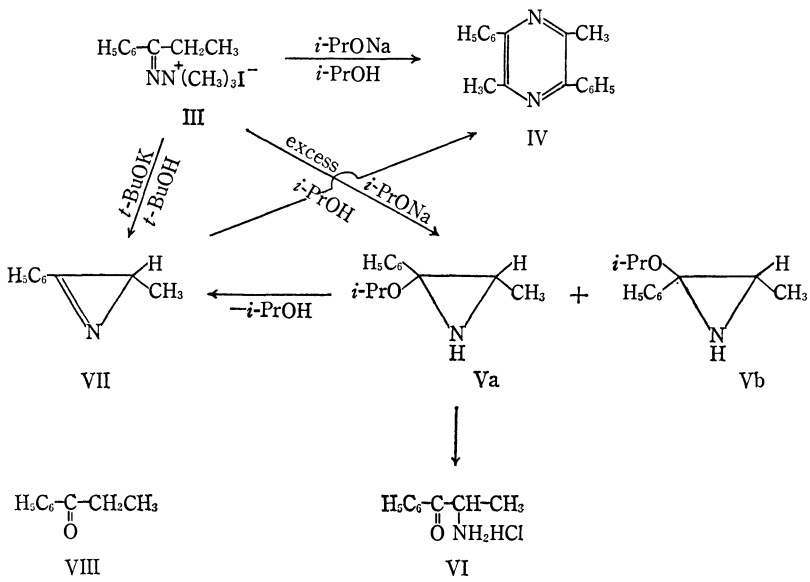
When **I** was treated with a slightly less than one equivalent amount of sodium isopropoxide in isopropanol, 2,4-diphenylpyrrole (II) was obtained in a 32% yield, but 2-phenylazirine or its hydrolyzed product could not be isolated.

When propiophenone dimethylhydrazone methiodide (III), which possesses a *sec*-carbon atom in the α-position to the C=N double bond, was treated with a slightly less than one equivalent amount of sodium isopropoxide in isopropanol, 2,5-diphenyl-3,6-dimethylpyrazine (IV) was obtained in a 33% yield. The mechanism of the formation of IV is not clear, but it might be possible to consider that the reaction proceeds through the initial formation of the intermediate 2-phenyl-3-methylazirine,

1) Part I and II: S. Sato, H. Kato and M. Ohta, This Bulletin, **40**, 2936, 2938 (1967).

2) P. A. S. Smith and E. E. Most, *J. Org. Chem.*, **22**, 358 (1957).

3) R. F. Parcell, *Chem. & Ind.*, **1963**, 1396.



followed by dimerization to IV. Therefore, in order to clarify the above mechanism, the same reaction was attempted in the presence of an excess of sodium isopropoxide. In this case, if the reaction did proceed through an azirine, it might be expected to be trapped by the addition of isopropanol in the presence of a base-catalyst and so give a stable aziridine derivative. The reaction indeed gave 2-phenyl-2-isopropoxy-3-methylaziridine (V) in a 72% yield. This structure was supported by the results of elemental analysis; by the infrared absorptions at 3300 cm^{-1} for the NH group, at 1380 and 1370 cm^{-1} for the isopropyl group, and at 1120 cm^{-1} for the alkoxy group, and by the fact that hydrolysis by hydrochloric acid afforded α-aminopropiophenone. The vapor phase chromatography (vpc) analysis of this product suggested that it is a mixture of three components (A, B and C) in a ratio of 21 : 53 : 26.[4] Accordingly, its NMR spectrum was rather complex: it shows superimposed doublets at τ 8.85 (total of 9H, $J=7$ cps) for the methyl groups, a pair of singlets, at 8.18 and 8.08 (total of 1H), for the proton on the ring nitrogen and a pair of quartets centered at 7.04 and 6.65 (total of 1H, $J=7$ cps) and a pair of superimposed septets at 6.28 and 5.99 (total of 1H, $J=7$ cps) for the methine proton of the isopropyl group, besides a multiplet of the phenyl group at 2.5—2.9 (10H). The ratio of the *cis* and *trans* isomers was 2 : 1 judging from the vpc peak area ratio of 2.6 : 1 and by the NMR peak height ratio of the imine proton. These spectral data suggest that the product is a mixture of *cis* and *trans* isomers, Va and Vb.

Next, when the rearrangement of III was effected in the presence of an excess of potassium *t*-butoxide in place of sodium isopropoxide, an oily product boiling at 85—90°C/5 mmHg was obtained. Infrared spectrum of this product exhibits a band at 1740 cm^{-1} for the C=N bond of an azirine and one at 1690 cm^{-1} for the carbonyl, and the vpc peak shows the presence of two components (D and E) in a ratio of 55 : 45. The component E was found to have the same vpc retention time as an authentic specimen of propiophenone. The NMR spectrum of this product shows a double at τ 8.2 (3H) for the methyl group on the 3-position of the ring, a quartet at 7.8 (1H) for the hydrogen on the 3-position of the ring, a multiplet at 2—3 (10H) for the phenyl group and a triplet at 8.8 (3H) for the methyl group of propiophenone, and a quartet at 7.2 (2H) for the methylene group of propiophenone. These spectral data suggest that the component D is 2-phenyl-3-methylazirine (VII) and that the component E is propiophenone (VIII). The *t*-butanol addition product could not be isolated; this is probably because the addition of a bulky *t*-butyl group to the C=N double bond was more hindered than the addition of an isopropyl group.

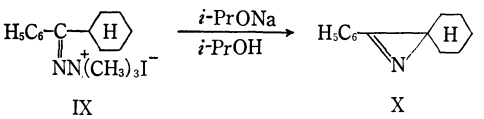
Parcell reported that 2-phenyl-3,3-dimethylazirine was re-produced by the azeotropic distillation of isopropanol from a solution of the 2-phenyl-2-isopropoxy-3,3-dimethylaziridine in toluene in the presence of a catalytic amount of sodium isopropoxide.[3] Accordingly, compound V was treated by the same procedure in order to find out whether or not such a reaction can be used in the preparation of 3-monoalkylazirine. An oily product which boils at 75—82°C/1 mmHg was

4) Component A may be a decomposition product during the v.p.c. analysis, because the product gave a good elemental analysis and its spectrum did not show prominent peaks which may be assigned to the presence of an impurity.

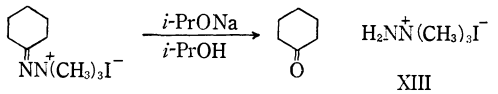
obtained. The infrared spectrum of this product exhibits a band at 3300 cm^{-1} for the NH group, at 1740 cm^{-1} for the C=N double bond of an azirine and one at 1120 cm^{-1} for the alkoxy group. These infrared data suggest that this product is a mixture of azirine (VII) and aziridine (V); the vpc peak shows the presence of four components (F, G, H and I) in a ratio of 50 : 2 : 40 : 8. The components H and I had the same vpc retention times as the components B and C (azirdidine Va,b) described above, and the component F had the same retention time as that of the component D (azirine VII) described above, but the components F and G could not be separated because their retention times were very close to one another. However, the product partly solidified on standing in a refrigerator for one week; the melting point of this solid was undepressed on admixture with compound IV. Thus, it may be concluded that this product is a mixture of *cis*, *trans* aziridine Va, Vb and azirine VII.

When cyclohexyl phenyl ketone dimethylhydrazone methiodide (IX), which possesses a *t*-carbon on the α-position of the C=N bond, was treated with sodium isopropoxide in isopropanol, 2-phenyl-3,3-pentamethyleneazirine (X) was isolated in an 80% yield. This compound was identified by elemental analysis and by its showing an infrared absorption at 1740 cm^{-1} for the C=N double bond of azirine.

In order to examine the applicability of this method to a cyclic ketone,[5] cyclohexanone dimethylhydrazone methiodide (XI) was treated with sodium isopropoxide in isopropanol. In this case



IX X



XI XII XIII

no ring formation occurred, but XI dissociated to cyclohexanone and trimethylhydrazinium iodide (XIII).

Compound XI probably dissociated because XI is a very unstable compound and is readily dissociated by isopropanol to XII and XIII; indeed, XIII was formed by an attempted recrystallization of XI from ethanol.

When this rearrangement was tried by means of methyl sulfinyl carbanion in DMSO, only an intractable red-brown resinous matter was formed. Similarly, an attempt to synthesize ethyl benzoylacetate dimethylhydrazone methiodide from ethyl benzoylacetate dimethylhydrazone and methyl iodide in ether gave only trimethylhydrazinium iodide.

In summary, it may be said that this method of preparing an azirine ring is affected by the activity of the hydrogen atom on the α-position of the C=N double bond, by the stability of the reaction product, and by the properties of catalyst and solvent. Namely, when the α-position was *t*-carbon, the reaction gave an azirine ring in a good yield, and when it was *sec*-carbon, it was attacked by the base to give unstable azirine, which was easily dimerized. When the α-position was primary carbon, the reaction gave a completely different product. Therefore, this method of preparation seems to be limited by the structure of the starting materials.

Experimental

The melting points were measured on a micro hot stage and are not corrected; all boiling points are uncorrected. The infrared spectra were taken on KBr tablets or neat liquid films. The vpc analysis was performed at a column temperature of 150°C, using a 150 cm column packed with 10% Apiezone Grease L on Diasolid A.

Propiophenone Dimethylhydrazone. A mixture of 25 g (0.18 mol) of propiophenone, 15 g (0.25 mol) of dimethylhydrazine, 2 g of anhydrous sodium acetate, and 2 drops of glacial acetic acid was heated, in a sealed tube, on an oil bath under reflux for 16 hr (bath temperature 120°C). After the two layers had been separated, the aqueous layer was extracted with ether, the combined organic layers were washed with water and dried over sodium sulfate, and the solvent was removed by distillation. The residual oil was distilled under reduced pressure to give 30 g (90%) of a pale yellow liquid boiling at 120—122°C/20 mmHg.

Found: C, 75.08; H, 8.92; N, 15.56%. Calcd for $C_{11}H_{16}N_2$: C, 74.95; H, 9.15; N, 15.96%.

Cyclohexyl Phenyl Ketone Dimethylhydrazone. A mixture of 10 g (0.053 mol) of cyclohexyl phenyl ketone,[6] 6 g (0.1 mol) of dimethylhydrazine, 1 g of anhydrous sodium acetate, and one drop of glacial acetic acid was treated in essentially the same manner to give 12 g of a pale yellow oil boiling at 115—118°C/1—2 mmHg.

5) Hassner and Fowler reported the synthesis of fused azirines by photolysis of the corresponding vinyl azides but the azirine fused to a six-membered ring could not be isolated probably because of a highly strained structure of the expected compound. In our experiment, however, if the desired fused azirine I was formed, it may readily add a molecule of isopropanol to give isolable stable fused aziridine II under the reaction conditions.

A. Hassner and F. W. Fowler, *Tetrahedron Letters*, **1967**, 1545.

6) V. Meyer and W. Scharvin, *Ber.*, **30**, 1942 (1897).

Found: C, 77.98; H, 9.75; N, 11.98%. Calcd for $C_{15}H_{22}N_2$: C, 78.21; H, 9.63; N, 12.16%.

Ethyl Benzoylacetate Dimethylhydrazone. A mixture of 19.2 g (0.1 mol) of ethyl benzoylacetate, 12 g (0.2 mol) of dimethylhydrazine, 2 g of anhydrous sodium acetate, and 2 drops of glacial acetic acid was treated in the same manner to give 11 g (48%) of a pale yellow liquid boiling at 130—135°C/1 mmHg.

Found: C, 66.72; H, 7.47; N, 11.97%. Calcd for $C_{13}H_{18}O_2N_2$: C, 66.64; H, 7.74; N, 11.96%.

Propiophenone Dimethylhydrazone Methiodide (III). To a solution of 25 g of propiophenone dimethylhydrazone in 50 m*l* of absolute ethanol, there was added 80 g of methyl iodide, and then the mixture was refluxed for five hours. After cooling, the white crystals which separated out were collected, further crops being obtained by dilution with ether. Recrystallization from ethanol gave 31 g of white prisms melting at 157—159°C.

Found: C, 45.15; H, 5.78; N, 8.88%. Calcd for $C_{12}H_{19}N_2I$: C, 45.30; H, 6.02; N, 8.80%.

Cyclohexyl Phenyl Ketone Dimethylhydrazone Methiodide (IX). To a solution of 12 g of cyclohexyl phenyl ketone dimethyl hydrazone in 30 m*l* of dry ether, there was added 15 g of methyl iodide; the mixture was refluxed for one hour, and then allowed to stand overnight at room temperature. The crystals which separated out were collected and then washed with acetone to give 9.5 g of colorless prisms melting at 148—149°C.

Found: C, 50.66; H, 6.38; N, 7.10%. Calcd for $C_{16}H_{24}N_2I$: C, 50.18; H, 6.46; N, 7.52%.

Cyclohexanone Dimethylhydrazone Methiodide (XI). To a solution of 20 g of cyclohexanone dimethylhydrazone[2] in 30 m*l* of dry ether, 50 g of methyl iodide was added; the mixture was then treated in essentially the same manner as above to give 23 g of very hygroscopic white needles melting at 95—103°C.

Found: C, 36.92; H, 6.76%. Calcd for $C_9H_{19}N_2I$: C, 38.31; H, 6.78%.

2,4-Diphenylpyrrole (II). 15 g of I was added to a solution of 1.4 g (0.06 g-atom) of sodium in 150 m*l* of isopropanol at 40°C. Stirring was continued for one hour, after which the solvent was removed on a rotary evaporator. The residual oil solidified on cooling, and the solid was recrystallized from methanol-water to give 1.6 g of 2,4-diphenylpyrrole as pale yellow leaflets melting at 177—179°C. The IR spectrum was identical with that of an authentic sample.[1]

2,5-Diphenyl-3,6-dimethylpyrazine (IV). To a solution of 0.65 g (0.028 g-atom) of sodium in 60 m*l* of isopropanol, 10 g (0.031 mol) of III were added at 40°C; the mixture was then stirred for one hour at 40°C. The solvent was removed on a rotary evaporator. The residual paste was extracted with *n*-hexane, and the extracts were dried over sodium sulfate. The solvent was then removed by distillation under reduced pressure to give an oily residue. The residual oil which solidified on cooling was washed with *n*-hexane and was recrystallized from ethanol to give 1.2 g of colorless leaflets melting at 125—126°C (lit. 124—125°C).[7] (Found: C, 83.48; H, 6.12; N, 10.48%). Picrate, mp 153—154°C (lit. 153—154°C).[6]

2-Phenyl-2-isopropoxy-3-methylaziridine (V). To a solution of 0.9 g (0.034 g-atom) of sodium in 80 m*l* of isopropanol, 10 g (0.03 mol) of III were added at 40°C, after which the mixture was stirred for one hour. The solvent was removed on a rotary evaporator. The residual paste was extracted with *n*-hexane, and the extracts were dried over sodium sulfate. The solvent was then removed by distillation under reduced pressure, and the residual oil was distilled under reduced pressure, giving 4.3 g (72%) of V boiling at 105—108°C/8—9 mmHg. IR: 3350 (NH), 1380, 1370 (isopropyl) and 1120 cm^{-1} (alkoxy).

Found: C, 75.40; H, 8.86; N, 7.32%. Calcd for $C_{12}H_{17}ON$: C, 75.35; H, 8.96; N, 7.32%.

Hydrolysis of V. To a solution of 0.5 g of V in 20 m*l* of ether, 40 m*l* of 2 N hydrochloric acid was added, after which the mixture was stirred for 30 min. The reaction mixture was evaporated on a rotary evaporator at 50—60°C to a volume of 5—10 m*l*. The solid which separated out was collected by filtration, and then washed with ether and dried to give 0.3 g of white crystals melting at 187—189°C, while its picrate melted at 168—169°C. These melting points are identical with the literature values of α-aminopropiophenone hydrochloride and its picrate.[8]

Found: C, 47.83; H, 3.50; N, 15.16%. Calcd for $C_{15}H_{14}O_8N_4$: C, 47.62; H, 3.73; N, 14.81%.

2-Phenyl-3-methylazirine (VII). a) To a solution of 1.4 g (0.036 g-atom) of potassium in 150 m*l* of *t*-butanol, 10 g (0.03 mol) of III was added at 50°C, after which the mixture was stirred for 1.5 hr at 50—55°C. The solvent was removed on a rotary evaporator, the residual paste was extracted with *n*-hexane, and the extracts were dried over sodium sulfate and distilled to give 1.2 g of a pale brown liquid boiling at 85—90°C/5 mmHg. IR: 1740 (C=N) and 1690 cm^{-1} (C=O).

b) To a solution of 0.1 g of sodium in 10 m*l* of isopropanol, 2 g of V and 15 m*l* of dry toluene were added. The mixture was slowly distilled through a short column on an oil bath until the toluene distilled off; the residual oil was then distilled under reduced pressure to give 1 g of a product boiling at 75—82°C/1—2 mmHg. IR: 3350 (NH), 1740 (C=N), 1380, 1370 (isopropyl) and 1120 cm^{-1} (alkoxy).

2-Phenyl-3,3-pentamethyleneazirine (X). To a solution of 0.46 g (0.02 g-atom) of sodium in 60 m*l* of isopropanol, 9.0 g (0.025 mol) of IX was added at 40°C, after which the mixture was stirred for one hour at 40°C. The solvent was then removed on a rotary evaporator. The residual paste was extracted with ether, the extracts were dried over sodium sulfate, and the solvent was removed by distillation under reduced pressure. The residual oil was distilled under reduced pressure, giving 3.5 g (80%) of X boiling at 110—111°C/1—2 mmHg.

Found: C, 84.07; H, 7.80; N, 7.45%. Calcd for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56%. IR: 1740 cm^{-1} (C=N).

Rearrangement of XI. To a solution of 1.2 g (0.05 g-atom) of sodium in 150 m*l* of isopropanol, 10 g (0.035 mol) of XI were added at 45—50°C, after which the mixture was stirred for one hour at 50°C. After cooling, the solid which separated out was collected by filtration; then it was washed with ether, dried, and recrystallized from ethanol to give 2.5 g of white

8) S. Gabriel, *Ber.*, **41**, 1152 (1908).

prisms of trimethylhydrazinium iodide, mp 239°C (dec.).[2] The filtrate was treated with a 2,4-dinitrophenylhydrazine reagent. There was thus obtained cyclohexanone 2,4-dinitrophenylhydrazone, mp 159°C.

The author wishes to express his deep gratitude to Professor M. Ohta and Dr. H. Kato, Tokyo Institute of Technology, for their advice and guidance on this study. Thanks are also due to Dr. S. Ogihara, President of the Kyorin Pharmaceutical Co., Ltd., and to Dr. T. Irikura, Director of the Kyorin Chemical Laboratory, for their permission to publish this work.

NOTES

The Potassium Fluoride-Catalyzed Reaction. V. Aldol Condensation of Nitroalkanes and Aliphatic Aldehydes

Satoshi KAMBE

Oyama College of Technology, Oyama, Tochigi

and Heinosuke YASUDA

Laboratory of Chemistry, Utsunomiya University, Utsunomiya

(Received August 26, 1967)

Midorikawa and his collaborators first reported base-catalyzed reactions by potassium fluoride.[1a-f] This apparent basic property of the fluoride was recently illustrated by Rand *et al.*[2a-d] and by LeGoff.[3] In extension of our own previous studies,[4,5] the action of nitroalkanes on aliphatic aldehydes under the catalytic influence of the fluoride has now been investigated. In general, most aldehydes, especially paraformaldehyde, react conventionally with nitroalkanes in the presence of bases, giving the next higher homologs, or mixtures of them and non-distillable materials.[6,7] The condensation of paraformaldehyde and nitromethane, for example, readily afforded the final tris-product, nitroisobutylglycerol, along with a very poor yield of 2-nitroethanol (I). More recently, Namba and Yamashita[8] reported a convenient method for the preparation of the alcohol (I) using ethanolic potash, but the yield was only 25%. The nitroalcohol (I), on the other hand, can be obtained from ethylene and fuming nitric acid[9] or liquid nitrogen peroxide on direct nitration, although, these procedures have not generally been utilized in synthesis.

In the present base-catalyzed reaction of nitromethane with paraformaldehyde, it is noted that the yield of I is very high (73%) and is dependent upon the concentration of potassium fluoride used. The use of 0.05 mol of the fluoride per mol of paraformaldehyde appreciably alters the yield of I. Furthermore, the nature of the solvent has a remarkable effect on the rate of the reaction and on the product yield; thus, as is shown in Table 1, the 2-nitroethanol formation in isopropanol consistently gives higher yields than those in other solvents. The polymer formation may be avoided completely at temperatures below 50°C. It is difficult to isolate pure di- or tri-hydric derivatives in any case.

A systematic study of the aldol condensation of

various nitroalkanes with aliphatic aldehydes was attempted (see Table 2). The solvent employed was isopropanol. In the condensation of paraformaldehyde with a primary nitroalkanes, such as nitroethane or 1-nitropropane, a di-hydric compound can be isolated in a low yield.

There are great differences in reactivity between the aldehydes used; *i. e.*, the yield decreases in the following order:

$$CH_3CHO \approx C_2H_5CHO > n\text{-}C_3H_7CHO > i\text{-}C_3H_7CHO$$

This suggests that the substitution of the methyl group at the α-position of the aldehyde would offer a steric hindrance to nitroalkane addition. The results obtained are shown in Table 2.

Experimental*1

Preparation of 2-Nitroethanol (I) (in Isopropanol as a Recommended Solvent). Paraformaldehyde (30 g, 1 mol) was stirred into isopropanol (300 ml)

*1 All boiling and metling points are uncorrected.

containing potassium fluoride (2.9 g, 0.05 mol), and the stirring was continued until the aldehyde had completely dissolved. To a stirred alcoholic solution then was added, drop by drop, nitromethane (120 g, 2 mol) at 30—35°C within 2 hr. After this addition stirring was continued for 4 more hours, and then the catalyst was removed by filtration. The residue, on the removal of the solvent, was poured into water, and the residual oily matter was extracted with ether. After the ethereal extract had then been dried over anhydrous sodium sulfate, the solvent was removed. The desired reaction product was distilled at 86—87°C/4 mmHg was collected (*cf.* Table 1).

Preparation of Other Nitroalcohols. To a mechanically stirred solution of 0.05 mol of potassium fluoride and 1 mol of the appropriate aldehyde in 150 m*l* of isopropanol, then was added, drop by drop, 1 mol of the appropriate nitroalkane below 40°C; the stirring was continued for a suitable period. After the catalyst had then been removed, the residual oily matter was treated by the procedure described above. The results are listed in Table 2.

The authors wish to express their gratitude to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research for his continued encouragement.

Rotational Isomers of *n*-Pentane

Atsushi TOMONAGA and Takehiko SHIMANOUCHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 19, 1967)

The *n*-pentane molecule has three possible rotational isomers, TT (trans-trans), TG (trans-gauche) and GG(gauche-gauche). It was reported by Mizushima *et al.*[1] and Sheppard *et al.*[2] that in the solid state only the TT form exists and in the liquid state the TT and TG forms coexists. Theoretical considerations[1,3,4] forecast the stability of the GG form. However, no experimental evidence has been reported as yet. We have recently measured the far infrared spectra of *n*-pentane in the liquid and solid states and succeeded in finding a band due to the GG form.

In Fig. 1 the spectra in the region 500—100 cm^{-1} are shown. The solid state spectrum shows only the

				121	130	153
				112	101	104

* This band is weak and the frequency somewhat deviates from what calculated for the TT form. This band may be ascribed to the impurity band.

bands of the TT form. In the liquid state new bands appear. The details of the spectra in the region 600—300 cm^{-1} are shown in Fig. 2. In the liquid state at −90°C the bands at 470, 386 and 334 cm^{-1} appear in addition to the 400 cm^{-1} band of the TT form. The 470 and 334 cm^{-1} bands are assigned to the TG form, since they are in agreement with the frequencies of the TG form calculated from the force constants of propane (see Table 1).[5] The TG form does not have any calculated frequencies near 386 cm^{-1}. The intensity of the 386 cm^{-1} band increases far more largely than the 470 and 334 cm^{-1} bands at higher temperatures as shown in Fig. 2 Furthermore, the observed frequency, 386 cm^{-1}, corresponds very well to the value, 395 cm^{-1}, calculated for the GG form. Accordingly, this band is assigned to the GG form. The intensity increase in the absorption of the 386 cm^{-1} GG band at higher temperature shows that the GG form is less stable than the TG form. The energy difference between the two forms could not be accurately obtained, since the 386 cm^{-1} band has a shoulder due to the TT band at 400 cm^{-1}. All the observed bands shown in Fig. 2 are assigned to the TT, TG, and GG forms as shown in Table 1. The bands due to the GG′ form could not be found.

After this work was finished Snyder[6] proved existence of the GG form from the CH_2 wagging vibrations. The conclusion is in agreement with ours.

A Consideration of the Micelle Formation of an Ionic-Nonionic Surfactant through Its Ionization Energy

Fumikatsu TOKIWA and Kenji OHKI

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received September 21, 1967)

It is a widely-accepted concept that the micelle formation of ionic surfactants in aqueous solutions is governed by two factors, the cohesive energy among the hydrocarbon chains and the repulsive electrical energy among the charged heads.[1-3] In previous papers,[3,4] we have discussed the micelle formation of surfactants, such as dimethyldodecylamine oxide[3] and sodium decylbenzene sulfonate,[4] by means of these two factors. With a surfactant whose electrical state depends on the pH of the solution, however, there is yet another way to discuss its micelle formation—through the ionization energies of the micellar and monodispersed species. In the present paper an attempt is made to treat micelle formation in terms of the ionization energy of an ionic-nonionic surfactant. The surfactant studied is dimethyldodecylamine oxide, which can exist in either nonionic or cationic form, depending upon the pH of the solution. These two forms are related by the equation:

$$C_{12}H_{25}N(CH_3)_2O + H^+ \rightleftarrows C_{12}H_{25}N^+(CH_3)_2OH$$

Figure 1 sets out the relationship between micellization equilibria at $\beta=0$ and $\beta=p$, where β is the degree of ionization of the surfactant. The process 1 represents the micellization in the nonionic form at $\beta=0$. The standard free energy change

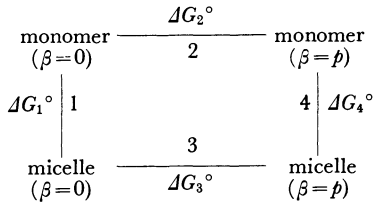

Fig. 1. The diagram of micellization and ionization equilibria.

in micellization per mole, ΔG_1°, is given[5,6] by:

$$\Delta G_1^\circ = \boldsymbol{R}T \ln \mathrm{CMC}_{\beta=0} \quad (1)$$

The process 4 represents the micellization in the cationic form at $\beta=p$, whose free energy change, ΔG_4°, is given by:

$$\Delta G_4^\circ = \boldsymbol{R}T \ln \mathrm{CMC}_{\beta=p} \quad (2)$$

when one assumes that the system is ideal in the presence of excess added salt.[7,8] The processes 2 and 3 represent the ionization of the monomer and micelle, respectively, from $\beta=0$ to $\beta=p$. In the process 2 the free energy change in ionization, ΔG_2°, may be written by:

$$\Delta G_2^\circ = \boldsymbol{R}T\int_{\beta=0}^{\beta=p} \ln K_\mathrm{m}(\beta)\mathrm{d}\beta = -2.3\boldsymbol{R}T\int_{\beta=0}^{\beta=p} \mathrm{p}K_\mathrm{m}(\beta)\mathrm{d}\beta \quad (3)$$

where K_m is the ionization constant of the monomer, which, in the present case, is constant independently of β, as may be seen in Fig. 2.[9] Therefore, the right-hand side of Eq. (3) may be reduced to $-2.3\,p\cdot\boldsymbol{R}T\cdot\mathrm{p}K_\mathrm{m}$. In the process 3, the free energy change in ionization, ΔG_3°, may be written by:

$$\Delta G_3^\circ = \boldsymbol{R}T\chi\int_{\beta=0}^{\beta=p} \ln K_\mathrm{M}(\beta)\mathrm{d}\beta = -2.3\boldsymbol{R}T\chi\int_{\beta=0}^{\beta=p} \mathrm{p}K_\mathrm{M}(\beta)\mathrm{d}\beta \quad (4)$$

where K_M is the ionization constant of the micelle, which depends on β as is shown in Fig. 2.[9] The χ in Eq. (4) is a correction factor for the ionization energy of the micelle, which may have some relation, for example, with the number of gegenions around the micelle and with the change in micellar-aggregation number with β. In the diagram under consideration, the following energy balance should hold:

$$\Delta G_1^\circ + \Delta G_3^\circ = \Delta G_2^\circ + \Delta G_4^\circ \quad (5)$$

Therefore:

$$\Delta G_4^\circ = \Delta G_1^\circ - \Delta G_2^\circ + \Delta G_3^\circ \quad (6)$$

Table 1 gives the values of χ, which were calculated to satisfy Eq. (6) from the observed values of CMC at different pH values in the presence of 0.10 M NaCl. (The addition of excess salt is required if one is to use Eq. (2) and also obtain a constant value of χ at a constant ionic strength.) The correction factor, χ, is nearly equal to 0.86 and is independent of the pH (or β) value except at a low pH. Thus, the CMC value at a certain degree of ionization, p, may be estimated by the equation:

$$\log \mathrm{CMC}_{\beta=p} = \log \mathrm{CMC}_{\beta=0} + p\cdot\mathrm{p}K_\mathrm{m} - 0.86\int_{\beta=0}^{\beta=p} \mathrm{p}K_\mathrm{M}(\beta)\mathrm{d}\beta \quad (7)$$

In Fig. 3 the CMC values obtained from Eq. (7) are plotted against pH in comparison with those experimentally obtained in the presence of 0.10 M NaCl. The similar plots in the absence of added

6.1	0.19	1.00	6.45	$5.18+1.50\chi$	0.85
7.1	0.052	0.95	6.48	$6.13+0.41\chi$	0.86
9.5	0.00	0.95	6.48	$6.48+0.00$	—

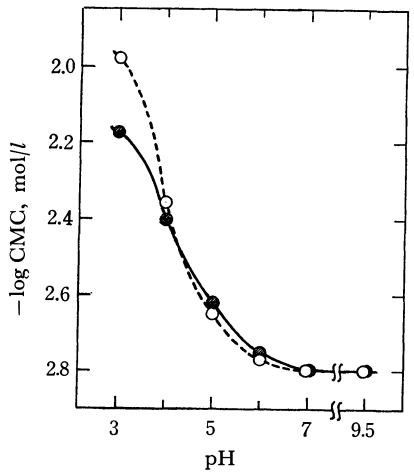

Fig. 4. The CMC *vs.* pH plots obtained from Eq. (7) (○) and from the experiment (◍) in the absence of added salt.

salt, obtained by Eq. (7), are shown in Fig. 4. The discrepancy in the calculated CMC values from the observed values at low pH values in the absence of added salt is somewhat larger than that in the presence of excess added salt. Probably, the assumption described in Eq. (2) is no longer reasonable in the absence of added salt, especially in the lower pH region.

From the preceding considerations, it can be said, in conclusion, that the CMC of a surfactant whose ionized state depends on the pH of the solution can be estimated by using the ionization constants of the monomer and micelle of the surfactant. At any degree of ionization, p, the CMC can be expressed by Eq. (7) as long as Eq. (2) is valid.

Experimental

The CMC values at different pH values were determined by the solubilization method using an oil soluble dye, Yellow-OB, as a solubilizate.[9,10] The ionization constants of the monomer and micelle were obtained from the potentiometric titration of the surfactant, the details of which have been presented in a previous paper.[9]

The Substituent Effects on the Chemical Shifts for Substituted Benzyl Acetates

Satoshi ARAKAWA and Masahisa HASHIMOTO

Research Laboratory, Dainippon Pharmaceutical Co., Ltd., Fukushima-ku, Osaka

(Received October 24, 1967)

A number of studies of the NMR spectra of substituted benzene derivatives, with particular attention paid to substituent effects, have been reported in the literature.[1-6] The relative chemical shifts arising from substituent effects have been known to be affected primarily by changes in the local electron-charge-density distribution caused by the substituents. The substituent effects have been discussed in terms of electronic transmission for the system of $X-C_6H_4-Y-H$, where X = the substituent,

C_6H_4-Y=the transmitting group, and H=the terminal proton in the side chain.[6,7] However, there has been no report on the molecules where the terminal proton is separated from the aromatic ring by four atoms.

This study will deal with substituted benzyl acetates ($Y=CH_2OCCH_2$), which were originally
O
studied as model compounds for side chains of poly-β-(p-substituted)-benzyl-L-aspartates.[8]

The insertion of the -OC- group between two
O
methylene groups of ethylbenzene ($Y=CH_2CH_2$) was found to attenuate the electronic transmission to a lesser extent.

Experimental

Materials. The substituted benzyl acetates were prepared by the reaction of benzyl chlorides with potassium acetate. They were purified by distillation or recrystallization, and were checked by elementary analyses and by a study of their IR and NMR spectra.

Measurements. The NMR spectra were recorded on a Varian A-60 spectrometer. The magnet-gap temperature was 31°C. The chemical shifts were determined by the side-band technique relative to tetramethylsilane (TMS) as the internal standard. The concentrations were in the 0.2—0.15 mol/l range in a carbon tetrachloride solution; the dilution shifts were examined for in four compounds, but were not found. The data shown are the mean values of five measurements and are precise to ± 0.2 cps.

Results and Discussion

The chemical shifts of the acetyl protons and the benzylic methylene protons of substituted benzyl acetates in a carbon tetrachloride solution are shown in Table 1. Figure 1 shows the plots of the relative

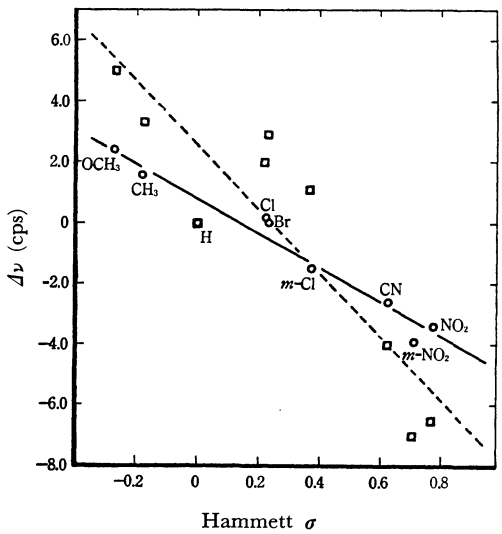

Fig. 1. Plots of the relative chemical shifts in substituted benzyl acetates against Hammett σ.
—○—: Acetyl methyl protons
---□---: Benzylic methylene protons

chemical shifts against the Hammett σ constants. The relative chemical shifts have been correlated with several substituent constants, such as σ^0, σ^+, σ^-, σ_I, and σ_R. In the present study, however, the plottings against these constants do not improve greatly and lead to such correlations as are shown in Fig. 1.

In the present study the substituent effects are examined in the form of the Hammett equation, $\Delta\nu=\rho\sigma+\Delta\nu_0$,[6] in order to make possible the comparison of the present data with those published for related series of compounds. The constants in this equation were obtained by the least-squares method. Table 2 lists the constants thus obtained, together with some of the published data. The ρ values in Table 2 represent a measure of the transmission of electronic effects of the substituent, X, through the side chain, Y, in the X-C_6H_4-Y-H type.

The ρ values for methylene and methyl protons of benzyl acetates are −10.45 and −5.63 respectively. This may indicate that substituent effects are decreased to about a half by the side-chain, $-OCCH_2-$,
O
group. On the other hand, the ρ value for methyl protons of ethylbenzene is about a half of that for toluene (ρ-ethylbenzene/ρ-toluene=0.53), as shown in Table 2. This means that the methylene group in the side chain transmits about a half of the electronic effects. For the carbonyl group, the transmission of electronic effects may be estimated to be 0.65 from the ρ values for the methyl protons of acetophenones and toluenes. On the other hand, the insertion of an oxygen atom into toluene, that is, anisole, increases the electronic effects (ρ-anisole/ρ-toluene=1.26). The oxygen atom is known to be a superconducting

(X-C_6H_4-$\underline{CH_2O\overset{\overset{O}{\|}}{C}CH_3}$)	—	10.45	2.56	0.898	2.133	

a) ρ Values are given in the units of cycle per second per Hammett σ unit.
b) The intercept. c) The correlation coefficient. d) The standard deviation.

group.[6] For the methyl protons of substituted benzyl acetates, the ρ value is found to be similar to that reported for the methyl protons of substituted ethylbenzenes, even though benzyl acetate corresponds to the insertion of an ester group (-$O\overset{\overset{O}{\|}}{C}$-) between the methylene and methyl groups of ethylbenzene. If the ester group can be regarded simply as a combination of oxygen and the carbonyl group in relation to the transmission of electronic effects, the ester group may somewhat decrease the electronic transmission ($1.26\times0.65=0.82$). The ρ value of benzyl acetates can, then, be estimated as about -5.54 ($=0.82\times\rho$-ethylbenzene). This value is very close to the ρ value of -5.63 observed for benzyl acetates.

The methylene group of the side chain attenuates about a half for the transmission of the electronic effects of substituents, while the ester group does so slightly. The latter can be accounted for by a combination of the transmission properties of the oxygen atom and the carbonyl group.[9] The present study shows that the substituent effects on the chemical shifts of the terminal proton in the side chain of benzyl acetates can be estimated, if only roughly, by a simple combination of the transmission property of each group involved in the side chain.

Anomalous behavior in halogen substituents, deviating from the correlation line, has been established.[10] As is evident from Fig. 1, considerable deviations were found for the methylene protons, whereas slighter deviations were found for the methyl protons. The deviations observed for the latter are decreased more than was to be expected from the decrease in the ρ value. Slighter deviations similar to these can be estimated for the methyl protons of acetophenones.[3,6] These facts suggest that the deviation of halogen substituents is primarily due to anisotropy and to field effects, which are consistent with the following finding. It should be noted that good linear correlation-lines, even including halogen substituents, were found among the chemical shifts of three series of benzylic protons: toluenes *vs.* ethylbenzenes ($\Delta\nu_{CH_2\text{-ethylbenzene}}=+1.08\Delta\nu_{CH_3\text{-toluene}}-1.08$, $S=0.605$, $r=0.995$), toluenes *vs.* benzyl acetate ($\Delta\nu_{CH_2\text{-benzyl acetate}}=+0.84\Delta\nu_{CH_3\text{-toluene}}+0.61$, $S=0.156$, $r=0.996$). This finding indicates that the anomalous effects of halogen substituents are almost identical among the protons attached to the α-carbon atoms, even in different side-chains.[10]

The authors wish to express their gratitude to Drs. Shinsuke Ose, Hideji Takamatsu and Kiyoshi Nakamura of this laboratory for their encouragement.

9) This is consistent with the kinetic results that similar σ values have been found for the saponifications both of substituted benzyl benzoates ($\sigma=0.990$) and of substituted ethyl phenylacetates ($\sigma=0.978$); Y. Yukawa, Y. Tsuno and M. Sawada, *ibid.*, **39**, 2274 (1966).

10) In private discussion, Dr. Yuho Tsuno suggested that he and his coworkers have found similar evidences for other series of compounds.

Investigation of Copper(II) Chelate with Chromotropic Acid

Ryousuke WAKE,*1 Haruo MIYATA and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received November 9, 1967)

Copper(II)-chelate with chromotropic acid was investigated by potentiometric titration. The measurements have been carried out at 25.0±0.1°C and $\mu=0.10$ (with KNO_3). The acid dissociation constant of chromotropic acid, the formation constant of the 1 : 1 chelate (the molar ratio of ligand to copper(II) ion) and the hydrolysis constant of this chelate were determined.

Experimental

Reagents. Chromotropic acid disodium salt (1,8-dihydroxynaphthalene-3,6-disulfonic acid disodium salt) was supplied by Dojindo Co., Ltd., and was used without further purification. The concentration of the acid was determined by potentiometric titration with standard potassium hydroxide solution. Analytical grade cupric nitrate was used. The solution of Copper(II) ion was standardized by chelatometric titration.

Potentiometric Measurements. The same apparatus and procedures as in a preceding paper[1] were used for the potentiometric titrations.

Results and Discussion

The corrected potentiometric titration curves of chromotropic acid with and without copper(II) ion are shown in Fig. 1. Two sulfonic acid groups in chromotropic acid are completely dissociated even at a very low $-\log[H^+]$ range. The third dissociation constant pK_{H_2L} is 5.30±0.1. Schwarzenbach *et al.*,[2] Zollinger *et al.*[3] and Tôei *et al.*[4] have reported that pK_{H_2L} is 5.36, 5.53 and 5.44, respectively, at ≃20°C. The fourth dissociation is very weak because of the hydrogen bridge between two naphtholic hydroxyl groups and thus the fourth dissociation constant, pK_{HL}, can not be determined by usual potentiometric titration. Therefore, $pK_{HL}=15.6$, which was reported by Schwarzenbach *et al.*,[2] was used for the calculation of the formation constant and the hydrolysis constant of the copper(II) chelate. When the concentration of chromotropic acid is 1.0×10^{-3} M, the concentration of copper(II) ion should be less than 1.0×10^{-3} M, otherwise, copper hydroxide precipitates above $-\log[H^+]$ 7.

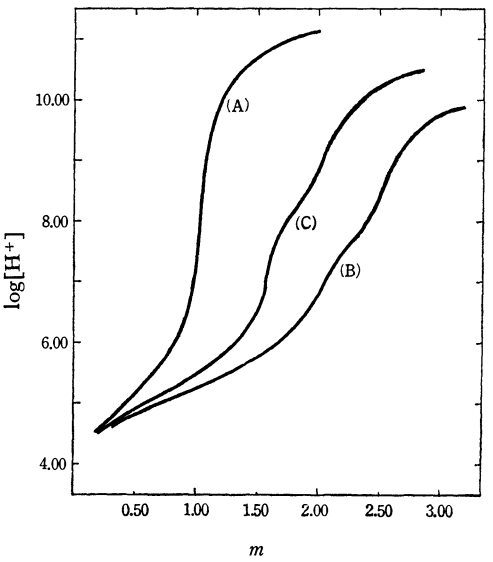

Fig. 1. Potentiometric titration curves with and without cupric ion. (A) Chromotropic acid alone; (B) and (C) are the curves of 1 : 1 and 2 : 1 (the ratio of ligand to cupric ion).
m=moles of base added per mole of ligand.
$T_L=1\times10^{-3}$ M

The formation constant of the copper(II)-chelate was calculated through the following equations:

$$H_2L^{2-} \rightleftharpoons H^+ + HL^{3-}$$

$$K_{H_2L^{2-}} = \frac{[H^+]\cdot[HL^{3-}]}{[H_2L^{2-}]} \quad (1)$$

$$HL^{3-} \rightleftharpoons H^+ + L^{4-}$$

$$K_{HL^{3-}} = \frac{[H^+]\cdot[L^{4-}]}{[HL^{3-}]} \quad (2)$$

$$Cu^{2+} + L^{4-} \rightleftharpoons CuL^{2-}$$

$$K_{CuL} = \frac{[CuL^{2-}]}{[Cu^{2+}]\cdot[L^{4-}]} \quad (3)$$

From the relationships among the electroneutrality, the total copper(II) concentration and the total ligand concentration, Eq. (4) is derived:

$$K_{CuL}=\frac{\left(T_{OH}+[H^+]-[OH^-]-T_L\right)-[L^{4-}]+[H_2L^{2-}]}{\left(\{T_{Cu}+T_L+[OH^-]-T_{OH}-[H^+]+[L^{4-}]-[H_2L^{2-}]\}[L^{4-}]\right)} \quad (4)$$

T_L, T_{Cu} and T_{OH} represent the total concentration of the ligand, copper and potassium hydroxide

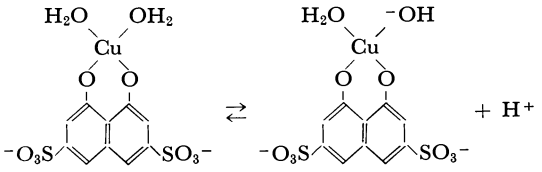
added, respectively. Data obtained from B and C in Fig. 1 were employed in this calculation, and the results obtained are identical up to $-\log[H^+]=7.0$ for both titrations (Table 1).

The titration curves also indicate that 1 : 1 (ligand to metal ion) chelate is predominant in the low $-\log[H^+]$ region. Jantti[5] has considered species of copper(II)-L and copper(II)-HL, and has evaluated the equilibrium constants of these complexes (Table 1). However, Eq. (4) was fairly well satisfied by the data up to $-\log[H^+]=7.0$, and the existence of the copper(II) chromotropate chelate was verified, but copper(II)-HL was not observed in this experiment. The existence of the 2 : 1 chelate (copper(II)-L_2) could not be determined from the calculations and titration curves.

The second inflection on the titration curves, which is striking in the 2 : 1 titration, indicated more complicated reactions, such as hydrolysis, olation of the chelate or precipitation of $Cu(OH)_2$. As described above, the equations were not satisfied above $-\log[H^+]$ 7.5 at all, and the formation of $Cu(OH)_2$ and $Cu_2(OH)_2^{2+}$ did not improve the situation. Then, assuming that the hydrolysis of the chelate occurs according to the following equation

$$CuL^{2-}(H_2O)_2 \rightleftharpoons CuL(OH)(H_2O)^{3-} + H^+,$$

the authors tried to determine the hydrolysis constant.



$$K_{CuL(OH)} = \frac{[CuL(OH)^{3-}]\cdot[H^+]}{[CuL^{2-}]} \qquad (5)$$

From the relationship concerning electroneutrality, the total copper(II) content and the amount of hydroxide, Eq. (6) is derived.

$$K_{CuL(OH)} = \frac{\left(\begin{array}{l}\{T_{OH}-2T_L+[H^+]-[OH^-]\\ +2[H_2L^{2-}]+[HL^{3-}]\}[H^+]\end{array}\right)}{\left(\begin{array}{l}3T_L-T_{OH}-[H^+]+[OH^-]\\ -3[H_2L^{2-}]-2[HL^{3-}]-[L^{4-}]\end{array}\right)} \qquad (6)$$

In this calculation, it is difficult to consider all four equations (1), (2), (3) and (5) at once, so $\log K_{CuL}=13.45$, which was determined at a low $-\log[H^+]$ range, was employed. The result is shown in Table 1. In a high $-\log[H^+]$ range, these equations did not explain the system, for the titration curves are unexpectedly low above $-\log[H^+]$ 9.5. It may be due to the olation of the chelate, the pecipitation of $Cu(OH)_2$ and so on. It is too complicated to study this system quantitatively above $-\log[H^+]$ 9.5.

Jantti[5] studied copper(II) chelate potentiometrically at a low pH range and Rahman[6] investigated the chelate spectrophotometrically; however they treated chromotropic acid as a monobasic acid in their calculations. The results are shown in Table 1 and they are very different from each other, the present authors' result being far apart from their values.

A similar potentiometric titration was carried out for solutions of a 1 : 1 molar ratio of chromotropic acid to other bivalent transition metal ions, such as manganese, cobalt, nickel and zinc. However, depression of the hydrogen ion concentration was not observed in any of these cases. This fact indicates that copper(II) forms the most stable chelate with chromotropic acid among the metals of the Irving-Williams stability series.

Table 1

The authors	$\log K_{CuL}=13.45\pm0.1$	$-\log K_{CuL(OH)}=8.3$

An Improved Photometric Method for the Determination of Sulfite with Pararosaniline and Formaldehyde

Yoshiko ARIKAWA,*1 Takejiro OZAWA and Iwaji IWASAKI

Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received November 14, 1967)

Many investigations have been made on the determination of sulfur dioxide based on the reaction of rosaniline and/or *p*-rosaniline with formaldehyde.[1-10] West and Gaeke[4] developed a method which involved the process of absorbing sulfur dioxide into a solution of sodium tetrachloromercurate, followed by the addition of the *p*-rosaniline hydrochloride and the formaldehyde to form a purple-colored sulfonic acid derivative of *p*-rosaniline. Present authors tried to apply the method to the analysis of sulfur in igneous rocks. The reproducible results, however, were not obtained

under such experimental conditions,[4,7,8,10] because the color development depended on both the temperature and concentration of sulfite. Previous studies[3,4,7,10] on the effect of temperature on the color development were not satisfactory to the determination of sulfite at the various concentrations and temperatures.

Preparation of 0.04% *p*-Rosaniline Hydrochlolic Acid Solution. Exactly weighed 0.2 g of *p*-rosaniline hydrochloride was added in a small volume of redistilled water containing 15 m*l* of concentrated hydrochloric acid and then mixed well. After *p*-rosaniline dissolved completely, 15 m*l* of concentrated hydrochloric acid was added into the mixture, which was diluted exactly to 500 m*l* with the redistilled water. The color of this solution faded gradually from red to pale yellow. Reagent prepared by this method always showed constant absorbance and was stable for at least three months and also stable against light. No significant difference was observed in experimental results with the use of three *p*-rosaniline reagents from different sources.

Effects of Temperature and Concentration of Sulfite on Color Development. The effect of temperature on color development was examined for the solutions containing about 0, 5, 20 and 40 μg of sulfur as sulfite in 50 m*l*, respectively. A series of temperatures was chosen : 10, 20, 25 and 30°C. All the reagents and the redistilled water freshly boiled and cooled were kept in a thermostat adjusted at a desired temperature. Five milliliters each of the 0.04% *p*-rosaniline hydrochloric acid solution and the 0.2% formaldehyde solution were added to the sodium sulfite standard solution in the 50 m*l* volumetric flask. Then the contents were mixed well and diluted to the mark with the redistilled water or a 0.1 M sodium tetrachloromercurate solution. Flasks were kept in the thermostat. The absorbance of the colored solution was measured every several minutes at the wavelength of 562 mμ using the redistilled water as a reference. Results for sulfite in the redistilled water and for sulfite in the 0.1 M sodium tetrachloromercurate solution were shown in Figs. 1 and 2, respectively. As can be seen in Figs. 1 and 2, each colored solution had a time range in which the absorbance remained maximum. The length of these ranges depended on both the temperature and the concentration of sulfite. In order to obtain the reproducible results, the measurement of

Table 1. Time ranges of constant absorbance

AsO_4^{3-}	$Na_2HAsO_4 \cdot 7H_2O$	5	0.057	0.513

absorbance must be made within these time ranges of constant absorbance. The optimum ranges for the determination of sulfite up to the concentration of 40 μg of sulfur were decided referring to Figs. 1 and 2. These were shown in Table 1.

Calibration Curves. Using sodium sulfite standard solution, calibration curves were obtained by measuring the absorbance within the time ranges shown in Table 1 at each temperature. The calibration curve for sulfite in the redistilled water was straight and that for sulfite in the 0.1 M sodium tetrachloromercurate solution was somewhat curved. In both cases the calibration curves at each temperature were parallel with each other.

Effects of Diverse Ions. To examine the effects of diverse ions on this method, some experiments were made in the presence of 20 μg of sulfite sulfur and its absence at 20°C. The results were shown in Table 2.

Reactions of Nitrogen Atom with Methane and with Ethylene

Shozo MIYAZAKI and Saku TAKAHASHI

Department of Chemistry, Defense Academy, Yokosuka

(Received November 18, 1967)

Recent works on the reactions of nitrogen atom with methane and with ethylene have shown that these can not be discussed adequately by the simple mechanisms.[1] However, the appearent over-all rate constants of these reactions can be defined respectively as follows[2];

$$N + CH_4 \xrightarrow{k_1} HCN + \tfrac{3}{2}H_2\,, \qquad (1)$$

$$N + \tfrac{1}{2}\,C_2H_4 \xrightarrow{k_2} HCN + \tfrac{1}{2}H_2\,. \qquad (2)$$

In this paper, we evaluate the values of k_1 and k_2 at room temperature from the measurements of decay rate of afterglow intensity in the mixture of nitrogen atom and a reactant.

Experimental

The investigations were made with conventional flow techniques.[3] The afterglow was monitored by an RCA 6217 photomultiplier tube. The nitrogen was activated by a microwave discharge. Only a few percent of nitrogen molecules were decomposed into nitrogen atoms. The reactant was introduced between the discharge and entry of the quartz observation tube. The afterglow intensity was observed at a selected level. The observed lights were in the regions of 1st and 2nd positive bands of the nitrogen molecule.

In order to take a picture of the decay rate of afterglow intensity a single sweep from a synchroscope was used.

The concentration of nitrogen atom at the observation level was determined by nitric oxide titration.

Results and Discussion

Rate of Recombination of Nitrogen Atom. For the reaction

$$N + N + N_2 \xrightarrow{k_3} N_2 + N_2 + h\nu\,, \qquad (3)$$

the differential form of the rate equation is

$$-\frac{d[N]}{dt} = k_3[N]^2[N_2]\,.$$

It may be considered that the concentration of nitrogen keeps an approximately constant value through the reaction. In this case, if the concentration of nitrogen atom is equal to the half of its initial concentration, $a/2$, after time τ, the following equation is obtained:

$$k_3 = 1/[N_2]\tau a^2\,. \qquad (4)$$

Table 1 lists values of [N] or a, τ, $[N_2]$, flow rate and evaluated value of k_3.

Rate Constant of Reaction of Nitrogen Atom with Methane. At room temperature, a few percent of methane reacts with nitrogen atom.[4] Hydrogen cyanide is the only product of the reaction obtained in measurable quantities.

For competitive reaction

$$N + N + N_2 \xrightarrow{k_3} N_2 + N_2 + h\nu\,, \qquad (3)$$

$$N + CH_4 \xrightarrow{k_1} HCN + \tfrac{3}{2}H_2\,, \qquad (1)$$

the differential form of the rate equation is

$$-\frac{d(a-x)}{dt} = k_3[N_2](a-x)^2 + k_1[CH_4](a-x).$$

Since the concentrations of methane and nitrogen may be considered to keep an approximately constant values through the reaction, when t is τ, x is equal to $a/2$, the following equation is obtained;

$$1+\frac{k_1[CH_4]}{a\,k_3([N_2]+[CH_4])}=\frac{1}{2(0.6723-k_1[CH_4]\tau)}. \quad (5)$$

Inserting the observed values into Eq. (5), the rate constant k_1 is evaluated. The results are listed in Table 2.

Rate Constant of Reaction of Nitrogen Atom with Ethylene. In the reaction of nitrogen atom with ethylene, it is found that the reaction proceeds rapidly with a low activation energy and hydrogen cyanide is the only gas product.[4]

4) C. A. Winkler and H. I. Schiff, "The reactivity of free radical" General discussion of Faraday Society, 63 (1953).

TABLE 4. RATE CONSTANTS FOR SOME REACTIONS OF NITROGEN ATOM

Reaction	Rate constant	Reference
$N + N + N_2 \rightarrow N_2 + N_2$	1.5×10^{-32} cc^2/molecule^2 sec	5
	2.2×10^{-32} cc^2/molecule^2 sec	6
	$1.4-1.5\times10^{-32}$ cc^2/molecule^2 sec	This paper
$N + 1/2C_2H_4 \rightarrow HCN + 1/2H_2$	1.6×10^{-13} cc/molecule sec	7
	9.7×10^{-14} cc/molecule sec	8
	$2.4-0.8\times10^{-14}$ cc/molecule sec	9
	$3.8-0.6\times10^{-14}$ cc/molecule sec	This paper
$N + CH_4 \rightarrow HCN + 3/2H_2$	$1.0-2.2\times10^{-16}$ cc/molecule sec	This paper

For competitive reactions

$$N + N + N_2 \xrightarrow{k_3} N_2 + N_2 + h\nu\,,$$

$$N + \tfrac{1}{2}C_2H_4 \xrightarrow{k_2} HCN + \tfrac{1}{2}H_2\,,$$

it is quite plausible to assume that the rate of recombination of nitrogen atom is negligible, compared to the rate of reaction of nitrogen atom with ethylene. In this case, the following differential form of the rate equation is obtained;

$$-\frac{d(a-x)}{dt} = k_2(a-x)(b-x/2)$$

where b is the initial concentration of ethylene and $(b-x/2)$ is the concentration of ethylene at time t. From this equation, when t is τ, x is equal to $a/2$, the following equation is derived;

$$\frac{2}{(2b-a)}\ln\frac{4b-a}{2b} = k_2\tau\,. \qquad (6)$$

Table 3 lists the observed values and the evaluated value of k_2.

Our measured values of rate constants are listed in Table 4 along with the values measured by other workers. It is known that the results obtained in this paper are in agreement with them.

Solvent-Extraction Behavior of Carrier-Free Rhodium

Tomitaro ISHIMORI, Yoshii KOBAYASHI and Yoshie USUBA

Japan Atomic Energy Research Institute, Tokai, Ibaraki

(Received November 21, 1967)

Distribution of carrier-free rhodium in the 21 extraction system given in Table 1 was studied with aids of Rh-105.

Distribution ratio, K_d, was obtained in a similar manner to that previously reported.[1] Namely, 2 m*l* each of the pre-equilibrated organic and aqueous phases were shaken in a 5 m*l* glass-stoppered cylinder for 2 min. After the separation of the two phases, aliquots of each phase were taken into two glass tubes respectively for radioassay. The K_d value was determined as the total activity of the organic phase divided by that of the aqueous phase. All procedures were carried out at the room temperature.

The 35.5 h-^{105}Rh tracer was prepared in a hydrochloric acid solution according to Kobayashi's procedure.[2] The solution was evaporated to dryness, then the tracer was taken up into hydrochloric, nitric or sulfuric acid solution and used without any further treatment.

Results obtained are summarized in Fig. 1, where K_d values in logarithmic scale are shown as the function of the acidity of the aqueous phase for the respective extraction system. In Fig. 1, average values of several measurements are represented by dots with their standard deviations, while values obtained by a single measurement as only dots. Figures given here can be compared with those for many other elements of the corresponding systems in the previous works of the present authors.[3]

Synthetic Studies of the Flavone Derivatives. VI.*1 The Synthesis of 3′,6-Dimethoxy-4′,5,7-triethoxyflavone

Tokunaru HORIE and Mitsuo MASUMURA

Department Applied of Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

and Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received November 27, 1967)

In 1963, a flavonoid pigment was isolated from *Digitalis lanata* L. by Whalley *et al.*[1] They established that the pigment was 3′,6-dimethoxy-4′,5,7-trihydroxyflavone (I) on the basis of degradative studies of its trimethyl ether (II) and triethyl ether (III). In this paper, we wish to report the synthesis of 3,6′-dimethoxy-4′,5,7-triethoxyflavone (III), which confirms the proposed structure (I) of the pigment by an unambiguous method.

The esterification of 4,6-diethoxy-2-hydroxy-5-methoxyacetophenone (IV)[2] with 4-ethoxy-5-methoxybenzoyl chloride in the presence of anhydrous pyridine yielded 4,6-diethoxy-2-(4′-ethoxy-3′-methoxybenzoyloxy)-5-methoxyacetophenone (V) (mp 102—103°C). According to the Baker-Venkataraman rearrangement,[3] the subsequent reaction of the acetophenone (V) with sodium amide gave 3′,5-dimethoxy-2-hydroxy-4,4′,6-triethoxy-dibenzoylmethane (VI) (mp 124.5—125.5°C). The cyclization of the dibenzoylmethane (VI) with concentrated sulfuric acid afforded the desired flavone (III) (mp 172—173°C) (lit.[1] mp 165—168°C). The structure of this compound was confirmed by a study of its infrared, ultraviolet, and NMR spectra.

4,6-Diethoxy-2-hydroxy-5-methoxyacetophenone (IV). This acetophenone was prepared from 3,5-diethoxy-4-methoxyphenol[4] in the manner described by Farkas *et al.*[2]; bp 135—137°C/1.5 mmHg (62%).

Found: C, 61.69; H, 7.17%. Calcd for $C_{13}H_{18}O_5$: C, 61.40; H, 7.14%.

4,6-Diethoxy-2-(4′-ethoxy-3′-methoxybenzoyloxy)-5-methoxyacetophenone (V). A mixture of IV (2.5 g), 4-ethoxy-3-methoxybenzoyl chloride (2.5 g), and anhydrous pyridine (4.0 m*l*) was heated in an oil bath at 120°C for 1.5 hr. After having then been cooled, the reaction mixture was poured into ice-cold dilute hydrochloric acid and extracted with ether. The ether solution was washed with dilute hydrochloric acid, with an aqueous sodium carbonate solution, and finally with water. The resulting solution being dried over sodium sulfate and evaporated, the residual product was recrystallized from methanol to give V in the form of colorless needles, mp 102—103°C; yield 2.2 g (52%).

Found: C, 64.18; H, 6.57%. Calcd for $C_{23}H_{28}O_8$: C, 63.88; H, 6.53%.

3′,5-Dimethoxy-2-hydroxy-4,4′,6-triethoxy-dibenzoylmethane (VI). The acetophenone (V) (1.9 g) was heated with finely-powdered sodium amide (1.9 g) in anhydrous xylene (15 m*l*) at 110°C for 1 hr. After the excess sodium amide had been completely decomposed with ice water, the resulting solution was saturated with carbon dioxide. The precipitate was collected, washed with water, and recrystallized from ethanol to give VI in the form of golden yellow prisms, mp 124.5—125.5°C; yield 760 mg (40%). This substance gave a green ferric reaction in ethanol.

Found: C, 63.86; H, 6.50%. Calcd for $C_{23}H_{28}O_8$: C, 63.88; H, 6.53%.

3′,6-Dimethoxy-4′,5,7-triethoxyflavone (III). To a solution of VI (360 mg) in glacial acetic acid (8.0 m*l*), concentrated sulfuric acid (1 m*l*) was added; the mixture

Preparation and Properties of Polyhexamethyleneguanidine*1,*2

Rokuro KITAWAKI, Kozo SHIRAI*3 and Kiichiro SUGINO

Department of Applied Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 28, 1967)

In previous studies,[1,2] we prepared alkylenedicyanamide in a pure state for the first time and studied its polymerization, which yielded a transparent, insoluble-infusible polymer. In the first paper,[1] it was also pointed out that alkylenedicyanamide reacted with alkylenediamine to give an anion exchange resin which might have the structure of polyalkyleneguanidine.

This is the first report on polyalkyleneguanidine and its properties. In regard to this problem, one previous patent[3] had indeed been granted. However, the polyhexamethyleneguanidine described in the patent was questionable because of the erroneous method used for the preparation of hexamethylenedicyanamide.

Preparation of Polyhexamethyleneguanidine. A methanolic or aqueous methanolic (or ethanolic) solution of a mixture of hexamethylenedicyanamide (I) and hexamethylenediamine dihydrochloride (II) was refluxed until no crystal was separated by cooling. The condensation was accelerated by adding a small amount of hexamethylenediamine. The removal of the solvent at a reduced pressure left a colorless, transparent gel which was in turn solidified by simple heating. The solubility of the resulting polymers in water varied with the molar ratio of the starting materials, as is shown in Table 1.

TABLE 1. SOLUBILITY OF THE POLYMERS IN WATER

Starting materials I mole	Starting materials II mole	Solubility
1	1	soluble
1	0.9	soluble
1	0.8	insoluble
1	0.7	insoluble
1	0.6	insoluble
1	0.5	insoluble

As is clear from the table, water-insoluble polymers could be obtained when 1 mol of I was reacted with less than 0.8 mol of II. The product obtained was a colorless, transparent glassy mass which was infusible and insoluble (in the case of water-insoluble polymers) in all common solvents.

Structure of the Polymer. The reaction of I with II may be supposed to proceed as follows:

$$n\,\mathrm{NCHN(CH_2)_6NHCN} + n\,\mathrm{ClH\cdot H_2N(CH_2)_6NH_2\cdot HCl} \rightarrow \cdots(\mathrm{CH_2})_6\mathrm{NH\cdot C(NH\cdot HCl)\cdot NH(CH_2)_6NH\cdot C(NH\cdot HCl)\cdot NH(CH_2)_6}\text{-}\mathrm{NH\cdot C(NH\cdot HCl)\cdot NH(CH_2)_6}\cdots$$

That is, the result expected is a polymer having guanidine linkage. It is also supposed that the product obtained using a mixture of I and II in a molar ratio of 1 : 1 will have a simple polyguanidine structure, but that when a mixture of the

same compounds in a molar ratio of 1 : less than 0.8 is reacted, the polymerization of I itself occurs simultaneously, resulting in the formation of insoluble polymers.

One piece of evidence for the presence of guanidine linkage in the polymer molecule is that when the resin was decomposed by digesting it with hot concentrated hydrochloric acid, the resulting solution gave a distinctly positive Sakaguchi test.

Another piece of evidence for the polyguanidine structure of the polymer is its infrared spectrum. It is shown in Fig. 1, along with that of hexamethylenediguanidine dihydrochloride[4] for comparison.

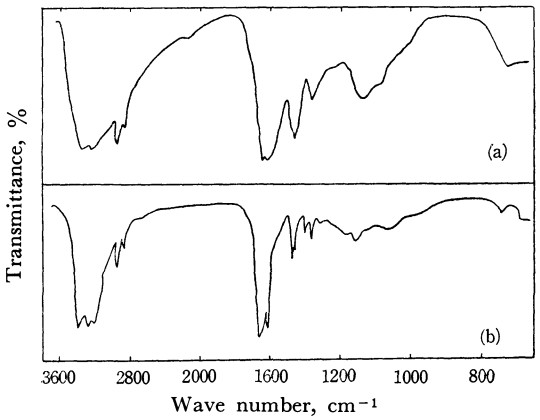

Fig. 1. Infrared spectra of the polymer and hexamethylenediguanidine 2HCl. (KBr pellet method)
(a) The polymer
(b) Hexamethylenediguanidine

The two spectra may be seen to be very similar to one other. Moreover, the spectrum of the polymer indicates the presence of methylene-group bands at 2920 cm^{-1}, 2860 cm^{-1}, and 1470 cm^{-1}, of imino-group bands at 3220—3240 cm^{-1}, and of C=N band at 1650 cm^{-1}.

Ion-exchange Property of the Polymer. When the polymer was pulverized into particles and treated with an aqueous solution of sodium hydroxide, it swelled and released the chloride ion into the solution. After it had been allowed to stand, it was collected, washed with water, and dried, resulting in a resin of the OH^- type. The resin thus obtained was found to have a strong anion-exchange property, as was expected from its guanidine structure. Figure 2 shows the rate of the adsorption of hydrochloric acid by the resin.

The exchange capacities of this resin were found to be 7.68 mmol/g and 3.34 mmol/g for Cl^- in a 0.5 N hydrochloric acid and in a 1 N sodium chloride solution respectively.

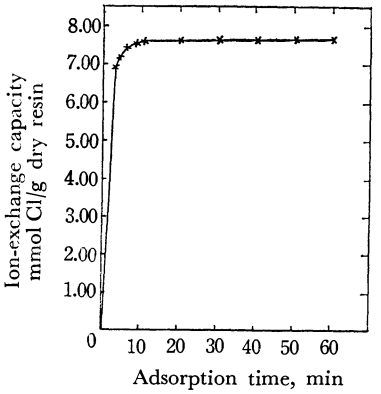

Fig. 2. The rate of adsorption of 0.5 N HCl by the resin.

Experimental

Hexamethylenedicyanamide (I). It was prepared by the procedure described earlier.[1,2] Mp 64—65°C.

Hexamethylenediamine Dihydrochloride (II). A commercially available reagent was used after recrystallization. Mp 248°C.

Preparation of Polyhexamethyleneguanidine Hydrochloride. *Water-soluble Polymer:* A mixture of 8.3 g of I, 8.5—9.6 g of II, and 0.2 g of hexamethylenediamine (III) was dissolved in 40 cc of 50% aqueous ethanol, and the solution was refluxed on a water bath for 2—5 hr. After the reaction, the ethanol and water were removed by distillation at reduced pressure, leaving a colorless, transparent gel-like mass. It was solidified by being heated at 100—110°C for 2—5 hr, resulting in a water-soluble resinous product.

Water-insoluble Polymer: A mixture of 16.6 g of I and 9.6 g of II was dissolved in 60 cc of methanol or 60 cc of 50% aqueous methanol, and the solution was refluxed on a water bath for 3 hr in the presence of III. After the reaction, the methanol (and the water) were removed by distillation at reduced pressure, leaving a colorless, transparent gel-like mass. It was solidified by being heated at 100—110°C for 2 hr, resulting in a water-insoluble resinous product.

Preparation of an Anion-exchange Resin. The water-insoluble polymer was softened with swelling by treating it with hot water at 80—90°C. Then it was pulverized, dried, and sieved into particles of 50—60 mesh. The resulting powdered resin was agitated with a 1 N sodium hydroxide solution for 2 hr. Then it was collected by filtration, thoroughly washed with water, and dried at 60—70°C.

Measurement of the Exchange Capacities of the Resin. 4.000 g of the OH^--type resin thus obtained, after being completely dried in an air bath, was placed in a flask containing 200 cc of 0.5 N hydrochloric acid, and the mixture was stirred by magnetic stirrer. The concentration of hydrochloric acid was determined by using a 5 cc sample every 10 min.

2.000 g of the same resin were placed in a flask contaiaing 200 cc of a 1 N sodium chloride solution, and the mixture was stirred by magnetic stirrer. The pH of the solution reached a constant value of 11.86 after 2 hr. The concentration of Cl^- in the solution was then determined.

This investigation was supported by a grant from Nippon (Japan) Carbide Industries, Inc., for which the authors wish to express their deep appreciation. The authors also wish to thank Dr. M. Takimoto and his staff in the Research Laboratory of the above company (at Uozu, Toyama Pref.) for the measurement of the infrared spectra.

The Mechanism of the Base Catalyzed Cleavage of Diphenyl Sulfide, Sulfone and Sulfonic Acid Ester[1]

Naomichi FURUKAWA, Hideoki TANAKA and Shigeru OAE

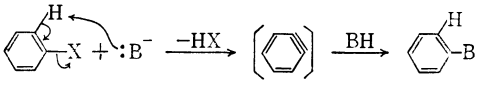
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received December 4, 1967)

The cleavage reactions of diphenyl sulfide, sulfone and phenyl benzenesulfonate by strong bases have been known for many decades and studies on their product assay have been made by previous workers.[2] However, the mechanisms of these reactions have remained totally unclarified. Only recently the mechanism of the alkaline fusion of diphenyl sulfone has been rather extensively studied by the aid of ^{14}C and ^{18}O tracer techniques[3] and was suggested to involve the S_N2 type substitutions on both carbon and sulfur atoms.

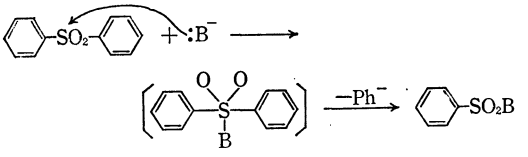
Recently, Brotherton and Bunnett have demonstrated that diphenyl sulfone, sulfide and sodium benzenesulfonate react with sodium amide in boiling piperidine to give rise to *N*-phenylpiperidine and sulfinic acid or thiophenol in comparative yields.[4] They suggest that the reaction has proceeded by way of the initial attack of piperidide anion on the carbon atom bearing sulfonyl or sulfenyl group. In view of this particular reaction condition in which a very strong base is used, there remains a possibility that the reaction may proceed through the initial abstraction of *o*-hydrogen followed by the elimination of sulfone or sulfide group to form "benzyne" intermediate, to which piperidine adds to result the final product. Another possibility is that the reaction may proceed *via* the initial attack of the base on the sulfur atom as in the case of the alkaline fusion of diphenyl sulfone. These possible mechanisms are schematically illustrated as shown below.

1) Benzyne Mechanism



2) S_N2 Substitution on Carbon

3) S_N2 Substitution on Sulfur



X=$-SO_2Ar$, $-SAr$; : B=a base

This paper will describe the detailed account of the mechanisms of the base cleavage reaction of diphenyl sulfide, sulfone and phenyl benzenesulfonate together with the corresponding *p*-methyl derivatives.

Results and Discussion

The reactants, bases used and the products obtained are shown in Table 1. The reactions were usually carried out in boiling piperidine in the presence of sodium amide or in hot DMSO containing potassium *t*-butoxide. The products were then carefully isolated by conventional distillation and recrystallization and identified by comparing their bp, mp, gas chromatograms and infrared absorption spectra with those of the authentic samples.

The results are summarized in Table 1.

Diphenyl Sulfide and Sulfone. Products isolated from the reaction of diphenyl sulfide were *N*-phenylpiperidine (I), thiophenol and diphenyl disulfide, while the reaction of diphenyl sulfone

gave *N*-phenylpiperidine (I) and benzenesulfinic acid. All these products are apparently formed by the initial attack on benzene carbon bearing sulfur atom (mechanism 2). In no case, we could detect the formation of any product which is formed by the initial attack of the amide ion on the sulfur atom (mechanism 3). In order to examine the other possible route (benzyne mechanism), di-(*p*-tolyl) sulfide and sulfone were subjected to the reaction, since the mechanism 1 would require the formation of both meta- and para-substituted *N*-tolylpiperidines. The identification of both meta- and para-*N*-tolylpiperidines can be readily done by the comparison of their characteristic infrared absorption bands (*m*-derivative 10.5 μ, 12.95 μ; *p*-derivative 12.32 μ)[5] and also gas chromatograms. When the reactions were actually performed, we obtained only the para-substituted compound and could not detect the presence of the meta-*N*-tolylpiperidine among the products. Now that the mechanism 1 is also eliminated, the best plausible route for these reactions is shown to be the one involving the aromatic S_N2 process (mechanism 2).

Phenyl Benzenesulfonate. The reaction of phenyl benzenesulfonate gave not only *N*-phenylpiperidine but also benzenesulfonyl amide and phenol. While *N*-phenylpiperidine is a product formed by the substitution at the aromatic carbon, the other two products are considered to form by the initial attack of amide ion on the sulfur atom. In this case, *N*-phenylpiperidine would be a product of aromatic S_N2 type reaction (mechanism 2), but there remains a route involving benzyne intermediate. In our case, however, *p*-cresyl benzenesulfonate gave only *p*-tolylpiperidine, suggesting that the reaction proceeds through the aromatic S_N2 reaction process (mechanism 2), similar to the nucleophilic substitution of *p*-nitrohalobenzenes.

The Reaction of *t*-Butoxide in DMSO. Potassium *t*-butoxide catalyzed reactions of diphenyl sulfide and sulfone gave several products among which were identified *t*-butyl phenyl ether and phenol and much of the starting sulfide and sulfone were recovered unchanged.

5) R. Huisgen and J. Sauer, *Chem. Ber.*, **91**, 1453 (1958).

Problem of Attacking Sites of Nucleophilic Reagents. All the above results indicate that the base cleavage reactions of diphenyl sulfide and sulfone proceed through the initial attack of the base on aromatic carbon atom bearing the functional group, while with the sulfonate, the main route is the initial attack of base on sulfonyl sulfur along with a side reaction involving the attack on the aromatic carbon atom similar to the case of the sulfide and sulfone. The reason of the difference between these two passways can easily be explained on the basis of the relative stabilities of the leaving groups. The initial attack of the sulfur atom of the sulfide or sulfone would have to give rise to the unstable phenyl anion as the leaving group, whereas the initial attack on the aromatic carbon atom bearing the sulfone or sulfide group should give either sulfinate or thiophenolate ion which would be a good leaving group. Thus the substitution on carbon atom will be more facile. While, in the case of the sulfonate, no matter which atom the nucleophile would attack, the leaving group is a very good one, namely, stable phenoxide ion in the case of sulfur attack, and benzenesulfonate ion in the case of the aromatic carbon attack. Therefore, both the sulfur and the carbon attack are expected to be quite facile and in fact it was found to be the case.

Experimental

Reagents. Diphenyl sulfide, sulfone, phenyl benzene-sulfonate, di-*p*-tolylsulfide, sulfone, *p*-tolyl benzenesulfonate were prepared by the standard procedures. Sodium amide commercially available was washed with anhydrous *n*-hexane before use. Potassium *t*-butoxide was prepared from *t*-butanol and potassium. Commercial piperidine was dried with sodium, bp 105—106°C. DMSO was distilled and dried over molecular sieve conventionally as usual.

Reaction and Product Isolation. A typical example of the experiments is as follows.

Diphenyl Sulfide with Sodium Amide in Piperidine. Sodium amide (2 g) was refluxed in 8 m*l* of piperidine for 30 min. To this solution was added 3 g of diphenyl sulfide and then the mixture was refluxed for 6 hr. After cooling, the solution was quenched with ice water to decompose sodium amide. The

aqueous solution was extracted with ether. The aqueous layer was acidified with concentrated hydrochloric acid and extracted again with ether. After evaporation of ether, thiophenol was obtained (0.964 g) (54%). The first ether layer was extracted with concentrated hydrochloric acid and the separated ether layer gave the unreacted sulfide. The aqueous acidic solution was made alkaline with aqueous sodium hydroxide and extracted with ether, from which 1.19 g of *N*-phenylpiperidine was obtained (74%). All the products isolated were identified by comparing those IR spectra and gas chromatograms with those of the authentic samples.

All other sulfides, sulfones and sulfonates were treated similarly to diphenyl sulfide.

Potassium *t*-Butoxide in DMSO with Diphenyl Sulfide. Diphenyl sulfide 1.0 g and potassium *t*-butoxide 1.5 g were dissolved into 10 m*l* of DMSO. The solution was sealed into a glass tube and heated for 3 hr at 150°C. After cooling, the sealed tube was broken and the products were detected by gas chromatograph. The products are summarized in Table 1.

Sesquiterpene Alcohols and a Phenol Ether of the Essential Oil of the Kusunoki (*Cinnamomum Camphora*, Sieb.)

Shûichi HAYASHI, Katsumi YANO, Nanao HAYASHI and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received December 7, 1967)

In connection with a previous report[1] on sesquiterpene hydrocarbons in camphor blue oil, which is a high-boiling fraction of the essential oil of the Kusunoki, the present work will deal with the sesquiterpene alcohol fraction of the blue oil. Five alcohols, elemol (6%), guaiol (10%), α-cadinol (13%), β-eudesmol (trace), and juniper camphor (2%), and a kind of phenol ether, myristicin (trace), have been identified.

The high-boiling fraction of camphor oil has been taken up by several workers as a subject of investigation, but no oxygen-containing constituents of this fraction have been identified up to the present time*1 except nerolidol.[2] In the present investigation, however, we could not detect nerolidol in spite of our great care.

Experimental

A sesquiterpene alcohol fraction, bp 120—160°C/4 mmHg, 456 g, which was separated from a camphor oil commercially supplied, was precisely fractionated through a packed-type distillation column under reduced pressure; it was divided into 19 fractions.

Myristicin. The first fraction, bp 115—116°C, $[\alpha]_D^{25}$ +11.31°C, was eluted on a silica gel-packed column with petroleum ether; an oily substance, n_D^{25} 1.5370, was thus isolated, a substance which showed only one peak, at t_R 12.6 min, in gas chromatography (DEGS-Diasolid-L, 125°C). Found: C, 68.93; H, 6.60%. Calcd for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

The IR spectrum of this substance coincided with that of myristicin,[3] and bromination in chloroform produced white needles, mp 129—130°C, of dibromomyristicin dibromide.[4] The NMR spectrum of the substance, consisting of signals at 2.30 (2H, d, J=6 cps), 3.80 (3H, s), 5.00 (2H, m), 5.80 (2H, s), 5.80 (1H, m), and 6.25 ppm (2H, s), had a strong resemblance with that of safrole,[5] and so the substance could easily be identified as myristicin on the basis of a comparison of the two spectra. The mass spectrum[6] also fit myristicin.

Elemol. A white crystalline mass was isolated from fraction 4, bp 122—124°C/4 mmHg, $[\alpha]_D^{25}$ −8.99°, by eluting it on an alumina (Grade II) column with petroleum ether. The substance showed an IR spectrum which agreed with that of elemol;[7] the gas chromatography (Thermol-1) also showed it to be elemol.

Guaiol. A white crystalline mass separated from fraction 5, bp 124—126°C/4 mmHg, $[\alpha]_D^{25}$ −9.31°C, by keepting it in a refrigerator was recrystallized from petroleum ether; white needles, mp 92.5°C, $[\alpha]_D^{25}$ −30.1° (c 1.5, ethanol), were thus obtained. The IR spectrum of the needles coincided with that of guaiol,[8] and the 3,5-dinitrobenzoate, mp 134.5—135.5°C, was established to be that of guaiol by a mixed melting point determination.

*1 Hikino *et al.* reported on the structure of the main sesquiterpene alcohols, kusunol and campherenol, of camphor oil at the 11th Symposium on the Chemistry of Terpenes, Essential Oils, and Aromatics, held in October, 1967, at Matsuyama.

α-Cadinol and β-Eudesmol. Two spot portions, of R_f 0.33 and 0.10, were gathered in the thin-layer chromatography of fraction 9, bp 132—134°C/4 mmHg, $[\alpha]_D^{25}$ +16.91°, with silica gel-G coating with silver nitrate; these portions were then extracted with ether to isolate two kinds of white crystalline matter. The IR spectra of these substances agreed with those of α-cadinol (R_f 0.33)[9] and β-eudesmol (R_f 0.10)[10] respectively.

Juniper Camphor. A crystalline mass which appeared in fraction 14, bp 142—144°C/4 mmHg, $[\alpha]_D^{25}$ +1.79°, when it was left standing at room temperature was separated, and then recrystallized repeatedly from ethanol. White crystals, mp 166.7°C, were thus obtained. This melting point and the IR spectrum agreed with those of juniper camphor.[11] Furthermore, the NMR spectrum, which had three methyl singlets, at 0.96 ppm (3H, a tertiary methyl group), 1.15 ppm (3H, a tertiary methyl attached to a carbon atom carrying a hydroxyl group), and 1.18 ppm (6H, two methyl groups in a isopropylidene), and the signals of the two methylene groups adjacent to a double bond at 2.14—2.80 ppm (4H), fit the structure of juniper camphor well.

The authors are indebted to Professor Shô Ito of Tohoku University for his kind measurement of the NMR spectra and to Dr. Hiroshi Satô of the Hitachi Co., Ltd., for his measurement of the mass spectra.

Hydrogen Atom Abstraction by a Cumyloxy Radical

Etsuo NIKI, Yoshio KAMIYA and Nobuto OHTA

Department of Fuel Technology, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 7, 1967)

It has been generally understood that the rates of hydrogen atom abstraction from liquid hydrocarbons increase in the sequence: primary, secondary, and tertiary. This order has been considered to be independent of the nature of the attacking species, and has been explained as being due to the strengths of the C–H bonds being broken. In the course of our investigation of the autoxidation of hydrocarbons in the liquid phase, the relative reactivities of a series of hydrocarbons toward cumyloxy radicals were measured in view of the fact that, although many data had been reported on the relative reactivities toward atoms and free radicals,[1] the reactivities of a series of hydrocarbons toward cumyloxy radicals had not yet been obtained. Another purpose is to compare the reactivities (and selectivities) of cumyloxy and cumylperoxy radicals,*1 since there are no definite data on the reactivities of two oxy radicals with the same alkyl group, the hydrocarbon portion in the radical.

Dicumyl peroxide was chosen as the source of the cumyloxy radicals since its thermal decomposition had been studied in detail by Kharasch and his co-workers,[2] and by Bailey and Godin.[3] These authors showed that dicumyl peroxide decomposed by a strictly first-order non-chain mechanism up to almost completion, the rate-determining step being the breakdown of the peroxide into free alkoxy radicals.[2,3] Kharasch and his co-workers[2] used cumene, *t*-butylbenzene, diisopropylcarbinol, and dodecane as solvents, and found the rates of decomposition to be nearly independent of the solvents.

The decomposition products were reported to be cumyl alcohol, acetophenone, methane, and the dimer of the solvent hydrocarbon.[2,3] In addition to these products, a small amount of α-methylstyrene was found to be formed. No ethane, acetone, or α,α-dimethylbenzyl methyl ether was detected.

The first step in the decomposition of dicumyl peroxide is the scission of the peroxidic bond to produce two cumyloxy radicals. This radical either abstracts a hydrogen atom from the solvent to form cumyl alcohol, or decomposes to acetophenone and a methyl radical. The absence of acetone in the product mixture shows that the fission of the cumyloxy radical occurs at the carbon-methyl bond and not at the carbon-phenyl bond; this is in agreement with thermochemical predictions[4] that the elimination of a methyl group requires an enthalpy increase of 0.3 kcal/mol, while that of a phenyl group would require 8.0

Table 1. The products of the thermal decomposition of dicumyl peroxide[a)]
(140°C, [peroxide] = 1.00×10^{-3} mol)

Solvent	Products in mol$\times10^3$			k_1/k_2	Relative k_1[b)]
	I+II	III	(I+II)/III		
Tetralin	1.58	0.295	5.35	0.728	1.9
Phenylcyclohexane	1.12	0.740	1.52	0.285	
p-Xylene	0.961	0.990	0.972	0.119	0.20
Ethylbenzene	0.833	0.990	0.843	0.103	0.51
Cumene	0.797	1.14	0.700[c)]	0.0972	1.00
Toluene	0.725	1.07	0.677	0.0721	0.24
Diphenylmethane	0.748	1.28	0.585	0.0922	0.48

a) All experiments were performed in duplicate.
b) Relative reactivities per active α-hydrogen relative to cumene.
c) The values of 0.71 and 0.74 are given in Refs. 2 and 3 respectively.

kcal/mol. The absence of both ethane and α,α-dimethylbenzyl methyl ether, and the formation of methane in an amount equimolar to acetophenone,[2,3)] show that most of the methyl radicals attack the solvent and abstract the hydrogen atom. α-Methylstyrene is expected to be produced by the dehydration of cumyl alcohol.[5,6)] The amount of α-methylstyrene formed was always less than 5% of the cumyl alcohol formed.

These observations lead to the following scheme for the decomposition of dicumyl peroxide in a hydrogen-donor solvent:

$$C_6H_5(CH_3)_2COOC(CH_3)_2C_6H_5 \rightarrow 2C_6H_5(CH_3)_2CO\cdot$$

$$C_6H_5(CH_3)_2CO\cdot + RH \xrightarrow{k_1} C_6H_5(CH_3)_2COH + R\cdot \quad (I)$$

$$C_6H_5(CH_3)_2COH \rightarrow C_6H_5(CH_3)C{=}CH_2 + H_2O \quad (II)$$

$$C_6H_5(CH_3)_2CO\cdot \xrightarrow{k_2} C_6H_5COCH_3 + CH_3\cdot \quad (III)$$

$$CH_3\cdot + RH \rightarrow CH_4 + R\cdot$$

$$R\cdot + R\cdot \rightarrow R\text{–}R$$

The rates of the formation of cumyl alcohol and acetophenone can be expressed as Eqs. (1) and (2) respectively:*2

$$\mathrm{d(cumyl\ alcohol)}/dt = k_1[C_6H_5(CH_3)_2CO\cdot][RH] \quad (1)$$

$$\mathrm{d(acetophenone)}/dt = k_2[C_6H_5(CH_3)_2CO\cdot] \quad (2)$$

Hence,

$$\mathrm{cumyl\ alcohol/acetophenone} = k_1[RH]/k_2 \quad (3)$$

Since k_2 may well be assumed to be constant in aromatic hydrocarbon solvents*3 and since [RH] is known, the relative k_1 value can be measured on the basis of the knowledge of the amounts of cumyl alcohol and acetophenone formed.

The products obtained in eight solvents are shown in Table 1.

More than 90% of the initial peroxide was accounted for. The relative reactivities of the hydrocarbons toward cumyloxy radicals are also shown in Table 1. As Table 1 shows, toward the cumyloxy radical, the normal order of hydrogen reactivity, namely, primary<secondary<tertiary, is followed in the series of *p*-xylene, toluene<ethylbenzene, diphenylmethane<cumene. However, the secondary hydrogen atom of tetralin is much more reactive than that of cumene. The steric effect may be one of the reasons why cumene is less reactive than tetralin, since the α-hydrogen of cumene is rather hindered by two methyl groups. Another possibility is that, although the β-hydrogens of tetralin are not benzylic and although the derived radical can not be stabilized by resonance, the β-hydrogen atoms as well as the β-hydrogens may also be abstracted by the cumyloxy radical, since the *t*-butoxy radical abstracts hydrogen from cyclohexane more readily than from toluene.[7,8)]

Phenylcyclohexane has one tertiary and ten secondary hydrogen atoms. For the same reason as has been given above, the secondary hydrogens must also be abstracted by the cumyloxy radical; all the more, then, is the tertiary hydrogen in

phenylcyclohexane hindered by phenyl and cyclohexyl groups.

Experimental

Dicumyl peroxide was obtained from the Nippon Oils and Fats Co. and had a purity of 99.3%. Tetralin, cumene, ethylbenzene, *p*-xylene, and toluene were shaken successively with sulfuric acid, water, sodium hydroxide, and water, dried with calcium chloride, and then distilled under a reduced pressure of nitrogen. Diphenylmethane and phenylcyclohexane were fractionally distilled. All the solvents were passed through an activated alumina column immediately before use.

Decompositions were carried out in a sealed flask equipped with a condenser, a sample inlet, and two side arms. An aliquot of the solution of dicumyl peroxide was introduced into the reaction vessel, the concentration of the peroxide being maintained at 0.200 mol/*l*. The reaction mixture was degassed under a vacuum through one side arm, while through the other nitrogen was introduced. This procedure was repeated four times. The vessel was then immersed to an oil bath thermostated at 140±0.5°C, and the reaction mixture was stirred by means of a magnetic stirrer.

Acetophenone, cumyl alcohol, and α-methylstyrene were determined by gas-liquid chromatography; Polyethylene Glycol 6000 column, at 170°C and with helium carrier gas. Methane and ethane were analyzed by glc; Molecular Sieve-13X, 30°C, He carrier gas. It was found that methane was the only gaseous product. The injection of an initial solution of dicumyl peroxide to glc gave peaks of both acetophenone and cumyl alcohol. In order to avoid this interference, dicumyl peroxide was decomposed almost completely. The injection of cumyl alcohol did not give any other peak, indicating that the decomposition of cumyl alcohol in the glc was negligible.

Lactone Carboxylic Acids. V.*[1] A Way of Preparing a Lignans Skeleton

Akira TAKEDA

Department of Synthetics Chemistry, Okayama University, Okayama

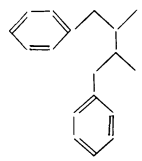
and Sigeru TORII

Department of Industrial Chemistry, Okayama University, Okayama

(Received December 20, 1967)

In a previous paper,[1] we described the benzylation of γ,γ-dialkyl-α,β-dicarbethoxybutyrolactones at the α-position of the lactone ring, which is reminiscent of a synthetic route to lignans derivatives.[2]

It is the aim of the present study to apply this method to the synthesis of compounds with a lignans skeleton (I) (see Scheme 2). The required materials, γ-aryl-α,β-dicarbethoxybutyrolactones (IIa, R=4-methoxy or 3,4-methylene dioxy), were prepared by the condensation of ethyl β-arylglycidates with sodiomalonate.[3] In order to elucidate the course of the fission of the epoxy ring on the glycidates, the products (IIa or IIb) were converted into well-known compounds (VI),[4] as is shown in Scheme 1.



(I)

The hydrolysis of II was carried out with an 1 N aqueous alcoholic potassium hydroxide solution;[5] it gave *ca.* 70% yield of an acidic component

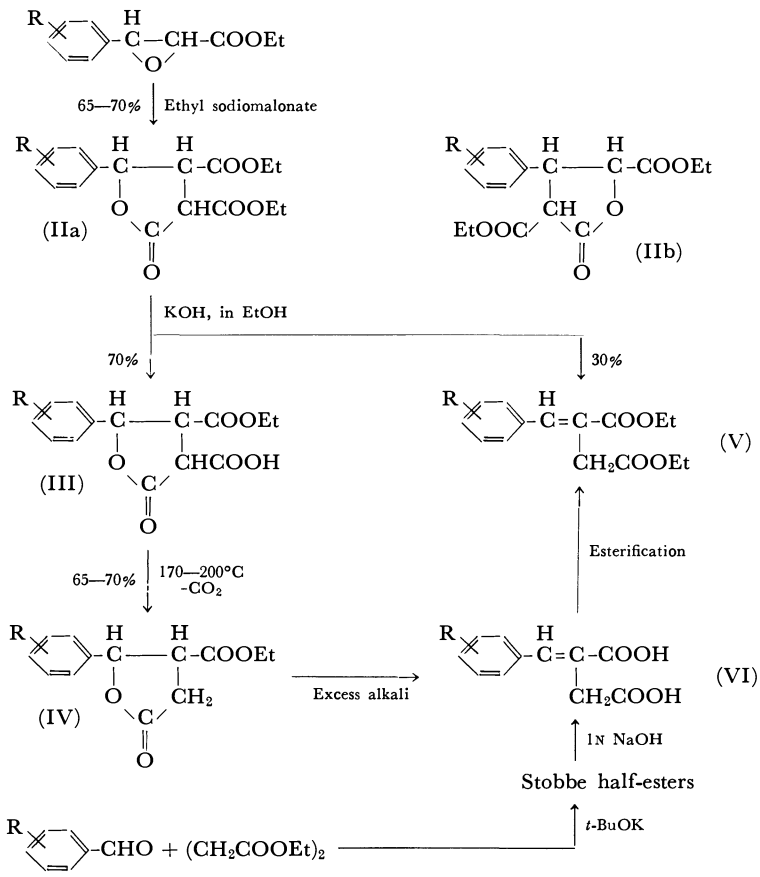
Cornforth, G. K. Hughes, and F. Lions, *J. Proc. Roy. Soc. N. S. Wales*, **72**, 228 (1939).

5) In the case of the hydrolysis of γ,γ-dialkyl-α,β-dicarbethoxybutyrolactones, only acidic components, γ,γ-dialkyl-β-carbethoxy-α-carboxybutyrolactones, were isolated under these conditions; see A. Takeda and S. Torii, *Memoirs of School of Engineering, Okayama Univ.*, **1**, 44 (1966). On the other hand, the hydrolysis of α-benzylated γ,γ-dialkyl-α,β-dicarbethoxybutyrolactones gave exclusively neutral lactone derivatives, such as γ,γ-dialkyl-β-carbethoxy-α-benzylbutyrolactones.[1]



Scheme 1

(III), a viscous yellow oil, and *ca.* 30% yield of a neutral component (V).

The acidic materials (III), when heated to 170—200°C, were converted into ethyl γ-aryl-paraconates (IV), which were then further hydrolyzed with reflux in a 1 N aqueous sodium hydroxide solution to give dibasic acids (VI).[4] The authentic samples of VI were prepared by the Stobbe condensation[6] of aromatic aldehydes with diethyl succinate and by the subsequent hydrolysis of the Stobbe half-esters.[4a]

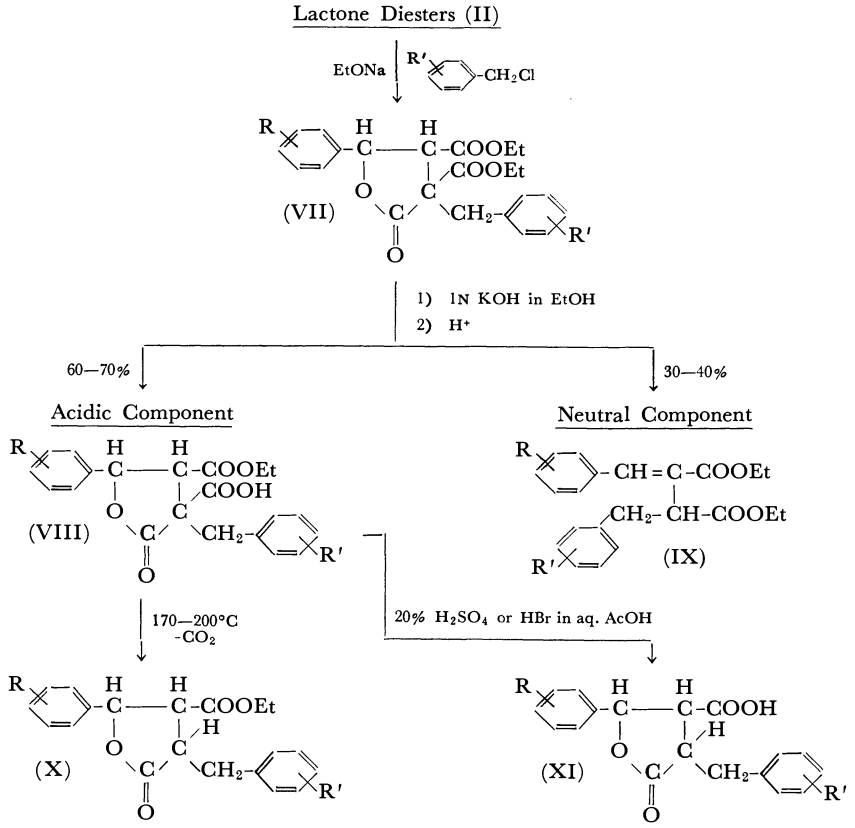
The structure of the neutral materials (V) was readily confirmed by means of these spectral data in comparison with those of an authentic sample prepared by the esterification of VI. These facts reveal that the attack of the carbanion of malonate occurs exclusively at the α-position of the β-aryl-glycidates.[7]

The benzylation of IIa (R=4-methoxy) was carried out with the use of an equimolar amount of 4-chlorobenzyl chloride, as a model compound, in the presence of sodium ethoxide in dry ethanol.[1] The structure of the condensation product (VII, R=4-methoxy and R'=4-chloro), which was not distillable but which was condensed at 170—180°C/1—2 mmHg, was supported by its infrared spectrum, which showed enhanced peaks at 1513, 1490, and 835 cm^{-1} assignable to the *p*-chlorobenzyl group.

Without being purified further, VII was subjected to hydrolysis in an 1 N alcoholic potassium hydroxide solution to afford a 65% yield of acidic materials (VIII) and a 35% yield of neutral materials (IX). The structure of VIII (R=4-methoxy and R'=4-chloro), a sticky oil, was indicated by its infrared spectrum, which exhibited peaks at 3500—2400, 1770, 1735, and 1700 cm^{-1}, consistent with carboxylic acid, lactone, and ester groups respectively. The neutral material (IX, R=4-methoxy and R'=4-chloro) was purified by distillation and showed the expected combustion analytical results. Further proof of the structure of IX (R=4-methoxy and R'=4-chloro)

6) W. S. Johnson and G. H. Daub, "Organic Reactions," Vol. VI, John Wiely and Sons, New York, N. Y. (1951), p. 1.

7) Detailed studies of the ring opening of the epoxide group upon the reaction of ethyl β-alkyl- and β,β-dialkylglycidates with sodiomalonate have been reported; see A. Takeda, Y. Kariya and S. Torii, *Memoirs of School of Engineering, Okayama Univ.*, **2**, 74 (1967); K. Sisido, S. Torii, and M. Kawanisi, *J. Org. Chem.*, **29**, 904 (1964).



Scheme 2

was given by the following evidence. The absorption spectrum of IX (R=4-methoxy and R'=4-chloro), when carefully compared with that of V (R=4-methoxy), showed enhanced peaks at 1513 and 840—820 cm^{-1} due to the newly-introduced *p*-chlorobenzyl group. A Beilstein test was positive also.

Experimental

The microanalyses were performed by Miss Teruko Nisi of our department. All melting and boiling points are uncorrected.

Reaction of Ethyl β-(4-Methoxyphenyl)glycidate with Sodiomalonate. Following the method described in the previous paper,[1] to a mixture of 13.6 g (0.2 mol) of sodium ethoxide and 37.6 (0.25 mol) of diethyl malonate in 120 m*l* of anhydrous ethanol, 22.2 g (0.1 mol) of ethyl β-(4-methoxyphenyl)glycidate, bp 158°C/3 mmHg (lit.[8] bp 187—191°C/18 mmHg), were added. The mixture was refluxed for 25 hr with stirring, extracted with ether after the addition of ice water, and dried over anhydrous sodium sulfate. Upon the distillation of the residue *in vacuo*, there were obtained 22.5 g (67% based on the glycidate) of the γ-(4-methoxyphenyl)-α,β-dicarbethoxybutyrolactone (IIa, R=4-methoxy), bp 215—225°C/2 mmHg, ν_{max} (cm^{-1}) 1790 (lactone $\nu_{C=O}$) and 1735 (ester $\nu_{C=O}$). Found: C, 61.02; H, 6.04%. Calcd for $C_{17}H_{20}O_7$: C, 60.71; H, 5.99%.

Similarly, a 60% yield [based on ethyl β-(3,4-methylenedioxyphenyl)glycidate, bp 157—160°C/2.5 mmHg, lit.[8] bp 205—210°C/17 mmHg] of γ-(3,4-methylenedioxyphenyl)-α,β-dicarbethoxybutyrolactone, (IIa, R=3,4-methylenedioxy), bp 215°C/0.5 mmHg, ν_{max} (cm^{-1}) 1790 (lactone $\nu_{C=O}$) and 1730 (esters $\nu_{C=O}$) was obtained. Found: C, 58.45; H, 5.08%. Calcd for $C_{17}H_{18}O_8$: C, 58.29; H, 5.18%.

Hydrolysis of γ-(4-Methoxyphenyl)-α,β-dicarbethoxybutyrolactone (IIa, R=4-methoxy). A mixture of 2.8 g (0.05 mol) of potassium hydroxide with a trace of water and 4.5 g (0.013 mol) of IIa (R=4-methoxy) in 70 m*l* of ethanol was stirred for 2 days, neutralized to pH 6.5—7.0 with dilute sulfuric acid, and extracted with ether. The ethereal solution was then extracted several times with a saturated sodium bicarbonate solution, washed with water, dried over anhydrous magnesium sulfate, and evaporated. The distillation of the residual oil gave a *ca.* 30% yield of a neutral substance (V, R=4-methoxy), bp 183—186°C/0.5 mmHg (lit.[9] bp 285°C/4 mmHg), ν_{max} (cm^{-1}) 1730 and 1700 (esters $\nu_{C=O}$), which was identical with the authentic sample prepared by the esterification of the Stobbe half-ester.[4a]

8) K. W. Rosenmund and H. Dornsaft, *Ber.*, **52** 1734 (1919).

9) F. G. Baddar, L. S. El-Assal, N. A. Doss and A. H. Shehab, *J. Chem. Soc.*, **1959**, 1016.

The alkaline extracts were acidified with dilute sulfuric acid. The organic layer was taken up in ether, washed with a saturated sodium chloride solution, and dried over anhydrous sodium sulfate. The concentration of the ethereal solution gave a *ca.* 70% yield of III (R=4-methoxy), viscous oil, ν_{max} (cm^{-1}) 1785 (lactone $\nu_{C=O}$), 1730 (ester $\nu_{C=O}$), and 3500—2400, 1700 (COOH).

III (R=4-methoxy) was heated to 170—230°C for 30 min and then taken up in ether. The organic layer was washed with a saturated sodium bicarbonate solution and water, and dried over sodium sulfate. The distillation of the extract gave a 65—70% yield (based on III, R=4-methoxy) of ethyl γ-(4-methoxyphenyl)-paraconate, pale yellow oil, ν_{max} (cm^{-1}) 1785 (lactone $\nu_{C=O}$) and 1735 (ester $\nu_{C=O}$).

Found: C, 63.80; H, 6.25%. Calcd for $C_{14}H_{16}O_5$: C, 63.60; H, 6.19%.

In a similar manner, a 60—63% yield (based on III, R=3,4-methylenedioxy) of ethyl γ-(3,4-methylenedioxyphenyl)paraconate, bp 160°C/0.5 mmHg, ν_{max} (cm^{-1}) 1790 (lactone $\nu_{C=O}$) and 1730 (ester $\nu_{C=O}$) was obtained.

Found: C, 60.46; H, 5.37%. Calcd for $C_{14}H_{14}O_6$: C, 60.43; H, 5.07%.

By acidifying the alkaline extracts with dilute sulfuric acid, III (R=4-methoxy) was recovered unaffected.

Hydrolysis of Ethyl γ-(4-Methoxyphenyl)paraconate (IV, R=4-Methoxy). A mixture of 2.76 g (0.01 mol) of ethyl γ-(4-methoxyphenyl)paraconate (IV, R=4-methoxy) and 4.0 g (0.1 mol) of sodium hydroxide in 100 m*l* of water was refluxed for 10 hr. After it had then cooled to room temperature, the solution was neutralized with dilute sulfuric acid and extracted with ether. The organic layers were washed with a saturated sodium chloride solution and dried over anhydrous sodium sulfate. After the solvent had then been removed *in vacuo*, the residual solid was recrystallized to give VI (R=4-methoxy), mp 192°C (lit. mp 202.3°C[4a] and 187—188°C[4b]), whose infrared spectrum was identical with that of the specimen prepared by the hydrolysis of the corresponding Stobbe half-ester.[4a]

***p*-Chlorobenzylation of γ-(4-Methoxyphenyl)-α,β-dicarbethoxybutyrolactone (IIa, R=4-Methoxy).** Into a mixture of 6.72 g (0.02 mol) of γ-(4-methoxyphenyl) - α,β - dicarbethoxybutyrolactone (IIa, R=4-methoxy) and 1.34 g (0.02 mol) of sodium ethoxide in 10 m*l* of dry ethanol, 3.2 g (0.02 mol) of 4-chlorobenzyl chloride were stirred over a 14-hr period. The mixture was then neutralized with dilute sulfuric acid, extracted with ether, washed with water, and dried over anhydrous sodium sulfate. After the removal of the solvent, the residue was distilled. The forerun fraction which was distilled below 170°C/2 mmHg was removed. The residual high-boiling fraction, ν_{max} (cm^{-1}) 1790 (lactone $\nu_{C=O}$), 1735—1720 (esters $\nu_{C=O}$), with enhanced absorption bands at 1610, 1513, 1490, and 835 (4-chlorobenzyl group), which were decomposed as the distillation continued, was hydrolyzed with an excess 1 N alcoholic potassium hydroxide solution at 30—40°C for 20 hr and then neutralized to pH 6.5—7.0 with dilute sulfuric acid. The organic layer was taken up in ether, washed with a saturated sodium chloride solution, and extracted with a saturated sodium bicarbonate solution. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After the solvent had been removed *in vacuo*, the distillation of the residue gave 2.5 g (30% based on IIa) of diesters (IX, R=4-methoxy and R'=4-chloro), bp 170—175°C/0.05 mmHg, ν_{max} (cm^{-1}) 1730 (esters $\nu_{C=O}$), enhanced absorption bands at 1605, 1513, 840, and 820, due to the 4-chlorobenzyl group, in comparison with that of V (R=4-methoxy).

Found: C, 65.92; H, 6.52%. Calcd for $C_{23}H_{25}ClO_5$: C, 66.26; H, 6.04%.

The alkaline extracts were neutralized with dilute sulfuric acid to pH 6.5—7.0. The organic layer was taken up in ether, washed with a saturated sodium chloride solution and with water, and dried over anhydrous magnesium sulfate. Upon removing the solvent *in vacuo*, there was obtained 5.04 g of a viscous oil (VIII, R=4-methoxy and R'=4-chloro), ν_{max} (cm^{-1}) 1770 (lactone $\nu_{C=O}$), 1730 (ester $\nu_{C=O}$), 3400—2400, 1700, 930—900 (COOH).

The viscous oil (VIII), when heated to 170—220°C, gave a 30% yield of the lactone ester (X, R=4-methoxy and R'=4-chloro), bp 195—200°C/2 mmHg, ν_{max} (cm^{-1}) 1790 (lactone $\nu_{C=O}$) and 1735 (ester $\nu_{C=O}$).

Found: C, 64.90; H, 5.59%. Calcd for $C_{21}H_{21}ClO_5$: C, 64.83; H, 5.44%.

The viscous oil (VIII), when boiled with excess 20% sulfuric acid for 8 hr or with an excess 1 N sodium hydroxide solution for 4 days, gave a 45% yield of lactone acid (XI, R=4-methoxy and R'=4-chloro), mp 130°C, ν_{max} (cm^{-1}) 1770 (lactone $\nu_{C=O}$), and 1730 and 1705 (carboxylic acid $\nu_{C=O}$).

Found: C, 63.29; H, 4.94%. Calcd for $C_{19}H_{17}ClO_5$: C, 63.24; H, 4.76%.

Synthesis of 5-Deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene and Its Benzylmercaptan Adduct

Saburo INOKAWA, Hiroshi YOSHIDA, Chih-Cheng WANG and Roy L. WHISTLER

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu, and Department of Biochemistry, Purdue University, Lafayette, Indiana

(Received December 26, 1967)

The present report will describe the synthesis of a new unsaturated sugar, 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene [4] from 1,2-*O*-isopropilydene-5-*O*-*p*-toluenesulfonyl-α-D-xylofuranose [1], and the photocatalyzed addition of benzylmercaptan to the unsaturated sugar [4], which gives 5-benzylthio-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [5]

1,2-*O*-Isopropylidene-5-*O*-*p*-toluenesulfonyl-α-D-xylofuranose [1][1] was treated with methyl iodide and silver oxide in dimethylformamide (DMF)[2] to give, in a 72% yield, a white crystalline product analyzed as 1,2-*O*-isopropylidene-3-methyl-5-*O*-*p*-toluenesulfonyl-α-D-xylofuranose [2]. This [2] was heated with tetraethylammonium bromide in DMF to give, in a 73% yield, a colorless, oily product analyzed as 5-bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [3]. This [3] was then treated with silver fluoride[3] in pyridine to give, in a 60% yield, a colorless, oily product identified as 5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene [4] by infrared and NMR spectrum and by elementary analysis.

The infrared absorption spectrum of [4] shows absorption bands at about 800 cm^{-1} (s) (out-of-plane deformation vibration of the >C=CH_2 group), at about 1650 cm^{-1} (s) (C=C stretching vibration of >C=CH_2), and at about 3100 cm^{-1} (m) (C–H stretching vibration of the >C=CH_2 group). The NMR spectrum of [4] permits a straightforward analysis, as shown in Fig. 1.

The unsaturated sugar [4] was treated with benzylmercaptan, under ultraviolet light[4] to give, in a 85% yield, a white crystalline adduct analyzed as 5-benzylthio-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [5]. The structure of this product was established by elementary analysis, by a study of its NMR spectrum (shown in Fig. 2), and by comparison with an authentic sample prepared by the treatment of [3] with sodium benzylmercaptanate in ethanol.

Experimental

General Methods. The infrared spectra were determined on a liquid film with a Perkin-Elmer 337 grating infrared spectrophotometer. The NMR spectra were measured at 60 Mc with a Hitachi Perkin-Elmer R-20 spectrometer. The ultraviolet illumination was from a Halos PIH-100 (100W) (a high-pressure mercury lamp).

Preparation of 1,2-*O*-Isopropylidene-3-*O*-methyl-5-*O*-*p*-toluenesulfonyl-α-D-xylofuranose [2]. [1] (12 g) was dissolved in 120 m*l* of dry DMF, 20 g of silver oxide and 15 m*l* methyl iodide were added, and then the whole was shaken at room temperature in the dark for 20 hr. The solution was filtered, and, after the addition of water, the filtrate was extracted four times with chloroform. The combined extracts were filtered again to remove white precipitates, washed thoroughly with water, and dried over sodium sulfate, and the chloroform was distilled *in vacuo*. The resulting crystalline residue was recrystallyzed from ethyl acetate-petroleum

benzine to give colorless prisms of [2] (9.1 g, 72% yield), mp 116—117°C.

5-Bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [3]. A solution of 5 g of [2] and 10 g of tetramethylammonium bromide in 100 m*l* of DMF was heated at 100°C for 14 hr and then concentrated *in vacuo*. After the subsequent addition of water, the solution was extracted with chloroform three times, and the combined extracts were washed thoroughly with water, dried over sodium sulfate, and concentrated *in vacuo* to give a sirup. The fractional vacuum distillation of the sirup gave, in a 73% yield (3.8 g), pure [3]. bp 67°C/0.2 mmHg, $[\alpha]_D^{18}$ −77.6° (*c* 10, chloroform).

Found: C, 40.1; H, 5.72%. Calcd for $C_9H_{15}O_4Br$: C, 40.5; H, 5.66%.

5-Deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose-4-ene [4]. A mixture of 5 g of [3] and 7 g of silver fluoride in 40 m*l* of dry pyridine was warmed at 50°C for 30 hr. The product and the pyridine were separated from the inorganic salts by repeated extractions with ether. After filtration, the combined extracts were washed with an aqueous sodium carbonate solution and water, dried over sodium sulfate, and concentrated *in vacuo*. The fractional vacuum distillation of the resulting sirup gave, in a 60% yield (2.1 g), pure [4], bp 80°C/7 mmHg, $[\alpha]_D^{18}$ −66.0° (*c* 10, chloroform), NMR data (see Fig. 1).

Found: C, 57.8; H, 7.63%. Calcd for $C_9H_{14}O_4$: C, 58.2; H, 7.53%.

5-Benzylthio-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose [5]. i) A solution of 3 g of [4] in 5 m*l* of redistilled benzylmercaptan in a Vycor tube was irradiated for 1 hr with a high-pressure mercury ultraviolet lamp (100 W) under a nitrogen atmosphere. The solution was then concentrated *in vacuo*, and the residue was recrystallized from methanol to give, in a 82% yield (3.9 g), colorless needles of [5], mp 68°C, $[\alpha]_D^{18}$ +25.6 (*c* 5, chloroform), NMR data (see Fig. 2).

Found: C, 61.3; H, 7.20%. Calcd for $C_{16}H_{22}O_4S$: C, 61.9; H, 7.09%.

ii) To a solution of 0.1 g of metallic sodium in 2 m*l* of ethanol, 2 m*l* of redistilled benzylmercaptan and 1 g of [4] were added, and the whole was refluxed for 3 hr under a nitrogen atmosphere. The solution was then concentrated *in vacuo*, the residue was extracted with ether, and the extracts were washed with water, dried over sodium sulfate, and concentrated *in vacuo* to give crystals. Recrystallization from methanol yielded, in a 40% yield (0.6 g), colorless needles of [5], mp 68°C.

The authors are very grateful to Hashimoto Kaseikogyo, Ltd. for supplying them silver fluoride.

Preparation of Decamethyltetrasilane by Coupling of Pentamethylchlorodisilane with Lithium

Hideki SAKURAI, Hisayoshi YAMAMORI, Mineo YAMAGATA and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received December 28, 1967)

In a previous paper,[1] we have described the preparation of (chloromethyl)pentamethyldisilane by coupling of chlorobromomethane and pentamethylchlorodisilane with lithium metal in tetrahydrofuran (THF). However, the yield was not reasonably good and among other products, a considerable amount of decamethyltetrasilane was obtained. This fact indicating the coupling of pentamethylchlorodisilane to decamethyltetrasilane seemed interesting to us, since usually trialkylchlorosilanes do not undergo the coupling easily in this reaction condition. Shackelford *et al.*[2] reported that triethylbromosilane did not afford hexaethyldisilane by the coupling with lithium metal in THF. Preparation of hexamethyldisilane by the coupling of trimethylchlorosilane requires usually drastic conditions.[3]

On the other hand, coupling reactions of halosilanes having at least one phenyl group on silicon are known to proceed quite smoothly.[3]

We are now reporting a facile coupling of pentamethylchlorodisilane with lithium metal in THF to give decamethyltetrasilane. Pentamethylchlorodisilane is by no means a *trialkylchlorosilane* but it is interesting to compare the present results with those of chloromonosilanes.

Pentamethylchlorodisilane underwent the coupling reaction very smoothly with lithium in THF to give decamethyltetrasilane in good yield (~84%).

$$2(CH_3)_3SiSi(CH_3)_2Cl + 2Li \xrightarrow{THF} CH_3[Si(CH_3)_2]_4CH_3 + 2LiCl$$

Coupling of pentamethylchlorodisilane with sodium-potassium alloy was reported to give tetrasilane in 27%[4] or in 50% yield[5], previously.

5) M. Kumada and M. Ishikawa, *J. Organometal. Chem.*, **1**, 153 (1963).

The yield of the present reaction is therefore exceptionally high compared with these results. Accordingly, it provides a preferable route to decamethyltetrasilane.

Observations of such a smooth reaction prompted us to attempt isolating a possible intermediate of the reaction, pentamethyldisilanyllithium. Stolberg[6] has reported that the cleavage of decamethyltetrasilane by sodium-potassium alloy followed by coupling with trimethylchlorosilane gave a complicated mixture containing several lower homologs of methylpolysilanes. The result has been interpreted in terms of an intermediate pentamethyldisilanyl anion which would be stabilized by the charge distiribution over two silicon atoms.

$$(CH_3)_3Si\text{–}\overset{\ominus}{Si}(CH_3)_2 \longleftrightarrow (CH_3)_3\overset{\ominus}{Si}\text{=}Si(CH_3)_2$$

However, even in the presence of an excess amount of lithium metal, pentamethylchlorodisilane afforded no stable solution of pentamethyldisilanyllithium; quenching of the solution with trimethylchlorosilane gave only a trace amount of octamethyltrisilane. Therefore, it is concluded that pentamethyldisilanyllithium could be produced at first but it reacts very rapidly with pentamethylchlorodisilane. Cleavage of decamethyltetrasilane with lithium in THF is a very slow process contrary to cases of phenyl-substituted disilanes.[7]

$$(CH_3)_3SiSi(CH_3)_2Cl + 2Li \rightarrow (CH_3)_3SiSi(CH_3)_2Li + LiCl$$

$$(CH_3)_3SiSi(CH_3)_2Li + (CH_3)_3SiSi(CH_3)_2Cl \rightarrow CH_3[Si(CH_3)_2]_4CH_3$$

$$(CH_3)_3SiSi(CH_3)_2Li + (CH_3)_3SiCl \rightarrow CH_3[Si(CH_3)_2]_3CH_3$$

Experimental

Materials. Pentamethylchlorodisilane was prepared from hexamethyldisilane by the procedure described before.[8] Trimethylchlorosilane, generously supplied by the Tokyo Shibaura Electric Co. Ltd., was distilled before use. Tetrahydrofuran was distilled from a stock solution containing lithium aluminum hydride.

Coupling of Pentamethylchlorodisilane with Lithium Metal. To a fine powdered lithium metal (2.5 g, 0.36 g atom) in 100 m*l* of THF, was added with stirring 15 g (0.090 mol) of pentamethylchlorodisilane dissolved in 20 m*l* of THF. The reaction mixture was heated to keep a gentle reflux during the addition. After addition was complete, the mixture was stirred and refluxed for 8 hr. After hydrolysis and work-up, 9.6 g (0.037 mol, 82% yield) of decamethyltetrasilane was obtained as a colorless liquid (homogeneous on vpc). Physical constants, IR spectra and retention times on vpc agreed with those of the authentic sample.[5]

An Attempt to Isolate Pentamethyldisilanyllithium. By the essentially same procedure, 17 g (0.1 mol) of pentamethylchlorodisilane in 100 m*l* of THF was allowed to react with 1.4 g (0.2 g atom) of lithium powder placed in 100 m*l* of THF. A grey solution was obtained but a considerable amount of lithium was remained unreacted. After filtering through an L-shaped sidearm packed with glass wool into a dropping funnel, this solution was added to 22 g (0.2 mol) of trimethylchlorosilane quickly. No appreciable heat evolution was observed. After refluxing 6 hr and standing overnight, solvent and then products were removed from the mixture under reduced pressure. Gas-chromatographic examination of the products showed existence of octamethyltrisilane only in a very small amount. Redistillation of the products gave 11 g (0.042 mol 84% yield) of decamethyltetrasilane, bp 109°C (16 mmHg), $n_D^{20}=1.4893$, $d_4^{20}=0.8126$, $MR_D=92.41$ (calcd 92.43).

Reaction of Propylene with a Mixture of Iodine and Iodosobenzene or Phenyl Iodine Diacetate*[1]

Keizo Aoki and Yoshiro Ogata

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received December 28, 1967)

In our kinetic study of iodination by a mixture of iodine and peracetic acid, it has been postulated that acetyl hypoiodite, CH_3COOI, is a probable attacking species.[1] Recently, our further study has revealed that iodosobenzene or phenyl iodine diacetate is a more effective oxidizing agent than peracetic acid for iodinating aromatic compounds, but here again acetyl hypoiodite can be postulated as the attacking species[2]:

$$I_2 + PhI(OCOCH_3)_2 \rightarrow 2CH_3COOI + PhI \quad (1)$$

$$ArH + CH_3COOI \rightarrow ArI + CH_3COOH \quad (2)$$

The addition of the acetyl hypohalite formed by the reaction of silver acetate with elementary halogen to olefin has been called the "Prévost reaction."[3] Prévost products have also been observed in the reaction of cyclohexene[4] or propylene[5] with a mixture of iodine and peracetic acid, *e. g.*,

$$2CH_3CH{=}CH_2 + I_2 + CH_3CO_3H + CH_3CO_2H \rightarrow 2CH_3CH(OCOCH_3)CH_2I + H_2O \quad (3)$$

Therefore, we reacted olefin with a mixture of iodine and phenyl iodine diacetate or iodosobenzene.

The reaction of propylene with a mixture of iodine and phenyl iodine diacetate in a mixed solvent of acetic acid and ethyl ether at 21—27°C was found to give 1-iodo-2-acetoxypropane in a yield of 56%:

$$2CH_3CH{=}CH_2 + I_2 + PhI(OCOCH_3)_2 \rightarrow 2CH_3CH(OCOCH_3)CH_2I + PhI \quad (4)$$

Also, the reaction of propylene with a mixture of iodine and iodosobenzene in acetic acid-ethyl ether at 22—28°C was found to give a lower yield (37%) of 1-iodo-2-acetoxypropane:

$$2CH_3CH{=}CH_2 + I_2 + PhIO + 2CH_3CO_2H \rightarrow 2CH_3CH(OCOCH_3)CH_2I + PhI + H_2O \quad (5)$$

The reaction of propylene with a mixture of iodine and peracetic acid in a similar method gave 1-iodo-2-acetoxypropane in a 56% yield.

Although the reaction of phenyl iodine diacetate with olefin alone is known to give *vic*-diacetoxy alkane,[6] 1,2-diacetoxypropane was not detected in the present reaction products.

These results suggest that iodine is converted by phenyl iodine diacetate to acetyl hypoiodite, which then adds to propylene to give an iodoacetoxy compound.

Experimental

Materials. The iodobenzene was prepared by the reaction of benzene with a mixture of iodine and peracetic acid, bp 182—185°C.[1] The phenyl iodine diacetate was prepared by the peracetic acid oxidation of iodobenzene, mp 157—159°C (lit., mp 158°C[7] and 161.1—162.2°C[8]). The iodosobenzene was prepared from iodobenzene *via* iodobenzene dichloride.[9] Ethyl ether and iodine were reagent-grade. 99.5% acetic acid and 99.5% propylene were used. The peracetic acid solution was prepared by stirring acetic anhydride (407 g) drop by drop into a solution of 60% hydrogen peroxide (100 g) and concentrated sulfuric acid (1 m*l*) as a catalyst at 30—40°C over a period of 3 hr.[10] The 1,2-diacetoxypropane was prepared by the reaction of propylene and peracetic acid in a mixture of ether and acetic acid, bp 51—52°C/1.3 mmHg.[5]

Analysis of the Products. The infrared spectra were determined by a Perkin-Elmer Model 333 spectrophotometer. The products were analyzed by means of gas chromatography employing a Yanagimoto Model GCG 550 F apparatus equipped with a flame ionization detector operated with a 2 m×3 mm column packed with Apiezon grease L 15% on Celite 545 (80—100 mesh), using nitrogen as a carrier (18—12.5 m*l*/min) at 80—200°C (6°C/min); hydrogen flow rate 25 m*l*/min, injection temperature 255°C, detector temperature 250°C. The retention times of 1-iodo-2-acetoxypropane, iodobenzene, and 1,2-diacetoxypropane were 9.7, 12.5, and 7.1 min respectively.

Reaction of Propylene with a Mixture of Iodine and Phenyl Iodine Diacetate. Into a stirred ethereal solution (100 m*l*) of iodine (2.54 g, 0.01 mol), phenyl

iodine diacetate (3.22 g, 0.01 mol) was added. Propylene was passed into the solution, but apparently no reaction occurred, because phenyl iodine diacetate is virtually insoluble in ether. Therefore, acetic acid (50 m*l*) was added to the solution to dissolve it, and propylene was passed into the solution at 21—27°C over a period of 35 min. The mixture was then kept standing for additional 1 hr. Finally, the solution became transparent. The mixture was transferred into a separatory funnel containing ether (50 m*l*) and water (100 m*l*). The ether layer was washed three times with a 5% sodium hydroxide solution (each 50 m*l*) to remove the acetic acid, and finally washed with 5% sodium thiosulfate (50 m*l*) and dried over anhydrous sodium sulfate. The ether was evaporated under reduced pressure (42 mmHg) at 17°C. The residual liquid (4.01 g) was analyzed by gas chromatography in order to estimate the yields of 1-iodo-2-acetoxypropane (56% on the basis of the iodine) and iodobenzene (72% on the basis of the phenyl iodine diacetate). The infrared spectrum of the liquid is consistent with a binary mixture of the corresponding authentic samples. The absorption bands at 2970, 1740, 1370, 1240, 1023, and 600 cm^{-1} are characteristic of 1-iodo-2-acetoxypropane, and while those at 3050, 1570, 1470, 1440, 730, 685, and 655 cm^{-1} are characteristic of iodobenzene. Gas chromatography shows that the products do not contain 1,2-diacetoxypropane.

Reaction of Propylene with a Mixture of Iodine and Iodosobenzene. Iodosobenzene (2.20 g, 0.01 mol) was added to a stirred ethereal solution (100 m*l*) of iodine (2.54 g, 0.01 mol). The iodosobenzene was insoluble in ether. Acetic acid (50 m*l*) was then added to the mixture, and propylene was passed into the solution at 22 −28°C over a period of 30 min, and the mixture was left standing overnight. The solution gradually turned pale yellow and transparent, and some unreacted iodosobenzene settled at the bottom of the flask. The reaction mixture was then worked up as above, giving a residual liquid (2.89 g). The yields of 1-iodo-2-acetoxypropane (37%) and iodobenzene (60%) were estimated by gas chromatography.

Reaction of Propylene with a Mixture of Iodine and Peracetic Acid. Into a stirred ethereal solution (100 m*l*) of iodine (2.54 g, 0.01 mol) there was added, drop by drop, an acetic acid solution of 1.79 M peracetic acid (30 m*l*, 0.0537 mol). Propylene was passed into the solution at 16—25°C over a period of 110 min. The product was worked up as above, giving 1-iodo-2-acetoxypropane (2.56 g, 56%), bp 33.5—35.5°C/0.7—0.8 mmHg.[5] This was used as the authentic sample for the infrared spectrum study and for the gas chromatography.

Use of Anhydrous Hydrogen Fluoride in Peptide Synthesis. III. Synthesis of Bradykinin

Shumpei SAKAKIBARA, Nobuhiro NAKAMIZO*1 Yasuo KISHIDA and Shoko YOSHIMURA

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received December 30, 1967)

During repeated synthesis of bradykinin following a recently published procedure,[1] the final stage of removal of the nitro group from the nitroarginine residue by catalytic hydrogenolysis was found to be unsatisfactory; that is, the biological activity of the final product varied within a range of 100 to 60%, with the quality of the palladium black catalyst used, even though the same protected nona-peptide was subjected to each reaction. This variance in the biological activity of the product was probably due to the formation of some side products during the reduction of the nitro group, as pointed out for general cases by Iselin.[2] Furthermore, removal of the nitro group from large arginine peptides by catalytic hydrogenolysis is known to be a time-consuming reaction. Recently,[3,4] anhydrous hydrogen fluoride (HF) has been shown to be useful for removal of various protective groups from peptides, and it was noted especially that a nitro group can be removed quickly from nitroarginine peptides in the presence of anisole.[3-5] This procedure was applied in the present study for removal of protecting groups from a nonapeptide, tricarbobenzoxy-L-arginyl-L-prolyl-L-prolylglycyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-N^G-nitro-L-arginine benzyl ester (V). Synthesis of the starting material V was carried out following the original procedure[1] with several improvements as described in the experimental part of this paper. This material V was treated with HF at 0°C for 30 min in the

presence of anisole as described in a preceding paper.[4] The HF which contaminated the final reaction product was eliminated by passing the aqueous solution through a column of Dowex 1 (OH^- form). Then the HF free product was converted to the acetate form, and was lyophilized. If a faint pink color remained in the product, it will be removed easily by passing the aqueous solution through a short column of Sephadex G 10. The biological activities of three different batches of bradykinin acetate synthesized in this way were assayed by the contraction test with guinea-pig ileum,*2 and they were found to show essentially the same biological activity which was as strong as that of an available authentic sample.[6] The purity of bradykinin synthesized by the HF procedure was also compared with that of another sample which was synthesized by catalytic hydrogenolysis of the same protected nonapeptide V. Both samples were converted to the DNS-derivatives,[7] and were analyzed by thin-layer chromatography with Silica-gel H.*3 The chromatogram clearly indicated the great advantage of the HF method, as shown in Fig. 1. Thus, it was concluded that homogeneous bradykinin can be obtained easily by the present HF method without the use of any additional purification procedure, while catalytic hydrogenolysis of the nitroarginine peptide may result in contamination with undesirable compounds.

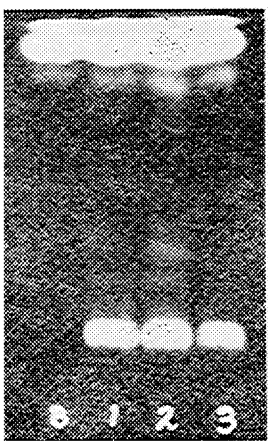

Fig. 1. Thin-layer chromatogram of DNS-bradykinin (10^{-8} mol) with Silica-gel H.
The solvent system was methyl acetate: isopropanol: 28% ammonia (9 : 7 : 4) containing mercaptoethanol (1%).
B: Control. 1: An available sample as the standard bradykinin. 2: Bradykinin synthesized by catalytic hydrogenolysis. 3: Bradykinin synthesized by the HF method.

Lenard and Robinson[8] have mentioned recently in a short communication that the HF method is also useful to release bradykinin from the Merrifield's polymer support. Although they reported the presence of four extra peaks in a distribution curve of their sample when it was analyzed by the counter current method, formation of such by-products did not occur on careful treatment of this peptide with HF.

Experimental

***t*-Amyloxycarbonyl-L-phenylalanyl-N^G-nitro-L-arginine Benzyl Ester (I).** This material was synthesized as described previously.[1] The melting point of the final product increased to 132—135°C on repeated recrystallization from ethyl acetate and petroleum ether; $[\alpha]_D^{24}$ −15.6° (*c* 3, ethanol), $[\alpha]_D^{26}$ −14,2° (*c* 1.6, pyridine). Cited values[1] were mp 120—124°C, $[\alpha]_D$ −15.8° (*c* 3, ethanol).

***p*-Methoxybenzyloxycarbonyl-L-prolyl-L-phenylalanyl-N^G-nitro-L-arginine Benzyl Ester (II).** The same procedure was followed for its synthesis as that described in the previous paper[1] for the preparation of *t*-amyloxycarbonyl-L-prolyl-L-phenylalanyl-N^G-nitro-L-arginine benzyl ester. *p*-Methoxybenzyloxycarbonyl-L-proline[9] was used instead of *t*-amyloxycarbonyl-L-proline. This *p*-methoxybenzyloxycarbonyl derivative was more easily crystallizable than the former *t*-amyloxycarbonyl compound. The yield of this compound after recrystallization from a mixture of methanol and chloroform by the addition of ether was 79%; mp 179—182°C, $[\alpha]_D^{26}$ −40.8° (*c* 1, dimethylformamide).

Found: C, 60.46; H, 6.30; N, 13.65%. Calcd for $C_{36}H_{43}O_9N_7$: C, 60.24; H, 6.04; N, 13.67%.

***t*-Amyloxycarbonyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-N^G-nitro-L-arginine Benzyl Ester (III).** This material was prepared as described in the previous paper,[1] but compound II was used instead of the *t*-amyloxycarbonyl derivative. Although the compound was reported to be an amorphous powder, it was crystallized in this case from hot ethyl acetate or methanol by the addition of ether; yield 80%, mp 175—177°C, $[\alpha]_D^{24}$ −37.1° (*c* 1, dimethylformamide). Reported value[1] mp 100—115°C, $[\alpha]_D^{22}$ −38.2° (*c* 0.5, dimethylformamide).

***t*-Amyloxycarbonyl-L-prolyl-L-prolylglycine *p*-Nitrophenyl Ester (IV).** Although this material was used without purification in the previous case,[1] it was crystallized in the present study by trituration with ether; the yield of crude product was 85%. The crude crystals were recrystallized from ethyl acetate and petroleum ether; yield 80%, mp 191—192°C, $[\alpha]_D^{19}$ −92.7° (*c* 1, dimethylformamide).

*2 The biological tests were performed by Professor Tomoji Suzuki of Osaka University and his colleagues, to whom the authors are deeply grateful.

6) Obtained from Sandoz AG., Basel, Switzerland, (Batch No. 65226, BRS 640) as 0.1 mg/ml solution.

Found: C, 57.11; H, 6.34; N, 11.10%. Calcd for $C_{24}H_{32}O_8N_4$: C, 57.13; H, 6.39; N, 11.11%.

Bradykinin Triacetate. A protected nonapeptide V (402 mg, 0.25 mmol), which was synthesized by following a previously published procedure[1] with compound III and IV, was placed in an HF-reaction cylinder together with anisole (0.28 m*l*, 10 eq).[3] HF (5 m*l*) was added into the cylinder using an HF-reaction apparatus,[3] and the mixture was allowed to react at 0°C for 30 min with stirring. Excess HF was removed under reduced pressure at 0°C, and the residue was kept at reduced pressure (3 mmHg) for 5 hr at room temperature. The product was dissolved in water (10 m*l*), insoluble material was removed by filtration with Hyflo Supercel, and the clear solution thus obtained was passed through a column of Dowex 1 (X 2, OH^- form, 1 cm × 15 cm). The column was washed with distilled water (about 100 m*l*) until the pH of the washing became 7. The eluate and washing were collected together in a receiver which contained acetic acid (0.5 mol), and the solution was lyophilized. After drying in a desiccator over phosphorus pentoxide *in vacuo* for 24 hr, the yield of the product was 257 mg (77% as triacetate pentahydrate); mp 170—171°C; $[\alpha]_D^{13}$ −80.6° (*c* 0.28, water).*4

Found: C, 50.45; H, 7.30; N, 16.26%. Calcd for $C_{50}H_{73}O_{11}N_{15}\cdot 3CH_3COOH\cdot 5H_2O$: C, 50.57; H, 7.15; N, 15.80%.

After drying this compound at 110°C for 18 hr *in vacuo*, the anhydrous compound was obtained.

Found: C, 54.34; H, 7.10; N, 17.73%. Calcd for $C_{50}H_{73}O_{11}N_{15}\cdot 3CH_3COOH$: C, 54.22; H, 6.91; N, 16.94%.

*4 The concentration was calculated as dry bradykinin triacetate.

Empirical Estimations of the Taft σ^*

Isao MOCHIDA and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 6, 1968)

In the previous paper,[1] the heats of formation of gaseous carbonium ions were well estimated by the group contribution method. In the present work, the estimation of the Taft σ^*[2] is tried by means of both group contribution method and quantum-chemical calculations with simple LCAO-MO. The Taft σ^* has been used as an empirical reactivity index to understand the reactivities in the heterogeneous catalysis,[3] as well as in liquid-phase organic reactions. The additivity of the σ^* was demonstrated by Taft,[4] and Leffler and Grunwald,[4a] hence the group contribution method should be applicable also for the extended estimation of the σ^*.

The reactivities of hydrocarbons have been extensively discussed with the simple LCAO-MO by Fukui.[5] On the other hand, many works have been reported concerning relations among σ, σ°, σ^+, and quantum chemical indexes.[6] In the present work, a correlation was also investigated between the Taft σ^* and $|C_r^N|$ determined by the simple LCAO-MO method for σ systems.[5]

Results and Discussion

Simple LCAO-MO Method. The absolute value of the coefficient, $|C_r^N|$, of a sp^3 hybridized orbital of an unpaired electron belonging to the non-bonding molecular orbital of an alkyl radical is reported to be correlated with the bond strength of R-H by Fukui *et al.*[7]: in their paper, the bond strength was given by $\Delta H_{C^+}(R_1)$, the enthalpy change in the hydride abstraction reaction from a paraffin, R_1H. The value of $\Delta H_{C^+}(R_1)$ has been suggested to have empirically a linear relation to σ^*.[3a] Thus, the value of σ^* may be correlated with the value of the above $|C_r^N|$ which is calculated by the simple LCAO-MO for σ electron systems.

The calculated values of $|C_r^N|$ are given in Table 1, where the values of Coulomb and resonance integrals were all taken from the paper by Fukui *et al.*,[7] and the calculation was carried out with a computation program named CHEMO-MO-2, which permits the chemical formula inputs.

a) From Ref. 2. b) By the group contribution method. c) By definition.

The correlation is very fine for alkyl groups whose σ^* values are known, as shown in Fig. 1. Thus, σ^* is empirically given by Eq. (1),

$$\sigma^* = -5.16 + 5.75|C_r^N|. \quad (1)$$

However, the correlation with groups containing π-electrons or heteroatoms is poor, some examples of which are also given in Fig. 1.

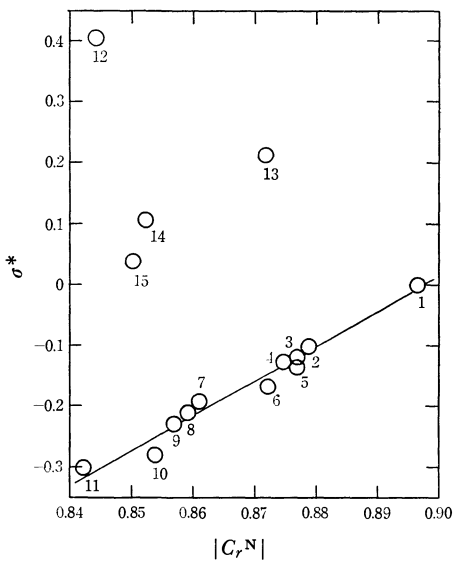

Fig. 1. A correlation between $|C_r^N|$ and σ^*. Numbers refer to Table 1.

Group Contribution Method. The principle of the group contribution method[1] for the calculation of σ^* is mathematically expressed by Eq. (2) with a methyl group as the base group,

$$\sigma^*(R) = \sigma^*(CH_3) + \sum n_i Z(X_i) \quad (2)$$

where $\sigma^*(R)$ is the Taft σ^* of a group R, $\sigma^*(CH_3)$ is that of a methyl group defined to be zero, $Z(X_i)$ is the group contribution of the part-structure to σ^*, and n_i is the number of the equivalent substitutions. The values of $Z(X_i)$ for three kinds of methyl substitutions are considered: primary,*1 next-adjacent secondary and two-next secondary.*2 These values together with those of primary phenyl and primary hydroxyl substitutions were obtained by the method of least-squares from seventeen σ^* values in Table 1. They are shown in Table 2, where primary phenyl and hydroxyl groups substitute the primary methyl group.

Table 2. Contribution of the substituting groups

	Contribution	St. error
CH_3		
Primary	−0.098	0.004
Next-adjacent secondary	−0.023	0.004
Two-next secondary[a]	−0.009	0.017
Primary phenyl[b]	0.297	0.007
Primary OH[b]	0.658	0.012

a) Calculated from $CH_3CH_2CH_2CH_2$ alone.
b) Substituting the primary methyl group.

*1 For the estimation of the heats of formation of carbonium ions (Ref. 1), primary methyl substitutions were classified into three kinds, however, here only a kind is considered for them.

*2 In C_4-C_3-C_2-C_1- of n-butyl group, C_1 is the base group, C_2 is primary, C_3 is next-adjacent secondary, and C_4 is two-next secondary.

The value for two-next secondary methyl group has a comparatively large standard error, which should be due to its estimation from only one value of $\sigma^*(CH_3CH_2CH_2CH_2)$. It may be, however, not so far from the true value, because the calculated σ^* of an isopentyl group agrees sufficiently with the one estimated in Fig. 1 from $|C_r^N|$ of an isopentyl radical.*3 The contribution of the farther than two-next should be zero, which is indicated by $|C_r^N|$ of *n*-pentyl and *n*-hexyl radicals.

The agreement of the calculated σ^* with the observed ones is satisfactory, except for $C_6H_5(CH_3CH_2)CH$. Thus, the σ^* values of homologous groups can be estimated by Eq. (2). The validity of the group contribution cannot be established for other part structures because σ^* was not observed upon many groups which have equivalent substitutions.

The attenuation of the inductive effect by methylene group has been discussed.[4,8] As regards σ^*, Taft gave 1/2.8 to methylene group as the attenuation factor for some functional groups.[4] In the present paper, it will be discussed on all available data, based on the group contribution concept. Because the σ^* values of the groups having fluorine, chlorine, phenyl, propenyl, and methoxyl substituents at the various locations are known, the contribution of the substituents can be calculated by using $Z(X_i)$ already obtained. An example of the calculation is shown by the case of $CF_3CH_2CH_2$,

$$\sigma^*(CF_3CH_2CH_2) = \sigma^*(CH_3) + Z(\text{primary } CH_3) + Z(\text{next-adjacent secondary } CH_3) + 3W(F)_3 \quad (3)$$

where the suffix 3 of $W(F)_3$ is the length of the carbon chain. Thus, the contribution of F attenuated by three methylenes, $W(F)_3$, can be calculated. The results of the calculations are shown in Fig. 2, where the abscissa is the carbon chain length, *m*. As for methyl groups, the *Z* values in Table 2 are used as the *W* values. In the cases of fluorine, chlorine, and methyl group, linear relations are obtained, which are formulated as following,

$$W(X_i)_m = W(X_i)_0 \exp(-2.3\, a(X_i) \cdot m) . \quad (4)$$

The slopes of these linear relations, $a(X_i)$, give the attenuation effects of the one carbon chain for each functional group. The slopes are all about 0.43. Thus, the contribution of the functional group is diminished to about 1/2.7 for each carbon chain. As for phenyl group, the value for unattenuated point is out of the line and the slope is distinctly different from the others.

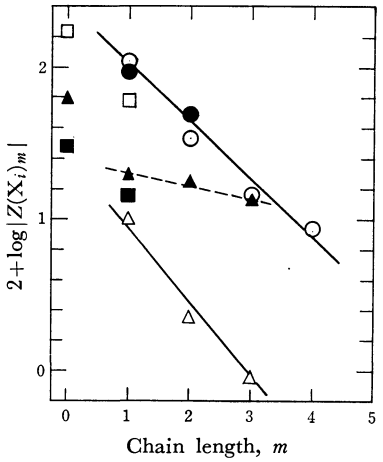

Fig. 2. The attenuation effect of methylene group for σ^*.

TABLE 3. THE σ^* VALUES OF X_i CH=CH GROUPS

Group (X_i CH=CH)	σ^*[a]	$W(X_i)_0$ or $\sigma^*(X_i)$
trans-$O_2NCH{=}CH$	1.70	3.73[b]
trans-$Cl_3CCH{=}CH$	1.188	2.65
trans-$HOOCCH{=}CH$	1.012	2.84[c]
$ClCH{=}CH$	0.900	2.84[d]
trans-$Cl_2CHCH{=}CH$	0.882	1.94
$CH_2{=}CH$	0.653	0.490
$C_6H_5CH{=}CH$	0.420	0.600
$CH_3CH{=}CH$	0.360	0

a) From Ref. 2.
b) Calculated from $O_2NCH_2CH_2$.
c) Calculated from $HOOCCH_2$.
d) Calculated from $ClCH_2$.

An attenuation effect of the CH=CH group is studied on eight σ^* values shown in Table 3. The values of $W(X_i)_0$ are the observed or calculated $\sigma^*(X_i)$ by Eq. (4), of which $a(X_i)$ of the methylene group for various X_i is assumed to be 0.43. The calculation of the attenuation is made by the following equation,

$$\sigma^*(X_iCH{=}CH) = \text{const.} + a_{CH=CH}\ W(X_i)_0 \quad (5)$$

where the const. is the contribution of the CH=CH group and $a_{CH=CH}$ is its attenuation effect. The value of $a_{CH=CH}$ is statistically calculated as 0.29 ± 0.05. This figure means that the attenuation effect of CH=CH is smaller in comparison with that of two methylene groups.

If the attenuation effect is generally described, the application of the group contribution method for σ^* may be extended further.

*3 −0.132 from the $|C_r^N|$ value of 0.8764 and −0.139 by the group contribution method.

Correlation of α-Asymmetric Carbon Atom of α-Methylglutaric Acid to Methyladipic Acid: a Correction

Ichiro KAWASAKI and Takeo KANEKO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 11, 1968)

Previously, Kaneko *et al.* reported that (−)-α-methyladipic acid is considered to have the S-configuration on the basis of its synthesis from (−)-α-methyl-γ-butyrolactone, which configuration was correlated with S(−)-methylsuccinic acid.[1] Recently, however, Turner *et al.* showed that (−)-α-methyladipic acid must have the R-configuration because R(−)-α-methylglutaric acid, R(+)-β-methyladipic acid and (−)-α-methyladipic acid were isolated from the oxidation products of cytochalasin A and B, metabolites of *Helminthosporium dematioideum*.[2]

In order to confirm the configuration by an unequivocal process, the stereochemical relation between methyladipic acid and α-methylglutaric acid, absolute configuration of which was already known,[3] was established directly by the Arndt-Eistert synthesis of optically active α- and β-methyladipic acid from the ester chloride of α-methylglutaric acid. Treatment of S(+)-α-methylglutaric anhydride with methanol and then with thionyl chloride afforded the methyl ester chloride, which gave diazoketones with the treatment of ethereal diazomethane. The diazoketones were rearranged with silver benzoate as a catalyst in methanol to give a mixture of α- and β-methyladipic ester, which were separated into (+)-α- and S(−)-β-methyladipic ester[4] by vapor phase chromatography.

It is evident, therefore, (−)-α-methyladipic acid should have R-configuration as pointed out by Turner *et al.* The incorrect assignment presented in our previous paper was probably due to the very small optical rotation of α-methyladipic acid, decreased by the racemization occurred at the condensation of optical active ethyl γ-chloro-α-methylbutyrate with diethyl malonate.

Experimental

S(+)-α-Methylglutaric Acid. This compound was obtained by the resolution with the aid of strychnine,[5] mp 81°C; $[\alpha]_D^{15}$ +22.3° (*c*, 5.38 in abs EtOH).

S(+)-α-Methylglutaric Anhydride. (+)-α-Methylglutaric acid (4.3 g) afforded 3.4 g of the anhydride (93%), bp 112—114°C/2 mmHg, mp 56°C.[5]

Methyl Hydrogen α-Methylglutarate. To the above anhydride (3.4 g) was added methanol (0.9 g). The solution was heated on the water bath for 30 min and then distilled at 93—103°C/1 mmHg to give 4.1 g of the half ester (94%).

Methyl Ester Chloride of α-Methylglutaric Acid. A mixture of above half ester (4.1 g) and thionyl chloride (12 m*l*) was warmed at 50°C for 30 min and then distilled at 110—114°C/20 mmHg to give 3.6 g of the ester chloride (79%).

Dimethyl Methyladipate. The ester chloride (3.6 g) was converted into the diazoketone by means of diazomethane in ether solution. After standing for 3 hr, excess diazomethane and ether was removed. The residue was dissolved in absolute methanol (30 m*l*) and a mixture of silver benzoate (0.5 g) and trimethylamine (4.5 m*l*) was added to the solution with stirring. After a gentle evolution of gas a vigorous reaction occurred. The mixture was heated under reflux for 30 min. The catalyst was then filtered off, and the filtrate was evaporated. After the residue was dissolved in ether, the solution was washed with sodium carbonate solution and dried. The solvent was removed and the residual oil was distilled at 65—73°C/0.1 mmHg; yield, 2.95 g (79% from the ester chloride).

Separation of α- and β-Methyladipic Ester. The mixture of above ester was separated into dimethyl α- and β-methyladipate by vapor phase chromatography in a Varian Aerograph Model A-700 using a column (3/8 inch × 20 ft aluminum column) packed with 20% carbowax 20 M on chromosorb W with a helium as carrier gas at 200°C.

First fraction gave dimethyl (+)-α-methyladipate which was identical with authentic specimen in IR spectra; $[\alpha]_D^{23}$ +13.5° (*c*, 1.48 in EtOH), NMR; 1.12 ppm (doublet J=7 cps). From which (+)-α-methyladipic acid was obtained by acid hydrolysis and recrystallised from benzene, mp 81—83°C; $[\alpha]_D^{23}$ +13.8° (*c*, 1.91 in EtOH).

Found: C, 52.62; H, 7.57%. Calcd for $C_7H_{12}O_4$: C, 52.49; H, 7.55%.

Second fraction gave dimethyl (−)-β-methyladipate which was identical with authentic specimen in IR spectra; $[\alpha]_D^{23}$ −2.5° (*c*, 1.18 in EtOH), NMR; 0.95 ppm (doublet J=6 cps). From which (−)-β-methyladipic acid was obtained by acid hydrolysis and recrystallised from benzene, mp 86—87°C; $[\alpha]_D^{23}$ −3.4° (*c*, 2.75 in EtOH).

Found: C, 52.60; H, 7.51%.

Reaction of *cis*-1,4-Hexadiene with Iron Pentacarbonyl

Jitsuo KIJI*1 and Masao IWAMOTO

Central Research Lab., Toyo Rayon Company, Ltd., Sonoyama, Otsu

(Received January 13, 1967)

Nonconjugated dienes, such as 1,4-pentadiene and 1,5-hexadiene, react with iron pentacarbonyl ($Fe(CO)_5$) to give diene-iron tricarbonyl complexes, in which the ligand is an isomeric conjugated hydrocarbon.[1] Recently, *cis*-1,4-hexadiene has been easily obtainable by the reaction of butadiene with ethylene using a cobalt catalyst.[2] It is of interest now to study the migration of double bonds and to compare the structure of the ligand with that of free diene. The present paper is concerned with the reaction of *cis*-1,4-hexadiene with $Fe(CO)_5$.

The reaction of this hydrocarbon with $Fe(CO)_5$ affords the *trans*-1,3-hexadiene-iron tricarbonyl complex (I), plus a small amount of the *trans,trans*-2,4-hexadiene complex(II). The reactions were carried out in a stainless steel autoclave. The results are summarized in Table 1, in which the results obtained by the reactions of 1,3-hexadiene and 2,4-hexadiene are also included. The results of the elemental analysis of the complex obtained from 1,4-hexadiene were as follows; Found: C, 49.3; H, 4.8%. Calcd for $C_9H_{10}FeO_3$ ($(C_6H_{10})Fe(CO)_3$):

Table 1. Reactions of hexadiene with $Fe(CO)_5$

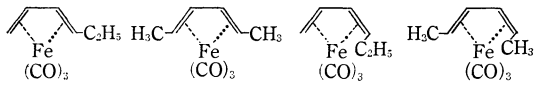
C, 48.6; H, 4.5%. The NMR spectrum is shown in Fig. 1. The multiplets centered at 5.1 and 0.2 ppm were assigned to the olefinic protons of I, and that at 5.0 ppm, to that of II.[3] The absence of the peaks in the 2—3 ppm range shows that the *cis*-1,3-hexadiene complex (III) and the *trans,cis*-2,4-hexadiene complex (IV) were not formed.



(I) (II) (III) (IV)

To examine the structure of the liganded dienes, an ethereal solution of the complex was treated with an excess 10% aqueous solution of ferric chloride at 0°C for 3 hr.[4] After it had been washed with water, the ethereal solution was gas-chromatographically analyzed. (Apiezon Grease L; column, 5 m; 100°C). *trans*-1,3-Hexadiene and *trans,trans*-2,4-hexadiene were detected (Table 1), with the former predominant. The reaction of $Fe(CO)_5$ with an isomeric mixture of 2,4-hexadiene (the *cis,trans*-isomer was predominant) gave II as the sole product.*2 The compositions of the hexadiene recovered as unreacted hydrocarbon are also shown in Table 1; it was indicative that 1,4-hexadiene was catalytically isomerized to the conjugated dienes with $Fe(CO)_5$. The fact that a considerable amount of *trans,trans*-2,4-hexadiene was found in both the unreacted dienes and the liganded dienes shows that *cis-trans* isomerization occurred during the reaction with $Fe(CO)_5$. The isomerization by $Fe(CO)_5$ proceeded so as to favor the end products lacking *cis*-substitutions, though the isomerization of *cis*-1,4-hexadiene with a carbanion (*e. g.*, $CH_3SOCH_2^-$ at 50°C) or a Ziegler catalyst (*e. g.*, $CoCl_2(DPE)_2$*3-Et_3Al, at 150°C) gave an isomeric mixture containing *trans, cis*-2,4-hexadiene as the main component.

SHORT COMMUNICATIONS

Transacylation from Acid Amides to Amines Catalyzed by Carbon Dioxide

Yoshio OTSUJI, Noboru MATSUMURA and Eiji IMOTO

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka

(Received January 18, 1968)

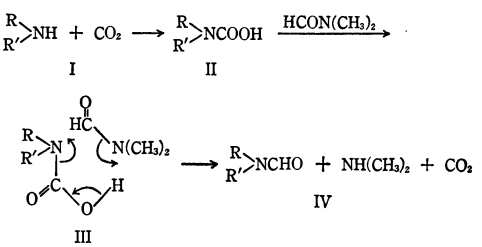
We wish to report our recent finding that certain acid amides undergo transacylation to amines when a mixture of the two compounds is simply heated in the presence of carbon dioxide.

A typical experiment for the transformylation from dimethylformamide (DMF) to amines was carried out as follows: a mixture of 10 g of *n*-butylamine in 50 m*l* of DMF was warmed at 60°C for 5 hr under a stream of dry carbon dioxide, and then the solvent, DMF, was evaporated under reduced pressure. The distillation of the residue gave 6.4 g (46%) of *N*-butylformamide, bp 107—109°C/3 mmHg. A similar transformylation from DMF was observed in *n*-tetradecylamine (66%), piperidine (48%), and morpholine (67%), giving the corresponding *N*-formyl derivatives in the yields indicated in the parentheses. These reactions did not occur in the absence of carbon dioxide. Aromatic amines such as aniline and tertiary amines such as pyridine were not formylated by this method.

Transacylation from acetamide or cyanoacetamide to amines was also attempted by heating a mixture of the amide and amine in dioxane under a stream of carbon dioxide. The transcyanoacetylation from cyanoacetamide took place in both *n*-hexadecylamine and *n*-hexylamine, giving *N*-*n*-hexadecylcyanoacetamide (63%) and *N*-*n*-hexylcyanoacetamide (37%) respectively. On the other hand, the transacetylation from acetamide took place only in *n*-hexadecylamine, giving *N*-*n*-hexadecylacetamide (6%).*1 The attempt at transacetylation from *N*,*N*-dimethylacetamide to amines was unsuccessful.

These results indicate that the reactivity of the amides for transacylation to amines decreases in the order: DMF>cyanoacetamide>acetamide>*N*,*N*-dimethylacetamide. This order of reactivity would seem to show that the ability of the amides to transacylate decreases with a decrease in the positive charge on the carbonyl carbon atom of the amides.

All of the results presented here might be explained in terms of the following mechanism:



R: alkyl, R: alkyl or H

The amine (I) reacts with carbon dioxide to produce the corresponding carbamic acid (II), which itself subsequently reacts with DMF to form an intermediate (III). This intermediate III spontaneously collapses to the product (IV), ejecting carbon dioxide and dimethylamine. At this stage of the reaction the nucleophilic reactivity of the amine may be enhanced to some extent, because the temporary formation of an amide ion would be expected at the moment of the elimination of carbon dioxide and a proton which is taken up by the amino nitrogen of formamide.

A similar mechanism would operate in the other transacylation reactions. It is interesting to point out that carbon dioxide, which is an inert gas, might be able to play an important role in some chemical reactions such as those reported in this communication. In this connection, it is also noteworthy that carbon disulfide acts as an effective dehydrating reagent in the formation of pyrophosphates from phosphates.[2]

*1 The long-chain aliphatic amines such as *n*-hexadecylamine are known to react readily with carbon dioxide to form the stable carbamic acid.[1] This seems to be a reason for the relatively high reactivity for the transacylation from acid amides to *n*-hexadecylamine.

A Simple Electron Source for Impact Experiments

Kogoro MAEDA

Electrotechnical Laboratory, Tanashi P.O., Tokyo

(Received January 23, 1968)

A narrow energy width is necessary in the bombarding electron beam to derive useful information on the energy levels of a molecule from the ionization efficiency curve, and several techniques were proposed for the purpose. Amongst them the RPD method by Fox[1] and the electrostatic filter utilized first by Clarke[2] have been used widely in many laboratories. But the methods require some expensive and delicate devices, and they are sometimes not practical.

A hair-pin type filament is proposed for the purpose in the present note. A tungsten filament of 0.125 mm in dia. had a V shape with an angle about 60° and a tiny slice of the same metal was tipped at its point. The ion source was simply composed of the tungsten filament and a gold-plated cylindrical cage (8.5 mm dia. and 15 mm length) with an electron entrance aperture (1 mm dia.) and a trap at each side. No other electrode was used to narrow the energy spread it the electron beam. Ions produced by the beam were extracted through the system of electrodes of extractor and field adjuster around the cage, and then introduced to an analyzer after collimation by an intermediate electrode. Mass analysis of the ions was made by a quadrupole mass filter, which corresponds to no usage of auxiliary magnet for the bombarding electron collimation.

Samples used for the test were rare gases, Ne, Ar, Kr and Xe, and two hydrocarbons, CH_4 and C_2H_4. The sample was introduced at a pressure of $(3—6)\times10^{-5}$ Torr into the system, and intensity of the bombarding electron beam was set at about $(1—2)\times10^{-8}$ A. Ion current of the order of $10^{-12}—10^{-14}$ A was obtained at about 1V above the ionization potential with a multiplier in the mass filter system.

The results obtained in the efficiency curves are all in good agreement with those of the RPD or other methods. In the case of Kr, distinct changes in the slope of the curve are observed, which probably correspond to the states $^2P^\circ_{3/2}$ and $^2P^\circ_{1/2}$[3] (see Fig. 1). At least three breaks were also observed for CH_4^+ in the case of methane, at

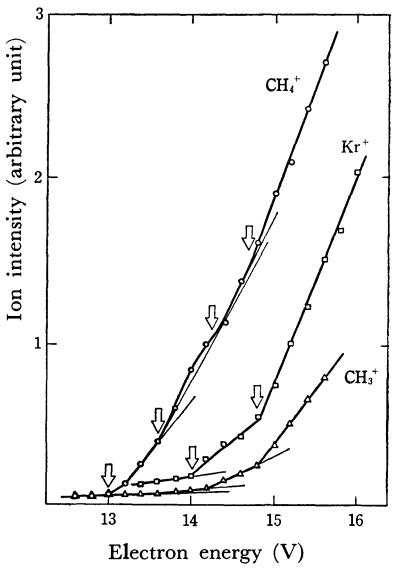

Fig. 1. Ionization efficiency curves for Kr^+ and for CH_4^+ and CH_3^+ from methane.
Sample pressure: $5—6\times10^{-5}$ Torr
Bombarding current: $1.5—2\times10^{-8}$ A.

0.6 V, 1.2 V, and 1.7 V above the ionization threshold. The result is also shown in Fig. 1, together with the results of CH_3^+. These features in the curves are almost the same with the results by the RPD method.[4] Ethylene also gave the same results with the RPD method, *i.e.*, breaks were found at 0.6 V, 1.2 V and 2.0 V above the ionization potential[4], and the difference of the appearance potentials of $C_2H_2^+$ and $C_2H_3^+$ was observed with a value about 0.4 V.

The obtained results show the present simple method is sufficiently good for obtaining the ionization efficiency curve with some structure. It might not be applicable for precise experiments, but practical enough compared with the RPD method because it requires no complicated electronic circuit and no delicate operation, nevertheless gives the adequate resolution. The width of the electron energy is now under measurement and details of the experiments will be presented in subsequent publications.

Lateral Nitroxylation of Penta-alkylbenzenes

Hitomi SUZUKI, Kiyomi NAKAMURA and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received January 25, 1968)

Nitrations of pentamethylbenzene have been reported to yield either nitropentamethylbenzene (I) or dinitroprehnitene (II).[1] However, the products were found not to be as simple as had generally been thought. Nitrations carried out at -10—$+5$°C by fuming nitric acid ($d=1.50$) in a variety of solvents, always gave, besides I, an appreciable amount of a non-crystallizable, syrupy substance, which, by careful chromatographic treatment on silica gel using light petroleum and benzene as eluants, could be separated into several side-chain substituted products. The main component (III) recrystallized from light petroleum melted at 45—46°C (Found: C, 63.06; H, 7.41; N, 6.69%. Calcd for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%) and showed strong infrared bands (in Nujol) at 1270 and 1636 cm^{-1} ($-ONO_2$); PMR peaks (in CCl_4) at 7.82 (2 CH_3), 7.77 (2 CH_3), 4.64 (CH_2) and 3.05 τ (aromatic H). The mixed acid converted III into II, so it was identified as 2,3,4,5-tetramethylbenzyl nitrate, the structure of which was further confirmed by synthesis from prehnitene through chloromethylation and by the subsequent treatment of the chloride with silver nitrate in acetonitrile. The other products were 2,3,4,5-tetramethylbenzyl alcohol, mp 81—82°C (Found: C, 79.76; H, 9.89%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%), probably formed by the hydrolysis of III; 6-nitro-2,3,4,5-tetramethylbenzyl nitrate, mp 100—101°C (Found: C, 52.03; H, 5.83; N, 10.94%. Calcd for $C_{11}H_{14}N_2O_5$: C, 51.96; H, 5.55; N, 11.02%), and 2,3,4,5-tetramethylbenzaldehyde (semicarbazone, mp 209—210 and 235—242°C*[1]; Found: C, 65.51; H, 7.88%. Calcd for $C_{12}H_{17}N_3O$: C, 65.72; H, 7.81%). The preferential attack by nitric acid on the side-chain rather than on the nuclear position becomes predominant with an increase in crowding around the ring. Thus, a similar treatment of pentaethylbenzene with fuming nitric acid gave a syrup, nearly half of which was found by means of a study of its PMR spectra to be composed of a nitrate. The chromatography of the syrup gave impure nitropentaethylbenzene (mp 86—90°C), a vinyltetraethylbenzene (IV), α-methyl-2,3,4,5-tetraethylbenzyl alcohol (mp 49—62°C), and a trace of a carbonyl compound. The last three compounds were doubtless the decomposition products of the unstable nitrate. The main product (IV), bp 103—104°C/2.5 mmHg (Found: C, 88.99; H, 11.22%. Calcd for $C_{16}H_{24}$: C, 88.82; H, 11.18%), had infrared bands at 888 (isolated ring H), 905, 989 and 1624 cm^{-1} ($-CH=CH_2$); PMR peaks at 8.69—9.02 (4 CH_3), 7.15—7.60 (4 CH_2), 4.83, 4.48 and 2.97 ($-CH=CH_2$; $J_{trans}=17.8$ cps; $J_{cis}=11.0$ cps; $J_{gem}=1.8$ cps), and 2.87 τ (aromatic H). Its structure was proved to be 2,3,4,5-tetraethylvinylbenzene by comparison with an authentic specimen prepared from 2,3,4,5-tetraethylacetophenone through the lithium aluminum hydride reduction and subsequent dehydration of the alcohol. This result differs from the earlier findings that the nitration of pentaethylbenzene mainly yielded *p*-dinitrotetraethylbenzene,[2] although the use of the mixed acid partly confirmed the latter results. The amounts of nitrous acid formed roughly paralleled the degree of side-chain substitution. Other mixed penta-alkylbenzenes were found to behave similarly.

The anomalous substitution may be explained by a process similar to that postulated for the side-chain chlorination of hexamethylbenzene;[3] *i. e.*, a process involving the initial attack of the nitronium ion on the open place of the ring, followed by the hyperconjugative release of a proton from the neighboring methyl group and the rearrangement of the unstable intermediate (V) to the benzyl nitrite, which may then further be transformed into the nitrate or decomposed into the aldehyde.[4]

On the Phase Transitions of 1,2-Dibromo-1,1,2,2-tetrachloroethane

Tsutomu KOIDE, Yoshihiko SAWAMURA and Tsutomu ODA

Laboratory of Physical Chemistry, the Osaka Kyoiku University, Tennoji, Osaka

(Received March 4, 1968)

The three solid phases of C_2Cl_6 have been well studied from the standpoint of crystal structure and molecular motion by the methods of X-ray diffraction,[1] heat capacity measurement,[2] nuclear quadrupole resonance,[3] *etc.* Similar studies have also been reported in the case of C_2Br_6.[4]

For the case of $BrCl_2C\text{-}CCl_2Br$, the interest is not only in the polymorphism[5] but in the isomerism between trans- and gauche-forms of the molecule in the solid state. From such standpoint, the polymorphism and the crystal structure are studied and the results will be described in this paper.

The material was prepared by bromination of tetrachloroethylene with bromine under the sun light.[6] Crude crystals were recrystallized three times from ethyl alcohol and sublimed twice at about 10^{-2} mmHg at about 50°C. The crystals melt at about 200°C in a sealed tube with decomposition.

A differential thermal analysis examination between about −190°C and about 230°C showed three phase transitions at 75, 101, and 108°C on heating. However, in the cooling direction transition occurred at 59, 99, and 105°C, indicating at large thermal hysteresis with regard to the lowest transition. The rate of temperature change was controlled to be at about 1/4 degree per minute.

The sample began to melt at about 200°C with decomposition, and the color of free bromine was observed.

The transition at 101°C was not reported by Gossner,[5] who described only two transitions at 80°C and at 108—109°C under a polarized microscope. Two transition temperatures, 75 and 108°C, agree with his optical results. Our reexamination of Gossner's experiment revealed that the transition at 101°C caused no detectable change in the optical properties, this explains the apparent discrepancy in the number of solid phase transitions reported. The solid phase above 108°C is optically isotropic.

The existence of these four solid phases was acertained also by X-ray diffraction method with powder samples.

The X-ray diffraction pattern of the phase above 108°C was consistent with a body-centered cubic lattice, the unit cell having a dimention of 7.7 Å at 130°C and containing two molecules (d_{cal}= 2.34 g/cc). This result suggests that the molecules undergo molecular rotation about the lattice points, taking the statistically high symmetry.

The lowest solid phase (IV), below 75°C, is orthorhombic with the crystal parameters a= 11.81, b=10.25, and c=6.51 Å, and these values are in accordance with the results given by Yardley.[7] The phase (III) in the temperature range of 75—101°C is of lower symmetry, possibly triclinic. The phase II between 101 and 108°C resembles the phase III but is different from the other three.

The crystal structure below 75°C will be studied in detail in future using single crystals.

An ESR Study of the Oxidation-Reduction Reaction of Piperidine with a Copper(II) Bis-dithiocabamate Complex

Hiroshi YOKOI and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received March 14, 1968)

Copper(II) ion, some copper(II) complexes and some copper proteins are known to undergo oxidation-reduction reactions with various organic compounds.[1] When piperidine is added to a solution of copper(II) bis-*N,N*-dialkyldithiocarbamate complex, the deep greenish-brown color of the complex in the solution disappears gradually. This is thought to bo due to the reduction of copper(II) ion to copper(I) ion in the complex by the strongly basic secondary amine, piperidine. The purpose of this work is to investigate the mechanism of the above oxidation-reduction reaction by detecting the unstable free radicals produced during reaction by an ESR technique. The ESR spectra were measured in solution below −70°C with a Hitachi K-band ESR spectrometer. The sample solution was a mixture of 1 vol of piperidine and 9 vol of 10^{-2}—10^{-3} M toluene solution of copper(II) bis-*N,N*-diethyldithiocarbamate complex. The ESR spectra obtained are shown in Figs. 1 and 2.

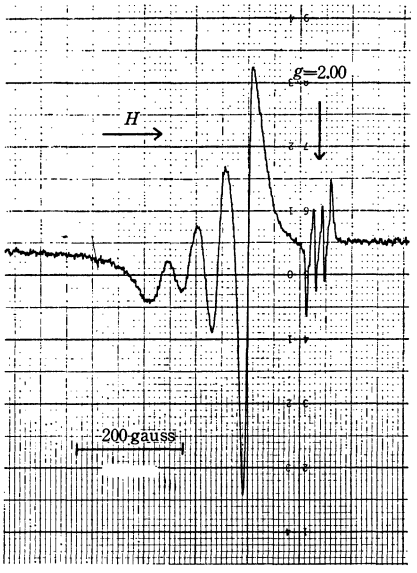

Fig. 1. The ESR spectrum (first derivative, 23808 Mc/s, at about −80°C) of the reaction mixture of piperidine and copper(II) bis-*N,N*-diethyldithiocarbamate in toluene.

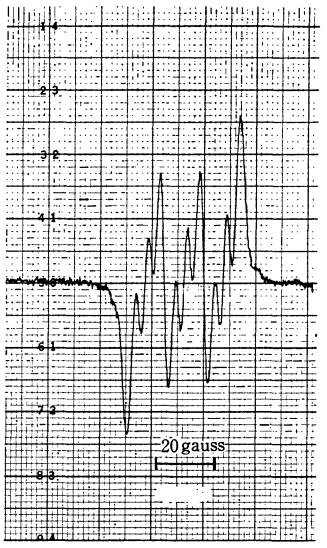

Fig. 2. The enlarged ESR spectrum of the free radical observed in the high field part of the spectrum in Fig. 1.

The ESR spectrum shown in Fig. 2 indicates that the spectrum was due to a free radical, and was composed of two triplets with intensity ratios of 1 : 1 : 1, whose hyperfine splitting constants were 17.6 gauss and 5.4 gauss. It is certain that the nitrogen of piperidine accounts for at least one of the triplets, and, therefore, that the initial step of the oxidation-reduction reaction is an electron transfer from the nitrogen lone pair of piperidine to the copper(II) complex. However, a definite conclusion on the structure of the free radical produced can not be safely drawn at this stage. The problem of investigating the mechanism of this type of oxidation-reduction reaction is very important from the standpoint of organic reactions, coordination chemistry and biochemistry. Interestingly, pyrrolidine and 2-methylpiperidine were also found to undergo a reaction similar to piperidine, but the ESR signals of their free radicals could not be so clearly detected.

Details, together with optical absorption spectral data, will be published elsewhere.

Red Chemiluminescence of Pyrene

Mizuka SANO and Fukuji EGUSA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 26, 1968)

Light emission has been reported to occur by the reaction of aromatic hydrocarbon radical anions with various oxidants.[1,2] The emission thus produced has been interpreted as resulting from the formation of an excited singlet, since the spectrum of the emission corresponds to the normal fluorescence of the parent hydrocarbons. The electrical generation of a triplet has also been indicated for the explanation of a delayed electroluminescence in anthracene crystals,[3] and of a green emission from phenanthrene in solution.[4] We wish to report here the observation of a red emission, together with a blue emission during direct-current electrolysis of a solution of pyrene at room temperature.

Two platinum-wire electrodes separated from each other by about 1 cm were immersed into a 10^{-3} M solution of pyrene in anhydrous dimethylformamide, which included 10^{-3} M tetraethylammonium bromide as supporting electrolyte. When a direct-current voltage of about 7.5 V was switched on, a blue emission was detected on the electrode surface with negative polarity. The emission had extremely short duration, and then changed its color to red under the constant current passage. The blue emission was dim, but it was visually identified as the fluorescence of pyrene.

The red emission, on the other hand, was clearly visible in a dimly-lit room, and occurred continuously with a constant brightness as long as the constant current passed through. At the same time gas was evolved from a cathode, and the emitting species diffused upwards along streams of gas. When the applied voltage was turned off, the evolution of gas stopped immediately, but the emission continued to occur in a solution for more than 5 sec.

Pyrene is essential for the red emission because no red emission was observed at the same current when only supporting electrolyte and solvent were used, or when phenanthrene, perylene, *p*-quarterphenyl, 9,10-diphenylanthracene, or rubrene was used in place of pyrene. The possibility that the emission originated from a singlet state of dissolved oxygen was ruled out by the observation of the same emission from a carefully deoxygenated solution. The emission from oxygen, *e. g.*, the emission produced by the reaction of hydrogen peroxide with sodium hypochlorite in aqueous solution shows a different tint. The red emission was also observed by employing tetraethylammonium iodide or tetra-*n*-butylammonium bromide as supporting electrolyte. The applied voltage was far beyond the decomposition potentials of dimethylformamide and of supporting electrolyte, so that carbon monoxide would be evolved from a cathode,[5] and some kind of oxidant would be generated at an anode.

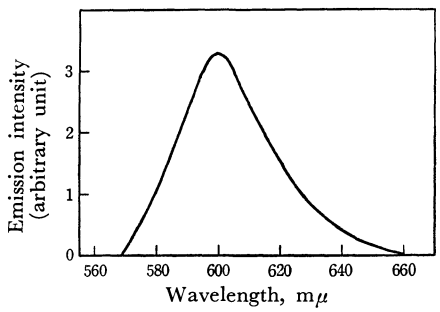

Fig. 1. Chemiluminescence spectrum of pyrene in dimethylformamide.

As shown in Fig. 1, the spectrum of the red emission recorded with a spectrophotometer was found to range from 570 to 660 mμ with a maximum around 600 mμ. This corresponds to the emission range of pyrene phosphorescence in rigid glass reported by Hochstrasser.[6]

From these observations, it is concluded that the red emission was derived from a pyrene molecule in a triplet state, resulting from the reaction of an electro-generated pyrene anion with an electrochemically generated oxidant.

Oxidation of Halomagnesium *sec*-Alkoxides to Ketones

Teruaki MUKAIYAMA, Katsuji TAKAHASHI and Isao KUWAJIMA

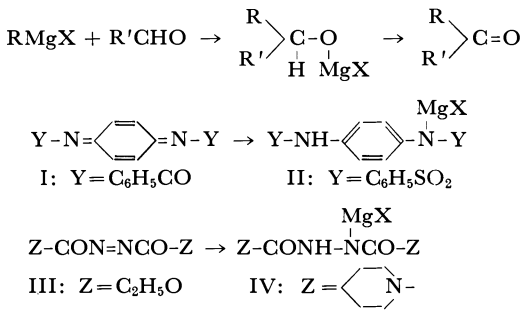
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 1, 1968)

It is well known that alcohols are oxidized by carbonyl compounds such as acetone and cyclohexanone, in the presence of alminum alkoxide (Oppenauer Reaction).[1] It is expected from the above fact that aldehydes will be converted into ketones by oxidation of halomagnesium alkoxides, obtained from the reaction of aldehydes and Grignard reagents, with suitable dehydrogenating reagents.

This communication reports oxidation of halomagnesium alkoxides by the use of various dehydrogenating reagents such as *p*-quinone dibenzimide (I), *p*-quinone dibenzenesulfonimide (II), diethyl azodicarboxylate (III) and azodicarbonpiperidide (IV). When an equimolar amount of I in benzene was added dropwise to an ethereal solution of magnesium alkoxide, resulted by the reaction of phenylmagnesium bromide and benzaldehyde, at room temperature, bromomagnesium salt of *p*-phenylene dibenzamide deposited soon. The corresponding ketone, benzophenone, was produced in 58% yield after the reaction mixture was heated at 60—65°C for 1 hr. In a similar manner, bromomagnesium salts of 1-phenylpentanol and 1-phenyl-1-penten-3-ol, prepared by Grignard reaction, were converted into the corresponding aralkyl ketones. In the case of aliphatic alkoxide, however, the yield of the ketone was low and a large amount of tarry product resulted. For example, 3-octanone was produced in only 29% yield by treating the corresponding bromomagnesium alkoxide in benzene at 60—65°C for 3 hr.

Similar results were observed when bromomagnesium alkoxides were treated with II; the corresponding aromatic ketones were produced in fairly good yields, however, in the case of aliphatic ketone, the yield was comparatively low.



Next, it was found that aliphatic ketones were successfully prepared by treating the halomagnesium alkoxides with III, known to be a strong hydrogen abstracting reagent.[2] Treatment of butylmagnesium bromide with butyraldehyde, followed by the addition of diethyl azodicarboxylate under ice-cooling gave a brownish precipitate immediately. After keepting the reaction mixture to stand overnight at room temperature, 3-octanone was obtained in 66% yield. Similarly, 7-methyl-4-octanone, benzophenone and valerophenone were obtained in fairly good yields by treating the corresponding bromomagnesium alkoxide with the azo compound.

Furthermore, it was established that IV is also an effective dehydrogenating reagent in this type of reaction (see Table 1.)

Thus it can he noted that this procedure is a useful method for converting aldehydes to ketones *via* a Grignard route without isolating the intermediate alcohols.

Novel Dicyano Complexes of Cobalt(III)

Hiroaki NISHIKAWA, Kazuo KONYA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa

(Received April 8, 1968)

Mixed cyano complexes of cobalt(III) have been synthesized by the use of particular methods,[1] and it has been recognized that the reactions of familiar complexes of cobalt(III), such as those of the luteo or praseo type, with cyanides in an aqueous solution are usually unsuccessful when used for the synthesis of such mixed cyano complexes.

We have found a new method of preparing several mixed cyano complexes in which suitable complexes of cobalt(III) are treated with a suitable cyanide near 0°C in cold solvents containing activated charcoal. Here we wish to report the synthesis of $K[Co(CN)_2(acac)_2]$ (I) from tris(acetylacetonato)cobalt(III) in methanol by this new method, and also the synthesis of $[Co(CN)_2(acac)(P\phi_3)_2]$ (II) from (I) and $P\phi_3$. We have also studied the preparation of cobalt(III) complexes of cyanoammine or cyanodiamine series in an aqueous solution[2] by this method.

The treatment of a slurry of $Co(acac)_3$ in methanol with the calculated amount of powdered KCN in the presence of activated charcoal at −5—0°C for 4 hr gave a dark red solution. After the filtration and concentration of the reaction mixture at about 5°C, the concentrate was chromatographed on an alumina column in order to separate the (I) from the other substances. By the use of a methanol-ethanol mixture (2 : 1) as the eluant, several fractions were obtained.*1 From the third fraction, red crystals of (I) were obtained in a 20% yield; they were recrystallized from a solution of potassium acetylacetonate in a mixture of methanol and ethanol (3 : 1). Elemental analysis was undertaken after the substance had been dried for several hours in a vacuum at room temperature. Found: C, 41.09; H, 4.22; N, 7.76%. Calcd for $C_{12}H_{14}O_4N_2KCo$: C, 41.38; H, 4.05; N, 8.04%.

The complex I reacted readily with an excess of triphenylphosphine in boiling ethanol for one hour. After the evaporation of the solvent, the residue was extracted with small portions of boiling benzene and separated on an alumina column, using a mixture of benzene and acetone (5 : 1) as the eluant. From the second fraction*2 orange crystals of II were obtained. Found: C, 69.86; H, 5.45; N, 3.75%. Calcd for $C_{43}H_{37}O_2N_2P_2Co$: C, 70.30; H, 5.08; N, 3.81%.

The complexes I and II, having $Co(C)_2(O)_4$ and $Co(C)_2(O)_2(P)_2$ configurations respectively, are the first examples of compounds with such configurations. The IR spectra of I and II show sharp peaks at 2130 and 2100 cm^{-1} respectively, and strong peaks in the 1500—1600 cm^{-1} region, indicating the presences of the CN^- and the acetylacetonate groups. The PMR spectrum of (I) in CD_3OD shows that methyl protons of acetylacetone ions are not equivalent, exhibiting two sharp peaks (at 7.79 and 8.06 ppm) with the same intensity. This suggests the *cis*-configuration of the bisacetylacetonato complex.[3] The UV spectrum of (I) shows two absorption components at 57×10^{13} sec^{-1} ($\log\varepsilon$: 1.97) and *ca.* 70×10^{13} sec^{-1} ($\log\varepsilon$: *ca.* 2.45), while no component appears to be spin allowed in the longer-wavelength region. These features will be discussed in detail later. The PMR spectrum of II in $CDCl_3$ shows only one sharp peak of the CH_3 group, at 8.94 ppm. This suggests that the complex has the *trans*(C) or the *trans*-(P) configuration. The UV spectrum of II in dichloromethane shows a large absorption band with a distinct maximum in the visible region (at 63×10^{13} sec^{-1}, $\log\varepsilon$ 3.58, half width: 12×10^{13} sec^{-1}). No known triphenylphosphine complexes of cobalt(III) belonging to the Werner type have ever shown such a distinct maximum but only vague shoulders in the region of the ligand-field bands. The absorption data on II may be also useful for the determination of the position of the $P\phi_3$ molecule in the spectrochemical series. The complex I reacts readily with other phosphine derivatives; the detailed results will be reported elsewhere.

A New Bromoallene Alcohol. Its Isolation and Reaction

Fumio TODA, Takao KOMODA and Katsuhiko AKAGI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama

(Received April 15, 1968)

It has been postulated[1] that bromoallene alcohol II is an intermediate in the reaction of 1,1,4,4-tetraphenylbut-2-yne-1,4-diol (I) and phosphorus tribromide in acetic acid to give 2,2,5,5-tetraphenyl-3-bromodihydrofuran (IV) and 1,10,10-triphenylbenzofulvene (VI). We now wish to report the isolation and some reactions of a new bromoallene alcohol II.

The treatment of I with phosphorus tribromide in acetic acid at 0°C, followed by immediate decompostion with water, afforded 1,1,4,4-tetraphenyl-2-bromobuta-2,3-diene-1-ol (II) in a 35% yield, as colorless prisms (from ethyl acetate), mp 118.5—119.5°C. Found: C, 73.87; H, 4.37%; mol wt (Rast), 431. Calcd for $C_{28}H_{21}BrO$: C, 74.17; H, 4.64%; mol wt, 453. NMR: in $CDCl_3$, 2.75 (multiplet, 20 H) and 3.25 τ (singlet, 1H). UV: $\lambda_{max}^{dioxane}$, 290 mμ (ε, 27100). The UV spectrum was comparable to that of 1,1-diphenyl-3-bromopropadiene,[2] $\lambda_{max}^{dioxane}$, 280 mμ (ε, 21700). IR: 2.20×10^{-3} mol in 1 *l*. CCl_4, 3566 (νOH) and 1947 cm^{-1} (νC=C=C). The νOH band, at a lower frequencies than that of a usual *t*-alcohol, *ca.* 3620 cm^{-1},[3] shows the presence of intramolecular hydrogen-bonding, even though it is not clear whether allene or bromine is the electron-donating site.

The treatment of II in acetone with catalytic amounts of hydrobromic acid at room temperature for a few minutes gave IV[1] in a 53% yield. The reaction can be explained by the protonation of allene, followed by cyclization and deprotonation.

The action of equimolar amounts of phosphorus tribromide on II in acetic acid at room temperature for 30 min afforded IV and VI[1] in 14 and 80% yields respectively. Since the cyclization of tetraphenylbutatriene (V) to VI in acidic media has been well known,[4] the reaction leading to VI can be explained by assuming the formation of V as an intermediate. The transformation of II into V may be a similar reaction mode to that of I and phosphorus tribromide to give V.[5]

The treatment of II in acetone with catalytic amounts of conc. sulfuric acid at 50°C for a few minutes gave VIII in a quantitative yield, as red prisms, mp 160—161°C. Found: C, 77.20; H, 4.07%; mol wt (Rast), 420. Calcd for $C_{28}H_{19}Br$: C, 77.24; H, 4.37%; mol wt, 435. UV: $\lambda_{max}^{dioxane}$, 252 (24100), 295 (sh) (10600) and 368 mμ (ε, 14500). The UV spectrum was comparable to that of the chloro-analog of VIII.[6] The for mation of VIII may be explained by the intramolecular cyclization of the cation, VII, produced by the dehydroxylation of II.

A New Route to Iodomethyl-substituted Methylpolysilanes[1]

Hideki SAKURAI, Mitsuo KIRA and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 17, 1968)

In a previous communication,[2] we have described a new method of preparing methylthiomethyl-substituted silanes using a novel methylthiomethyl Grignard reagent. We wish to report the reaction of these methylthiomethylsilanes with methyl iodide leading to iodomethyl-substituted silanes.

(Methylthiomethyl)pentamethyldisilane (I) gave an expected sulfonium salt, $(Me_2S^+CH_2Si_2Me_5)\,I^-$, mp 98.5°C, when I was treated with methyl iodide in ether solution at room temperature. However, when I was refluxed in benzene with an excess amount of methyl iodide, (iodomethyl)-pentamethyl disilane, bp 79.5—80.0°C/17 mmHg, was obtained in 73.3% yield together with trimethylsulfonium iodide.

$$(CH_3)_3SiSi(CH_3)_2CH_2SCH_3 + CH_3I$$
$$\leftrightarrows [(CH_3)_3SiSi(CH_3)_2CH_2S^+(CH_3)_2]I^-$$
$$\rightleftarrows (CH_3)_3SiSi(CH_3)_2CH_2I + (CH_3)_2S$$
$$(CH_3)_2S + CH_3I \rightarrow [(CH_3)_3S^+]I^-$$

Many procedures for preparing carbon-functional silanes such as halogenations or other reactions with electrophiles[3] cannot be extended generally to higher polysilanes because of extensive silicon-silicon bond cleavage. Alternatively, nucleophilic substitutions on a silicon atom would be a preferred route to the carbon-functional organopolysilanes.[4] Therefore, the present procedure, methylthiomethylation of chlorosilanes followed by conversion to iodomethylsilanes, may be of value to open a new route to the iodomethyl-substituted silanes.

As another example was prepared 1,2-bis(iodomethyl)tetramethyldisilane, bp 113—116°C/8 mmHg, n_D^{20} 1.5820, d_4^{20} 1.7097. This compound has been once reported[5] but later disclosed to be a mixture of 1,2- and 1,1-bis(iodomethyl)tetramethyldisilane.[6]

Satisfactory analyses and NMR spectra were obtained for these compounds.

The Substituent Effect on the Magnetic Interaction and d-d Bands in Dimeric Copper(II) Halide Complexes with Pyridine *N*-Oxides

Yoneichiro MUTO,* Michinobu KATO,** Hans B. JONASSEN*** and Koji KAKIUCHI*

* *Department of Chemistry, Saga University, Saga*
** *Aichi Prefectural University, Mizuho-ku, Nagoya*
*** *Department of Chemistry, Tulane University, New Orleans, La., U. S. A.*

(Received April 23, 1968)

In the previous papers,[1] we reported the correlation between the magnetic moments and d-d bands in dimeric copper(II) halide complexes with 3- or 4-substituted pyridine *N*-oxides. In these dimeric complexes, no correlation was observed between Hammett's constants and the magnetic moments or the d-d band positions. In order to elucidate why Hammett's rule is not obeyed in these complexes, we have now prepared copper(II) halide complexes with pyridine *N*-oxides with substituents in 2-, 3- and 4-positions on the pyridine ring and measured the magnetic susceptibilities and the reflectance spectra (*cf.* Table 1).

From the data in Table 1 the following conclusions about the substituent effect can be obtained: 1) For the same substituent group, the closer the site of substitution to the central metal ion is, the greater are the demagnetization and the blue shift of the d-d band. In the case of ethyl group, *e. g.*, these effects increase in the following order of substitution: 2->3->4-. It can also be seen that the difference between the λ_{max} of the d-d bands of 2- and 3-substituted complexes is fairly large, whereas the difference between those of 3- and 4-substituted complexes is small. 2) As for different substitutions at the same site (ethyl *vs.* methyl), the more bulky group has a greater demagnetization effect. This can also be observed in the greater demagnetization in the quinoline *N*-oxide complexes in comparison with pyridine *N*-oxide complexes.

These data seem to indicate that, in these dimeric complexes, the steric factor is more important in determining the extent of magnetic interaction or λ_{max} of d-d bands than the electronic effect.

The molecular framework model built up on the basis of the determined structure of the parent complex, $(CuCl_2 \cdot PyO)_2$,[2] indicates that, the ethyl groups attached in the 2 position of pyridine rings, which are almost perpendicular to the copper-oxygen plane, come above or below the plane to shield the fifth coordination sites of the copper ions. Such shielding of the coordination sites by chemically inert groups usually increases the tetragonality of complexes and the strength of the four coordinate bonds in the plane, as is seen in the unusual red color or the extremely large values of tetragonality ratio R of bis(*N*,*N*-dialkylethylenediamine)copper(II) complexes.[3] Therefore, it is very probable that, in the dimeric pyridine *N*-oxide complexes, the covalent bonding between the copper and the bridging oxygen atoms, through which the magnetic interaction occurs, is strengthened by the shielding effect of inert groups on the pyridine rings, and a much greater demagnetization or blue shift of d-d bands than expected from the electronic effect of the group is produced through it.

TABLE 1. MAGNETIC MOMENTS CORRECTED TO THOSE AT 25°C[a] AND d-d BANDS

Ligand	1 : 1 $CuCl_2$ Complex		1 : 1 $CuBr_2$ Complex

Studies of the Mechanism of the Isomerization of *n*-Butene over *p*-Toluene Sulfonic Acid by Means of Microwave Spectroscopy

Yuzo SAKURAI, Yoshihiro KANEDA, Shigeo KONDO, Eizi HIROTA
Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 19, 1968)

Recently the microwave spectra of 1-butene, *cis*-2-butene and their deuterated species were successfully assigned. This presented a new powerful tool for studying the isomerization of butene, both *cis-trans* and double-bond migration over solid acids.

The monodeuterated species of 1-butene are designated as 1-d_1 ($CHD{=}CHCH_2CH_3$), 2-d_1 ($CH_2{=}CDCH_2CH_3$), 3-d_1 ($CH_2{=}CHCHDCH_3$), and 4-d_1 ($CH_2{=}CHCH_2CH_2D$), each of them giving different rotational spectra. As for *cis*-2-butene, however, there exist only two different monodeuterated species: 1-d_1 ($CH_2DCH{=}CHCH_3$) and 2-d_1 ($CH_3CD{=}CHCH_3$). The amounts and distribution of deuterium among each of the 1-butenes could be determined by measuring the relative intensities of the neighboring peaks of the species. In the case of *cis*-2-butene mass spectroscopy was also employed to determine the deuterium concentration, but the deuterium distribution or the relative amounts of 1-d_1 and 2-d_1 species could be determined only by means of microwave spectroscopy.

The isomerization of butene was carried out over *p*-toluene sulfonic acid (PTS) deposited on an equal amount of silica gel to get a greater surface area. The *p*-toluene sulfonic acid was pretreated with an amount of pure D_2O (99.8% or above) sufficient to deuterate its proton, and then it was evacuated at 50°C for 5 hr. This procedure was repeated three times to assure the complete deuteration of the PTS.

trans-2-Butene was isomerized over the deuterated PTS at room temperature for the purpose of studying both *cis-trans* isomerization and double-bond migration simultaneously.

The gas-chromatographic technique was employed to analyze the reaction mixture, and 1-butene and *cis*-2-butene were separated for microwave spectroscopic measurements in order to study the deuterium content and distribution. The results are summarized in the following tables.

Conversion to *cis*-2-butene from *trans*-2-butene	d_0	2-d_1	d_2
1.0%	51.3%	47.2%	1.5%
3.2	35.9	60.3	3.8
6.4	29.8	66.8	3.4
7.0	28.7	68.6	2.7
8.5	31.5	63.9	4.6
13.6	27.2	68.5	4.3
17.4	34.2	61.8	4.0

Conversion to 1-butene from *trans*-2-butene	3-d_1	2-d_1	d_0
0.20%	92.0%	6.0%	2.0%
0.58	85.5	7.5	7.0
0.75	78.4	13.1	8.5
1.00	75.3	14.7	10.0
2.86	67.1	20.9	12.0

The striking features of these results are as follows: 1) The amounts of the d_0 and 2-d_1 species of the *cis*-2-butene isomerized from *trans*-2-butene were approximately equal at the initial stage of the reaction. As the reaction proceeded, however, the 2-d_1 species predominated over the d_0 species, and the d_2 species, which was not detected at the initial stage, became appreciable, though its amount was not considerable at any time during the reaction. 2) The only 1-butene produced by the double-bond migration from *trans*-2-butene was the 3-d_1 species at the initial stage of the reaction; thereafter the relative concentration of the 3-d_1 species decreased continuously with the isomerization. The d_0 and 2-d_1 species, which could not be detected at the initial stage, appeared increasingly with the progress of the reaction.

The results thus obtained lead to the following reaction mechanism: the PTS behaves as a typical Brönsted acid, and the *cis-trans* isomerization of 2-butene over the PTS proceeds *via* the *s*-butyl carbonium ion, producing approximately equal amounts of the d_0 and 2-d_1 species of 2-butene, while the double-bond migration of 2-butene to 1-butene also takes place, taking a proton from the PTS at =CH– and giving it back to the PTS from the methyl group on the opposite side. The deuterated PTS acts as the reaction site, and the deuterium is replaced with a hydrogen on the reaction. These nondeuterated 1-butenes accordingly increase with the progress of the reaction; this is in accordance with the results obtained. Similarly, the 2-d_1 species of 1-butene produced may be interpreted to have been formed by the double-bond migration of the 2-d_1 of the *cis*-2-butene on the nondeuterated PTS.

The microwave spectroscopic measurements have thus been demonstrated to be capable of being use dsuccessfully in elucidating the reaction mechanism of the isomerization of *n*-butene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1497—1501 (1968)

Infrared Spectra and Stereochemistry of Bis-pyridine Complexes of Tin(IV)

Toshio TANAKA, Yoshio MATSUMURA and Rokuro OKAWARA

Department of Applied Chemistry, Osaka University, Suita, Osaka

and Yoshihiko MUSYA and Susumu KINUMAKI

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received October 13, 1967)

Assignments are given for the infrared spectra of bis-pyridine complexes of SnX_4, $(CH_3)_2SnX_2$ (X=Cl, Br and I), and $(C_2H_5)_2SnCl_2$ in the 80—1610 cm^{-1} region. These complexes show the Sn-N stretching band near 200 cm^{-1}. Most pyridine vibrations shift to a higher or a lower frequency upon complex formation. Among these, the ν_{10}, in-plane ring deformation vibration is the most sensitive to the substituents on the tin atom as well as to the complex formation. Thus, the frequency may be a qualitative measure of the tin-pyridine coordination bond strength. The infrared spectra suggest a *cis*-configuration for the tin tetrahalide complexes and a distorted octahedral configuration for the dimethyltin diiodide complex. The remaining complexes may be assumed to have *trans*-alkyl and *cis*-halogen configurations.

It is well known that pyridine (Py) is a Lewis base which can coordinate to metal atoms or ions. For instance, it forms stable 2 : 1 adducts with SnX_4[1,2] and $(CH_3)_2SnX_2$[3] (X=Cl, Br and I), and a 1 : 1 adduct with $(CH_3)_3SnCl$.[4] Of these adducts, only $(CH_3)_3SnCl\cdot Py$ has been studied by X-ray crystallographic analysis; this analysis indicated that the adduct has a triangular bipyramidal structure, in which the pyridine molecule and the chlorine atom are located in the axial positions.[4] The infrared spectra of the tin(IV)-pyridine complexes have been described only for the CsBr region, in which tin-halogen and tin-carbon stretching vibrations are expected to be observed. For the $SnCl_4\cdot 2Py$ complex a *trans*-configuration has initially been assumed on the basis of the infrared study.[2] However, X-ray powder photographs showed that the complex is a crystal structure closely similar to that of $SnBr_4\cdot 2Py$, whose infrared spectrum, with three well-resolved Sn–Br stretching bands, indicates a *cis*-configuration.[3] On the other hand, the infrared spectra of $(CH_3)_2SnX_2\cdot 2Py$ (X=Cl, Br and I) have suggested *trans*-methyl and *cis*-halogen configurations.[3]

This paper will report on the assignments for the infrared spectra in the 80—1610 cm^{-1} region and the stereochemistry of bis-pyridine complexes of SnX_4, $(CH_3)_2SnX_2$ (X=Cl, Br and I) and $(C_2H_5)_2SnCl_2$; for the $(CH_3)_2SnI_2\cdot 2Py$ complex a distorted octahedral configuration is proposed; this is unlike that previously reported.[3]

Experimental

Preparation of Complexes. Bis-pyridine complexes of tin(IV) were prepared by reactions of the corresponding tin(IV) compounds with pyridine (mole ratio of about 1 : 2) in benzene, except for the case of the dimethyltin dibromide and diiodide complexes, which were synthesized in petroleum ether. Since the tin tetrahalide complexes are insoluble in common organic solvents, the precipitates resulting from the reactions were washed by petroleum ether until the pyridine smells had vanished. The dimethyltin dichloride complex was purified by sublimation under a reduced pressure, and the other three, by recrystallization from dichloromethane. The melting points and the analytical data are shown in Table 1.

Infrared Spectra. The spectra were recorded in Nujol and hexachlorobutadiene mulls using Hitachi EPI-2G (400—5000 cm^{-1}) and EPI-L (200—700 cm^{-1}) spectrophotometers, and in solid paraffin of a low melting point on a Hitachi FIS-1 vacuum spectrophotometer (80—500 cm^{-1}), all equipped with gratings. These spectrophotometers were calibrated with polystyrene film, CO_2 gas, and H_2O vapor.

Results and Discussion

Pyridine Vibrations. Assignments of the infrared spectra and a normal-coordinates analysis of pyridine and deuterated pyridines have been made by Long *et al.*[5,6] Using their results, the

infrared absorption bands related to the pyridine vibrations of bis-pyridine complexes of tin(IV) can easily be assigned, except for the ν_{17}, ν_{18}, and ν_{23} vibrations,*1 which are sometimes difficult to observe because of their weak intensities in the complexes. The observed frequencies of the pyridine vibrations and their probable assignments are given in Table 2.

As may be seen in Table 2, most pyridine vibrations shift to a higher or a lower frequency upon complex formation. It has already been indicated for the transition-metal complexes that the ν_{10} and ν_{27} vibrations undergo shifts to significantly higher frequencies upon the coordination of pyridine to metal,[7] and that the magnitude of these shifts depends on the stereochemistry of the complexes and on the metal atoms.[8] In the bis-pyridine complexes of tin(IV), the frequencies of ν_4, ν_9, ν_{10}, ν_{24}, and ν_{27} vibrations are sensitive to the substituents on the tin atom as well as to the complex formation; the most remarkable one is the ν_{10} vibration.

It has previously been described by the present authors, in reporting on the infrared spectra of $YZSn(acac)_2$*2 and $Y_2Z_2Sn \cdot 2DMSO$*2 (Y, Z= Cl, Br, I, alkyl and aryl), that the inductive effect of the substituents on the tin atom affects mainly the Sn–O coordination bond strength; the Sn–O stretching band shifts to a higher frequency with an increase in the electronegativity of the substituents on the tin atom.[9,10] This trend is not always clear in the Sn–N stretching frequency of the bis-pyridine complexes of tin(IV), probably because of its mixing with tin-halogen stretching vibrations, as will be described below. However, the ν_{10} vibration showed quite a similar tendency to the Sn–O vibrations of $YZSn(acac)_2$ and $Y_2Z_2Sn \cdot 2DMSO$, suggesting that the ν_{10} vibrational frequency may be used qualitatively as a measure of the bond strength of the tin-pyridine coordination bond. The ν_{27} vibration also shifted to a higher frequency with an increase in the electronegativity of the substituents on the tin atom, except for the diethyltin dichloride complex, which showed the band at an unexpected high frequency.

Skeletal Vibrations. Since the first-row transition metal-pyridine stretching vibration has been placed near 220 cm^{-1},[8] the tin-pyridine vibration might be expected to occur in a rather lower frequency region in view of mass considerations. Figures 1 and 2 show the far infrared

spectra of bis-pyridine complexes of tin(IV). These complexes are considered to be non-ionic in the solid state.*3 Therefore except for the ν_{27} vibration of pyridine, the infrared spectra below 600 cm^{-1} may tentatively be assigned to skeletal vibrations around the hexa-coordinated tin atom, as is shown in Table 3. Among these, the bands of the dimethyltin and the diethyltin dihalide complexes in the 480—570 cm^{-1} range can undoubtedly be assigned to Sn–C stretching modes.

The three dimethyltin dihalide complexes showed a medium-intense band at 190—200 cm^{-1}. These frequencies decrease with a decrease in the electronegativity of the substituents on the tin atom, which is a similar trend to that of the Sn-O stretching frequencies of $YZSn(acac)_2$[9] and $Y_2Z_2Sn \cdot 2DMSO$.[10] The bands in this region may, therefore, be associated with the Sn-pyridine stretching mode. For the $(C_2H_5)_2SnCl_2 \cdot 2Py$ and $SnX_4 \cdot 2Py$ (X=Cl, Br and I) complexes, the assignment of the Sn–N vibration is not unambiguous, because these complexes give Sn-halogen stretching bands near 200 cm^{-1}, which could be mixed with the Sn–N stretching. This may spread the Sn–N stretching vibration over two or more frequencies.

It has previously been mentioned by one of the present authors that the Sn-halogen stretching bands of dimethyltin dichloride and dibromide shift to considerably lower frequencies upon the coordination of some donor molecules, such as DMSO[10] and dimethylselenoxide.[11] A similar shift of the Sn-halogen stretching bands might also be expected upon the coordination of pyridine. Thus, each strong band of the dimethyltin dihalide complexes at 245, 160, and 147 cm^{-1} may be associated with Sn-halogen stretching vibrations. The latter two frequencies may be contributed by the deformation vibrations around the tin atom, some of which may appear near these frequencies. The diethyltin dichloride complex showed split broad bands near 210 cm^{-1}. These are also assigned to Sn–Cl stretching vibrations, although they are probably mixed with Sn–N vibrations.

The far infrared spectrum of the tin tetrachloride complex (Fig. 1a) showed a fairly strong band due to the Sn–Cl stretching mode at 324 cm^{-1}, with a

*3 Although the electric conductance has not been measured for these complexes in solution, 2,2′-bipyridyl complexes of dimethyltin dichloride and dibromide gave non-conducting solutions in acetonitrile; T. Tanaka *et al.*, to be published.

11) T. Tanaka and T. Kamitani, *Inorg. Chim. Acta*, in press.

shoulder at 304 cm^{-1}; this finding is in agreement with that of the previous workers,[3] who also reported another weak shoulder at 327 cm^{-1}.*4 Another strong band, at 225 cm^{-1}, is more likely to be due to the ν(Sn–Cl) fundamental, in which there might be some contribution by the Sn–N stretching vibration.

The tin tetrabromide complex showed several absorption bands in the skeletal stretching region (Fig. 1b). The two highest frequencies are assigned to Sn–Br stretching modes because of their strong intensities. The remaining three may be associated with the Sn–Br and the Sn–N stretching vibrations, which are presumably coupled with each other. The four infrared bands of the tin tetraiodide complex, 218, 183, 163, and 145 cm^{-1} (Fig. 1c), are comparable with those of the corresponding bis(pyridine-*N*-oxide) complex, 210, 184, 157, and 140 cm^{-1}.[12] Therefore, these four bands of the $SnI_4 \cdot 2Py$ are likely to be associated with Sn–I stretching modes, although the Sn–N stretching may also contribute to these frequencies.

Stereochemistry. We shall assume the presence of discrete hexa-coordinated species for the solid bis-pyridine complexes of tin(IV). There is some disagreement on the stereochemistry of the $SnCl_4 \cdot 2Py$ complex. Beattie *et al.* initially considered, on the basis of the infrared spectrum, that the complex was more likely to be the *trans* than the *cis*-configuration.[2] On the contrary, Clark and Wilkins concluded it to have the *cis*-configuration after comparing an X-ray powder photograph with one of $SnBr_4 \cdot 2Py$ and after considering the infrared spectrum.[3] In the present infrared study, at least two strong bands (324 and 225 cm^{-1}) have been assigned to ν(Sn-Cl) fundamentals; therefore, it is reasonable to assume the *cis*-configuration for the $SnCl_4 \cdot 2Py$ complex. The tin tetrabromide and tetraiodide complexes showed several infrared bands associated with tin-halogen stretching modes, indicating the *cis*-configuration for these complexes also.

The dimethyltin dichloride and dibromide complexes showed only the asymmetric Sn–C stretching band in their infrared spectra, no symmetric ones (Fig. 2a and 2b), suggesting a linear geometry of the $(CH_3)_2Sn$ moieties.[10] The Sn–Cl stretching frequency of the former complex is close to those of $(CH_3)_2SnCl_2 \cdot 2DMSO$ and $(CH_3)_2SnCl_2 \cdot$bipyridyl, whose chlorine atoms are in *cis*-positions.[10] On the other hand, this frequency is quite a bit lower than that of $Cl_2Sn(acac)_2$ (345 cm^{-1}),[9] which has a *trans*-configuration,[13] as well as dimethyltin dichloride (361 and 356 cm^{-1}).*5 The Sn–Br stretching frequency of the $(CH_3)_2SnBr_2 \cdot 2Py$ complex is also markedly lower than those of dimethyltin dibromide (252 and 241 cm^{-1}).*5 These results would indicate the *trans*-methyl and *cis*-halogen configuration for the $(CH_3)_2SnCl_2 \cdot 2Py$ and $(CH_3)_2SnBr_2 \cdot 2Py$ complexes, which is in agreement with the findings of previous workers.[3]

On the other hand, the dimethyltin diiodide complex gave the symmetric Sn–C stretching band with less intensity as well as the asymmetric one (Fig. 2c), although the former had not been observed by the previous workers.[3] This is suggestive of a non-linear geometry of the C–Sn–C linkage. Thus, it is reasonable to assume a distorted octahedral configuration for the $(CH_3)_2SnI_2 \cdot 2Py$ complex, as is shown in Fig. 3. This configuration

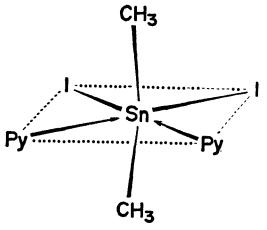

Fig. 3. Distorted octahedral configuration of $(CH_3)_2SnI_2 \cdot 2Py$.

is comparable with those of dimethyltin diacetate[14] and dimethyltin bis(kojate).[15]

The diethyltin dichloride complex also showed two Sn–C stretching bands. The considerable intensity of the symmetric one may be due to coupling with the inner vibrations of ethyl groups, as has been mentioned in the cases of bis-DMSO[10] and bis-dimethylselenoxide[11] complexes of diethyltin dichloride. The $(C_2H_5)_2SnCl_2 \cdot 2Py$ complex is, therefore, assumed to have a similar around the tin atom geometry to that of the dimethyltin dichloride complex, although a more or less distorted configuration can not be ruled out.

*4 This shoulder is not unambiguous in the present study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 41 1502—1512 (1968)

Electron Spin Resonance of Anion Radicals of Aromatic Esters. IV. The Anion Radicals of Some Substituted Methyl Benzoates*[1]

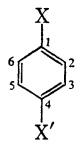
Masatoshi HIRAYAMA and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received November 22, 1967)

ESR spectra are observed for the anion radicals of methyl *p*-, *m*- and *o*-nitrobenzoates, methyl ester of *p*-phthalaldehydic acid, and methyl and ethyl *p*-cyanobenzoates. Both the electrolytic and alkali-metal reduction methods are used for the radical generation. The spin densities calculated by McLachlan's procedure only with the adjustment of the resonance-integral parameter for the ester group-ring bond are in good agreement with those obtained experimentally for most of the substituted positions in these radicals. The result for the methyl *o*-nitrobenzoate anion suggests that the ester group is twisted considerably by the large steric hindrance between the ester and nitro groups. The ring-proton splittings of three *p*-substituted methyl benzoate anions show that the known order of electron-withdrawing effects of the substituents, $NO_2>CHO>COCH_3>COOCH_3>CN$, holds also for these anions. And it is suggested that the electron-withdrawing power of a XM^+ group produced on the alkali-metal reduction increases in the order of free NO_2, NO_2Cs^+, NO_2K^+, NO_2Na^+ and NO_2Li^+, and that the groups $CHONa^+$ and $CHOK^+$ are more electron-withdrawing than a free CHO group. The ring-proton splittings obtained from the VB-superposition calculations for all the anions except for the *o*-derivative are in satisfactory agreement with those from the MO calculations. Structural models of ion complexes are proposed for the *p*- and *m*-nitro derivatives and methyl ester of *p*-phthalaldehydic acid with the assistance of MO calculations.

A series of the anion radicals of aromatic esters has been studied by one of the present authors.[1-3] The present paper reports the ESR spectra of the anion radicals of methyl *p*-, *m*- and *o*-nitrobenzoates, methyl ester of *p*-phthalaldehydic acid, and *p*-cyano methyl and ethyl benzoates.



The di-*p*-substituted benzene anions with electron-withdrawing groups prepared by electrolysis are known to show some interesting correlations between the relative electron-withdrawing effect of X to that of X', and the ring proton splittings;[4] in the case of $X'=NO_2$, $a_2+a_3=-2.3$ gauss, irrespective of X,[5] and in the case of $X=X'$, the larger is the electron-withdrawing effect of X, the smaller is $|a_2|$,[2,4-6] and furthermore, when the electron-withdrawing effect of X is larger than that of X', $|a_2|>|a_3|$.[4-6] All these experimental results have been discussed by using the following relation to electron-withdrawing effects

$$NO_2>CHO>COCH_3>COOCH_3>CN$$

which was determined from the ESR measurements[1,6-8] and from the theoretical consideration of monosubstituted benzene anions.[9] This order is in accord with that predicted from the valence-bond superposition model proposed by Karplus and collaborators.[10]

In the present experiments on the *p*-substituted methyl benzoate anions, the measured values of ring-proton splittings are expected to satisfy the above mentioned relations. An alkali metal cation can be considered to interact with the group having a larger electron-withdrawing effect in the unsymmetrical di-*p*-substituted benzene anion. The effect of alkali metal cation on the splittings

of protons and nitrogen is discussed by the MO calculation of spin densities.

Experimental

The anion radicals studied in this work were prepared by the electrolytic reduction mainly in acetonitrile (ACN) using tetra-*n*-propylammonium perchlorate as the supporting electrolyte, and by the alkali-metal reduction mainly in dimethoxyethane (DME) and tetrahydrofuran (THF) using, sodium, potassium and cesium metals and lithium amalgam. The ESR spectra were measured with a Hitachi X-band ESR spectrometer, model MPU-3B, using a field modulation of 100 kc/s. The experimental techniques were detailed elsewhere.[1]

Methyl *p*-, *m*- and *o*-nitrobenzoates and methyl ester of *p*-phthalaldehydic acid obtained commercially were used without further purification. Methyl *p*-cyanobenzoate was prepared from silver salt of *p*-cyanobenzoic acid and methyl iodide, while ethyl ester was synthesized by the Sandmeyer method after the esterification of *p*-aminobenzoic acid.

Results

The measured splitting constants are listed in Table 1.

Methyl *p*-Nitrobenzoate. A red-purple solution was obtained by both reduction methods of this compound, except for a purple solution obtained with cesium metal in THF. Dimethylformamide (DMF) was used as the solvent for electrolysis so that the spectrum could be precisely compared with those of the other *p*-substituted nitrobenzene anions measured already. The magnitude of each splitting constant observed by the electrolysis in DMF was slightly different from that measured in ACN by Maki and Geske.[5] All the radicals prepared were very stable at room temperature. The spectra observed at room temperature are shown in Fig. 1.

Methyl *m*-Nitrobenzoate. This compound yielded a green-brown solution on the electrolysis in ACN and on the reduction with lithium amalgam

(The arrow shows the center of each spectrum.)

and potassium metal in THF, and a yellow solution with cesium metal in THF. The radicals were very stable at room temperature. The observed spectra are shown in Fig. 2.

Methyl *o*-Nitrobenzoate. A yellow-brown solution was obtained by the electrolysis of this compound in ACN. The radical prepared was comparatively stable at room temperature. The spectrum is shown in Fig. 3. No ESR signals could be observed by the reduction with sodium metal in THF.

Methyl Ester of *p*-Phthalaldehydic Acid. The electrolytic reduction of this compound in DMF gave a purple-red solution, which yielded a spectrum shown in Fig. 4(a). Although the spectrum was poorly resolved, because of instability of this radical at room temperature, the analysis was performed with reference to the result of analysis for the spectrum obtained with potassium metal (Fig. 5(b)). The result led the five doublets arising from an aldehyde proton and four unequivalent ring protons, and a quartet assignable to the three equivalent methyl protons. Since a number of lines occurred within the narrow total-width, a resolution of lines was very poor. Consequently, the reconstruction based on the coupling constants listed in Table 1 did not agree exactly with the measured spectrum, as is shown in Fig.

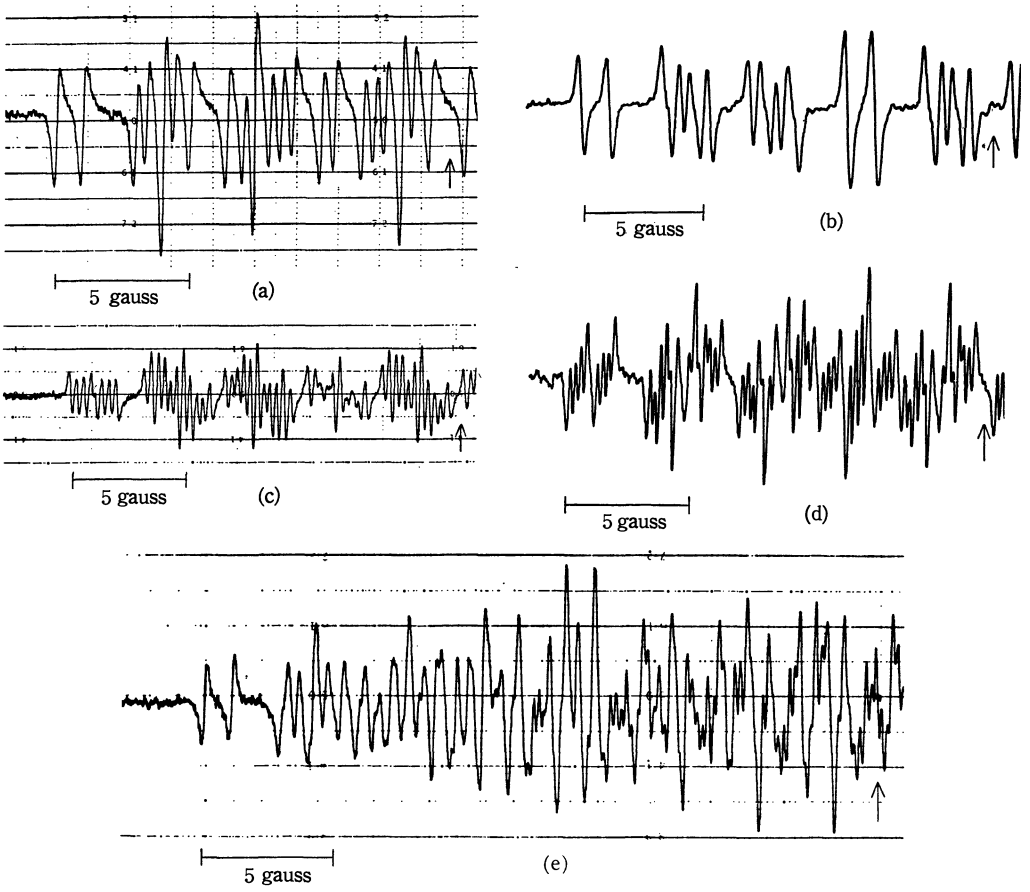

Fig. 2. Halves of ESR spectra of the methyl *m*-nitrobenzoate anions.

(The arrow shows the center of each spectrum.)

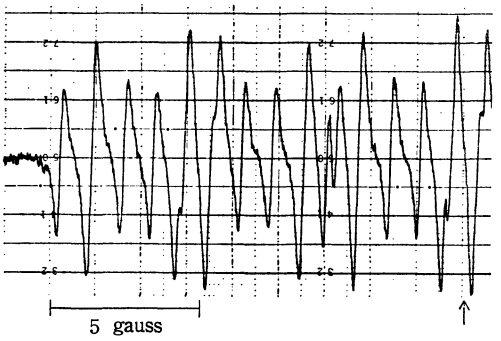

Fig. 3. Half of ESR spectrum of the methyl *o*-nitrobenzoate anion prepared by the electrolysis in ACN.
(The arrow shows the center of spectrum.)

4(b). The solution obtained by the electrolysis in ACN was liable to turn into brown from purple-red. The brown solution displayed a quite different spectrum from that measured in DMF. This spectrum has not yet been analyzed.

The spectrum obtained by the reduction with potassium metal in DME, shown in Fig. 5(a), was completely identical with that obtained with sodium metal in DME, except that the average line-width was slightly narrower than that of the latter. This spectrum was composed of four doublets and a quartet (Fig. 5(b)). A small doublet arising from the fourth ring proton may be covered within the line-width.

Methyl *p*-Cyanobenzoate. The electrolysis of this compound in ACN yielded a purple-red solution, the radical produced being not very stable at room temperature. The spectrum observed is shown in Fig. 6(a). Since 108 lines might occur within the narrow total width (about 12 gauss), they were anticipated to superpose extremely one another. The intensity of each line in the reconstruction based on the coupling constants listed in Table 1 did not agree well with that of the measured spectrum. Then, it was assumed that there was a small difference, though not measurable, between the splittings of two

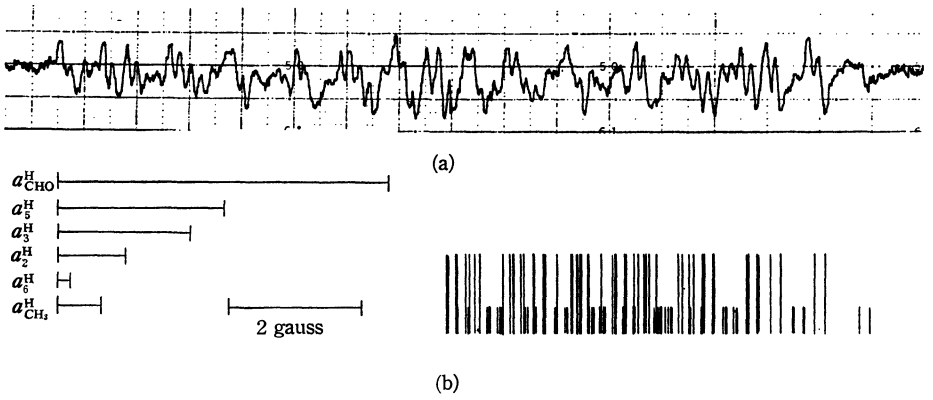

Fig. 4. ESR spectrum of the anion of methyl ester of *p*-phthalaldehydic acid prepared by the electrolysis in DMF (a) and half of its reconstruction (b).

ring-protons in ortho position to the ester group, and consequently that the center line of this triplet was much broader and the peak-to-peak height of its first derivative was much smaller than in the case of a complete equivalence of these two ortho-protons. Thus, the spectrum was again reconstructed; the result is shown in Fig. 6(b), where the dotted lines show these lines of small height. As is seen from Fig. 6(b), the spectrum could be well explained by these coupling constants. This inequivalence of two protons in ortho position to the ester group may not be surprising, because in such anions having the comparatively large splittings of ring protons in ortho position to the ester group, a difference between the α-effects of two oxygen atoms in the ester group is considered to be effective to a difference between the two ortho-proton splittings.[2] In order to confirm the validity of this analysis, the spectrum of ethyl *p*-cyanobenzoate anion was measured and analyzed. Figure 7 shows that each of the splitting constants measured is equal to that of the methyl ester anion, and further that the above-mentioned technique is required for the analysis.

Also by the alkali-metal reductions of these two esters, purple-red solutions were obtained. The measured patterns of spectra were different from that obtained by electrolysis, though the total width was about 12 gauss. However, since they were further poorly-resolved, probably because of the existence of some alkali metal splittings, analyses of them were very difficult. On the

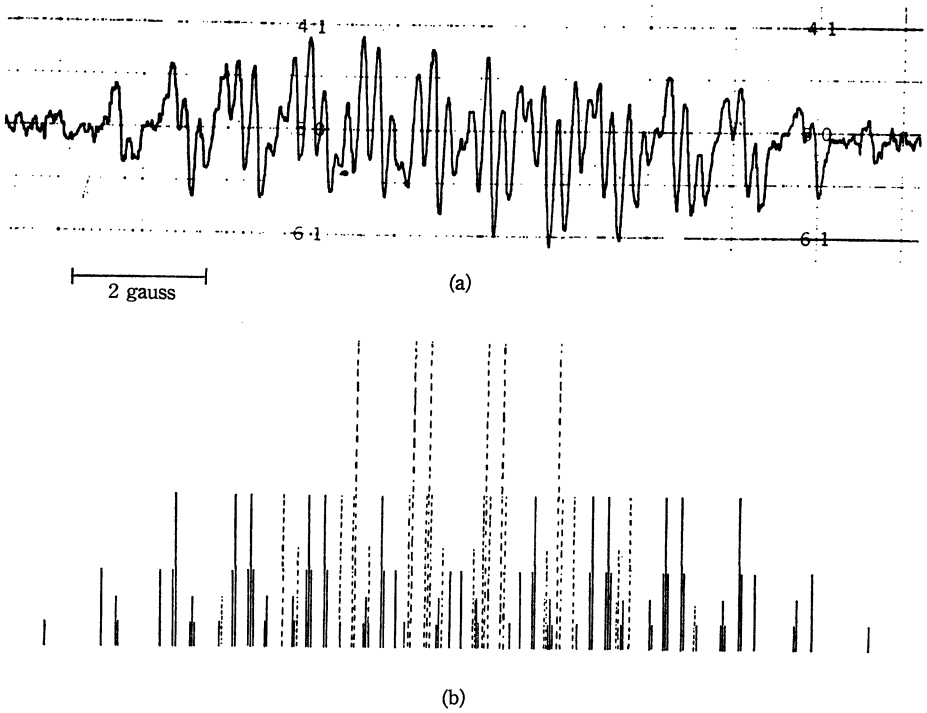

Fig. 6. ESR spectrum of the methyl *p*-cyanobenzoate anion prepared by the electrolysis in ACN (a) and its reconstruction (b).

other hand, the spectrum, measured at −45°C, of methyl ester anion prepared with sodium metal in THF was resolved better than that measured at room temperature, and was similar to that obtained by the electrolysis in ACN. This fact suggests that this ion-pair complex dissociates into a free anion and a cation under such condition.

Discussion

Molecular-Orbital Calculations of Spin Densities. Hückel molecular-orbital calculations with the approximate configuration interaction corrections of McLachlan[11] were performed for the anion radicals studied here in order to estimate the spin density distribution and to assist in the assignment of proton splittings. The values of parameters used here for the ester group, except for γ_{1-1a}, are those which have been determined to have the best fit of the calculated spin densities to the experimental ones for the methyl benzoate anion,[1] while those for the nitro, cyano, and aldehyde groups were taken from the works of Fraenkel *et al.*[8,9,12] These values of parameters are summarized in Table 2; the parameter $\lambda=1.2\beta$ was used in the correction terms. The results of calculations are given in Table 3. In the methyl

Table 2. The values of MO parameters

	$\delta_{O(C=O)}=1.5$ $\delta_{O(C-O)}=2.0$ $\gamma_{CO(C=O)}=1.6$ $\gamma_{CO(C-O)}=1.2$
	$\delta_N=2.2$ $\delta_O=1.4$ $\gamma_{NO}=1.67$ $\gamma_{NC'}=1.2$
	$\delta_O=1.5$ $\gamma_{CO}=1.6$ $\gamma_{CC'}=0.9$ $\delta_{C''}=-0.15$

$\delta_X=(\alpha_X-\alpha_C)/\beta_{CC}$, $\gamma_{XY}=\beta_{XY}/\beta_{CC}$

p-cyanobenzoate anion, the value of $\gamma_{1-1a}=1.2$ gave a relatively good fit to the experimental spin density at the position 2, but not at the position 3. In the anion of methyl ester of *p*-phthalaldehydic acid, the calculated result with $\gamma_{1-1a}=0.85$ was in good agreement with the experimental data, while in the methyl *p*- and *m*-nitrobenzoate anions, the values of 0.75 and 0.6 for γ_{1-1a} gave the best

fits, respectively. In the methyl *o*-nitrobenzoate anion, a large steric hindrance between the ester and nitro groups may be considered to affect the spin-density distribution on the ring. Figure 8 shows that the normal value of $\gamma_{1-1a}=1.0$ does not give the fit to the experimental spin densities, and that the best fit, also for the nitrogen splitting, is obtained with $\gamma_{1-1a}=0.2$. This calculated result seems to show a structure with the ester group twisted considerably by the steric effect.

Electron-Withdrawing Effects. As is indicated in the section of introduction, the ester group has been experimentally determined to be more electron-withdrawing than the cyano group and less electron-withdrawing than the acetyl group. This has been also verified by the fact that the ring-proton splitting of dimethyl terephthalate anion in ACN, -1.56 gauss,[2] is situated between those of the terephthalonitrile and *p*-diacetylbenzene anions, *i. e.*, between -1.59[6] and -1.33 gauss.[4]*2

In a series of the *p*-substituted methyl benzoate anions, the ring-proton splittings in ortho position to the ester group, $|a_O|$, increase in the order of NO_2, CHO, $COOCH_3$ and CN derivatives, while conversely, those in meta position to the ester group, $|a_m|$, decrease in the same order, and furthermore, the methyl proton splittings increase according to this order. All these data imply that the order in the electron-withdrawing effect of the substitutents described in the introduction holds also for the anions studied here, and moreover, these data are consistent with the results from the superposition model of the valence-bond method described later. Similarly, the correlations among the ring proton splittings of each of *p*-substituted methyl benzoate anions and those of the other *p*-disubstituted benzene anions already measured[2,4-6] are approximately satisfactory in view of this order.

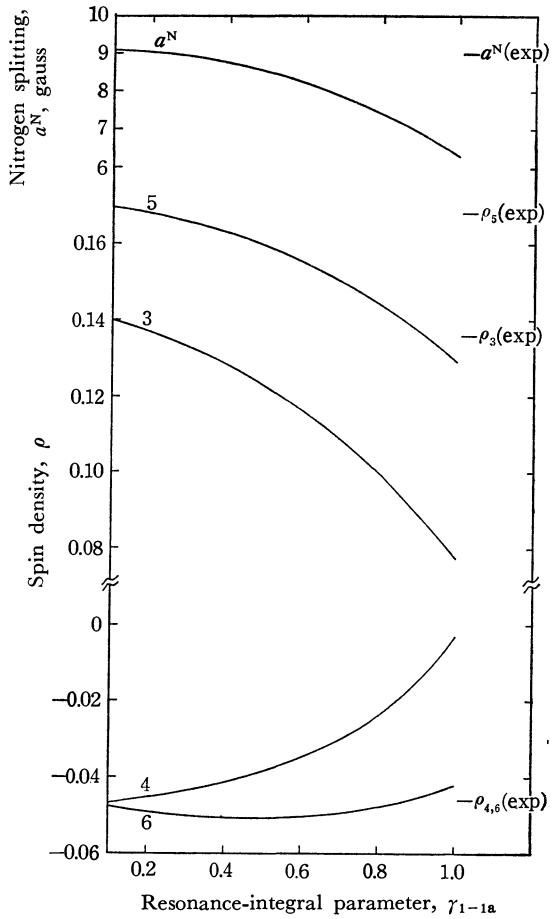

Fig. 8. Spin densities ρ and nitrogen splitting constant a^N calculated by the McLachlan modification of MO theory for the methyl *o*-nitrobenzoate anion as a function of the resonance-integral parameter for the 1-1a bond, γ_{1-1a}, and those obtained by the experiments.
The numbers on the curves indicate the positions in the radical.
The experimental values are shown in the right column.

It is reasonable to consider that the group having the larger electron-withdrawing effect in an unsymmetrical di-*p*-substituted benzene anion may interact with an alkali metal cation. Thus, regarding a group XM^+ produced on alkali-metal reduction as a new electron-withdrawing group, one may predict the effect of this group relative to the cation-free group X or to the other groups by comparing each ring proton splitting with the others. In the methyl *p*-nitrobenzoate-alkali metal ion pairs, a series of the values of a_2 and a^N in Table 1 indicates obviously that the order in the electron-withdrawing effects is $NO_2Li^+ > NO_2Na^+ > NO_2K^+ > NO_2Cs^+ >$ Free NO_2, and furthermore, the values of a_3 and a_{CH_3} seem to show that this order is reasonable within the experimental errors.

Also in the case of the methyl *m*-nitrobenzoate anion, it may be seen from a series of the values of a^N that there exists the same order of electron-withdrawing powers.

Similarly, since an aldehyde group has been decided to be more electron-withdrawing than a ester group, the aldehyde group (probably the oxygen atom) may interact with an alkali metal cation in the anion of methyl ester of *p*-phthalaldehydic acid. Thus, the $CHOK^+(Na^+)$ is compared with the free aldehyde group or the others in Table 1. One may recognize from the increment of a_{CHO} and of the splittings of ring protons in ortho position to the aldehyde group,*3 and further from the decrement of a_{CH_3}, that this group is more electron-withdrawing than the free aldehyde group. Furthermore, it may be suggested that the group $CHONa^+(K^+)$ is still slightly weaker than the free nitro group, and is strong as much as the $COOCH_3Li^+$ group[2] in the electron-withdrawing power. In the case of the methyl *p*-cyanobenzoate anion, although the spectrum of the ion pair complex could not be analyzed, the splittings in ortho position to a group $COOCH_3M^+$, may be expected to be larger than those in ortho position to the free ester group.

Valence-Bond Superposition Model. Karplus and collaborators[10] have developed an approximate valence-bond superposition theory which is applicable to the benzene anion radicals with strongly electron-withdrawing substituents; if $\rho_N(X)$ and $\rho_N(X')$ are spin densities for the monosubstituted species ϕX and $\phi X'$, respectively, the spin density ρ_N in the disubstituted anion can be written

$$\rho_N = \{k(X)\}^2\rho_N(X) + \{k(X')\}^2\rho_N(X'),$$

where $\{k(X)\}^2$ and $\{k(X')\}^2$ represent the contributions made by the ϕX and $\phi X'$ structures to the ground state of the system. By using this procedure, one of the present authors has predicted the ring proton splitting, -1.63 gauss, for the dimethyl terephthalate anion from the *m*-, and *o*-ring proton splittings of the methyl benzoate anion observed by the electrolysis in acetonitrile; this value has been in good agreement with the experimental value of -1.56 gauss.[2]

This theory has also given satisfactory results to most of the unsymmetrical di-*p*-substituted benzene anions, though inconclusive. Then, the model will be testified for the three *p*-substituted methyl benzoate anions studied here and further for the methyl *m*-nitrobenzoate anion.

At first, the relative weight of the methyl benzoate anion structure, $\{k(X)\}^2$, of each *p*-substituted methyl benzoate anion, was calculated by using the largest ring proton splitting. The calculated results are 9.2% for *p*-nitro, 36.8% for *p*-aldehyde, and 66.9% for *p*-cyano derivatives, respectively. The correlations between these values and those for the other *p*-disubstituted benzene anions having been already measured, are satisfactory in view of the order of the electron-withdrawing effects of these substituents. The predicted values of the remaining ring-proton splittings were then calculated by using the corresponding splittings of the monosubstituted benzene anions, the results being shown in Fig. 9 with those obtained from the MO calculations. These predicted values are in comparatively good agreement with the experimental values, except for the value of a_6 in the anion of methyl ester of *p*-phthalaldehydic acid and the value of a_3 in the methyl *p*-cyanobenzoate anion. These assignments are in accord with those made by the MO calculations.

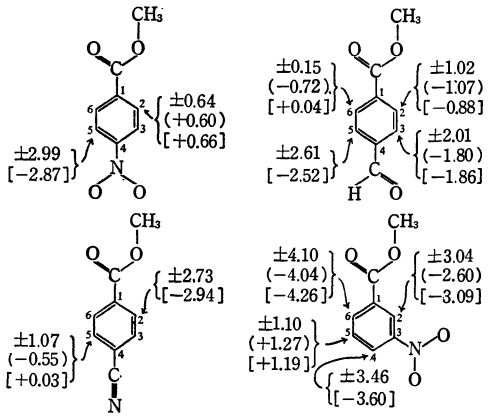

Fig. 9. Comparison of the valence-bond superposition and the molecular-orbital calculations for the ring proton splittings (gauss). Numbers not in parentheses or brackets are the experimental splittings using the MO assignments. Those in parentheses are from the valence-bond superposition procedure and those in brackets are from the MO calculation.

The spectrum of the methyl *m*-nitrobenzoate anion can be fitted comparatively well by the superposition model if the largest splitting of 4.10 gauss is assigned to the position 4. The weight of the methyl benzoate anion structure in the superposition is then 16.7%, a value of which is found to be reasonable from the comparison with the value of 22.0% predicted for the weight of the acetophenone anion structure in the *m*-nitroacetophenone anion.[4] The predicted splittings are shown in Fig. 9. However, the assignments required by the superposition model at the positions 4 and 6 are the opposite of those predicted by the MO calculations. Such the different assignments have occurred for the other meta isomers with electron-withdrawing groups.[9,12]

Interpretation of the Ion Complexes by MO Calculations. Assuming that the alkali metal cation may exist between two oxygen atoms of

*3 The average value of the splittings at the positions 3 and 5.

the nitro group, MO calculations of spin densities were performed with the modification that a small increase in the Coulomb-integral parameter of the oxygen atoms of a nitro group, $\delta_{O(NO_2)}$, was introduced. The dependence of spin density at each position on the Coulomb-integral parameter of oxygen atom is shown in Figs. 10 and 11 for methyl *p*- and *m*-nitrobenzoate anions, respectively. As is illustrated in Fig. 10, in the methyl *p*-nitrobenzoate anion, ρ_3 and $|\rho_2|$ increase with an increment of $\delta_{O(NO_2)}$ from 1.4, while conversely,

$a^M/Q^M(p)$	$<6.28\times10^{-4}$	1.01×10^{-3}	$<1.46\times10^{-3}$	3.11×10^{-3}
$a^M/Q^M(m)$	$<1.75\times10^{-3}$	9.48×10^{-4}	2.67×10^{-3}	3.50×10^{-3}

a^M: The splitting constant of metal nucleus.
Q^M: The splitting constans of free metal nucleus.
a^M/Q^M: The spin density at the metal nucleus.

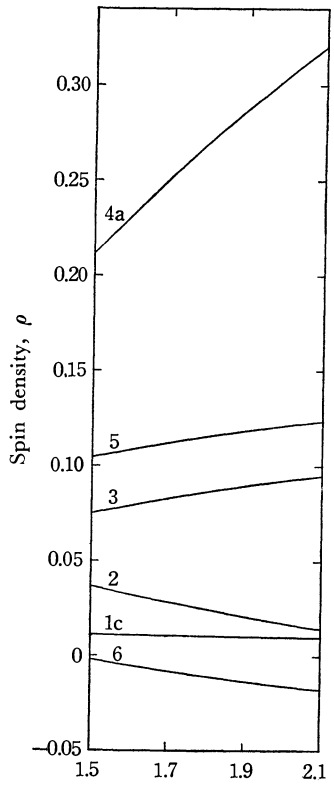

Fig. 12. Spin densities ρ calculated by McLachlan modification of MO theory for the anion of methyl ester of *p*-phthalaldehydic acid as a function of the Coulomb-integral parameter for the oxygen atom of aldehyde group, $\delta_{O(CHO)}$. The numbers on the curves indicate the positions in the radical.

ρ_{1c} decreases gradually. Furthermore, the value of a^N calculated from the values of ρ_{4a} and ρ_{4b} by using the equation proposed by Fraenkel *et al.*,[12] increases also with an increment of $\delta_{O(NO)_2}$. These results are consistent with the tendency of change of any splitting constant of the free anion to that of the ion complex listed in Table 1. Similarly, it is seen from Fig. 11 that in the methyl *m*-nitrobenzoate anion, the dependence of the values of ρ_2, ρ_4, ρ_5 and a^N on the value of $\delta_{O(NO_2)}$ is in accord with those to be expected from the experimental data, but ρ_6 is inconsistent with the experimental splitting constants.

Thus, the above-mentioned assumption on the position of the metal cation may be theoretically confirmed. Furthermore, one may determine that the smaller is the cationic radius, the stronger is the interaction between the alkali metal cation and the oxygen atoms.

On the other hand, the magnitude of spin density at the metal nucleus, a^M/Q^M,[13] increases in the order of increasing ionic radius, that is, Li<Na<K<Cs, as is shown in Table 4; this order is in contrast with that in the *o*-phthalate-alkali metal ion complexes.[2]

It seems to be plausible to consider that in the anion of methyl ester of *p*-phthalaldehydic acid the alkali metal cation may exist near the carbonyl oxygen atom. Then, a small increase in the Coulomb-integral parameter of carbonyl oxygen atom was introduced, the calculated result being shown in Fig. 12. In Fig. 12, ρ_3, ρ_5, ρ_{4a} and $|\rho_6|$ increase with an increment of $\delta_{O(CHO)}$ from 1.5, while ρ_2 decreases, and ρ_{1c} decreases gradually. These results explain very well the change in each splitting constant of the free anion to that of the ion complex, except for ρ_6. Thus, a model in which the alkali metal cation may interact with the carbonyl oxygen atom in the aldehyde group, may be supported by the theroetical consideration.

The numerical calculations were carried out on the NEAC 2230 at the Computation Center, Tohoku University.

The authors wish to thank Professor Masamoto Iwaizumi for his helpful discussions and encouragement through the course of this work. They are also indebted to Mrs. Masako Azumi for the synthesis of some of the samples.

Intramolecular Energy Transfer in Europium Chelates Due to Excitation of the Triplet State

Yoshihisa MATSUDA,*1 Shoji MAKISHIMA and Shigeo SHIONOYA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 25, 1967)

The purpose of this paper is to clarify whether intramolecular energy transfer in europium chelates occurs *via* the triplet state of the ligand. It is attempted to excite the triplet state of europium dibenzoylmethide (EuD) by utilizing intermolecular triplet-triplet energy transfer from lanthanum dibenzoylmethide (LaD). In mixed solutions of EuD and LaD, the intensity and decay time of the ligand phosphorescence of LaD decreases with increasing molar fraction of EuD at liquid nitrogen temperature. Nearly in proportion to this, the intensity of the europium emission of EuD is enhanced, veryfying the occurrence of energy transfer from LaD to EuD. This fact is taken as clear evidence that intramolecular energy transfer takes place *via* the triplet state.

Chelates of trivalent europium and some other rare earth ions emit luminescence of line spectrum characteristic of central rare earth ions due to f–f transitions. This luminescence is mainly caused by absorption by the ligand accompanied by subsequent intramolecular energy transfer to the central ions. Recently, these chelates have attracted great attention, since several investigators have suggested[1,2] the possibility of their use as laser materials, and succeeded[3-5] in achieving laser action with europium(III) β-diketonates. As for laser materials, one has to find chelates in which intramoecular energy transfer occurs efficiently. It is important, for this purpose, to clarify the mechanism of this intramolecular energy transfer.

Crosby *et al.*[6] investigated intramolecular energy transfer in chelates of various trivalent rare earth ions. They found that if the lowest triplet level of the ligand is located below the emitting levels of the chelated rare earth ions, luminescence attributed to the rare earth ions is not observed even if the singlet excited level of the ligand is located above them. Based on this fact, they suggested that intramolecular energy transfer takes place *via* the lowest triplet state of the ligand. El-Sayed and Bhaumik[7] reported that it is possible to enhance the luminescence of the chelated europium ion by intermolecular triplet-triplet energy transfer from benzophenone as energy donor. In this case, however, it is considered that the energy donor is further coordinated to the hexa-coordinated europium ion studied by them. If it is the case, the enhancement of the europium emission due to the addition of the energy donor would be attributed to the direct intramolecular energy transfer from the energy donor. Furthermore, Bhaumik and El-Sayed[8] showed that some aromatic compounds whose triplet levels are located between the emitting level of europium ion and the triplet level of the ligand of europium chelates quench the emission due to the europium ion. We have also showed[9] that the emission intensity of the chelated rare earth ion decreases if the triplet state of the ligand is quenched by the heavy-atom effect.

These observations all suggest that intramolecular energy transfer takes place *via* the triplet state of the ligand. However, clear evidence has not yet been reported, since it is difficult to excite the chelates directly from the ground state to the triplet state by optical absorption because of the very small probability of the singlet-triplet transition.

The purpose of this paper is to clarify whether energy transfer from the ligand to the europium ion takes place *via* the triplet state of the ligand. In this work, excitation of europium chelate to the triplet state is attempted by utilizing a phenomenon

of intermolecular triplet-triplet energy transfer.

Europium dibenzoylmethide (EuD) was used as energy acceptor, because it shows intramolecular energy transfer of relatively high efficiency. Also, it is easily prepared and purified.[1] As energy donor, lanthanum dibenzoylmethide (LaD) was chosen, and the effect of its addition on the intensity of the europium emission of EuD investigated. Dibenzoylmethides of lanthanum, gadolinium, lutetium and samarium exhibit phosphorescence attributed to the transition from the ligand triplet state to the ground state. There is no significant differences in their phosphorescence.[1] This suggests that the energy level of the triplet state is independent of the species of coordinated rare earth ion. It is expected that if EuD is mixed with some other rare earth dibenzoylmethide showing ligand phosphorescence, intermolecular energy transfer takes place from the triplet state of the latter chelate to the triplet state of the former, since there is sufficient energy mathcing between the triplet states of the two chelates. We found that LaD has the longest lifetime of ligand phosphorescence among the various rare earth dibenzoylmethides. Therefore, LaD was chosen as energy donor.

Experimental Methods

Samples. EuD and LaD were prepared by the ordinary piperidine method at first, and then kept in vacuum at 150°C for 24—30 hr. In the optical measurements, these chelates were dissolved in either ethanol or ethanol-methanol (3 : 1). These solutions become rigid glasses when cooled to liquid nitrogen temperature.

Emission Spectra. A high pressure mercury arc lamp connected with a Bausch & Lomb grating monochromator was used as the exciting light source. A Kipp & Zonen double monochromator with flint prisms was used for spectral measurement. Emission spectra were obtained for the alcohol solutions of LaD and EuD of concentrations 10^{-4}—10^{-3} M.

Excitation Spectra. A 500 W xenon arc lamp and a 500W tungsten lamp combined with the Kipp & Zonen double monochromator with quartz and flint prisms, respectively, were used for the excitation sources. Emission from the samples was filtered by color and interference filters. For EuD, measurement was made for the strongest emission line of 612 mμ, due to the transition $^5D_0 \rightarrow {}^7F_2$ of the trivalent europium ion. For LaD, the excitation spectrum was measured for ligand phosphorescence at a wavelength of 490 mμ, and ligand fluorescence at 425 mμ.

Emission Lifetime. An Edgerton FX-3 1 joule and a Miyata 20 joule xenon flash lamp with durations of 2μ sec and 20μ sec, respectively, were used as excitation sources with ultraviolet pass glass filters and a 365 mμ interference filter. The output of the photomultiplier, RCA 931A, was fed to a synchroscope, and the decay curve photographed. The concentrations of the solutions were 10^{-3}—10^{-5} M for the pure solutions of EuD and LaD, and 2×10^{-4} M for the mixed solutions of LaD and EuD.

Time-Resolved Emission Spectra. An Edgerton FX-3 xenon flash lamp was used as the exciting light source with ultraviolet pass filters and a 365 mμ interference filter. This lamp was operated at a frequency of 10 cps. High pulse voltage with a 2 μ sec width was applied to the photomultiplier tube, RCA 931 A, with the delay time changing from zero to 1 msec for the light flash.

Results and Discussion

The emission spectra of LaD and EuD in ethanol solution at liquid nitrogen temperature are given in Fig. 1. EuD exhibits only sharp emission lines due to the f–f transition of trivalent europium ion. The strongest line is the one for the transition $^5D_0$

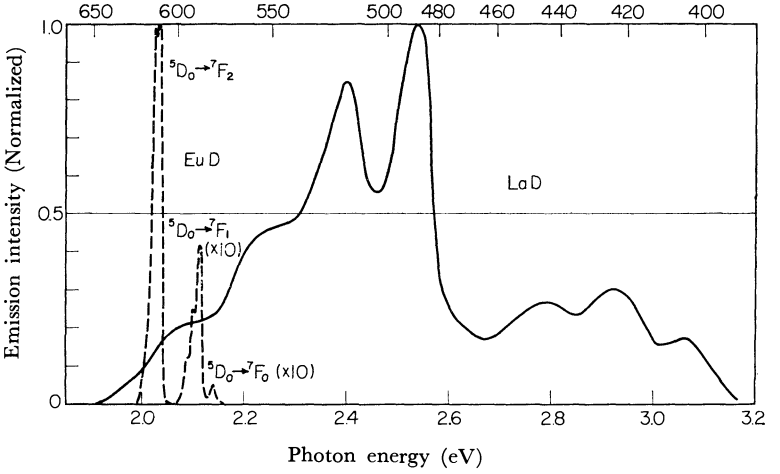

Fig. 1. Emission spectra of EuD and LaD in alcohol solutions at liquid nitrogen temperature. The intensities of EuD emission lines due to the transitions of $^5D_0 \rightarrow {}^7F_0$ and $^5D_0 \rightarrow {}^7F_1$ are magnified ten times.

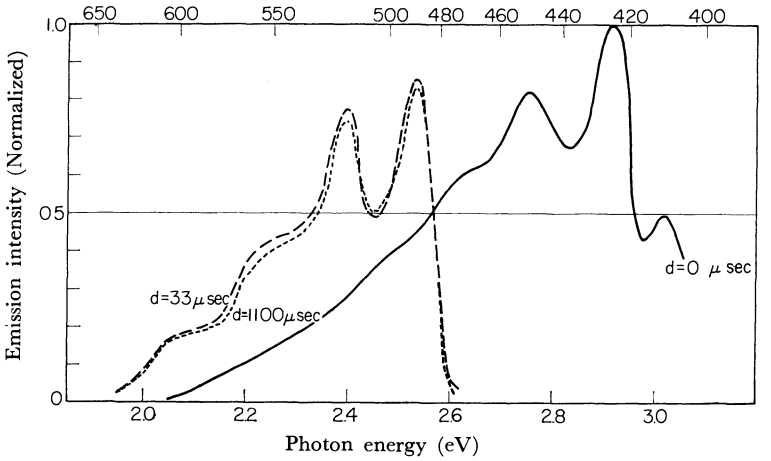

Fig. 2. Time-resolved emission spectra of LaD in alcohol solution at liquid nitrogen temperature. The delay time after the flash of exciting light is given by d. The relative intensities of emission bands for $d=33$ and 1100 μsec are magnified ten times.

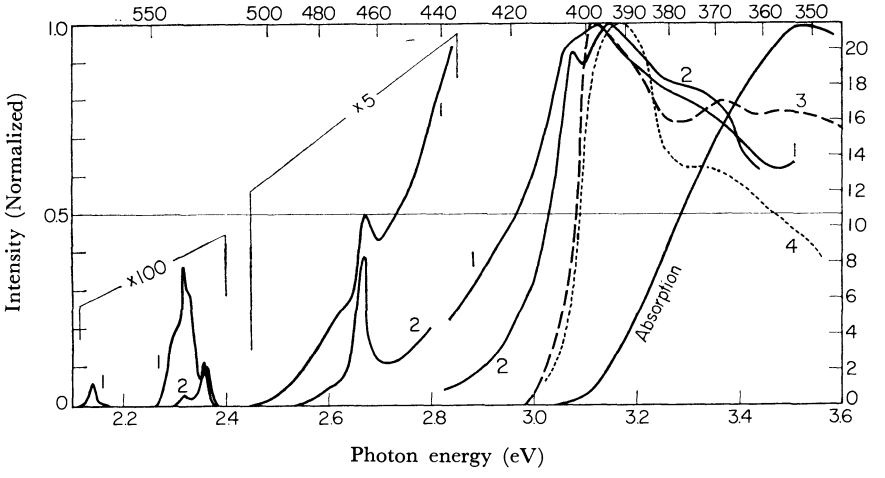

Fig. 3. Excitation spectra of EuD and LaD solutions at room and liquid nitrogen temperatures. No. 1: for europium emission of EuD at room temperature. 2: for europium emission at liquid nitrogen temperature. 3: for ligand phosphorescence of LaD at liquid nitrogen temperature. 4: for ligand fluorescence of LaD at liquid nitrogen temperature. The intensities of excitation bands in the region of 2.4—2.8 eV and 2.1—2.4 eV are magnified five and one hundred times, respectively. The absorption spectrum of EuD at room temperature is given for reference.

$\rightarrow {}^7F_2$. The emission spectrum of LaD consists of broad emission bands attributed to fluorescence and phosphorescence of the ligand. LaD exhibits no emission at room temperature. This is thought to be due to the collision of molecules in solution. At liquid nitrogen temperature, on the other hand, the sample is a rigid glass and no collisions take place; thus phosphorescence appears. EuD shows the emission both at room and liquid nitrogen temperatures although the emission intensity is much weaker at room temperature than at liquid nitrogen temperature.

The time-resolved emission spectra of LaD in ethanol solution at liquid nitrogen temperature are shown in Fig. 2. The higher energy bands in the spectra at 2.6 to 3.0 eV show very rapid decay, while the lower energy bands at 2.0 to 2.6 eV decay slowly. Thus the former is regarded as fluorescence due to the singlet-singlet transition and the later as phosphorescence due to the triplet-singlet transition.

The excitation spectra for europium emission due to the transition ${}^5D_0 \rightarrow {}^7F_2$ in EuD and also those for the ligand fluorescence and phosphorescence of LaD are shown in Fig. 3. The low energy edge of the excitation bands for the fluorescence and phosphorescence of LaD are located at nearly the same wavelength, 410 mμ. Comparing Fig. 3

with Figs. 1 and 2, it is obvious that the probability of excitation of the triplet state of the ligand due to direct optical absorption from the ground state is extremely small. As for europium emission, narrow excitation bands are found at 402 mμ, 464 mμ, 530 mμ and 580 mμ, in addition to the excitation band due to absorption by the ligand. These bands are attributed to transitions in the chelated europium ion, $^7F_{0,1}\rightarrow{}^5D_3$, $^7F_{0,1}\rightarrow{}^5D_2$, $^7F_{0,1}\rightarrow{}^5D_1$ and $^7F_{0,1}\rightarrow{}^5D_0$, respectively.

The decay curves of europium emission from EuD and of phosphorescence from LaD were measured at liquid nitrogen temperature. The decay time of the fluorescence from LaD could not be measured. The decay of the europium emission was exponential with a decay time of 0.394 msec. The phosphorescence from LaD also showed exponential decay with a decay time of 31.9 msec. This was found to be the longest decay time found among the various rare earth dibenzoylmethides.

The phosphorescence lifetime of LaD was measured in mixed solutions of LaD and EuD at liquid nitrogen temperature, in order to investigate whether energy transfer takes place from LaD to EuD. The total concentration, $C_{LaD}+C_{EuD}$, was kept at 2×10^{-4} M, while the ratio of C_{LaD} to C_{EuD} was changed. The result is shown in Fig. 4 as a function of the molar fraction of EuD (X_{EuD}). The lifetime is nearly constant in the region of X_{EuD} from 0 to 0.5, but in the region of X_{EuD} greater than 0.5, it decreases rapidly, becoming one fourth of the initial value at $X_{EuD}=0.9$. This fact indicates that the triplet state of LaD is quenched by the existence of EuD in the mixed solution.

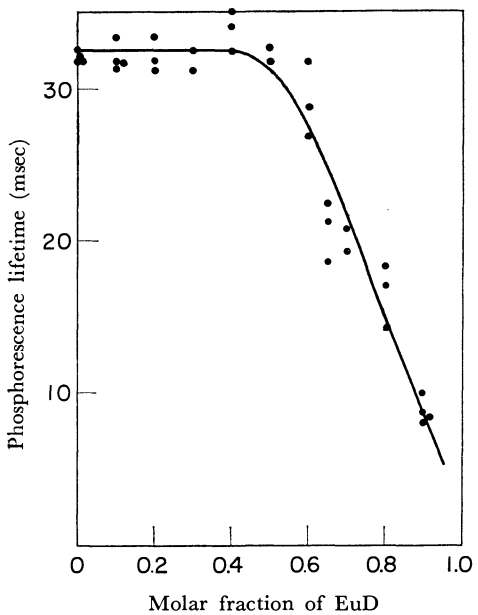

Fig. 4. The phosphorescence lifetime of LaD in mixed solutions of EuD and LaD at liquid nitrogen temperature.

The relative change of the europium emission intensity with the EuD molar fraction in the series of mixed solutions of EuD and LaD was measured with 546 mμ light excitation through the absorption of europium ion, and also with 365 mμ light excitation through the absorption by the ligand. The results at room temperature are given in Fig. 5. The intensities are normalized to unity at $X_{EuD}=1$ for both cases. It is seen that the europium emission intensity is exactly proportional to the EuD molar fraction.

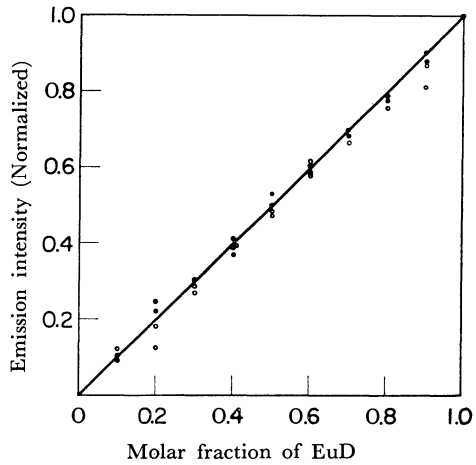

Fig. 5. The relative emission intensities of EuD in mixed solutions of EuD and LaD at room temperature. The mark ○ denotes the intensity obtained with direct excitation of europium ion (546 mμ), and ● indicates the intensity obtained with excitation of the ligand (365 mμ).

The absorbance of 546 mμ light by EuD is very small, and the optical density for a 1 cm thick layer of the solution with an EuD concentration of nearly 5×10^{-1} M is much smaller than 0.1. Therefore, the number of photons absorbed by the sample solution, n, is proportional to C_{EuD}, since

$$n = aI_0\{\exp(-\alpha C_{EuD}d)^{-1}\} \simeq a'I_0C_{EuD},$$

where I_0 is the intensity of light, α the absorption coefficient, and a and a' constants. If quenching of the emission from the chelated europium ion due to direct interaction between the europium ions does not occur, its emission intensity with 546 mμ excitation in the mixed solution, denoted by $I_{Eu}(546)$, should be

$$I_{Eu}(546) = \eta n = \eta a'IC_{EuD},$$

where η is the efficiency of the inner transition of europium ion. Figure 5 shows that this is actually the case.

For excitation with 365 mμ light, the absorption coefficient, α, of the ligand of EuD and LaD is nearly 2.0×10^4 l/mol cm. Therefore, light is

absorbed mostly in the vicinity of the front surface of the sample solution in the case of a concentration of $C_{LaD}+C_{EuD}=5\times10^{-3}$ M. The number of photons absorbed by EuD, n', is given by

$$n' = n_0 X_{EuD} = a' I_0' X_{EuD},$$

where n_0 is the number of photons absorbed by the mixed solution sample and I_0' the intensity of light. If intermolecular energy transfer from LaD to EuD is negligible, the europium emission intensity should be

$$I_{Eu}(365) = \eta' n' = \eta' a' I_0' X_{EuD},$$

where η' is the product of the efficiency of the intramolecular energy transfer and that of the emitting tansition of EuD. This agrees well with the experimental result given in Fig. 5. At room temperature, the phosphorescence of LaD, even in a solution of LaD only, is perfectly quenched, as mentioned above, because of the collision of molecules. This indicates that the lifetime of the triplet state of LaD is very short. Therefore, energy transfer from LaD to EuD at room temperature might be resonably neglected.

At liquid nitrogen temperature, since LaD shows phosphorescence, intermolecular energy transfer from LaD to EuD is expected to occur. In this case, it was difficult to measure directly the relative change of the europium emission intensity with EuD molar fraction in the mixed solutions. For this reason, the relative intensity was estimated from the excitation spectra in the following way. As mentioned above, at room temperature the concentration quenching of the europium emission due to interaction between chelated europium ions does not take place at the concentrations studied. This would also be the case at liquid nitrogen temperature. Then the relative change of the europium emission intensity with EuD molar fraction under 365 mμ light excitation, I_{Eu} (365), can be estimated by comparing the intensity of the excitation band due to ligand absorption with that of the excitation band due to europium absorption in the excitation spectrum for europium esmission. Namely,

$$I_{Eu}(365) = X_{EuD}\frac{J_{Eu}(365)}{J_{Eu}(568)\{\text{or } J_{Eu}(464)\}},$$

where $J_{Eu}(456)$ and $J_{Eu}(528)$ are the areas of the excitation bands at 456 and 528 mμ due to europium absorption, respectively, and $J_{Eu}(365)$ is the area of the excitation band due to ligand absorption between 360 and 380 mμ. The result is given in Fig. 6(a). The values are normalized to unity at $X_{EuD}=1.0$. If intermolecular energy transfer from LaD to EuD does not occur, $I_{Eu}(365)$ should be proportional to X_{EuD}. In the figure, it is seen that the curve of the intensity of the europium emission is located above the 45° line. This fact indicates that intermolecular energy transfer takes place from LaD to EuD, thus giving rise to an enhancement of the europium emission.

The relative change of the intensity of phosphorescence from LaD with EuD molar fraction in the mixed solutions was measured in a way similar to the case of europium emission. The relative intensity of the phosphorescence with 365 mμ excitation, $I_{ph}(365)$, is given by

$$I_{ph}(365) = X_{EuD}\frac{J_{ph}(365)}{J_{Eu}(464 \text{ or } 528)},$$
