In our studies, SDS was chosen as the surfactant because it is the most typical anionic surfactant and because the properties of its aqueous solution have been extensively studied by many workers and by various methods. In order to obtain some information about the micelle structure, the effect of additives on the properties of the aqueous solution of SDS was investigated. On the other hand, since there is no direct means to determine simultaneously both the size and shape of the micelle, it is difficult to discuss the micelle structure by only one method. In this studies, therefore, the micelle structure of the aqueous solution of SDS was investigated mainly in the concentration region above the 1st CMC, through systematic studies including measurements of the conductivity, light-scattering, density, viscosity, and depolarization of fluorescence. In the present paper, which is the first of a series of our studies, the results of the conductivity measurements will be reported.

Experimental

Materials. SDS was synthesized according to the method of Dreger.[14] Dodecyl alcohol (DA) was obtained from the Wako Pure Chemical Co., and its purity was determined by means of gas chromatography as 99.7%. The sulfonation of the DA was carried out by adding the DA, drop by drop, to an acetic acid solution of chlorosulfonic acid. The SDS thus obtained was recrystallized several times from the conductivity water and butyl alcohol respectively, and was then purified by a liquid/liquid extraction technique in which a 10% solution of SDS in 50% aqueous alcohol was extracted with 60/80 petroleum ether for 48 hr.[15] Reagent-grade benzene and hexane were purified by fractional distillation. Ultra-pure sodium chloride was obtained from the E. Merck Co. and was used without further purification.

Procedures. The conductivity measurements were carried out by using the apparatus previously described.[16,17] Unplatinized electrodes were employed in order to minimize the adsorption.[18] The concentration of the solution was changed successively by diluting it with conductivity water. The conductivity was measured in a water-thermostat of 25.000±0.005°C after the temperature equilibrium had been established.

In the case of the presence of organic additives, the solutions for conductivity measurements were prepared as follows. Thirty milliliters of a 0.15 M SDS solution were taken in a glass ampoule, and a known amount of DA was added to it. The amount of DA added was below the saturation point.[19] The ampoule was sealed after having been cooled by liquid nitrogen and shaken in a thermostat of 25°C for 48 hr in order to attain an equilibrium of solubilization. A series of ampoules was prepared, each of which contained DA; the molar ratios of DA to SDS were 1/200, 1/100, 1/50, 1/10, and 1/5. The same procedure was also used in the preparation of SDS solutions containing various amounts of solubilized benzene or hexane.[20,21]

Results

No Additives. In general, the 1st CMC of a surfactant solution is determined graphically as the break point in the plot of the specific conductivity *vs.* the concentration. The results of the conductivity measurement of an aqueous solution of SDS in the absence of additives are shown in Fig. 1, where the specific conductivity (κ) is plotted against the concentration of the SDS solution. It may be seen from this figure that a break point appears at about 65 mM in addition to that at 8.3 mM, the latter corresponds to the 1st CMC, while the former, the so-called 2nd CMC, agrees fairly well with the results obtained by other methods.[11-13] It may also be noted that the specific conductivity-concentration curve breaks upward at the 2nd CMC.

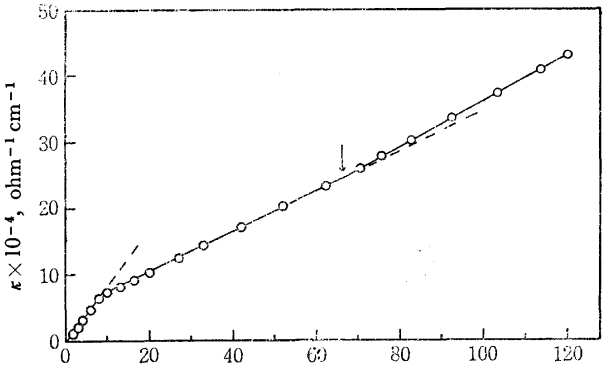

Fig. 1. Specific conductivity of SDS solution. The arrows in Figs. 1 and 2 indicates the 2nd CMC.

Effect of Sodium Chloride. In general, crude SDS is apt to contain sodium chloride as an impurity, for the latter is formed as a by-product in the process of the synthesis of SDS. Therefore, the effect of sodium chloride on the 2nd CMC of the aqueous solution of SDS was investigated. The specific conductivities of SDS solutions containing various amounts of sodium chloride are plotted against the concentration of SDS in Fig. 2. The 1st CMC of the SDS solution lowers with an increase in the concentration of sodium chloride; this is in agreement with the results obtained by other workers. It is interesting to note that the 2nd CMC lowers and the slope of straight line above the 2nd CMC rises with an increase in the sodium chloride concentration.

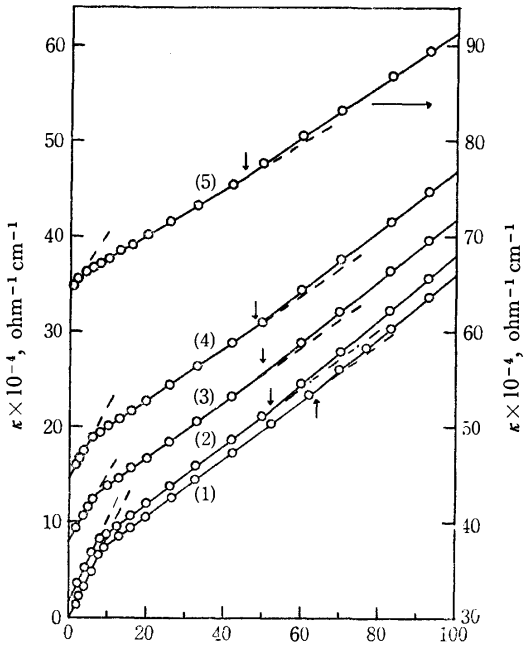

Fig. 2. Specific conductivities of SDS solutions in the presence of NaCl; concentration of NaCl: (1) 0 M, (2) 0.001 M, (3) 0.005 M, (4) 0.01 M, (5) 0.05 M. The plot in the presence of 0.0005 M NaCl was omitted in this figure.

Figure 3 shows the deviation of the specific conductivity ($\Delta\kappa$) from the extrapolation of the linear plot of the specific conductivity *vs.* the concentration below the 2nd CMC in Fig. 2 to a higher concentration. It may be seen from the figure that $\Delta\kappa$ is positive regardless of the sodium chloride concentration and that the angle (α) formed by the two straight lines increases with the sodium chloride concentration.

Effect of Dodecyl Alcohol. It is well known that DA, which is the main starting material in the syntheses of SDS, is apt to remain unreacted as a contaminant in crude SDS and has a profound influence upon the properties of the SDS solution. Therefore, the effect of DA on the 2nd CMC of the aqueous solution of SDS was investigated. DA was added to a SDS solution in a molar ratio of DA to SDS, 1/200, 1/100, 1/50, 1/10, or 1/5. The results of the conductivity measurements are presented in Fig. 4, where $\Delta\kappa$ is plotted against the concentration of SDS. The

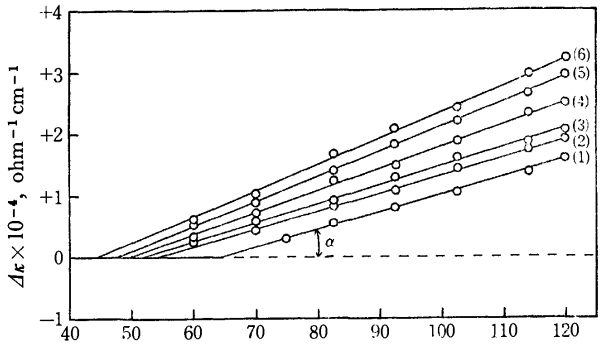

Fig. 3. $\Delta\kappa$ of SDS solutions in the presence of NaCl; concentration of NaCl: (1) 0 M, (2) 0.0005 M, (3) 0.001 M, (4) 0.005 M, (5) 0.01 M, (6) 0.05 M.

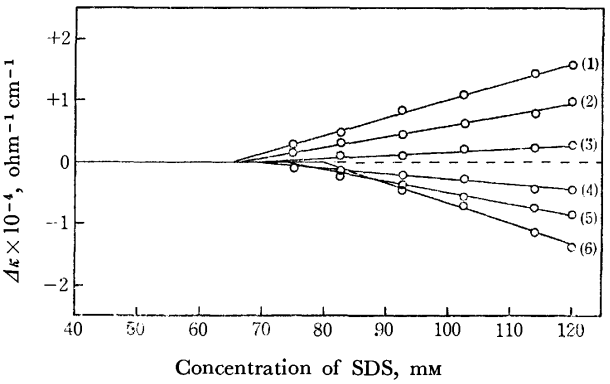

Fig. 4. $\Delta\kappa$ of SDS solutions in the presence of DA; molar ratio of DA to SDS: (1) 0, (2) 1/200, (3) 1/100, (4) 1/50, (5) 1/10, (6) 1/5.

slope of the straight line above the 2nd CMC becomes lower with an increase in the concentration of DA, that is, $\Delta\kappa$ decreases and at last becomes negative when the DA is added in a molar ratio of 1/50 or more to the SDS solution. Moreover, the 2nd CMC increases with the DA concentration. It is of great interest that the results in the presence of DA are quite the opposite of those in the presence of sodium chloride.

Effects of n-*Hexane and Benzene.* Next the effect of non-polar compounds on the properties of the SDS solution were studied. Here, *n*-hexane with a

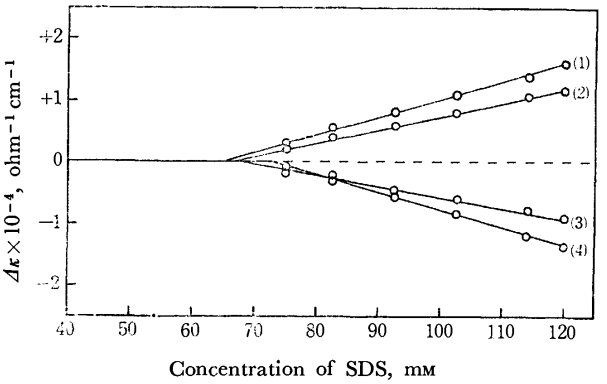

Fig. 5. $\Delta\kappa$ of SDS solutions in the presence of *n*-hexane; molar ratio of *n*-hexane to SDS: (1) 0, (2) 1/100, (3) 1/15 (4) 1/4.

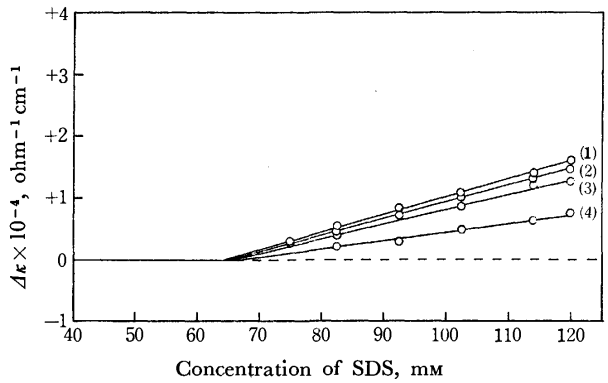

Fig. 6. $\Delta\kappa$ of SDS solutions in the presence of benzene; molar ratio of benzene to SDS: (1) 0, (2) 1/100, (3) 1/10, (4) 1/2.

chain structure and benzene with a ring structure were selected as representatives of nonpolar compounds. The results obtained in the presence of *n*-hexane and those obtained in the presence of benzene are shown in Figs. 5 and 6 respectively. The effect of *n*-hexane is quite similar to that of DA, while benzene does not have such a marked effect.

Effect of Sodium Chloride and DA. Since sodium chloride and DA generally coexist in crude SDS, the effect of these two compounds on the conductivity behavior of the SDS solution was studied; the results are shown in Fig. 7. As may be in Figs. 3 and 4, the results in the presence of sodium chloride are opposed to those in the presence of DA with respect to the 2nd CMC and the slope of the specific conductivity *vs.* the concentration curve above the 2nd CMC. However, when the two compounds coexist, their effects on these two properties compensate each other, as can be seen in Fig. 7.

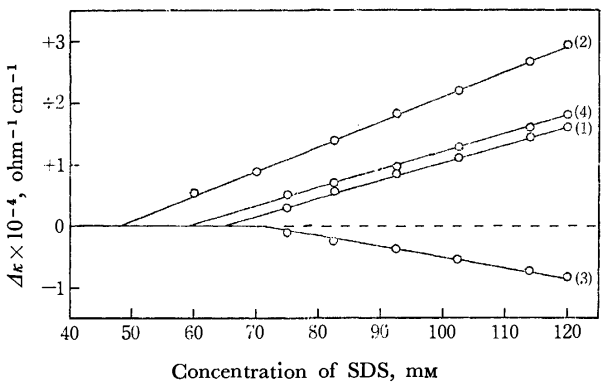

Fig. 7. $\Delta\kappa$ of SDS solutions; (1) no additive, (2) 0.01 M NaCl, (3) DA to SDS 1/10, (4) 0.01 M NaCl and DA in molar ratio of DA to SDS 1/10.

Discussion

As is obvious from Fig. 1, the specific conductivity *vs.* concentration curve of the pure SDS solution breaks upward at the 2nd CMC. When a certain amount of DA is added to the SDS solution, the curve breaks downward, as is seen in Fig. 4. Similar results were obtained for the system of sodium decyl sulfate and decyl alcohol, as is shown in Fig. 8, where the sodium

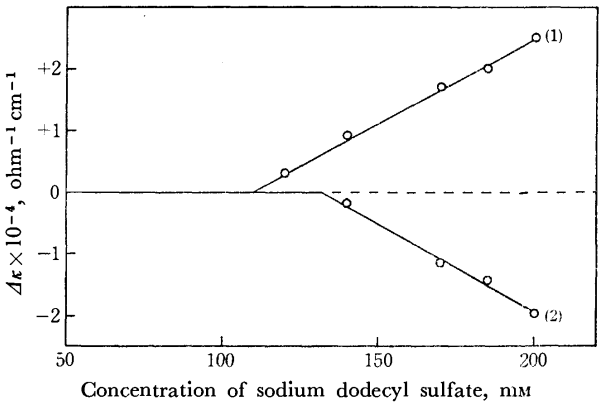

Fig. 8. $\Delta\kappa$ of sodium decyl sulfate solutions; (1) no additive, (2) decyl alcohol in its molar ratio to sodium decyl sulfate 1/10.

decyl sulfate used was carefully purified. In our previous study,[12] the curve bent toward the concentration axis. This may result from the presence of organic impurities such as DA.

In general, the purity of the surfactant can be checked by means of the value of the 1st CMC or by the presence or absence of the minimum in the surface tension *vs.* concentration curve. By the present study, another criterion for the purity of the surfactant was found: the presence of organic contaminants in the surfactant solution can be checked by means of the value of the 2nd CMC and the slope of the specific conductivity *vs.* concentration curve.

In the presence of sodium chloride, the 2nd CMC as well as the 1st CMC lowers, and at the same time $\Delta\kappa$ increases, with an increase in its concentration. On the other hand, in the presence of DA or *n*-hexane, though the 1st CMC loweres, as is well known, the 2nd CMC increases and $\Delta\kappa$ decreases and finally becomes negative with an increase in the concentration of DA or *n*-hexane. It is clear from these results that nonelectrolytes have the same influence on the 1st CMC, but have quite the opposite influence on the 2nd CMC, as compared with electrolytes. These facts may afford a clue for elucidating the micelle structure above the 2nd CMC.

As can be expected from the results shown in Figs. 4 and 5, the specific conductivity *vs.* concentration curve may show no change at the concentration corresponding to 2nd CMC when an appropriate amount of non-electrolyte is present, *e.g.*, an intermediate quantity between 1/100 and 1/50 in molar ratio in the case of DA. The same situation can be deduced when an electrolyte coexists with a non-electrolyte in a certain molar ratio, as can be seen in Fig. 7. In such cases, there may be no 2nd CMC; the presence of a proper amount of the impurities of non-electroytes may stabilize the micelle formed in the region of low concentrations.

Though both *n*-hexane and benzene are nonpolar compounds, the former has a much larger influence upon the 2nd CMC than the latter, as may be seen in Figs. 5 and 6. This may arise from the difference in the mode of solubilization between these two compounds.

Distribution Studies of Alkali Metal Picrates

Tadashi IWACHIDO

College of Liberal Arts, Okayama University, Tsushima, Okayama

(Received March 26, 1971)

Alkali metal picrates are extractable from an aqueous solution into nitrobenzene. The picrates exist mainly as the dissociated form in both the aqueous and the nitrobenzene phases, whereas picric acid exists mainly as the undissociated form in the organic phase. The distribution ratio of the picrates and picric acid at any pH can well be explained in terms of these equilibrium constants. The distribution coefficient of picric acid is evaluated to be $10^{2.63}$.

Polynitroderivatives of phenol and diphenylamine are known as extracting agents of alkali metal cations. However, little is known about the extraction mechanism. Only for alkali metal picrates[1] and hexanitrodiphenylaminates,[2] the distribution coefficient between aqueous and nitrobenzene phases and the association constants in the aqueous phase have been determined by means of the extraction method. As the association constants of the picrates in nitrobenzene phase, the values obtained by means of conductivity measurements have been cited. Such equilibrium constants show that these salts strongly dissociate in nitrobenzene as well as in the aqueous phase. From these data, it can be concluded that the distribution ratio of alkali metals increases with an increase in the dissociation constant in the organic phase and with a decrease in that in the aqueous phase. The present paper will describe that the introduction of the new constant, that is, the dissociation constant of picric acid in the aqueous phase and the distribution coefficient of the acid made it possible to interpret the dependence of the distribution ratio upon the pH of the aqueous solution.

Experimental

Reagents. All the alkali metal picrates except lithium salt were prepared by dissolving picric acid into an aqueous solution containing alkali metal hydroxide or carbonate. The resultant precipitates were recrystallized thrice from water containing a small amount of the corresponding alkali metal hydroxide or carbonate.

Citric acid-lithium citrate buffers (0.1 M) and 0.1 M phosphoric acid-lithium phosphate buffers were used to adjust the pH of the solution to pH 1.5—5 and pH 6—8 respectively.

Extraction. Into a 50-m*l* separatory funnel, 5 m*l* of a 1.000×10^{-2} M picric acid or alkali metal picrate solution were transferred; then the same volume of the buffer solution of a definite pH was added. The resultant aqueous solution was then shaken with 10 m*l* of nitrobenzene for two hours at 25°C.

Determination of Alkali Metal and Picrate Ions. The concentration of alkali metals extracted into the nitrobenzene was determined using an atomic absorption spectrophotometer (Nippon Jarrell Ash, Type AA-1); the concentration of picrate in the aqueous solution was estimated spectrophotometrically at 353 mμ after diluting the solution 250 times with water, and the pH of the solution was adjusted at pH 12. The nitrobenzene existing as a contaminant in the aqueous solution also shows an appreciable absorbance at the same wavelength, but in such a high dilution as 250 times the interference can be almost extinguished.

After equilibration, the pH of the aqueous solution was measured in order to analyse the distribution equilibrium.

Theoretical

Writing the formulae for picric acid and alkali metal picrates as HR and MR respectively, the reactions involved can be represented schematically as in Fig. 1.

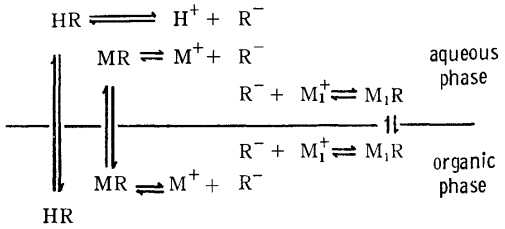

Fig. 1. Schematic representation of the equilibria involved in the extraction.

1) Dissociation of Picric Acid.

$$HR \rightleftarrows H^+ + R^- \qquad K_a^{HR} = \frac{[H^+]_a[R^-]_a}{[HR]_a} \tag{1}$$

2) Association of Alkali Metal Picrates.

$$M^+ + R^- \rightleftarrows MR \qquad K_a^{MR} = \frac{[MR]_a}{[M^+]_a[R^-]_a} \tag{2}$$

$$K_o^{MR} = \frac{[MR]_o}{[M^+]_o[R^-]_o} \tag{3}$$

$$M_I^+ + R^- \rightleftarrows M_IR \qquad K_a^{M_IR} = \frac{[M_IR]_a}{[M_I^+]_a[R^-]_a} \tag{4}$$

$$K_o^{M_IR} = \frac{[M_IR]_o}{[M_I^+]_o[R^-]_o} \tag{5}$$

3) Distribution of the Neutral Molecules.

$$D^{HR} = \frac{[HR]_o}{[HR]_a} \tag{6} \qquad D^{MR} = \frac{[MR]_o}{[MR]_a} \tag{7}$$

$$D^{M_IR} = \frac{[M_IR]_o}{[M_IR]_a} \tag{8}$$

In these equilibrium expressions, the a and o subscripts refer to the aqueous and the organic phases respectively; the brackets, to the molar concentration, and M_I^+, to a competing cation. As the competing cation it is desirable to choose a cation which associ-

ates with the picrate ion most weakly in the aqueous solution and most strongly in nitrobenzene. In the present case, the lithium ion suits this purpose.

i) Distribution of Picric Acid. The distribution ratio or the concentration ratio of the reagent species at equilibrium between the two phases can be written as:

$$q^{R}=\frac{[HR]_o+[MR]_o+[M_IR]_o+[R^-]_o}{[HR]_a+[MR]_a+[M_IR]_a+[R^-]_a} \tag{9}$$

Each of the last three terms in the numerator can be expressed in terms of the corresponding constants as follows:

$$[MR]_o=\frac{D^{MR}K_a^{MR}K_a^{HR}[M^+]_a}{D^{HR}\quad[H^+]_a}[HR]_o \tag{10}$$

$$[M_IR]_o=\frac{D^{M_IR}K_a^{M_IR}K_a^{HR}[M_I^+]_a}{D^{HR}\quad[H^+]_a}[HR]_o \tag{11}$$

$$[R^-]_o=\frac{D^{MR}K_a^{MR}K_a^{HR}[M^+]_a}{D^{HR}K_o^{MR}[M^+]_o[H^+]_a}[HR]_o \tag{12}$$

Thus, substituting Eqs. (10), (11), and (12) into Eq. (9) gives the equation:

$$q^{R}=D^{HR}\frac{1+\left\{\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a+D^{M_IR}K_a^{M_IR}[M_I^+]_a\right\}\frac{K_a^{HR}}{D^{HR}[H^+]_a}}{1+(1+K_a^{MR}[M^+]_a+K_a^{M_IR}[M_I^+]_a)\frac{K_a^{HR}}{[H^+]_a}} \tag{13}$$

A useful approximation for q^R may be obtained from Eq. (13) by making the appropriate assumptions.

(a) If the fourth term in the numerator is assumed to be small enough compared to the second and the third, Eq. (13) can be simplified to:

$$q^{R}=D^{HR}\frac{1+\left\{\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)\frac{D^{MR}K_a^{MR}K_a^{HR}[M^+]_a}{D^{HR}[H^+]_a}\right\}}{1+(1+K_a^{MR}[M^+]_a+K_a^{M_IR}[M_I^+]_a)\frac{K_a^{HR}}{[H^+]_a}} \tag{14}$$

(b) If the alkali metals are absent in this system, Eq. (13) can be further simplified to the well-known equation:

$$q^{R}=\frac{D^{HR}}{1+\frac{K_a^{HR}}{[H^+]_a}} \tag{15}$$

Equation (13) is the most general expression, but practically Eq. (14) may be the most convenient.

When the aqueous solution is sufficiently acidic, the second and the succeeding terms in the numerator of Eq. (14) may be neglected compared to the first, and in the denominator the first term may be negligible. Thus, Eq. (14) can be simplified to:

$$q^{R}=\frac{D^{HR}}{(1+K_a^{MR}[M^+]_a+K_a^{M_IR}[M_I^+]_a)K_a^{HR}}[H^+]_a \tag{16}$$

The concentration of alkali metals in the aqueous solution can be regarded as constant, because the amounts of these salts extracted into nitrobenzene are very small. Hence, q^R becomes a function of pH alone. A plot of log q^R *vs.* pH will give a straight line with a slope of -1, and from the intercept we can calculate the ratio of the distribution coefficient to the dissociation constant of picric acid, D^{HR}/K_a^{HR}. If the constant, K_a^{HR}, is known, D^{HR} can be calculated.

On the other hand, when the aqueous solution is sufficiently alkaline, the second and the succeeding terms in both the numerator and the denominator of Eq. (14) will become much larger than the first, giving:

$$q^{R}=\frac{\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a}{1+K_a^{MR}[M^+]_a+K_a^{M_IR}[M_I^+]_a} \tag{17}$$

If $[M^+]_0$ is assumed to reach a certain constant value under sufficiently alkaline conditions, q^R may become a constant value in such a pH region.

The pH value at the intersection of the two constant-slope portions represented by Eqs. (16) and (17) may be calculated using the following equation:

$$[H^+]_a=\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)\frac{D^{MR}K_a^{MR}K_a^{HR}[M^+]_a}{D^{HR}} \tag{18}$$

ii) Distribution of Alkali Metals. At equilibrium, the distribution of alkali metals between the two phases can be written as:

$$q^{M}=\frac{[MR]_o+[M^+]_o}{[MR]_a+[M^+]_a} \tag{19}$$

The total concentrations of the reagent, C^R, and of alkali metals, C^M, are represented as:

$$C^{R}=[HR]_a+[HR]_o+[MR]_a+[MR]_o+[M_IR]_a+[M_IR]_o+[R^-]_a+[R^-]_o \tag{20}$$

$$C^{M}=[MR]_a+[MR]_o+[M^+]_a+[M^+]_o \tag{21}$$

The electroneutrality in the organic phase is expressed as:

$$[R^-]_o=[M^+]_o+[M_I^+]_o \tag{22}$$

Combining Eqs. (20), (21), and (22) and solving for $[R^-]_a$ gives the following relationships:

$$C^{R}-C^{M}=[HR]_a+[HR]_o+[M_IR]_a+[M_IR]_o+[R^-]_a-[M^+]_a+[M_I^+]_o \tag{23}$$

$$\frac{1}{[R^-]_a}=\frac{1+\frac{(1+D^{HR})}{K_a^{HR}}[H^+]_a+(1+D^{M_IR})K_a^{M_IR}[M_I^+]_a}{C^{R}-C^{M}+[M^+]_a-[M_I^+]_o} \tag{24}$$

On the other hand, the rearrangement of Eq. (19) gives:

$$q^{M}=\frac{[MR]_o\left(1+\frac{1}{K_o^{MR}[R^-]_o}\right)}{[MR]_a\left(1+\frac{1}{K_a^{MR}[R^-]_a}\right)} \tag{25}$$

The substitution of Eq. (24) into Eq. (25) gives this useful expression:

$$q^{M} = D^{MR}\frac{\left\{1+\frac{1}{K_0^{MR}[R^-]_0}\right\}}{\left\{1+\frac{1+(1+D^{HR})[H^+]_a/K_a^{HR}+(1+D^{M_IR})K_a^{M_IR}[M_I^+]_a}{K_a^{MR}(C^R-C^M+[M^+]_a-[M_I^+]_0)}\right\}} \tag{26}$$

If the extraction is carried out when $C^R-C^M=0$, Eq. (26) reduces to:

$$q^{M} = D^{MR}\frac{\left\{1+\frac{1}{K_0^{MR}([M^+]_0+[M_I^+]_0)}\right\}}{\left\{1+\frac{1+(1+D^{HR})[H^+]_a/K_a^{HR}+(1+D^{M_IR})K_a^{M_IR}[M_I^+]_a}{K_a^{MR}([M^+]_a-[M_I^+]_0)}\right\}} \tag{27}$$

Equation (27) is so complex that the dependence of the q^M value upon the pH can not be understood easily from the equation. However, a useful approximation for q^M may be obtained from Eq. (27) by making the following assumptions:

a) that the concentration of alkali metals in the aqueous solution is much greater than that of the competing ion in the organic phase: $[M^+]_a \gg [M_I^+]_0$;

b) that the distribution coefficient of lithium picrate is negligible compared to 1, whereas that of picric acid is much larger than 1: $1 \gg D^{M_IR}$ and $D^{HR} \gg 1$;

c) that the dissociated species are dominant in both phases: $q^M \approx [M^+]_0/[M^+]_a$ and

d) that the concentration of metal ions to be tested in the organic phase is much larger than that of the lithium ion: $[M^+]_0 \gg [M_I^+]_0$. In this manner, Eq. (27) can be simplified to the following expression:

$$(q^M)^2 = D^{MR}\frac{\left([M^+]_0+\frac{1}{K_0^{MR}}\right)}{\left\{[M^+]_a+\frac{1}{K_a^{MR}}\left(1+\frac{D^{HR}}{K_a^{HR}}[H^+]_a+K_a^{M_IR}[M_I^+]_a\right)\right\}} \tag{28}$$

When the aqueous solution is sufficiently acidic, the third term in the denominator will become by far larger than the residual terms, and the first term in the numerator, much smaller than the second, thus yielding:

$$(q^M)^2 = \frac{D^{MR}K_a^{MR}K_a^{HR}}{K_0^{MR}D^{HR}}\frac{1}{[H^+]_a} \tag{29}$$

A plot of log q^M *vs.* pH gives a straight line with a slope of 1/2, and the intercept is given by 1/2 log-$D^{MR}K_a^{MR}K_a^{HR}/K_0^{MR}D^{HR}$.

Alternatively, when the aqueous solution is kept sufficiently alkaline, the term involving $[H^+]_a$ can be neglected; hence, Eq. (28) reduces to:

$$(q^M)^2 = D^{MR}\frac{\left([M^+]_0+\frac{1}{K_0^{MR}}\right)}{\left([M^+]_a+\frac{1}{K_a^{MR}}+\frac{K_a^{M_IR}}{K_a^{MR}}[M_I^+]_a\right)} \tag{30}$$

Since $[M^+]_a$ and $[M^+]_0$ remain almost constant, as has been mentioned, a plot of log q^M *vs.* pH gives a horizontal line.

The logarithm of the q^M-pH curve appears as two constant-slope portions joined by a short curve; the point of intersection can be calculated from Eq. (28) by assuming $[M^+]_0 \ll 1/K_0^{MR}$:

$$\frac{1}{[H^+]_a} = \frac{D^{HR}}{(K_a^{MR}[M^+]_a+1+K_a^{M_IR})K_a^{HR}} \tag{31}$$

Equation (31) shows that the value of D^{HR}/K_a^{HR} can be obtained not only from the log q^R-pH curve, but also from the log q^M-pH curve.

Results and Discussion

i) Equilibria Involved in the Extraction System. The equilibria shown in Fig. 1 are fundamental ones. Of course, these simple expressions are used for convenience to represent the possible complex equilibria in which the solvent molecules participate. Some other equilibria, such as:

$$2HR \rightleftarrows (HR)_2$$

$$RHR^- \rightleftarrows HR + R^- \qquad K_0^{RHR^-} = \frac{[HR]_0[R^-]_0}{[RHR^-]_0}$$

$$HR \rightleftarrows H^+ + R^- \qquad K_0^{HR} = \frac{[H^+]_0[R^-]_0}{[HR]_0}$$

may exist. As has been pointed out by Moore[3] and Brønsted,[4] the dimerization of picric acid need not be considered in the aqueous phase or even in the organic phase. Kolthoff[5] and his collaborators have mentioned that a homoconjugation reaction of picrate anions may be expected to exist in a nitrobenzene solution, and that the dissociation constant evaluated from the solubility measurements is above 10^{-2}. In the same paper, he has also estimated spectrophotometrically the dissociation constant for picric acid in nitrobenzene to be 3.5×10^{-8} at 25°C. Judging from the magnitude of the constants, these reactions were assumed not to be taken into account under the present experimental conditions.

The association constants and the distribution coefficients of the alkali metal picrates are listed in Table 1. It must be noted that K_0^{MR} in this table is used to designate the association constant of the picrates in water-saturated nitrobenzene in place of the $K_0^{MR}{}_{(H_2O)}$ in the original paper.[1]

ii) Distribution of Picric Acid. Plots of log-q^R *vs.* pH are shown in Figs. 2 to 6. Each curve gives a straight line with a slope of exactly −1 in a suf-

ficiently acidic solution. A horizontal line was observed only in the extraction of potassium, rubidium, and cesium picrates, which is in accord with the expectation based on Eq. (17). As the errors inherent in the spectrophotometric method are of the order of 1 per cent, small distribution ratios below 10^{-2} can not be determined accurately. Therefore, the values of q^R below $10^{-2.5}$ are not shown in these figures. This is the case for lithium and sodium picrates.

The values of D^{HR}/K_a^{HR} are estimated to be approximately $10^{3.05}$. The evaluation of D^{HR} requires the dissociation constant for picric acid in water saturated with nitrobenzene. For the lack of available data on K_a^{HR}, the constant was replaced by the one obtained in an aqueous solution. The D^{HR} values thus obtained are listed in the fourth column of Table 2. These five values are close to each other within the limits of experimental error, and the mean value, $10^{2.63}$, is in fairly good agreement with $10^{2.41}$.[7] The totals concentration of the picrate ions existing in both phases at a sufficiently high pH were 4.96×10^{-3}, 4.98×10^{-3}, 4.95×10^{-3}, 4.97×10^{-3}, and 4.94×10^{-3} M for lithium, sodium, potassium, rubidium, and cesium picrates respectively. This shows that the accuracy of the experiments is satisfactory.

iii) Estimation of $K_a^{M_1R}$, D^{M_1R}, and $K_0^{M_1R}$.

Due to the very low extractability of lithium picrate, $K_a^{M_1R}$ and D^{M_1R} can not be determined by the extraction method.[1] For the other alkali metal picrates, a plot of log K_a^{MR} or log D^{MR} *vs.* the ionic radii of these cations helps in the evaluation of these values for lithium picrate. The linear extrapolation of each line to r=0.68 Å gives the approximate values of $K_a^{M_1R}$ and D^{M_1R} (Fig. 7). However, the validity of such an approximation is difficult to justify.

Witschonke and Kraus[8] have reported that the dissociation constant of lithium picrate in nitrobenzene containing 0.03 M water is $10^{5.80}$. The dissociation constant tends to increase with the water content in nitrobenzene. Therefore, a somewhat greater value than $10^{5.80}$ might be expected with water-saturated (0.1 M)

TABLE 3. CONSTANTS CHARACTERISTIC OF log q^M-pH CURVES

Salts	Intercept at pH=0		pH-independent q^M values				$[H^+]_a$ values at the intersection	
	(Meas)	(Calcd)	(Meas)	(Calcd by Eq. (32))	(Calcd by Eq. (30))	(Calcd by Eq. (27))	(Meas)	(Calcd)
Na-Pic	10^{-4}	$10^{-3.91}$	$10^{-2.85}$	$10^{-2.42}$	$10^{-2.54}$	$10^{-2.71}$	10^{-2}	$10^{-2.77}$
K-Pic	$10^{-3.11}$	$10^{-3.08}$	$10^{-1.73}$	$10^{-1.57}$	$10^{-1.69}$	$10^{-1.69}$	$10^{-2.80}$	$10^{-2.74}$
Rb-Pic	$10^{-2.68}$	$10^{-2.74}$	$10^{-1.30}$	$10^{-1.18}$	$10^{-1.33}$	$10^{-1.37}$	$10^{-2.76}$	$10^{-2.77}$
Cs-Pic	$10^{-2.39}$	$10^{-2.33}$	$10^{-0.94}$	$10^{-0.77}$	$10^{-0.91}$	$10^{-0.85}$	$10^{-2.92}$	$10^{-2.77}$

nitrobenzene; however, because of the lack of a way to estimate the extent of the effect, $K_o^{M_IR}$ is approximated by $10^{5.80}$ in the present paper.

iv) Distribution of Alkali Metal Picrate. Figures 2 to 6 show a plot of log q^M *vs.* pH by means of solid circles. Each curve consists of two constant-slope portions; that is, one is a line with a constant slope of 1/2, and the other, a horizontal line independent of the pH. These results are in good accord with the expectations based on the formulation.

The q^M values at the intercepts of the log q^M-pH curves agree well with those to be expected from Eq. (29), as is shown in Table 3. For sodium and lithium picrates, the q^M values below pH 2 were so erroneous that the values measured in this pH region are shown without drawing a line.

The pH-independent q^M values obtained and calculated by means of Eq. (30) are listed in the fourth and the sixth columns of Table 3 respectively. The values increased in proceeding from sodium to cesium, and the agreement between the observed and the calculated values was satisfacotry. It must be noted that the such q^M values can also be approximated by the following equation:

$$(q^M)^2 = \frac{D^{MR}K_a^{MR}}{K_o^{MR}} \tag{32}$$

The fifth column of Table 3 shows that such a simple relationship is still valid for potassium, rubidium, and cesium picrates.

Figures 2 to 4 show that, in both the log q^M-pH and the log q^R-pH curves, the q^M and q^R values tend to approach each other in the high pH region. The situation can be well understood by rewriting Eq. (17) as follows:

$$q^R = \frac{\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a}{1+K_a^{MR}[M^+]_a+K_a^{M_IR}[M_I^+]_a} \tag{17}$$

$$= D^{MR}\frac{\left(\frac{1}{K_o^{MR}}+[M^+]_o\right)}{\left(\frac{1}{K_a^{MR}}+[M^+]_a+\frac{K_a^{M_IR}}{K_a^{MR}}[M_I^+]_a\right)}\frac{[M^+]_a}{[M^+]_o} \tag{17a}$$

The approximation of $[M^+]_a/[M^+]_o$ by $1/q^M$ gives:

$$q^Rq^M \approx D^{MR}\frac{\left(\frac{1}{K_o^{MR}}+[M^+]_o\right)}{\left(\frac{1}{K_a^{MR}}+[M^+]_a+\frac{K_a^{M_IR}}{K_a^{MR}}[M_I^+]_a\right)} \tag{33}$$

The term on the right-hand side of the above equation is identical with $(q^M)^2$ (cf. Eq. (30)), so Eq. (33) reduces to:

$$q^R \approx q^M \tag{34}$$

Such a relationship can also be directly derived from Eq. (9) in a somewhat different manner. If the aqueous solution is kept sufficiently alkaline, the hydrolysis of the picrate ions can be neglected. Thus, Eq. (9) reduces to:

$$q^R = \frac{[M_IR]_o+[MR]_o+[R^-]_o}{[M_IR]_a+[MR]_a+[R^-]_a} \tag{35}$$

If $[M_IR]_a$ and $[M_IR]_o$ are assumed to be negligibly small, $[R^-]_a$ and $[R^-]_o$ in Eq. (35) can be replaced by $[M^+]_a$ and $[M^+]_o$ respectively, because C^R and C^M are kept equal in the present case. This leads to the same relationship:

$$q^R \approx q^M$$

The eighth column in Table 3 shows that the pH value at the intersection of these two constant-slope portions is characteristic of all the picrates, as is to be expected from Eq. (31). The agreement between the observed and the calculated values is very good. This means that, from the intersect, the D^{HR}/K_a^{HR} value can be calculated correctly in the opposite sense.

v) Corrections for the Competing Ions. In the above treatments, the lithium ions in the organic phase have been neglected. Since appreciable amounts of lithium picrate are also extractable by nitrobenzene, as is shown in Fig. 6, the effect of the lithium ions must be taken into account when a stricter treatment is required. Equation (27) is useful for this purpose. The pH-independent q^M values as corrected by the equation are shown in the seventh column of Table 3. As might be expected, the corrections are larger for sodium picrate; this results in a marked improvement of the agreement between the observed and the calculated values. These facts may indicate the validity of the values ($K_a^{M_IR}$ and D^{M_IR}) estimated by the graphical method.

The author wishes to express his gratitude to Professor Kyoji Tôei for his guidance throughout the course of this work.

Kinetics and Mechanisms of the Reaction of Fe(III) with Variamine Blue, [*N*-(*p*-Methoxyphenyl)phenylenediamine] in Aqueous Perchlorate Media

Taira IMAMURA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 21, 1971)

The kinetics of the non-complementary reaction of Fe(III) with Variamine Blue was studied under nitrogen atmosphere in perchlorate media of ionic strength $\mu=1.0$ M. The iminoquinone form of Variamine Blue was followed spectrophotometrically by a stopped-flow technique. The rate constants of the stepwise reaction, $Fe(III)+(V.B.)\underset{k_r}{\overset{k_\alpha}{\rightleftarrows}}Fe(II)+(V.B.)_{sox}$, $Fe(III)+(V.B.)_{sox}\xrightarrow{k_\beta}Fe(II)+(V.B.)_{ox}+2\,H^+$, were evaluated to be $k_\alpha=3.28\times10^2$ and $k_\beta=4.29\times10^2$ M^{-1} sec^{-1} at pH$\simeq$2.2 and 25°C. The apparent activation energy was 10 ± 1 kcal·mol^{-1} for both k_α and k_β. The formation rate was not seriously affected by hydrogen ion concentration (pH 2.2—0.77).

Variamine Blue (abbr. V.B.) is used as a redox indicator with many applications.[1] It has been reported that the colorless solution of V.B. undergoes two-electron oxidation to a violet-red iminoquinone (abbr. $(V.B.)_{ox}$) by oxidizing agents such as Ce(IV), Fe(III) and I_2, as follows.[2,3]

(V. B.) (V. B.)$_{ox}$

Erdey *et al.*[4-6] suggest the following reaction scheme of V.B. with oxidizing agents.

$$(V.B.)\rightleftharpoons(V.B.)_s\rightleftharpoons 1/2(V.B.)_D\rightleftharpoons(V.B.)_{ox},$$

where $(V.B.)_s$ is a semiquinone form, and $(V.B.)_D$ a dimeric one.

We are interested in the possibility of the existence of such intermediates during the course of the reaction, and the mechanisms of the reactions of V.B. with various oxidizing agents such as Co(III), Ce(IV), Tl(III), Fe(III), and I_2.

The present paper reports the reaction of V.B. with Fe(III) in 1.0 M perchlorate media. The reaction was spectrophotometrically followed by a stopped-flow technique at 550 nm corresponding to the λ_{max} of $(V.B.)_{ox}$ under the condition $[Fe(III)]\gg[V.B.]$.

Experimental

Measurements. A Hitachi recording spectrophotometer model EPS-3T was used for spectral measurements. Variations of spectra with time were measured at wavelengths 350—700 nm with a Hitachi RPS-1 rapid scan apparatus. The rates of rapid reactions were measured using a Yanagimoto stopped-flow apparatus SPS-1. Purified nitrogen gas was passed through the reservoirs of the solutions during the course of measurements.

Materials. Deionized and distilled water was used. Iron(III) perchlorate was prepared by heating iron(III) chloride with a small excess of 60% perchloric acid under reduced pressure at about 60—65°C until no trace of chloride ion was detected. Sexihydrate thus obtained was dissolved in water. The concentration of Fe(III) was determined with EDTA titrimetrically.

Iron(II) perchlorate solution was prepared by electrolytic reduction of 1.07×10^{-2} M iron(III) perchlorate in 0.2 M perchloric acid under nitrogen atmosphere until negative tests were attained with thiocyanate. The solution was titrated with Ce(IV) using ferroin as an indicator and stored in a Pyrex bottle under nitrogen atmosphere.

Reagent grade sodium perchlorate and perchloric acid were used to maintain ionic strength at $\mu=1.0$. Sodium perchlorate solution was standardized by titrating with sodium hydroxide the hydrogen ions eluted from a column of Dowex 50W-X8 in the hydrogen form.

Variamine Blue hydrochloride (Dojindo, Kumamoto) was dissolved in water free from oxygen by bubbling with nitrogen purified through an alkaline pyrogallol solution. Variamine Blue solution was freshly prepared before use.

Results

Spectra. The violet solution formed by mixing a large excess of Fe(III) and V.B. has a single absorption peak at 550 nm. With oxidizing agents such as Co(III), Ce(IV), Tl(III), and I_2 the solution also gave similar spectra with a single peak at 550 nm. We have thus ascribed the absorption peak at 550 nm to the iminoquinone form of the Variamine Blue, $(V.B.)_{ox}$.

The absorbance in acidic media was gradually reduced over the visible range, while the absorption peak at 550 nm showed no shift.

Figure 1 shows the fast spectral change in the visible region just after the mixing of Variamine Blue with Fe(III) at pH$\simeq$2.2. Each scan requires 300 millisec. Fourteen scans were manually triggered for about 12 seconds just after mixing the Variamine Blue with Fe(III) in the optical cell from the sample syringes. In the course of the reaction, the peak at 550 nm showed no shift. Thus, under the experimental conditions, any species other than $(V.B.)_{ox}$ do not interfere with the kinetic measurements of the $(V.B.)_{ox}$ using the absorbance at 550 nm.

Reaction Stoichiometry. Erdey reported on the polarographic data suggesting the two-electron transfer reaction between Fe(III) and V.B.[1] We have

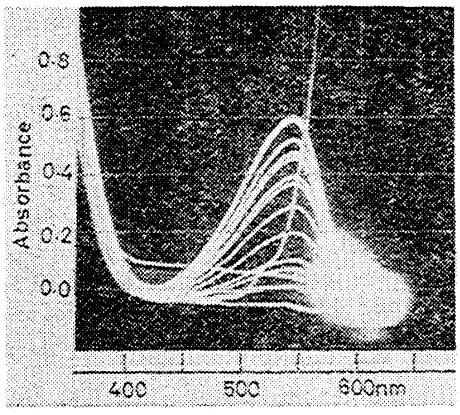

Fig. 1. Fast spectral change in the visible region.
$[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=5.00\times10^{-5}$ M, pH≃2.2, room temperature (≃20°C).

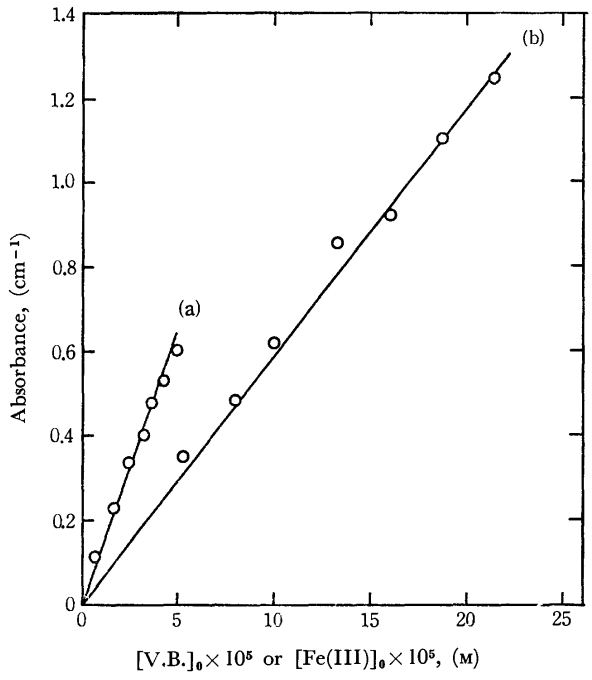

Fig. 2. Absorbance at 550 nm with varying concentration of Variamine Blue or Fe(III) at 25.0°C and $\mu=1.0$ M.
(a) $[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0$=abscissa, pH=2.20,
(b) $[Fe(III)]_0$=abscissa, $[V.B.]_0=2.50\times10^{-4}$ M, pH=1.76.

determined the reaction stoichiometry spectrophotometrically at 550 nm by the stopped-flow technique assuming $(V.B.)_{ox}$ as the main product of the reaction even under the condition $[Fe(III)]_0<[V.B.]_0$. Figure 2 suggests that the reaction of Variamine Blue with Fe(III) requires 2 moles of Fe(III) for 1 mole of Variamine Blue, *viz.*, a two-electron transfer reaction.

The molar absorption coefficient of $(V.B.)_{ox}$ in the protonated form at 550 nm was found to be 1.3×10^4 M^{-1} cm^{-1} in the acidic media at 25°C and ionic strength $\mu=1.0$.

Kinetics. In the following two-electron transfer reaction

$$V.B. \xrightarrow{-2e} (V.B.)_{ox} + 2H^+$$

the rate of formation of $(V.B.)_{ox}$ in the presence of large excess of Fe(III) does not obey the first-order rate law. It is assumed that there are some intermediate oxidation states of Variamine Blue in the course of the reaction due to a non-complementary reaction between one mole of reductant, Variamine Blue, and two moles of oxidant, Fe(III).

With Tl(III) as an oxidizing agent under the same conditions, however, the formation rate of $(V.B.)_{ox}$ was expressed by a pseudo-first-order rate law.[7]

Hydrogen Ion Concentration Dependence. The formation rate of $(V.B.)_{ox}$ was not seriously influenced by the hydrogen ion concentration between pH 2.20 and 0.77. The final concentration of $(V.B.)_{ox}$ of this reaction was also not affected by the hydrogen ion concentration (Fig. 3).

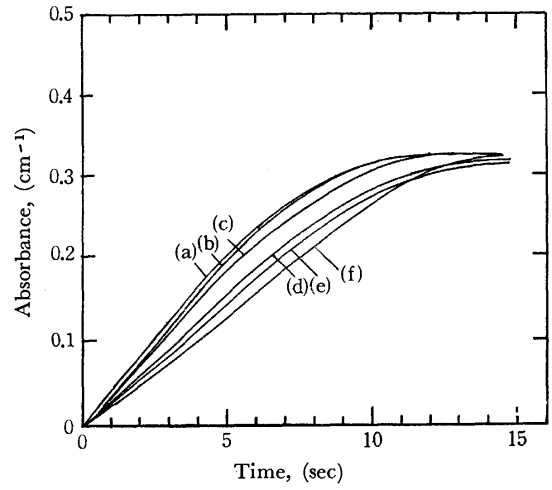

Fig. 3. Hydrogen ion concentration dependence.
$[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=2.50\times10^{-5}$ M, 25°C, $\mu=1.0$: (a) pH=2.195, (b) pH=1.90, (c) pH=1.74, (d) pH=1.20, (e) pH=0.935, (f) pH=0.77.

The initial rate of the formation of $(V.B.)_{ox}$ at pH 2.2 was proportional to the initial concentration of Variamine Blue, the half-life being independent of the initial concentration (Fig. 4).

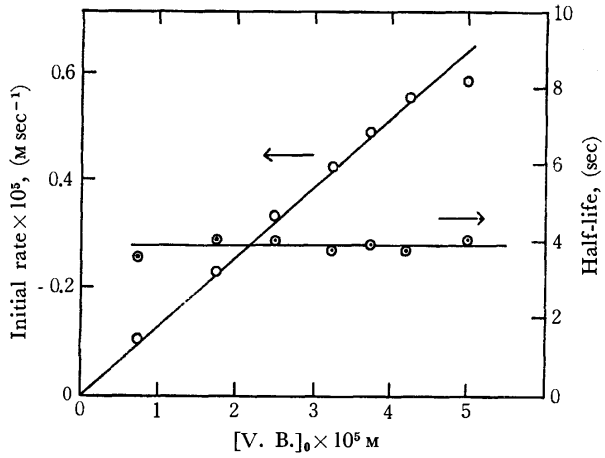

Fig. 4. Initial rate and half-life of the formation of $(V.B.)_{ox}$.
$[Fe(III)]_0=1.07\times10^{-3}$ M, pH=2.20, $\mu=1.0$, 25°C.

Effects of Fe(II). Figure 5 shows the effects of Fe(II) on the rate of formation of $(V.B.)_{ox}$. It is

7) T. Imamura and M. Fujimoto, This Bulletin, **45**, 442 (1972).

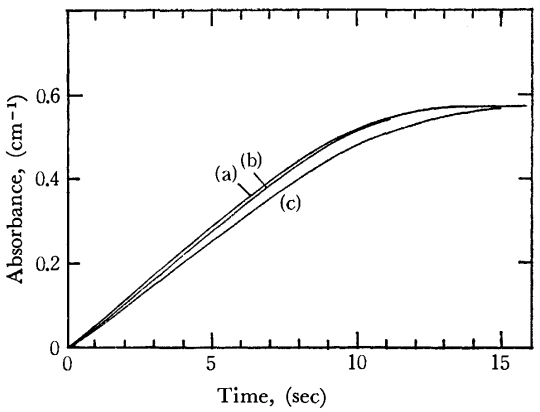

Fig. 5. Effects of Fe(II) on the formation of $(V.B.)_{ox}$ at 25°C and $\mu=1.0$ M.
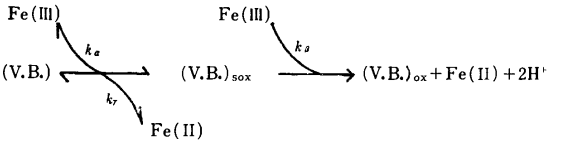
$[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=5.00\times10^{-5}$ M: (a) $[Fe(II)]_0=0$ M, (b) $[Fe(II)]_0=1.01\times10^{-3}$ M, (c) $[Fe(II)]_0=2.02\times10^{-3}$ M.

suggested that the formation rate of $(V.B.)_{ox}$ was not affected even for $[Fe(II)]_0 \geq [Fe(III)]_0 \gg [V.B.]_0$.

Discussion

Kinetics. The formation of $(V.B.)_{ox}$ in the reaction of Variamine Blue and Fe(III) does not obey the pseudo first-order rate law even with a large excess of Fe(III). It was ascribed to the fact that the intermediate of V.B. was to be considered and the reaction was a non-complementary one.

The overall reaction scheme would be as follows.



or

where $(V.B.)_{sox}$ shows a semi-oxidized form of Variamine Blue as semiquinone.

With large excess of $[Fe(III)]_0$ and $[Fe(II)]_0$, the formation of $(V.B.)_{ox}$ is expressed as follows.

$$[(V.B.)_{ox}] = \frac{[(V.B.)]_0}{2q}e^{-pt}[-(p+q)e^{qt}+(p-q)e^{-qt}] + [(V.B.)]_0 \quad (1)$$

where $p=\dfrac{k_1+k_{-1}+k_2}{2}$, $q=\dfrac{\sqrt{(k_1+k_{-1}+k_2)^2-4k_1k_2}}{2}$

and $k_1=k_\alpha[Fe(III)]_0$, $k_2=k_\beta[Fe(III)]_0$, $k_{-1}=k_\gamma[Fe(II)]_0$.

The effect of Fe(II) and hydrogen ion on the formation rate of $(V.B.)_{ox}$ was so small that k_{-1} in the equation was negligible.

Equation (1) is rewritten as follows:

$$[(V.B.)_{ox}] = [(V.B.)]_0\left[1+\frac{1}{k_1-k_2}(k_2e^{-k_1t}-k_1e^{-k_2t})\right]. \quad (2)$$

Let $\tau=k_1t$ and $\kappa=k_2/k_1$, then the equation becomes

$$r=\frac{[(V.B.)_{ox}]}{[(V.B.)]_0}=1+\frac{1}{1-\kappa}(\kappa e^{-\tau}-e^{-\kappa\tau}) \quad (3)$$

where r is the ratio of $[(V.B.)_{ox}]$ to $[(V.B.)]_0$, that is, $r=0$ in the initial state of the reaction, and $r=1$ in the final state, when the reaction is complete. The value of the relative rate constant, $\kappa=k_2/k_1$, obtained by the time ratio method[8,9] was 1.5 at 25°C. The value of k_1 was calculated to be 0.525 sec^{-1} with the observed reaction at $\mu=1.0$, $[Fe(III)]_0=1.067\times10^{-3}$, $[V.B.]_0=5.00\times10^{-5}$ M, 25°C, and pH=2.2.

The specific rates k_α and k_β for the first step and the second step of the reaction were calculated to be 3.28×10^2 M^{-1} sec^{-1} and 4.92×10^2 M^{-1} sec^{-1}, at ionic strength 1.0, pH≃2.2 and 25°C from $k_1/[Fe(III)]_0$ and $k_2/[Fe(III)]_0$, respectively.

In Fig. 6 the concentrations of $(V.B.)_{ox}$ calculated from these values are plotted as a function of time. It is shown that the calculated concentrations of $(V.B.)_{ox}$ agree with the observed ones in the course of the reaction.

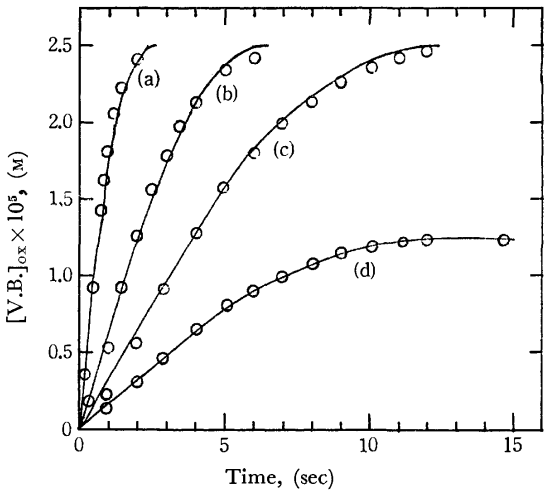


Fig. 6. Calculated concentration of $(V.B.)_{ox}$. Solid lines show the observed concentrations of $(V.B.)_{ox}$.
○ indicate the concentrations of $(V.B.)_{ox}$ calculated with the values, $k_\alpha=3.28\times10^2$ and $k_\beta=4.29\times10^2$ M^{-1} sec^{-1} at 25°C and $\mu=1.0$: (a) $[Fe(III)]_0=6.40\times10^{-3}$ M, $[V.B.]_0=2.50\times10^{-5}$ M, (b) $[Fe(III)]_0=2.13\times10^{-3}$ M, $[V.B.]_0=2.50\times10^{-5}$ M, (c) $[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=2.50\times10^{-5}$ M, (d) $[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=1.25\times10^{-5}$ M.

Temperature Dependence. Values calculated for (k_α, k_β) at 15, 20, 25, 30, and 35°C were found to be (197, 295), (272, 407), (328, 492), (487, 731), and (675, 1010 M^{-1} sec^{-1}) at ionic strength $\mu=1.0$ and pH≃2.2 (see Fig. 7). Apparent energies of activation calculated from these values are 10±1 kcal·mol^{-1} for both k_α and k_β.

Influence of Chloride Ion. Chloride ion was added to the solutions of the reactants in order to investigate the dependence of the reaction rate on the formation of iron(III) chloride complexes.

The formation rate of $(V.B.)_{ox}$ in the presence of large excess of chloride ion was higher than that with

8) A. Frost, R. G. Pearson, "Kinetics and Mechanism," John Wiley & Sons, Inc., New York, London (1961), p. 170.
9) A. A. Frost and W. C. Schwement, *J. Amer. Chem. Soc.*, **74**, 1268 (1952); W. C. Schwemer and A. A. Frost, *ibid.*, **73**, 4541 (1951).

no chloride ion added (Fig. 8). However, the chloride ion affects the reaction rate only slightly.

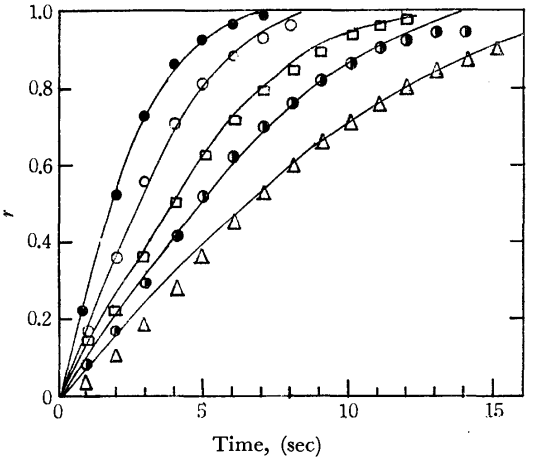

Fig. 7. Temperature dependence.
Solid lines show the observed concentrations of $(V.B.)_{ox}$. ●, ○, □, ◑, and △ indicate the calculated concentrations of $(V.B.)_{ox}$ at 35, 30, 25, 20, and 15°C, respectively: $[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=2.5\times10^{-5}$ M, pH≃2.2, $\mu=1.0$ M.

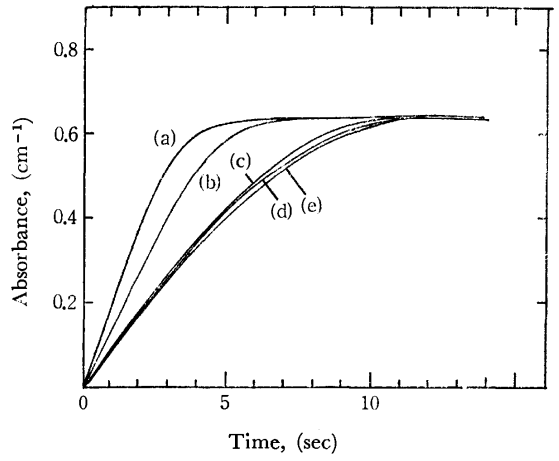

Fig. 8. Influence of chloride ion.
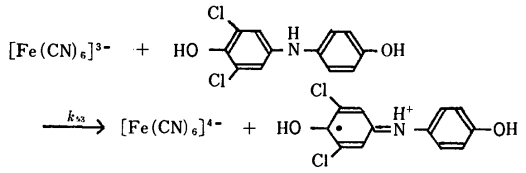
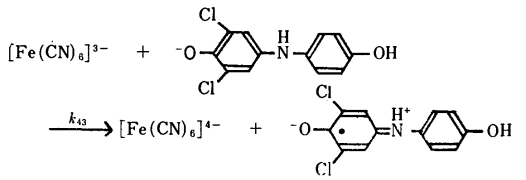
$[Fe(III)]_0=1.07\times10^{-3}$ M, $[V.B.]_0=5.00\times10^{-5}$ M, pH=2.2, 25°C, $\mu=1.0$ M, (a) $[NaCl]=1.0\times10^{-1}$ M, (b) 5.0×10^{-2} M, (c) 1.0×10^{-2} M, (d) 5.0×10^{-3} M, (e) 0 M.

In the reaction of hydroquinone and Fe(III),[10] it was reported that the reaction was either inner- or outer-sphere mechanism. In the reaction of V.B. and Fe(III), it is not clear whether the reaction proceeds by an inner-sphere mechanism or outer-sphere mechanism, as the kinetics was followed by Variamine Blue oxidized form.

That the formation rate of $(V.B.)_{ox}$ is not affected by acid concentration suggests the possibility of the inner-sphere mechanism for the reaction, since $FeOH^{2+}$ would influence the reaction rate for the outer-sphere mechanism. The rate constants as reported in the reaction of $[Fe(CN)_6]^{3-}$ with dichloroindophenol[11] that proceeds by outer-sphere mechanism or by hydrogen-atom transfer are much higher than those in the reaction of Fe(III) with V.B., *viz.*,



$k_{53} = 1.2\ (\pm0.3) \times 10^4\ M^{-1}sec^{-1}$



$k_{43} = 3.3\ (\pm0.8) \times 10^7\ M^{-1}sec^{-1}$

The authors wish to thank Prof. H. Baba, Research Institute of Applied Electricity of our University, for use of the rapid scan spectrometer.

Kinetics and Mechanisms of the Reaction of Tl(III) with Variamine Blue, [*N*-(*p*-Methoxyphenyl)phenylenediamine] in Aqueous Perchlorate Media

Taira IMAMURA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 21, 1971)

A stopped-flow apparatus was used to study the kinetics of the redox reaction of Tl(III) with Variamine Blue under nitrogen atmosphere in acid (0.2—0.6 M) perchlorate media of ionic strength $\mu=1.0$ M. The observed second-order rate constant increases inversely with hydrogen ion concentration. The proposed mechanism involves the overall rate-determining steps

$$Tl^{3+} + (V.B.) \overset{k_1}{\rightleftharpoons} Tl^{+} + (V.B.)_{ox} + 2H^{+}$$

$$TlOH^{2+} + (V.B.) \overset{k_2}{\rightleftharpoons} Tl^{+} + (V.B.)_{ox} + H_2O + H^{+}$$

where (V.B.) and $(V.B.)_{ox}$ are a reduced form and an oxidized form of Variamine Blue respectively. The rate constants are evaluated to be $k_1 \leq 10^2$ M^{-1} sec^{-1}, and $k_2=3.6\times10^4$ M^{-1} sec^{-1} at 25°C. The activation energy E_2 for k_2 is 11 ± 0.8 kcal·mol^{-1}.

It has been reported[1-3] that the aqueous solution of Variamine Blue (abbr. V.B.) undergoes two electron oxidation to yield a violet-red iminoquinone (abbr. $(V.B.)_{ox}$) by oxidizing agents such as Ce(IV), Fe(III), and I_2, as follows.

(V.B.) $(V.B.)_{ox}$

In the reaction of V.B. with Fe(III)[4] and Ce(IV),[5] the formation of $(V.B.)_{ox}$ does not obey the pseudo-first-order rate law in the presence of a large excess of metal ions. It was ascribed to the non-complementary reaction, where 2 mol of the oxidizing agent react with 1 mol of the reducing agent.

In the present paper we report the reaction of Tl(III) with V.B. in aqueous perchlorate media. Formation of $(V.B.)_{ox}$ obeys the first order rate law under the condition $[Tl(III)]_0 \gg [(V.B.)_{ox}]$. It seems that the complementary reaction of Tl(III) with V.B. does not proceed through the semioxidized form of Variamine Blue as semiquinone.

Experimental

Materials. Deionized and distilled water was used. The solution of Tl(III) perchlorate was prepared by electrolytic oxidation of Tl(I) perchlorate in 2 M perchloric acid.[6] Thallium(I) perchlorate was precipitated from solutions of Tl(OAc) and $HClO_4$ and purified by repeated recrystallization. The concentration of Tl(III) was standardized with EDTA titrimetrically. Variamine Blue (hydrochloride, Dojindo, Kumamoto) was dissolved in boiled water before use.

Sodium perchlorate and perchloric acid (reagent grade, Koso, Tokyo) were used to maintain the ionic strength at $\mu=1.0$ throughout the work. The concentration of sodium perchlorate was standardized by titrating the eluent from a column of ion-exchange resin, Dowex 50W-X8, in the acid form.

Kinetics. The reaction of V.B. with Tl(III) was followed spectrophotometrically using a stopped-flow apparatus (SPS-1, Yanagimoto, Kyoto) at 550 nm, the λ_{max} of $(V.B.)_{ox}$.

Nitrogen gas purified through an alkaline pyrogallol solution was passed through the solutions in the reservoirs during the course of measurements in order to avoid undesirable air oxidation.

Since in perchloric acid media the absorbance of Variamine Blue at 280 nm decreases gradually on exposure to the air, the solution of Tl(III) in perchloric acid media was mixed with a solution of V.B. of pH about 5. No decrease in absorbance was observed when solid Variamine Blue was directly dissolved *in vacuo* in the 2 M perchloric acid solution freed from oxygen by freezing a few times.

Measurements of the reaction of V.B. with Tl(III) were performed under the conditions $5.0\times10^{-3} > [Tl(III)] > 1.0\times10^{-3}$, $5.0\times10^{-5} \geqq [V.B.]_0 \geqq 5.0\times10^{-6}$, and $0.6 > [H^+]_0 \geqq 0.2$ M.

Results

Stoichiometry. The stoichiometry of the reaction of Tl(III) with V.B. was determined spectrophotometrically at 550 nm using a stopped-flow apparatus.

A definite excess of Tl(III) was mixed with V.B. to determine the molar extinction coefficient of $(V.B.)_{ox}$ as 1.3×10^4 M^{-1} cm^{-1} at 550 nm. The value agreed with that observed in the reaction of Fe(III) with V.B.[4]

Table 1 shows the concentration of $(V.B.)_{ox}$ formed

from various concentrations of Tl(III) and V.B. The derived stoichiometry is $\Delta[(V.B.)_{ox}]/\Delta[Tl(III)]_0 = -1.0$.

Kinetics. With a large excess of Tl(III) the appropriate pseudo-first-order absorbance plots gave a straight line, as shown in Fig. 1, according to the following equation.

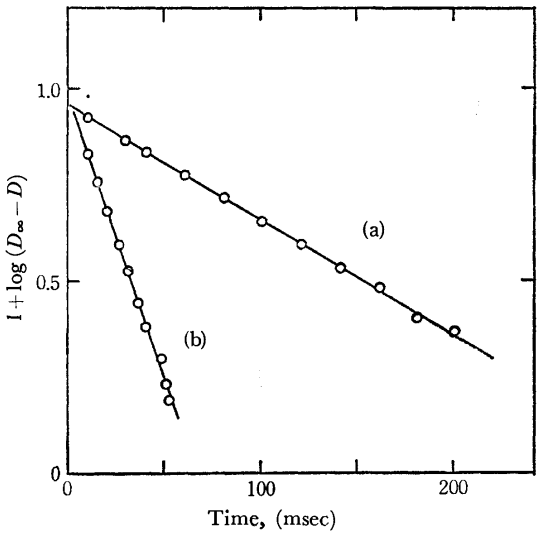

Fig. 1. Typical first-order rate plots at 25°C and $\mu=1.0$. (a) $[Tl(III)]_0=1.68\times10^{-3}$ M, $[V.B.]_0=5.00\times10^{-5}$ M, $[H^+]=0.45$ M, (b) $[Tl(III)]_0=3.36\times10^{-3}$ M, $[V.B.]_0=5.00\times10^{-5}$ M, $[H^+]=0.20$ M.

$$\log(D_\infty - D) = \log(D_\infty - D_0) - \frac{k'}{2.303}t$$

where D_∞, D, and D_0 are the optical densities at 550 nm at equilibrium and $t=t$ and $t=0$, respectively. The observed rate constant k' was plotted against the concentration of Tl(III). Figure 2 shows that the

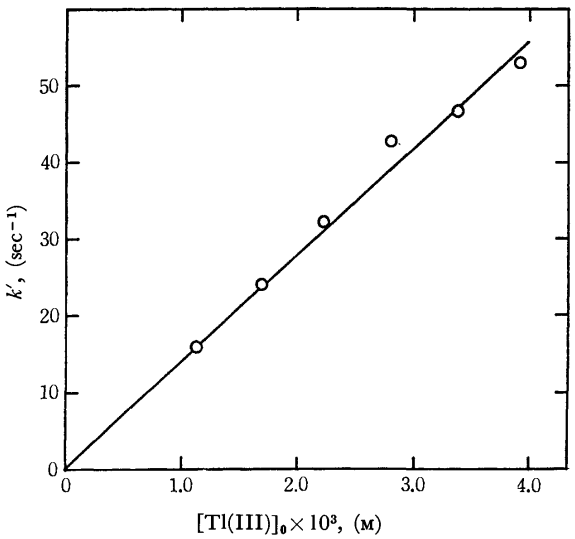

Fig. 2. Plot of pseudo-first-order rate constants against $[Tl(III)]_0$.
$[V.B.]_0=5.00\times10^{-5}$ M, $[H^+]=0.2$ M, 25°C, $\mu=1.0$.

value of k' is proportional to the initial concentration of Tl(III) under the conditions, $\mu=1.0$, $[H^+]=0.2$ M, and 25°C, suggesting the rate equation to be

$$d[(V.B.)_{ox}]/dt = k_a[Tl(III)][(V.B.)]$$

The dependence of the second-order rate constant k_a on $[H^+]$ and temperature was measured in a range $0.6>[H]\geqq0.2$. The plots of k_a *versus* $1/[H]$ at 15, 20, 25, 30, and 35°C fall on a series of straight lines with the intercepts near the origin as shown in Fig. 3.

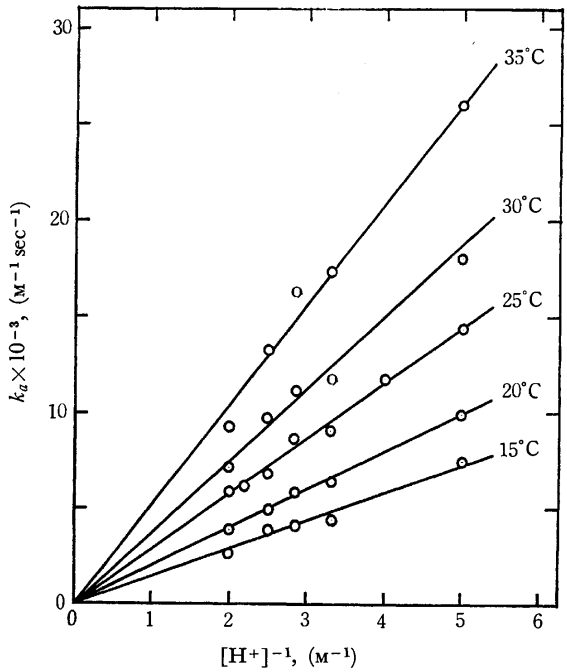

Fig. 3. Plot of second-order rate constants against $1/[H^+]$.

Mechanism and Discussion

In the non-complementary reactions of Tl(III) with Fe(II), the existence of Tl(II) as an intermediate of the reaction is suggested.[7] The reactions of Tl-(III) with V(III) and V(IV) also seem to proceed through the formation of Tl(II).[8] Oxidation of V.B. with Fe(III) and Ce(IV) proceeds through a semi-oxidized form of Variamine Blue as semiquinone to form $(V.B.)_{ox}$.[4,5]

In the complementary reaction of Tl(III) with V.B., however, one mole of Tl(III) reacts with one mole of V.B., and the intermediates as Tl(II) and semiquinone of V.B. seem to be very unstable during the course of the reaction.

Assuming that all protolytic equilibria are rapidly established with respect to Tl(III) and V.B., the mechanism of the reaction is suggested to be as follows.

$$Tl^{3+} \overset{k_1}{\rightleftharpoons} TlOH^{2+} + H^+ \quad (1)$$

$$Tl^{3+} + V.B. \overset{k_1}{\longrightarrow} Tl^+ + (V.B.)_{ox} + 2H^+ \quad (2)$$

$$H^+ + TlOH^{2+} + V.B. \overset{k_2}{\longrightarrow} Tl^+ + (V.B.)_{ox} + 2H^+ + H_2O \quad (3)$$

7) K. G. Ashurst and W. C. E. Higginson, *J. Chem. Soc.*, **1953**, 3044.

8) W. C. E. Higginson, D. R. Rosseinsky. J. B. Stead, and A. G. Sykes, *Discuss. Faraday Soc.*, **29**, 39 (1960).

The second-order rate constant k_a is thus rewritten as $k_a = (k_1[H^+]+k_2K)/([H^+]+K)$, where K is an acid dissociation constant of aqueous Tl(III), $K=7.94\times 10^{-2}$.[7]

When K is neglected against $[H^+]$, we have $k_a = k_1+k_2K/[H^+]$. Values of $k_1 \leq 10^2$ M^{-1} sec^{-1} and $k_2 = 3.63\times 10^4$ M^{-1} sec^{-1} at $\mu=1.0$ and 25°C are evaluated from the intercept and the slope of the straight line shown in Fig. 3.

In Fig. 4 the function $k_a([H^+]+K)$ is plotted against $[H^+]$, from which the value $k_2=3.56\times 10^4$ M^{-1} sec^{-1} is obtained. The value k_2 agreed with the value obtained from the slope of the straight line in Fig. 3 within relative error of about 15%.

Activation energy for k_2, E_a, is also evaluated as 11 ± 0.8 kcal·mol^{-1} from the plot of k_2 against the reciprocal absolute temperature (Fig. 5). The activation energy of the reaction of Tl(III) with V.B. is about the same as that of Fe(III).[4] The apparent activation energy of the reaction of Ce(IV)[5] with V.B. is about zero, the same as observed in the reaction of Ce(IV) with hydroquinone.[9]

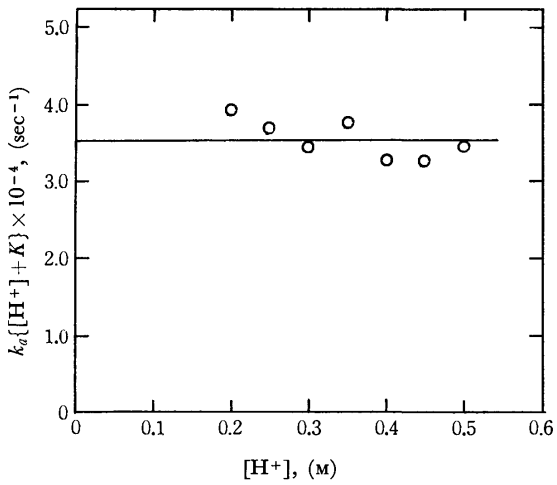

Fig. 4. Plot of $k_a\{[H^+]+K\}$ against $[H^+]$ at 25°C and $\mu=1.0$.

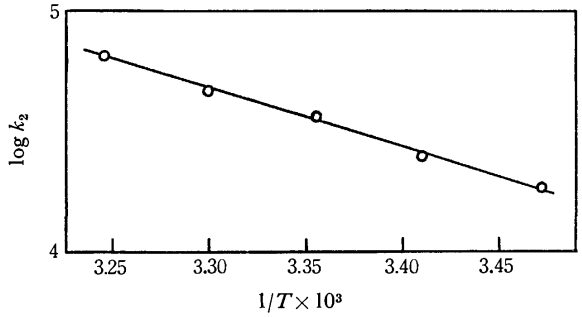

Fig. 5. Plot of second-order rate constant, k_2 against $1/T$.

The apparent rate constant of the reaction of Tl(III) with V.B. is about 10^2 times higher than that of Fe(III) with V.B. It may be ascribed to the difference in the redox potentials of metal ions, $E^0=1.28$ V for Tl(III)[6] and $E^0=0.71$ V for Fe(III).[10]

The values of the apparent second-order rate constants $(1—6)\times 10^4$ M^{-1}sec^{-1} as obtained for the complex formation of Tl(III) with Semi-xylenol Orange at $[H^+]=0.2—0.5$ M and at 25°C[11] suggest the possibility of the complex formation between Tl(III) and V.B. as a rate-determining step for the redox reaction.

Polarographic Investigation of Alkali Metal Ions in Hexamethylphosphoramide

Kosuke IZUTSU, Sachiko SAKURA, and Taitiro FUJINAGA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto
(Received May 27, 1971)

The polarographic behavior of alkali metal ions in hexamethylphosphoramide (HMPA) has been found to be greatly influenced by the cations of the supporting electrolytes. With 0.05 M Et_4NClO_4 as the supporting electrolyte, cesium and rubidium ions give diffusion-controlled, reversible waves at −2.32 and −2.35 V, respectively, *vs.* the Ag/0.1 M $AgClO_4$ electrode, but sodium and lithium ions are not reduced until the reduction of the supporting electrolyte (−3.1 V). The potassium ion gives a wave at −2.37 V with a limiting current controlled by the rate of the preceding process. In 0.05 M Bu_4NClO_4 solutions, the reduction wave of the potassium ion is diffusion-controlled, but that of the sodium ion is kinetic and is very small. The lithium ion is not reduced until −3.1 V. In 0.05 M $LiClO_4$, even the sodium ion is reduced reversibly with $E_{1/2}$ at −2.47 V, while the reduction of the lithium ion starts from -2.6_5 V. In mixed supporting electrolytes, the presence of the tetraethylammonium ion is the determining factor of the electrode processes. From the measurements of the electrocapillary curves and of the conductivities, the effect has been attributed to the change in the double-layer properties with the cations of the supporting electrolytes.

Hexamethylphosphoramide(HMPA) is a dipolar aprotic solvent which is often used for organic reactions.[1] It has a highly basic character and solvates strongly to various metal ions.[2] Moreover, it can dissolve alkali metals to yield a blue solution; this solution has been attributed to the formation of solvated electrons.[3]

Voltammetric study at a rotated platinum electrode has been carried out by Dubois *et al.*[4] in HMPA and its mixtures with water. They used lithium and sodium perchlorates as the supporting electrolytes and observed that the behavior of the residual current-potential curves obtained in these two supporting electrolytes differ considerably from each other.

In the present study, the polarographic behavior of alkali metal ions has been investigated in order to elucidate some of the solvation phenomena of these ions in HMPA. The reductions of alkali metal ions in this solvent, being different from those in other aprotic solvents,[5] are greatly influenced by the supporting electrolyte. This effect was found to be due to the change in the double-layer properties with the cation of the supporting electrolyte.

Apparatus and Reagents

Apparatus. The DC polarograms were recorded with a Yanagimoto three-electrode polarograph, Type P8-DP, and the AC polarograms, with a Yanagimoto polarograph, Type 102. An H-type polarographic cell with a fine-porosity sintered glass disc between the two compartments was used. All the potentials were referred to a freshly-prepared Ag/0.1 M $AgClO_4$ (HMPA) electrode, which had a potential of +0.36 V *vs.* aq. SCE when both electodes were immersed in HMPA-0.05 M Et_4NClO_4. A platinum wire served as an auxiliary electrode. The dropping mercury electrodes had the following characteristics in HMPA-0.05 M Et_4NClO_4 and at the mercury head of 62 cm: the A electrode, m=1.72 mg/sec with the circuit open and t=1.40 sec at −2.6 V *vs.* the Ag/Ag^+ electrode, and the B electrode, m=1.88 mg/sec and t=1.39 sec. Except otherwise described, the A electrode was used. Most measurements were carried out at 25°±0.1°C.

Reagents. The cesium and rubidium perchlorates were prepared by adding silver perchlorate to the respective chloride solutions. The sodium perchlorate was prepared by recrystallizing it from its aqueous solution at 70—80°C. The potassium and lithium perchlorates were obtained commercially. All of these alkali perchlorates were vacuum dried at 200°C. The tetraethylammonium perchlorate (Et_4NClO_4), tetrapropylammonium perchlorate (Pr_4NClO_4), and tetrabutylammonium perchlorate (Bu_4NClO_4) were prepared following the procedures in the previous reports[6] and were dried at 80°C under a vacuum. Tetramethylammonium perchlorate (Me_4NClO_4) was prepared from $AgClO_4$ and Me_4NBr and was recrystallized from water.

The HMPA was a product of the Nippon Oil Seal Co., Ltd. It was refluxed over barium oxide under reduced pressure for several hours and then vacuum-distilled. The middle fraction, about 70%, was collected (bp *ca.* 90°C). It was refluxed again over metallic sodium and vacuum-distilled from it. The distillations were carried out with an adiabatic vacuum fractional-distillation column (Shibata Chemical Apparatus Mfg. Co., Ltd.). The HMPA thus obtained gave a specific conductivity of $3—4\times10^{-8}$ ohm^{-1} cm^{-1}, and the water content, as determined by Karl Fischer titration, was approximately 0.01%. It was also confirmed to be pure enough both polarographically and UV-spectrophotometrically. The potential range applicable with a DME was from −0.1 V to −3.1 V *vs.* the Ag/Ag^+ electrode in HMPA-0.05 M Et_4NClO_4. Because the contact of HMPA with air produces an impurity which interferes with the polarographic investigation, the fresh distillate was usually used within a few hours after distillation. Storing at the temperature of dry ice and under a nitrogen atmosphere or under a vacuum was effective in keeping the distillate fresh for more than 24 hr.

Results and Discussion

Reductions of Alkali Metal Ions in Tetraalkylammonium Perchlorates as the Supporting Electrolytes. Cesium and Rubidium Ions: With 0.05 M tetraalkylammonium perchlorates as the supporting electrolytes, cesium and rubidium ions give diffusion-controlled, reversible reduction waves at −2.32 and −2.35 V respectively *vs.* the Ag/Ag^+ electrode. The reversibility of the waves was also confirmed AC polarographically. The results are summarized in Table 1 and Fig. 1.

Potassium Ion: When Bu_4NClO_4 or Pr_4NClO_4 is used as the supporting electrolyte, the potassium ion gives a diffusion-controlled wave with a diffusion current constant comparable to those of cesium and rubidium ions in 0.05 M Et_4NClO_4 (see Table 1). In both DC and AC polarographic methods, the wave is reversible and the temperature coefficient of the DC wave height is approximately 1.3%/°C.

If Et_4NClO_4 is used as the supporting electrolyte, however, the reduction of the potassium ion becomes rather complicated. Though the reduction seems to be fairly reversible, judging from both the analysis of the DC wave and the measurement of the AC polarogram, the DC wave height is considerably smaller than in the cases with Bu_4NClO_4 or Pr_4NClO_4 as the supporting electrolyte (Tabe 1) and its temperature coefficient is much larger (ca. 4%/°C in 0.05 M Et_4NClO_4). The test of the dependence of the DC wave height on the height of the mercury column shows that the limiting current is controlled partly by diffusion and partly by chemical reactions.

In Fig. 2, the values of $i_1C^{-1}h^{-1/2}$ are plotted against $h^{-1/2}$ for the reduction waves of 1, 2 and 3 mM potassium ions both in 0.05 M Bu_4NClO_4 and in 0.05 M Et_4NClO_4. Here, i_1 is the limiting current in μA; C, the concentration of the potassium ion in mM, and h, the height of the mercury column corrected

a) Values in parentheses are in 0.05 M Bu_4NClO_4 and others in 0.05 M Et_4NClO_4.

b) i_p: AC peak height in μmho; τ: drop time at the peak potential, in sec; i_1: limiting current in μA; n: number of electrons. The value of $i_p/i_1n\tau^{1/2}$ for Pb^{2+} in aq. 0.1 M KNO_3 (pH 2) was 101. Measured with the DME B.

c) This value is less negative than the reversible half-wave potential (Ref. 11, p. 376).

for the back pressure. In 0.05 M Bu_4NClO_4 the values of $i_1C^{-1}h^{-1/2}$ are almost independent of $h^{-1/2}$, as is to be expected for the diffusion-controlled current. In 0.05 M Et_4NClO_4, however, the values of $i_1C^{-1}h^{-1/2}$ are smaller than those in 0.05 M Bu_4NClO_4, and they increase with an increase in $h^{-1/2}$, showing that a kinetic factor is involved.

The simplest mechanism considered is that the solvated potassium ion, which is the predominant species in HMPA, is converted into the electroactive state preceding its reduction:

$$K^+_{solvated} \underset{k'}{\overset{k}{\rightleftharpoons}} K^+_{electroactive} \overset{e}{\rightleftharpoons} K(Hg) \qquad (1)$$

$$K=k/k'$$

where the electroactive ion, $K^+_{electroactive}$, seems to be either a (partially) desolvated ion or a solvated ion which has approached to the electrode surface by penetrating through the layer of tetraethylammonium ions, as will be discussed later. According to the theoretical treatment by Koutecky,[7] the average limiting current, i_1, obtained for the above mechanism is shown by Eq. (2):

$$i_1 = i_d\frac{0.886(Kkt)^{1/2}}{1+0.886(Kkt)^{1/2}} \qquad (2)$$

where i_d is the currnt which will be observed if the solvated potassium ion is reduced by diffusion control. ($t^{1/2}$ is equal to $9.1_6h^{-1/2}$ with the A electrode at -2.6 V in 0.05 M Et_4NClO_4.) It seems reasonable to use the limiting current in 0.05 M Bu_4NClO_4, corrected for the change in drop time (see Fig. 8), as the approximate value of i_d in 0.05 M Et_4NClO_4. Curve 1 in Fig. 2 was theoretically obtained by using Eq. (2) for i_d $C^{-1}h^{-1/2}=0.140$ and $(Kk)^{1/2}=1.23$. The good agreement of the curve with the experimental results seems to show that the mechanism expressed by Eq. (1) is valid.

The kinetic current is considerably affected by the experimental conditions. With 0.05 M Et_4NClO_4 as the supporting electrolyte, the values of $(Kk)^{1/2}$ are 0.4_8 at 12.4°C, 1.2_3 at 25°C, and $3._4$ at 41°C. The value of $(Kk)^{1/2}$ also increases with a decrease in the concentration of Et_4NClO_4; thus, $(Kk)^{1/2}$ at 25°C is 0.6_0 in 0.1 M Et_4NClO_4, 1.2 in 0.05 M Et_4NClO_4, and 2.1 in 0.02 M Et_4NClO_4.

Figure 3 shows the effect of water on the limiting current of the potassium ion. In 0.05 M Bu_4NClO_4, the limiting current decreases slightly upon the addition of water (probably due to the increase in viscosity), while, in 0.05 M and 0.1 M Et_4NClO_4, it increases and approaches the value of the purely-diffusion-controlled wave.

In Me_4NClO_4 as the supporting electrolyte, the potassium wave becomes diffusion-controlled again. (See below for a further discussion of the role of the supporting electrolyte.)

Sodium Ion: The polarograms of the sodium ion in HMPA and HMPA-H_2O mixtures containing 0.05 M Et_4NClO_4 as a supporting electrolyte are shown in Fig. 4. The sodium ion in water-free HMPA does not give a reduction wave up to the potential of the reduction of the supporting electrolyte. A fairly large amount of water should be added in order to obtain a well-defined sodium wave. In Bu_4NClO_4 (or Pr_4NClO_4) as the supporting electrolyte, the sodium ion gives a very small wave (probably kinetic in nature) at about -2.4_2 V *vs.* the Ag/Ag^+ electrode (Fig. 5); the wave height is increased more easily by the addition of water than when Et_4NClO_4 is the supporting electrolyte.

Lithium Ion: The reduction of the lithium ion in HMPA-tetraalkylammonium perchlorate solutions is more difficult than that of other alkali metal ions (Fig. 1), and no further experiments were carried out.

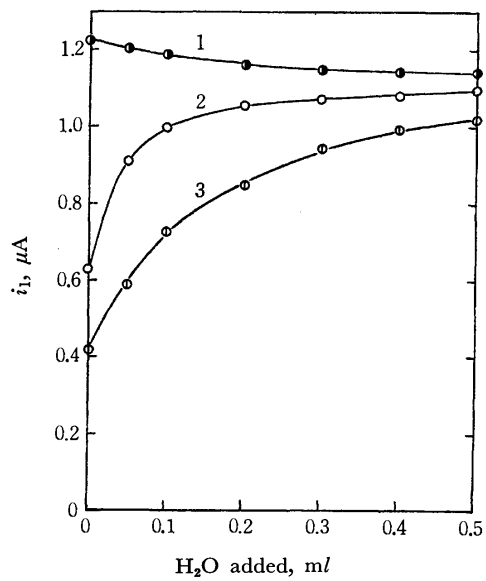

Fig. 3. Effect of water on the limiting current of potassium ions in HMPA. Original volume of the soln.: 10 ml. Concn. of potassium ion: 1 mM. Curve 1, in 0.05 M Bu_4NClO_4; 2, in 0.05 M Et_4NClO_4; and 3, in 0.1 M Et_4NClO_4. (Corrected for the volume change)

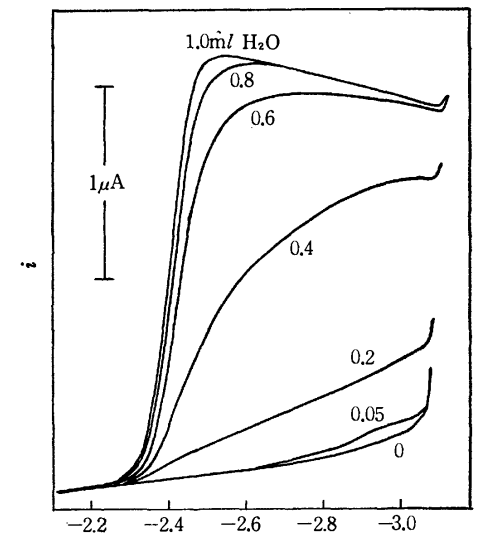

Fig. 4. Effect of water on the sodium wave in HMPA-0.05 M Et_4NClO_4. Water was added to 10 ml of 2.24 mM Na^+ solution. Corrected for the volume change.

Reductions of Alkali Metal Ions in Lithium Perchlorate as the Supporting Electrolyte. As is shown in Fig. 6, the behavior of alkali metal ions in 0.05 M $LiClO_4$-HMPA solutions is quite different from that in tetraalkylammonium perchlorate solutions. The reductions of cesium and rubidium ions in these solutions occur at approximately the same potentials as with the Et_4NClO_4 supporting electrolyte (−2.32 and −2.35 V respectively), though maxima are observed in these waves. The potassium ion also gives a diffusion-controlled wave at −2.37 V, and even the sodium ion, which can not be reduced in the Et_4NClO_4 solution, gives a reversible wave at −2.47 V. The reduction of the lithium ion starts from -2.6_5 V.

Reductions of Sodium and Potassium Ions in Mixed Supporting Electrolytes. The effect of Et_4NClO_4 on the reduction of the sodium ion in 0.05 M $LiClO_4$ was examined. The results are shown in Fig. 7. The sodium wave, which is controlled by diffusion in the absence of the tetraethylammonium ion, is markedly interfered with by the presence of very small amounts of Et_4NClO_4. The presence of Et_4NClO_4 also decreases the drop-time significantly, as is shown in Fig. 7a, indicating that the tetraethylammonium ion is preferentially attracted onto the electrode surface. The reduction of the lithium ion, which starts from about −2.65 V in the absence of the tetraethylammonium ion, is also inhibited by the presence of small amounts of Et_4NClO_4 (Figs. 6 and 7).

In mixed supporting electrolytes, such as $LiClO_4$+Et_4NClO_4, Bu_4NClO_4+Et_4NClO_4, and Pr_4NClO_4+Et_4NClO_4, the reduction of the potassium ion is again

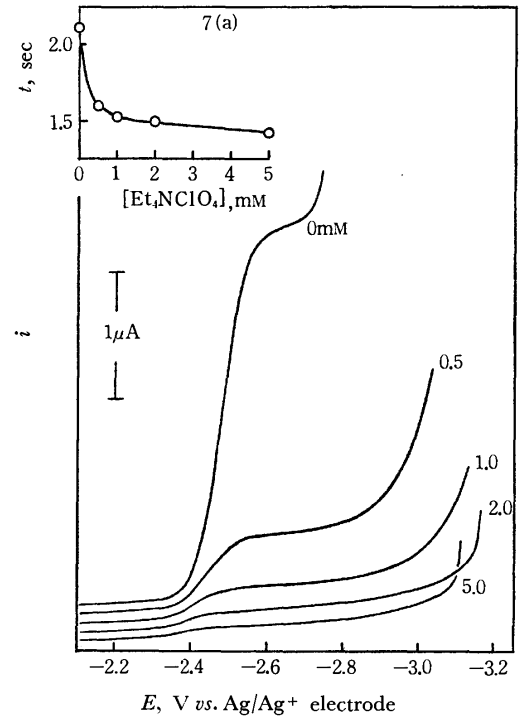

Fig. 7. Effect of Et_4NClO_4 on the sodium wave in 0.05 M $LiClO_4$-HMPA. Concn. of sodium ion: 2.27 mM. Concn. of Et_4NClO_4 is shown on the curves. With the DME B.

controlled by the tetraethylammonium ion and a kinetic current is observed, just as when the supporting electrolyte is Et_4NClO_4 only.

Effect of the Supporting Electrolytes on the Electrical Double Layer. The electrocapillary curves obtained by measuring the drop time are shown in Fig. 8. The drop time at extremely negative potentials changes considerably with the supporting electrolytes used; it is largest in 0.05 M $LiClO_4$, smallest in 0.05 M Et_4NClO_4, and between these two in 0.05 M Bu_4NClO_4. The charge densities on the electrode, calculated from the slopes of these electrocapillary curves, are plotted in Fig. 9. The negative charge on the electrode is much larger in 0.05 M Et_4NClO_4 than in 0.05 M Bu_4NClO_4 and $LiClO_4$, showing that the tetraethylammonium ion is more easily attracted to the electrode surface. This difference is probably due to the difference in the sizes of the solvated ions. Figure 10 shows the Stokes law radii of mono-valent cations in HMPA, calculated from the results of conductivity measurements.[8] Though it is questionable to consider that the Stokes law radii are a direct measure of the sizes of solvated ions, it is reasonable to assume that, among the ions in Fig. 10, the tetraethylammonium ion is smallest and the lithium ion is largest. It is natural that the tetraethylammonium ion, which is the smallest cation, is the most easily (or preferentially in the mixed electrolytes) attracted onto the negatively-charged electrode surface.

The big influence of the supporting electrolyte on the reductions of alkali metal ions can be explained by the effect of a competitive approach to the electrode surface of the cation of the supporting electrolyte and of the depolarizing cation. With $LiClO_4$ as the supporting electrolyte, for example, all the alkali metal ions can easily approach the electrode surface and can be reduced. With the Et_4NClO_4 supporting electrolyte, on the other hand, the tetraethylammonium cation is attracted preferentially and its layer inhibits the approach of the bigger solvated cations to the electrode surface. In this case, either the penetration of the solvated cations through the layer or some chemical reactions, such as the (partial) desolvation of the solvated cation, should precede the reduction. If the preceding process is rapid, the reduction is diffusion-controlled (the cases of cesium and rubidium ions), but if it is very slow, the reduction does not occur at all (the cases of sodium and lithium ions). When the rate of the preceding process is in between these two extremes, a kinetic current is observed, as in the case of the potassium ion. With 0.05 M Bu_4NClO_4 as the supporting electrolyte, the inhibition by the tetrabutylammonium ion is less than that by the tetraethylammonium ion, and the potassium ion can be reduced by diffusion control. The reduction of the sodium ion, however, is still controlled by the rate of the preceding process.

The influence of the supporting electrolyte can

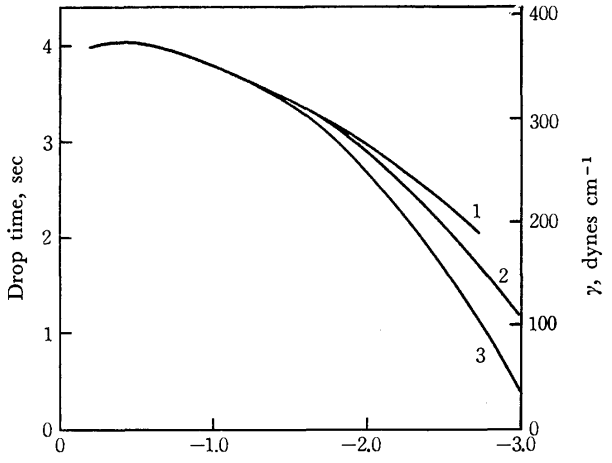

Fig. 8. Drop time-potential curves. Curve 1, in 0.05 M $LiClO_4$; 2, in 0.05 M Bu_4NClO_4; and 3, in 0.05 M Et_4NClO_4. For conversion of drop time t to surface tension γ, the values of t and γ at the ecm in aq. 0.1 M KCl were used as reference. The values of γ at very negative potentials are approximate because correction was not made for the variation of back pressure. With the DME B.

also be explained qualitatively by means of the double-layer effect. Recently, the kinetics of electrode reactions have been treated by taking into account separately the distance of the outer Helmholtz plane from the geometrical electrode surface (x_2) and that of the plane at the charge center of the reacting species in the transtion state (x_r).[9,10] In HMPA, x_2 is expected to increase with the size of the cation of the supporting electrolyte in the order $Et_4N^+ < Bu_4N^+ < Li^+$, and the x_r values for potassium and sodium ions seem to be between x_2 in $LiClO_4$ and that in Et_4NClO_4. Thus, the potential, ϕ_r, at the plane of the closest approach of these ions will be more negative in $LiClO_4$ than in Et_4NClO_4. The preceding reactions of the depolarizing cations, as shown by Eq. (1), are accelerated significantly when the ϕ_r-potential becomes more negative.[11]

The above explanations are still only tentative. Further studies are now in progress in this laboratory on the electrode double layer at extremely negative potentials and its effects on electrode processes in HMPA and other organic solvents.[12,13]

Electronic Spectra and Electronic Structure of Iron(II) Tetraphenylporphins

Hiroshi KOBAYASHI and Yasuo YANAGAWA

Department of Chemistry, Tokyo Institute of Technology Ookayama, Meguro-ku, Tokyo

(Received June 11, 1971)

Tetraphenylporphiniron(II) was synthesized and isolated in a pure state. The iron(II) porphin was in the state of $S=2$. The spin state of iron(II) porphin varies with the axial ligand field. Oxygeneous axial ligands such as tetrahydrofuran and dioxane gave an intermediate spin state ($S=1$), while nitrogeneous ligands such as pyridine gave a diamagnetic state ($S=0$). The electronic spectra of tetraphenylporphin complexes of iron(II) were measured for the three types of the spin state.

Iron of the prosthetic groups in hemoglobin and myoglobin participates as a ferrous ion in oxygen carrying. Iron(II) is stable against oxidation in the hemoproteins even though it is directly bound with an oxygen molecule, whereas iron(II) in the synthetic complexes is hardly stable in the presence of oxygen. Iron(II) in the synthetic porphyrins is not so stable in the presence of oxygen and moisture in the air. However, iron(II) is fairly stabilized in the diamagnetic state obtained for a strong ligand field such as in tris(2,2′-bipyridine)-, tris(1,10-phenanthroline)- or hexacyano complex. The iron(II) porphyrin with a strong axial field is in a diamagnetic state and is relatively stabilized against oxidation.

A systematic study of the effect of axial ligands to the electronic structure of the iron(II) porphyrins was found necessary for the synthetic porphyrins. Recently we succeeded in the preparation of a new series of iron(II) complexes of tetraphenylporphin. In this paper, we present their electronic absorption spectra with special attention to the spin state of the central iron(II).

Experimental

Synthesis of Tetraphenylporphinbis(pyridine)iron(II). Tetraphenylporphinbis(pyridine)iron(II), TPPFe(II)·2Py (TPP is an abbreviation of tetraphenylporphin and Py, pyridine) was prepared by two different methods in a vacuum system.

(A) *Reduction of TPPFe(III)X Complex.* Tetraphenylporphiniron(III) acetate, TPPFe(III)$OCOCH_3$, (500 mg) was dissolved in a mixed solvent of 20 m*l* of pyridine, 150 m*l* of chloroform and 80 m*l* of methanol. After bubbling with dried nitrogen, 300 mg of sodium borohydride was added to the solution. The mixture was stirred for 3 hr at 50—60°C. Chloroform and methanol were distilled off until the volume of the solution became 20—30 m*l*. About 100 m*l* of methanol saturated with dried nitrogen, was added to the concentrated solution. After the solution had been allowed to stand for several hours, blue violet crystals were collected, washed several times with methanol saturated with dried nitrogen and dried in a vacuum. Since TPPFe(II)·2Py was sensitive to the air, it was kept in a glass capsule with inert gas.

(*B*) *Reaction of Iron(II) Acetate with the Metal-Free Base of TPP.* The metal-free base (500 mg) was dissolved in a mixed solvent of 20 m*l* of pyridine and 50 m*l* of chloroform. The solution was sufficiently saturated with dried nitrogen and to it was quickly added about 130 m*l* of a saturated solution of iron(II) acetate in acetic acid prepared by refluxing iron powder in acetic acid saturated with dried nitrogen. Care was taken not to contaminate the porphin solution by unreacted iron powder. The mixture was stirred for 3 hr at 50—60°C. Blue violet crystals were collected and kept in the same way as in (A).

The products prepared by both methods were identified by their characteristic absorption spectra. The product prepared by the method (A) was also identified by elemental analysis.

Found: C, 77.57; H, 4.81; N, 9.99; Fe, 6.80%. Calcd for $C_{54}H_{38}N_6Fe$: C, 78.47; H, 4.88; N. 10.17; Fe, 6.76%.

Synthesis of Tetraphenylporphiniron(II). A capsule of TPPFe(II)·2Py was joined to a vacuum line of 10^{-2} mmHg and was heated for 5 hr in an oil bath at 200°C. TPPFe-(II) was obtained in reddish purple crystalline state. It was much more sensitive to the air than TPPFe(II)·2Py, and was kept in a glass capsule in a vacuum.

Found: C, 80.89; H, 4.35; N, 8.53; Fe, 8.30%. Calcd for $C_{44}H_{28}N_4Fe$: C, 79.00; H, 4.52; N, 8.41; Fe, 8.34%.

Synthesis of Tetraphenylporphinbis(tetrahydrofuran)iron(II). TPPFe(II)·2THF (THF is an abbreviation of tetrahydrofuran) could not be synthesized by the same method as for TPPFe(II)·2Py. This was because of unstable binding of iron(II) and tetrahydrofuran. TPPFe(II)·2THF was prepared from TPPFe(II) with the apparatus shown in Fig. 1. The apparatus was joined to a vacuum line. From

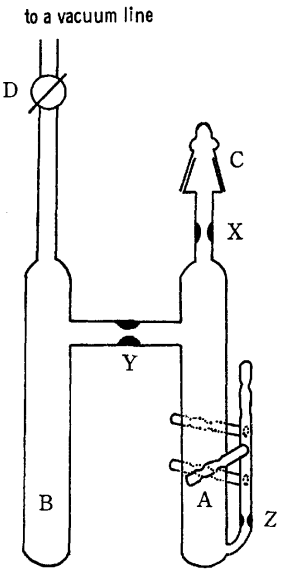

Fig. 1. Apparatus for preparation of TPPFe(II).

C, TPPFe(II)·2Py was carefully placed at the bottom of A under dried nitrogen atmosphere. TPPFe(II)·2py was heated for 5 hr in an oil bath at 200°C, while the apparatus was being evacuated by a vacuum line. After the reaction product had been allowed to stand at room temperature, a sufficient amount of THF saturated with dried nitrogen was added to the reaction product at A. While the THF solution in branch A was cooled in liquid nitrogen, the apparatus was sealed at X and evacuated by a vacuum line. After the cock D had been closed, the frozen solution was allowed to stand at room temperature. The solution was shaken for a while. The solvent THF was then completely transferred to branch B by cooling the branch in liquid nitrogen. Cooling of the frozen THF in the branch B was continued in liquid nitrogen. The apparatus was evacuated down to 10^{-2} mmHg, while the reaction product at A was allowed to stand at room temperature to dry. When the product was dried, the apparatus was sealed off at Y and the product was transferred into a branch of capsules. The branch of capsules was then sealed off at Z.

Found: C, 74.95; H, 4.79; N, 7.06; Fe, 6.91%. Calcd for $C_{52}H_{44}N_4O_2Fe$: C, 76.82; H, 5.45;N, 6.92; Fe, 6.87%.

Synthesis of Tetraphenylporphinbis(pyridine)manganese(II). Tetraphenylporphinmanganese(III) chloride, TPPMn-(III)Cl, (500 mg) was dissolved in a mixed solvent of 20 m*l* of pyridine, 40 m*l* of chloroform and 140 m*l* of methanol. After bubbling with dried nitrogen, 300 mg of sodium borohydride was added to the solution. The mixture was vigorously stirred for 3 hr at 50—60°C. After the reaction mixture was concentrated to 10—30 m*l* by distillation, the crystal of tetraphenylporphinbis(pyridine)manganese(II), TPPMn(II)·2Py, was precipitated by addition of methanol saturated with dried nitrogen. Blue violet lustrous crystals were collected, washed several times with dried oxygen-free methanol, and kept in a glass capsule with dried nitrogen. Since TPPMn(II)·2Py was sensitive to oxygen and moisture in the air, the whole process should be carried out under nitrogen atmosphere.

Found: C, 78.74; H, 4.36; Mn, 6.63%. Calcd for $C_{54}H_{38}N_6Mn$: C, 78.53; H, 4.46; Mn, 6.65%. Manganese was oxidized to permanganate and was determined by colorimetry.

Measurements of Absorption Spectra. Electronic absorption spectra were measured by a Shimadzu automatic recording spectrophotometer Model MPS-50 and a Beckman DU spectrophotometer using quartz cells of 0.1 cm or 1 cm light path. The solvents for absorption measurement were benzene, pyridine, piperidine, tetrahydrofuran, and dioxane purified by the usual methods.[1] They were distilled just before the use and degassed by successive freeze-thaw pumping cycles. Solutions for measurements were prepared in a vacuum system.

Measurements of Magnetic Susceptibilities. Magnetic moments were determined by means of the Gouy method.[2] Measurements were carried out at room temperature with the sample sealed in a capsule with dried nitrogen. After calibrating for the diamagnetic term, the magnetic moment of complex was calculated from the data obtained.

Results and Discussion

Tetraphenylporphiniron(II) has a planar structure as shown in Fig. 2. The central iron might be slightly out of the porphin plane. Such a structure has been found in various metal porphyrins including metal tetraphenylporphins.[3,4] Iron(II) in tetraphenylporphiniron(II), a planar complex, is in the spin state of $S=2$. In the case of TPPFe(II)·2Py, however, σ donation of the nitrogeneous donor of two coordinating pyridines gives rise to a strong axial field and all spins in the central iron are quenched ($S=0$). This was shown by magnetic susceptibility measure-

ments. When the axial ligand field is of moderate strength, the central iron might be in the intermediate spin state, $S=1$. The ligand field of intermediate strength is furnished by such a relatively weak ligand as oxygeneous donor of tetrahydrofuran or dioxane. TPPFe(II)·2THF showed an intermediate value of the magnetic moments for $S=0$ and $S=2$. If a thermal equilibrium exists between the states $S=0$ and $S=2$ of a complex, an intermediate value is expected to be the average of the magnetic moments of two components. In the case of Fe(III) porphyrins, a thermal equilibrium actually exists between two spin states of a complex, giving a mixture absorption spectrum of the species with different spin states.[5] TPPFe(II)·2THF, however, shows no mixture spectrum of the species $S=0$ and $S=2$, but a spectrum characteristic of a species in a spin state other than $S=0$ or $S=2$. Mössbauer spectrum also shows a spectrum characteristic of the intermediate spin state, which differs from a spectrum expected for a mixture of the high spin state and the diamagnetic one.[6] The observed magnetic moments are summarized in Table 1.

The absorption spectra of TPPFe(II) and TPPFe(II)·2Py were measured in benzene and in pyridine

TABLE 1. MAGNETIC MOMENTS OF IRON(II)- AND MANGANESE(II) TETRAPHENYLPORPHINS

Complex	Magnetic moment (Bohr magneton)	Number of unpaired electrons	Spin state
TPPFe(II)·2Py	0	0	$S=0$
TPPFe(II)·2THF	2.75	2	$S=1$
TPPFe(II)	4.75	4	$S=2$
TPPMn(II)·2Py	6.02	5	$S=5/2$

----: dioxane solution

molecules of pyridine coordinate to the iron(II) in TPPFe(II) upon dissolution in pyridine. The spectra in the visible region of TPPFe(II)·2Py both in benzene and in pyridine actually coincide. The absorption spectrum of the powder sample of TPPFe(II)·2Py measured by means of the opal glass technique[7] was in good agreement with the solution spectrum. This indicates that the coordination of pyridine in the molecular crystal does not differ much from that in solution. Among the iron(II) complexes of tetraphenylporphin, bis(pyridine) complex in the solid state seems to be the most inert to oxygen and moisture in the air. However, it is readily converted into a ferric complex such as $(TPPFe(III))_2O\cdot 2H_2O$,[8] when the benzene solution of TPPFe(II)·2Py is exposed to the air (Fig. 5).

The absorption spectrum of TPPFe(II) in THF differs from those observed in benzene ($S=2$) and in pyridine ($S=0$). The visible bands observed in THF are close to those observed in benzene, while the Soret band in THF is in fairly good agreement with that in pyridine. The spectrum of TPPFe(II) in THF can not be reproduced by a superposition of the spectra of high spin component and diamagnetic one. Since the intensity of the characteristic bands is almost in the same order in these two components, the mixture spectrum should be a simple superposed spectrum. The observed spectrum of TPPFe(II) in THF is not a simple superposed mixture spectrum. Thus it should be assigned to a spectrum characteristic of a single species other than high spin species or diamagnetic species. As a matter of fact, we could isolate solid TPPFe(II)·2THF from the THF solution of TPPFe(II). It shows an intermediate spin value. TPPFe(II) in dioxane shows a very similar spectrum to that in THF (Fig. 6).

In the case of Fe(III) complexes of tetraphenylporphin, high spin species ($S=5/2$) and low spin species ($S=1/2$) have been synthesized, but not the intermediate spin species ($S=3/2$).[6] In the case of Fe(II) complexes, however, three spin states could be obtained. The most probable d electron configurations of these three spin states are given in Fig. 7. The ordering of the ligand-fielded d orbitals is schematically shown in Fig. 8. The actual values obtained

depend on the model employed. However, a simple argument in terms of molecular orbital theory can readily give the ordering of split d orbitals.[9] The ordering in a planar ligand field:

$$\varepsilon(x^2-y^2)=\Delta,\ \varepsilon(z^2)=\Delta/3,\ \varepsilon(xy)=\varepsilon(yz)=\varepsilon(zx)=0.$$

Δ is the ligand-field splitting parameter. For the sake of simplicity, the small energy difference between yz, zx, and xy orbitals is ignored. Energy difference between x^2-y^2 and z^2 orbitals is crucial. It varies with the axial ligand field. $\varepsilon(x^2-y^2)-\varepsilon(z^2)$ is $2\Delta/3$ for a planar configuration, while it vanishes for an octahedral configuration. $\varepsilon(z^2)$ is parametrized as $\Delta/3+xB$, where xB is an index of the axial ligand field strength in terms of Racah's parameter B. The energy values of d orbitals in iron porphin, in general, are given in B units as follows: $\varepsilon(x^2-y^2)=\Delta=XB$, $\varepsilon(z^2)=\Delta/3+xB=(X/3+x)B$, $\varepsilon(xy)=\varepsilon(yz)=\varepsilon(zx)=0$. The energy of the ground state of iron(II) porphin can be approximately given as a function of the ligand field strength XB, the axial ligand field strength xB and Racah's electrostatic interaction parameters B and C.

$$^1A_1 \quad E_0 - 30B + 15C$$

$$^3E \quad E_0 - 26B + 12C + \frac{2}{3}XB + \frac{1}{2}xB - \frac{B}{2}\sqrt{\frac{4}{9}X^2 + \frac{16}{3}X - \frac{4}{3}xX + x^2 - 8x + 64}$$

$$^5B_2 \quad E_0 - 35B + 7C + \frac{4}{3}XB + xB$$

where E_0 denotes a common term of spherical symmetry. Assuming an empirical relationship $C=4B$,[10] we have

$$^1A_1 - {}^5B_2 \quad \left(37 - \frac{4}{3}X - x\right)B$$

$$^3E - {}^5B_2 \quad \left(29 - \frac{2}{3}X - \frac{1}{2}x - \frac{1}{2}\sqrt{\frac{4}{9}X^2 + \frac{16}{3}X - \frac{4}{3}xX + x^2 - 8x + 64}\right)B$$

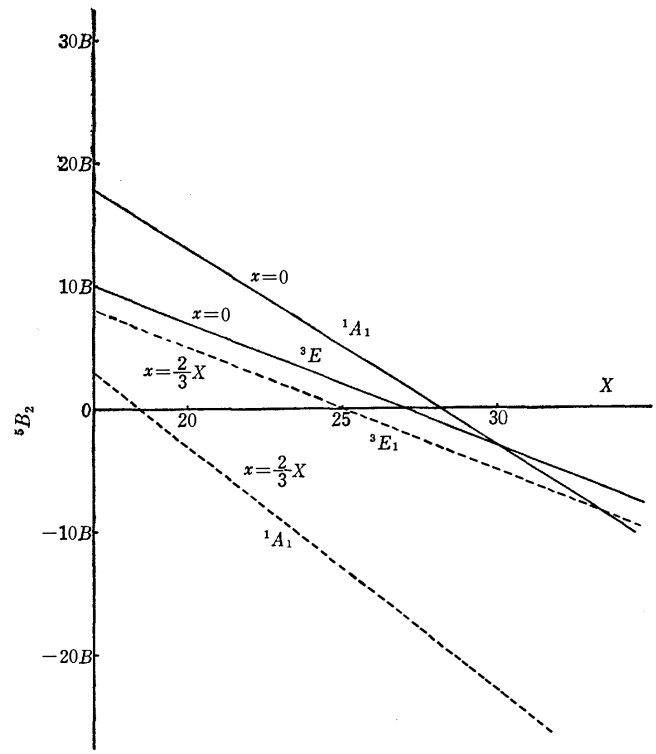

Fig. 9. Energy diagram as a function of the ligand field strength, X, and the axial ligand field strength, x.
----: $x=\frac{2}{3}X$ (octahedral configuration)
——: $x=0$ (planar configuration)

The energy diagram is readily drawn as a function of X and x and is shown in Fig. 9. $^1A_1$ and ^3E are stabilized to a greater extent than $^5B_2$ when X increases. With a fixed value of X, $^1A_1$ is more stabilized than ^3E when the axial ligand field x increases. Unless the axial field is fairly weak, the ground state could not be ^3E. B in iron(II) porphin is estimated to be about 800 cm^{-1} from spectroscopic data.[11] The value of Δ in porphin has been estimated to be 20,000—25,000 cm^{-1} by an extended Hückel molecular orbital calculation.[12] Thus X is in the region 25—31. The value of X predicts $^1A_1$ ground state for an octahedral environment, where $x=2/3X$ which is attained by strongly coordinating axial ligands. For an octahedral ligand field the intermediate spin state ^3E can not be the ground state. For a planar ligand field, where $x=0$, the ground state is $^5B_2$ if $X<27$ and ^1A if $X>30$. When $27<X<30$, the intermediate spin state ^3E is expected to be the ground state. As a matter of fact, the ground state of iron(II) phthalocyanine with no axial ligand is in the state of $S=1$.[13] The ground state of TPPFe(II), however, is in the state of $S=2$. The value of X in TPPFe(II) is smaller than that of iron(II) phthalocyanine. However, in the

presence of relatively weak axial ligands such as THF and dioxane, the ground state becomes ^3E. The ^3E ground state, in principle, is reached with a similar X value as in TPPFe(II) as long as the axial ligand field is low. However, a mechanism to enhance the value of X is expected to get the ^3E ground state of TPPFe(II) in THF or dioxane. An effective radius of the central iron in the $^5B_2$ state is rather large and the iron can not be in the central hole and is slightly out of the porphin plane. Once ^3E state or ^1A state is attained, however, the effective radius of the iron is reduced and the iron can be seated in the central hole of porphin. Thus the overlap integral of iron and nitrogen orbitals and the X value increase. The effective radius depends on the occupation number in $d_{x^2-y^2}$ orbital which partially accepts σ electron donated by four nitrogens of porphin. The geometrical change has been pointed out by means of X-ray studies.[4]

TPPMn(II)·2Py in the solid state shows the highest spin state (Table 1). The powder spectrum of TPPMn(II) obtained by the opal glass method was very close to that in benzene. This indicates no change of spin state involved in dissolution. The solution spectrum of TPPMn(II)·2Py in benzene is shown in Fig. 10. The absorption bands are assigned to pure (π, π^*) transitions as that of TPPZn(II).[14] The lowest (π, π^*) transitions are described as a 50–50

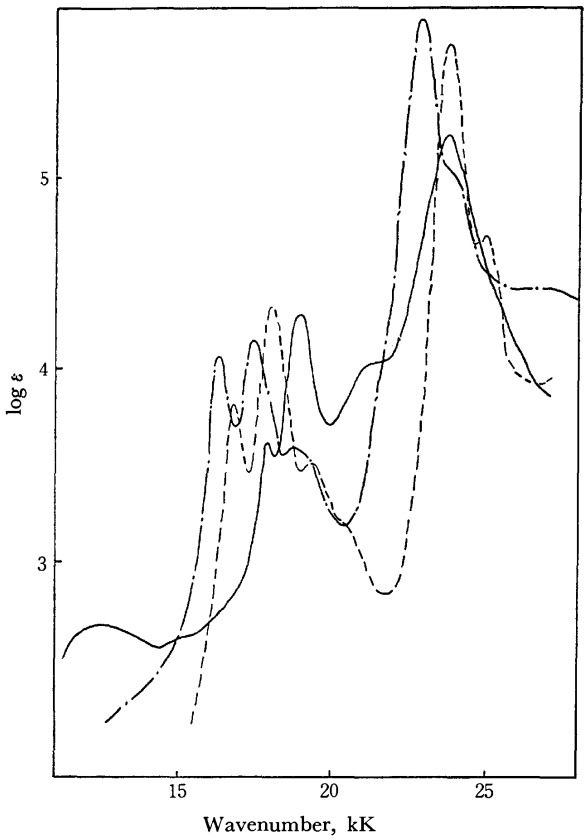

Fig. 10. Absorption spectrum of TPPMn(II)·2Py.

——: TPPFe(II)·2Py in pyridine
----: TPPZn(II) in THF

admixture of transitions $2a_1 \rightarrow 4e$ and $3a_2 \rightarrow 4e$.[14-16] When the central metal ion has no appreciable π interaction with the conjugated system of porphin, the lowest excited states can be described by the four-orbital model.[14] When the four-orbital model is applicable, a gap between Q and B bands is fairly constant for a series of central metal ions. This can be seen in the spectra of TPPMn(II)·2Py and TPPZn(II) as shown in Fig. 10. If the central metal ion is replaced by a highly π-donating metal ion, the conjugated system of porphin in the ground and excited states should suffer π electron migration from the central metal ion. Although the absorption spectrum of diamagnetic TPPFe(II)·2Py apparently preserves a character of Q and B bands of a metal porphin less contributed by $d\pi$ electron, a gap between Q and B bands is remarkably smaller than those of TPPMn(II)·2Py and TPPZn(II). Since $d\pi$ ionization potential of the diamagnetic iron(II) in porphin is fairly low, the energy of the charge-transfer from metal $d\pi$ orbitals to the lowest antibonding ligand π orbitals is not so high. Both metal $d\pi$ orbitals zx and yz and the lowest antibonding porphin orbitals $4e$ are of E symmetry. Thus the "metal to ligand" charge-transfer states can mix with the ground state and the lowest exciting states of the π electron system of porphin. In the case of TPPFe(II)·2Py, weak absorption bands are observed in the near-infrared region. These weak bands might be assigned to "metal to porphin" and/or "metal to pyridine" charge-transfer transitions. However, the charge-transfer excited states and the Q and B excited states can not be very pure when their symmetries are the same and their energies are close. The lowest excited states representing the observed spectrum should be described in terms of a configuration interaction admixture of "metal to ligand" charge-transfer excited states and (π, π^*) excited state of porphin ring. As a result, lower charge-transfer states raise the Q state, and thus the gap of Q and B states are reduced. Another charge-transfer is possible from metal to axial ligand. When piperidine which lacks acceptable antibonding π molecular orbitals is used as the axial ligand, the possibility of the "metal to axial ligand" π charge-transfer can be eliminated. The spectrum of TPPFe(II) in piperidine still shows a contribution of charge-transfer states. The charge-transfer is ascribed to "iron to porphin." On the contrary, the spectrum of TPPFe(II) in pyridine gives an evidence of "iron to pyridine" charge-transfer transition at about 21 kK, whereas TPPFe(II) in piperidine lacks the absorption peak (Fig. 11).

Absorption spectrum of a coordination complex, in general, depends upon both the central metal and the ligands. In the case of metalloporphins, especially of iron porphins, the spectrum is predominantly influenced by the spin state of the central metal rather than particular axial ligands. The spin state of the central metal, however, depends upon the axial ligand

——: pyridine solution
----: piperidine solution

field and the spectrum varies with the axial ligands only when the axial ligands can change the spin state of the central metal. It should depend on the properties of the low energy absorption bands of metalloporphin.

When an open shell exists in the central metal ion as in TPPFe(II), "metal to ligand" or "ligand to metal" charge-transfer excited states can mix not only with singlet (π, π^*) excited states but also with triplet (π, π^*) excited states. When a delocalization interaction between iron $d\pi$ orbitals and $4e$ orbitals of porphin is sufficient, such a configuration mixing becomes significant. The usual metalloporphins have two pairs of the spin forbidden singlet-triplet transitions in the near-infrared region.[15,16] The lowest triplet emits phosphorescence. The charge-transfer interaction between the open shell iron and the excited states of porphin will carry an appreciable amount of transition probability to these spin forbidden transitions from the allowed transitions. As a matter of fact, TPPFe(II) shows a rather complicated spectrum in the lower energy region. The near-infrared bands of high spin porphin TPPFe(II), and also intermediate spin porphin TPPFe(II)·2THF should be assigned mainly to weak "metal to porphin" charge-transfer transitions. However, a contribution of the porphin triplets in the near-infrared absorption bands of the open shell iron(II) porphins should be pointed out. Generally speaking, the spin selection rule of molecular electronic transitions is released when the molecule is connected with an open shell system by a charge-transfer process.[17] If the interaction is not so strong as in TPPMn(II)·2Py, it shows just a weak absorption shoulder at the position of the lowest singlet-triplet transition. In the case of the open shell iron(II) porphins, however, the charge-delocalization effect increases mainly due to higher $d\pi$-donating power of iron(II) and thus a configuration mixing of various excitations gives rise to a shift in transition energy and also a redistribution of spectral intensity.

The authors are grateful to Dr. Y. Kaizu for his technical advice in chemical preparations using the vacuum system. One of the authors (H. K.) wishes to express his thanks to Profs. M. Kotani and M. Gouterman for encouragement and helpful discussions.

The Reaction of Tris(acetylacetonato)cobalt(III) with Bromine in Dichloromethane

Yukio NAKAMURA, Mitsuru GOTANI, and Shinichi KAWAGUCHI
Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka
(Received June 28, 1971)

Dibromo(acetylacetone)cobalt(II), a new complex containing an acetylacetone molecule as the bidentate ligand, was formed by the reaction of tris(acetylacetonato)cobalt(III) with bromine in dichloromethane, and characterized by elemental and thermogravimetric analyses and electronic and infrared spectra. The same compound was also prepared by direct addition of acetylacetone to anhydrous cobalt(II) bromide. The radical nature of the redox step involved in the reaction pathway from the starting cobalt(III) chelate to the product cobalt(II) complex of acetylacetone was demonstrated by polymerization of methyl methacrylate and styrene remarkably enhanced by the reaction system.

In previous papers we have reported reactions of bromine with several metal acetylacetonates. All metal chelates of this ligand examined so far reacted with bromine quickly in dichloromethane, but products differed depending on the nature of the central metal. In the case of bis(acetylacetonato)copper(II), for instance, the chelate ring was broken, giving γ-bromoacetylacetone and copper(I) bromide or copper(II) bromide according to the reactant mole ratio.[1] In contrast, beryllium and aluminum chelates were so stable as to be subjected to electrophilic ring substitution by bromine at the γ-position of the chelated acetylacetone.[2] Such a direct bromination by elemental bromine without the aid of any buffering mixture was known only for tris(acetylacetonato)-chromium,[3] and the quasiaromatic halogenation[4] of various metal acetylacetonates was effected by making use of *N*-halosuccinimides.[5]

When tris(acetylacetonato)cobalt(III) is allowed to react with excess bromine in dichloromethane, the chelate ring is broken producing cobalt(II) bromide and brominated acetylacetone ultimately. This paper reports the isolation and characterization of a novel cobalt(II) complex of molecular acetylacetone as an intermediary product, and presents some evidence for the radical nature of a redox step involved in the reaction.

Experimental

Materials. Tris(acetylacetonato)cobalt(III) was synthesized according to the standard method.[6] Found: Co, 16.47; C, 50.96; H, 6.22%. Calcd for $Co(C_5H_7O_2)_3$: Co, 16.54; C, 50.57; H, 5.94%. Commercial bromine and dichloromethane were purified by the usual methods.[1] Acetylacetone from Daicel, Ltd. was distilled under reduced pressure and dried with molecular sieves Type 4A8—12, Linde Co. Anhydrous cobalt(II) bromide was prepared by the dehydration of hexahydrate at 135—140°C and purified by sublimation *in vacuo*. Purified methyl methacrylate and styrene were obtained from Prof. Otsu's laboratory and used without further treatment.

Reaction of Tris(acetylacetonato)cobalt(III) with Bromine. The reaction of tris(acetylacetonato)cobalt(III) with bromine in dichloromethane was carried out in a three-necked flask equipped with a burette, a glass tube containing phosphorus pentaoxide, and another tube connected to a filtration equipment by means of a polyethylene tubing. To a chelate solution in the flask of the desired concentration in the range from 0.05 to 0.15 M, was added a bromine solution of the same concentration from the burette with vigorous stirring. The precipitate produced by the reaction was transferred *via* a polyethylene tubing to a vacuum filtration apparatus set up in a desiccator containing phosphorus pentaoxide to remove moisture.

Polymerization Experiments of Vinyl Monomers. When tris(acetylacetonato)cobalt(III) was allowed to react with equimolar bromine in dichloromethane at 0°C, no precipitate was formed. About 10 m*l* of the green solution was quickly transferred to an ampoule, which was then attached to a vacuum line and deaerated by repeated freezing and thawing cycles. Care was taken to keep the sample at temperatures below 0°C. A weighed quantity (about 5 m*l*) of a vinyl monomer was distilled into the ampoule *in vacuo*, which was then sealed off and kept in a thermostat at 35°C for 41 hr. An intermediary compound produced by the reaction between the cobalt(III) chelate and bromine at 0°C underwent further reactions upon heating, concurrently giving rise to the polymerization of a monomer. When the ampoule was opened and the reaction mixture poured into methanol, the cobalt(II) compound was dissolved and a white precipitate of polymer was obtained. This was filtered, washed with methanol and dried *in vacuo*. The polymer specimen for the infrared assay was purified by reprecipitation with benzene-methanol. As a reference the vinyl polymerization was pursued in a similar system including tris(acetylacetonato)cobalt(III) but excluding bromine.

Direct Synthesis of Dibromo(acetylacetone)cobalt(II). About 1 g of anhydrous cobalt(II) bromide was put into an ampoule quickly, evacuated for a while at about 135°C and kept in an ice bath. Into this ampoule about 40 m*l* of purified acetylacetone was distilled *in vacuo*. During the procedure the ice bath was removed occasionally and the reacting mixture was agitated magnetically by means of a small stirrer equipped in the ampoule to prevent aggregation and stimulate dissolution of cobalt(II) bromide. The mixture was then kept at room temperature with continuous stirring. A purple fuzzy product increased as green cobalt(II) bro-

mide diminished. One or two days were required before the complete disappearance of the latter. The precipitate was increased further by vacuum distillation of some quantity of acetylacetone, filtered and washed with petroleum ether in dry conditions. The product was first evacuated at room temperature. A specimen gave the analytical data: Found: Co, 13,77; Br, 37.84%, which are close to those Calcd for $CoBr_2(C_5H_8O_2)_2$: Co, 14.07; Br, 38.14%. However, the weight decreased gradually with prolonged evacuation. Thus it was finally evacuated at 60°C for about 5 hr to attain constant weight. The color turned from purple to light blue. The compound is very hygroscopic. Found; Co, 18.27; Br, 49.98; C, 19.32; H, 2.83%. Calcd for $CoBr_2$-$(C_5H_8O_2)$: Co, 18.48; Br, 50.12; C, 18.83; H, 2.53%. The purple substance might have contained another molecule of acetylacetone as a solvent of crystallization.

Analysis and Measurements. Solid products were dried *in vacuo* at room temperature and subjected to elemental analysis. Cobalt was determined gravimetrically as sulfate and bromine as silver bromide.

The infrared spectra of solid specimens were measured in Nujol by means of a Hitachi EPI-2 infrared spectrophotometer (4000—700 cm^{-1}) and a Hitachi EPI-L grating infrared spectrophotometer (700—200 cm^{-1}). The infrared spectra of polymers were taken as thin films. Absorption spectra of solutions were obtained using a Hitachi EPS-2 recording spectrophotometer. When the observation was performed at 0°C, ice water was circulated around the cell and dry air was forced to blow against the cell windows to prevent clouding. A solid specimen was ground with Nujol, placed between two plates of opal glass and its transmission spectrum was measured with a Hitachi EPU-2A photoelectric spectrophotometer.[7]

A thermo-spring balance C-282 of Hamada Denki Seisakusho, Ltd. was used for thermogravimetric analysis. The temperature of the sample was raised at a rate of 30°/hr *in vacuo*. The volatile decomposition product was collected in a trap cooled with dry ice and subjected to gas chromatographic analysis. A column of Apiezon Grease L carried on Neosorb NC (Nishio Industries Co., Ltd.) was employed at 59°C, on which hydrogen gas was passed at a flow rate of 72 cm/min. On the other hand the solid decomposition residue was fused together with potassium carbonate. Cobalt and bromine contents were determined gravimetrically.

Magnetic susceptibility was determined at room temperature by the Gouy method with an automatically recording magnetic balance (Naruse Kagakukikai Co., Ltd.). The sample was put into a tube (2 mm in diameter and 70 mm in length) quickly in a dry box. An aqueous solution of nickel(II) chloride was used as a reference.

Results

If tris(acetylacetonato)cobalt(III) is allowed to react with an equimolar quantity of bromine in dichloromethane at 0°C, no precipitate is formed and the dark green solution is quite stable as long as it is kept at 0°C. As shown in Fig. 1 the visible absorption spectrum of this solution is similar to that of the starting complex, suggesting that the intermediary species involved is a cobalt(III) compound. The solution was concentrated by vacuum evaporation at 0°C to isolate a light blue precipitate. The same precipitate

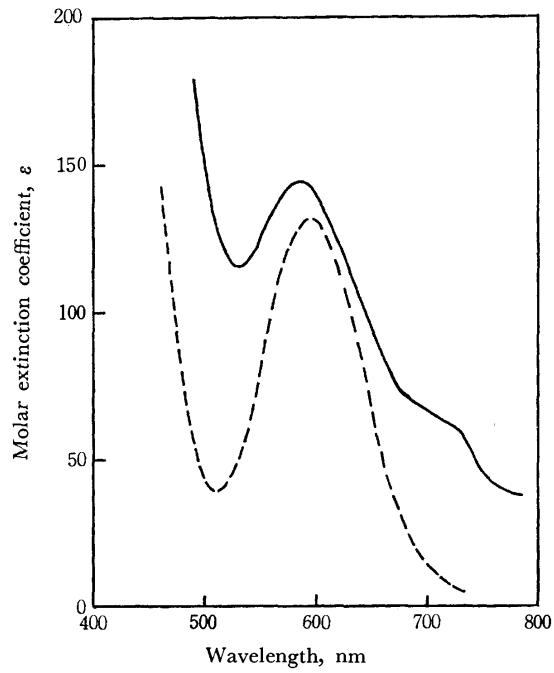

Fig. 1. Absorption spectra in dichloromethane of tris(acetylacetonato)cobalt(III) (----) and a reaction mixture of the chelate and bromine in the mole ratio of 1:1 at 0°C (——).

was also formed by the addition of petroleum ether. However, the solid thus obtained was no longer soluble in dichloromethane, indicating that this is a different compound from the desired soluble intermediate. Elemental analysis disclosed that the secondary product is a cobalt(II) complex of molecular acetylacetone.[8] Found: Co, 18.96; Br, 50.03; C, 18.24; H, 2.60%.

The infrared spectrum of the new complex $CoBr_2$-(acacH) in Fig. 2 shows a characteristic carbonyl band at 1705 cm^{-1} together with a shoulder at 1720 cm^{-1}, coinciding with those observed at 1707 and 1727 cm^{-1} for ketonic molecules of acetylacetone (Table 1).[9] No absorption bands assignable to enolic molecules or chelated enolate anions are observed. The Co–O stretching absorption at 375 cm^{-1} is lower than 422 cm^{-1} of that in $Co(acac)_2$,[10] reflecting weakness of the Co–O bond in the present complex compared to that in the usual enolate chelate. The spectral data reveal unequivocally that a ketonic molecule of acetylacetone is coordinated to the cobalt atom.

a) From ref. 9

The magnetic measurement gave a value of 4.25 B.M. as the effective magnetic moment, indicating the tetrahedral structure[11a] of this cobalt(II) compound.

Since the compound is not soluble in the usual non-coordinating solvents, the absorption spectrum was observed in acetylacetone. The transmission spectrum of a solid specimen was also measured by the Nujol mull method and confirmed to be similar to that in an acetylacetone solution. As depicted in Fig. 3 the absorption curve resembles that observed for $CoBr_2(acetone)_2$ which is considered to assume a tetrahedral structure.[11]

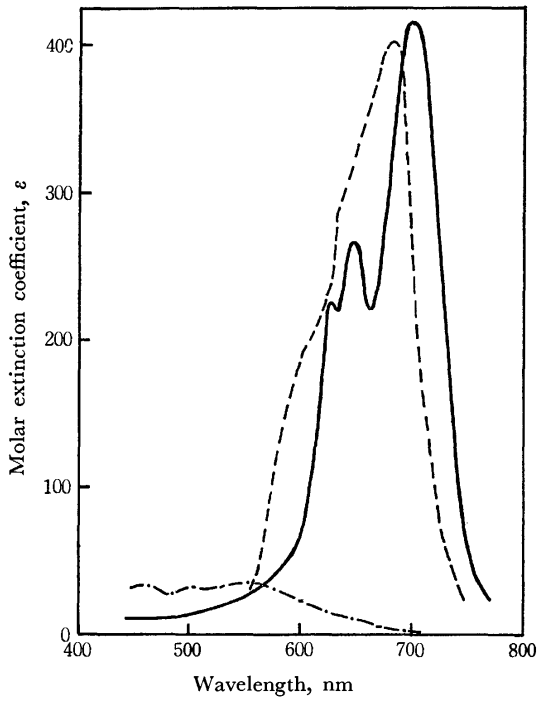

Fig. 3. Absorption spectra of $CoBr_2(acacH)$ in acetylacetone (——), $CoBr_2$ in acetone (----), and $Co(acac)_2$ in dichloromethane (—·—).

In accordance with the supposition that the linkage of acetylacetone to cobalt is weak, the compound begins to decompose at around 70°C. This should be compared with the behavior of bis(acetylacetonato)-cobalt(II), which is quite stable and easily sublimes *in vacuo*. As illustrated in Fig. 4 the weight decrease

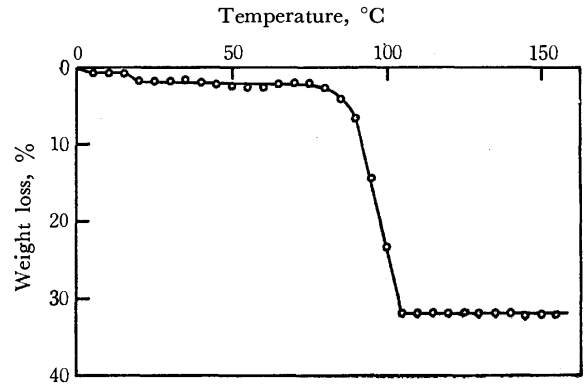

Fig. 4. Thermogravimetric analysis of $CoBr_2(acacH)$. Heating rate: 30°C/hr.

amounts to 30% which coincides with the value 31% calculated for the loss of acetylacetone. The evaporated substance was collected in a trap cooled with dry ice and identified to be acetylacetone by gas chromatography, while the decomposition residue was characterized to be cobalt(II) bromide by elemental analysis (Found: Co, 27.43; Br, 70.54%).

The new complex $CoBr_2(acacH)$ was also prepared by the direct addition reaction of acetylacetone to anhydrous cobalt(II) bromide (see Experimental). Data of the elemental analysis and infrared spectra showed a good coincidence.

When more than 1 mol of bromine was added to 1 mol of tris(acetylacetonato)cobalt(III) in dichloromethane at 0°C, a light blue precipitate appeared. The precipitate produced by the reaction in the reactant mole ratio of 2 : 1 showed an infrared spectrum closely resembling that of $CoBr_2(acacH)$, but gave analytical data showing contamination with cobalt(II) bromide and water. Found: Co, 19.06; Br, 50.64; C, 15.88; H, 2.65; H_2O (Karl Fischer method), 2.82%. Calcd for a mixture $[CoBr_2(acacH)+0.22CoBr_2+0.59H_2O]$: Co, 19.04; Br, 51.63; C, 15.90; H, 2.45; H_2O, 2.82%. Part of the bromine molecules seem to have attacked $CoBr_2(acacH)$, brominating coordinated acetylacetone and liberating cobalt(II) bromide, although the reaction between bromine and a soluble cobalt(III) intermediate occurred predominantly. When a dichloromethane solution of bromine was added dropwise to a dichloromethane solution of tris(acetylacetonato)cobalt(III) at room temperature, a light blue precipitate appeared from the beginning, the amount of which increased with bromine addition. The precipitate was also a mixture of $CoBr_2(acacH)$ and $CoBr_2$. The reaction pattern at room temperature does not differ essentially from that at 0°C, but the reactivity of the cobalt(III) intermediate observed at 0°C (Fig. 1) is much increased at higher temperatures.

A redox process is involved in the conversion of the soluble cobalt(III) intermediate into $CoBr_2(acacH)$. To ascertain the possible radical nature of this redox process, polymerization reactions of methyl methacrylate and styrene were examined in the system. Tris(acetylacetonato)cobalt(III) is known to initiate

10) K. Nakamoto, P. J. McCarthy, and A. E. Martell, *J. Amer. Chem. Soc.*, **83**, 1272 (1961).

11) a) R. L. Carlin, "Transition Metal Chemistry," Vol. 1, Marcel Dekker, New York (1965), p. 1; b) D. A. Fine, *J. Amer. Chem. Soc.*, **84**, 1139 (1962).

TABLE 2. RESULTS OF POLYMERIZATION OF METHYL METHACRYLATE AND STYRENE INITIATED BY $Co(acac)_3$ AND THE $Co(acac)_3$-Br_2 SYSTEM (35°C, 41 hr IN DICHLOROMETHANE)

Monomer	$[Co(acac)_3]$, M	Polymer yield, %	
		$Co(acac)_3$ only	$Co(acac)_3$ + Br_2
MMA	3.41×10^{-2}	2.22	27.6
Styrene	4.11×10^{-2}	0.28	7.7

the radical polymerization of the vinyl monomers,[12,13] but the efficiency is rather low under the present reaction conditions, as shown in Table 2. In contrast the $Co(acac)_3$–Br_2 system exhibits a remarkable initiating ability for vinyl polymerization, revealing that some initiating radicals are formed when the cobalt(III) intermediate is warmed.

The difference in the polymer yield (Table 2) observed for the two monomers reflects the difference in the nature of the monomer. Methyl methacrylate is known to be much more reactive than styrene towards free radicals. The infrared spectrum of a polystyrene film showed a weak but definite absorption peak of the carbonyl group at around 1700 cm^{-1}. This is considered to be due to the acetylacetone radical or its fragment attached to the polymer end. A similar observation was also reported by Otsu, Minamii, and Nishikawa[13] on polystyrene which was prepared employing tris(acetylacetonato)manganese(III) as an initiator. The infrared spectrum of poly(methyl-methacrylate) obtained closely resembles those of polymers prepared by virtue of typical radical initiators such as benzoyl peroxide and azobisisobutyronitrile, but the carbonyl bands due to the acetylacetone group can not be discriminated because of a strong absorption by the ester group.

Discussion

Although the starting material was a cobalt(III) complex, the isolated stable products were cobalt(II) compounds. The reaction step in which cobalt(III) was reduced is not clear enough, but the solution resulting from the addition of equimolar bromine to tris(acetylacetonato)cobalt(III) in dichloromethane at 0°C gave an absorption curve similar to that of the original chelate as shown in Fig. 1, indicating that the first soluble intermediate is an octahedral cobalt(III) complex. Attempts to isolate this compound as a pure solid were unsuccessful, but it could be supposed that a binuclear cobalt(III) complex (A) was formed by the reaction represented by Eq. (1). Either bromine atoms or acetylacetone groups are able to function as bridging ligands.

$$Co(acac)_3 + Br_2 \rightarrow 1/2\,[CoBr(acac)_2]_2 + acacBr \quad (1)$$

$[Co(acac)_2bipy]ClO_4$ in CH_3OH	553	2.19

a) R. D. Archer and B. P. Cotsoradis, *Inorg. Chem.*, **4**, 1584 (1965).

Visible absorption bands of several related compounds are shown in Table 3. The absorption maximum of the present solution lies on the longer wavelength side corresponding to the weak field of bromine in comparison with other ligands in Table 3. The value of molar absorptivity, however, is similar to values of the related compounds.

The binuclear intermediate (A) changed to the cobalt(II) compound, $CoBr_2(acacH)$ by addition of petroleum ether, concentration at 0°C, or warming to room temperature. We imagine that disproportionation of the intermediate (A) as expressed by Eq. (2) occurred spontaneously, followed by the redox process (3).

$$[CoBr(acac)_2]_2 \rightarrow [CoBr_2(acac)] + Co(acac)_3 \quad (2)$$
(B)

$$[CoBr_2(acac)] + RH \rightarrow CoBr_2(acacH) + R\cdot \quad (3)$$

Here the intermediate (B) is an imaginary compound. Either a solvent molecule or γ-bromoacetylacetone might play the role of the hydrogen donor RH. Similarly the reaction of the intermediate (A) with bromine to produce the ketonic complex will be represented by the following equation followed by (3).

$$1/2\,[CoBr(acac)_2]_2 + Br_2 \rightarrow [CoBr_2(acac)] + acacBr \quad (4)$$

In one experiment 7.14 mmol of tris(acetylacetonato)cobalt(III) was allowed to react with an equimolar quantity of bromine in dichloromethane at room temperature. After 20 hr 2.97 mmol of $CoBr_2(acacH)$ was isolated. If the overall reaction be reproduced by Eqs. (1), (2) and (3) 2.97 mmol of $Co(acac)_3$ and $7.14-2\times2.97=1.2$ mmol (in the monomer basis) of the dimeric intermediate (A) must be contained in the filtrate. The absorption curve of the solution was calculated on this basis by making use of the spectral data as presented in Fig. 1, and found to nearly coincide with the observed one. This supports the proposed scheme (1) through (3).

If a vinyl monomer is mixed with the intermediate (A) in dichloromethane and warmed to higher temperatures, a monomer molecule (M) may take an acetylacetone radical away from (B) liberating cobalt(II) bromide.

$$CoBr_2(acac) + M \rightarrow CoBr_2 + (CH_3CO)_2CHM\cdot \quad (5)$$

Alternatively the intermediate (B) might abstract a hydrogen atom predominantly from γ-bromoacetylacetone, the radical produced initiating polymeri-

zation in turn.

Molecular adducts of acetylacetone with antimony(V) and titanium(IV) chlorides were prepared by Rosenheim, *et al.*[14] in 1903, but the bonding nature was not confirmed. The mercury(II) chloride complex $HgCl_2(acacH)$ was studied by Paoloni[15] in detail, and it was concluded on the basis of the carbonyl stretching band at 1698 cm^{-1} that a ketonic molecule of acetylacetone was coordinated to the mercury atom with two carbonyl oxygen atoms. The present complex $CoBr_2(acacH)$ as well as similar nickel(II) complexes reported by van Leeuwen,[16] $[Ni(acacH)_3](ClO_4)_2$, $[Ni(acacH)_2(AcOH)_2](ClO_4)_2$, and $[Ni(acacH)_2(H_2O)_2](ClO_4)_2$, also contain ketonic molecules of acetylacetone.

In contrast, the acetylacetone adduct of dioxobis(acetylacetonato)uranium(VI) was concluded to involve an enolic molecule of acetylacetone as a unidentate ligand on the basis of IR and NMR data.[17] More recently the same bonding nature was established by X-ray analysis of dibromobis(acetylacetone)manganese(II).[18] It is very interesting that two tautomeric forms of acetylacetone can exist in metal complexes, but factors for preference of one form over the other are not clear. More examples are wanted.

The authors thank Dr. S. Kawai of Osaka University for the magnetic measurement, and Mr. J. Gohda for the elemental analyses. They are also grateful to Professor T. Otsu and Dr. S. Aoki for the supply of purified vinyl monomers, and to Daicel Co., Ltd. for the gift of acetylacetone. Aknowledgement is made to the Ministry of Education for financial support.

Magnetic Moments and Electronic Spectra of Low-spin Cobalt(II) Complexes

Yuzo NISHIDA and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka, Japan

(Received June 30, 1971)

Comprehensive elucidation of optical and magnetic properties of low-spin cobalt(II) complexes of various types has been attempted. The g-values and magnetic susceptibilities of the complexes have been calculated, the necessary numerical data being obtained from the spectral data and reasonable assumptions. Fairly good agreement has been obtained between the calculated and experimental values.

As is known, values of magnetic moments of low-spin cobalt(II) complexes fluctuate in a wide range (1.9~2.8 BM., see Table I)[1] higher than the spin-only value (1.73 BM.) for one unpaired electron. High magnetic moments compared to the spin-only value have been attributed to the orbital contribution to the ground state.[2] Theoretical approach to the elucidation of the magnetic properties of phthallocyanine cobalt(II) was reported by Griffith.[3] Recently Martin and Mitra[4] carried out cryomagnetic measurements of the single crystal of the same compound, and were successful in explaining the magnetic anisotropy of the crystal in terms of the ligand field theory. However, such studies were restricted to a few specific compounds, and no comprehensive elucidation of the large variation of the orbital contribution in low-spin cobalt(II) complexes has been given. In order to achieve this, it is necessary to discuss optical spectra and magnetic properties simultaneously, since the orbital contribution is mainly due to mixing of higher ligand-field terms into the ground term through spin-orbit coupling. The theoretical interpretation of electronic spectra of low-spin cobalt(II) complexes does not seem to be satisfactory. In the present study, therefore, we have attempted to elucidate the magnetic and optical properties of various types of low-spin cobalt(II) complexes in terms of ligand field theory.

Table 1. The magnetic moment of the low-spin cobalt(II) complexes

	Complex	Coordination number	$\mu_{eff.}$(r. t.)
(1)	$[Co(NO_2)_6]^{4-}$	6	1.88[20]
(2)	$[Co\ diars_3](ClO_4)_2$[a]	6	1.92[21]
(3)	$[Co\ BrAP_2]ClO_4$[b]	5	2.18[19]
(4)	$[Co\ en_2](AgI_2)_2$[d]	4	2.46[5]
(5)	[Co pc][e]	4	2.72[14]
(6)	[Co sals][c]	4	2.30

a) diars=diarsine
b) AP=Diphenyl(*o*-diphenylarsinophenyl)phosphine
c) sals=Bis(salicylaldehyde)-meso-stilbenediimine
d) en=ethylenediamine
e) pc=phthallocyanine

Some spectral and magnetic measurements were carried out to obtain numerical data necessary for the calculations.

Experimental

$[Co\ en_2](AgI_2)_2$ and [Co sals] were prepared by the methods of Lever, Lewis and Nyholm[5], and Nishikawa and Yamada,[6] respectively, where sals represents bis(Salicylaldehyde)stilbenediimine.

The ESR spectra of polycrystalline sample of $[Co\ en_2](AgI_2)_2$ were measured with a JEOL ESR-apparatus model JES-ME-3X at room temperature using an X-band. Manganese(II) doped in MgO powder was used as a standard marker.

The reflection spectra of $[Co\ en_2](AgI_2)_2$ and [Co sals] were measured with a Shimadzu Multipurpose Spectrophotometer model MPS-50L at room temperature.

The magnetic moment of [Co sals] was determined by the Gouy method at room temperature.

The Theoretical Basis for Calculation

Generally, low-spin cobalt(II) complexes are under the effect of the Jahn-Teller distortion to form complexes of axial symmetry changing from a slightly distorted octahedron to a square-planar configuration. The axial symmetry being assumed, the qualitative one-electron energy diagram as shown in Fig. 1 may be drawn from the energy level splitting of copper(II) complexes of similar geometry.[7,8] The qualitative energy-level splitting for the $3d^7$ system of D_{4h} symmetry can be described as the functions of energy differences between *d*-orbitals, δ_1, δ_2 and δ_3 (Fig. 1) and of Slater-Condon parameters, F_2 and F_4, according to the strong field approximation scheme for the d^3 configuration[9] (see Table 11 and Fig. 4). When F_2 and F_4 are estimated as usual at 1000~1200 cm^{-1} and 90~100 cm^{-1}, respectively.[10,11] The relative energy levels of the states might be as given in Fig. 4.

As a result of the above consideration, the case in which an unpaired electron lies in d_{z^2} orbital appears to be most probable for the ground state.[12] Thus, the ground state ($S=1/2$) can be represented by

$$\Psi_{z^2}{}^{+} = |(x^2-y^2)^{+}(x^2-y^2)^{-}(z^2)^{+}|$$
$$\Psi_{z^2}{}^{-} = |(x^2-y^2)^{+}(x^2-y^2)^{-}(z^2)^{-}|.$$

The spin-orbit interaction gives rise to the mixing of some Russell Saunders states. Following the perturbation theory, the ground state is written as

$$\Psi_0{}^{+} = N\left(\Psi_{z^2}{}^{+} + \sum_i \frac{\langle\Psi_i|\zeta\kappa\boldsymbol{L}\boldsymbol{S}|\Psi_{z^2}{}^{+}\rangle}{\Delta E}\Psi_i\right), \quad (1)$$

where N, ζ, and κ represent normalization constant, one-electron spin-orbit coupling constant for 3d orbitals and the orbital reduction factor, respectively, and $\Psi_0{}^{+}$, $\Psi_{z^2}{}^{+}$, Ψ_i are the wave functions of the perturbed ground state, unperturbed ground state, and the excited states respectively. The *g*-values can be calculated according to the equations,

$$g_{\parallel} = 2\langle\Psi_0{}^{+}|\kappa\boldsymbol{L}_z+2\boldsymbol{S}_z|\Psi_0{}^{+}\rangle$$
$$g_{\perp} = 2\langle\Psi_0{}^{+}|\kappa\boldsymbol{L}_x+2\boldsymbol{S}_x|\Psi_0{}^{-}\rangle. \quad (2)$$

Neglecting the second order terms we finally obtain the results.

$$g_{\parallel} = 2N,$$
$$g_{\perp} = N\left(2-\frac{6\kappa^2}{\Delta_1}\right), \quad (3)$$

where Δ_1 is the energy difference between the states $|(x^2-y^2)^{+}(x^2-y^2)^{-}(z^2)^{+}|$ and $|(x^2-y^2)^{+}(x^2-y^2)^{-}(xy)^{+}|$.

According to Van Vleck's theory,[13,14] and assuming a metal complex where the separation between the levels of the ground term is small compared to kT, and the next excited level has an energy large compared to kT (we believe that this is true for the low spin cobalt(II) complexes), the magnetic susceptibility is found to be given by

$$\chi_i = \frac{N\beta^2 g_i^2}{3kT}S(S+1) + N\alpha_i \quad (i=x, y, z), \quad (4)$$

where N and k denote the Avogadro number and the Boltzmann constant, respectively, and Na_i is the temperature-independent term of the susceptibility which is often called the high-frequency term of the susceptibility. α_i can be calculated by the equation

12) Other possibilities for the ground state are where an unpaired electron is (1) in d_{xy} orbital and (2) in d_{xz} (or d_{yz}) orbital. these cases, we could give equations corresponding to equations (2) and (3) on the basis of the same principle. However, it has been found in many compounds that the calculation according to these equation gives results considerably deviating from experimental values, as long as we have assumed reasonable values for the energies of excited states, in contrast to the nice agreement when an unpaired electron is assumed to lie in d_{z^2} orbital.

14) J. H. Van Vleck, "The Theory of Electric and Magnetic Susceptibilities," Oxford University Press, Oxford (1932).

$$\alpha_i = 2\sum_{n,m}\frac{\{\langle\Psi_{0,m}|\beta(\boldsymbol{L}_i+2\boldsymbol{S}_i)|\Psi_{n,m}\rangle\}^2}{j_m(E_0-E_n)}$$

where n and m specify the electronic excited states and the magnetic sub-levels, respectively, and j_m and E_0 are the multiplicity and the energy of the ground state.

In the case of low-spin cobalt(II) complexes, the integrals in equation (5) can be evaluated on the assumption of the energy-level splitting similar to that shown in Fig. 4. Thus we obtain

$$\alpha_z = \alpha_\parallel = \frac{16}{\Delta_3}\beta^2, \tag{6}$$

$$\alpha_x = \alpha_y = \alpha_\perp = \frac{4}{\Delta_2}\beta^2 + \frac{6}{\Delta_1}\beta^2. \tag{7}$$

By combining (4), (6), and (7), we find that χ is expressed by

$$\chi = \frac{N\beta^2}{12kT}(g_\parallel{}^2+2g_\perp{}^2) + \frac{N\beta^2}{3}\left(\frac{12}{\Delta_1}+\frac{8}{\Delta_2}+\frac{16}{\Delta_3}\right), \tag{8}$$

where Δ_1, Δ_2, and Δ_3 are the energy differences between the states $^2A_{1g}$ and ^2E_g, $^2A_{1g}$ and $^2E_g'$, and $^2A_{1g}$ and $^2A_{2g}$, respectively (see Fig. 4 and Table II).

Results and Discussion

Phthalocyanine cobalt(II): The magnetic moment of this complex was reported to be 2.72 BM. at room temperature and 2.22 BM. at 90°K.[15] It is known that this compound has a square-planar structure,[16] and $g_\parallel$ and $g_\perp$ were determined by ESR study[17] to be 1.92 and 2.92, respectively. Substituting the experimental g- and ζ-values ($\zeta=-515\ \mathrm{cm}^{-1}$) into equations (2) and (3), and assuming $k^2=0.8$ as usual,[18] we obtain $\Delta_1 = 2373\ \mathrm{cm}^{-1}\approx 2.4$ kK, which seems to be a reasonable value for the separation of the states $^2A_{1g}$ and ^2E_g.

We can now calculate the low frequency term of equation (8),

$$\chi_l = \frac{N\beta^2}{12kT}(g_\parallel{}^2+2g_\perp{}^2) \approx \frac{N\beta^2}{12kT}\times 20.74. \tag{9}$$

If we neglect the high frequency term of equation (8), the magnetic moment μ would be given by

$$\mu = \sqrt{\frac{3kT}{N\beta^2}\chi_l} = 2.28\ BM.$$

The result is not satisfactory when compared with the experimental value 2.72 BM. Thus, it is evident that we can not neglect the high-frequency term of equation (8). Since it is difficult in this case to estimate the energy differences experimentally, we estimate[19] the probable values of Δ_2 and Δ_3 both at 15 kK on the basis of the estimated energy diagram for a planar Co(II) complex in Fig. 4 (Δ_1 was already estimated at 2.4 kK). Then, we obtain

$$\chi = \frac{20.74N\beta^2}{4kT} + 2.20N\beta^2\times 10^{-3}.$$

This leads to the results

$$\mu_{300°K} = 2.56\ BM$$

$$\mu_{90°K} = 2.37\ \mathrm{BM},$$

which show a fairly good agreement with experimental values.

From this result we may conclude that the remarkably high magnetic moment of the phthalocyaninecobalt(II) relative to the spin-only value is attributable to the orbital contribution through spin-orbit coupling and also to the so called Van Vleck's high frequency term. This conclusion agrees with the result of the recent cryomagnetic measurements by Martin and Mitra.[4] It should be noted that our final formulation for χ_i with the assumption of the above numerical values is essentially the same as that of Martin and Mitra[4], their formulation giving a successful explanation for their results which show that the relation $\mu_\perp > \mu_\parallel$ and $\mu_\parallel$ is nearly independent of temperature whereas $\mu_\perp$ decreases considerably with the lowering of temperature.

Bis(ethylenediamine)cobalt(II)diiodo argentate(I) $[\mathrm{Co\ en_2}](\mathrm{AgI_2})_2$: This compound is known to have the magnetic moment of 2.46 BM[5] and the structure of its cation is thus expected to be square planar. We have measured the optical and the ESR spectra. The results are shown in Figs. 2 and 3. From the latter g-values were obtained to be as follows according to the usual method for the case of $S=1/2$.

$$g_\parallel = 2.00 \text{ and } g_\perp = 2.58. \tag{11}$$

Assuming the energy level splitting similar to that of Fig. 4, we may tentatively assign the bands observed at 7.2 kK and at about 21 kK to the transitions $^2A_{1g}\rightarrow{}^2B_{2g}$ and $^2A_{1g}\rightarrow{}^2E_g'$ (Δ_2) respectively. The transition $^2A_{1g}\rightarrow{}^2E_g$ (Δ_1) can then be estimated at 4~5 kK. The same g-values as the experimental ones (11) were obtained by the calculation according to equation (3) with $\Delta_1 = 4.8$.

Thus we can calculate the susceptibility by use of equation (8), substituting 4.8, 20, and 20 kK into Δ_1, Δ_2, and Δ_3, we get

$$\chi = \frac{0.54}{T} + 320\times 10^{-6}.$$

Hence

$$\mu_{300°K} = 2.26\ \mathrm{BM}\ (\text{exp. } 2.46\ \mathrm{BM}).$$

This is a fairly satisfactory results, considering the degree of the present approximation.

Bis(salicylaldehyde)stilbenediiminatocobalt(II) [Co sals]: Among the derivatives of so-called "Salcomine type" complexes, this compound seems to be the most suitable for the purpose of the present study, since it is known to be unreactive with atmospheric oxygen,[6] and accessible with the usual techniques of optical and magnetic measurements.

16) A. B. P. Lever, "Advances in Inorganic Chemistry and Radiochemistry," ed. by H. J. Emeleus and A. G. Sharpe, Vol. 7, pp. 27—114.

17) J. F. Gibson, D. J. E. Ingram, and D. Shonland, *Discuss. Faraday Soc.*, **26**, 72 (1958).

18) B. N. Figgis, "Introduction to the Ligand Field", John Wiley & Sons, New York, (1964), pp. 278—291.

19) Since Δ_2 and Δ_3 are much larger than Δ_1, the high-frequency term of (8) will be only sensitive to Δ_1 as readily seen from Eq. (8). Thus, a rough estimation of the values of Δ_2 and Δ_3 is enough for the present purpose.

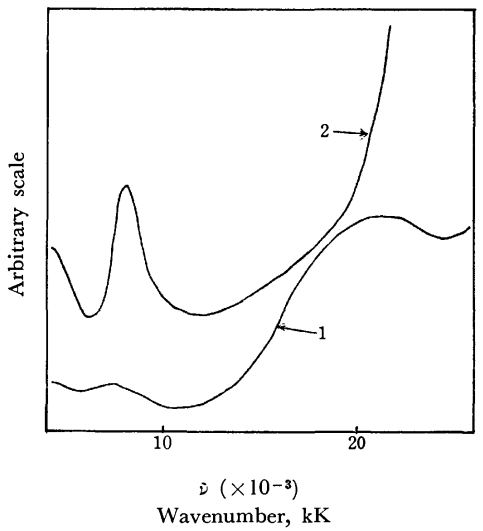

Fig. 2. Reflection spectra of

2 - [Co sals]

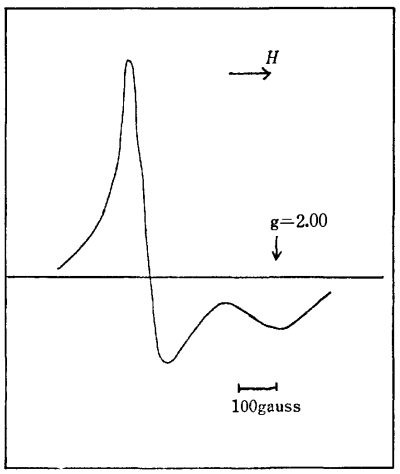

Fig. 3. ESR spectra of [Co en$_2$](AgI$_2$)$_2$ polycrystalline sample at room temperature.

TABLE 2. ELECTRONIC REPULSION ENERGY OF THE LOW-SPIN COBALT(II) COMPLEX

$^2A_{1g}$	$\lvert(x^2-y^2)+(x^2-y^2)-(z^2)+\rvert$	$3F_0-8F_2+33F_4$
$^2B_{2g}$	$\lvert(x^2-y^2)+(x^2-y^2)-(xy)+\rvert$	$3F_0+12F_2-67F_4$
^2E_g	$\lvert(x^2-y^2)+(x^2-y^2)-(xz)+\rvert$	$3F_0-3F_2+8F_4$
$^2B_{1g}$	$\lvert(x^2-y^2)+(z^2)-(z^2)+\rvert$	$3F_0-8F_2+33F_4$
$^2A_{2g}$	$\lvert(x^2-y^2)+(xy)-(z^2)+\rvert$	$3F_0-8F_2-37F_4$
$^2E_g'$	$\lvert(x^2-y^2)+(xz)-(z^2)+\rvert$	$3F_0-8F_2-37F_4$
$^4A_{2g}$	$\lvert(x^2-y^2)+(xy)+(z^2)+\rvert$	$3F_0-4F_2-120F_4$
^4E_g	$\lvert(x^2-y^2)+(xz)+(z^2)+\rvert$	$3F_0-4F_2-120F_4$

In this case, we again assume an energy level splitting similar to that given in Fig. 4-b. Then, the band observed at ~8 kK pointed out by Nishikawa *et al.*[6] as characteristic of the square planar low-spin cobalt(II) complexes and tentatively assigned to the spin-forbidden transition ($^2B_{2g}\rightarrow{}^4A_{2g}$ or ^4E_g), should be assigned to the $^2A_{1g}\rightarrow{}^2B_{1g}$ transition. Accordingly, the transition $^2A_{1g}\rightarrow{}^2A_{2g}$ can be assigned to the shoulder at ~20 kK, and the transition $^2A_{1g}\rightarrow{}^2E_g$ will appear at 5 kK or the lower wave number. Thus, the g-values and magnetic susceptibility can be calculated with the use of equations (2), (3) and (8) with the numerical values $\Delta_1=5$, $\Delta_2=20$, and $\Delta_3=20$ kK as follows.

$$g_{\parallel}=2.0,\ g_{\perp}=2.5$$

$$\chi=\frac{0.52}{T}+310\times10^{-6},$$

and this leads to

$$\mu_{300^\circ K}=2.21\ \text{BM}$$

which is in good agreement with the experimental value 2.30 BM.

Dipotassium barium hexanitrocobaltate(II). $K_2Ba[Co(NO_2)_6]$: This complex has been known to show the lowest magnetic moment (1.88 BM) among the low-spin cobalt(II) complexes. Since the nearly isotropic g-value was observed in the ESR measurements,[21] it is almost evident that this compound has a nearly octahedral structure. Thus, the energy level splitting will be similar to that given Fig. 4-a. We can assign the band observed at 15.5 kK to the $^2A_{1g}\rightarrow{}^2E_g$ transition. The transitions $^2A_{1g}\rightarrow{}^2E_g'$ and $^2A_{1g}\rightarrow{}^2A_{2g}$ would then, correspond to the absorption around 18 kK. Accordingly, we can evaluate the susceptibility using equation (8) with $\Delta_1=15.5$ kK, $\Delta_2=18$ kK and $\Delta_3=18$ kK.

$$\chi=\frac{0.41}{T}+180\times10^{-6}.$$

This leads to

$$\mu_{300^\circ K}=1.92\ \text{BM}.$$

This is in fairly good agreement with the experimental value 1.88 BM.

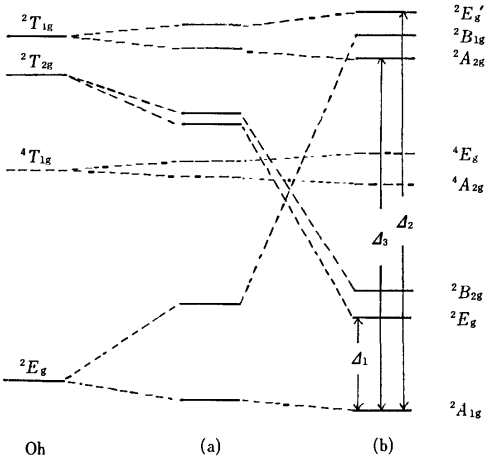

Fig. 4. Energy levels of low-spin cobalt(II) complexes with ground state, $^2A_{1g}$ in D_{4h}-symmetry.

Bromo-bis-diphenyl(o-diphenylarsinophenyl)phosphine cobalt(II) perchlorate $[CoBr(Ap)_2]ClO_4$: Dyer and Meek[20] proposed a five-coordinated square pyramidal structure for this compound from the results of spectral and magnetic measurements. In the optical spectrum they found three peaks at 7 kK, 13 kK, and 22 kK, and have assigned them to the transitions $d_{xy}\rightarrow d_{z^2}$, d_{xz},

20) G. Dyer and D. W. Meek, *J. Am. Chem. Soc.*, **89**, 3983 (1967).

$d_{yz} \rightarrow d_{z^2}$ and $d_{z^2} \rightarrow d_{x^2-y^2}$, assuming that an unpaired electron lies in d_{z^2} orbital in the ground state. Granted this assignment, we might deduce that $\Delta_1 = 13$ kK, $\Delta_2 = 22$ kK, and $\Delta_3 = 22$ kK. Using these numerical values and following equation (8), we obtain

$$\chi = \frac{0.42}{T} + 180 \times 10^{-6}$$

$$\mu_{300^\circ K} = 1.95 \text{ BM}$$

whereas the experimental value is 2.18 BM.

The alternative assignment for the electronic transitions is possible on the assumption of the energy level splitting similar to that given in Fig. 4-b, and this leads to a better agreement between the calculated and experimental values, *viz.*, the bands at 7 kK and 13 kK are assigned to the transitions d_{xz}, $d_{zy} \rightarrow d_{z^2}$ ($^2A_{1g} \rightarrow {}^2E_g$) and $d_{xy} \rightarrow d_{z^2}$ ($^2A_{1g} \rightarrow {}^2B_{2g}$) respectively, and Δ_1, Δ_2, and Δ_3 are evaluated to be 7 kK, 22 kK, and 22 kK. By use of equation (8) and the above numerical values, we obtain a better accordance with the experimental value.

$$\chi = \frac{0.47}{T} + 240 \times 10^{-6}$$

$$\mu_{300^\circ K} = 2.08 \text{ BM}.$$

Conclusion

A quantitative knowledge of the energy-level splittings of the complexes was necessary for the calculation of the magnetic quantities such as *g*-values and susceptibilities. Although we tried to avoid arbitrary methods for obtaining the numerical values necessary for the calculations, some assumptions had to be made. However, it should be noted that (1) all the assumptions are reasonable and probable ones, drawn from other experimental data as well as theoretical considerations, (2) consistency between the calculated results, experimental data and starting assumption is satisfactory throughout this work, and (3) any alternative choice for the energy level splitting of the complexes would not lead to reasonable and consistent results. This implies that our energy level diagrams and assignments of the electronic spectra are correct.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 465—469 (1972)

Studies on Mixed Chelates. I. Mixed Copper(II) Chelates with *N,N,N′,N′*-Tetramethylethylenediamine and a Bidentate Ligand

Yutaka FUKUDA and Kozo SONE

Department of Chemistry, Faculty of Science, Ochanomizu University, Ohtsuka, Bunkyo-ku, Tokyo

(Received July 5, 1971)

Six new mixed copper(II) chelates with *N,N,N′,N′*-tetramethylethylenediamine and a bidentate ligand, *i.e.*, [Cu tmen en] $(ClO_4)_2$, [Cu tmen en] $(NO_3)_2 \cdot H_2O$, [Cu tmen en]$(SO_4) \cdot 4H_2O$, [Cu tmen gly](ClO_4), [Cu-tmen ox]$\cdot 4H_2O$ and [Cu tmen aca](ClO_4) were prepared, and their visible absorption spectra were compared with those of the bis-chelate ions and molecules, $[Cu\ en_2]^{2+}$, $[Cu\ gly_2]$, $[Cu\ ox_2]^{2-}$, and $[Cu\ aca_2]$. The results obtained indicate that steric factors play an important role in the formation and structure of these mixed chelates. The effects of various organic solvents on the electronic spectra of these chelates were also studied. (tmen=*N,N,N′,N′*-tetramethylethylenediamine, en=ethylenediamine, gly=glycinate ion, ox=oxalate ion, aca=acetylacetonate ion.)

Copper(II) chelates with *N,N,N′,N′*-tetramethylethylenediamine (tmen) were investigated by several workers. Meek and Ehrhardt[1] showed that copper(II) ion readily combines with tmen to form a dimeric chelate cation, [tmen $Cu(OH)_2$ Cu tmen]$^{2+}$, while the monomeric bis-chelate cation, $[Cu\ tmen_2]^{2+}$ could not be prepared in spite of all their efforts. These results indicate that, when two molecules of tmen approach the central copper(II) ion, the bulky methyl groups on their donor *N* atoms collide strongly with each other, and the interligand steric hindrance is so large that the formation of bis-chelate becomes practically impossible.[2] On the other hand, Bertini and Mani[3] studied the metal complexes of tmen and related ligands, and showed that various monomeric copper(II) chelates containing one molecule of tmen and simple anionic ligands (Cu tmen X_2) can be prepared.

Recently we studied the formation of mixed copper(II) chelates with tmen and another chelating ligand. The ligands used are common ones (en, gly, ox, and aca) with no bulky groups around the donor atoms, and little steric hindrance is expected when one of them combines with copper(II) together with a tmen molecule. In agreement with this expectation, it was found that all these ligands form quite stable mixed chelates with tmen, the preparation and properties of which will be reported in this paper.

4) Elementary analyses were performed at the Organic Microanalytical Section of the Institute of Physical and Chemical Research.

Experimental

Materials. The ligands used were obtained from Wako Pure Chemical Industries Ltd., and Tokyo Kasei Kogyo Co., Ltd. They were reagent grade samples and were used without further purification. Solvents used for spectral measurements were of "extra pure" or "spectro" grade.

Preparation of Mixed Chelates. a) [Cu tmen en]-$(ClO_4)_2$: 10 mmol of copper(II) perchlorate hexahydrate was dissolved in a small amount of water, and equimolar amounts of tmen and en were added with stirring. The resulting solution was concentrated on a water bath. The crude product which separated out was recrystallized from water. Reddish violet crystals (μ=1.84 B.M.).

Found: C, 21.70; H, 5.22; N, 12.69%. Calcd for Cu tmen en $(ClO_4)_2$: C, 21.90; H, 5.51; N, 12.79%.[4]

b) [Cu tmen en]$(NO_3)_2\cdot H_2O$: The method for preparation was the same as in the case of (a) except that copper(II) nitrate trihydrate was used instead of perchlorate. Violet crystals (μ=1.86 B.M).

Found: C, 25.97; H, 6.90; N, 21.37%. Calcd for Cu tmen en $(NO_3)_2\cdot H_2O$: C, 25.16; H, 6.86; N, 22.20%.

c) [Cu tmen en]$(SO_4)\cdot 4H_2O$: 10 mmol of copper(II) sulfate pentahydrate was mixed with equimolar amounts of tmen and en in a small amount of water. A violet paste deposited from the solution. This crude gummy product was purified by suspending it in acetone, and the violet crystalline powder obtained was washed with acetone and ether (μ=2.11 B.M.).

Found: C, 23.24; H, 7.23; N, 13.97%. Calcd for Cu tmen en $SO_4\cdot 4H_2O$: C, 23.55; H, 7.90; N, 13.73%.

d) [Cu tmen gly](ClO_4): 5 mmol of the dimeric chelate, [tmen Cu $(OH)_2$ Cu tmen] $(ClO_4)_2$, prepared according to literature[1] with some modifications and identified by elementary analyses, and 10 mmol of glyH were mixed in a mortar, and about 50 m*l* of methanol was added with stirring. The mixture was filtered and concentrated on a water bath. The crude product which separated out was recrystallized from methanol. Blue-violet crystals (μ= 1.94 B.M.).

Found: C, 27.25; H, 5.79; N, 11.70%. Calcd for Cu tmen gly (ClO_4): C, 27.20; H, 5.70; N, 11.89%.

e) [Cu tmen ox]$\cdot 4H_2O$: The method of preparation was the same as in the case of (a), except that aqueous solutions of copper(II) sulfate pentahydrate, tmen, and potassium oxalate were used as starting materials. Pale blue crystals (μ=2.19 B.M.).

Found: C, 28.54; H, 7.12; N, 8.32%. Calcd for Cu tmen ox$\cdot 4H_2O$: C, 28.26; H, 7.12; N, 8.25%.

f) [Cu tmen aca](ClO_4): 10 mmol of copper(II) perchlorate hexahydrate dissolved in aqueous ethanol (1 : 1) and solutions of tmen and acaH (10 mmol each) in the same solvent were mixed together, and 5 mmol of anhydrous sodium carbonate was added to neutralize acaH. The mixed solution was concentrated on a water bath, and the crude product separated out was recrystallized from ethanol. Reddish violet crystals (μ=1.92 B.M.).

Found: C, 34.81; H, 6.00; N, 7.12%. Calcd for Cu tmenaca(ClO_4): C, 34.92; H, 6.13; N, 7.40%.

Physical Measurements. The electronic absorption spectra of the solutions between 1000 nm (10.0 kK) and 340 nm (29.4 kK) were recorded with a Shimadzu multi-convertible D-40R spectrophotometer and 10 mm silica cells. The reflection spectra of solid samples were obtained with the same spectrophotometer with the reflection attachment and a MgO disks for reference. The magnetic susceptibility measurements were performed by the Gouy method with conventional technique. The IR spectra between 4000 cm^{-1} and 400 cm^{-1} were recorded with a JASCO IR-G spectrophotometer by means of Nujol-mull method.

Results and Discussion

All the mixed chelates obtained are fine crystals or apparently crystalline powders, with compositions shown in the experimental section. All of them have normal magnetic moments (1.84—2.19 B.M.), showing that there is no Cu–Cu interaction in them.

The reflection spectra of these crystals and the absorption spectra of their solutions in various solvents were studied in some detail. Figure 1 illustrates the reflection spectra of four mixed chelates which contain tmen and en, gly, ox, and aca. Figure 2 shows those of three $[Cu\ tmen\ en]^{2+}$ chelates, *i.e.*, perchlorate, nitrate, and sulfate.

We see from Fig. 1 that among the mixed chelates the value of ν_{max} increases in the order en>aca>gly> ox. While the order en>gly>ox is that of the ordinary spectrochemical series, it is noteworthy that the value of the mixed acetylacetonate is remarkably larger than that of the mixed glycinate[5] (in aqueous solution, however, these values are nearly the same; *cf.* Fig. 6).

From Fig. 2, it can be seen that the band maximum

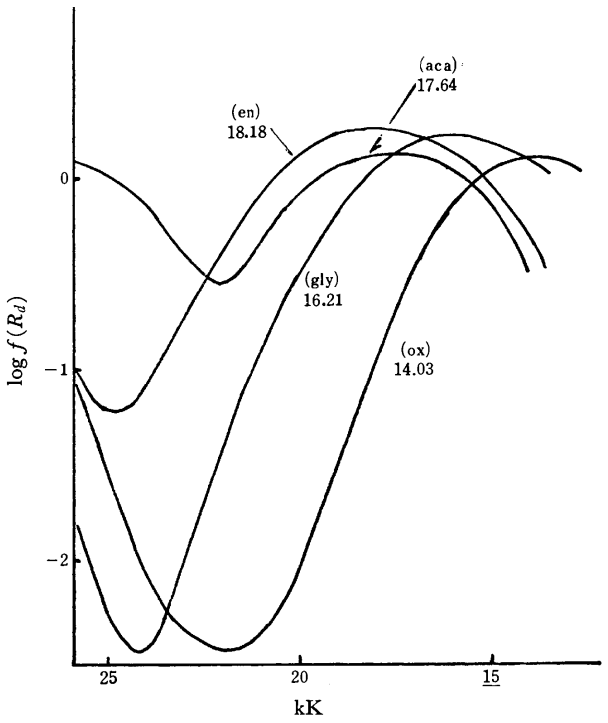

Fig. 1. Reflection spectra of the mixed chelates. Curves denoted by (en), (gly), (aca), and (ox) are those for [Cu tmen en]$(ClO_4)_2$, [Cu tmen gly](ClO_4), [Cu tmen aca](ClO_4) and [Cu tmen ox]$\cdot 4H_2O$, respectively. ν_{max} values are also given.

5) A somewhat similar situation was already pointed out in the spectra of [Cu aca_2] and [Cu gly_2]. Y. Fukuda and K. Sone, This Bulletin, **43**, 556 (1970).

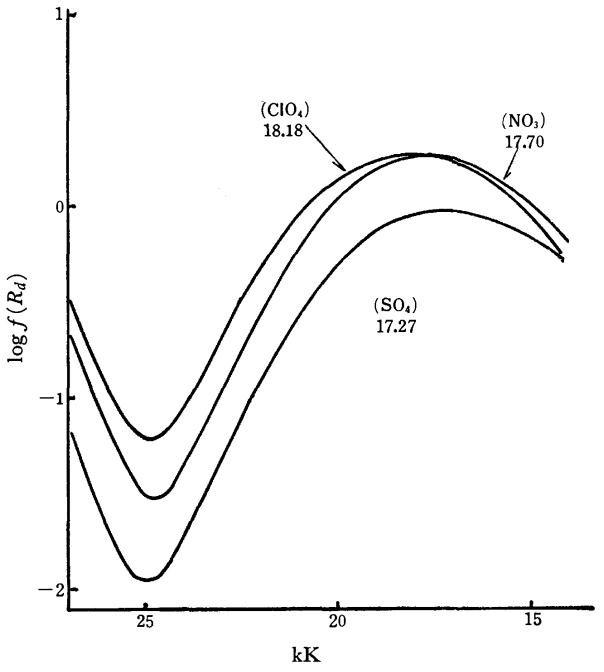

Fig. 2. Reflection spectra of the mixed chelates. Curves denoted by (ClO_4), (NO_3), and (SO_4) are those for [Cu tmen en]$(ClO_4)_2$, [Cu tmen en]$(NO_3)_2 \cdot H_2O$ and [Cu tmen en]$(SO_4) \cdot 4H_2O$, respectively. ν_{max} values are also given.

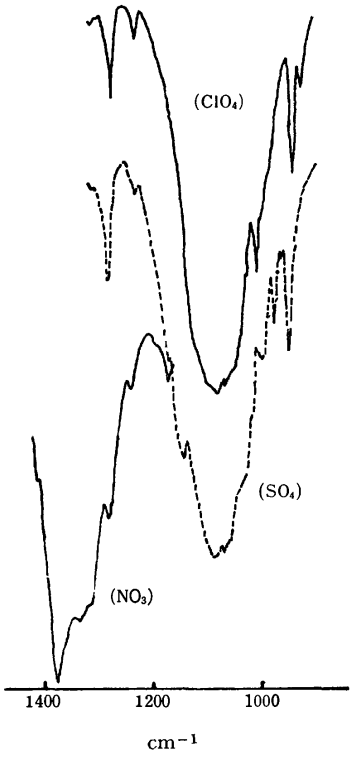

Fig. 3. Anion absorption bands in the infrared spectra of the three chelates shown in Fig. 2. The sharp band at 1375 cm^{-1}, which appears near the top of the NO_3^- band, is due to Nujol.

of [Cu tmen en]X_2 gradually moves to the red in the following order of X: $ClO_4^- \rightarrow NO_3^- \rightarrow SO_4^{2-}$. At first sight this seems to indicate that these anions interact to some extent with the complex cation in the crystals, and that the stronger the interaction (or, in other words, the anion's coordination ability), the lower the ν_{max} value of the mixed chelate. However, the IR spectra of these chelates illustrated in Fig. 3 clearly indicate that the bands of the anions are not remarkably split, *i.e.*, the interaction between the anion and the metal ion in these chelates is quite weak; this result seems reasonable because the mixed chelates contain a very bulky ligand (tmen), which will make the attachment of the oxo-acid anions above and below the planar chelate cation difficult. Therefore, it is more probable that the lowering of the ν_{max} value described above is due to the effect of the water of crystallization in the nitrate and sulfate, the molecules of which probably can coordinate more readily to the chelate cation than the oxo-acid anions.

Figure 4 illustrates the absorption spectra of [Cu tmen aca](ClO_4) in various solvents. This mixed chelate is especially soluble in many organic solvents, and the color of the solution obtained strongly depends on the solvent, varying from reddish violet (in 1,2-dichloroethane) to blue (in dimethylformamide). Figure 5 shows the relation between the ν_{max} value of this chelate in a solution and the donor number (DN) of the solvent; the latter, which was originally proposed by Gutmann,[6] is a measure of the donor strength (coordination or solvation ability) of the sol-

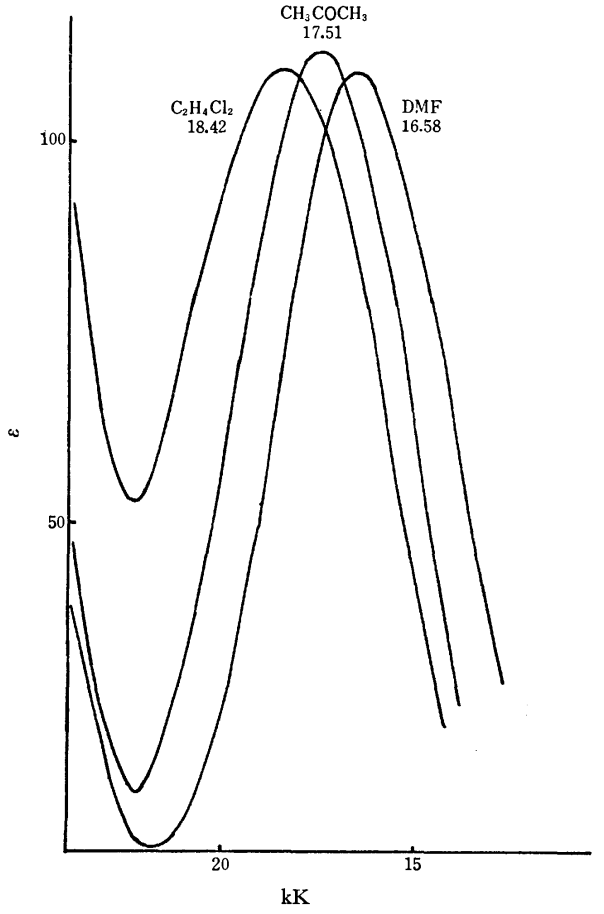

Fig. 4. Absorption spectra of [Cu tmen aca](ClO_4) in 1,2-dichloroethane, acetone, and *N*,*N*-dimethylformamide (DMF). ν_{max} values are also given.

6) V. Gutmann, "Coordination Chemistry in Non-Aqueous Solutions," Springer-Verlag, Wien & New York (1967).

vent. It can be seen that there is an approximately linear relation between ν_{max} and DN, and, the larger the coordinating ability of the solvent, the smaller the corresponding ν_{max} value, the order of change being $CH_3NO_2 > C_2H_4Cl_2 > CH_3COCH_3 \gtrsim C_6H_5CN > CH_3CN > THF > MeOH \gtrsim H_2O > DMF > DMSO$. This solvent effect can be explained in the same manner as in the case of the data in Fig. 2, *i.e.*, by assuming the coordination of the solvent molecules above and below the chelate cation which is in solution. The strength of this coordination will increase with the increase of DN, making the ligand field more and more octahedral, and shifting the absorption band to the lower frequencies.[7]

The spectra of other mixed chelates obtained also show a similar solvent effect; but they are not soluble in many organic solvents, and in certain cases, apparent decomposition takes place. In Table 1 are shown the band maxima of these chelates in some solvents. The reason why the ν_{max} values in DMF of the en, gly, and ox chelates are generally higher than those in H_2O is not clear as yet.

TABLE 1. ν_{max}(kK) AND ε_{max} VALUE (THE LATTER IN PARENTHESES) OF THE MIXED CHELATES IN VARIOUS SOLVENTS

Mixed chelate	CH_3OH	H_2O	DMF
[Cu tmen en]$(ClO_4)_2$	18.25(95)	17.64(85)	17.70(97)
[Cu tmen gly](ClO_4)	17.33(97)	16.95(98)	17.12(102)
[Cn tmen ox]$\cdot 4H_2O$	16.53(127)	16.21(126)	16.72(119)

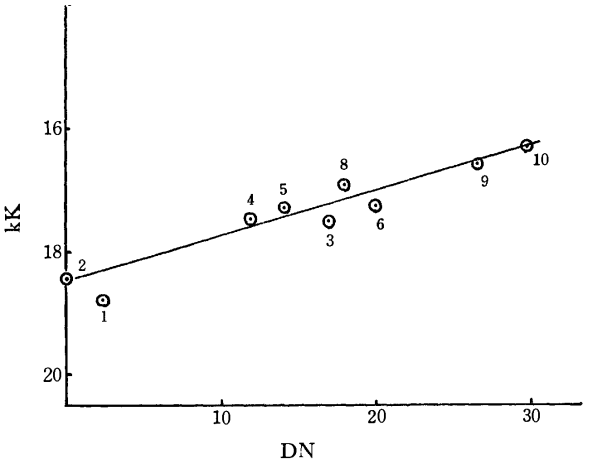

Fig. 5. The relation between ν_{max} and DN in the solutions of [Cu tmen aca](ClO_4) in various solvents. The circles 1 to 10 refer to: 1, CH_3NO_2 (18.80, 2.7); 2, CH_2ClCH_2Cl (18.42, —); 3, CH_3COCH_3(17.51, 17.0); 4, C_6H_5CN(17.48, 11.9); 5, CH_3CN(17.30, 14.1); 6, THF (17.27, 20.0); 7, (not shown) CH_3OH(16.98, —); 8, H_2O(16.92, 18.0); 9, DMF(16.58, 26.6); 10, DMSO(16.31, 29.8). (The numbers in parentheses are those of ν_{max} and DN in each solvent).

Spectral Comparison of the Mixed and Parent Chelates. Recently the nature of the mixed chelates has attracted the interest of many workers[8] and a large number of studies have been published. Among them, Sone and co-workers[9] studied mixed copper(II) chelates containing 2,2′-bipyridine (or 1,10-phenanthroline) and another bidentate ligand(A-A)(=en, gly, ox, or aca), and concluded that the strong interligand steric hindrance in $[Cu\ bip_2]^{2+}$ plays an important role in the following equilibrium:

$$[Cu\ bip_2]^{2+} + [Cu(A\text{-}A)_2]^{m+} \rightleftarrows 2[Cu\ bip(A\text{-}A)]^{n+} \quad (1)$$

In other words, an equilibrium of this type is forced strongly to the right hand side by the fact that the repulsion between two bulky ligands in $[Cu\ bip_2]^{2+}$ disappears in the course of mixed chelate formation.

From the results of the present study, it is easy to see that, in an equimolar mixture of Cu^{2+}, tmen and (A-A), an extreme case of type (1) equilibrium takes place, where one of the components on the left hand side of the equation (*i.e.* $[Cu\ tmen_2]^{2+}$) is so unstable sterically that it cannot exist at all.[1] On the other hand, in the mixed chelate formed, model studies show that the ligand(A-A) does not exhibit any remarkable steric hindrance with tmen; therefore, its formation by way of type (1) equilibrium will be very strongly favored. The facts that the mixed tmen chelates can be obtained easily from such solutions, and they seem to be quite stable in aqueous solutions,[10] are in conformity with this view.

The importance of steric factors in the formation and structure of these mixed chelates is also reflected in Fig. 6, where the positions of the maxima of the mixed and parent chelates in aqueous solutions are illustrated. It is known that, in many types of mixed copper chelates, Kida's rule[11] holds well, which states that the following relation

$$\nu_{AB} = 1/2(\nu_{A_2} + \nu_{B_2}) \quad (2)$$

exists between ν_{AB} (the ν_{max} value expected for a mixed chelate [Cu AB]) and ν_{A_2} and ν_{B_2} (the ν_{max} values of its parent chelates, $[Cu\ A_2]$ and $[Cu\ B_2]$). To test the applicability of this rule to the present data, however, it is necessary to know the value of ν_{tmen_2}. Although this can not be obtained experimentally, an estimate of its magnitude can be made in the following way.

Table 2 shows the data of Meek, Ehrhardt, Yokoi, and Isobe on the ν_{max} values of the bis-chelates $[Cu\text{-}A_2]^{2+}$ of some *N*-alkylated ethylenediamines.[1,12] It can be seen, in general, that the value decreases with

7) a) Other examples of similar spectral effects caused by solvent molecules are found in C. K. Jørgensen, "Inorganic Complexes," Academic Press, London & New York (1963), p. 106, and also in K. Sone and S. Utsuno, This Bulletin, **39**, 1813 (1966). b) Increase of ion-pairs in relatively nonpolar solvents might also influence the spectra to some extent. However, the effect of solvation would be of primary importance since in most cases solvent molecules will be more easily bound by the metal ion than ClO_4^-, which is a very poor donor and also very bulky (*cf.* the preceding text).

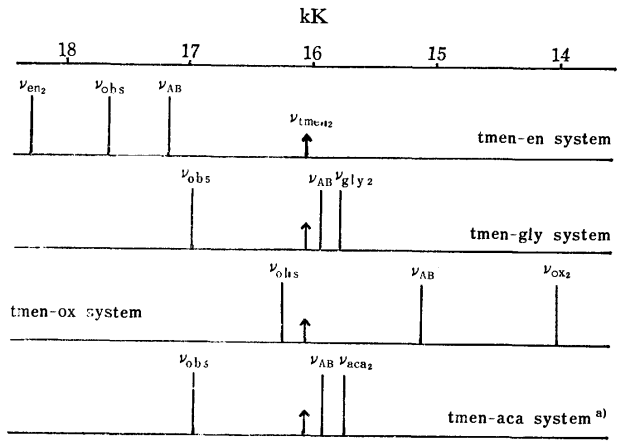

Fig. 6. ν_{max} values of the mixed chelates and the parent bis-chelates in aqueous solutions. The observed values for the mixed chelates and those calculated from Kida's rule are denoted by ν_{obs} and ν_{AB}, respectively, and the imaginary ν_{tmen_2} value (see text) is shown by a short arrow in each system.

(a) Since [Cu aca_2] is insoluble in H_2O, its ν_{max} given in this figure is that of DMF solution, so that only approximate comparison can be made. However, the shift of ν_{obs} from ν_{AB} described in the text is still very evident.

TABLE 2. ν_{max} VALUES (kK) OF THE COPPER(II) CHELATES OF EN AND ITS *N*-ALKYLATED DERIVATIVES (DIFFERENCES NEIGHBORING VALUES ARE SHOWN IN ITALIC; IMAGINARY BETWEEN VALUES ARE SHOWN IN PARENTHESES)

Complex	Solid[1]			Aqueous solution[12] a)
I. [Cu en_2]$(ClO_4)_2$	19.05	→	*0.77*	→ 18.28
	↓ *0.53*			
II. [Cu (*N*,*N'*-Me_2en)$_2$]-$(ClO_4)_2$	18.52	→	*0.85*	→ 17.67
	↓ *0.82*			
III. [Cu (*N*,*N*,*N'*-Me_3en)$_2$]-$(ClO_4)_2$	17.70			
	↓ *(0.82)*			
IV. [Cu $tmen_2$]$(ClO_4)_2$	(16.88)[b]	→	*(0.85)*	→ (16.03)[b]

a) The original data of Yokoi and Isobe refer to solutions in CH_3OH-H_2O (1:1), but it was found that the values in H_2O are nearly the same.

b) Extrapolations leading to these values are based on the assumption that (i) there is a decrease of *ca.* 0.82 kK in going from III to IV, just as in going from II to III, and (ii) there is a shift of *ca.* 0.85 kK in going from solid to solution spectrum of IV. Naturally these assumptions are not entirely reliable, and it is possible that the true values are considerably lower, since the introduction of a fourth CH_3 group in the ligand (*N*,*N*,*N'*-Me_3en) to form tmen will increase the interligand repulsion much more than that of the third in *N*,*N'*-Me_2en. However, even a considerable variation of these values (and those of ν_{AB} derived from them) will not alter the general picture described in the text.

TABLE 3. ν_{max} (kK) VALUES OF EN AND TMEN MIXED CHELATES IN AQUEOUS SOLUTIONS

[Cu en gly]$^+$ [8]	16.95	[Cu tmen gly]$^+$	16.95
[Cu en ox][10]	16.18	[Cu tmen ox]	16.21
[Cu en aca]$^+$ [10]	17.01[a]	[Cu tmen aca]$^+$	16.92

a) 75% dioxane solution.

increasing *N*-methyl groups, indicating the loosening of the coordinate bonds caused by interligand steric repulsion, and there is also a shift of *ca.* 0.8 kK in going from solid to aqueous solution. Extrapolation of these values to the case of aqueous solution of the imaginary bis-chelate [Cu $tmen_2$]$^{2+}$ gives an approximate value of 16.0 kK for its ν_{max}. Substituting this value and the values of ν_{en_2}, ν_{gly_2}, and ν_{ox_2} taken from literature into Eq. (2), the values of ν_{AB} shown in Fig. 6 can be obtained. It can be seen readily that, in all the cases studied, Kida's rule does not hold and ν_{obs} of a mixed chelate is remarkably larger than its ν_{AB}. It is only in the case of [Cu tmen en]$^{2+}$ that ν_{obs} lies between ν_{tmen_2} and ν_{en_2}; in all other cases, ν_{obs} is much larger than both ν_{tmen_2} and $\nu_{(AA)_2}$, and the difference between ν_{obs} and ν_{AB} increases in the order:

$$\text{en} < \text{gly} \simeq \text{aca} < \text{ox} \qquad (3)$$

The reason for these results can be explained in terms of the following two factors. (1) The steric effect is very plausible. Although there will be no remarkable interligand repulsion in any of the mixed chelates studied, it is quite possible that a slight repulsion exists in the case of [Cu tmen en]$^{2+}$, since the four protruding H atoms of the amino groups of en will contact the four methyl groups of tmen to some extent. This repulsion will weaken the coordinate bonds; therefore, the ν_{max} of this chelate will be shifted to the red in comparison with ν_{en_2}, and will be approximately the same as that of [Cu(*N*,*N'*-Me_2en)$_2$]$^{2+}$ in which a repulsion of similar magnitude is expected. On the other hand, this kind of repulsion is probably much smaller in [Cu tmen gly]$^+$, since gly has only one amino group, and is practically absent in [Cu tmen ox] and [Cu tmen aca]$^+$, so that their spectra will generally resemble those of the corresponding en chelates. All these expectations agree quite well with the observed results, as can be seen from the data in Table 2 and Table 3.

(2) The charge of the mixed chela temust also be taken into account. As already pointed out by other investigators,[13] the coordination of a doubly negative ox anion to [Cu tmen]$^{2+}$ will be energetically more favorable than that of a neutral en. Furthermore, the entropy change due to the reduced solvation will also favor the formation of neutral [Cu tmen ox] from the components, in preference to the singly charged gly or aca mixed species and still higher charged [Cu tmen en]$^{2+}$. It is therefore possible that these electrostatic effects also contribute to some extent to the spectral changes described above.

The authors wish to thank Mr. Naoe Tani and Miss Akiko Sakai for their help in carrying out the experiments, Dr. Shunji Utsuno and Mr. Toshio Suzuki whose pioneering work led them to the present study, and also Professor Sigeo Kida of Kyushu University for his stimulating interest in this problem. The work was performed in part by a grant for fundamental research from the Ministry of Education.

Complexes Coordinated by 2,2′-Bipyridine Negative Ion. II. Sodium 2,2′-Bipyridinetetracarbonylchromium, -molybdenum, and -wolfram

Youkoh KAIZU and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 8, 1971)

Bipyridinetetracarbonylchromium, -molybdenum and -wolfram and their related complexes were reduced with sodium metal in tetrahydrofuran. Some products in the first stage of reduction were isolated. On the basis of the electronic absorption spectrum and the electron spin resonance, the complex formed in the reduction was concluded to be a complex coordinated by mononegative ion of bipyridine. Metal $d\sigma$ orbital in the complex is still higher than bipyridine π^* orbital, even if it is fairly lowered by a positive charge arising from the "metal to carbonyl" back-donation. Trapped electrons in the bipyridine π^* orbital are, however, readily transferred into $d\sigma$ orbital depending upon molecular environment. This gives rise to the formation of a pentacoordinate complex or complex dimer evolving carbon monoxide.

Coordinating bipyridine captures electrons when a bipyridine complex of less electron-acceptable metal is reduced by strong reducing reagents such as sodium metal. Bipyridine, with its strong σ-donating and π-accepting powers, gives a strong ligand-field to the central metal and a sufficient energy gap between $d\sigma$ and $d\pi$ orbitals. When a tris-bipyridine complex of metal with vacancies in $d\pi$ shell is reduced, electrons furnished by the reducing reagent are captured by the central metal ion. However, a tris-bipyridine complex of metal with no vacancy in $d\pi$ shell should capture electrons either in metal $d\sigma$ orbitals or in the vacant antibonding π molecular orbitals of the coordinating bipyridine. In the higher oxidation states, transition metal ions with $d\sigma$ electrons can exist in various stable coordination complexes.[1] In the lower oxidation states, however, electrons trapped in $d\sigma$ orbitals give rise to a dissociation of the coordinating ligand. Unless some electrostatic attraction between metal and ligand is present as in the higher oxidation states, $d\sigma$ electrons in the antibonding orbital of coordination binding destabilize the coordination binding. Although it shows a trend to form $[Co(bipy)_2]^+$, $[Co(bipy)_3]^+$ can trap two electrons in the metal $d\sigma$ orbitals (bipyridine is abbreviated to bipy).[2] On the contrary, however, $[Mn(bipy)_3]$ and $[Fe(bipy)_3]$ showed an evidence of coordinating bipyridine negative ion.[3] When a vacant antibonding π molecular orbital of the coordinating bipyridine is sufficiently lower than $d\sigma$ orbital of the central metal, electrons furnished upon reduction should be trapped by the coordinating bipyridines.

Porphyrin and phthalocyanine are as highly σ-donating and π-accepting as bipyridine and trap electrons in the conjugated system when the metal complexes are reduced.[4] Such coordinating negative ions have been obtained only for the conjugated nitrogen bases.

In the case of metal carbonyls, sufficient migration of $d\pi$ electron into the antibonding π molecular orbital of coordinating carbon monoxides makes the central metal more positive and therefore more σ-acceptable. Even so, reduction of the metal carbonyls with closed $d\pi$ shell gives rise to a reduction of coordination number or a formation of dimer with metal-metal bond or with carbonyl bridgings. As a matter of fact, a metal carbonyl with d^8 exists in a pentacoordinate structure as in $[Mn(CO)_5]^-$ or $[Cr(CO)_5]^{2-}$,[5] while the one with d^7, in a dimer structure as in $[Mn_2(CO)_{10}]$ or $[Cr_2(CO)_{10}]^{2-}$.[6] Central metal atom in a stable compound has an electronic configuration of the rare gases. It is required by Sidgwick's rule that no open shell exists in a stable structure. However, some monomeric metal carbonyls with open shell have in recent years been successfully prepared. An open shell metal carbonyl $[V(CO)_6]$ was prepared by oxidation of a closed shell metal carbonyl $[V(CO)_6]^-$.[7] In this case, however, a hole exists in a $d\pi$ orbital. Recently we succeeded in the isolation of the first stage reduction product of $[Cr(CO)_4(bipy)]$.[8] If an electron was trapped by the central metal, evolution of carbon monoxide should be expected. In fact, the evolution of carbon monoxide was observed during the second or further stage. As is seen in the formation of $[Cr_2(CO)_{10}]^{2-}$, an electron-capture at the central metal results in a dimer formation. However, in the first stage of reduction, a monomeric open shell species $[Cr(CO)_4(bipy)]^-$ was formed. Thus an electron given by sodium metal was predominantly localized on the coordinating bipyridine. In this paper, we will present a unified study on chromium-, molybdenum-, and wolfram carbonyls with coordinating negative ion of 2,2′-bipyridine.

Experimental

Materials. 2,2'-bipyridine (bipy) and its 4,4'-dimethyl- (4dmbip) and 5,5'-dimethyl- (5dmbip) derivatives were prepared by the method of Sasse and Whittle.[9] Hexacarbonylmolybdenum [$Mo(CO)_6$] and hexacarbonylwolfram [$W(CO)_6$] were of reagent grade (Pressure Chem. Co., Penn., U. S. A.) and were used without further purification. All other reagents and solvents were commercially available. Tetrahydrofuran (THF) used for solvent was dehydrated by KOH, refluxed on CuCl, carefully distilled under nitrogen atmosphere and a trace of water was removed by $LiAlH_4$.

Preparation of Compounds. [$Mo(CO)_4$bipy] was prepared by the method of Stiddard.[10] Dimethyl substituted bipyridine complexes also were prepared by the same method. [$Mo(CO)_4$bipy]: Hexacarbonylmolybdenum (1.4 g) and bipyridine (0.8 g) were refluxed in toluene (50 m*l*) for 1.5 hr under oxygen-free, dry nitrogen atmosphere. After cooling, reddish orange needle crystals were collected, washed with petroleum ether (60 m*l*) and dried *in vacuo*.

[$Mo(CO)_4$bipy] (reddish orange) Found: Mo, 26.8%. Calcd for [$Mo(CO)_4$bipy]: Mo, 26.3%.

[$Mo(CO)_4$4dmbip] (reddish orange) Found: Mo, 24.9%. Calcd for [$Mo(CO)_4$4dmbip]: Mo, 24.5%.

[$Mo(CO)_4$5dmbip] (yellow) Found: Mo, 24.5%. Calcd for [$Mo(CO)_4$5dmbip]: Mo, 24.5%.

Preparation of [$Mo(CO)_3P(C_6H_5)_3$bipy]. [$Mo(CO)_4$bipy] (0.182 g) and [$P(C_6H_5)_3$] ([$P(C_6H_5)_3$] is abbreviated to $P\phi_3$) (0.184 g) were refluxed in benzene for 5 hr. After cooling, violet needle crystals precipitated were collected by filtration, washed with petroleum ether and dried *in vacuo*.

[$Mo(CO)_3P\phi_3$bipy] (violet needle) Found: Mo, 16.0%. Calcd for [$Mo(CO)_3P\phi_3$bipy]: Mo, 16.0%.

[$Mo(CO)_3P\phi_3$4dmbip] (red purple) Found: Mo, 15.7%. Calcd for [$Mo(CO)_3P\phi_3$4dmbip]: Mo, 15.3%.

[$Mo(CO_3)P\phi_3$5dmbip] (red purple) Found: Mo, 15.0%. Calcd for [$Mo(CO)_3P\phi_3$5dmbip]: Mo, 15.3%.

[$W(CO)_4$bipy] was prepared in xylene instead of toluene by the same method as for molybdenum complexes.[10]

[$W(CO)_4$bipy] (red purple) Found: W, 40.7%. Calcd for [$W(CO)_4$bipy]: W, 40.7%.

Preparation of [$Cr(CO)_4$bipy], [$Cr(CO)_4$4dmbip] and [$Cr(CO)_4$5dmbip] were given elsewhere.[8]

Reduction of [$M(CO)_4L$]. Na[$Mo(CO)_4$L], where L denotes bipy, 4dmbip, or 5dmbip, were prepared by reduction with sodium metal in an apparatus (Fig. 1) in a high vacuum by a similar method as for the preparation of Na[$Cr(CO)_4$L].[8,11]

Na[$Mo(CO)_4$bipy] Found: Mo, 25.5%. Calcd for Na[$Mo(CO)_4$bipy]: Mo, 24.8%.

Na[$Mo(CO)_4$4dmbip] Found: Mo, 22.9%. Calcd for Na[$Mo(CO)_4$4dmbip]: Mo, 23.1%.

Na[$Mo(CO)_4$5dmbip] Found: Mo, 22.5%. Calcd for Na[$Mo(CO)_4$5dmbip]: Mo, 23.1%.

Electronic Absorption Spectra. Absorption spectra were taken on a Shimadzu automatic recording spectrophotometer Model MPS-50. Measurements of the spectra of air-sensitive compounds were described in a previous paper.[11]

Electron Spin Resonance. ESR spectra in THF solution were measured at room temperature using a Japan Electron Optics Laboratory spectrometer Model JES-3BSX. The g-value was determined with the aid of the standard sample of Mn^{2+} ion.

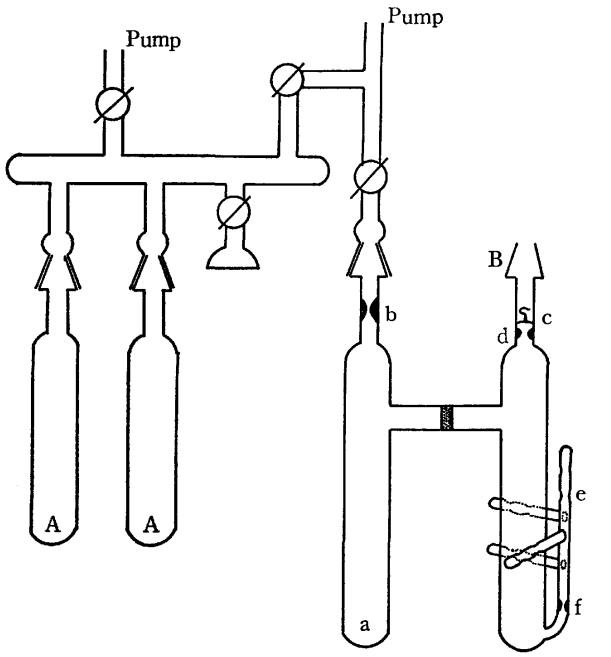

Fig. 1. Apparatus for reduction.
After [$M(CO)_4L$] was placed at a with a slight excess of sodium metal, the apparatus was evacauted up to 10^{-3} mmHg. Dried THF at A, after being thoroughly degassed, was transferred to a by distillation, a being cooled with liquid nitrogen. After being sealed off at b, the THF solution was shaken for about 10 hr and then filtrated. The apparatus was joined with a vacuum line at B. The solvent of the filtrate was then removed by distillation into the vacuum system and the residue was dried *in vacuo*. After being sealed off at d, the product was collected in e and then a branch of sample tubes was sealed off at f. The sample should be stored *in vacuo* and in a dark place.

Results and Discussion

The spectral change of the reduction process of [$Cr(CO)_4$bipy] with sodium metal is shown in Fig. 2. During the first stage of reduction, the spectrum gently changed with the isosbestic points from that of the starting material [$Cr(CO)_4$bipy] to the one shown as (a) in Fig. 2. After that, the curve changed to the spectrum (b), the isosbestic points being shifted. This indicates that the reduction proceeds stepwise. Two steps, at least, are involved in the process. In a previous paper we reported on the isolation of the first stage reduction product of [$Cr(CO)_4$bipy].[8] The spectrum of the isolated Na[$Cr(CO)_4$bipy] is shown in Fig. 3. It coincides with the spectrum (a).

A similar stepwise spectral change was observed in the reduction processes of [$Mo(CO)_4$L], [$W(CO)_4$L], and [$Mo(CO)_3P\phi_3$L] (L: bipy, 4dmbip, 5dmbip) with sodium metal. As a matter of fact, the first reduction product Na[$Mo(CO)_4$L] (L: bipy, 4dmbip, 5dmbip) could be isolated. Absorption spectra of Na[$Mo(CO)_4$L] are shown in Fig. 4. Absorption spectra of the first stage reduction product were obtained for Na[$Mo(CO)_3P\phi_3$L] and Na[$W(CO)_4$L]

(Figs. 5 and 6), although they were not intended to isolate.

Three intense characteristic absorption bands were observed from near-infrared to ultraviolet region. These bands are slightly shifted with a variety of central metals. The second band at about 20,000 cm^{-1} is blue-shifted in the order Cr<Mo≦W. Dimethyl substitutions in the coordinating bipyridine give rise to a blue-shift in the first band in the order 5dmbip< bipy≦4dmbip and a blue-shift in the second band in the order 5dmbip≦4dmbip<bipy, regardless of the central metal species.

upper: Na[Cr(CO)$_4$bipy], lower: K bipy

(CO)$_4$bipy] are shown in Figs. 7—10. ESR spectra of bipyridine negative ions, K bipy, K 4dmbip, K 5dmbip and also Na 4dmbip are shown in Fig. 7 and Figs. 11—13. Observed g-value and line widths are summarized in Table 1. ESR spectrum of Na[Cr(CO)$_4$bipy] is similar to that of K bipy. In the case of K bipy, the binding between K^+ and $bipy^-$ is essentially ionic and the trapped electron in $bipy^-$ has a very poor population on K^+. The ESR spectrum of K bipy does not show a hyperfine structure due to

Table 1. g-value and line width

	g-value	line width
Na[Cr(CO)$_4$bipy]	2.0023	14.5G
Na[Cr(CO)$_4$4dmbip]	2.0019	17.1G
Na[Cr(CO)$_4$5dmbip]	2.0004	15.6G
Na[Mo(CO)$_4$bipy]	2.0021	12.7G
Na[W(CO)$_4$bipy]	2.0031	12.6G
K bipy	2.0026	12.0G
K 4dmbip	2.0024	11.6G
K 5dmbip	2.0025	14.0G

the nuclear spin of potassium ion. The ESR spectrum of Na bipy, however, clearly shows a hyperfine structure due to the nuclear spin of sodium ion (Fig. 13). This phenomenon has been generally observed in

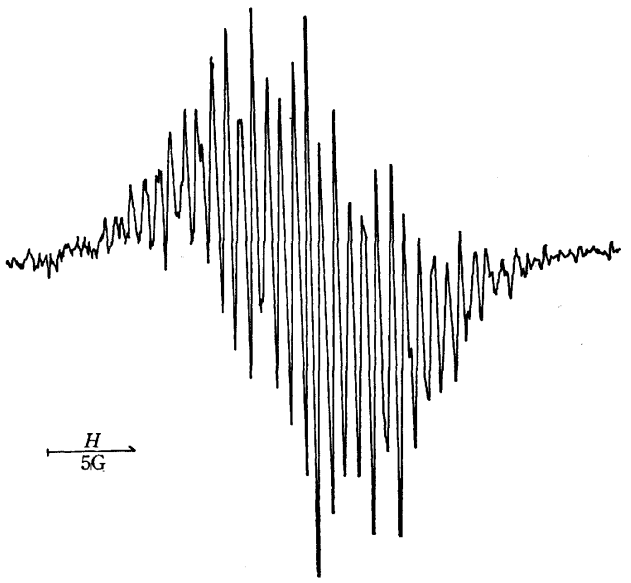

Fig. 11. ESR spectrum of K 4dmbip in THF at room temperature.

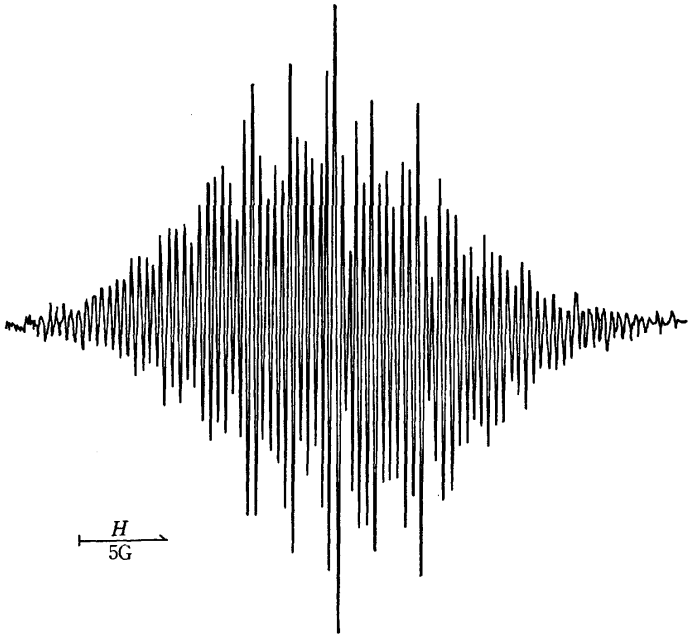

Fig. 12. ESR spectum of K 5dmbip in THF at room temperature.

various aromatic negative ions.[12] Thus ESR spectra of the negative ions obtained by reduction with potassium metal are regarded as those of the respective free negative ions. Na[Cr(CO)$_4$bipy] does not show any hyperfine structure due to either sodium or chromium. An unpaired electron in an antibonding π orbital of bipyridine can not strongly interact with the closed $d\pi$ shell of chromium and also does not migrate over the outer sodium ion.

Apparently the ESR of K bipy, K 4dmbips, and K 5dmbip differs a great deal each other (Figs. 7, 11—

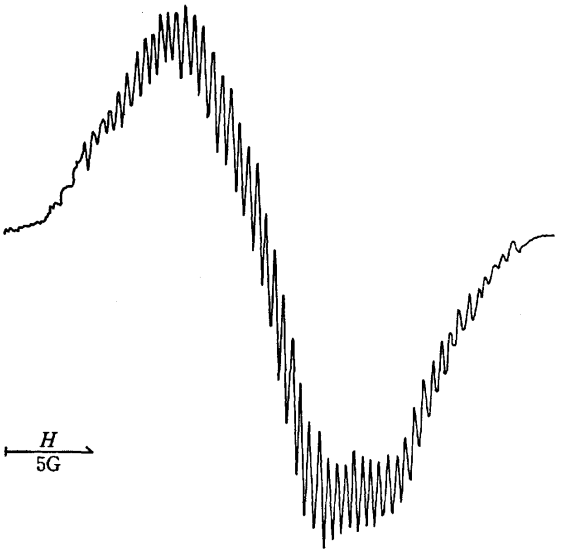

Fig. 13. ESR spectrum of Na 4dmbip in THF at room temperature.

12). Thus many hyperfine structure lines are observed for K 5dmbip, but not so many for K 4dmbip. The hyperfine structure of the ESR of K bipy has been analysed.[13] A similation analysis predicted the highest spin density at 5 and 5′.[14] The highest spin density at the positions 5 and 5′ and lower spin density at 4 and 4′ can give an interpretation of the hyperfine structure due to the dimethyl substitutions. We have never succeeded in similations of the ESR of K 5dmbip and K 4dmbip, however, we can point out that a higher hyperfine constant of six protons of two methyl groups introduced at the positions 5 and 5′ gives a well-resolved hyperfine structure, while the hyperfine constant of 4,4′-dimethyl protons is so small that it just gives an apparent broad line. Actually K 4dmbip gives the simplest ESR spectrum. Another possible interpretation is that the hyperfine structure of K 5dmbip arises from potassium nuclear spin (I=3/2). As shown in Fig. 12, odd number peaks of hyperfine splitting are observed, while even number peaks are expected for I=3/2.

The reduced bipyridine complexes show ESR spectra which actually coincide with those of the corresponding bipyridine negative ions prepared by reduction with potassium metal. Although the magnitude of the hyperfine splitting is, in fact, slightly changed, g-values in the reduced bipyridine complexes actually coincide with that of K bipy (Table 1). In the case of 5,5′-dimethyl bipyridine, however, hyperfine splitting in the reduced bipyridine complex is appreciably changed from that of the negative ion, and g-value of the complex (2.0004) is significantly smaller than the free-spin value, g=2.0023. This indicates that a small interaction between the closed $d\pi$ shell of chromium and the antibonding π orbital of bipyridine changes slightly the electron-trapping molecular orbital and thus spin density at the posi-

tions 5 and 5'. Although the spectra have never been reproduced by similation, the electronic structure of bipyridine in the reduced complex is concluded to be very close to that of bipyridine negative ion.

Three characteristic absorption bands of the reduced complexes correspond to respective three bands of bipyridine negative ions. Although these bands are slightly shifted for a variety of the central metal, spectral behavior of the complexes upon a weak perturbation such as dimethyl substitution corresponds to that of bipyridine negative ions regardless of the central metal. As previously reported, the second band at about 20,000 cm^{-1} of bipyridine negative ion is blue-shifted with increasing electrostatic potential due to the coordinating counter cation.[11] The second band of the complexes reported in this paper is blue-shifted in the order $Cr<Mo\leq W$. However, the fact that three characteristic bands of the complexes are changed in spectral intensity and position for the central metal and do not exactly coincide with the corresponding bands of bipyridine negative ion, indicates a binding effect of bipyridine negative ion and metal species. Although an evidence of the existence of bipyridine negative ion is also obtained from the observed *g*-value which is close to the free-spin value, ESR measurements in this particular case do not give a decisive direct evidence of the binding of bipyridine negative ion and metal species. If the coordinating bipyridine is set free upon reduction, the ESR spectrum should show a signal observed for Na bipy in THF. ESR spectrum does not show any hyperfine structure of sodium when $[Mo(CO)_4bipy]$ is reduced with sodium metal in THF. This might be an evidence of the binding.

When $[Cr(CO)_4bipy]$ is reduced by Na bipy instead of sodium metal, absorption spectrum of the first stage reduction product ((a) in Fig. 2) is obtained. The absorption spectrum is observed with no contamination of that of Na bipy unless excess of Na bipy is added. This indicates that Na bipy is wasted to reduce

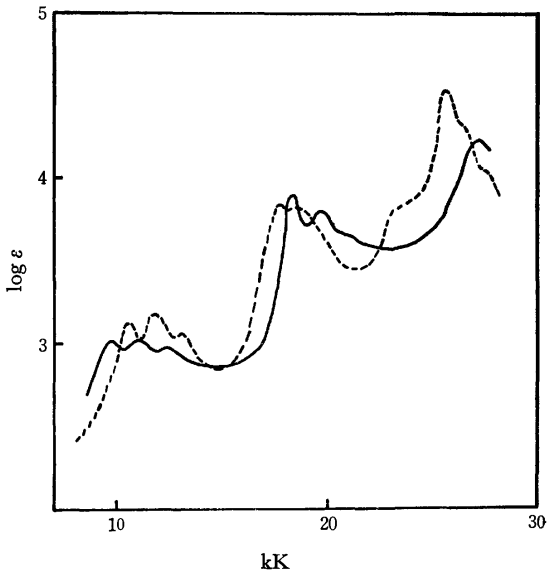

Fig. 14. Electronic absorption spectra of $Na[Cr(CO)_4bipy]$ and Na bipy in THF.

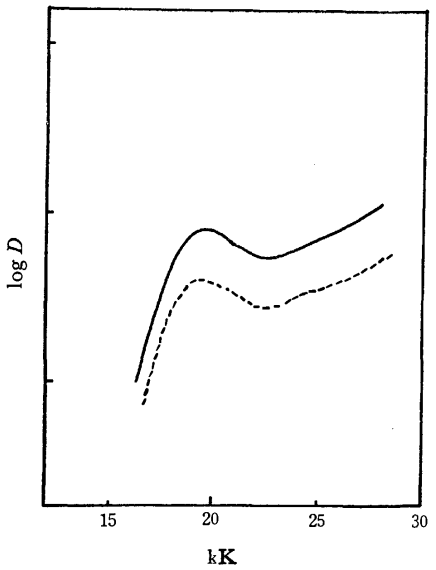

Fig. 15. "Metal to bipyridine" charge-transfer band of a complex formed by oxygen-oxidation of $Na[Cr(CO)_4bipy]$ in THF. ----: $[Cr(CO)_4bipy]$

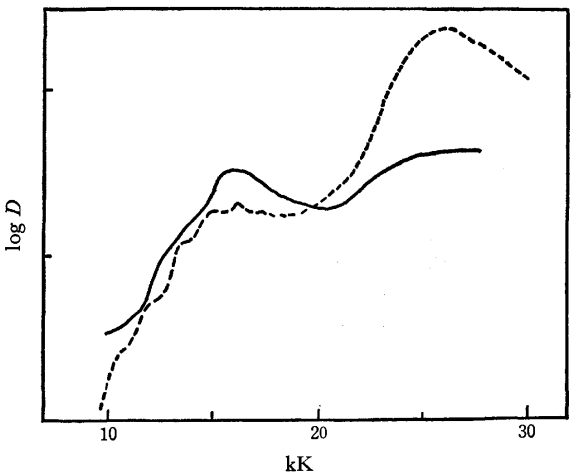

Fig. 16. Electronic absorption spectra of a complex formed in the second stage of reduction (——) and bipyridine dinegative ion, Li_2bipy (----).

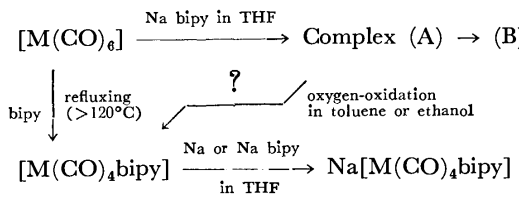
the coordinating bipyridine in $[Cr(CO)_4bipy]$. The spectra of the reduced complex and bipyridine negative ion are similar but the difference can be detected (Fig. 14). When the reduced complex is oxidized by oxygen, it gives rise to a characteristic "metal to bipyridine" charge-transfer band in the visible region. From this, a complex formed upon the oxygen-oxidation should be a complex with certain coordinating bipyridine (Fig. 15). Since free bipyridine produced by oxygen-oxidation of free negative ion could not react with a metal carbonyl at room temperature, bipyridine negative ion should be binding to the central metal in the reduced complexes. The second stage complex (b) in Fig. 2 is obtained by reduction with sodium metal but not with Na bipy, a one-electron reducing reagent. Howɔver, the spectrum of complex (b) is different from that of bipyridine dinegative

ion, Li_2bipy, and therefore a complex formed in the second stage could not be assigned to a complex coordinated by dinegative ion (Fig. 16). The first stage reduction product, complex (a), can be obtained even by one-electron donating Na bipy. Thus it is assigned to a one-electron trapping state.

A complex coordinated by bipyridine negative ion, $Na[M(CO)_4L^-]$, could not be obtained by a direct reaction of $[M(CO)_6]$ and Na bipy. When $[M(CO)_6]$ was added with Na bipy in THF, evolution of carbon monoxide was followed by formation of a pale green complex (A). Complex (A) in the solid state was labile at room temperature even in a vacuum. It did not show any similar spectrum of $Na[M(CO)_4L]$. When the isolated solid sample of (A) was oxidized by washing with oxygen-containing toluene or ethanol under nitrogen atmosphere, it gives a very similar spectrum of $[M(CO)_4bipy]$. However, this may indicate the formation of a metal carbonyl complex with bipyridine other than $[M(CO)_4bipy]$. Since free bipyridine could not react with a metal carbonyl at room temperature, bipyridine is expected to enter into the coordination sphere during the reducing process but not the oxidizing process. During the first stage of reaction of $[M(CO)_6]$ and Na bipy, reduction of $[M(CO)_6]$ by Na bipy forms a reactive intermediate $[M(CO)_5]$ evolving carbon monoxide and then, taking a bipyridine molecule, complex (A), probably a metal carbonyl dimer which includes bipyridine. When electrons are trapped in $d\sigma$ orbital, hexacoordinate metal carbonyl gives rise to a pentacoordinate complex or a dimer complex with metal-metal bond or



carbonyl bridgings. On the other hand, the first stage of reaction of $[M(CO)_4bipy]$ and Na bipy is just electron-transfer reaction from bipyridine negative ion in Na bipy to the coordinating bipyridine in $[M(CO)_4bipy]$. Since the antibonding vacant π molecular orbital of bipyridine is lower than that of the coordinating carbon monoxide and also is lower than $d\sigma$ orbital which is predominantly localized on the central metal atom, an electron given by Na bipy is trapped in the vacant π orbital of the coordinating bipyridine. The lowest charge-transfer transition in $[M(CO)_4bipy]$ is of "metal to bipyridine" type but not of "metal to carbonyl." Recently we succeeded in the observation of luminescence of $[M(CO)_4bipy]$. The luminescence arises from not a $d\sigma$-$d\pi$ transition but a "bipyridine to metal" charge-transfer transition. As far as a sufficient difference of interelectronic terms does not reverse the order, these observations may indicate that the lowest vacant π molecular orbital of the coordinating bipyridine is the lowest vacant.

An electronic configuration of the rare gas is required for the central metal atom in a stable compound of transition metal in the lower oxidation state. No open shell exists in a stable compound. In various systems including organic and organometallic species, this rule is satisfied. Since $d\sigma$ orbital is occupied in the case of d^7 and d^8 systems, the rule requires d^7 system to form a metal-metal bond with or without carbonyl bridgings ($[Mn_2(CO)_{10}]$ and $[Cr_2(CO)_{10}]^{2-}$) and for d^8 system to decrease the coordination number ($[Mn(CO)_5]^-$ and $[Cr(CO)_5]^{2-}$). In the higher oxidation state, however, transition metal ions with open d shell exist in various stable coordination complexes. Tris-bipyridine complexes, even if in the lower oxidation states, can exist in monomeric state with open shell electronic configurations. In the case of $[Co(bipy)_3]^+$, two electrons with parallel spins are trapped in $d\sigma$ orbitals, though migration of $d\pi$ electron into the antibonding π molecular orbital is appreciable.[2] In the case of isoelectronic $[Fe(bipy)_3]$, however, electrons are trapped in the coordinating bipyridine rather than in the $d\sigma$ orbitals.[3] Electrostatic potential due to a positive charge on the central metal should play an important role to cause the difference. The observed maximum of the lowest (π, π^*) transition of coordinating bipyridine is a function of formal charge on the central metal. The bipyridine (π, π^*) transition of $[Cr(CO)_4bipy]$ is observed at 33,400 cm^{-1} which is close to those observed in $[Cr(bipy)_3]^+$ and $[Co(bipy)_3]^+$. Since back-donation of metal $d\pi$ electrons towards the coordinating carbon monoxides is appreciable and thus the central metal becomes more positive, the coordinating bipyridine in $[Cr(CO)_4bipy]$ is polarized as in $[Cr(bipy)_3]^+$ and $[Co(bipy)_3]^+$ (Fig. 17). Although +1 charge of the complex $[Cr(bipy)_3]^+$ or $[Co(bipy)_3]^+$ is delocalized over the whole

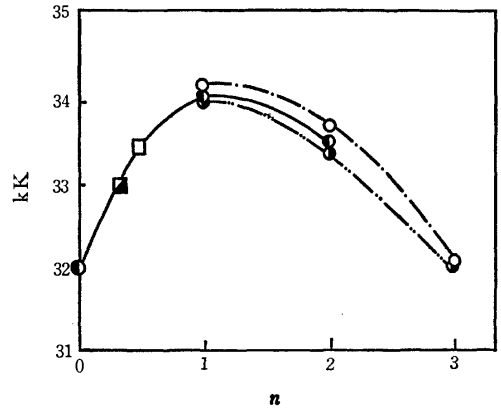


Fig. 17. Energy of the lowest (π, π^*) transition of the coordinating bipyridine *vs.* formal charge of tris-bipyridine complexes, n of $[M(bipy)_3]^{n+}$. The lowest (π, π^*) transition of the coordinating bipyridine in $[M(CO)_4bipy]$ is numerically rather close to those of $[M(bipy)_3]^{2+}$. $P\phi_3$ is a stronger σ donor than CO and therefore a positive charge on Mo of $[Mo(CO)_3P\phi_3bipy]$, for example, should be lower than that of $[Mo(CO)_4bipy]$. The lowest (π, π^*) transition of the coordinating bipyridine is red-shifted for the substitution of CO by $P\phi_3$. This indicates the transition energy of $[M(CO)_4bipy]$ should be plotted in the region from $n=0$ to $n=1$ but not near $n=2$.
-◐-: vanadium compounds, -◑-: chromium compounds
-○-: cobalt compounds, □ : $[M(CO)_4bipy]$
◪ : $[M(CO)_3P\phi_3bipy]$

complex, electron affinity of the metal atom in such an environment is still higher than that of such a neutral complex as $[Cr(CO)_4bipy]$. In the former, metal $d\sigma$ orbital is appreciably lower than bipyridine π^* orbital, while in the latter, metal $d\sigma$ orbital is still higher than bipyridine π^* orbital, even though it is fairly lowered by a positive charge arising from the "metal to carbonyl" back-donation. Actually $[Cr(CO)_4bipy]$ traps an electron in the bipyridine π^* orbital in the first stage of reduction, however, the trapped electron can be readily transfered into the $d\sigma$ orbital. Another electron furnished in the second stage of reduction may occupy $d\sigma$ orbital. When metal $d\sigma$ orbital is occupied, a hexacoordinate complex turns out to be a pentacoordinate complex or a complex dimer evolving carbon monoxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 477—481 (1972)

Studies on New Derivatives of 8-Quinolinol as Chelating Agents. I. Syntheses, Coloration Reaction with Metal Ions and Acid Dissociation Constants of Some Azomethine and Aminomethyl Derivatives

Takehisa HATA and Toyozo UNO

Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received July 28, 1971)

Azomethine derivatives of 8-hydroxyquinoline-2-carbaldehyde with aromatic and aliphatic amines and their aminomethyl derivatives were synthesized for the purpose of investigating their applications as analytical reagents. Spot tests with metal ions revealed that azomethine derivatives form intensely colored chelates, whereas aminomethyl derivatives form less intensely colored chelates. The acid dissociation constants were determined by means of potentiometric titration in 50 v/v% aqueous dioxane solution at 25±0.1°C. The values of pK_{NH^+} and pK_{OH} of 8-hydroxyquinoline-2-carbaldehyde, 2-(*o*-hydroxyphenylaminomethyl)-, 2-(*p*-chlorophenylaminomethyl)-, 2-(*p*-tolylaminomethyl)- and 2-(naphthylaminomethyl)-8-quinolinol are lower than those of 8-quinolinol. The phenyl substituent in 2 position of oxine moiety exerts an acid strengthening effect on these ligands. The basicity of the ligand *N*,*N'*-bis-(8-hydroxy-2-quinolylmethyl) ethylenediamine is higher than that of other oxine derivatives.

A number of derivatives of oxine have been prepared for the purpose of finding analytical reagents. However, the search has been confined to derivatives containing only the same coordinative groups as oxine, and little effort has been made to find multidentate ligands. As the ligands having additional coordinative groups, the azo derivatives,[1] 2-aminomethyl-,[2] and 2-hydroxymethyl-8-quinolinol[2] havebeen studied. In fact, 2-aminomethyl-8-quinolinol was confirmed to act as terdentate ligand with Cu^{2+}, Ni^{2+}, Co^{2+}, and Zn^{2+} ions to produce more stable chelates than oxine.

Expecting the multidentate ligands derived from oxine to have excellent properties as analytical reagents, we attempted to synthesize 8-hydroxyquinoline-2-carbaldehyde, azomethine, and aminomethyl derivatives.

Azomethine derivatives were prepared from 8-hydroxyquinoline-2-carbaldehyde and primary amines. Condensation of the aldehyde with ethylenediamine, *o*-aminophenol, *p*-chloroaniline, *p*-toluidine, and naphthylamine in ethanol proceeded easily with gentle warming to give azomethine derivatives. Aminomethyl derivatives were prepared by the reduction of the azomethine derivatives with sodium borohydride in dioxane or ethanol at room temperature. The reaction scheme is given in Chart 1a and 1b.

We investigated the coloration reaction with metal ions and the acid dissociation constants of these derivatives in comparison with those of oxine in order to obtain information on their applicability as analytical reagents.

Experimental

Preparation. 8-Acetoxyquinoline-2-carbaldehyde: To a suspension of 5.8 g of freshly sublimed selenium dioxide in 400 m*l* of dioxane warmed with stirring on a water bath at 50—55°C, was added a solution of 11.4 g of 2-methyl-8-

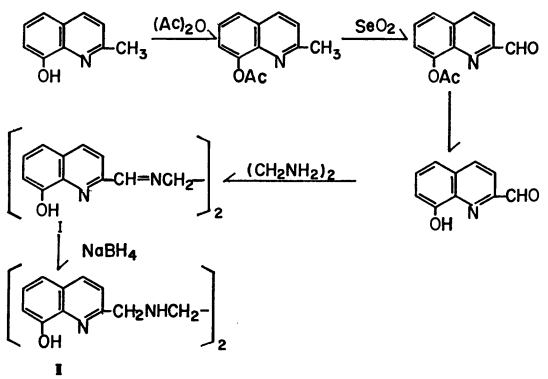

Chart 1a.

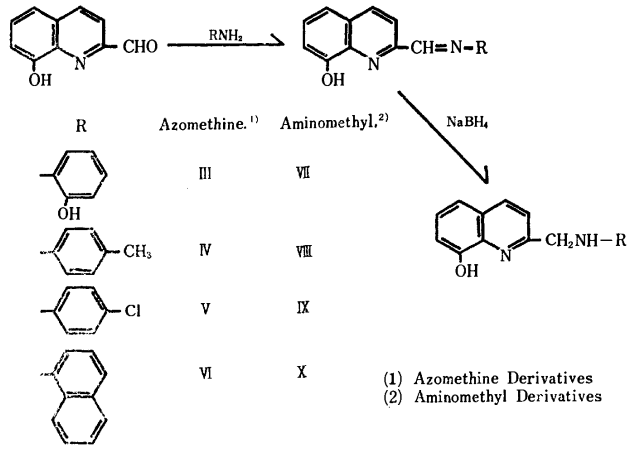

Chart 1b.

acetoxyquinoline in 50 m*l* of dioxane during the course of 3 hours. The mixture was heated to 75—80°C, allowed to stand for 2 hr, filtered, and dioxane was distilled off under reduced pressure. The residue was recrystallized from dioxane to give 9.0 g of light yellow crystals, mp 94—95°C. Found: C, 67.23; H, 4.37; N, 6.71%. Calcd for $C_{12}H_9NO_3$: C, 66.98; H, 4.21; N, 6.51%.

8-Hydroxyquinoline-2-carbaldehyde. A solution of 20 g of 8-acetoxyquinoline-2-carbaldehyde in toluene was cooled to −3°C, and stirred vigorously while 1440 m*l* of aqueous potassium hydroxide was added over 40—50 minutes. The mixture was allowed to stand at room temperature for 30 minutes, and neutralized with 20% aqueous acetic acid. The yellow powder precipitated was recrystallized from cyclohexane to give 13.5 g of yellow crystals, mp 98°C. Found: C, 69.25; H, 3.97; N, 8.26%. Calcd for $C_{10}H_7NO_2$: C, 69.36; H, 4.07; N, 8.08%.

N,N-*Bis(8-hydroxy-2-quinolylmethylene)ethylenediamine (I):* To a solution of 2 g of 8-hydroxyquinoline-2-carbaldehyde in ethanol, was added a solution of 0.35 g of ethylenediamine in ethanol. The mixture was warmed on a water bath for 30 min., cooled in an icebath, and the crystals were filterd. Recrystallization from ethanol gave 1.9 g of white crystals.

N,N′-*Bis(8-hydroxy-2-quinolylmethyl)ethylenediamine (II):* To a suspension of 2.0 g of I in 25 m*l* of ethanol, was added dropwise a solution of 0.8 g of sodium borohydride in ethanol at room temperature. The mixture was kept standing for 1 hr., filtered, and ethanol was removed under reduced pressure. Yellow powder obtained was dissolved in 30% aqueous acetic acid, neutralized with aqueous sodium carbonate. An oily substance appeared on the surface crystallized gradually on standing. Recrystallization from dioxane gave 1.2 g of light yellow crystals.

N-*(8-Hydroxy-2-quinolylmethylene)*-o-*aminophenol (III):* To a solution of 2 g of 8-hydroxyquinoline-2-carbaldehyde in boiling ethanol was added a solution of 1.26 g of *o*-aminophenol in ethanol. The mixture was cooled in an ice bath, and the crystals were filtered and recrystallized from ethanol to give 2.8 g of yellow crystals.

2-(o-Hydroxyphenylaminomethyl)-8-quinolinol (VII): To a suspension of 0.4 g of sodium borohydride in 25 m*l* of dioxane was added dropwise a solution of 1 g of III in 10 m*l* of dioxane at room temperature. The mixture was kept standing for 1.5 hr and was added to the 2—4 equivalent volume of water. This solution was concentrated and the oil separated was crystallized with chilling in an ice bath. Recrystallization from aqueous ethanol gave 0.6 g of white crystals.

The other azomethine and aminomethyl derivatives were prepared by the same method as described above. The melting points and analytical data of the synthesized derivatives are given in Table 1.

Potentiometric titration. Since all the aminomethyl derivatives synthesized are insoluble in water, the potentiometric titration was carried out in 50 v/v% aqueous dioxane solution. A solution containing the ligands (10^{-3} mol/*l*) and perchloric acid ($1.0-2.0\times10^{-3}$ mol/*l*) in 50 v/v% aqueous dioxane solution was titrated with carbonate free 0.1 N KOH solution prepared according to Armstrong's method[3] and standardized against potassium hydrogen phthalate. During the course of titration, the temperature was maintained at 25±0.1°C and a stream of CO_2 free nitrogen was passed through the titration vessel. All the potentiometric measurements of pH were carried out with a Radiometer Titrator TTT 1 and Titrigraph equipped with a Radiometer G 203 B glass electrode and K 401 saturated calomel electrode. The instrument was standardized at pH 4.01 and 6.86 using a Toa Electronics buffer solution. The pH meter correction and ion products of water for solution of 50 v/v% aqueous dioxane were determined to be −0.12 and 15.38, respectively. These values are in agreement with those reported recently by Irving,[4] and Taka-

moto.[5)]

Results and Discussion

The results of the spot tests are shown in Table 2. The color reaction of the ligands obtained differs considerably from that of oxine as seen in Table 2. The results imply that the ligands may be useful as a metallochromic indicator and the reagents for colorimetric or gravimetric analysis.

The chelates of Fe^{3+}, Fe^{2+}, Cu^{2+}, Ni^{2+}, and Co^{2+} with azomethine derivatives can be extracted into the organic solvents such as isoamyl alcohol and chloroform. Among the ligands whose structures are given in Chart 1, ligands I and III form the most intensely colored chelates.

3. 2-(*o*-hydroxyphenylaminomethyl)-8-quinolinol
4. *N*,*N*-bis(8-hydroxyquinolyl)ethylenediamine

Azomethine derivatives studied in this work were found to hydrolyze readily in aqueous solution and their acid dissociattion constants could not be determined. The acid dissociation constants of aminomethyl derivatives were determined in 50 v/v% aqueous dioxane solution. The potentiometric titration curves of these ligand are shown in Fig. 1.

As regards the curves of ligands VIII, IX, and X, the separation of two dissociation steps is shown clearly by the pH jump at $a=1$. The first and second steps correspond to the dissociation of proton from the quinoline nitrogen and hydroxyl groups, respectively. The titration curve of ligand VII indicates that the dissociation of proton from quinoline nitrogen occurs in acidic region and the dissociation of two hydroxyl groups overlaps in alkaline region. The titration curve of ligand II exhibits two pH jumps at $a=1$ and $a=2$. This shows that the dissociation of proton from the imino groups occurs in the neutral region and the dissociation from the hydroxyl groups overlaps in the alkaline region.

The acid dissociation constants were calculated by Schwarzenbach's[6)] method with the use of the following equations.

$$K_1 = \frac{[HL]}{[L]\cdot[H^+]},\ K_2 = \frac{[H_2L]}{[HL]\cdot[H^+]},\ \cdots,$$
$$K_j = \frac{[H_jL]}{[H_{j-1}L]\cdot[H^+]} \quad (1)$$

$$[L]_t = \sum_{j=0}^{m}[H_jL] \quad (2)$$

$$[H]_t = [H^+] - [OH^-] + \sum_{j=0}^{m} j\cdot[H_jL] \quad (3)$$

$$\sum_{j=0}^{m}(g-j)\cdot[H^+]^j\cdot\overline{K}_j = 0 \quad (4)$$

$$(\overline{K} = K_1\cdot K_2\cdot K_3\cdots K_j)$$

where

$K_1, K_2, K_3, \cdots, K_j$: the successive acid stability constants

$[L]_t$: total acid concentration

5) S. Takamoto, Q. Fernand, and H. Freiser, *Anal. Chem.*, **37**, 1249 (1965)

6) G. Schwarzenbach, *Helv. Chim. Acta*, **33**, 947 (1950)

$[H]_t$: total acid concentration

g: average number of moles of proton bound per mole of ligand

m: maximum number of moles of proton per mole of ligand

Applying Schwarzenbach's method to ligand [II] (H_4L^{2+}), Eq. (4) is modified to be

$$g + (g-1)\cdot K_1\cdot[H^+] + (g-2)\cdot \bar{K}_2\cdot[H^+]^2 + (g-3)\cdot \bar{K}_3\cdot[H^+]^3 + (g-4)\cdot \bar{K}_4\cdot[H^+]^4 = 0 \quad (5)$$

As is apparent from the titration curve 4 in Fig. 1, there exist two species H_4L^{2+} and H_3L^+ between $a=0$ and $a=1$, two species H_3L^+ and H_2L between $a=1$ and $a=2$, and three spcies H_2L, HL^-, and L^{2-} between $a=2$ and $a=4$. Thus, Eq. (5) can be approximated by the following equations in the first, second, and third buffer regions, respectively.

$$(g-3) + (g-4)\cdot K_4\cdot[H^+] = 0 \quad (6)$$

$$(g-2) + (g-3)\cdot K_3\cdot[H^+] = 0 \quad (7)$$

$$g + (g-1)\cdot K_1\cdot[H^+] + (g-2)\cdot \bar{K}_2\cdot[H^+]^2 = 0 \quad (8)$$

Since g and $[H^+]$ are determined experimentally, the acid stability constants K_3 and K_4 can be calculated from Eqs. (6) and (7), and the overlapping acid stability constants K_1 and K_2 are calculated by the least squares method from Eq. (8). The results are summarized in Tables 3 and 4, and are compared with the dissociation constant of oxine.

As shown in Table 3, the pK_{NH^+} (the dissociation constant of quinoline nitrogen) and pK_{OH} values of these ligands are lower than the corresponding values of oxine. In 8-hydroxyquinoline-2-carbaldehyde, the dissociation constants are in agreement with the values reported in literature (pK_{NH^+} <3, pK_{OH}=10.24).[2]

The pK_{OH} values of 2-(tolylaminomethyl)-, 2-(*p*-chloroaminomethyl)-, and 2-(α-naphthylaminomethyl)-8-quinolinol are almost the same and pK_{NH^+} values increase in the order IX<X<VII<oxine. Thus it is supposed that the electron-withdrawing effect of phenyl group affects the quinoline ring through the $=CH_2NH-$ group and the substituent in the phenyl ring influences 1 position to some extent, but not 8 position of quinoline. Since the methyl group in 4 position of benzene ring behaves as an electron-donating group and the chloro group as an electron-withdrawing group, the pK_{NH^+} value of ligand VIII is higher than that of ligand IX.

In the *o*-hydroxy derivative 2-(*o*-hydroxyphenylaminomethyl)-8-quinolinol (VII), assingnment of the two values of pK_{OH} is very difficult. In 5-(*o*-hydroxyphenylazo)-8-quinolinol,[5] the dissociation constant of the quinoline hydroxyl group and that of the phenyl hydroxyl group have been reported to be 8.51 and 12.0, respectively. As shown in Table 3, the pK_{OH} values of ligands VIII, IX, and

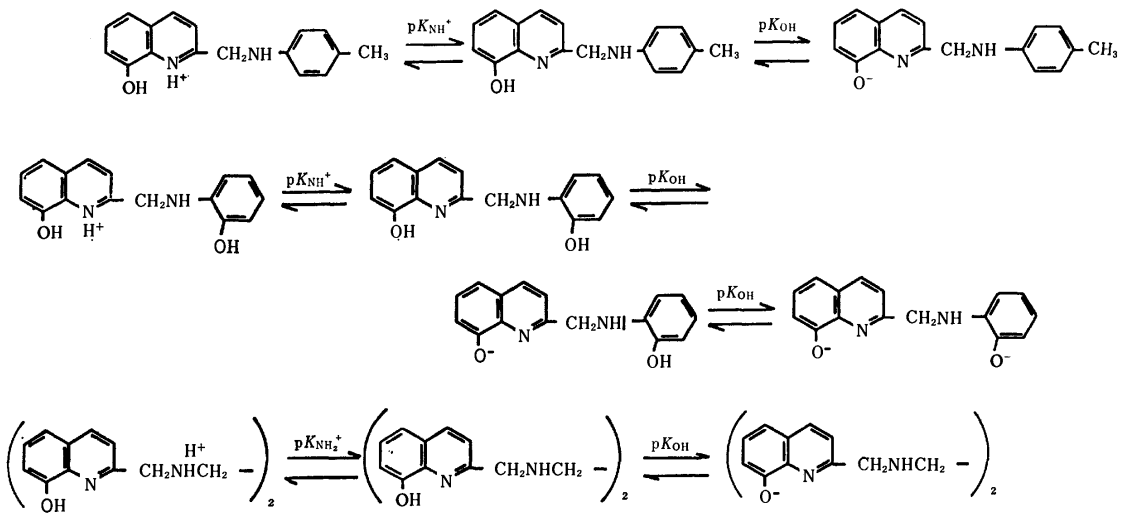

Chart 2

X are lower than those of oxine by about 0.4 log unit. Thus, we assigned the lower value (10.86) of pK_{OH} to the dissociation constant of the hydroxyl group in the quinoline ring and the higher value (11.35) to that of the hydroxyl group in the benzene ring.

In Table 4, the two $pK_{NH_2^+}$ values of ligand II corresponding to the dissociation of the imino groups are compared with those of the aliphatic analog, ethylenediaminediacetic acid (EDDA)[7] and the aromatic analog, ethylene-bis(2-aminomethyl)pyridine (EDAMP).[8] The $pK_{NH_2^+}$ values are similar to those of EDAMP and lower than those of EDDA. This suggests that the dissociation steps between $a=0$ and $a=2$ in the titration curve 4 in Fig. 1 do not correspond to the dissociation of proton from quinoline nitrogen, but to that from the imino group.

Since the basicity of ligand II is higher than that of other oxine derivatives and the ligand is expected to behave as the multidentate ligand, it is presumed that it forms more stable chelates with various metal ions than other oxine derivatives.

The equilibria involving quinoline nitrogen, hydroxyl groups and imino groups in 50 v/v% aqueous dioxane solution may be represented as shown in Chart 2. The dissociation steps of the hydroxyl groups of ligand VII are not completely clarified.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 481—484 (1972)

Syntheses of Some Medium Sized Cyclic Triamines and Their Cobalt(III) Complexes[1)]

Hiroyuki KOYAMA* and Tamotsu YOSHINO

Department of Chemisty, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 30, 1971)

Four cyclic triamines of a medium ring size (9—12-membered ring) which form three mutually-adjacent five- and/or six-membered chelate rings on complexation, such as 1,4,7-triazacyclononane (abbreviated TACN), 1,4,7-triazacyclodecane (TACD), 1,4,8-triazacycloundecane (TACUD), and 1,5,9-triazacyclododecane (TACDD) were synthesized and isolated as their trihydrobromides. The complexation of TACN and TACD with a cobalt(III) salt yielded metal complexes of a sandwich-type structure, such as $[Co(TACN)_2]Br_3$ and $[Co(TACD)_2]Br_3 \cdot H_2O$, which were then isolated. In the case of TACUD, a complex $[Co(TACUD)BrCl_2]$ containing only one molecule of the triamine was isolated. However, although the formation of a cobalt(III) complex with TACDD in solution was inferred spectroscopically, no expected complex was isolable. On the basis of the spectrophotometric data, the ligand-field strength was found to increase in the following order:

$$[Co(NH_3)_6]^{3+} < [Co(TACD)_2]^{3+} < [Co\ en_3]^{3+} < [Co(TACN)_2]^{3+}.$$

In this decade a large number of metal chelates with a quadridentate macrocyclic compound have been synthesized, and most of them have been investigated in considerable detail.[2)] In contrast with this, only a few metal complexes with cyclic tridentate ligands of a medium ring size have been studied.[3,4)] It is well known that an appreciable strain exists in a cyclic hydrocarbon of a medium ring size.

A similar strain appears to exist also in a comparable cyclic triamine,[5)] whose coordination to a metal ion may result in the formation of three mutually-adjacent five- and/or six-membered chelate rings.

The stability of the complex formed by the coordination of such a cyclic triamine to metal ions is expected to depend on the sizes of the three chelate rings in addition to the above-mentioned strain. It seems to be of interest to synthesize such cyclic triamines and to examine the relative stability of their metal complexes.

With this in mind, we synthesized four cyclic triamines of a medium ring size (9—12-membered ring), such as 1,4,7-triazacyclononane (abbreviated TACN, formula I, expected to form three 5-membered chelate rings), 1,4,7-triazacyclodecane (TACD, II, one 6-membered and two 5-membered rings), 1,4,8-triazacycloundecane (TACUD, III, two 6-membered and

one 5-membered rings), and 1,5,9-triazacyclododecane (TACDD, IV, three 6-membered rings), and isolated them as their trihydrobromides; we also characterized the intermediates obtained in the course of the syntheses as well as the products.

As the central metal ion to which the ligand coordinates, we chose the cobalt(III) ion, which is noted for its typical octahedral coordination, and studied the electronic spectra of the metal complexes formed. We wish now to report the results.

Experimental

All the melting and decomposition points are uncorrected. The infrared spectra were determined in potassium bromide disks on a Hitachi EPI-S2 spectrophotometer.

The NMR spectra were recorded at 60 MHz with a Hitachi R-20 spectrometer with $CDCl_3$ as the solvent, and the chemical shifts were reported in τ values relative to tetramethylsilane as the internal standard except for those attributable to *p*-toluenesulfonyl groups in VIII, IX, and X. The NMR data are given in the order of increasing multiplicity (*s*=singlet, *t*=triplet, *q*=quintet, and *m*=unresolved multiplet), integration, and coupling constant. The molecular weights were determined on a Hitachi Osmometer, type 115, using benzene as the solvent in the case of the tritosyl derivative of cyclic triamines and methanol in the case of the TACUD complex.

N,N',N''-*Tri*(p-*toluenesulfonyl*)*derivative of Open-chain Triamines V, VI, and VII.* To a solution of a triamine $H_2N(CH_2)_{2-3}NH(CH_2)_{2-3}NH_2$ (0.1 mol) and sodium hydroxide (0.3 mol) in water (80 m*l*), there was added, drop by drop, a solution of *p*-toluenesulfonyl chloride (0.3 mol) in ether (150 m*l*); the mixture was then stirred for 1 hr at room temperature. A white precipitate thus formed was collected by filtration, washed with water, and recrystallized from a large amount of methanol to give colorless needles. VII was left as a pale yellow oil and used in the next step without further purification. The data are summarized in Table 1.

N,N',N''-*Tri*(p-*toluenesulfonyl*)*derivative of Cyclic Triamines VIII, IX, and X.* To a vigorously-stirred mixture of anhydrous potassium carbonate (40 g) in dimethylformamide (2 *l*) maintained at 120°C, there was added, drop by drop, a solution of tritosyl triamine (V,VI of VII) (0.03 mol) and 1,3-dibromopropane (0.03 mol) in dimethylformamide (350 m*l*) through a Hershberg's dropping funnel for 30—40 hr at the rate of one drop per 10 sec; the mixture was further stirred for 7 hr at 115—120°C, and then it was cooled to room temperature and filtered to remove any inorganic substances. The filtrate was concentrated to one tenth of the original volume and water (3 *l*) was added to deposit a precipitate, which was then extracted with hot benzene (2 *l*).

The benzene extract was dried over anhydrous sodium sulfate. The solvent benzene was removed to leave a viscous brown-yellow oil of crude tritosyl derivative of the cyclic amine, which was dissolved in ethanol (200 m*l*) and then left to stand to separate colorless needles, which were subsequently recrystallized from ethanolic benzene. The data are summarized in Table 1.

NMR for VIII: τ 7.80 (*m*, 2H), 6.79 (*t*, 4H, J=6 Hz), 6.62 (*s*, 8H).

NMR for IX: τ 8.10 (*m*, 4H), 6.98 (*t*, 4H, J=6 Hz), 6.71 (*s*, 4H), 6.56 (*t*, 4H, J=7 Hz).

NMR for X: τ 8.80 (*q*, 6H, J=6.5 Hz), 6.76 (*t*, 12H, J=6.5 Hz).

Trihydrobromide of 1,4,7-Triazacyclononane (I). This compound (TACN·3HBr) was obtained by hydrolyzing *N,N'*-ditosyl TACN[6] with 30% hydrobromic acid and acetic acid.[7]

Trihydrobromides of Cyclic Triamines II, III, and IV. A tosyl derivative of the cyclic triamine (VIII, IX, or X)

6) D. H. Peacock and Y. S. Gwan, *J. Chem. Soc.*, **1937**, 1468.
7) A mixture prepared by adding glacial acetic acid (9 volume) to 47% hydrobromic acid (16 volume).

(0.004 mol) was dissolved by heating it in 30% hydrobromic acid and acetic acid[7] (300 ml) and then refluxed with stirring for 2 days. The solution was concentrated to one tenth of the original volume; after cooling, ether (200 ml) was added to separate crystals, which were collected, washed repeatedly with ether and then with ethanol, and recyrstallized from 95% acetic acid. The data are summarized in Table 1.

Syntheses of Co(III) Complexes. The amounts of cobalt(II) salt, the cyclic triamine trihydrobromide, and alkali were chosen so as have a molar ratio of 1 : 2 : 5.

Bis(1,4,7-triazacyclononane)cobalt(III) Tribromide (TACN Complex). A solution of $CoCl_2 \cdot 6H_2O$ (94 mg) in water (2 ml) was mixed with a solution of TACN·3HBr(I) (294 mg) and sodium hydroxide (79 mg) in water (3 ml). Air bubbles were passed through the mixture until yellow plates separated fully on the wall of the vessel. After the orange-yellow color of the solution had turned deep red, the precipitate was collected by filtration and washed with ethanol. The concentration of the filtrate gave an additional product (127 mg, 58%); dp>280°C, Λ_M 376 ohm^{-1} cm^2mol^{-1}.

Found: C, 25.95; H, 5.63; N, 14.98%. Calcd for $CoC_{12}H_{30}Br_3N_6$: C, 25.87; H, 5.43; N, 15.08%.

IR: 3080, 3020 (νNH), 990, 905 cm^{-1} (δ_{rock} CH_2).

Bis(1,4,7-triazacyclodecane)cobalt(III) Tribromide Monohydrate (TACD Complex). Air was bubbled for 7 hr into a solution of $CoCl_2 \cdot 6H_2O$ (94 mg), TACD·3HBr(II) (334 mg), and sodium hydroxide (87 mg) in water (10 ml). After the reddish-orange color of the solution had turned dark purple, the solution was concentrated to a half of its original volume; ethanol of twice the volume of the concentrated solution was then added to separate orange needles (135 mg, 56.9%); dp 230—270°C, Λ_M 350 ohm^{-1} cm^2 mol^{-1}.

Found: C, 28.34; H, 6.20; N, 13.50%. Calcd for $CoC_{14}H_{34}Br_3N_6 \cdot H_2O$: C, 27.88; H, 6.02; N, 13.93%.

IR: 3095, 3030 (νNH), 980, 910 cm^{-1} (δ_{rock} CH_2).

Bromodichloro(1,4,8-triazacycloundecane)cobalt(III) (TACUD Complex). Air was bubbled for 6 hr into a solution of $CoCl_2 \cdot 6H_2O$ (85 mg), TACUD·3HBr(III) (286 mg), and potassium hydroxide (100 mg) in 60% aqueous ethanol (10 ml). The mixture was evaporated to dryness. The residue was dissolved in a small amount of hot ethanol. Undissolved inorganic materials were removed by filtration. The filtrate was concentrated on a steam-bath, and the wall of the vessel was rubbed with a glass rod to separate dull red prisms. After the repetition of the treatment to remove the undissolved materials, the crystals were collected, washed with a small amount of ethanol, and dried at 65°C *in vacuo* (51 mg, 38.9%); dp 195—210°C, Λ_M 176 ohm^{-1} cm^2 mol^{-1}.

Found: C, 26.01; H, 5.60; N, 11.21%; mol wt 371. Calcd for $CoC_8H_{19}BrCl_2N_3$: C, 26.18; H, 5.22; N, 11.45%; mol wt 367.0.

IR: 3255, 3095 (νNH), 985, 900 cm^{-1} (δ_{rock} CH_2).

An Attempt to Isolate the TACDD Complex. Although the initial yellow-orange color of a solution of cobalt(II) salt, the ligand (TACDD·3HBr), and alkali in 60% ethanol turned dull red upon an air oxidation similar to that described above, an attempt to isolate the complex was unsuccessful.

Results and Discussion

The trihydrobromide of TACN (I) was obtained by hydrolyzing *N,N'*-ditosyl TACN,[6] whose IR spectrum showed, as expected, a band of medium intensity at 3360 cm^{-1} due to the NH stretching vibration, indicating the existence of a hydrogen atom attached to a nitrogen atom.

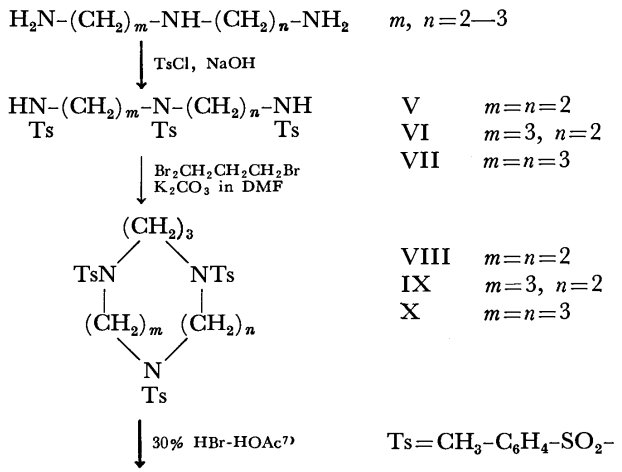

Fig. 2. The synthetic schemes of cyclic triamines (10 - 12-membered ring).

The synthetic schemes of cyclic triamines (10—12-membered ring) are shown in Fig. 2. The tritosylates of TACD (VIII), TACUD (IX), and TACDD (X) were each synthesized by the cyclization of an appropriate tritosylated open-chain triamine with 1,3-dibromopropane in the presence of anhydrous potassium carbonate in dimethylformamide under the conditions of a high dilution. These tritosylated triamines showed no NH stretching band. This means that the tritosylates have no end $-NH-SO_2C_6H_4CH_3$ group. The NMR spectra also supported the lack of the end group. The absence of the end group, coupled with the results of the elementary analyses and of the molecular-weight determination, indicates that these tritosylated triamines are monomers with a cyclic structure.

These tritosylated triamines were hydrolyzed with 30% hydrobromic acid and acetic acid[7] to yield the corresponding trihydrobromides of the triamines.

The IR spectra of the trihydrobromides exhibited complicated absorption bands with a strong intensity between 2900 and 2200 cm^{-1} characteristic of secondary amine salt, and also exhibited two resolved peaks or a peak with a shoulder between 1595 and 1545 cm^{-1} due to the bending vibration of NH_2^+. These facts are also consistent with the cyclic structure of the triamines. In order to study the metal complex, a mixture containing cobalt(II) salt, the cyclic triamine trihydrobromide, and alkali in a molar ratio of 1 : 2 : 5 was oxidized by passing air bubbles through; the separated metal complex was thus isolated. The composition of cobalt(III) complexes of TACN, TACD, and TACUD was confirmed by elementary analyses. The cobalt(III) complexes of TACN and TACD were formulated as, respectively, $[Co(TACN)_2]Br_3$ and $[Co(TACD)_2]Br_3 \cdot H_2O$. Their molar conductance data showed that the complexes of TACN and TACD were 3 : 1 electrolytes.

These facts, as well as their electronic spectra, indicated that all six nitrogen atoms of the cyclic ligands were coordinated to a central metal atom. This means that the complexes of TACN and TACD probably

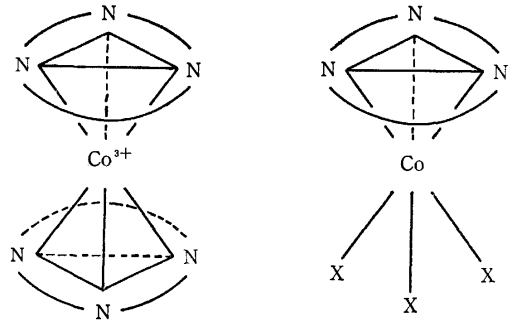

Fig. 3. A sandwich-type complex and a complex molecule (X=halogen).

have the sandwich-type structure shown in Fig. 3. The cobalt(III) complex of TACUD was formulated as $[Co(TACUD)BrCl_2]$. Its electronic spectrum is distinctly different from that of the complex of TACN and TACD described above. These facts suggest that three nitrogen atoms of the cyclic ligand occupy the corners of one octahedral face of the central metal atom, as is shown in Fig. 3. The TACUD complex showed molar conductance data nearly corresponding to those of a 2 : 1 electrolyte.

This suggests that the TACUD complex may be subject to hydrolysis in an aqueous solution much like a diethylenetriamine complex $[Co(dien)Cl_3]$.[8]

The formation of a complex with TACDD in an aqueous solution was inferred from its visible spectral similarity with the TACUD complex. The complexes of TACN, TACD, and TACUD exhibited two NH stretching bands of a strong intensity in the range of 3095 to 3020 cm^{-1}, and also exhibited two bands of medium intensity between 990 and 900 cm^{-1}; they were assigned to the CH_2 rocking vibration. On the basis of X-ray analysis[9] and infrared studies[10] of ethylenediamine complexes, it was confirmed that the conformation of the ethylene portions in the chelate ring of cyclic triamine complexes was nearly *gauche*. The electronic absorption maxima of the complexes in aqueous solutions are summarized in Table 2, along with those of the other $Co-N_6$ complexes. The ligand-field strength increased in the following order:

$$[Co(NH_3)_6]^{3+} < [Co(TACD)_2]^{3+} < [Co\,en_3]^{3+} < [Co(TACN)_2]^{3+}$$

From an examination of the Dreiding model, in the cases of TACN and TACD complexes the interatomic distances for the three inner-oriented hydrogens in a cyclic ligand were estimated to be 2.0—2.2 Å and 1.7—1.9 Å; the distances between hydrogens projecting from the two separate cyclic ligands were measured as 1.9—2.1 Å and 1.8—2.0 Å respectively. From the above investigation, the TACN complex can be said to be almost strain-free with respect to bond lengths and bond angles; therefore, the non-bonded H–H interaction must be negligible. It is interesting to note that TACN has stronger ligand-field strength than ethylenediamine. On the contrary, it appears that the TACD complex is more unstable than the TACN complex because of the increasing repulsion between non-bonded atoms and the expansion of the bond angles of nitrogen-metal-nitrogen.

On the other hand, the sandwich-type complexes of TACUD and TACDD were no longer formed because of cumulative ring strain and repulsion; in return, only one cyclic tridentate ligand and three halogens were coordinated to a metal ion.

TABLE 2. ELECTRONIC ABSORPTION MAXIMA OF THE COBALT(III) COMPLEXES IN AQUEOUS SOLUTIONS

The Reaction of Bis(acetylacetonato)cobalt(II) with Bromine in Dichloromethane

Yukio NAKAMURA, Nobuko KANEHISA, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 30, 1971)

When bis(acetylacetonato)cobalt(II) is allowed to react with twice molar quantity of bromine in dichloromethane, cobalt(II) bromide and γ-bromoacetylacetone are produced ultimately. From a deep blue solution of an equimolar reaction mixture at 0°C an intermediary product was isolated and characterized to be dimeric bromo(acetylacetonato)cobalt(II) by means of elemental analysis and molecular weight determination. The structure of this compound was inferred to be tetrahedral from absorption spectra and magnetic data. Acetylacetonate groups were supposed to act as bridging ligands on the basis of IR data in the lower frequency region. Dibromobis(acetylacetonato)dicobalt(II) was also derived from dibromo(acetylacetone)cobalt(II) by the reaction with sodium acetylacetonate in acetylacetone at 0°C.

It is very interesting that products of reactions between bromine and various metal acetylacetonates in dichloromethane differ depending on the nature of the central metal. Quasiaromatic γ-substitution was observed in cases of beryllium[1] and aluminum[2] acetylacetonates, but copper(II)[3] and cobalt(III)[4] chelates underwent a rupture of chelate rings. In the latter cases copper(II) and cobalt(III) were reduced to lower oxidation states. In the case of the nickel(II) chelate which is known to be trimeric,[5] stepwise displacement of the acetylacetonate ligand by the bromide anion was observed prior to the final breakdown of the trimeric structure, resulting in nickel(II) bromide and γ-bromoacetylacetone.[6]

Bis(acetylacetonato)cobalt(II) is known to exist as a tetrameric molecule in crystals[7] and is trimeric in non-coordinating solvents.[8] Although the oligomeric structure seems to be much less stable in comparison with the trimeric structure of the nickel(II) chelate, some intermediate might be obtained in the reaction with bromine. In order to confirm this view the present study on the reaction between bis(acetylacetonato)cobalt(II) and bromine in dichloromethane has been undertaken, and a dimeric intermediary product dibromobis(acetylacetonato)dicobalt(II) was isolated and characterized.

Results and Discussion

Final Reaction Products. When a dichloromethane solution of bromine was added dropwise to a dichloromethane solution of bis(acetylacetonato)cobalt(II) at room temperature, the original purple color gradually turned violet, blue, and then greenish blue. The solution became turbid when an equimolar bromine was added, and then a yellow green precipitate separated and increased with further addition of bromine. Finally the solution became colorless after twice molar bromine was added to the chelate. The precipitate was filtered, washed, dried *in vacuo* at 130°C, and identified to be cobalt(II) bromide. Found: Co, 26.62; Br, 72.29%. The yield was 0.969 mol/mol of the starting chelate. The organic bromide in the filtrate was determined by iodimetry to be 1.92 g equiv/mol of the starting chelate. Thus the mass balance in the 1 : 2 reaction is given by

$$Co(acac)_2 + 2Br_2 = CoBr_2 + 2acacBr. \quad (1)$$

Here acac stands for an acetylacetonate anion and acacBr for γ-bromoacetylacetone.

Isolation and Characterization of the Intermediary Product. In order to get some clue to the intermediary product the reaction was studied at 0°C. Even at 0°C when twice molar bromine is allowed to react with bis(acetylacetonato)cobalt(II) in dichloromethane, the same stoichiometry as that at room temperature (1) is observed. On the contrary, when equimolar bromine was added at 0°C, no precipitation took place and the greenish blue solution did not become turbid.

The solution was concentrated by evaporation *in vacuo* at 0°C, to which petroleum ether was added to form a greenish blue precipitate. The precipitate was filtered in a desiccator containing phosphorus pentoxide, washed repeatedly with petroleum ether, and dried *in vacuo* at 100°C. Results of elemental analysis conformed to the formula CoBr(acac). Found: Co, 24.23; Br, 33.32; C, 24.47; H, 3.02%. Calcd for $CoBrC_5H_7O_2$: Co, 24.77; Br, 33.58; C, 25.24; H, 2.97%. When the 1 : 1 reaction was performed in a mixed solvent of dichloromethane and petroleum ether (1 : 5 in volume) at 0°C, the same compound precipitated without evaporation. This compound is stable in dry state even at room temperature. It is readily soluble in dichloromethane and chloroform, but less soluble in dioxane. When a dichloromethane solution is kept standing at room temperature, decomposition proceeds gradually and the solution becomes turbid after about 10 min. However, a dioxane solution is stable enough to allow determination of molecular weight. Special care was

taken in the isolation and manipulation of this compound to exclude atmospheric moisture.

Molecular weight was determined cryoscopically in dioxane to be 445, close to the value 475 calculated for the dimer $[CoBr(acac)]_2$. However, ebullioscopic determination in a methanol solution gave a value of 252 which is rather near that of monomeric form. It is conceivable that bromo(acetylacetonato)cobalt(II) exists as a dimer in solid state and also in non-donor solvents, but is monomeric in a coordinating solvent such as methanol. Thus the stoichiometry of the 1 : 1 reaction between bis(acetylacetonato)-cobalt(II) and bromine in dichloromethane at 0°C is represented by

$$Co(acac)_2 + Br_2 = \frac{1}{2}[CoBr(acac)]_2 + acacBr. \quad (2)$$

As shown in Fig. 1 the visible absorption spectrum of this compound in dichloromethane at 0°C is quite different from that of bis(acetylacetonato)cobalt(II) in the same solvent, but resembles that of cobalt(II) bromide in acetone,[9a] which is considered to assume a tetrahedral structure.[9] However, the spectrum in methanol is in turn similar to that of bis(acetylacetonato)cobalt(II) in dichloromethane, where the latter complex is oligomeric and seems to maintain the octahedral structure. These spectral data are well reconciled with the results of molecular weight determination, revealing that bromo(acetylacetonato)-cobalt(II) exists as a tetrahedral dimer in dichloromethane and as an octahedral monomer solvate in methanol.

The effective magnetic moment was determined by the Gouy method to be 4.30 B.M. per g-atom cobalt at room temperature. This value is appreciably lower than 5.02 B.M. at 302.6°K of octahedral bis-(acetylacetonato)diaquocobalt(II)[10] and near the usual value of 4.4—4.7 B.M. for tetrahedral cobalt-(II) compounds,[9b] supporting again the tetrahedral structure of the dimeric compound in question.

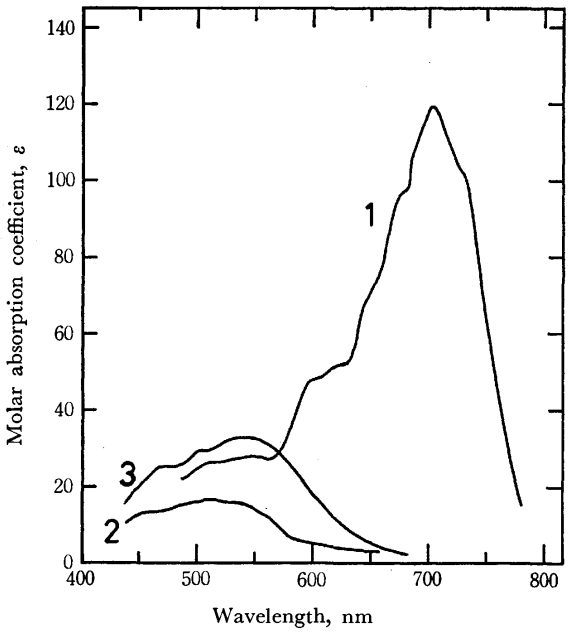

Fig. 1. Absorption spectra of CoBr(acac) in CH_2Cl_2 (curve 1) at 0°C and in methanol (curve 2) at room temperature, and of $Co(acac)_2$ in CH_2Cl_2 (curve 3).

Bromo(acetylacetonato)cobalt(II) is very hygroscopic and it is difficult to get an IR spectrum showing no band due to water. Broadening of the absorption curve in the 1600—1650 cm^{-1} region (Fig. 2) is due to the OH bending absorption of the contaminant water.

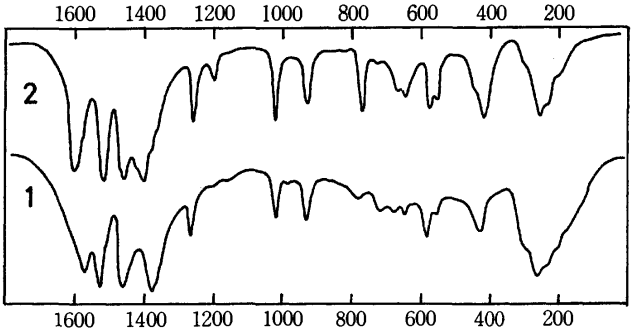

Fig. 2. Infrared spectra of CoBr(acac) (curve 1) and $Co(acac)_2$ (curve 2) in Nujol.

Absorption bands at 435 and around 260 cm^{-1} are assigned to the Co–O stretching vibration.[11] The former frequency is slightly higher than 422 cm^{-1} observed for bis(acetylacetonato)cobalt(II). Recently Nakamoto and his collaborators[12] studied the Co–Br stretching vibrations of $CoBr_2L_2$ type complexes (L=py, 4-chloro-py, or 4-bromo-py), and found that the stretching absorption of the bridging Co–Br bond in the polymeric octahedral form appeared at 118—143 cm^{-1}, while that of the terminal Co–Br bond in the monomeric tetrahedral form was observed at 265 cm^{-1}. Brierley, Geary, and Goldstein[13] also assigned 130 and 168 cm^{-1} bands to the stretching vibration of the bridging Co–Br bond in octahedral $CoBr_2$[1,2-di(4-pyridyl)ethylene], and 247 and 270 cm^{-1} bands to that of the terminal Co–Br bond in tetrahedral $CoBr_2L$ [L=1-(2-pyridyl)-2-(3-pyridyl)-ethylene, or 1-(2-pyridyl)-2-(4-pyridyl)ethylene]. The present compound shows a quite broad absorption in the 200—320 cm^{-1} region exhibiting a maximum at 270 cm^{-1}. This might be due to the terminal Co-Br stretching, but it is not certain since the parent bis(acetylacetonato)-complex also has a broad maximum at 260 cm^{-1} due to the Co–O stretching vibration. However it could be concluded that no band is observed in the 100—150 cm^{-1} region attributable to the bridging Co–Br stretching, and we propose the structure depicted in Fig. 3 for the dimeric bromo(acetylacetonato)cobalt(II) molecule instead of

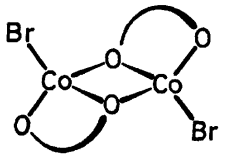

Fig. 3. A proposed structure of dimeric CoBr(acac).

the bromide-bridged structure illustrated previously.[14]

Figure 4 indicates the results of thermogravimetric analysis. The dimeric compound begins to decompose gradually at around 110°C and attains a constant weight at 185°C, but the weight decreases again at around 195°C due to the sublimation of a decomposition product. Heating was discontinued at 300°C and the residue was subjected to elemental analysis. The weight loss by heating up to 185°C was 20.8% corresponding to the release of one acetylacetone group from $[CoBr(acac)]_2$, and acetylacetone collected in a trap cooled by dry ice was identified by gas chromatography.

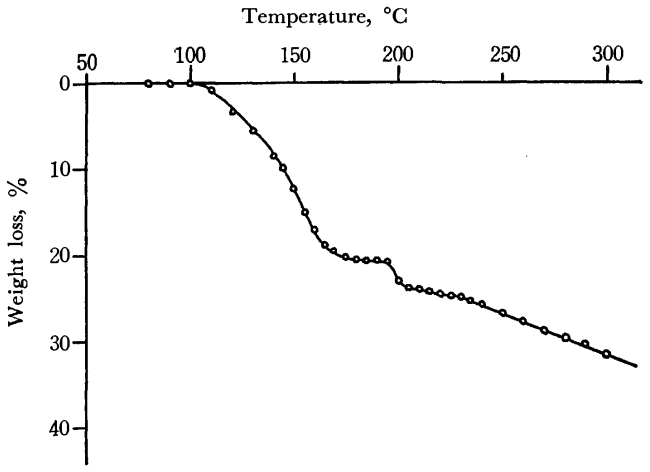

Fig. 4. Thermal decomposition of CoBr(acac) which was dried at 100°C in advance. The rate of temperature elevation was 30°C/hr.

Woodburn and Magee[15] reported that two molecules of dibenzoylmethane (DBMH) were released from an octahedral tetramer, $[Co(DBM)_2]_4$, resulting in a tetrahedral dimer, $(DBM)Co\langle^{OH}_{DBM}\rangle Co(DBM)$. In the present case a corresponding pyrolytic intermediate could not be identified probably because of the succeeding disproportionation, decomposition, or oxidation as represented by

$$[CoBr(acac)]_2 \rightarrow (CoBr)_2acac \rightarrow Co(acac)_2 + CoBr_2 + \text{Co-oxide(s)}. \quad (3)$$

The sublimate deposited on the glass wall was identified by IR assay to be bis(acetylacetonato)cobalt(II). The decomposition residue (0.1089 g) was found to contain 0.0294 g of cobalt and 0.0505 g of bromine. These values should be compared with 0.0369 g of cobalt and 0.0492 g of bromine in the starting specimen [0.1601 g of CoBr(acac)]. It is apparent that a certain quantity of cobalt was lost as a volatile product, but the whole bromine remained in the residue.

The disproportionation reaction of bromo(acetylacetonato)cobalt(II) was also examined in deaerated dichloromethane. Starting with 0.6121 g (2.57 mmol) of CoBr(acac), 0.1935 g of precipitate resulted after being kept standing at room temperature for 160 hr. This was found to contain 0.0441 g (0.84 mg-atom) of cobalt and 0.1267 g (1.59 mg-atom) of bromine indicating that the precipitate was cobalt(II) bromide contaminated with some impurity. Thus the main reaction is represented by

$$[CoBr(acac)]_2 = CoBr_2 + Co(acac)_2. \quad (4)$$

Dimeric bromo(acetylacetonato)cobalt(II) is rather stable in dichloromethane and the extent of the disproportionation reaction (4) was about 65% even after 160 hr.

Derivation of Dimeric Bromo(acetylacetonato)cobalt(II) from Dibromo(acetylacetone)cobalt(II). A new cobalt(II) complex containing a ketonic molecule of acetylacetone as a ligand was prepared by the reaction between tris(acetylacetonato)cobalt(III) and bromine in dichloromethane and also by direct addition of acetylacetone to anhydrous cobalt(II) bromide.[4] As postulated by Pedersen[16] on the mechanism of the metal-ion catalyzed bromination of β-dicarbonyl compounds, a ketonic molecule of acetylacetone coordinated to cobalt(II) is expected to exhibit enhanced acidity by virtue of the polarization effect of the metal ion. In order to verify the postulate the reaction of the ketonic complex with sodium acetylacetonate as a base was forced to occur in deaerated acetylacetone to yield dimeric bromo(acetylacetonato)-cobalt(II) as represented by

$$CoBr_2(acacH) + acacNa \rightarrow \tfrac{1}{2}[CoBr(acac)]_2 + acacH + NaBr. \quad (5)$$

All the procedures of the reaction and separation of products were conducted in a vacuum system to exclude moisture completely. The product obtained after drying at 60°C *in vacuo* was a solvate, $[CoBr(acac)]_2(acacH)$ and was transformed to $[CoBr(acac)]_2$ by prolonged evacuation at 100°C, which showed the same IR and electronic absorption spectra as those of dimeric bromo(acetylacetonato)cobalt(II) obtained by the reaction of bis(acetylacetonato)-cobalt(II) with equimolar bromine in dichloromethane at 0°C.

Experimental

Materials. Bis(acetylacetonato)diaquocobalt(II) was prepared by the method of Charles and Pawlikowski[17] and dehydrated to anhydrous bis(acetylacetonato)cobalt(II) by evacuation at 70°C for 7 hr. Found: Co, 22.98;

C, 46.28; H, 5.63%. Calcd for $Co(C_5H_7O_2)_2$: Co, 22.91; C, 46.71; H, 5.49%. Bromine and dichloromethane were purified by the usual methods as described previously.[3] Acetylacetone was distilled under reduced pressure and dried with Molecular Sieves Type 4A8—12, Linde Co.

Reaction of Bis(acetylacetonato)cobalt(II) with Bromine. The reaction of bis(acetylacetonato)cobalt(II) with bromine in dichloromethane was conducted in a three-necked flask equipped with a burette, a glass tube containing phosphorus pentoxide, and another glass tube connected to a filtration equipment by means of polyethylene tubing. To a chelate solution in the flask of the desired concentration, usually in the range 0.05—0.20 M, was added a bromine solution of the same concentration from the burette with vigorous stirring. The precipitate formed was transferred *via* polyethylene tubing to a vacuum filtration apparatus set up in a desiccator containing phosphorus pentoxide. The reaction was performed at 0°C or room temperature, the usual precaution being taken against moisture.

Preparation of Dibromobis(acetylacetonato)dicobalt(II) from Dibromo(acetylacetone)cobalt(II). Dibromo(acetylacetone)cobalt[4] (0.957 g, 3 mmol) was dissolved in about 30 m*l* of acetylacetone in an ampoule (A) connected *via* the ground glass joint to a glass tube containing phosphorus pentoxide. To this solution cooled at 0°C, powder of sodium acetylacetonate (0.366 g, 3 mmol) was added and stirred at 0°C for about 2 hr. Ampoule (A) was then attached to the vacuum line as depicted in Fig. 5, and deaerated by cycles of freezing and thawing. Acetylacetone was then distilled *in vacuo* at 0°C into another ampoule (D) leaving deep blue viscous residue, into which dichloromethane was distilled at 0°C. A deep blue solution resulted containing white powder of sodium bromide. The lower ampoule system was detached from the vacuum line at the ground glass joint (C), and the solution was filtered into ampoule (B) through a glass filter (G). After the solvent was vacuum-distilled back into ampoule (A), ampoule (B) was cut and the deep blue viscous residue was dried *in vacuo* at room temperature and finally at 60°C for 5 hr. Results of elemental analyses of the deep blue powder agreed with the formula $[CoBr(acac)]_2(acacH)$. Found: Co, 19.94; Br, 27.16; C, 31.21; H, 4.03%. Calcd for $Co_2Br_2C_{15}H_{22}O_6$: Co, 20.46; Br, 27.74; C, 31.27; H, 3.86%. This adduct lost acetylacetone gradually on evacuation at 100°C and the following analytical results were obtained after 4 hr. Found: Co, 23.14; Br, 31.70; C, 27.54; H, 3.47%. Calcd for $Co_2Br_2C_{10}H_{14}O_4$: Co, 24.77; Br, 33.58; C, 25.24; H, 2.97%. Such poor coincidence suggests the difficulty of complete liberation of excess solvent.

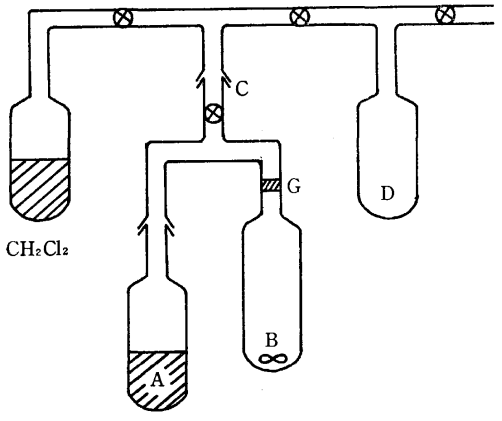

Fig. 5. The ampoule system employed for preparation of CoBr(acac) from $CoBr_2(acacH)$.

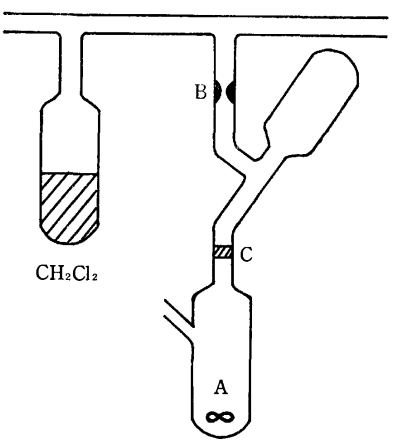

Fig. 6. The ampoule system employed for the disproportionation reaction of CoBr(acac) in dichloromethane.

The Disproportionation Reaction of Dibromobis(acetylacetonato)dicobalt(II) in Dichloromethane. Dibromobis(acetylacetonato)dicobalt(II) (0.6121 g) was put into an ampoule (A) which had been connected to a vacuum system (Fig. 6), and the side tube was sealed off. In the evacuated ampoule (A) about 40 m*l* of dried dichloromethane was distilled, and the ampoule system was sealed off at B from the vacuum line. The solution was kept at around 25°C with stirring for 160 hr. A green precipitate was separated from the solution by virtue of a glass filter (C), dried and subjected to elemental analysis.

Analyses. Solid products were dried at room temperature *in vacuo* unless otherwise stated. Cobalt was determined gravimetrically as sulfate, and bromine as silver salt. For the determination of organic bromide in the filtrate, the solvent was evaporated under reduced pressure. An acetic acid solution of potassium iodide was added to the residue, and the liberated iodine was titrated with a solution of sodium thiosulfate.

Measurements. Infrared spectra were taken in Nujol on Hitachi EPI-2(4000—700 cm^{-1}), EPI-L(700—200 cm^{-1}), and FIS-3(400—30 cm^{-1}) infrared spectrophotometers. Absorption spectra of solutions were measured by means of a Hitachi EPS-2 recording spectrophotometer. For the observation at 0°C, ice-water was circulated through the cell holder and dry air was forced to blow against the cell window to prevent clouding.

A thermo-spring balance C-282 of Hamada Denki Seisakusho, Ltd. was used for the thermogravimetric analysis, and the heating rate was adjusted to 30°C/hr *in vacuo*. The volatile decomposition product was collected in a trap cooled by dry ice and subjected to gas chromatographic analysis. A column (1.5 m) of Apiezon Grease L on Neosorb NC (Nishio Industries Co., Ltd.) was used at 59°C and hydrogen was passed at a flow rate of 72 cm/min. The decomposition residue was fused with potassium carbonate, and cobalt and bromine contents were determined.

The magnetic susceptibility was measured at room temperature by the Gouy method with an automatic recording magnetic balance (Naruse Kagakukikai Co., Ltd.). The sample was kept together with phosphorus pentoxide in a dry box, and then put quickly into a tube (2 mm in diameter and 70 mm in length) and stoppered with silicone grease.

Molecular weight of bromo(acetylacetonato)cobalt(II) was determined by cryoscopy in dioxane and osmometry in methanol with an apparatus manufactured by Knauer,

Germany. Solutions of around 10^{-2} M in the monomer basis were used, and benzil was adopted as a reference.

The authors thank Dr. S. Kawai, Osaka University for the magnetic measurement, and Mr. J. Gohda for the elemental analysis. They are also grateful to the Ministry of Education for financial assistance and to Daicel Co., Ltd. for the supply of acetylacetone.

Dimethyltin-bis(*N*,*N*-dimethylthioselenocarbamate), $(CH_3)_2Sn[SSeCN(CH_3)_2]_2$, dimethyltin-bis(*N*,*N*-dimethyldiselenocarbamate), $(CH_3)_2Sn[Se_2CN(CH_3)_2]_2$, and dimethyltin-bis(*N*-methyl-*N*-phenyldiselenocarbamate), $(CH_3)_2Sn[Se_2CN(CH_3)(C_6H_5)]_2$, react with dibromoalkanes to give bis(1-thia-3-selenacycloalkyl-2-dimethylimminium)dimethyltin tetrabromide, $[(CH_3)_2SnBr_4]^{2-}[(CH_2)_m\langle S, Se\rangle C{=}N(CH_3)_2]_2^{+}$ ($m=2$, 3), 1,3-diselenacycloalkyl-2-dimethylimminium dimethyltin bromides, $[(CH_3)_2SnBr_{n+2}]^{n-}[(CH_2)_m\langle Se, Se\rangle C{=}N(CH_3)_2]_n^{+}$ ($n=1$, $m=2$ and $n=2$, $m=3$), and 1,3-diselenacyclopentyl-2-methylphenylimminium bromide, $[(CH_2)_2\langle Se, Se\rangle C{=}N(CH_3)(C_6H_5)]^{+}Br^{-}$, respectively. The infrared and PMR spectra indicate that the positive charges of 1-thia-3-selena- and 1,3-diselenacycloalkylimminium ions are more delocalized in the higher homologs than in the lower ones.

We have previously reported on the reactions of dihalogenoalkanes with *N*,*N*-dimethyldithiocarbamate and *N*-methyl-*N*-phenyldithiocarbamate complexes of tin(IV), $(CH_3)_2Sn[S_2CN(CH_3)_2]_2$ and $(CH_3)_2Sn[S_2CN(CH_3)(C_6H_5)]_2$.[1,2] The main products of these reactions are 1,3-dithiacycloalkyl-2-dimethylimminium salts (I) and alkylene bis(*N*-methyl-*N*-phenyldithiocarbamate) (II) respectively, depending on the sort of reactant.

$$[(CH_3)_2SnX_{n+2}]^{n-}\left[(CH_2)_m\langle S, S\rangle C{=}N\langle CH_3, CH_3\rangle\right]_n^{+} \quad \text{(I)}$$

($n=1$ or 2; $m=2$, 3, or 4; X=Cl, Br, or I)

$$\begin{matrix} CH_3 \\ C_6H_5 \end{matrix}\rangle N-\overset{\overset{S}{\|}}{C}-S-(CH_2)_m-S-\overset{\overset{S}{\|}}{C}-N\langle \begin{matrix} CH_3 \\ C_6H_5 \end{matrix} \quad \text{(II)}$$

($m=2$, 3, or 4)

1,3-Dithiacycloalkylimminium ions are considered to be intermediates in the formation of ethylene bis(*N*,*N*-disubstituted-dithiocarbamate).[2,3]

Recently, one of the present authors synthesized some *N*,*N*-dialkylthioseleno-[4] and *N*,*N*-dialkyldiselenocarbamate[5] complexes of tin(IV). The purpose of this paper is to study the reaction of dibromoalkanes with dimethyltin-bis(*N*,*N*-dimethylthioselenocarbamate), $(CH_3)_2Sn[SSeCN(CH_3)_2]_2$, -bis(*N*,*N*-dimethyldiselenocarbamate), $(CH_3)_2Sn[Se_2CN(CH_3)_2]_2$, and -bis(*N*-methyl-*N*-phenyldiselenocarbamate), $(CH_3)_2Sn[Se_2CN(CH_3)(C_6H_5)]_2$ (abbreviated as $(CH_3)_2Sn(dmtsc)_2$, $(CH_3)_2Sn(dmdsc)_2$ and $(CH_3)_2Sn(mpdsc)_2$ respectively).

Results and Discussion

The reactions of $Br(CH_2)_nBr$ ($n=2$, 3) with $(CH_3)_2(dmtsc)_2$ give bis(1-thia-3-selenacycloalkyl-2-dimethylimminium)dimethyltin tetrabromide (III) and (IV), and $(CH_3)_2Sn(dmdsc)_2$ reacts with $Br(CH_2)_nBr$ ($n=2$, 3) to yield 1,3-diselenacycloalkyl-2-dimethylimminiumdimethyltin tribromide and tetrabromide, (V) and (VI):

$$[(CH_3)_2SnBr_4]^{2-}\left[(CH_2)_2\langle S, Se\rangle C{=}N\langle CH_3, CH_3\rangle\right]_2^{+} \quad \text{(III)}$$

$$[(CH_3)_2SnBr_4]^{2-}\left[(CH_2)_3\langle S, Se\rangle C{=}N\langle CH_3, CH_3\rangle\right]_2^{+} \quad \text{(IV)}$$

$$[(CH_3)_2SnBr_3]^{-}\left[(CH_2)_2\langle Se, Se\rangle C{=}N\langle CH_3, CH_3\rangle\right]^{+} \quad \text{(V)}$$

$$[(CH_3)_2SnBr_4]^{2-}\left[(CH_2)_3\langle Se, Se\rangle C{=}N\langle CH_3, CH_3\rangle\right]_2^{+} \quad \text{(VI)}$$

On the other hand, $(CH_3)_2Sn(mpdsc)_2$ reacts with $Br(CH_2)_2Br$ to preferentially give 1,3-diselenacyclopentyl-2-methylphenylimminium bromide (VII):

Table 1. Relevant infrared frequencies (cm^{-1}) of 1,3-dichalcogenacycloalkyl-2-dimethylimminium dimethyltin bromides and the related compounds[a,b]

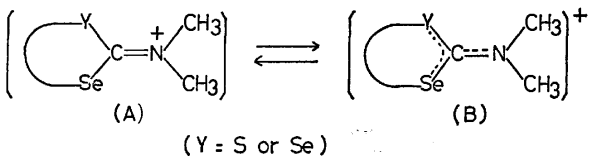
	Compound	ν(C=N)	ν_{as}(Sn-C)	ν_{s}(Sn-C)	ν(Sn-Br)
(Ia)	$[(CH_3)_2SnBr_3]^-$	1587 s	559 s	511 s	215 s
(Ib)[c]	$[(CH_3)_2SnBr_4]^{2-}$	1538 s	568m	505m	210 s
(III)	$[(CH_3)_2SnBr_4]^{2-}$	1588 s	562 s	—	214 s
(IV)	$[(CH_3)_2SnBr_4]^{2-}$	1538 s	561 s	—	215 s
(V)	$[(CH_3)_2SnBr_3]^-$	1574 s	566 s	511 s	216 s
(VI)	$[(CH_3)_2SnBr_4]^{2-}$	1554 s	564 s	—	?
(VII)	Br^-	1520 s	—	—	—

a) Nujol mull. b) The abbreviations used in this table are as follows: s, strong; m, medium. c) This compound is an equimolar mixture of $Br^-[(CH_2)_3(S)_2C{=}N(CH_3)_2]^+$ and $[(CH_3)_2SnBr_3]^-[(CH_2)_3(S)_2C{=}N(CH_3)_2]^+$.

$$Br^-\left[(CH_2)_2(Se)_2C{=}N\begin{matrix}CH_3\\C_6H_5\end{matrix}\right]^+ \quad \text{(VII)}$$

This is in contrast to the reaction of dimethyltin bis(*N*-methyl-*N*-phenyldithiocarbamate) with $Cl(CH_2)_2Cl$, which yields ethylene bis(*N*-methyl-*N*-phenyldithiocarbamate), besides 1,3-dithiacyclopentyl-2-methylphenylimminium salt.[2] The difference between these two reactions seems to result from the different solubilities of 1,3-diselena- and 1,3-dithiacyclopentyl-2-methylphenylimminium salts, which are intermediates in the production of ethylene bis(*N*-methyl-*N*-phenylcarbamate) in the 1,2-dihalogenoethane used as the solvent.

The relevant infrared frequencies of the compounds obtained here are listed in Table 1, together with those of the related 1,3-dithiacycloalkyl-2-dimethylimminium compounds. These 1,3-dichalcogenacycloalkylimminium ions exhibit the ν(C=N) bands at relatively high frequencies, suggesting an appreciable double-bond character of the C=N bond. The ν(C=N) frequencies of IV and VI, with the six-membered rings, are lower than those of III and V, which contain the five-membered ring. This tendency may reflect the fact that the higher homologs are more contributed from the canonical structure (B) than from (A), similar to the case of the 1,3-dithiacycloalkyl-2-dimethylimminium cation described in a previous paper.[2]



The ν(C=N) band of VII appears at a frequency considerably lower than those of the other 1,3-dichalcogenacyclopentyl-2-dimethylimminium salts, (III and V). This may be interpreted as indicating the decreasing double-bond character of the C=N bond conjugated with the phenyl group.

As is shown in Table 1, the $(CH_3)_2SnBr_3^-$ ion of V exhibits both asymmetric and symmetric ν(Sn–C) bands, while the $(CH_3)_2SnBr_4^{2-}$ ions of III, IV, and VI show only the asymmetric one. This is consistent with the previous report;[2] the former is a trigonal bipyramid with two methyl groups located in equatorial positions, while the latter is an octahedron with an almost linear C–Sn–C moiety.

In the PMR spectra, the N–CH_3 proton signals of the

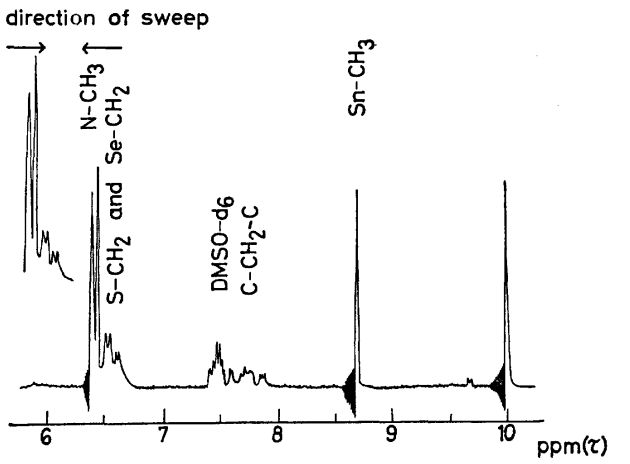


Fig. 1. PMR spectrum $[(CH_3)_2SnBr_4]^{2-}[CH_2(CH_2{-}S)(CH_2{-}Se)C{=}N(CH_3)_2]^+$ in DMSO-d_6, 7 wt%.

(V)	8.70 s	—	5.78 s	6.41 s	10.5	—	114
(VI)	8.70 s	7.70 q	6.59 t	6.42 s	c)	7.2	114
(VII)	—	—	5.78m	6.09 s	c)	—	—

a) The abbreviations used in this table are as follow: s, singlet; t, triplet; q, quintet; m, multiplet.
b) The S-CH_2- and Se-CH_2- protons were almost magnetically equivalent, resulting in a slightly broad singlet.
c) Not observed for the main signal being multiplet.

1-thia-3-selenacycloalkyl-2-dimethylimminium ion (III and IV) occur as a doublet at room temperature, because the rotation about the C=N bond is hindered. The lower-field signal is lower and broader than the higher one (Fig. 1). The former may be assigned to the CH_3 protons *trans* to the selenium atom with respect to the C=N bond, since the ^{77}Se (I=1/2, natural abundance 7.58%) could couple more strongly with the *trans*-CH_3 protons than with the *cis*-CH_3 protons, resulting in a decrease in the height and a broadening of the CH_3 proton signal.[4] As is shown in Table 2, the N—CH_3 proton chemical shifts of III are practically in agreement with those of 1,3-dithiacyclopentyl-2-dimethylimminium salt (Ia) and the diselena derivative (V). Quite similarly, the N–CH_3 proton spectrum of IV is observed to be a superposition of those of 1,3-dithiacyclohexyl-2-dimethylimminium salt (Ib) and the diselena derivative (VI). The 4- and 6-CH_2 proton signals of Ib and VI are a simple triplet due to spin-spin coupling with the 5-CH_2 protons, but those of IV shows a doublet of triplets (Fig. 1), although a pair of the lowest signals are concealed by the N–CH_3 proton signals. In addition, the 5-CH_2 proton signals occur as a complicated multiplet. These results may be due to different magnetic environments of the 4- and 6-CH_2 protons attached to the selenium and sulfur atoms respectively.

The J(^{119}Sn–CH_3) value of $(CH_3)_2SnBr_3^-$ and $(CH_3)_2SnBr_4^{2-}$ in DMSO-d_6 is in agreement with that of $(CH_3)_2SnBr_2$ in the same solvent,[6,7] which is known to exist as an octahedral complex ion of $(CH_3)_2Sn(DMSO\text{-}d_6)_4^{2+}$.

Experimental

$(CH_3)_2Sn(dmtsc)_2$,[4] $(CH_3)_2Sn(dmdsc)_2$,[5] and $(CH_3)_2Sn(mpdsc)_2$[5] were prepared elsewhere, while the dihalogenoalkanes are commercially available. The general procedure for the reactions was the same as has been described in the previous paper.[2]

Bis(1-thia-3-selenacyclopentyl-2-dimethylimminium)-dimethyltin Tetrabromide (III). A solution of $(CH_3)_2Sn(dmtsc)_2$ (3.0 g) in 1,2-dibromoethane (20 m*l*) was stirred at 100°C for 10 min to give a yellow precipitate. After the solution had then been cooled to room temperature, the precipitate (III) was filtered off and recrystallized from acetonitrile (4.8 g, 90% yield); mp 146—149°C.

Found: C, 16.71; H, 3.37; N, 3.34%. Calcd for $C_{12}H_{26}N_2S_2Se_2Br_4Sn$: C, 16.78; H, 3.06; N, 3.27%.

Bis(1-thia-3-selenacyclohexyl-2-dimethylimminium)-dimethyltin Tetrabromide (IV). A solution of $(CH_3)_2Sn(dmtsc)_2$ (3.0 g) in 1,3-dibromopropane (20 m*l*) was kept at a temperature of about 100°C for 1 hr in order to liberate a yellow precipitate. Recrystallization from acetonitrile then yielded light yellow crystals of IV (4.6 g, 85% yield); mp 104—106°C.

Found: C, 18.65; H, 3.54; N, 3.12%. Calcd for $C_{14}H_{30}N_2S_2Se_2Br_4Sn$: C, 18.96; H, 3.42; N, 3.16%.

1,3-Diselenacyclopentyl-2-dimethylimminium-dimethyltin Tribromide (V). A solution of $(CH_3)_2Sn(dmdsc)_2$ (5.0 g) in 1,2-dibromoethane (20 m*l*) had been stirred for 1 hr at 100°C and then filtered; the solid product thus obtained was recrystallized from acetonitrile to give light yellow crystals of V (2.2 g, 65% yield); mp 157—159°C.

Found: C, 13.71; H, 2.58; N, 2.64%. Calcd for $C_{17}H_{16}NSe_2Br_3Sn$: C, 13.32; H, 2.54; N, 2.22%.

Bis(1,3-diselenacyclohexyl-2-dimethylimminium)-dimethyltin Tetrabromide (VI). A solution of $(CH_3)_2Sn(dmtsc)_2$ (2.0 g) in 1,3-dibromopropane (20 m*l*) was maintained for 1 hr at 100°C. After it had been cooled to room temperature, yellow solid product (VI) was filtered off and recrystallized from acetonitrile (2.2 g 65% yield); mp 132—133°C.

Found: C, 16.59; H, 2.95; N, 3.06%. Calcd for $C_{14}H_{30}N_2Se_4Br_4Sn$: C, 17.15; H, 3.09; N, 2.86%.

1,3-Diselenacyclopentyl-2-methylphenylimminium Bromide (VII). A solution of $(CH_3)_2Sn(mpdsc)_2$ (2.0 g) in 1,2-dibromoethane (20 m*l*) was stirred for 5 min at 100°C to give a yellow precipitate, which was then recrystallized from an acetonitrile-ether mixture to give pale yellow crystals of VIII (0.76 g 69% yield); mp 190—192°C.

Found: C, 31.38; H, 3.21; N, 3.69%. Calcd for $C_{10}H_{12}NSe_2Br$: C, 31.28; H, 3.15; N, 3.65%.

Infrared and NMR Spectra. The infrared spectra were recorded on Hitachi EPI-2G(5000—400 cm^{-1}) and EPI-L (700—200 cm^{-1}) spectrophotometers. The NMR spectra were measured on a Japan Electron JNM-3H-60 spectrometer operating at 60 MHz at room temperature, using tetramethylsilane as the internal standard.

We are grateful to the Shinko Chemical Co., Ltd., for supplying the elemental selenium.

The Structure of the Pteridine Glycoside from *Aspergillus oryzae*

Sadao MATSUURA, Masaki YAMAMOTO,* and Yasuyuki KANEKO**

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received June 11, 1970)

The structures of two blue-fluorescent substances, asperopterin-A and -B, isolated from *Aspergillus oryzae* were investigated. Asperopterin-B was identified as 2-amino-3,4,7,8-tetrahydro-6-hydroxymethyl-8-methyl-4,7-dioxopteridine (**7**) by studying its chemical degradation, pK_a values, and UV spectra; the structure was confirmed by synthesis. Asperopterin-A was shown to be the β-D-ribofuranoside of **7**, 2-amino-3,4,7,8-tetrahydro-8-methyl-4,7-dioxo-6-pteridinylmethyl β-D-ribofuranoside (**10**).

Two blue-fluorescent substances, asperopterin-A (**1**) and -B (**2**), have been isolated as crystals from *Aspergillus oryzae* T-17.[1,2] In a previous communication,[3] **1** was shown to be a D-riboside of **2**, and a tentative approach to the structure of **2** was made. The present paper will record the complete structures of **1** and **2** as well as the synthesis of the latter.

Results and Discussion

Structure of Asperopterin-B (2). It has previously been established[3] that **2** is a derivative of isoxanthopterin bearing a CH_2OH group at the 6-position and an extra methyl group elsewhere in the molecule. In the present work, this was supported by the NMR spectrum of **2**, which showed two singlets, at 3.22 and 4.52 ppm, representing a methyl and methylene group respectively. Moreover, it is known that isoxanthopterin has the 2-amino-4,7-dioxo-form in an aqueous solution with its two pK_a values (7.34 and 10.06) arising from the hydrogen atoms attached to the N-3 and N-8 positions of the ring.[4] Since **2** has only one acidic pK_a value (8.07), one of these hydrogen atoms must be replaced by a methyl group. In order to find the position of this methyl group, **2** was oxidized with potassium permanganate and the oxidation product (**3**)[3] was compared with the three synthetic *N*-methylisoxanthopterin-6-carboxylic acids (**4a**—**c**); **4c** proved to be identical with **3** (Table 1). Thus, asperopterin-B (**2**) was assumed to be 2-amino-3,4,7,8-tetrahydro-6-hydroxymethyl-8-methyl-4,7-dioxopteridine (**7**); this assumption was eventually confirmed by the following synthesis. 6,8-Dimethylisoxanthopterin (**5**)[4] was brominated using bromine in 48% hydrobromic acid; without isolation, the bromo derivative (**6**) was converted by 0.5 N sodium hydroxide into the 6-hydroxymethyl compound (**7**) which was identical with **2** in R_f and in pK_a value, and also in its UV and IR spectra (Table 1, Fig. 1).

8 **9**

R = D-ribosyl

In order to distinguish between these possibilities, methylation with dimethyl sulfate was carried out. It had previously been reported[6] that isoxanthopterin in an alkaline solution was methylated at N-8, N-3, and the 2-amino group on treatment with dimethyl sulfate; moreover, when **2** was treated similarly, the hydroxyl group of the side chain was methylated together with the ring nitrogen atoms. Therefore, if **1** is **8**, the hydroxyl group of the side chain should be methylated; on the other hand, if **1** is **9**, no methylation could take place at that position, since the hydroxyl group would be protected by the ribosyl group. Using conditions under which no hydrolysis of the glycosidic link occurred, the methylation of **1** in an alkaline solution gave a mixture of products. When this mixture was boiled with 2 N hydrochloric acid, three products, $\mathbf{a}_1$, $\mathbf{b}_1$, and $\mathbf{c}_1$, were obtained. These were then chromatographically separated; $\mathbf{a}_1$ was identified as **2** from its R_f, its pK_a value, and its UV spectrum (Table 1); the permanganate oxidation of $\mathbf{b}_1$ and $\mathbf{c}_1$ gave two acids, $\mathbf{b}_2$ and $\mathbf{c}_2$, which were identical with **4d** and **4e** respectively (Table 1). Since 6-methoxymethylisoxanthopterin[7] was unaffected under the conditions

7) S. Matsuura, S. Nawa, H. Kakizawa, and Y. Hirata, *J. Amer. Chem. Soc.*, **75**, 4446 (1953).

used for the oxidation of **2**, $\mathbf{b}_1$, and $\mathbf{c}_1$, both $\mathbf{b}_1$ and $\mathbf{c}_1$ could be seen to have a hydroxymethyl group at the 6-position, and it could be seen that the glycoside was not methylated at this position, even in the presence of a large excess of dimethyl sulfate. Accordingly, the formula **9**, in which the hydroxymethyl group was protected by a ribosyl group, was confirmed to be that for asperopterin-A.

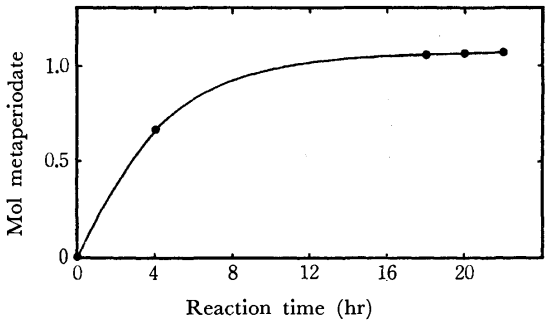

Fig. 4. Periodate oxidation of asperopterin-A.

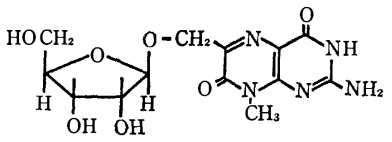
The structure of the sugar moiety of **1** was determined by periodate oxidation according to the method of Lythgoe[8] and Jackson;[9] **1** consumed one molar equivalent of the reagent and produced no formic acid (Fig. 4). It was clear, therefore, that **1** was a ribofuranoside. The anomeric configuration of **1** was deduced to be β by a comparison of its molecular rotation (−223°) with those of known D-ribofuranosides.[10] Thus, the formula **10** was given to asperopterin-A:



10

Experimental

All the melting points are uncorrected. The NMR spectrum was measured at 60 MHz with a JEOL Model JNM-3 spectrometer, using a 0.5 M KOD solution and TMS as the external reference. The UV spectra were measured on a Shimadzu SV-50 spectrometer and checked on a Shimadzu QR-50 manual instrument. The IR spectra were recorded on a Hitachi Model EPI-G spectrometer. Optical rotations were determined with a Shimadzu Lippich-type polarimeter. The ionization constants were determined spectroscopically.

Permanganate Oxidation of Asperopterin-B (2). 0.1 M Potassium permanganate was added, drop by drop, to **2** (77.6 mg) in 0.01 M sodium hydroxide (100 m*l*) at 60°C until a purple color remained. The solution was then set aside at this temperature for 20 min, and the excess of permanganate was decomposed with 0.05 M potassium sulfite. The manganese dioxide was filtered off and washed with hot water. The combined filtrate and washings were adjusted to pH 2 with hydrochloric acid and passed through a florisil column (1.5×10 cm). The pteridine, adsorbed on the top of the column, was then eluted with water; a small amount of the starting material remained on the column.[13] The eluate was concentrated to a volume of 50 m*l* and adjusted to pH 2. The repeated recrystallization of the precipitate from 1 M potassium hydroxide and finally from an aqueous buffer at pH 2 gave pale yellow needles (45 mg) of the product; mp>300°C.

Found: C, 39.86; H, 3.37; N, 29.02%. Calcd for $C_8H_7N_5O_4 \cdot 1/4H_2O$: C, 39.76; H, 3.13; N, 28.98%.
This product was identical with authentic **4c**.

2,5-Diamino-4-hydroxy-6-methylaminopyrimidine Hydrochloride.[4] 2-Amino-4-hydroxy-6-methylanino-5-nitrosopyrimidine[14] (35 g) and 10% palladized charcoal (5 g) in 400 m*l* water was shaken under hydrogen. After 3 min, 1 M sodium hydroxide (100 m*l*) was added and shaking was continued until the absorption of hydrogen ceased (9700 m*l* within 100 min). After the subsequent acidification of the mixture with 10 M hydrochloric acid (100 m*l*), the catalyst was removed by filtration. The concentration of the filtrate under reduced pressure gave the product in an 85% yield. The catalyst could be used repeatedly without any depression of its activity providing it was washed with ethanolic sodium hydroxide (4 g of sodium hydroxide in 100 m*l* of 20% aqueous ethanol).

In a similar way, 4,5-diamino-6-hydroxy-2-methylaminopyrimidine hydrochloride[4] was prepared from the corresponding 5-nitrosopyrimidine[15] in an 85% yield.

6-Carboxy-3,4,7,8-tetrahydro-2-methylamino-4,7-dioxopteridine (4a). This compound was prepared in an 80% yield from the above 4,5-diamino-6-hydroxy-2-methylaminopyrimidine hydrochloride using the method for its 3-methyl isomer (**4b**);[5] mp>300°C.

Found: C, 38.59; H, 3.67; N, 27.90%. Calcd for $C_8H_7N_5O_4 \cdot 2/3H_2O$: C, 38.56; H, 3.37; N, 28.11%.

2-Amino-3,4,7,8-tetrahydro-6-hydroxymethyl-8-methyl-4,7-dioxopteridine (7). Bromine (1.00 g) was added to **5**[4] (1.20 g) in 48% hydrobromic acid (100 m*l*) at 60°C. The mixture was heated at 80°C until the initially-formed precipitate had dissolved, and then cooled quickly. It was diluted with water (200 m*l*), and its pH was adjusted to 2 with crystalline sodium acetate. The solution was evaporated to dryness under reduced pressure, and the residue was heated at 80°C with 0.5 M sodium hydroxide (200 m*l*) for 15 min. The separated needles (1.01 g) were purified by repeated recrystallization from 1 M potassium hydroxide until only one spot was observed on a paper chromatogram.

9) E. L. Jackson and C. S. Hudson, *J. Amer. Chem. Soc.*, **61**, 1530 (1939).
10) It has been reported that methyl β-D-ribofuranoside has a molecular rotation of −102° in contrast to that of the α-isomer (+241°).[11] When the aglycon was replaced by a benzyl alcohol residue, the value for the β-isomer moved to −145°.[12] This displacement (43°) caused by the aglycon exchange is much smaller than the difference (343°) between the rotations of the α- and β-isomers.
11) G. R. Barker and D. C. C. Smith, *J. Chem. Soc.*, **1954**, 2151.
12) R. K. Ness, H. W. Diehl, and G. G. Fletcher, Jr., *J. Amer. Chem. Soc.*, **76**, 763 (1954).
13) The florisil column for chromatography was prepared as before.[2] The behavior of the adsorbed pteridines towards elution depends on their pK_a values. A pteridine with an acidic pK_a below 4 was eluted with water; one with a pK_a between 6 and 9 was eluted with 1% aqueous ammonia or, more effectively, with acetone-ammonia (acetone, 30 m*l*; 1.5% aqueous ammonia, 60 m*l*).
14) W. V. Curran and R. B. Angier, *J. Org. Chem.*, **28**, 2672 (1963).
15) R. Roth, J. M. Smith, Jr., and M. E. Hultquist, *J. Amer. Chem. Soc.*, **73**, 2864 (1951).

Finally, the pH value of the solution of the potassium salt in water (50 m*l*) was adjusted to 5 to give the product as pale yellow needles (270 mg, 22%); mp>300°C.

Found: C, 41.87; H, 4.00; N, 30.24%. Calcd for $C_8H_9N_5O_3 \cdot 1/2H_2O$: C, 41.38; H, 4.34; N, 30.15%.

*Methylation and Subsequent Hydrolysis of Asperopterin-A (**1**).* Dimethyl sulfate was added in portions (0.016 m*l*; 1 equivalent each) to **1** (56 mg, 0.016 mmol) in 0.1 M potassium hydroxide (20 m*l*); the mixture was then maintained at pH 10 by adding 10 M potassium hydroxide. After the addition of every five equivalents of the reagent, the mixture was examined by paper chromatography. Additions were continued until no spot of the starting material was visible. Seventy-five equivalents of dimethyl sulfate were added in all. The reaction mixture, after the inorganic salts had been removed using a florisil column, was heated with 2 M hydrochloric acid (5 m*l*) at 100°C for 10 min. This produced three compounds, $\mathbf{a}_1$, $\mathbf{b}_1$, and $\mathbf{c}_1$ (R_f: 0.20, 0.30 and 0.47 using *n*-butanol–acetic acid), which were separated by a paper-chromatographic method (*n*-butanol–acetic acid as a solvent) and purified using the florisil column.[13]

Permanganate Oxidation of b_1 and c_1. The above $\mathbf{b}_1$ fraction was oxidized with permanganate as has been described before. After the removal of the manganese dioxide, the product was adsorbed on a florisil column (0.3× 3 cm) and eluted with 1% aqueous ammonia. The product ($\mathbf{b}_2$), obtained by the evaporation of the eluate to dryness, was identified as **4d**.

Similarly, the $\mathbf{c}_1$ fraction was oxidized; the product, $\mathbf{c}_2$, was identified as **4e**.

5-Formamido-4-hydroxy-2,6-bismethylaminopyrimidine. Formic acid (98—100%; 60 m*l*) was added, drop by drop, to a vigorously-stirred solution of 4-hydroxy-2,6-bismethylaminopyrimidine[14] (27 g) and sodium nitrite (15 g) in formamide (200 m*l*). The mixture was heated to 90°C, and sodium dithionite (1.2 g) was added. An exothermic reaction occurred, and the nitroso compound dissolved. After 3 min, the formamido compound separated as needles (30.5 g, 90%); mp 282—283.5°C (recrystallized from water).

Found: C, 40.70; H, 6.32; N, 33.94%. Calcd for $C_7H_{11}N_5O_2 \cdot 1/2H_2O$: C, 40.77; H, 5.84; N, 33.97%.

5-Formamido-1,6-dihydro-1-methyl-2,4-bismethylamino-6-oxopyrimidine. Dimethyl sulfate (16.5 g) was added in portions to the above formamidopyrimidine (16 g) in 1 M sodium hydroxide (200 m*l*). The mixture was stirred for 1 hr at 25°C, during which time the pH value of the solution was maintained at 13 by the addition of 10 M sodium hydroxide throughout the reaction. After chilling overnight, the precipitate was collected and recrystallized from water to give colorless needles (9.0 g, 53%) of the product; mp 291—292°C (dec.).

Found: C, 45.23; H, 6.39; N, 33.20%. Calcd for $C_8H_{13}N_5O_2$: C, 45.49; H, 6.39; N, 33.16%.

*6-Carboxy-3,4,7,8-tetrahydro-3,8-dimethyl-2-methylamino-4,7-dioxopteridine (**4e**).* The above 5-formamido-1-methylpyrimidine (2.2 g) was dissolved in 12 M hydrochloric acid (10 m*l*) and set aside at room temperature overnight. Ethanol (20 m*l*) was then added to the mixture, and the precipitated 5-aminopyrimidine was used for condensation without further purification. The 5-aminopyrimidine was added to diethyl oxomalonate (3.2 g), sodium acetate (3 g), and potassium metabisulfite (100 mg) in water (50 m*l*), and the mixture was boiled for 10 min. The yellow needles (2.7 g) were collected and boiled in 1 M sodium bicarbonate (150 m*l*) for 55 min. The precipitate, dissolved in a 0.5 M potassium hydroxide solution (300 m*l*), was added, drop by drop, to boiling 20% acetic acid (300 m*l*) to give yellow needles (2.4 g, 87%); mp>300°C.

Found: C, 44.82; H, 4.19; N, 26.13%. Calcd for $C_{10}H_{11}N_5O_4 \cdot 0.1H_2O$: C, 44.98; H, 4.23; N, 26.23%.

*Periodate Oxidation of Asperopterin-A (**1**).* Sodium metaperiodate (0.113 M, 7.50 m*l*) was added to **1** (57.0 mg) in water (100 m*l*) and diluted to exactly 120.0 m*l*. The solution was incubated at 25°C. Samples (2.0 m*l*) were taken out at intervals, and the excess of metaperiodate in each was estimated iodometrically.[8,9] 0.68, 1.06, 1.07, and 1.07 molar equivalents of periodate were consumed after 4, 18, 20, and 22 hr respectively. After 22 hr, 10 m*l* of the solution was diluted with water and titrated with 0.02 M sodium hydroxide;[8] the diluted solution consumed no sodium hydroxide.

The authors wish to express their appreciation to Professor A. Albert and Dr. D. J. Brown of the Australian National University for their helpful discussions. They also wish to thank the staff of Fujisawa Seiyaku Co., Ltd., for performing the elementary analyses.

Synthetic Reactions by Complex Catalysts. XXIV. A New Catalyst of Copper-Isocyanide Complex for the Michael Addition

Takeo SAEGUSA, Yoshihiko ITO, Shimpei TOMITA, and Hideo KINOSHITA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December, 23, 1970)

It has been found that some binary systems of a copper compound (or metallic compounds) and an isocyanide catalyze the Michael addition reaction. As the copper component, Cu_2O, metallic copper and copper acetylacetonate are effectual, whereas CuCl, $CuCl_2$, and CuO are ineffectual. The catalyst of copper isocyanide complex is characterized by the selective activation of cyano olefin compounds such as acrylonitrile. This was demonstrated by the competitive addition of an active hydrogen compound to acrylonitrile and methyl acrylate. Some results of kinetics and spectroscopic studies have been explained by assuming a scheme involving coordination of olefin onto copper-isocyanide complex.

This paper deals with the catalyst behavior of some binary systems of a copper compound and an isocyanide for the Michael addition reaction. We have concentrated on new catalyst activity of the copper-isocyanide complexes in the field of synthetic organic reactions, and found several new reactions with the catalytic aid of these complexes. Copper catalyzed formimidation of amine,[1a] phosphine,[1b] alcohol,[1c,d] thiol,[1e] and silane[1f] constitutes a series of new reactions of isocyanide. Dimerization of α,β-unsaturated nitriles and carbonyl compounds (Eq. (1)) is the second series of reactions catalyzed by the copper-isocyanide complexes, where the isocyanide ligand is not incorporated in the products.[2-4]

$$\mathrm{RCH{=}CHX} \longrightarrow \mathrm{RCH{=}\underset{\displaystyle \mathrm{RCHCH_2X}}{\underset{|}{C}}{-}X} \qquad (1)$$

(R=H, primary and secondary alkyl groups; X=CN, CO_2R', COR'')

From the mechanistic consideration on the dimerization reaction, a nucleophilic addition of allyl and vinyl-copper complexes to α,β-unsaturated bond has been reasonably assumed as the key step.[3,4] This assumption prompted us to examine the catalysis of the copper-isocyanide complex in the Michael addition reaction. The expectation has been realized. In addition, the copper-isocyanide complex in the Michael addition is distinguished from the usual base catalysts by the selective activation of cyano olefins such as acrylonitrile.

Experimental

Materials. Commercial reagents diethyl malonate, acetylacetone, benzyl cyanide, malononitrile, *t*-butyl mercaptan, 2-nitropropane, indene, methyl crotonate, methyl acrylate, acrylonitrile, and triethylamine were purified by distillation. Methylacetylacetone (3-methylpentane-2,4-dione) was prepared from acetylacetone and methyl iodide using potassium carbonate catalyst.[5] Diethyl ethylmalonate was synthesized from diethyl malonate and ethyl bromide using sodium ethoxide catalyst.[6] Ethyl propiolate was prepared by the dehydrobromination of dibromosuccinic acid followed by decarboxylation and esterification.[7] Cyclohexyl isocyanide and *t*-butyl isocyanide were prepared according to Ugi's procedure.[8] Metal oxide and salts were all commercial reagents. Metallic copper powder was prepared by the reduction of cupric sulfate with zinc powder in acidic aqueous solution under nitrogen.[9]

Reaction of Diethyl Malonate with Methyl Crotonate. A mixture of diethyl malonate (1.6 g, 10 mmol), methyl crotonate (1.0 g, 10 mmol), cyclohexyl isocyanide (1.09 g, 10 mmol), and cuprous oxide (20 mg, 0.14 mmol) was heated under nitrogen at 90°C for 9 hr. The reaction mixture was subjected to fractional distillation. The fraction boiling at 152—153°C/4 mmHg was collected. The yield of the product was 2.46 g (95%). By IR and NMR spectra as well as elemental analysis, the structure of the product was shown to be $(EtO_2C)_2CHCH(CH_3)CH_2CO_2CH_3$ (I), an adduct of the Michael addition. Principal IR bands (neat): 1730 (s), 1300—1150 (s) cm^{-1}. NMR of I in CCl_4: τ 8.87 (d, CH_3–), 8.64 (t, $-CO_2CH_2CH_3$), 7.52 (d, $-\underset{|}{CH}-$), 7.30 (m, $CH_3\underset{|}{CH}$), 6.64 (d, $-CH_2CO_2CH_3$), 6.30 (s, $-CO_2CH_3$), and 5.79 (q, $-CO_2CH_2CH_3$).

Found: C, 55.43; H, 7.84%. Calcd for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75%.

The reactions of other active hydrogen compounds and acceptor olefins were carried out similarly. The products were identified by IR and NMR spectra. The results are summarized in Table 1.

Effect of Metal Component of Catalyst System. A mixture of 1.60 g (10 mmol) of diethyl malonate, 1.00 g (10 mmol) of methyl crotonate, 1.09 g (10 mmol) of cyclohexyl isocyanide and metal compound (0.14—0.31 mmol) was heated at 90°C for 9 hr under nitrogen. The reaction mixture was subjected to glpc analysis to determine the yield of the Michael adduct, $(EtO_2C)_2CH(CH_3)CH_2CO_2Me$.

Relative Reactivities of Acrylonitrile (AN) and Methyl Acrylate

(MA) in the Michael Addition. The ratio of the reaction rates of AN and MA in the Michael addition reactions by copper-isocyanide catalyst and by the conventional base catalysts were determined by a method of competitive reaction. An equimolar mixture of AN and MA, if necessary with a reaction solvent (toluene), was subjected to the Michael addition with an active hydrogen compound in the presence of a catalyst, and the reaction was short-stopped at a lower conversion. The amounts of the two Michael adducts from AN and MA were determined by glpc. The molar ratio of the two adducts was taken to indicate the ratio of the rate constants of AN (k_{AN}) and MA (k_{MA}) on the basis of the assumption that the Michael addition reactions of AN and MA proceed *via* the same reaction mechanism. The extent of reaction was controlled by the feed concentrations of active hydrogen compound and catalyst and the time of reaction. The rate ratios with various catalysts were determined at the same reaction temperature. The feed compositions, reaction temperatures, reaction times and conversion percentage as well as the rate ratio values are shown in Table 3.

Kinetic Study. An introductory kinetic study was carried out on the Michael addition of methylacetylacetone to MA in the presence of the copper acetylacetonate–cyclohexyl isocyanide system. A homogeneous catalyst solution was prepared by dissolving copper acetylacetonate in cyclohexyl isocyanide at room temperature.

1) *Rate Plot for Methylacetylacetone Concentration.* Under nitrogen, a mixture of MA (30.0 mmol) and methylacetylacetone (variable) was diluted with toluene to 10.0 m*l*, to which 10.0 m*l* of a toluene solution of catalyst containing 0.06 mmol of copper acetylacetonate and 6 mmol of cyclohexyl isocyanide was added. The reaction was carried out at room temperature. A small portion of the reaction mixture was taken out and analyzed by glpc. The initial tangent at time=0 of the time-conversion curve was taken as the rate. Several runs of reactions were performed with various amounts of methylacetylacetone. Fig. 1 shows the relationship between the rate and the concentration of methylacetylacetone.

2) *Rate Plot for MA Concentration.* The reaction was carried out in a similar way. The MA concentration was changed in a region from 1.03×10^{-1} mol l^{-1} to 5.00×10^{-1} mol l^{-1}. A linear relationship between the rate and the MA concentration was obtained as shown in Fig. 2.

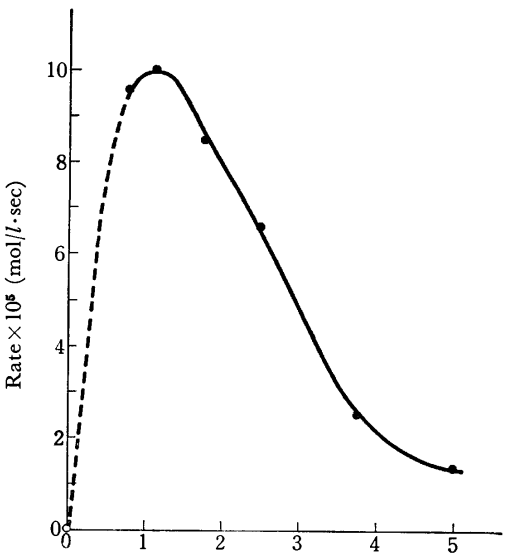

Fig. 1. Relation between the reaction rate and the concentration of methylacetylacetone.

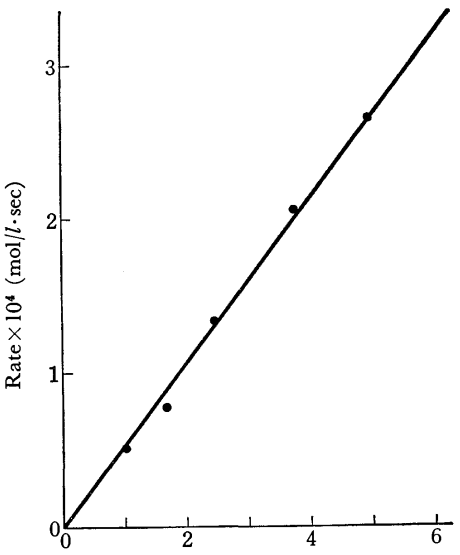

Fig. 2. Relation between the reaction rate and the concentration of methyl acrylate.

UV Examination on the Interaction of AN and MA with Cu_2O-Isocyanide System. 1) *AN - Cu_2O - Cyclohexyl Isocyanide System.* A mixture of 0.7 g (5 mmol) of Cu_2O, 2.18 g (20 mmol) of AN was diluted with acetonitrile to 10.0 m*l*. The mixture was stirred at room temperature for 1 hr. The insoluble Cu_2O was removed by decantation, and the clear homogeneous reddish-yellow solution was separated. This was diluted to AN and isocyanide concentrations of 6.6×10^{-4} mol l^{-1} with acetonitrile, and the diluted solution was subjected to UV spectroscopy examination (Shimadzu SV-50 spectrometer, Shimadzu Seisakusho, Japan). Two absorption bands were observed at $\lambda_{max}=300$ mμ and 360 mμ. The band at 300 mμ was assigned to the AN soluble oligomer formed during the course of preparation of the solution. The band at 360 mμ was observed only in the combination of the three components of AN, Cu_2O, and isocyanide. No single component and combination of two components showed absorption in this region.

2) *MA - Cu_2O - Cyclohexyl Isocyanide System.* A mixture of 0.7 g (5 mmol) of Cu_2O, 2.18 g (20 mmol) of cyclohexyl isocyanide and 1.72 g (20 mmol) of MA was diluted with acetonitrile to 10.0 m*l*, and the mixture was stirred at room temperature for 4 hr. The insoluble Cu_2O was removed by decantation, and the clear yellowish solution was diluted to MA and isocyanide concentration of 2×10^{-2} mol l^{-1} with acetonitrile, and analyzed by UV. A weak absorption band was observed at $\lambda_{max}=325$ mμ. This band was observed only in the combination of these three components.

Results and Discussion

The catalyst activity of the Cu_2O-isocyanide system for the Michael addition reaction is demonstrated in Table 1. As active hydrogen compounds, acetylacetone, malonate, benzyl cyanide, malononitrile, 2-nitropropane, alcohol, thiol, and indene were employed. No single component of Cu_2O and isocyanide alone caused the reaction. Semi-quantitative com-

Table 1. Michael addition reaction by Cu_2O-isocyanide system[a)]

a) A mixture of an active hydrogen compound, α,β-unsaturated compound, isocyanide, and cuprous oxide was heated at 90°C otherwise e, f, g, h.
b) MC: Methyl crotonate, MA: Methyl acrylate, AN: Acrylonitrile.
c) The adduct was 3-(carbomethoxyethyl)indene.
d) The adduct was $(CH_3OC)_2C(CH_3)CH{=}CHCO_2Et$ (*cis*/*trans* = 1/1).
i) **1** : $C_5H_5Cu(CN\text{-}Bu^t)$

parison of the product yields between the reaction of acrylonitrile (AN) and methyl acrylate (MA) suggests that the olefin component having cyano group at the olefin carbon atom is more reactive than the one bearing carbomethoxyl group. Selective activation of cyano-olefin will be discussed later. As a reaction intermediate, an organic complex of copper derived from the active hydrogen compound might be postulated. Requisiteness of isocyanide for the catalyst activity suggests an organic complex of copper having an essential ligand of isocyanide. In the reaction of indene, a cyclopentadiene homologue, an indenyl copper complex can be assumed to be the intermediate. In fact, we have isolated a cyclopentadienyl copper isocyanide complex (**1**) from Cu_2O, cyclopentadiene and *t*-butyl isocyanide.[10)]

1

An organocopper complex **1** has been found to cause the Michael addition reaction (See Table 1).

Table 2 shows that Cu_2O, $Cu(acac)_2$ and metallic copper are effective as the metallic component in combination with isocyanide. CuO, CuCl, and $CuCl_2$ are much less effective. Besides copper compounds, $Co(acac)_2$ is shown to be fairly effective. The results of the competitive reaction between AN and MA well characterize the Cu_2O - isocyanide system. The rate ratio k_{AN}/k_{MA} changes according to the nature of the catalyst. In the reaction by the Cu_2O-isocyanide system, the rate of AN is much higher than that of MA. The high values of the rate ratio k_{AN}/k_{MA} may be explained by the preferential coordination of AN onto copper in a copper isocyanide complex of a key intermediate. It is reasonable to assume that the coordination of AN by means of the cyano group is stronger than the coordination of MA. The effect of coordination might be explained by the following scheme 1.

$$\underset{\mathbf{2}}{Cu^I(R^1NC)_aL_b} \xrightarrow{R^2H(-LH)} \underset{\mathbf{3}}{R^2Cu(R^1NC)_c} \xrightarrow{Olefin}$$

$$\underset{\mathbf{4}}{R^2Cu(Olefin)(R^1NC)_e} \xrightarrow{R^2H} \text{Michael adduct} + \mathbf{3} \qquad (1)$$

$$(a+b \leqq 4,\ 1 \leqq c \leqq 3,\ 1 \leqq e \leqq 2)$$

The complex of copper compound and isocyanide (**2**) reacts with an active hydrogen (R^2H) to form an

organic complex of copper **3**. Replacement of a ligand of **3** by olefin gives rise to the formation of key intermediate **4**, in which the nucleophilic attack of R^2 ligand onto the coordinated olefin occurs in the sphere of ligands. In **4**, the coordination of olefin by means of cyano group will decrease the electron density of olefin bond and increase the electrophilic nature of olefin. In the competitive reaction, the higher rate of AN is due to the fact that the concentration of the complex species **4** of AN is higher than that of the corresponding species of MA. The coordination of olefin to copper/isocyanide complex has not been well established. However, UV absorption bands at 360 mμ of AN - Cu_2O - isocyanide system and at 325 mμ of MA - Cu_2O - isocyanide system might be due to the corresponding complexation. These absorptions were not observed in any single component system or in any combination of two components. Exact assignment of these bands requires further studies. Scheme-1 has been partly supported by some kinetics characters. Preliminary kinetic study was carried out on the reaction of MA with methylacetylacetone (MeAc) in the presence of the $Cu(acac)_2$ - cyclohexyl isocyanide system. As a copper component, copper acetylacetonate was employed in order to insure the homogeneousness of the reaction system. Kinetics has not been fully analyzed, and some fragmentary results which fit Scheme-1 are mentioned. Fig. 1 illustrates a strange dependence of the reaction rate upon the concentration of active hydrogen compound of MeAc. As the concentration of MeAc is increased, the rate first increases and then decreases after reaching a maximum. This exhibits a striking contrast to the corresponding relation in the base catalyzed Michael addition.[11] Anomalous change of the rate in Fig. 1 may be explained by the scheme involving coordination complexes. According to Scheme-1, the concentration of methylacetylacetonyl ligand will increase with the increase of the concentration of MeAc. However, the increase of MeAc concentration will be unfavorable to the coordination of olefin onto copper, and hence it decreases the concentration of the key intermediate of **4**. The decrease of concentration of **4** gives rise to the decrease of rate. The first order dependence of the rate upon the MA concentration is shown in Fig. 2, which is explained by an assumption that the equilibrium constant of the MA coordination onto copper is small and the concentration of **4** is regarded as being nearly proportional to the initial feed concentration of MA.

Kinetics of the γ-Ray Induced Polymerization of Ethylene in 1,2-Dichlorotetrafluoroethane

Fujio SUGANUMA, Miyuki HAGIWARA, Hiroshi MITSUI, and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma

(Received February 15, 1971)

The γ-ray induced polymerization of ethylene in bulk or in solution in the presence of 26.9—67.3 g of 1,2-dichlorotetrafluoroethane (R-114) was carried out in a 100-m*l* reactor under a pressure of 210—400 kg/cm² and at 30°C, with a dose rate of 1×10^4—9×10^4 rad/hr. The rate of the polymerization and the molecular weight of the polymer formed increased with the reaction time and the pressure. The rate also increased upon the addition of an appropriate amount of R-114. On the other hand, the molecular weight decreased with an increase in the amount of R-114. The dose-rate exponents of the rate and the molecular weight were found to be 0.8 and −0.2 respectively. These results were analyzed kinetically, and the rates and the rate constants of the initiation, propagation, transfer, and termination reactions were evaluated. Further, the roles of R-114 in the polymerization were discussed.

Polychloromethanes are known as effective radical sources for the initiation reaction of the radiation-induced polymerization of some vinyl monomers, such as styrene and methyl methacrylate.[1] The polymerizations of these monomers are promoted by the presence of such compounds. In the case of ethylene, on the contrary, both the rate of the polymerization and the molecular weight of the polymer formed are markedly depressed. In ethylene polymerization it has been found to be effective to add some fluorinated or chlorofluorinated ethanes, such as hexafluoroethane, chloropentafluoroethane, or 1,2-dichlorotetrafluoroethane.[2] Promotion by chlorofluorinated hydrocarbons is also found in the copolymerization of ethylene with tetrafluoroethylene.[3]

The purposes of this paper are to elucidate the effects of the reaction conditions on the polymerization of ethylene in the presence of 1,2-dichlorotetrafluoroethane (R-114), and to discuss the roles of R-114 in the initiation, propagation, transfer, and termination reactions from the viewpoint of kinetics.

Experimental

The reaction vessel used was a stainless-steel autoclave with a capacity of 100 m*l*. The ethylene monomer was 99.9% pure (free from CO and H_2S), containing less than 3 ppm of O_2. Reagent-grade R-114 was purified by distillation before use. After the reaction vessel had been evacuated, a definite amount of R-114 was charged in. Ethylene was then fed in at 30°C. By using a specially-designed autoclave with a quartz window, the mixture of the monomer and the solvent was observed to be existing in a homogeneous liquid phase, with no separation in the reaction vessel.[3] Polymerization runs were carried out in bulk or in solution in the presence of 26.9—67.3 g of R-114 under a pressure of 210—400 kg/cm² and at a temperature of 30°C, with dose rate of 1×10^4—9×10^4 rad/hr. During the reaction, the temperature was maintained constant within ±1°C by using an automatic controller; the pressure remained essentially constant since the monomer conversion to the polymer was kept less than 10% in all runs (in most cases, less than 5%).

The polymer yield was determined by the direct weighing of the polymer formed after it had been dried to a constant weight in a vacuum oven at room temperature. The number-average molecular weight of the polymer was obtained from osmotic pressure measurements of solutions of the polymer in tetralin at 110°C using a Hewlett-Packard osmometer, Model 502.

Results and Discussion

Effects of Reaction Conditions

Effects of R-114 and Reaction Pressure. The experimental results are summarized in Table 1.

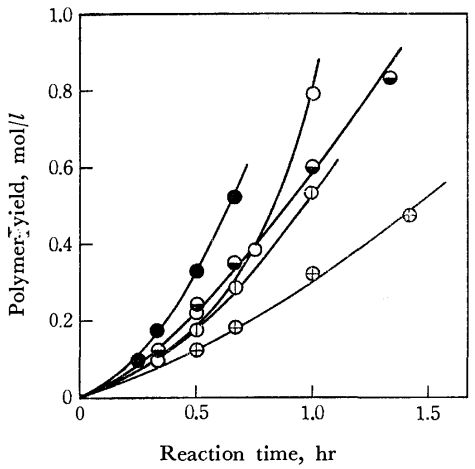

Fig. 1. Polymer yield *vs.* reaction time.
Reaction conditions: Temperature, 30°C; dose rate, 9.2×10^4 rad/hr; reactor volume, 100 m*l*; pressure (kg/cm²) and amount of R-114 (g), (○) 400, 0; (●) 400, 26.9; (◒) 400, 67.3; (◫) 310, 29.6; (⊕) 210, 29.6.

Figure 1 shows the relation between the polymer yield and the reaction time. It is clear that the rate of the polymerization increases with the time, since the time-yield relation gives an upward concave curve in all the polymerizations. A maximum rate was obtained when the amount of R-114 was varied in the range from zero to 67.3 g. The rate increased markedly with the reaction pressure, and was found to be proportional to 1.6 power of the pressure.

As can be seen in Fig. 2, the molecular weight also increases with the time, while it decreases with increase in the amount of R-114 and with the decrease in the pressure.

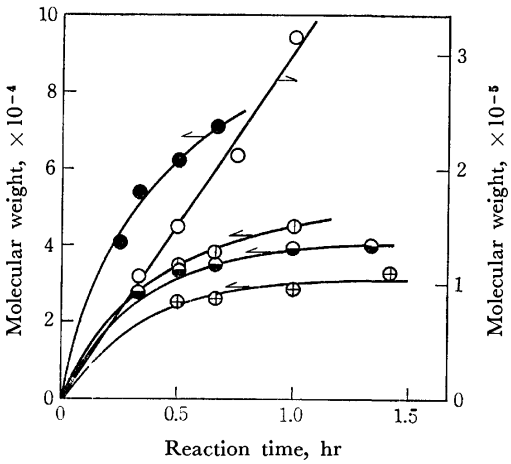

Fig. 2. Molecular weight *vs.* reaction time.
Reaction conditions are the same as in Fig. 1.

The observed increase in the rate and the molecular weight with the reaction time suggests that a stationary state with respect to the concentration of growing radicals is not realized in the polymerization. The time exponents of the polymer yield were found to be 1.9, 1.5, and 1.3 when the amounts of R-114 were 0, 26.9, and 67.3 g respectively at the pressure of 400 kg/cm². The fact that the time exponent of the polymer yield is close to 2.0 without a solvent suggests that the rate of termination is negligibly small in the bulk polymerization.[4] On the other hand, since the time exponent decreases towards unity as the amount of R-114 increases, the termination rate becomes large in the solution polymerization, which approaches a stationary state with an increase in the amount of R-114.[5]

The number of moles of the polymer chain, N_p (defined as the ratio of the polymer yield to the number-average molecular weight) given in Fig. 3 increases with the amount of R-114, and it is almost independent of the reaction pressure. The plots of N_p *vs.* the reaction time give an upward concave curve, while a straight line is obtained in the bulk polymerization. These facts suggest that the rate of transfer is small in the bulk polymerization, and that it increases with the amount of R-114.

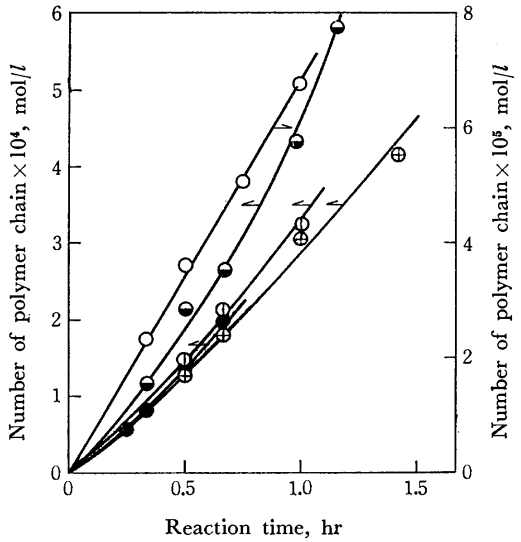

Fig. 3. Number of polymer chain *vs.* reaction time.
Reaction conditions are the same as in Fig. 1.

Effect of Dose Rate. The results are given in Table 2. Dose-rate exponents are determined from Fig. 4 to be 0.8 for the rate of the polymerization and

—0.2 for the molecular weight respectively. From this and the fact that R-114 is a precipitant of the polyethylene produced, it can be said that the termination by a mutual combination of growing radicals is not important in this polymerization.

Kinetical Consideration

Proposed Scheme of the Polymerization. On the basis of the experimental results presented above, the reaction scheme shown in Eqs. (1)—(6) can be proposed for this polymerization.

Initiation:

$$\text{M, or S} \rightsquigarrow \text{R}_1\cdot \qquad R_i=k_i f([\text{M}],[\text{S}])I \quad (1)$$

Propagation:

$$\text{M} \rightleftarrows \text{M}^*$$

$$\text{M}^* + \text{M} \overset{K_e}{\rightleftarrows} \text{M}_2^* \qquad f_{\text{M}_2^*}=K_e f_{\text{M}}^2 \quad (2)$$

.....

$$\text{R}_n\cdot + \text{M}_2^* \rightarrow \text{R}_{n+1}\cdot + \text{M}^* \qquad R_p=k_p[\text{R}_n\cdot]f_{\text{M}_2^*} = k_pK_e[\text{R}_n\cdot]f_{\text{M}}^2 \quad (3)$$

Transfer:

$$\text{R}_n\cdot + \text{XY} \rightarrow \text{R}_n\text{X} + \text{Y}\cdot \qquad R_{tr}=k_{tr}[\text{XY}][\text{R}_n\cdot] \quad (4)$$

Termination:

$$\text{S} \rightsquigarrow \text{S}\cdot \qquad R_S=k_S[\text{S}]I \quad (5)$$

$$\text{R}_n\cdot + \text{S}\cdot \rightarrow \text{R}_n\text{S} \qquad R_t=k_t[\text{S}\cdot]][\text{R}_n\cdot] \quad (6)$$

where M and S represent the ethylene monomer and R-114 respectively; M* is an excited ethylene monomer, and M_2^*, an excited ethylene dimer; f_{M} and $f_{\text{M}_2^*}$ are the fugacities of the substances indicated; $\text{R}_1\cdot$ is an initiating radical, and $\text{R}_n\cdot$, an active polymer chain composed of n monomers; XY is the substance to which the activity of $\text{R}_n\cdot$ is transferred, and S·, the primary radical formed by the radiolysis of R-114 which causes the termination; R_i, R_p, R_{tr}, R_t, and R_S are the rates of initiation, propagation, transfer, termination, and formation of S· respectively, and k's, the rate constants of these reactions; K_e is an equilibrium constant; [M], [S], [S·], and [XY], are the concentrations of M, S, S·, and XY respectively, and $f([\text{M}],[\text{S}])$, a function of [M] and [S]; where $[\text{R}_n\cdot]$ is the concentration of active polymer chains ($=\sum_{n=1}^{\infty}\text{R}_n\cdot$), and I is the dose rate.

In the above scheme, the initiating radicals are produced from both ethylene and R-114 under γ-ray irradiation. Although we can not entirely exclude the possibility that the initial stage of their formation is influenced by the presence of the hologenated solvent, which may act as a powerful electron scavenger, here it is assumed to be negligibly small. The formation of the excited ethylene dimer and its addition to a growing radical (reactions (2) and (3) are introduced with due consideration of the results of the bulk polymerization.[6,7] Further, the termination is assumed to be a combination of a growing radical with a primary radical from R-114 (reaction (6)).

Rate of Polymerization. For the reasons described above, the kinetics of the non-stationary state should be applied to this polymerization.[8] The overall rate of the polymerization, R, is expressed as:

$$R \fallingdotseq R_p = k_pK_ef_{\text{M}}^2[\text{R}_n\cdot] \quad (7)$$

where $[\text{R}_n\cdot]$ is given by:

$$[\text{R}_n\cdot] = \int_0^t R_i\text{d}t - \int_0^t R_t\text{d}t \quad (8)$$

Since the polymerization was stopped at a low conversion, [M], [S] and f_{M} are considered to be essentially constant during the reaction. Further, if a steady state is assumed with respect to the concentration of the primary radical, [S·], Eq. (9) is obtained from Eqs. (1), (6), and (8):

$$[\text{R}_n\cdot] = R_it - (k_t[\text{S}\cdot]/k_pK_ef_{\text{M}}^2)M_p \quad (9)$$

M_p is the amount of polymer formed, being approximately equal to $\int_0^t R_p\text{d}t$. Hence, the combination of Eqs. (3) and (9) leads to:

$$R_p = k_pK_ef_{\text{M}}^2R_it - k_t[\text{S}\cdot]M_p \quad (10)$$

$$M_p\Big/\int_0^t M_p\text{d}t = (1/2)k_pK_ef_{\text{M}}^2R_i\left(t^2\Big/\int_0^t M_p\text{d}t\right) - k_t[\text{S}\cdot] \quad (11)$$

According to Eq. (11), the plots of $M_p\Big/\int_0^t M_p\text{d}t$ *vs.* $t^2\Big/\int_0^t M_p\text{d}t$ should make a straight line if the proposed scheme is valid. The numerical values of these two terms are obtained from the data in Table 1, while the plots are given in Fig. 5. The intercept of the straight lines obtained gives $k_t[\text{S}\cdot]$, and the slope, $(1/2)k_pK_ef_{\text{M}}^2R_i$.

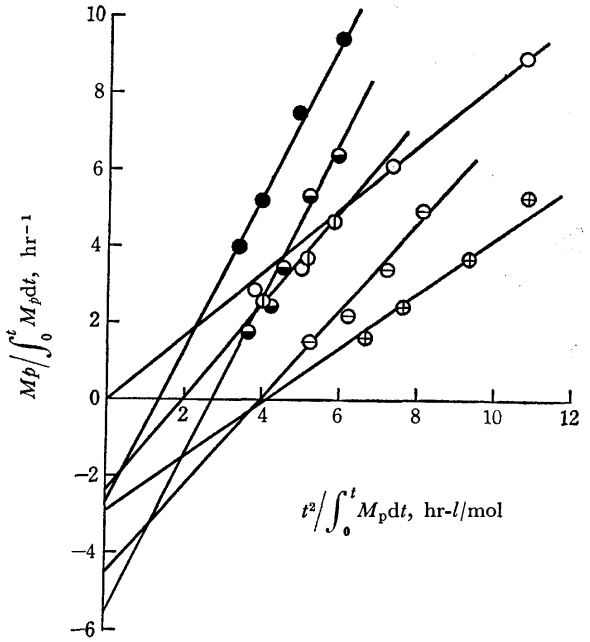

Fig. 5. $M_p/\int_0^t M_p dt$ *vs.* $t^2/\int_0^t M_p dt$.
Reaction conditions: pressure and amount of R-114, (⊖) 310 kg/cm², 57.4 g. Others are the same as in Fig. 1.

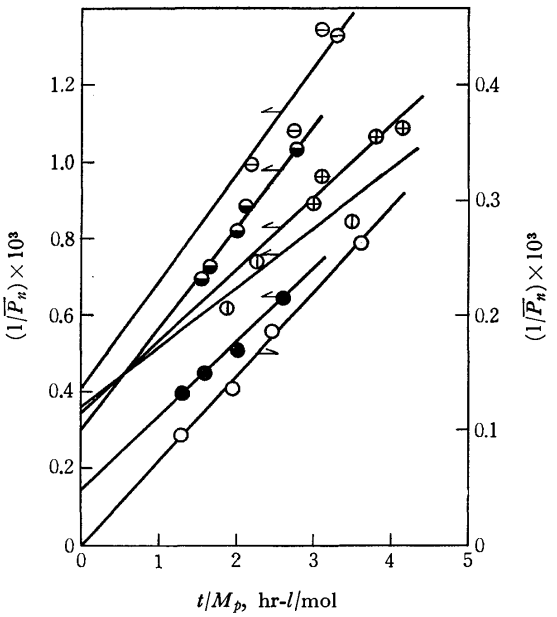

Fig. 6. $1/\overline{P}_n$ *vs.* t/M_p.
Reaction conditions are the same as in Fig. 5.

Degree of Polymerization. For the polymerization with no termination caused by the combination of growing radicals, the number-average degree of polymerization, $\overline{P}_n$, is given by Eq. (12):

$$\overline{P}_n = \int_0^t R_p dt \Big/ \left(\int_0^t R_i dt + \int_0^t R_{tr} dt \right) \qquad (12)$$

Hence, the reciprocal degree of polymerization, $1/\overline{P}_n$, is given as:

$$1/\overline{P}_n = R_i(t/M_p) + k_{tr}[XY]/k_p K_e f_M^2 \qquad (13)$$

In Eq. (13), [XY] can be assumed to be constant throughout the reaction. Figure 6 shows that the plots of $1/\overline{P}_n$ *vs.* t/M_p give a linear relation for every one of the polymerization runs. The slope of the lines is the overall rate of initiation, R_i, and the intercept on the ordinate is $k_{tr}[XY]/k_p K_e f_M^2$. After all, the numerical values of R_i, $k_p K_e$, $k_{tr}[XY]$, and $k_t[S\cdot]$ can be determined by the use of Eqs. (11) and (13). The results are summarized in Table 3.

Initiation Reaction. Since, as is shown in Table 3, the overall rate of initiation, R_i, increases markedly with the addition of R-114, it is clear that R-114 acts as an effective promotor for the initiation reaction. If the energy transfer between ethylene and R-114 does not occur, the overall rate of initiation can be represented as follows:

$$R_i = R_{iM} + R_{iS} = k_{iM}[M]I + k_{iS}[S]I = (k_{iM}[M] + k_{iS}[S])I \qquad (14)$$

where R_{iM} and R_{iS} are the rates of initiation from ethylene and R-114 respectively. Hence, R_{iS} can be evaluated with the use of R_{iM}, which is itself determined by the bulk polymerization. Although Fig. 7 shows some scatter, it can be seen that a linear relation exists between R_{iS} and the concentration of R-114. This indicates the validity of Eq. (14), and also the absence of energy transfer between ethylene and and R-114.

Table 3. Calculated rates and rate constants[a)]

Reaction pressure kg/cm²	Amount of R-114 g	Concentration mol/l		Fugacity[b)] kg/cm²		Rate and rate constant

Reaction conditions: pressure, 210—400 kg/cm²; temperature, 30°C; dose rate, 9.2×10^4 rad/hr; reactor volume, 100 m*l*.

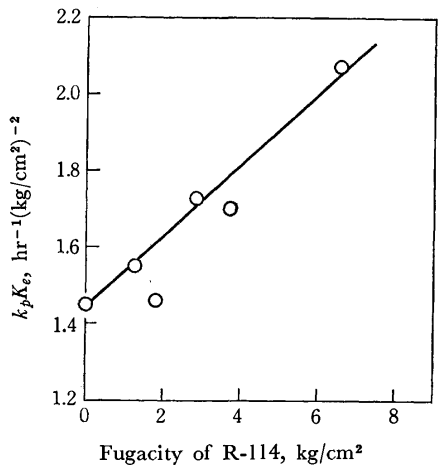

Fig. 8. Apparent rate constant of propagation, k_pK_e, *vs.* fugacity of R-114.
Reaction conditions are the same as in Fig. 7.

Propagation Reaction. The apparent rate constant of propagation, k_pK_e, is shown in Table 3 to increase with the amount of R-114. In Fig. 8 a linear relation is obtained between k_pK_e and the fugacity of R-114, f_{R-114}. This indicates that R-114 acts as promotor of the propagation reaction. The promotive effect of R-114 on the propagation reaction is also suggested by the studies of the copolymerization of ethylene with tetrafluoroethylene.[3] The mechanism of the promotion is not yet clear in detail, however, probably, strongly electronegative fluorine atoms in R-114 molecule have some effect on the reactivity of the growing radical in a solvated state. If that is the case, the linear relation between k_pK_e and f_{R-114} in Fig. 8 can be interpreted as follows.

Equation (15) shows that some of the growing radicals exist in a solvated state:

$$R_n\cdot + S \overset{K_S}{\rightleftarrows} R_n\cdots S \tag{15}$$

$$[R_n\cdots S] = K_S[R_n\cdot]f_{R-114} \tag{16}$$

If the propagation reaction in R-114 consists of the addition of M_2* to the growing radicals in a free state:

$$R_n\cdot + M_2^* \xrightarrow{k_{pf}} R_{n+1}\cdot + M^* \tag{17}$$

and to those in a solvated state:

$$R_n\cdots S + M_2^* \xrightarrow{k_{pS}} R_{n+1}\cdot + M^* + S \tag{18}$$

the rate of the propagation, R_p, can be written as Eq. (19):

$$R_p = \frac{(k_{pf}K_e + k_{pS}K_eK_Sf_{R-114})[R_n\cdot]f_M^2}{1+K_Sf_{R-114}} \tag{19}$$

Therefore, k_pK_e can be derived from a comparison with Eqs. (3) and (19) as follows:

$$k_pK_e = \frac{(k_{pf}K_e + k_{pS}K_eK_Sf_{R-114})}{1+K_Sf_{R-114}}$$

Further, if $f_{R-114}K_S$ is very small compared with unity, the above equation can be rewritten approximately as:

$$k_pK_e \fallingdotseq k_{pf}K_e + k_{pS}K_eK_Sf_{R-114} \tag{20}$$

which satisfies the linear relation in Fig. 8.

Transfer Reaction. As has been stated before, the transfer reaction is absent in the bulk polymerization, but it increases with the addition of R-114. Figure 9 shows that a straight line is obtained when k_{tr}-

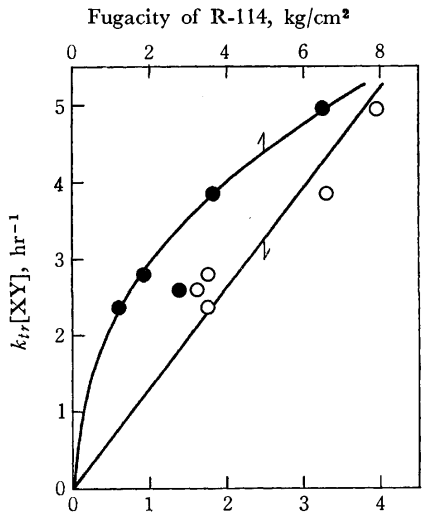

Fig. 9. Apparent rate constant of transfer, k_{tr}[XY], *vs.* concentration of R-114, and fugacity of R-114.
Reaction conditions are the same as in Fig. 7.

[XY] is plotted against the concentration of R-114, [S], rather than against its fugacity, f_{R-114}. This may indicate that radiation energy takes part in the transfer reaction. Since the transfer has been found in a previous work to increase with an increase in the number of the chlorine atoms of a halogenated hydrocarbon solvent,[2] the reaction may be the abstraction of Cl from an excited R-114 molecule by the growing radical:

$$R_n\cdot + ClCF_2CF_2Cl^* \rightarrow R_nCl + CF_2CF_2Cl \tag{21}$$

The existence of a linear relation between $k_{tr}[XY]$ and the concentration of R-114 supports the above conclusion that there is no energy transfer between ethylene and R-114.

Termination Reaction. As can be seen in Table 3, the apparent rate constant of termination, $k_t[S\cdot]$, increases with the addition of R-114. Figure 10 shows that $k_t[S\cdot]$ is nearly proportional to the concentration of R-114.

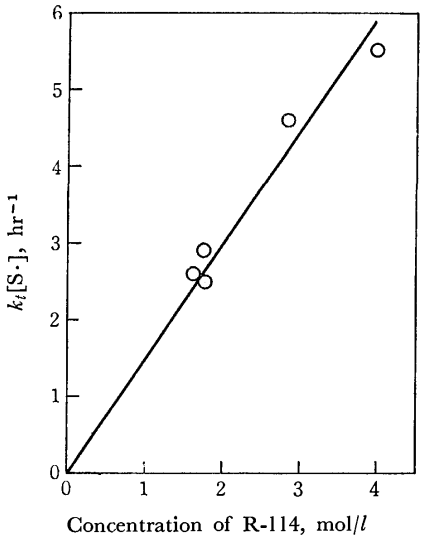

Fig. 10. Apparent rate constant of termination, $k_t[S\cdot]$, *vs.* concentration of R-114.
Reaction conditions are the same as in Fig. 7.

In this polymerization, as has been described above, the radicals formed from R-114 act both as initiators and as terminators. The mass spectrum of R-114 suggests that the radicals from R-114 are mainly CF_2Cl, plus smaller amounts of C_2F_4Cl and Cl.[2] Highly reactive radicals may contribute to the initiation more than those with less reactivity.

Recently, a semi-empirical Eq. (22) was proposed for use in estimating the activation energy of a radical-addition reaction to vinyl monomers (Eq. (23)):[10]

$$E_{a,R} = D_\pi - \phi D_\pi D_f \qquad (22)$$

$$R\cdot + \diagdown C{=}C \diagup \rightarrow R\text{-}\overset{|}{C}\text{-}\overset{|}{C}\cdot \qquad (23)$$

In Eq. (22), D_π is a π-bond dissociation energy of the monomer, D_f is that of the δ-bond formed in the reaction, and ϕ is a constant. Since D_π is constant in this polymerization, it is clear that the activation energy needed to form an initiating radical depends solely on D_f, and that it decreases with an increase in D_f. This means that the radical, R·, will make a greater contribution to the initiation reaction if it can form a strong R-C bond in the reaction with ethylene.

Table 4. Dissociation energy of the bond, R-CH_3

R	D_{R-CH_3} kcal/mol	$\Delta H_{f,R}$ kcal/mol
F	108[12]	
CF_3	90,[13] 117[14]	
CH_2Cl	84.3[a]	27.7[b]
CH_3	83.2[a]	31.5
C_2H_5	81.4[a]	25.1
$CHCl_2$	80.1[a]	20.9[b]
Cl	78.7[a]	28.5
CCl_3	77.7[2], 78.4[a]	16.2[b]

a) Calculated from, $D_{R-CH_3}=\Delta H_{f,R}+\Delta H_{f,CH_3}-\Delta H_{f,R-CH_3}$ where, ΔH_f=standard heat of formation.
b) Estimated from the values of bond dissociation energy listed in Table 9 (p 24) of Ref. 11.

Table 4 gives the dissociation energy of the bonds between several R·'s and the CH_3 radical. If R· is the fluorine atom or a fluorine-containing radical, the bond with CH_3 is stronger than that of such hydrocarbon radicals as CH_3 or C_2H_5. Substitution by the chlorine atom, on the contrary, generally weakens the bond, although one mono-substituted radical, CH_2Cl, exceptionally forms a strong bond. From these facts, it seems reasonable to speculate that the strength of the R-C bond may be in the order of:

$$CF_2Cl,\ C_2F_4Cl,\ CF_3 > CH_2Cl,\ CH_3 > CHCl_2 > Cl,\ CCl_3$$

Hence, the order of the activation energy may be given as:

$$E_{a,CF_2Cl},\ E_{a,C_2F_4Cl} \ll E_{a,Cl}$$

Thus, R-114 can probably contribute to the initiation through reactions (24) and (25):

$$CF_2Cl + CH_2{=}CH_2 \rightarrow CF_2Cl\text{-}CH_2\text{-}CH_2 \qquad (24)$$

$$C_2F_4Cl + CH_2{=}CH_2 \rightarrow C_2F_4Cl\text{-}CH_2\text{-}CH_2 \qquad (25)$$

and to the termination through reaction (26):

$$R_n\cdot + Cl \rightarrow R_nCl \qquad (26)$$

Reactions of Alkylidenetriphenylphosphoranes with Sulfur

Hirokazu TOKUNAGA, Kin-ya AKIBA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 25, 1971)

Reaction of diarylmethylenetriphenylphosphoranes with sulfur gave thiobenzophenones and triphenylphosphine sulfide in good yields. Reaction of benzylidenetriphenylphosphoranes with sulfur gave triphenylphosphine sulfide and 5,7-diphenyl-1,2,3,4,6-pentathiepane. More active alkylidenetriphenylphosphoranes such as isopropylidene- or *sec*-butylidenetriphenylphosphorane gave the corresponding phosphonium betaine containing sulfur atoms or phosphonium salt produced through air oxidation and hydrolysis of the betaine. α-Benzoylbenzylidenetriphenylphosphorane did not react with sulfur. Reactivity of alkylidenephosphoranes toward sulfur was briefly discussed.

Many examples are known on the formation of carbonyl or olefinic compounds by the reaction of alkylidenephosphoranes (I) with oxygen.[1-4] However, only a few examples have been reported on the reactions of I with sulfur,[5,6] although thiocarbonyl compounds could not be isolated.

We investigated the reaction of I with sulfur in more detail, in order to clarify this reaction.

Results and Discussion

Reaction of Diarylmethylenetriphenylphosphoranes (II). Phosphoranes (II) were prepared by adding the corresponding phosphonium bromide to sodium ethoxide in benzene or chlorobenzene, and were allowed to react with sulfur under reflux to give thiobenzophenones (III) and triphenylphosphine sulfide (IV) in good yields. Thiobenzophenones were identified by conversion into their phenylhydrazones. The results are summarized in Table 1.

Table 1. Reactions of II with sulfur

II	Solvent	III	(%)	Mp (Bp) (°C)	IV (%)
IIa	C_6H_6	IIIa	85	49—51	96
	C_6H_5Cl		80	(lit,[7] 53—54)	89
IIb	C_6H_6	IIIb	70[a]	71—76	69[a]
	C_6H_5Cl		52[a]	(lit,[8] 75—76)	62[a]
IIc	C_6H_6	IIIc	50[a]	85—87	67[a]
				(lit,[9] 90.5—91.5)	
IId	C_6H_6	IIId	70[a]	105—110	95[a]
				(lit,[9] 108.5—109.5)	
IIe	C_6H_6	IIIe	57[a]	(136—138/0.3 mmHg)	63[a]
	C_6H_5Cl		63[a]		67[a]
IIf	C_6H_6	IIIf	66[a]	(145—146/0.22 mmHg)	67[a]
	C_6H_5Cl		51[a]		66[a]

a) The yields were calculated on the basis of phosphonium salts used.

$$Ph_3P{=}CArAr' + S_8 \rightarrow ArAr'C{=}S + Ph_3P{=}S$$
II III IV

a: Ar=Ar'=Ph; b: Ar=Ar'=*p*-MeC_6H_4;
c: Ar=Ar'=*p*-ClC_6H_4; d: Ar=Ar'=*p*-BrC_6H_4;
e: Ar=Ph, Ar'=*p*-MeC_6H_4; f: Ar=Ph, Ar'=*p*-ClC_6H_4

Under the present conditions, thiobenzophenones did not react further with II to give olefinic compounds.

Reactions of Benzoylmethylenetriphenylphosphorane (V), α-Benzoylbenzylidenetriphenylphosphorane (VII) and Phenyliminotriphenylphosphorane. Benzoylmethylenetriphenylphosphorane (V) reacted easily with sulfur in refluxing benzene to give IV (88%) and an oily substance (VI), the structure of which corresponds to the trimer or tetramer of benzoylthioformaldehyde.

$$Ph_3P{=}CH{-}COPh + S_8 \rightarrow Ph_3P{=}S + (PhCOCHS)_n$$
V IV VI (n=3—4)

Desulfurization of VI with Raney Ni gave ethylbenzene and acetophenone which were identified by vapor phase chromatography (vpc). Distillation of VI gave only acetophenone.

The reaction of VII with sulfur was attempted in order to obtain monothiobenzil,[10] VII was recovered quantitatively.

$$Ph_3P{=}CPh(COPh) + S_8 \rightarrow \text{no reaction}$$
VII

Phenyliminotriphenylphosphorane did not react with sulfur in refluxing benzene even in the presence of basic catalysts.

Reaction of Benzylidenetriphenylphosphorane (VIII). The reaction of VIII with sulfur gave IV and a new compound (IX), $C_{14}H_{12}S_5$, in 83 and 14% yields in a short time, respectively. The prominent peaks in the MS spectrum of IX were *m/e* 340 (M^+, 4), 276 ($(PhCH)_2S_3^+$, 20), 220 ($PhCHS_4H_2^+$, 10), 219 ($PhCHS_4H^+$, 6), 218 ($PhCHS_4^+$, 48), 156 ($PhCHS_2H_2^+$, 12), 155 ($PhCHS_2H^+$, 35), 154 ($PhCHS_2^+$, 73), 153 ($PhCS_2^+$, 98), 124 ($PhCHSH_2^+$, 14), 123 ($PhCHSH^+$, 49), 122 ($PhCHS^+$, 93), 121 ($PhCS^+$, 100), 78 (PhH^+, 78) and 77 (Ph^+, 78).

$$Ph_3P{=}CHPh + S_8 \rightarrow Ph_3P{=}S + (PhCH)_2S_5$$
VIII IV IX

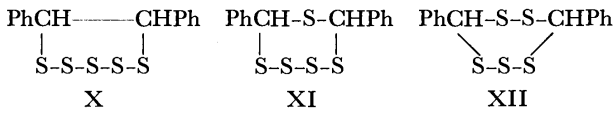
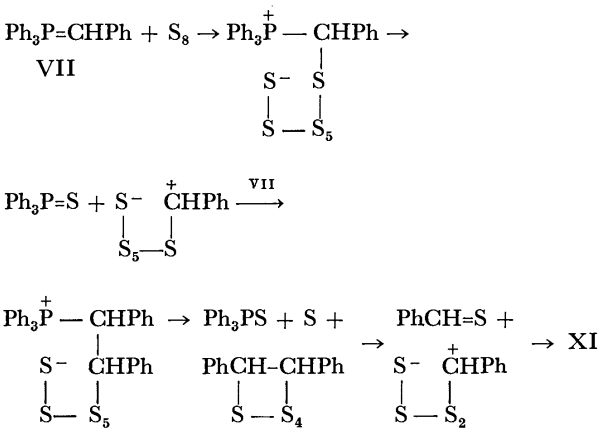
With regard to the structure of IX, three isomers, X, XI, and XII, are considered to be possible.



X XI XII

The structure X is excluded, because desulfurization of IX with Raney Ni gave no bibenzyl but toluene (58%). It is difficult to distinguish XI from XII with MS data, but the presence of the weak peak at *m/e* 212, which is attributable to stilbene episulfide, might favor XI to XII.

From the analogy of formation mechanism of ozonide,[11] the structure XI is also more favorable.

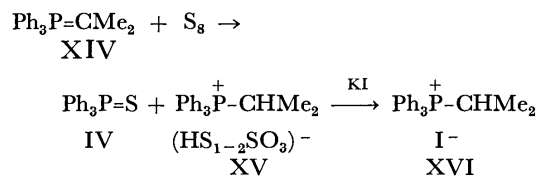


From the above facts, IX is tentatively assigned as 5,7-diphenyl-1,2,3,4,6-pentathiepane (XI).

Very recently, Mägerlein and Meyer have reported that arylmethylenetriphenylphosphoranes gave 1,2-diarylethylenes by reactions with sulfur at 100—120°C, and that triphenylphosphine sulfide and resinous material were obtained at 50—60°C.[12] In our case, a small amount of *cis*- and *trans*-stilbenes was also detected.

Reactions of Active Alkylidenephosphoranes. In the reaction of methylenetriphenylphosphorane (XIII) with sulfur at 70°C, brown precipitates appeared and unidentified gas evolved during the reaction. The gas reacted with metallic mercury but its structure could not be determined by means of IR spectrum. The brown precipitates gradually disappeared during the reaction and only IV was isolated in 74% yield after 6 hr.

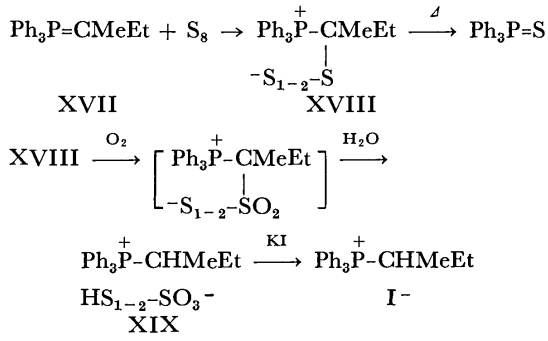
More active isopropylidenetriphenylphosphorane (XIV) gave large amounts of brown precipitates, which produced IV on heating at 200°C. During the usual treatment, the brown precipitates changed to phosphonium salt (XV), which possesses sulfonate group and gives isopropyltriphenylphosphonium iodide (XVI) with potassium iodide quantitatively. Absorptions at 1230, 1020, and 605 cm^{-1} in the IR spectrum of XV are consistent with those of sulfonate group.



XIV IV XV XVI

In the case of *sec*-butylidenetriphenylphosphorane (XVII), large amounts of brown precipitates appeared in a similar way. The brown precipitates did not show absorptions attributable to sulfonate group in the IR spectrum, when the IR spectrum was measured immediately, but underwent oxidation and hydrolysis in air to give phosphonium salt (XIX), which possesses sulfonate group and also gives the corresponding iodide with potassium iodide.

Therefore, in the cases of the most active phosphoranes the reaction stopped at a stage of addition of sulfur to the P=C bond to give betaine (*e.g.*, XVIII), which is oxidized in air and hydrolyzed to form phosphonium salt possessing sulfonate group during the course of treatment.



XVII XVIII XIX

Reactivities of Phosphoranes toward Sulfur. The activity of phosphoranes used is considered to decrease in the following order:

$Ph_3P{=}CMeEt \approx Ph_3P{=}CMe_2 > Ph_3P{=}CH_2 > Ph_3P{=}CHPh >$
XVII XIV XIII VIII

$Ph_3P{=}CArAr' > Ph_3P{=}CHCOPh \gg Ph_3P{=}CPh(COPh)$
II V VII

The most active phosphoranes (XIV and XVII) gave betaine with sulfur. The cleavage of the P=C bond scarcely occurred at 70—80°C. Phosphorane XIII also gave brown precipitates, which are considered to be betaine, but the precipitates disappeared after heating for a long period to produce triphenylphosphine sulfide, indicating that the cleavage of the P=C bond occurred very slowly.

The most stable phosphorane (VII) did not react with sulfur, and moderately active phosphoranes (VIII, II and V) underwent a cleavage of the P=C bond with sulfur easily.

Experimental

Materials. Diphenylmethylenetriphenylphosphorane (IIa) was prepared from diphenylmethyltriphenylphosphonium bromide and sodium ethoxide, mp 169—170°C (lit,[13] 174°C). Phosphonium salts were prepared from triphenylphosphine and the corresponding halides without solvent. They are summarized in Table 2.

Benzoylmethylenetriphenylphosphorane (V) was prepared by the method of Ramirez,[17] mp 180—181°C (lit, 178—180°C). α-Benzoylbenzylidenetriphenylphosphorane (VII) was prepared by the method of Trippett,[18] mp 190.5—191.8°C (lit, 191—192°C). Phenyliminotriphenylphosphorane was prepared by the method of Staudinger,[5] mp 129—131°C (lit, 131—132°C).

Reaction of Diphenylmethylenetriphenylphosphorane (IIa) with Sulfur. *a) In benzene*: A mixture of 23.4 g (0.055 mol) of IIa, 3.5 g (0.11 g atom) of sulfur, and 200 m*l* of dry benzene was heated at 80°C for one hour with stirring under nitrogen. The solvent was distilled off, and the residual blue oil was distilled at 104—107°C under a pressure of 0.5 mmHg. The deep violet distillate (IIIa) solidified, mp 49—51°C (mixt mp 49—51°C, lit,[7] 53—54°C), yield 9.3 g (85%). Recrystallization of the residue of the distillation twice from ethanol gave triphenylphosphine sulfide (IV) (15.5 g, 96%), mp 156—158°C (lit,[19] 157.5°C).

b) In Chlorobenzene: A mixture of 16.7 g (0.039 mol) of IIa, 2.54 g (0.078 g atom) of sulfur, and 150 m*l* of dry chlorobenzene was refluxed, and the reaction mixture was treated in a similar manner to that described in a) to give IIIa (6.2 g, 80%) and IV (10.2 g, 89%).

Reaction of Diarylmethylenetriphenylphosphoranes with Sulfur. A typical procedure is described for the reaction of di-*p*-tolylmethylenetriphenylphosphorane (IIb).

Sodium ethoxide was prepared from 1.17 g (0.051 g atom) of sodium metal and 100 m*l* of absolute ethanol. Ethanol was distilled off, and 400 m*l* of dry benzene was then added and about 100 m*l* of benzene was distilled off to remove ethanol as an azeotropic mixture. After the mixture was cooled to room temperature, 29.7 g (0.055 mol) of di-*p*-tolylmethyltriphenylphosphonium bromide was added. The color of the mixture slowly turned red. After one hour, the red solution was transferred through a G-4 glass-filter to a 500 m*l* three-necked flask, fitted with a reflux condenser, a gas-inlet tube and a stirrer under nitrogen. The filtrated red solution, 3.2 g (0.1 g atom) of sulfur was added. The mixture was then refluxed with stirring for one hour, during which the color of the reaction mixture turned blue rapidly. After the solvent was distilled off, the residual blue oil was distilled at 145—150°C under a pressure of 0.3 mmHg. The deep violet distillate (IIIb) (8.5 g, 70%) solidified, mp 71—76°C (lit,[8] 75—76°C). From the residue of the distillation, 11.0 g (69%) of IV was obtained.

When chlorobenzene was used as a solvent instead of benzene, the yields of IIIb and IV were 52 and 62%, respectively, on the basis of di-*p*-tolylmethyltriphenylphosphonium bromide.

Reaction of Benzylmethylenetriphenylphosphorane (V) with Sulfur. a) A mixture of 9.5 g (0.025 mol) of V and 1.6 g (0.05 g atom) of sulfur and 40 m*l* of dry benzene was refluxed with stirring for one hour under nitrogen and the solvent was distilled off. The residual oil was chromatographed on silica gel. Elution with benzene-petroleum ether (3 : 7) gave white crystals after evaporation of the solvent. White crystals (IV) were recrystallized twice from ethanol, mp 155—158°C, yield 6.5 g (88%). Elution with benzene gave an orange oil (VI) after the evaporation of the solvent. Purification of the oil was unsuccessful. The yield was 3.0 g (80%). IR (neat): 1650 cm^{-1} (C=O); NMR ($CDCl_3$): τ 2.3—3.0 (5H, multiplet) and 5.82 (1H, singlet).

Found: C, 64.49; H, 3.89; S, 17.09%; mol. wt., 450—600 (by freezing point depression of benzene). Calcd for C_8H_6OS: C, 63.97; H, 4.03; S, 21.35%; mol. wt., 150.

A mixture of Raney Ni (W-7) prepared from 4 g of commercial Raney alloy and 0.5 g of the orange oil in 30 m*l* of ethanol was refluxed with stirring for 3 hr. From the filtrate, ethylbenzene and acetophenone were detected by vpc.

b) From the reaction mixture of 19 g (0.05 mol) of V and 3.2 g (0.1 g atom) of sulfur in 200 m*l* of dry benzene, the solvent was distilled off. The residual oil was distilled at 105°C under a pressure of 33 mmHg. The distillate (1.0 g, 17%) was identified as acetophenone by IR and vpc, but acetophenone was not detected from the reaction mixture by vpc.

Reaction of Methylenetriphenylphosphorane (XIII) with Sulfur. XIII was prepared from 19.1 g (0.054 mol) of methyltriphenylphosphonium bromide and sodium amide in liquid ammonia. Ammonia was then removed. After addition of 200 m*l* of dry benzene, the mixture was refluxed for one hour to remove ammonia completely, cooled and transferred to a separating funnel through a glass-filter. The solution was added dropwise to a mixture of 3.2 g (0.1 g atom) of sulfur and 300 m*l* of dry benzene at 70°C with stirring over 2 hr. During the reaction, brown precipitates appeared and a gaseous product which reacted with mercury metal was formed. When refluxing was continued for 6 hr the brown precipitates disappeared. After removal of the solvent the residual oil was chromatographed on silica gel. Elution with benzene - petroleum ether (1 : 1) gave IV (11.7 g, 74%).

Reaction of Benzylidenetriphenylphosphorane (VIII) with Sulfur. VIII prepared from 22.1 g (0.051 mol) of benzyltriphenylphosphonium bromide in liquid ammonia and sodium amide, was added dropwise to a solution of 3.2 g (0.1 g atom) of sulfur in 300 m*l* of dry benzene over a period of two hours at 70°C. The reaction mixture was cooled and the solvent was distilled off. The residual oil was chromatographed on silica gel. Elution with benzene - petroleum ether (1 : 10) gave white crystals after evaporation of the solvent. The white crystals (IX) were recrystallized twice from benzene - petroleum ether (1 : 1) and chloroform, mp 179—181.5°C. The crude yield was 1.23 g (14%).

Found: C, 49.23; H, 3.56; S, 46.67%; mol. wt., 351 (Rast), 340 (MS). Calcd for $C_{14}H_{12}S_5$: C, 49.37; H,

3.55; S, 47.07%; mol wt, 340.

A mixture of Raney Ni (W-7), prepared from 2 g of commercial Raney alloy, 57 mg (0.168 mmol) of IX and 30 m*l* of ethanol was refluxed with stirring for 4 hr, and filtered. From the filtrate, toluene (58%) was detected by v.p.c.

Elution with benzene-petroleum ether (1 : 10) gave also a small amount of *trans*-stilbene, mp 122—124°C, and the presence of *cis*-stilbene was indicated by IR spectroscopy. Elution with benzene-petroleum ether (1 : 1) gave 12.5 g (83%) of IV.

Reaction of Isopropylidenetriphenylphosphorane (XIV) with Sulfur. XIV prepared from 25.9 g (0.06 mol) of isopropyltriphenylphosphonium iodide with sodium amide in liquid ammonia, was added dropwise to a solution of 4.0 g (0.12 g atom) of sulfur in 300 m*l* of dry benzene over a period of 3 hr at 70°C. Brown precipitates appeared and a gaseous product which reacted with mercury metal, evolved during the reaction. The reaction mixture was cooled and filtered. The brown precipitates which gave IV on heating to 200°C for 2 hr, were treated with active charcoal in ethanol several times to obtain white crystals (XV) (12.0 g, 46%), which were recrystallized three times from ethanol,mp181—182.0°C.

Found: C, 57.32; H, 5.20; S, 19.30%. Calcd for $C_{21}H_{23}PO_3S_{2.65}$: C, 57.40, H, 5.28; S, 19.34%.

After removal of the solvent from the filtrate, IV (6.8 g, 38.5%) was obtained by silica gel chromatography. Compound (XV) (0.125 g, 0.28 mmol) in 20 m*l* of chloroform was stirred with 1.68 g of potassium iodide in 20 m*l* of water for 10 hr. Yellow crystals obtained from the organic layer were recrystallized twice from ethanol, and identified as isopropyltriphenylphosphonium iodide by comparison of its IR spectrum with that of an authentic sample and by mixed melting point (mp 195.5—196.5°C) with an authentic sample (lit,[14] 195—196°C). The yield was 0.102 g (81%). A mixture of XV (0.457 g, 1.04 mmol) and 6 m*l* of aqueous hydrogen iodide (57%) quickly turned red and black precipitates appeared and hydrogen sulfide evolved. The black precipitates consisted of iodine and isopropyltriphenylphosphonium iodide.

Reaction of sec*-Butylidenetriphenylphosphorane (XVII) with Sulfur.* XVII, prepared from 22.7 g (0.05 mol) of *sec*-butyltriphenylphosphonium iodide with sodium amide in liquid ammonia, was added dropwise to a solution of 3.2 g (0.1 g atom) of sulfur in 300 m*l* of dry benzene over a period of two hours at 70°C. Brown precipitates appeared and a gaseous product which reacted with mercury metal evolved during the reaction. The reaction mixture was cooled and filtered. The yield of brown precipitates was 8.0 g, mp 125—130°C (dec) and the IR spectrum exhibited the absence of sulfonate group. The brown precipitates which also gave IV on heating up to 200°C were treated with active charcoal in ethanol several times. White crystals (XIX) thus obtained were recrystallized three times from ethanol, mp 183.0—185.0°C, yield 7.7 g (33%).

Found: C, 58.38; H, 5.67; S, 18.64%. Calcd for $C_{22}H_{25}PO_3S_{2.65}$: C, 58.28; H, 5.56; S, 18.74%.

After removal of the solvent from the filtrate and chromatography on silica gel, elution with benzene-petroleum ether (1 : 1) gave IV (7.9 g, 54%). Compound (XIX) (0.117 g, 0.25 mmol) in 20 m*l* of chloroform was stirred with 1.17 g of potsssium iodide in 20 m*l* of water for 2 hr. Yellow crystals from the organic layer were recrystallized twice from ethanol-ether, and identified as *sec*-butyltriphenylphosphonium iodide. The yield was 83.4 mg (75%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 509—515 (1972)

Reaction of Enol Ethers with Carbenes. X.[1] Ring Opening of 2,2-Dichlorocyclopropyl Phenyl Sulfides[2]

William E. PARHAM, Shoji KAJIGAESHI,[3] and Siemen H. GROEN[4]

School of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455, *U.S.A.*

(Received March 13, 1971)

The ring opening reactions of six known or new 2,2-dichlorocyclopropyl phenyl sulfides have been carried out with potassium *t*-butoxide in *t*-butyl alcohol and with pyridine. The products were enynes, butadienes, allenes and, as minor products, α,β-unsaturated aldehydes containing the phenylmercapto group. Reaction of a mixture of *cis*- and *trans*-1,1-dichloro-2-methyl-3-phenylmercaptocyclopropane (**2**) with pyridine gave unchanged *trans*-isomer. This apparent selectivity is explained on the basis of the steric effects for ring opening.

In recent years the ring opening of *gem*-dichlorocyclopropanes, derived from enol ethers with dichlorocarbene, have been investigated by Parham *et al.*[5] and by Skattebøl,[6] and the subject has been reviewed by Parham and Schweizer.[7] In order to gain additional information on such ring opening reactions, we have prepared the following six *gem*-dichlorocyclopropanes (**1**—**6**) by the reaction of the corresponding α,β-unsaturated sulfides with dichlorocarbene, and have studied their reactions with potassium *t*-butoxide in *t*-butyl alcohol and with pyridine.

The ring opening reactions probably occur by an El elimination process of the type illustrated in Eq. (1) in a manner analogous to that established for the alkoxy analogues.[5-7]

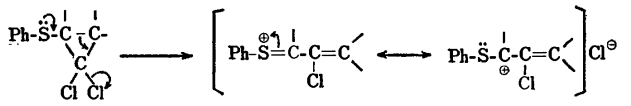
Scheme

In the case of the reaction of **2** with potassium *t*-butoxide in *t*-butyl alcohol, we isolated an α,β-unsaturated aldehyde. Such elimination reaction has been reported.[8] The results of these studies constitute the subject of this report.



(1)

Results

Preparation of α,β-Unsaturated Sulfides (Carbene Acceptors). 1-Methyl-1-phenylmercaptoethylene (**7**),[9] 2-phenylmercapto-2-butene, (**8**), and 3-methyl-2-phenylmercapto-2-butene (**10**) were prepared by distillation of acetone diphenylmercaptol,[10] ethyl methyl ketone diphenylmercaptol, and isopropyl methyl ketone diphenylmercaptol with potassium bisulfate, respectively. 2-Methyl-1-phenylmercapto-1-propene (**9**)[11] was obtained by isomerization of 2-

a) The distillate from acetone diphylmercaptol should be trapped in an alkali solution because product **7** is easily polymerized by acid (thiophenol) which co-distills.
b) Compound **8** is a mixture of *cis* and *trans* isomers.

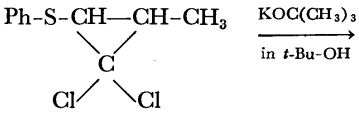
methyl-1-phenylmercapto-2-propene[12] with sodium ethoxide using a procedure described by Tarbell *et al.*[13] for phenyl propenyl sulfide from allyl phenyl sulfide. The yields, analytical results and some spectral data of the olefins are summarized in Tables 1 and 2.

Preparation of 2,2-Dichlorocyclopropyl Phenyl Sulfides. The reactions of **7**, **8**, **9**, and **10** with ethyl trichloroacetate and sodium methoxide in olefin-free petroleum ether gave **3**, **4**, **5**, and **6**, respectively. The yields, analytical results and some spectral data of the 2,2-dichlorocyclopropyl phenyl sulfides are summarized in Tables 3 and 4.

Ring Opening of 1,1-Dichloro-2-phenylmercaptocyclopropane (1). The product of reaction of **1**[14] with potassium *t*-butoxide in *t*-butyl alcohol was an unidentified black tar. The parent cyclopropane **1** was quite stable in hot pyridine (50 hr) and the starting material was recovered in 80% yield.

Ring Opening of 1,1-Dichloro-2-methyl-3-phenylmercaptocyclopropane (2). The reaction of **2**[14] with potassium *t*-butoxide in *t*-butyl alcohol gave a compound assumed to be 1-formyl-1-phenylmercaptopropene (mixture of two geometrical isomers) (**13**), and a mixture[15] of 1-phenylmercaptobut-3-en-1-yne (**11**)[16] and 1-phenylmercaptobut-1-en-3-yne (*cis*- and *trans*-isomers) (**12**) (Eqs. (2) and (3)). Further evidence for the structure of **11** and **12** was obtained by an independent synthesis (50% yield) of the mixture of **11** and **12** by the reactions of 1-chloro-1-



2 (*cis*-, *trans*-)

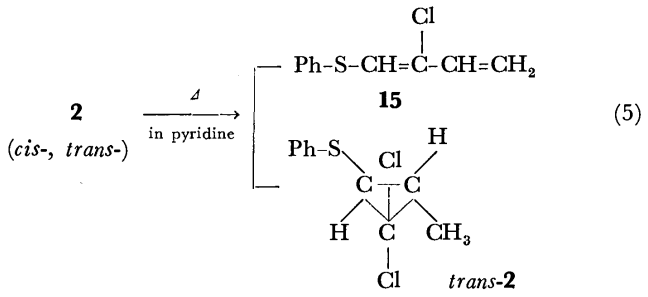
15) The mixture was not separated by fractional distillation.

16) A. A. Petrov, S. I. Radchenko, K. S. Mingaleva, I. G. Savich, and V. B. Lebedev, *J. Gen. Chem., (USSR)*, **34**, 1911 (1964).

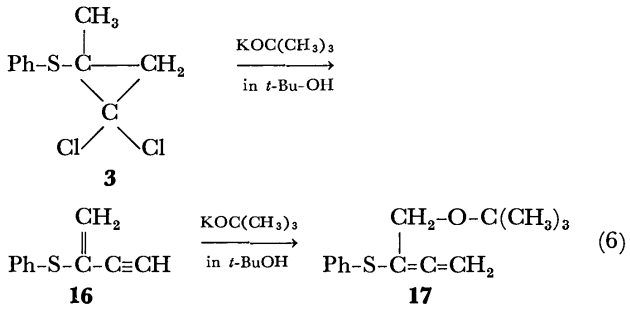
phenylmercaptobuta-1,3-diene (**14**)[17] with potassium *t*-butoxide in *t*-butyl alcohol (Eq. (4)).

The reaction of **2** with a large excess of pyridine under conditions of reflux for 40 hr was studied, and a mixture[15] of 2-chloro-1-phenylmercaptobuta-1,3-diene (**15**) and *trans*-**2** was obtained (Eq. (5)). Butadiene **15** and *trans*-**2** were detected by means of their NMR spectra. Compound **2** (mixture of *cis*- and *trans*-isomers) shows two doublets for S–CH, at τ 7.18 with J=10.0 Hz due to *cis*-isomer and at τ 7.68 with J=7.0 Hz due to *trans*-isomer.[14] The above reaction products showed only a doublet for S-CH due to the *trans*-isomer.



(5)

*Ring Opening of 1,1-Dichloro-2-methyl-2-phenylmercaptocyclopropane (**3**).* The products from the ring opening reaction of **3** with potassium *t*-butoxide in *t*-butyl alcohol were 2-phenylmercaptobut-1-en-3-yne (**16**) (20% yield) and 4-*t*-butoxy-3-phenylmercaptobuta-1,2-diene (**17**) (20% yield) contaminated with a trace amount of a compound containing aldehyde group (the aldehyde group was only detected by IR and NMR spectra: ν_{max} 1670 cm^{-1}; two doublets at τ −0.13, −0.03 (J=6 Hz), and at τ 0.23, 0.33 (J=6 Hz)). Compound **17** was a secondary product derived from **16**. These results are shown in Eq. (6).



(6)

In order to prove the structure of **17**, the reaction of **17** with Raney nickel (W-2) in ethyl alcohol was performed. Benzene and *n*-butyl *t*-butyl ether (**18**)[18] were identified as reduction products. On the other hand, the products from the reduction of **17** with hydrogen in the presence of Raney nickel (W-2) at room temperature were *sec*-butyl phenyl sulfide (**19**)[19] and *t*-butyl 2-phenylmercaptobutyl ether (**20**).

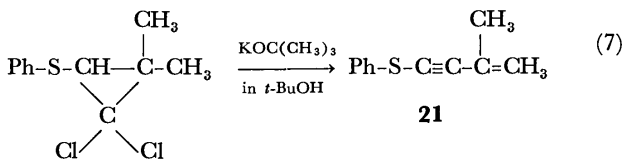
The isolated **16**[20] was converted into **17** (34% yield) by reaction with potassium *t*-butoxide in *t*-butyl alcohol.

When a solution of **3** in pyridine was refluxed for 70 hr, only black tar was obtained.

*Ring Opening of 1,1-Dichloro-2,3-dimethyl-2-phenylmercaptocyclopropane (**4**).* The products of reaction of **4** (mixture of *cis*- and *trans*-isomers) with potassium *t*-butoxide in *t*-butyl alcohol consisted of a considerable amount of black tar and very unstable enyne derivatives (IR, 3290, 2230, 2110, 920, and 800 cm^{-1}). The derivatives turned dark brown in contact with air, and polymerized. The reaction of **4** with hot pyridine was also studied. A large amount of black tar and a small amount of an unidentified liquid were obtained.

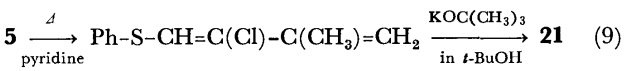
*Ring Opening of 1,1-Dichloro-2,2-dimethyl-3-phenylmercaptocyclopropane (**5**).* The product from the ring opening reaction of **5** using potassium *t*-butoxide was 3-methyl-1-phenylmercaptobut-3-en-1-yne (**21**) (60% yield) (Eq. (7)). The structure of **21** was confirmed by its independent synthesis by dehydrohalogenation of 1-chloro-3-methyl-1-phenylmercaptobuta-1,3-diene (**22**)[12] (Eq. (8)).

The ring opening reaction of **5** with pyridine was carried out, and 2-chloro-3-methyl-1-phenylmercaptobuta-1,3-diene (**23**)[21] (48% yield) was isolated. Compound **23** was easily converted into **21** by refluxing with a solution of potassium *t*-butoxide in *t*-butyl alcohol (50% yield) (Eq. (9)).



(7)

(8)



(9)

*Ring Opening of 1,1-Dichloro-2,3,3-trimethyl-2-phenylmercaptocyclopropane (**6**).* Attempts to effect ring opening of **6** with alkoxides (potassium *t*-butoxide in *t*-butyl alcohol, sodium ethoxide in ethyl alcohol and sodium methoxide in methyl alcohol) failed, and starting material **6** was recovered in high yield in every case. When hot pyridine was used as a base and a solvent, a product[21] assumed to be 3-chloro-2-methyl-4-phenylmercaptopenta-1,3-diene (**24**) or 3-chloro-4-methyl-2-phenylmercaptopenta-1,3-diene (**25**) was obtained in 70% yield (Eq. (10)).

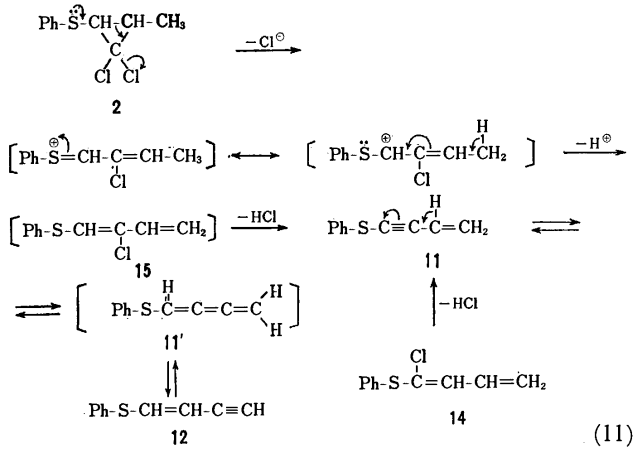
Discussion

The accelerating effect of the phenylmercapto group is considered to be a driving force for ring opening



(11)

reaction of these 2,2-dichlorocyclopropyl phenyl sulfides, since the sulfur lone-pair electrons can stabilize the positive charge developed in the transition state or intermediate (Eq. (1)). The formation of **11** and **12** from **2** or **14** by use of potassium *t*-butoxide is explained as shown in Eq. (11). In particular, compound **12** is obtained from an intermediate butatriene (**11'**) by means of retro-propargylic rearrangement[22] in the presence of base. The presumed intermediate **11'** will be derived from **11** by means of prototropic rearrangement.

The ring opening of **2** (mixture of *cis*- and *trans*-isomers) with weak base pyridine led to the mixture of **15** and *trans*-**2** (Eq. (5)). That is, it turned out that *cis*-**2** underwent ring opening more rapidly than *trans*-**2**. As in our previous discussion on the rates of solvolysis of *cis*- and *trans*-1,1-dichloro-2,3-di-*n*-propylcyclopropane,[23] and *cis*- and *trans*-1,1-dichloro-2-ethoxy-3-*n*-propylcyclopropane[24] in the presence of ethanolic silver nitrate, the above experimental results are explained on the basis of steric effects of intermediates (or transition states) derived from the concerted ring opening reactions. Some pertinent arguments for the related preferential formation of only a *trans*-olefin from both *cis*- and *trans*-1,1-dichloro-2-ethoxy-3-methylcyclopropane have been discussed by Skattebøl[6]. Similar steric arguments can account for the stability of **6** in hot *t*-butyl alcohol - potassium *t*-butoxide.

The allene derivative **17** is obtained from **16** by addition of *t*-butoxide ion to **16** as illustrated in Eq. (12).

17 (12)

Experimental

Infrared spectra were obtained on a Perkin-Elmer 257 or an Unicam SP 200 spectrometer. Ultraviolet spectra were obtained in spectral grade solvents on a Cary spectrophotometer. Nuclear magnetic resonance spectra were mainly obtained on a Varian Associates Model A-60 or T-60 spectrometer using 20% solutions in carbon tetrachloride and tetramethylsilane as an internal standard. Mass spectra were obtained on a Hitachi Perkin-Elmer RMU-6D mass spectrometer. Gas-liquid partition chromatography analyses were determined on a Beckman GC-4 apparatus.

Materials. Most of the α,β-unsaturated sulfides were prepared by distillation of the corresponding ketone diphenylmercaptol with potassium bisulfate (see Tables 1 and 2). 2,2-Dichlorocyclopropyl phenyl sulfides were prepared from the α,β-unsaturated sulfides, sodium methoxide (from a fresh bottle) and ethyl trichloroacetate by a procedure essentially the same as that for the reaction with phenyl propenyl sulfide[14] (see Tables 3 and 4).

Reaction of **2** *with Potassium* t-*Butoxide in* t-*Butyl Alcohol.* Potassium metal (5.9 g, 0.15 g-atom) was dissolved in *t*-butyl alcohol (150 m*l*) heated at the refluxed temperature in a dry nitrogen atmosphere. To the hot solution was added **2**[14] (9.1 g, 0.039 mol) slowly. The reaction mixture was refluxed for 5 hr, poured into water (300 m*l*) and then extracted with ether (200 m*l*). The organic layer was washed with water (200 m*l*) and dried ($MgSO_4$). Evaporation of the dry ether solution afforded a dark oil which gave two fractions on distillation.

A.—Mixture of 1-phenylmercaptobut-3-en-1-yne (**11**)[16] and 1-phenylmercaptobut-1-en-3-yne (*cis*- and *trans*-isomers) (**12**) : 2.9 g (46%); bp 54—65°C/0.005 mmHg; n_D^{25} 1.6205. A sample of the mixture was redistilled through a 10 cm Vigreux column for analysis: bp 50—53°C/0.002 mmHg; n_D^{25} 1.6208; IR (neat), 3280 cm^{-1} (≡C–H), 2160, 2100 (C≡C), 970, 925, (CH=CH_2); UV ($\lambda_{max}^{95\%EtOH}$), 219 mμ (sh., 12700), 228 (sh., 9500), 241 (9700), 250.5 (10100), 261 (10200); NMR (CCl_4), τ 2.52—2.98 (c, 5, C_6H_5), 2.92—3.43 (m, CH=CH), 3.70—4.83 (m, CH=CH_2), 6.66, 7.11 (two d, J=3 and 3 Hz, ≡C–H of *cis*- and *trans*-isomers), total wt of CH=CH, CH=CH_2 and ≡C–H was 3H; MS m/e, 160 (M^+). The ratio of **11** to **12** was about 7 to 4 (NMR spectrum).

Found: C, 74.51; H, 5.47; S, 20.17%. Calcd for $C_{10}H_8S$: C, 74.95; H, 5.03; S, 20.01%.

B.—A compound presumed to be 1-formyl-1-phenylmercaptopropene (two geometrical isomers) (**13**): 0.7 g (10%); bp 79—84°C/0.001 mmHg; n_D^{25} 1.5798; IR (neat), 1675 cm^{-1} (C=O), 820 (trisubstituted olefin); UV ($\lambda_{max}^{95\%EtOH}$), 252 mμ (ε 6520), 295 (15000); NMR (CCl_4), τ 2.26—3.05 (c, 6, C_6H_6 and C=CH–), 0.78 (s, 1, CHO), 8.66, 8.88 (two d, J=6.0 and 7.2 Hz, 3, CH_3).

Found: C, 67.94; H, 6.19%. Calcd for $C_{10}H_{10}OS$: C, 67.38; H, 5.66%.

2,4-Dinitrophenylhydrazone of **13**: Violet crystal, mp 221—222°C (corr) (from acetone).

Found: C, 53.54; H, 3.73; N, 15.43%. Calcd for $C_{16}H_{14}N_4SO_4$: C, 53.62; H, 3.94; N, 15.63%.

Reaction of **14** *with Potassium* t-*Butoxide in* t-*Butyl Alcohol.* To a hot (85—90°C) stirred solution prepared from potassium

23) W. E. Parham and K. S. Yong, *J. Org. Chem.*, **33**, 3947 (1968).
24) W. E. Parham and K. S. Yong, *ibid.*, **35**, 683 (1970).

metal (0.8 g, 0.02 g-atom) and *t*-butyl alcohol (90 m*l*) was added dropwise **14**[17] (8.9 g, 0.045 mole) in a nitrogen atmosphere. The reaction mixture was refluxed for 5 hr, and the solution was processed essentially as described for the reaction of **2** with potassium *t*-butoxide in *t*-butyl alcohol. A mixture of **11** and **12** was obtained: 3.7 g (51%); bp 62—64°C/0.007 mmHg; n_D^{27} 1.6208. The spectra (IR, UV and NMR) were essentially the same as those of the product derived from **2**.

(Found: C, 74.41; H, 5.31%. Calcd for $C_{10}H_8S$: C, 74.95; H, 5.03%).

*Reaction of **2** with Pyridine.* A mixture of **2** (7.0 g, 0.03 mol. The ratio of *cis*-**2** to *trans*-**2** was approximately 8 to 5—NMR spectrum) and pyridine (50 m*l*) was refluxed for 40 hr under a nitrogen atmosphere. By distilling the solution a considerable amount of residual black red tar and a mixture[15] of 2-chloro-1-phenylmercaptobuta-1,3-diene (**15**) and *trans*-**2** were obtained: 3.0 g; bp 81—82°C/0.06 mmHg; n_D^{25} 1.6235; IR (neat), 900, 980, 1620 cm^{-1} ($CH=CH_2$), 1380, 2920 (CH_3); NMR[25] (CCl_4), τ 2.60—3.10 (c, C_6H_5), 3.56 (s, –S–CH=), 3.60, 3.70, 3.76, 3.86 (J_{AX}=16.0 Hz, J_{BX}=10 Hz, $\underline{H}_X$–C=CH_AH_B), 4.56 (d, J_{AX}=16 Hz, H_X–C=$C\underline{H}_AH_B$), 4.94 (d, J_{BX}=10 Hz, H_X–C=$CH_A\underline{H}_B$), 7.68 (d, J(*trans*)=7.0 Hz, S–CH), 8.28—8.52 (m, $\underline{H}C$–CH_3), 8.60 (d, J=3.6 Hz, CH_3). The ratio of **15** to *trans*-**2** was about 1 to 2 (NMR spectrum).

*Reaction of **3** with Potassium* t*-Butoxide in* t*-Butyl Alcohol.* Potassium *t*-butoxide was prepared from potassium (3.90 g, 0.1 g-atom) and *t*-butyl alcohol (100 m*l*). Compound **3** (7.0 g, 0.03 mol) was added and the solution was heated under reflux and with stirring for 3 hr. Water (300 m*l*) was added and the products were extracted with 200 m*l* of petroleum ether (bp 72°C) and dried ($MgSO_4$). Fractionation gave two products (*A* and *B*) and a considerable amount of residual black tar.

A.—2-Phenylmercaptobut-1-en-3-yne (**16**): 0.9 g (19%); bp 48—51°C/0.02 mmHg; n_D^{25} 1.5712; IR (neat), 3290 cm^{-1} (≡C–H), 2120 (C≡C), 1645, 880 ($C=CH_2$); UV ($\lambda_{max}^{95\%EtOH}$), 253 mμ (ε 9470), 272 (sh., 5420); NMR (CCl_4), τ 2.42—2.88 (c, 5, C_6H_5), 4.33, 4.56 (two s, 2, CH_2=), 7.16 (s, 1, ≡C–H).

Found: C, 74.97; H, 5.35%. Calcd for $C_{10}H_8S$: C, 74.96; H, 5.03%.

B.—4-*t*-Butoxy-3-phenylmercaptobuta-1,2-diene (**17**): 1.3 g (19%); bp 87—90°C/0.02 mmHg. A sample of this product was redistilled for analysis: bp 78°C/0.002 mmHg; n_D^{25} 1.5581; IR (neat), 1950 cm^{-1} (C=C=C); UV ($\lambda_{max}^{95\%EtOH}$), 246 mμ (ε 10800), 270 (sh., 5120); NMR (CCl_4), τ 2.55—3.04 (c, 5, C_6H_5), 5.20 (t, J=2.4 Hz, 2, $=CH_2$), 6.11 (t, J=2.4 Hz, 2, CH_2), 8.88 (s, 9, *t*-Bu); MS m/e, 234 (M^+).

Found: C, 71.46; H, 7.32%. Calcd for $C_{14}H_{18}SO$: C, 71.75; H, 7.74%.

*Reduction of **17** with Raney Nikel (W-2).* A mixture of **17** (2.1 g, 0.009 mol), Raney nickel (W-2) (15 g) and 95% ethyl alcohol (100 m*l*) was refluxed for 5 hr. The alcoholic solution was analyzed by glpc (silicone oil, DC-710, 20% on Chromosorb W), and the spectrum showed the presence of two components (other than ethyl alcohol). The compounds were identified (by injection of authentic samples) as benzene and *n*-butyl *t*-butyl ether.[18]

*Reduction of **17** with Hydrogen Gas on Raney Nickel (W-2).* A mixture of **17** (1.1 g, 0.0047 mol), Raney nickel (W-2) (6 g) and methyl alcohol (150 m*l*) was shaken with hydrogen gas (50 lb) in a hydrogenation apparatus[26] for 28 hr at room temperature. The Raney nickel was filtered and washed with methyl alcohol (100 m*l*). The combined filtrate was distilled through a 10 cm Vigreux column, and a large portion of methyl alcohol was distilled. Further distillation of the brown residue (0.6 g) gave two products.

A.—*sec*-Butyl phenyl sulfide (**19**); 0.1 g (13%); bp 77—80°C/3 mmHg; n_D^{25} 1.5390; NMR (CCl_4), τ 2.57—3.12 (c, 5, C_6H_5), 6.95 (sextet, J=6.6 Hz, 1, –CH–), 8.11—9.22 (m, 8, CH_2—CH_3 and CH_3).

Found: C, 72.02; H, 8.37%. Calcd for $C_{10}H_{14}S$: C, 72.23; H, 8.49%.

This product was identical with an authentic sample of **19**.[19]

B.—*t*-Butyl 2-phenylmercaptobutyl ether (**20**): 0.4 g (36%); bp 72°C/0.001 mmHg; n_D^{25} 1.5191; IR (neat), 1070 cm^{-1} (C–O–C); UV ($\lambda_{max}^{95\%EtOH}$), 255 mμ (ε 5730); NMR (CCl_4), τ 2.56—3.04 (c, 5, C_6H_5), 6.49—7.18 (m, 3, C–CH_2–CH), 8.07—9.18 (m, 14, C_2H_5 and *t*-Bu, —a sharp peak at 8.88 due to *t*-Bu).

Found: C, 69.89; H, 8.93%. Calcd for $C_{14}H_{22}SO$: C, 70.54; H, 9.30%.

*Preparation of **17** from **16** and Potassium t-Butoxide.* Freshly prepared **16** (12 g, 0.0075 mol) was added to a stirred solution prepared from potassium (0.60 g, 0.015 g-atom) and *t*-butyl alcohol (20 m*l*) which was maintained in a nitrogen atmosphere. The reaction mixture was refluxed for 2 hr and then poured into water (100 m*l*), and the resulting mixture was extracted twice with 100 m*l* portions of ether. The ether solution was dried ($MgSO_4$) and concentrated in a rotatory evaporator. Distillation of the residue gave **17**: 0.6 g (34%); bp 80°C/0.005 mmHg; n_D^{26} 1.5678; IR and NMR spectra were identical with those of **17** obtained by the reaction of **3** with potassium *t*-butoxide in *t*-butyl alcohol.

*Reaction of **5** with Potassium* t*-Butoxide in* t*-Butyl Alcohol.* The reaction of **5** (4.94 g, 0.02 mole) with potassium *t*-butoxide (potassium 2.35 g, 0.06 g-atom; *t*-butyl alcohol 60 m*l*) was carried out for 3 hr as described for **2**. 3-Methyl-1-phenylmercaptobut-3-en-1-yne (**21**) was obtained: 2.1 g (60%); bp 60—62°C/0.004 mmHg; n_D^{25} 1.6075; IR (neat), 2140, 2170 cm^{-1} (C=C), 900 ($C=CH_2$), 2970, 2910, 1375 (CH_3); UV ($\lambda_{max}^{95\%EtOH}$) 218 mμ (sh., ε 14600), 228 (sh., 11500), 241 (11200), 249 (11800), 258 (11600): NMR[25] (CCl_4), τ 2.50—3.08 (c, 5, C_6H_5), 4.72, 4.82 (two s, 2, $=CH_2$), 8.06 (s, 3, CH_3).

Found: C, 75.71; H, 5.94%. Calcd for $C_{11}H_{10}S$: C, 75.82; H, 5.78%.

*Dehydrohalogenation of 1-Chloro-3-methyl-1-phenylmercaptobuta-1,3-diene (**22**).* The reaction of **22**[12] (3.7 g, 0.018 mole) with potassium *t*-butoxide (potassium 1.6 g, 0.04 g-atom; *t*-butyl alcohol 40 m*l*) was carried out as described for **14** and gave **21**: 2.3 g (73%); bp 62—65°C/0.005 mmHg; n_D^{27} 1.6041. This product was shown to be identical (IR spectrum) with **21** prepared from **5**.

Found: C, 75.55; H, 5.95%. Calcd for $C_{11}H_{10}S$: C, 75.82; H, 5.78%.

*Reaction of **5** with Pyridine.* The reaction of **5** (4.9 g, 0.02 mol) with pyridine (20 m*l*), carried out for 18 hr as described for **2**, gave 2-chloro-3-methyl-1-phenylmercaptobuta-1,3-diene (**23**): 2.0 g (48%): bp 88—90°C/0.01 mmHg; n_D^{30} 1.6210; IR (neat), 1615, 895 cm^{-1} ($C=CH_2$), 2960, 1370 (CH_3); UV ($\lambda_{max}^{95\%EtOH}$) 252 mμ (ε 5380), 268 (4970), 296 (5560), NMR (CCl_4), τ 2.42—2.97 (c, 5, C_6H_5), 3.42 (s, 1, –CH=), 4.56, 4.99 (two s, 2, $=CH_2$), 8.01 (s, 3, CH_3). The glpc (silicone oil, DC-710, 20% on Chromosorb W) of the product **23** showed only a single peak,

25) The NMR spectrum was obtained on a JEOL MH-100 spectrometer.

26) Made by Parr Instrument Co. Inc. (Moline, III., U. S. A.).

Found: C, 62.35; H, 4.99%. Calcd for $C_{11}H_{11}SCl$: C, 62.72; H, 5.26%.

Dehydrogenation of ***23***. The reaction of **23** (1.6 g, 0.008 mol) with potassium *t*-butoxide (potassium 0.6 g, 0.0016 g-atom; *t*-butyl alcohol 20 m*l*), carried out as described for **14**, gave **21**: 0.7 g (50%); bp 60—61°C/0.001 mmHg; n_D^{27} 1.6002. The IR and NMR spectra of this product were identical with those of authentic **21** prepared from **5** or **22**.

Reaction of ***6*** *with Pyridine*. The reaction of **6** (1.3 g, 0.005 mol) with pyridine (10 m*l*) was carried out for 70 hr as described for **2**, and a compound assumed to be 3-chloro-2-methyl-4-phenylmercaptopenta-1,3-diene (**24**) or 3-chloro-4-methyl-2-phenylmercaptopenta-1,3-diene (**25**) was obtained: 0.8 g (71.4%); bp 66—68°C/0.005 mmHg; n_D^{26} 1.5815; IR (neat), 1635, 890 cm^{-1} ($C{=}CH_2$), 2920, 1370 (CH_3); UV ($\lambda_{max}^{95\%EtOH}$), 218 mμ (sh., ε 10900), 251 (5470), 270 (sh., 3910); NMR (CCl_4), τ 2.38—2.96 (c, 5, C_6H_5), 4.81 4.91 (two s, 2, $CH_2{=}$), 8.00, 8.22 (two s, 6, $2CH_3$). The GLPC (silicone oil, DC-710, 20% on Chromosorb W) of the product showed only a single peak.

Found: C, 63.96; H, 5.74%. Calcd for $C_{12}H_{13}SCl$: C, 64.13; H, 5.84%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 515—519 (1972)

The Photochemical Decomposition of Benzotriazoles

Kazuo Tsujimoto, Mamoru Ohashi, and Teijiro Yonezawa

Department of Hydrocarbon Chemistry, Faculty of Engineering Kyoto University, Kyoto

(Received March 24, 1971)

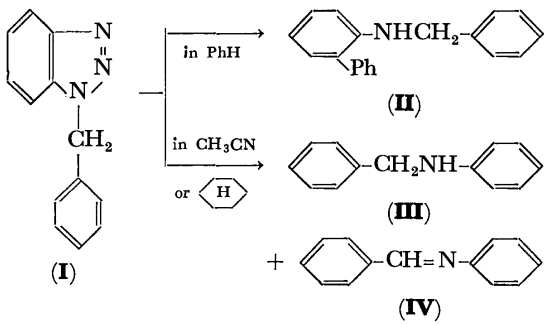
The photochemical decomposition of several 1-substituted benzotriazoles was investigated. It was observed that in contrast to the thermolytic decompositions of 1-benzyl and 1-benzoylbenzotriazole, the intermediates produced by the loss of nitrogen from these compounds upon irradiation react with hydrogen-donating solvents to yield either reduced or substituted products. The possibility of the presence of an antiaromatic benzoazacyclopropene as an intermediate can be excluded on the basis of the fact that the photolysis of 4′,5-dichloro-1-phenylbenzotriazole gave 3,6-dichlorocarbazole as the sole product. The acetone-sensitized photolysis of 1-benzoylbenzotriazole causes a Wolff rearrangement giving a cyclopentadiene derivative. On the basis of extended Hückel molecular orbital calculations on the intermediates, it is concluded that the photochemical loss of nitrogen from benzotriazoles gives excited-state 1,3-diradicals, while the thermolytic decompositions afford ground-state ones.

Recently Burgess and his co-workers[1] found that the photolysis of 1-phenylbenzotriazole gave carbazole quantitatively. In a previous paper,[2] we reported that the photolysis of various benzotriazoles gave products different from those of thermal decompositions. This fact implies that the spin-correlation effects[3] may be observed in these decomposition process, just as in the case of azides.[4]

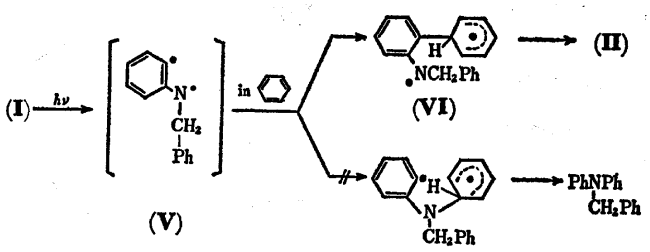
To shed some light on the nature of the intermediates produced upon the irradiation of some benzotriazoles, we have examined the difference of benzotriazoles; we based our examination on a molecular-orbital consideration of the electronic structure of the diradical intermediates.

Results and Discussion

The photolysis of 1-benzylbenzotriazole (**I**) in benzene gave *N*-(2-biphenylyl)benzylamine (**II**) in a 29% yield; this amine was the only product which was isolated by column chromatography on silica gel. However, when **I** was photolyzed in acetonitrile, **IV** was obtained together with benzylaniline (**III**), which must be produced by hydrogen abstraction from the solvent (**III** : **IV**=1 : 5).



In the photochemical reaction of **I**, two manners must be considered for the addition of benzene to the diradical (**V**), as shown in Scheme 1.



Scheme 1

It is more reasonable to assume that the more reactive center in the diradical (**V**), which presumably has the character of a reactive σ-radical, adds to benzene,[5] and that intramolecular hydrogen transfer in the

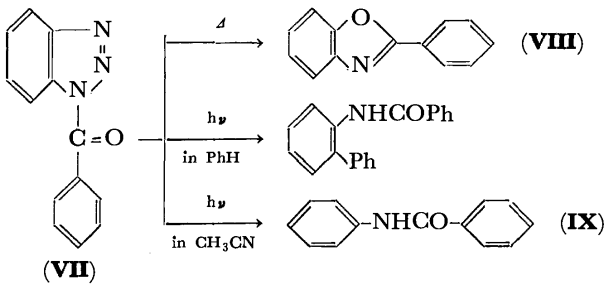
resulting adduct (**VI**) then leads to the observed product. When the photolysis of **I** was carried out in cyclohexane, which is thought to be more hydrogen-donating to the produced diradical than is acetonitrile,[6] benzylaniline (**III**) was obtained together with benzylideneaniline (**IV**) (**III**:**IV**=6 : 1).

The formation of **IV** in cyclohexane implies that the diradical resulting from the benzotriazole can abstract intramolecularly a hydrogen atom, even in a hydrogen-donating solvent.

Gibson has reported,[7] that the thermolysis of **I** gave phenanthridine, a cyclized product, in a small yield. However, in the photolysis of **I** we could obtain neither phenanthridine nor 9,10-dihydrophenanthridine, not even in acetonitrile (checked by glpc).

This difference in behavior between the thermolysis and photolysis of **I** suggests that the ground-state diradical of **V** is liable to cyclize and that the diradical produced upon irradiation is either an excited singlet or triplet state and that it abstracts a hydrogen atom intramolecularly or from a solvent cage.

The same sort of difference in behavior between the thermolysis and photolysis is also observed in the case of 1-benzoylbenzotriazole. Drulliner reported[8] that 1-benzoylbenzotriazole (**VII**) decomposed in diphenyl ether at a reflux temperature to give 2-phenylbenzoxazole of **VIII** in an 11% yield. However, in our experiments, only a trace of **VIII** could be obtained in its photolysis in acetonitrile (probably less than 1%). The major product was the amide (**IX**) which had been produced *via* a 1,3- or 1,5-diradical intermediate through hydrogen abstraction from the solvent. The fact that **VIII** could not be obtained in the photolysis of **VII** is analogous to the case of the photolysis of 1-benzylbenzotriazole (**I**), where neither phenanthridine nor 9,10-dihydrophenanthridine was obtained.



(**VII**) (**VIII**) (**IX**)

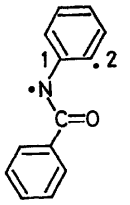
The difference in behavior between the thermolytic and photolytic decomposition of **VII** can be interpreted by means of an extended Hückel MO investigation of the electronic structure of the intermediate (**XI**). The atomic-bond populations of C_2-O cited in Table 1 (see Experimental section) show that it is bonding in the ground state but antibonding in the excited state. These results are consistent with the experimental results; that is the thermolytic[8] or mass spectrometric[9] decomposition of **VII** gives the cyclized product, while the photolytic one gives **VIII** in only a small amount.

Table 1. Total energy and atomic bond populations of **XI**.

	Ground state	Excited state
Total Energy	−1313.6 eV	−1311.8 eV
Atomic Bond Population of C_2-N	−0.180	−0.178
Atomic Bond Population of C_2-O	0.050	−0.006

These arguments point to the facts that the thermolytic decomposition of **VII** gives the ground state of **XI** and that the photolysis produces the excited state.

When the photolysis of **VII** was acetone-sensitized, benzanilide (**IX**) and a new type of compound (**X**) were obtained. The assignment of the structure of **X** rests on analytical and spectroscopic data as follows. The results of elemental analysis and the molecular peak (*m/e* 253) of the mass spectrum indicate that its molecular formula is $C_{16}H_{15}NO_2$, suggesting the addition of a molecule of acetone to the diradical intermediate (**XI**). The presence of a strong conjugated carbonyl absorption at 1650 cm^{-1} in the IR spectrum and a strong benzoyl peak at *m/e* 105 in the mass spectrum suggest the benzoyl group. Further information about the structure is obtained from the 220 MHz NMR spectrum. A singlet peak at



(**XI**)

δ 1.93 (6H) indicates two methyl groups. The complex ABCX signals were demonstrated in the region between δ 5.5 and δ 7.0 in Chart 1; the spectrum given at the bottom was obtained by computer simulation with LAOCOON III.[10]

From these spectral data, two structures, (**X**) and (**X'**), are conceivable. Considering the chemical

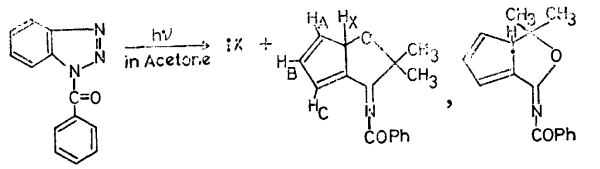
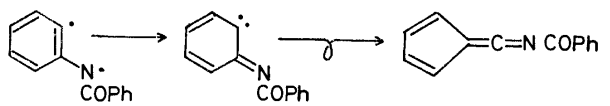
shift of the H_x proton (δ, 5.73 ppm), we concluded that the structure (**X**) must be favored over **X'**.



(**VII**) (**X**) (**X'**)

The formation of **X** implies that the reaction proceeds *via* the intermediate (**XI**) formed by triplet acetone-sensitization, which is presumably transformed into the more stable iminofulvene (**XII'**) through an iminocarbene (**XII**), followed by Wolff rearrangement.

No product corresponding to **X** was obtained in the acetophenone- and benzophenone-sensitized photolyses.



(**XI**) (**XII**) (**XII'**)

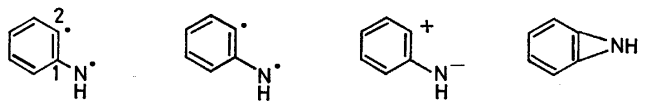
These results suggest that the reactions of these intermediates are intimately related to their electronic structures. Therefore, it becomes important to clarify the electronic structure of the intermediates. Boyer and Selvanjan investigated the photolysis of several benzotriazoles and concluded that the 1,3-diradical intermediates have carbene-like structures.[11]

We carried out MO calculations on **XIII'**, which has a fundamental, simple skelton, by means of the extended Hückel method.

Table 2. Atomic and atomic bond polulations of **XIII'**.

	N	C_2
N	6.618	−0.186
C_2	−0.186	3.689

Extended Hückel calculation indicates that the atomic-bond population between C_2 and N is negative (antibonding), and that the atomic-bond populations[12] on the N and C_2 atoms have negative and positive charges respectively. These calculations suggest that the possibility of making a bond between N and C_2 to produce benzoazacyclopropene (**XIIIc'**) is quite small and that the dipolar character predominant over the diradical structure (**XIIIa'**).

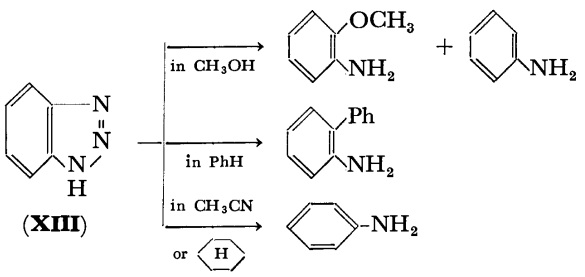


(**XIII'**) (**XIIIa'**) (**XIIIb'**) (**XIIIc'**)

The same calculations also show that the benzoazacyclopropene (**XIIIc'**) is less stable than the associated dipolar intermediate, the difference in their total energies being 3.4 eV (=78 kcal).

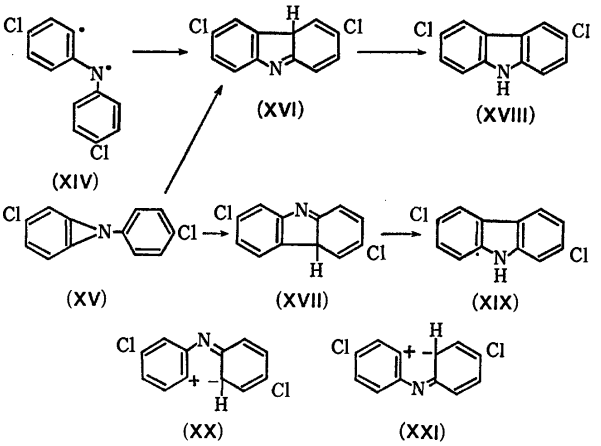
In accordance with these calculations, the photolysis of 1H-benzotriazole (**XIII**) in methanol gave *o*-anisidine as a major product (70% yield), along with aniline (30% yield). On the other hand, the photolysis of **XIII** in benzene gave *o*-biphenylamine in a 32% yield, and the similar irradiation of **XIII** in acetonitrile and in cyclohexane gave aniline in 6% and 20% yields respectively.

These results suggest that the character of the intermediate (**XIIIa'** or **XIIIb'**) depends on the polarity of the solvent.



(**XIII**)

Although these molecular orbital calculations indicate that the intermediate (**XIII'**) has no tendency to form benzoazacyclopropene (**XIIIc'**), an antiaromatic compound,[13] we attempted to prove this prediction experimentally. Thus, we examined the behavior of 4',5-dichloro-1-phenylbenzotriazole upon irradiation. The structures of the resulting carbazole were identified by means of the NMR spectra. 3,6-Dichlorocarbazole was isolated as the sole aromatic product in an 89% yield. No 2,6-dichlorocarbazole (**XIX**) was detected, even in the NMR specta of the unpurified product mixture.



(**XIV**) (**XV**) (**XVI**) (**XVII**) (**XVIII**) (**XIX**) (**XX**) (**XXI**)

If the intermediate was not **XIV** but **XV**, a comparable amount of **XVII** with **XVI** would be obtained in the case of the homolytic cleavage of the azirine ring in **XV**, while the antisymmetric carbazole (**XIX**)

would be produced when the heterolytic cleavage took place, because the positive charge of **XX** should be more stabilized than that of **XXI** in terms of the electronegativity of the chlorine atom at the *para* position.[14]

In conclusion, we have examined the photochemical decompositions of several 1-substituted benzotriazoles and have found that the photochemical decompositions of 1-benzyl and 1-benzoylbenzotriazoles give products different in their thermolytic and mass spectrometric decompositions.[9] This difference in behavior is accounted for in terms of the electronic structures of the diradical intermediates.

The photochemical loss of nitrogen from the benzotriazoles gives the excited-state intermediates, while the thermolytic decomposition must afford the electronic ground-state intermediates. One exception is the case of 1-phenylbenzotriazole, where both thermolytic and photolytic decompositions[1] gives carbazole almost quantitatively.

In this case, we have no evidence to confirm whether or not the same electronic structute of the intermediates must be considered in both reactions. A detailed investigation of the electronic multiplicities of the intermediates based on SCF-ASMO-CI calculations are now in progress.

Experimental

The IR spectra were recorded on a Hitachi Model 215 grating spectrometer.

The NMR spectra were recorded for solutions in deuteriochloroform (unless otherwise stated) with a Varian HR-220 apparatus, using TMS as the internal standard. The mass spectra were obtained on a double-focussing mass spectrometer, Model JMS-01SG. All the mps were measured on a micro hot stage and are not corrected.

Photolysis of ***I****.* *(A) In Benzene*: The triazole (1.0 g) was dissolved in benzene (500 m*l*), which had previously dried over phosphorus pentoxide and purified by distillation; the solution was than irradiated for 4 hr under a nitrogen atmosphere with a 200-W high-pressure mercury arc lamp surrounded by a quartz filter. The solvent and low-boiling-point materials were removed under reduced pressure. The reaction mixture thus obtained indicated two spots on tlc (silica gel) and was chromatographed on silica gel. Elution with methylene dichloride gave the unreacted triazole and **II** (40 mg); mp 87—88°C (lit, 84—86°C), mass spectrum M$^+$, 259 (93), 180 (32), 167 (28), 91 (100), IR-(KBr), ν_{NH} 3500 cm^{-1}.

(B) In Acetonitrile: The triazole (1.39 g) was irradiated in acetonitrile (330 m*l*) for 13 hr with a 200-W high-pressure mercury lamp. After the removal of the solvent under reduced pressure, the residue was chromatographed on basic alumina. Elution with benzene gave an orange-yellow oil (120 mg), which was discovered by means of vpc analysis using a column of 5% PEG 20 M on chromosorb G to be a mixture of two products. These products had the same retention times as had benzylaniline and benzylideneaniline respectively. The product ratio was determined by vpc using diphenylamine as the internal standard. The oil was rechromatographed on basic alumina, and subsequent elution with cyclohexane - benzene (3 : 1) gave **III** and **IV**, whose structures were identified by the comparison of their IR spectra with the standard IRDC cards.

Photolysis of 1-Benzoylbenzotriazole. *(A) In Benzene*: A solution of the triazole (1.0 g) in benzene (500 m*l*) was irradiated with a 200-W high-pressure mercury arc lamp for 4 hr under a nitrogen atmosphere. The solvent was then removed *in vacuo*, and the residue was chromatographed on silica gel (200 mesh 30$\phi \times$ 190 mm). Elution with methylene chloride (200 m*l*) recovered the unreacted triazole (600 mg). Further elution (400 m*l*) gave a solid (60 mg), which was then crystallized from ligroin to give *N*-(2-biphenylyl)benzamide (mp 88°C). Its IR spectrum was identical with that of an authentic sample. Elution with ethyl acetate and methanol gave polymeric materials which were not identified.

(B) In Acetonitrile: The triazole (120 mg) in acetonitrile (20 m*l*) was irradiated with a 5-W low-pressure mercury lamp for 2 hr under a nitrogen atmosphere. The solvent was then removed *in vacuo*. The residue was chromatographed on silica gel (200 mesh 10 g) with methylene chloride, thus giving three cuts. From the first fraction we obtained 21 mg of the unreacted triazole. The second one gave 9 mg of colorless needles which had a mp of 160—161°C; its IR spectrum agreed with that of the IRDC card of benzaniline. The third fraction gave an identified polymeric material.

(C) In Acetone: A solution of the triazole (1.02 g) in acetone (240 m*l*) was irradiated with a 10-W low-pressure mercury lamp for 15.5 hr under a nitrogen atmosphere. The solvent was then removed. The residue was chromatographed on silica gel. Subsequent elution with methylene dichloride gave three products, whose R_f values on tlc were 0.90, 0.70, and 0.40. The R_f 0.90 fraction (310 mg) turned out to be the unreacted triazole, while the R_f 0.40 fraction (93 mg) was identified as benzanilide by a comparison of its IR spectrum with that of the authentic sample. The recrystallization of the R_f 0.70 fraction (78 mg) from ethanol-water gave colorless needles which melted at 122.0—122.5°C; *m/e* 253 (M$^+$), λ_{max} 311 nm (EtOH), ν_{max} (KBr) 1650 cm^{-1}, δ1.93(s. 6H), 5.73 (d.d. 1H J=7.5 Hz and 0.6 Hz), 6.84(t.d. 1H, J=7.5 and 1.5 Hz), 6.75(d.d. 1H, J=7.5 and 1.5 Hz), 6.84 (t.d. 1H J=7.5 Hz, and 0.6 Hz), and 7.5(m. 5 H) ppm.

Found: C, 75.59; H, 5.86; N, 5.53%. Calcd for $C_{16}H_{15}NO_2$: C, 75.59; H, 5.97; N, 5.53%.

(D) In Acetophenone: The triazole (1.0 g) was dissolved in freshly-distilled acetophenone (240 m*l*). The solution was then irradiated with a low-pressure mercury lamp (10 W) for 13 hr under a nitrogen atmosphere. The solvent was then removed *in vacuo* (max. bath temp. at 63°C). The tlc of the residue on silica gel indicated that almost all of the material was the unreacted triazole. The residue was chromatographed on silica gel. Subsequent elution with benzene gave the starting material and polymeric materials whose structures were not identified.

(E) In Benzophenone: The triazole (500 mg) and benzophenone (508 mg) were dissolved in chloroform (80 m*l*). The solution was irradiated with a high-pressure mercury arc lamp (100 W), using a 2-mm pyrex filter, for 10 hr under a nitrogen atmosphere. The reaction mixture was chromatographed after the removal of the solvent in order to establish the recovery of the starting material.

Photolysis of 1H-Benzotriazole. *(A) In Methanol*: The triazole (1.0 g) in methanol (500 m*l*) was irradiated with a 200-W high-pressure mercury arc lamp for 18.5 hr. The solvent was then removed *in vacuo*, and the residue was chromatographed on silica gel. Elution with methylene

14) M. S. Ao. E. M. Burgess, A. Schauer, and E. A. Taylor, *Chem. Commun.* **1969**, 220.

dichloride gave a red-brown oil (136 mg). A part of the oil was distilled *in vacuo* to give *o*-anisidine, whose IR spectrum was identical with that of an authentic sample. The vpc of the oil on a column of 15% PEG 20 M on Chromosorb W showed the same retention time as that of *o*-anisidine. However, the vpc analysis of the total product showed the presence of an additional product which had the same retention time as that of aniline. A careful vacuum distillation of the oily product gave a colorless oil whose structure was identified by a comparison of its IR spectrum with the IRDC card of aniline.

(B) In Benzene. A benzene solution (500 m*l*) of 1*H*-benzotriazole (1.0 g) was irradiated with a high-pressure mercury arc lamp under bubbling nitrogen gas for 6 hr. The solvent was removed *in vacuo*, and then the residue was chromatographed on silica gel to give biphenylamine (164 mg), whose structure was identified by a comparison of its IR spectrum with the standard IRDC card.

Photolysis of 4',5-dichloro-1-phenylbenzotriazole. The triazole (104 mg) was irradiated in acetonitrile (20 m*l*) for 14 hr. The solvent was then removed, and the residue was chromatographed on silica gel. Subsequent elution with benzene gave colorless needles (81 mg); mp 200.5—201.2°C (lit: 202°C)[15]: IR spectrum (KBr) ν_{NH} 3530 cm^{-1}; *m/e* 237(64), 253(100), and 200(64).

The NMR spectrum showed resonances at δ7.03 (2H, A part of ABX pattern), 7.21 (2H, B part), 7.83 (2H, X part), and 10.0 (br. s. 1H) ppm acetone.

The calculation by means of the extended Hückel method has been described in detail by Hoffmann.[12] The resonance integrals were evaluated by the following equation:

$$KS_{rs}(H_{rr}+H_{ss})/2,\ K=1.75.$$

The Coulomb integrals were estimated by the use of $H_{rr}=-I_p$, where I_p is the ionization potential of the appropriate valence state.

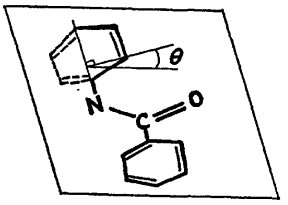
The following values were used in the text:

H	−13.6 eV	
C	−21.43	−11.42
N	−27.5	−14.47
O	−35.3	−15.45

The total energy calculated on the basis of various conformations of **XI** is summarized in Table 3.

Table 3. Dihedral angles θ and total energy

θ	Total Energy (eV)
0	−1313.580
10	−1313.576
90	−1313.559
180	−1312.361



The numerical calculations were carried out at the Kyoto University Computation Center. (FACOM 230—60)

The authors wish to express their hearty thanks to Professor Hiroshi Kato of Nagoya University for his kind advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 519—525 (1972)

Syntheses of All Isomers of Naphthalenetricarboxylic Acids

Yasuhiko DOZEN

Government Industrial Research Institute, Osaka, Ikeda-shi, Osaka

(Received May 8, 1971)

All the fourteen isomers of naphthalenetricarboxylic acids have been synthesized by the oxidation of trimethylnaphthalenes, dimethylacetonaphthones, dimethylnaphthoic acids, methylnaphthalenedicarboxylic acids, β-(dimethylnaphthoyl)propionic acid, or β-(acenaphthoyl)propionic acids with aqueous sodium bichromate or potassium ferricyanide. Most of these naphthalenetricarboxylic acids, acid anhydrides, and trimethyl esters are new compounds.

During the course of studies on the thermal transformation of alkali salts of naphthalenecarboxylic acids,[1] we realized the necessity of naphthalenetricarboxylic acids for comparison with possible intermediates in the reaction. However, only a limited number of these acids have been reported. Naphthalene-1,4,5-,[2,3] 1,3,8-,[3] and 1,2,8-[3,4] tricarboxylic acids have been prepared by the oxidation of acetylacenaphthenes or cyclohexylacenaphthenes. 1,2,5-[5–7] and 1,2,7-Isomers[8,9] have been synthesized from the corresponding trimethylnaphthalenes. 1,2,4-Tricarboxylic acid is obtained by the oxidation of 1-methylnaphthalene-3,4-dicarboxylic acid.[10] It has been reported that 1-acetyl-2,6-dimethylnaphthalene

gives 1,2,6-tricarboxylic acid,[11] but the position of the acetyl group in this acetyldimethylnaphthalene is doubtful.[12,13]

The suitable oxidation procedure of methyl and acetyl groups in naphthalene derivatives with aqueous sodium bichromate has been developed for methylnaphthoic acid,[14] dimethylnaphthalenes,[14] and methylacetonaphthone.[15] Methods for synthesizing the fourteen isomers of trimethylnaphthalene to be oxidized to naphthalenetricarboxylic acids have been reported by some workers,[16-18] but it is not easy to synthesize them all.

In this paper, we wish to report appropriate synthetic methods and the properties of all the fourteen isomers of naphthalenetricarboxylic acid.

Results and Discussion

The preparative methods of naphthalenetricarboxylic acids given so far can be classified into three groups: (1) carboxylation of bromodimethylnaphthalenes by the Grignard reaction, (2) acylation of dimethylnaphthalenes or acenaphthene and (3) cyclization of the methyl- or dimethylphenylbutyric acid derivatives to the naphthalene ring.

1-Bromo-2,4-, 2,3-, 2,6-, and 4,6-dimethylnaphthalenes were prepared by the method of Arnold and Liggett[19] from 1,3-, 2,3-, 2,6-, and 1,7-dimethylnaphthalenes. The orientation for the bromination of these dimethylnaphthalenes has been reported by Kim *et al.*[20] Bromodimethylnaphthalenes were carboxylated to the corresponding dimethylnaphthoic acids by the Grignard reaction with carbon dioxide and then were oxidized with aqueous sodium bichromate to 1,2,4-, 1,2,3-, 1,2,6-, and 1,4,6-naphthalenetricarboxylic acids (Table 3, **2**, **1**, **4**, and **14**).

It has been reported that 2,6-dimethylnaphthalene gives 1-acetyl-2,6-dimethylnaphthalene (mp 70—71°C) by the Friedel-Crafts acetylation reaction in carbon disulfide,[12,13] and the acetyl compound is oxidized with aqueous hypochlorite solution to 2,6-dimethyl-1-naphthoic acid (mp 203—204°C)[13] which is further oxidized with dilute nitric acid to naphthalene-1,2,6-tricarboxylic acid (mp of trimethyl ester: 139—140°C).[11] We prepared 2,6-dimethyl-1-naphthoic acid with mp 173—174°C by the Grignard reaction on 1-bromo-2,6-dimethylnaphthalene. The trimethyl naphthalenetricarboxylate obtained from this compound had mp 141—142°C. On the other hand, trimethyl naphthalenetricarboxylate(**13a**) obtained by the aqueous bichromate oxidation of acetyl-2,6-dimethylnaphthalene(**15**) had mp 172.5—173.5°C. The results indicate that the acetyl group in acetyl-2,6-dimethylnaphthalene(**15**) is not located in the position given in literature. The structure of this acetyl compound was confirmed to be 1-acetyl-3,7-dimethylnaphthalene(**15**) from the fact that both trimethyl naphthalenetricarboxylates(**13a**) obtained by the aqueous bichromate oxidation of acetyl-2,6-dimethylnaphthalene(**15**) (mp 70—71°C) and of acetyl-1,3-dimethylnaphthalene(**16**) (mp 96.5—97.5°C), in which the acetyl group should be located in 7-position as shown in Scheme 1, were the same compound.

β-(5-Acenaphthoyl)propionic acid which had been prepared by the Friedel-Crafts reaction of acenaphthene and succinic anhydride[21] was oxidized to naphthalene-1,4,5-tricarboxylic acid (Table 3, **8**) with aqueous sodium bichromate, but β-(3-acenaphthoyl)propionic acid[21] gave benzene-1,2,3-tricarboxylic acid (Table 3, **6**). On the other hand, β-(3-acenaphthoyl)propionic acid could be oxidized with aqueous potassium ferricyanide to naphthalene-1,2,8-tricarboxylic acid. Naphthalene-2,3,6-tricarboxylic acid(Table 3, **10**) was obtained by the aqueous sodium bichromate oxidation of β-[2-(6,7-dimethylnaphthoyl)]propionic acid prepared by the Friedel-Crafts reaction of 2,3-dimethylnaphthalene and succinic anhydride.[22]

Scheme 2.

γ-(3,4- or 2,4-Dimethylphenyl)butyric acid(**18a** or **b**) was prepared by the Clemmensen reduction of β-(3,4- or 2,4-dimethylbenzoyl)propionic acid(**17a** or **b**) synthesized from *o*- or *m*-xylene with succinic anhydride.[23] After ring closure of these γ-dimethylphenylbutyric acids(**18a**, **b**) to dimethyltetralones(**19a**, **b**) with polyphosphoric acid,[24,25] the dimethyltetralones were converted into 1,6,7- and 1,5,7-trimethyl-3,4-dihydronaphthalenes(**20a** and **b**) by the Grignard reaction with methylmagnesium iodide and then dehydrogenated to 2,3,5- and 1,3,5-trimethylnaphthalenes(**21a** and **b**) with sulfur as shown in Scheme 2. These trimethylnaphthalenes gave the corresponding naphthalenetricarboxylic acids (Table 3, **9** and **11**). Methyl β-(2,3- or 3,5-dimethylbenzoyl)propionate was obtained by the reaction of 3-bromo-*o*-xylene or 5-bromo-*m*-xylene and β-carbomethoxypropionyl chloride by the method of Dauben and Tilles,[26] who reported on the synthesis of methyl benzoyl- and toluylpropionates. The methyl β-(dimethylbenzoyl)propionates were hydrolyzed to the corresponding free acids(**17c** and **d**) and then converted into 1,2,5- and 1,3,8-trimethylnaphthalenes (**21c** and **d**) by a similar reaction route. These trimethylnaphthalenes gave naphthalene-1,2,5- and 1,3,8-tricarboxylic acids (Table 3, **3** and **7**).

Ethyl 5,7-dimethyl-3,4-dihydronaphthalene-2-carboxylate(**24**) was prepared by the reaction of ethyl γ-(2,4-dimethyl)butyrate (**22**) and ethyl formate in the presence of sodium ethoxide followed by the ring closure with phosphoric acid - sulfuric acid mixture as shown in Scheme 3. This reaction route has been reported on the synthesis of ethyl 6,7-dimethoxy-3,4-dihydronaphthalene-2-carboxylate[27] and ethyl 7-methyl-2-naphthoate.[28] Dihydro compound(**24**)

was dehydrogenated with sulfur to ethyl 5,7-dimethylnaphthalene-2-carboxylate(**25**), hydrolyzed to free acid and then oxidized to naphthalene-1,3,6-tricarboxylic acid (Table 3, **12**).

Ethyl α-carbethoxy-γ-(*p*-methylphenyl)butyrate(**27**) was synthesized by the reaction of γ-(*p*-methylphenyl)butyrate(**26**) and diethyl oxalate in the presence of sodium ethoxide. This compound was cyclized with sulfuric acid to 7-methyl-3,4-dihydronaphthalene-1,2-dicarboxylic anhydride(**28**) and then dehydrogenated with sulfur to 7-methylnaphthalene-1,2-dicarboxylic anhydride(**29**) as shown in Scheme 4. The preparative method has been reported on the naphthalene-1,2-dicarboxylic anhydride.[29,30]

An attempt to prepare 5-methylnaphthalene-3,4-dihydro-1,2-dicarboxylic anhydride from γ-(*o*-methylphenyl)butyrate by a similar method failed. 7-Methylnaphthalene-1,2-dicarboxylic anhydride gave naphthalene-1,2,7-tricarboxylic acid (Table 3, **5**).

The melting points and analytical data of trimethyl naphthalenetricarboxylates are summarized in Table 1. The esters were hydrolyzed with potassium hydroxide in aqueous ethanol to give free acids, and some of them were dehydrated with acetic anhydride to the corresponding acid anhydrides. Melting points, analytical data, and infrared absorption bands of carbonyl group of naphthalenetricarboxylic acid monoanhydrides are shown in Table 2. In the cases of naphthalene-1,2,8-, 1,3,8-, and 1,4,8-tricarboxylic acids, 1,8-anhydrides were directly obtained by acidification of hot alkaline solution of the corresponding acids.[31]

31) Naphthalene-1,8-dicarboxylic acid gives anhydride by recrystallization from nitric acid(S. G., 1,4): C. Graebe and E. Gfeller, *Ber.*, **25**, 653 (1892).

32) Infrared spectroscopy and micro analysis were performed with a Hitachi Infrared Spectrophotometer EPI-S2 (in Nujol) and a Yanagimoto C. H. N. Corder MT-1 apparatus, respectively. The methyl ester of the carboxylic acid was synthesized by the reaction of the silver salt of carboxylic acid and methyl iodide.

2,3-dimethyl-, 1-bromo-2,4-dimethyl-, 1-bromo-2,6-dimethyl-, and 1-bromo-4,6-dimethylnaphthalenes.

2,3-Dimethyl-1-naphthoic acid was prepared by the Grignard reaction of 1-bromo-2,3-dimethylnaphthalene[19]: 52% yield, mp 170—171°C (lit, mp 167—168°C[19]).

1-Bromo-2,4-dimethylnaphthalene gave 2,4-dimethyl-1-naphthoic acid by a similar method; 55% yield, mp 165.5—167.0°C (aqueous EtOH). Found: C, 78.02; H, 6.01%. Calcd for $C_{13}H_{12}O_2$: C, 77.96; H, 6.04%.

1-Bromo-2,6-dimethylnaphthalene gave 2,6-dimethyl-1-naphthoic acid (46.3%) and 2,6-dimethylnaphthalene (24.3%). The acid had mp 173—174°C(aqueous EtOH). Found: C, 77.64; H, 6.02% (the acid reported to have mp 203—204°C[11,13,33] should be assigned to 3,7-dimethyl-1-naphthoic acid). Methyl 2,6-dimethyl-1-naphthoate: mp 89.5—90.5°C (MeOH). Found: C, 78.23; H, 6.73%. Calcd for $C_{14}H_{14}O_2$: C, 78.49; H, 6.58%.

1-Bromo-4,6-dimethylnaphthalene gave 4,6-dimethyl-1-naphthoic acid; 59% yield, mp 196.5—197.0°C (benzene). Found: C, 78.02; H, 6.23%.

Acetylation of 2,6- and 1,3-Dimethylnaphthalenes. 2,6-Dimethylnaphthalene was acetylated with acetic anhydride and anhydrous aluminum chloride in carbon disulfide by the method of Clar, Wallenstein, and Avenarius[12] giving a fraction of bp 151—157°C/4 mmHg in 64.5% yield. This fraction which solidified partly was filtered and recrystallized from ethanol to give 3,7-dimethyl-1-acetonaphthone(**15**); mp 70—71°C(lit, mp 70—71°C).[11-13] This was reported to be 2,6-dimethyl-1-acetonaphthone. 3,7-Dimethyl-1-acetonaphthone (10 g) was oxidized with aqueous sodium hypobromite solution at room temperature for 20 hr to give 1.6 g of 3,7-dimethyl-1-naphthoic acid; mp 202—203°C (aqueous EtOH) (lit, mp 204—205°C[34]) or with aqueous sodium bichromate to naphthalene-1,3,7-tricarboxylic acid (Table 3, **13**). The tricarboxylic acid (2.0 g) was recrystallized from 50 m*l* of acetic anhydride, washed with benzene and dried. The infrared spectrum of this compound has no acid anhydride band.

1,3-Dimethylnaphthalene (37.7 g, 0.242 mol) in 50 m*l* of nitrobenzene was added to a solution of 19.4 g (0.248 mol) of acetyl chloride and 34 g (0.248 mol) of anhydrous aluminum chloride in 80 m*l* of nitrobenzene under chilling with ice-water. Stirring was continued for 2 hr at room temperature and then 2 hr at 60°C. After treatment in the usual manner, 1,3-dimethyl-7-acetonaphthone(**16**) which boiled at 152—159°C/3 mmHg was collected; mp 96.5—97.5°C (EtOH), 56.5% yield(37 g). Found: C, 84.74; H, 7.27%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.11%. The ketone gave naphthalene-1,3,7-tricarboxylic acid (Table 3, **13'**). The trimethyl ester(mp 172.5—173.5°C) was identified to be the same compound by means of mixed melting point and comparison of the infrared spectra with the sample obtained from 3,7-dimethyl-1-acetonaphthone (**15**).

Succinoylation of Acenaphthene and 2,3-Dimethylnaphthalene. β-(3- and 5-Acenaphthoyl)propionic acids were synthesized by the method of Fieser and Peters[21] from acenaphthene and succinic anhydride.

β-[2-(6,7-Dimethylnaphthoyl)]propionic acid was prepared by a modified method of Hawarth and Bolam.[22] 2,3-Dimethylnaphthalene (40.0 g, 0.256 mol) was added to a solution of 78 g (0.58 mol) of anhydrous aluminum chloride and 26.0 g (0.26 mol) of succinic anhydride in 250 m*l* of nitrobenzene under chilling with ice-water. Stirring was carried out overnight at room temperature. The reaction product was treated and purified by a similar method to that in the synthesis of β-(5-acenaphthoyl)propionic acid[21] to give 17.0 g (37%) of β-[2-(6,7-dimethylnaphthoyl)] propionic acid; mp 183.5—184.5°C. Recrystallization from methanol gave mp 184.0—185.0°C (lit, mp 179—180°C[22]).

2,3,5- and 1,3,5-Trimethylnaphthalenes. γ-(3,4- and 2,4-Dimethylphenyl)butyric acid[23] (**18a** and **b**) were cyclized with polyphosphoric acid (200 m*l* of 85% phosphoric acid and 240 g of phosphorus pentoxide)[24,25] to give 6,7- and 5,7-dimethyltetralones (**19a** and **b**); 89% yield, bp 128—130°C/4 mmHg and 90% yield, bp 137°C/5.5 mmHg, respectively. The dimethyltetralones were converted into 1,6,7- and 1,5,7-trimethyl-3,4-dihydronaphthalenes (**20a** and **b**) by the Grignard reaction with methylmagnesium iodide and then dehydrogenated with sulfur at 210°C for 8 hr to give 2,3,5- and 1,3,5-trimethylnaphthalenes (**21a** and **b**); bp 131—131.5°C/11 mmHg (lit, bp 138°C/12 mmHg[17]) and bp 115—116°C/5.5 mmHg, mp 42.5—44.5°C (lit, mp 43°C[16]), respectively.

1,3,8- and 1,2,5-Trimethylnaphthalenes. 4-Acetamido-*m*-xylene[35] was nitrated by a modified method of Haller, Adams, and Wherry.[36] 4-Acetamido-*m*-xylene (100 g, mp 129.5—130.5°C) in 100 m*l* of glacial acetic acid was dropped into 200 m*l* of fuming nitric acid (S. G., 1.52) under stirring at 10°C for 3 hr and further stirred for 20 min. The reaction mixture was poured into 1 *l* of water, filtered, washed with water and finally recrystallized from 500 m*l* of ethanol to give 5-nitro-4-acetamido-*m*-xylene; 70—79% yield, mp 175—176°C (lit, mp 172°C[35]). The compound was deaminated to 5-nitro-*m*-xylene,[36] reduced to 5-amino-*m*-xylene by the Béschamp reduction, brominated to 5-bromo-*m*-xylene by the method of Zanten and Nauta,[37] and then made to react with β-carbomethoxypropionyl chloride to give methyl β-(3,5-dimethylbenzoyl)propionate by the method of Dauben and Tilles[26]; 25.6% yield, bp 153—160°C/2 mmHg. The ester was hydrolyzed to β-(3,5-dimethylbenzoyl)propionic acid(**17d**); 70.3% yield, mp 117—118°C(aqueous EtOH). Found: C, 69.42; H, 7.28%. Calcd for $C_{12}H_{12}O_3$: C, 69.21; H, 7.74%. The Clemmensen reduction of the above keto-acid gave γ-(3,5-dimethylphenyl)butyric acid(**18d**) (95% yield, mp 60—61°C). 1,3,8-Trimethylnaphthalene(**21d**) was then prepared in a similar way *via* 6,8-dimethyltetralone(**19d**) and 1,6,8-trimethyl-3,4-dihydronaphthalene(**20d**); mp 45.5—46.5°C (MeOH) (lit, mp 48°C[5]).

Methyl β-(2,3-dimethylbenzoyl)propionate was prepared from 3-bromo-*o*-xylene[37] in a similar way to that described above; 21—24% yield; bp 145—148°C/2 mmHg. The free acid (**17c**) had mp 100.5—101.5°C (EtOH); 69—72% yield. Found: C, 69.63; H, 7.38%. 1,2,5-Trimethylnaphthalene(**21c**) was then synthesized by a similar way as described above *via* γ-(2,3-dimethylphenyl)butyric acid (**18c**) (mp 109.5—110.5°C from benzene), 5,6-dimethyltetralone(**19c**) (mp 58—59°C) and 1,5,6-trimethyl-3,4-dihydronaphthalene(**20c**); bp 132—134°C/4 mmHg (lit, bp 147—148°C/11 mmHg[16]).

5,7-Dimethyl-2-naphthoic Acid. Into a solution of sodium ethylate prepared from 7.0 g of sodium sand and 17 m*l* of absolute ethanol in 150 m*l* of dry ether, a mixture of 42.0 g (0.191 mol) of ethyl γ-(2,4-dimethylphenyl)butyrate (**22**)[23] and 21.0 g (0.284 mol) of ethyl formate in 100 m*l* of dry ether was added under stirring and chilling with ice-

salt bath for 20 min and stirred at room temperature for 50 hr. The reaction mixture was worked up as described by Holmes and Trevoy[27] to give 3,4-dihydro-5,7-dimethyl-2-naphthoate (**24**) in 36—40% yield (15.7—17.5 g), bp 163—165°C/2.5 mmHg, mp 75.5—76.5°C. The dihydro compound (52 g, 0.226 mol) was dehydrogenated with 7.5 g (0.234 atom) of sulfur at 240°C for 3 hr to give 44.1 g of ethyl 5,7-dimethyl-2-naphthoate (**25**); bp 165—175°C/3 mmHg. Crystallization three times from 50 m*l* portions of ethanol gave 18.7 g of pure ethyl ester; mp 57.5—58.5°C. Found: C, 79.09; H, 7.27%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%. The ester(20 g) was hydrolyzed with potassium hydroxide in aqueous ethanol for 30 hr to give 17.4 g of 5,7-dimethyl-2-naphthoic acid in 99% yield, mp 206.5—207.5°C (EtOH). Found: C, 78.09; H, 6.12%. Calcd for $C_{13}H_{12}O_2$: C, 77.97; H, 6.04%. Methyl 5,7-dimethyl-2-naphthoate had mp 70.0—71.0°C (MeOH). Found: C, 78.54; H, 6.66%. Calcd for $C_{14}H_{14}O_2$: C, 78.49; H, 6.58%.

7-Methylnaphthalene-1,2-dicarboxylic Anhydride. Diethyl oxalate (57.5 g, 0.393 mol) in 100 m*l* of dry ether was added to a solution of sodium ethylate prepared from 6.3 g (0.274 atom) of sodium sand and 13 g of absolute ethanol in 100 m*l* of dry ether, during the course of 30 min at room temperature and 53.5 g (0.260 mol) of ethyl γ-(*p*-methylphenyl)butyrate (**26**) in 50 m*l* of dry ether was then added for 5 min. After stirring for 30 hr at room temperature, the product was worked up as described by Fieser and Hershberg[29] to give 27.9 g (50.2%) of 3,4-dihydro-7-methylnaphthalene-1,2-carboxylic anhydride (**28**); mp 138—140°C (from petroleum benzine-benzene). Found: C, 73.00; H, 4.64%. Calcd for $C_{13}H_{10}O_3$: C, 72.88; H, 4.67%. The dihydro compound (21 g, 0.10 mol) was dehydrogenated with 3.2 g (0.10 atom) of sulfur at 200—250°C for 3 hr to give 13.7 g of 7-methylnaphthalene-1,2-dicarboxylic anhydride (**29**). Crystallization three times from benzene(active carbon) gave mp 161.5—163.5°C. The anhydride (26 g) was dissolved in aqueous sodium hydroxide solution by heating to remove trace of hydrogen sulfide, treated with active carbon and reprecipitated with hydrochloric acid. The acid (20.7 g) was treated with 80 m*l* of acetic anhydride at 150°C for 1 hr to give pure 7-methylnaphthalene-1,2-dicarboxylic anhydride (16.7 g); mp 164.5—165.5°C, ν_{CO}: 1842 and 1768 cm^{-1}. Found: C, 73.64; H, 3.45%. Calcd for $C_{13}H_8O_3$: C, 73.56; H, 3.82%. Dimethyl ester: mp 88—89°C (MeOH). Found: C, 69.42; H, 5.52%. Calcd for $C_{15}H_{14}O_4$: C, 69.76; H, 5.46%.

Sodium Bichromate Oxidation. Dimethylnaphthalenecarboxylic acids, methylnaphthalenedicarboxylic acid, dimethylacetonaphthones, β-(acenaphthoyl)propionic acid, β-(dimethylnaphthoyl)propionic acid and trimethylnaphthalenes were oxidized with aqueous sodium bichromate at

d) Separated as acid anhydride. e) Trimethyl hemimellitate.

250—280°C under autogeneous pressure (*ca.* 30—40 kg/cm²). Sodium bichromate was used 1.3—1.5 times excess per methyl or methylene group. Methylnaphthalenecarboxylic acids, dimethylnaphthoylpropionic acid and acenaphthoylpropionic acids were dissolved in equimolar amount of aqueous sodium hydroxide and oxidized. The reaction mixture was filtered at 70—80°C, and the filtrate was neutralized with hydrochloric acid to pH≃6, treated with active carbon and then acidified with hydrochloric acid to give naphthalenetricarboxylic acids. The reaction conditions and products are summarized in Table 3.

In the cases of naphthalene-1,2,3- and 1,2,5-tricarboxylic acids (Table 3, **1** and **3**), the reaction product was filtered, acidified with nitric acid, neutralized with sodium hydroxide to pH≃9 and treated with active carbon. Excess silver nitrate was then added in order to isolate the carboxylic acid as silver salt owing to the high solubility of these acids in water. The silver salts were converted into trimethyl naphthalenetricarboxylates with methyl iodide. The ester obtained from the 1,2,5-trimethylnaphthalene was dissolved in methanol, chromatographed through the alumina column and eluted with methanol. The eluted solution was evaporated and the residue was recrystallized from methanol to give 0.6 g of trimethyl hemimellitate; mp 100.5—101.5°C. It was identified by means of the mixed melting point and comparison of the infrared spectra with the authentic sample. The mother liquors were evaporated to dryness and the residue (4.5 g) was extracted with 15 m*l* of hot ligroin. After cooling of the ligroin solution, trimethyl naphthalene-1,2,5-tricarboxylate was isolated; 0.4 g, mp 89.0—89.5°C (MeOH).

From the oxidation product of β-(3-acenaphthoyl)propionic acid(Table 3, **6**), trimethyl hemimellitate (mp 101—102°C; 0.2 g) was isolated by a similar treatment to that in the case of 1,2,5-trimethylnaphthalene. The mother liquors gave 1.3 g of impure product; mp 83—93°C.

Potassium Ferricyanide Oxidation of β-(3-Acenaphthoyl)-propionic Acid. β-(3-Acenaphthoyl)propionic acid (5.4 g), 82 g of potassium hydroxide, 470 g of potassium ferricyanide, and 1200 m*l* of water were allowed to react at 60°C for 74 hr. A solution of 24 g of potassium hydroxide, 90 g of potassium ferricyanide, and 200 m*l* of water was added at 24 hr intervals. The product was cooled, acidified with hydrochloric acid and filtered. The filtrate was extracted fifteen times with 300 m*l* portions of ether. The ether was evaporated to give 3.5 g of naphthalene-1,2,8-tricarboxylic acid; mp 288—290°C.

The author wishes to thank Mrs. Shizu Fujishima for the micro analyses.

The Synthesis of the New 1,4,2-Dithiazine Ring[1)]

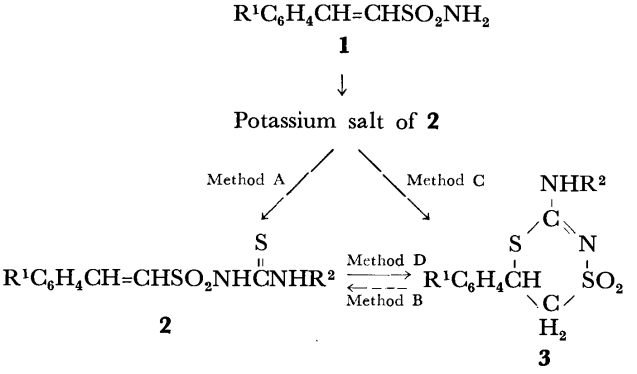
Kiyoshi HASEGAWA and Syuzi HIROOKA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi

(Received May 21, 1971)

Some derivatives of *N*-(2-phenylethene-1-sulfonyl)-*N'*-alkylthioureas of the $R^1C_6H_4CH{=}CHSO_2NHCSNHR^2$ **2** type were synthesized by a reaction between 2-phenylethene-1-sulfonamides **1** and isothiocyanates in acetone in the presence of K_2CO_3. A new heterocyclic system, 3-alkylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine **3**, was obtained by the intramolecular Michael cycloaddition of **2** in weakly basic media, and also by the thermal cyclization of **2**. The carbon-sulfur bond in **3** could be cleaved to give **2** again in strongly basic media.

A previous study[2)] in this laboratory has dealt with *N*-benzenesulfonyl-*N'*-alkylthioureas obtained from benzenesulfonamides and alkyl isothiocyanates. When 2-phenylethene-1-sulfonamide[3)] **1**, in which the α, β double bond is activated by a neighboring sulfonyl group,[4)] was used, either the corresponding sulfonylthioureas **2** or the intramolecular cycloadducts, 3-alkylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines **3**, were formed, depending upon the work-up procedure. Recently, the synthesis of **2** (R^1=H, R^2=allyl and phenyl) was briefly reported,[5)] but **3** has never yet been prepared. This paper will describe the synthesis, cleavage, and structural elucidation of a new heterocycle **3**. The process is outlined below.



Results

N-(2-Phenylethene-1-sulfonyl)-N'-alkylthioureas **2**. A mixture of **1**, potassium carbonate, and alkyl isothiocyanate in acetone was refluxed for 15—25 hr with stirring to yield the potassium salt of **2** as a normal product. This was filtered, dissolved in water, and acidified to give **2** (Table 1, Method A). The structure of **2** was confirmed by a study of its IR, NMR,

a) Method C, b) Method D.

and mass spectra and by the results of elemental analyses. The IR spectrum of **2a** displayed bands at 3320 (ν_{NH}) and 1610 ($\nu_{C=C}$) cm^{-1}. The NMR spectrum of **2a** exhibited an AB pattern centered at δ 7.28 and δ7.77 (J_{AB} = 15.2 Hz) due to the vicinal olefinic protons, H_A and H_B. The large magnitude of this coupling proves that **2** has the *trans* rather than the *cis* configuration.

3-Alkylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines ***3****. The Base-Catalyzed Intramolecular Cyclization of* ***2****.* When the potassium salt of **2** described above was dissolved in warm water (Table 2, Method C), or when **2** was dissolved in a dilute alkali (Table 2, Method D), a new heterocycle, **3**, began to separate out after a few minutes. This Michael-type reaction carried out at pH values below 12.55 gave **3** in a good yield, and the rate of cycloaddition increased with an increase in the base concentration. Only a one-fourth equivalent of the base was sufficient to effect the cycloaddition of the sulfonylthiourea. In the pH range from 12.55 to 13.40, a mixture of **2** and **3** was obtained. Under strongly basic conditions (pH>13.40), no cycloaddition occurred. The IR spectrum of **3a** displayed a strong band at 1560—1535 cm^{-1} due to the N=C bond, but no absorption due to the C=C group was observed in the region of 1610 $cm.^{-1}$ In NMR pattern of **3a**, ring protons, $H_AH_CH_B$ appeared as an ABX pattern consisting of three quartets of H_A centered at δ3.53, H_C δ 3.67 and H_B δ 5.00 (J_{AC}=14.0 Hz, J_{AB}=11.7 Hz, and J_{BC}=4.4 Hz) respectively (Fig. 1). The observed coupling constants, J_{AB} and J_{BC}, may be compared with those for the axial-axial and axial-equatorial protons respectively. The peak at *m/e* 121.011 in the mass spectrum was in entire agreement with the fragment ion $C_6H_5CS^+$, derived from only the six-membered heterocycle, **3**. The structures of **3b—3m** were inferred because they were analogous with **3a** in their preparations and spectral data. The Michael mechanism is assumed to be like Scheme 1.

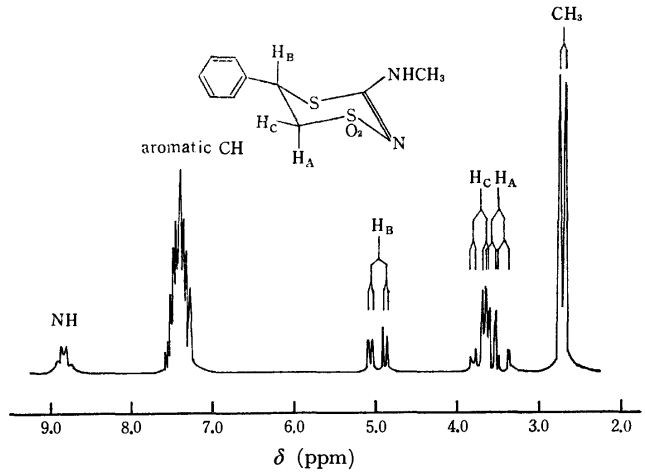

Fig. 1. NMR spectrum of **3a** in DMSO-d_6.

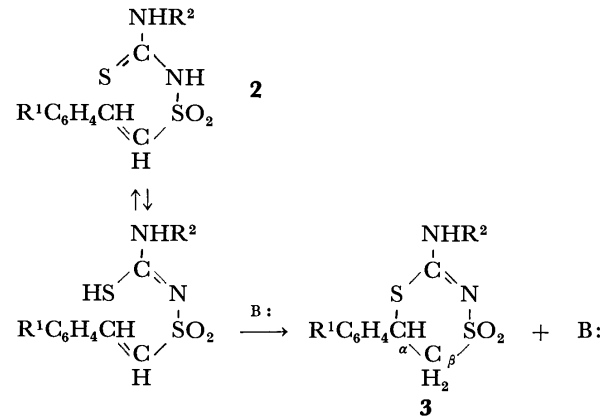
Thermal Cyclization of ***2****.* Thioureas, **2**, were cyclized to **3** by heating; they were then divided into two groups. The changes in their IR spectra showed that the first group, **2a—2d**, **2f**, **2j**, and **2k**, underwent a cyclization upon melting, while the second group, **2e** and **2g—2i**, underwent such a cyclization before melting. The cyclization temperatures of the latter, observed in their DTA curves, were as follows: **2e**, 141—146°C; **2g**, 131—135°C; **2h**, 140—145°C; **2i**, 157—160°C. These cycloadducts, when recrystallized, gave melting points identical with those of the products obtained by Methods C and D.



Scheme 1.

Base-Catalyzed Ring-Cleavage of ***3****.* The **3** cycloadduct could be split into **2** when the reaction media were more basic than those used in effecting the cycloaddition (Table 1, Method B). Cleavage proceeded very fast in a solvent such as alkaline aqueous acetone, even at 0°C. Only cleaved **2** was obtained when the pH of the solution was above 13.30. A mixture of **2** and **3** was obtained in the pH range from 12.70 to 13.30. This ring-cleavage is the reverse of the Michael cycloaddition, and a mechanism in the direction the reverse of that in Scheme 1 is assumed.

Discussion

We have been interested in **2** because the SO_2 group can conjugate with and activate a neighboring ethylenic double bond and stabilize the thiolate anion in basic media. As **2** has both donor and acceptor in one molecule, it should be possible to effect intramolecular Michael cycloaddition. It has indeed been found that **2** gives the intramolecular cycloadduct **3** in weakly basic media. Compounds with the general formulation $-CH=CHSO_2NHC(=S)-$ would give intramolecular Michael cycloadducts.

A Michael reversible system can be influenced by the basicity of the solution. Cleavage seems to require a base B:, strong enough to remove active β-hydrogen. A β sulfonyl group is known to accelerate the rate of the base-catalyzed elimination.[6] Cleavage proceeded too rapidly to determine certain details of this reaction, but the higher rate of cleavage was clearly associated with the higher concentration of the base.

Experimental

The melting points were determined on a Yanagimoto micro-melting-point measuring apparatus MP-S2 and are

6) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Holt, Rinehart, and Winston, New York (1959), p. 499.

uncorrected. The IR and UV spectra were recorded on JASCO IRA-1 and Hitachi EPS-3T spectrometers respectively. The NMR spectra were determined with a Varian HA-100 spectrometer, with TMS as the internal standard and the mass spectra, with a JMS-01SG spectrometer.

N-*(2-Phenylethene-1-sulfonyl)*-N'-*methylthiourea* ***2a***.

Method A: To 2-phenylethene-1-sulfonamide (3.00 g, 0.0164 mol) in acetone (30 m*l*), we added methyl isothiocyanate (1.32 g, 0.0180 mol) and anhydrous potassium carbonate (1.32 g, 0.0220 mol), after which the reaction mixture was refluxed for 20 hr with stirring. The resulting potassium salt of **2a** was collected on a filter and washed with acetone to remove the unchanged sulfonamide. This salt was dissolved in water (200 m*l*), and the solution was acidified with concentrated hydrochloric acid to give 4.0 g (95%) of **2a**. Recrystallization from methanol then gave colorless crystals. IR (KBr): 3320 (ν_{NH}), 1610 ($\nu_{C=C}$), 1570 (δ_{NH}), 1495, 1435, 1380 (ν_{SO_2}), 1150, and 1130 (ν_{SO_2}), 1050, 960, 885, 740, and 690 cm^{-1}. NMR (acetone-d_6): δ 3.08 (d, J_{NHCH}=5.0 Hz, 3H, CH_3), 7.28 (d, J_{AB}=15.2 Hz, 1H, H_A), 7.77 (d, J_{AB}=15.2 Hz, 1H, H_B), 7.47±0.05 (m, 5H, phenyl), 8.40 (broad, 1H, SO_2NH), 8.90 (broad, 1H, NH). Mass spectrum (75 eV) *m/e* (rel. intensity): 77 (56), 91 (24), 103 (41), 135 (41), 136 (100), 192 (29), 256 (M^+, 1.8).

Method B: To 3-methylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (0.51 g, 0.0020 mol) in acetone (30 m*l*), we added a 1.0 N NaOH solution (4.0 m*l*, 0.0040 mol) and then stirred the mixture for 1 hr at room temperature. The acetone was then evaporated under reduced pressure, and the residual solution was acidified with concentrated hydrochloric acid to give 0.48 g (94%) of ***2a***.

3-Methylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine ***3a***. *Method C*: When potassium salt of **2a** obtained from 2-phenylethene-1-sulfonamide (2.20 g, 0.0120 mol) by Method A was dissolved in warm water (150 m*l*), **3a** began to separate out after a few minutes. After the mixture had stood overnight, it was filtered to give 1.91 g (87%) of **3a**. Recrystallization from methanol gave colorless crystals. IR (KBr): 3280 (ν_{NH}), 1560—1535 ($\nu_{N=C}$), 1405, 1300 (ν_{SO_2}), 1125 (ν_{SO_2}), 960, 750, and 690 cm^{-1}. NMR (DMSO-d_6): δ 2.74 (d, J_{NHCH_3}=4.5 Hz, 3H, CH_3), 3.53 (q, J_{AC}=14.0 Hz, J_{AB}=11.7 Hz, 1H, H_A), 3.67 (q, J_{AC}=14.0 Hz, J_{BC}=4.4 Hz, 1H, H_C), 5.00 (q, J_{AB}=11.7 Hz, J_{BC}=4.4 Hz, 1H, H_B), 7.41±0.1 (m, 5H, phenyl), 8.70 (broad, 1H, NH). Mass spectrum (75 eV) *m/e* (rel. intensity): 77 (26), 78 (25), 91 (38), 104 (100), 119 (34), 121.011 (13), 135 (38), 136 (25), 177 (6), 191 (20), 256.032 (calculated molecular weight, 256.034, 21).

Method D: When **2a** (0.77 g, 0.0030 mol) was dissolved in a warm 0.1 M K_2CO_3 solution (30 m*l*, 0.0030 mol), **3a** began to separate out in a few minutes. After the mixture had stood overnight, it was filtered to give 0.63 g (82%) of **3a**.

The authors wish to thank Dr. M. Kondo, Mr. H. Kuwano, and Mr. T. Kinoshita of Sankyo Co., Limited, Tokyo, for their help in NMR and mass spectrum study. We are indebted to Mr. Y. Okabe, Mr. H. Yamada, and Mr. K. Hori for assistance in preparing some of the compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 528—531 (1972)

The Constituents of *Arthraxon hispidus Makino, Miscanthus tinctorius Hackel, Miscanthus sinensis Anderss,* and *Phragmites communis Trinius*

Makoto KANETA and Noboru SUGIYAMA*

Fukushima Technical College, Iwaki-shi, Fukushima

**Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo*

(Received May 21, 1971)

From the leaves and stems of *Arthraxon hispidus Makino*, aconitic acid, luteolin, luteolin-7-glucoside, and a new flavone, arthraxin, have been isolated. Luteolin, luteolin-7-glucoside, and arthraxin were also isolated from *Miscanthus tinctorius Hackel*, and tricin was isolated from *Miscanthus sinensis Anderss* and *Phragmites communis Trinius*.

Arthraxon hispidus Makino, called 'Kobunagusa,' in Japanese is widely distributed in Japan. This grass has been used as a source of natural dyestuff for coloring 'Kihachijo,' which is a traditional yellow silk cloth produced on Hachijo Island, Japan. As was stated in our previous paper,[1] a report on a chemical study of the dyestuff has been made by Hayashi *et al.*,[2] but without obtaining a pure material; they presumed that the yellow pigment of the grass was a glucoside of luteolin or quercetin. *Miscanthus tinctorius Hackel*, *Miscanthus sinensis Anderss*, and *Phragmites communis Trinius*, called 'Kariyasu,' 'Susuki,' and 'Yoshi' in Japanese respectively, have also been used as sources of natural yellow dyestuff.

Since no report on chemical studies of the coloring substance have been found in the literature, such a study has been undertaken by the present authors.

Arthraxin hispidus Makino

From the extract of the grass, the following four compounds, **1**—**4**, have been isolated. The methods of isolation for each of these compounds will be described in detail in the Experimental section.

*Arthraxin (**1**).* This substance is a new flavone named arthraxin, the structural formula of which **1** was described in a previous arthraxin paper.[1]

*Aconitic Acid (**2**).* This substance showed an acidic reaction with several reagents. Its analytical, IR and R_f values agreed with those of authentic

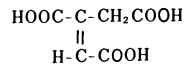
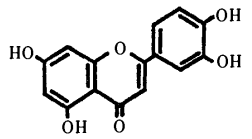
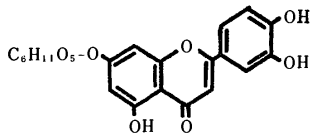
(1)



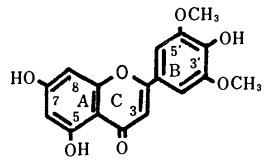
(2)



(3)



(4)



(5)

aconitic acid, and a mixed-melting-point determination with the authentic substance did not show any depression.

Luteolin (3). This substance showed a positive color reaction of flavone, and its analytical values agreed with those of the $C_{15}H_{10}O_6$ formula. On fusion with caustic potash, it yielded protocatechuic acid and phloroglucinol. The agreement of its melting point (325°C), R_f values, and UV spectra with those of luteolin[2-5] further supported its structure.

Luteolin-7-glucoside (4). This substance showed a positive color reaction of flavone, and its analytical values agreed with the $C_{21}H_{20}O_{11}$ formula. The hydrolysis of this compound produced luteolin and glucose. Since the UV λ_{max} of the II band did not shift significantly upon the addition of anhydrous acetate, the sugar was presumed to be attached to the 7-position of the aglycone. Thus, compound (**4**) was considered to be luteolin-7-glucoside. The final identification was based on the agreement of its melting point (255°C), R_f values, and UV spectra with those of luteolin-7-glucoside.[5-7]

Miscanthus tinctorius Hackel

A preliminary examination of the ethanol extract of the grass by tlc and ppc showed the presence of almost the same flavonoid compounds as in *Arthraxon hispidus Makino*.

The grass was treated by the procedure to be described in the Experimental section. Consequently, luteolin (**3**) and luteolin-7-glucoside (**4**) were isolated. Moreover, the presence of arthraxin (**1**) was proved by obtaining arthraxin penta methyl ether from the methylated extract of the grass. These compounds were identified by mixed-melting-point determinations, by co-chromatography, and by a comparison of their UV and IR spectra with those of the authentic samples obtained from *Arthraxon hispidus Makino*.

Miscanthus sinensis Anderss

A boiling-water extract of the fresh leaves and stems (approximately 30 kg) of this plant was treated by a method similar to that previously described for the isolation of arthraxin from *Arthraxon hispidus Makino*.[1] The yellow crystalline needles (25 mg) thus obtained were presumed to be tricin (**5**) by studying their behavior.

Tricin (5). This compound had the empirical formula of $C_{17}H_{14}O_7$, and gave a positive color reaction of a hydroxyl flavone with several reagents. Its UV spectrum in ethanol showed peaks at 270 mμ (Band II) and at 350 mμ (Band I). The single well-defined peak of the II band indicates that the compound is a flavone which has one or three substituents in the B ring.[8] The bathochromic shift of 45 mμ of the I band on the addition of aluminum chloride indicates the presence of the 5-hydroxyl group. The fact that the addition of sodium ethylate induced a bathochromic shift of 65 mμ of the I band without decreasing its intensity indicates the presence of the 4′-hydroxyl group and the absence of the 3-hydroxyl group. The fact that the λ_{max} of the I band did not shift significantly on the addition of boric acid and sodium acetate shows the absence of *o*-hydroxyl groups. The NMR spectrum of the compound in deuterated DMSO indicated the presence of hydrogen atoms at the 3-(τ 3.09, s, 1H), 6-(τ3.82, d, 1H, J=2.5), 8-(τ 3.48, d, 1H, J=2.5), 2′-, and 6′-positions (2′- and 6′-equivalent aromatic protons; τ 2.74, s, 2H), the presence of methoxyl groups at the 3′- and 5′-positions (3′- and 5′-equivalent methoxyl groups; τ 6.12, s, 6H), and the presence of hydroxyl groups at the 5-(τ-2.90, 1H), 7-(τ-0.73, 1H) and 4′-(τ0.71, 1H) positions. The mass spectrum of the compound showed *m/e* 330 ($C_{17}H_{14}O_7$), 315 ($C_{16}H_{11}O_7$), 302 ($C_{16}H_{14}O_6$), 287 ($C_{15}H_{11}O_6$), 259 ($C_{14}H_{11}O_5$), 216 ($C_{12}H_8O_4$), 178 ($C_{10}H_{10}O_3$), 163($C_9H_7O_3$), 152($C_7H_4O_4$), 148 ($C_8H_4O_3$), and 124 ($C_6H_4O_3$) ions. The

Scheme

parent molecular ion is found at *m/e* 330 as the base peak. The *m/e* 178, 152, and 124 ions are derived from the fission in the heterocyclic ring as is shown in the scheme. These kinds of fragment ions are always observed in the mass spectra of the common flavonoid compound.

Only about 25 mg of this compound were isolated; the lack of a larger sample precluded extensive structural studies. However, Formula (**5**), which is identical with that of tricin, was deduced to be the most probable structure for the compound on the basis of the presented above data.

Phragmites communis Trinius

Fresh leaves and stems of this plant (approximately 20 kg) were treated much as *Miscanthus sinensis Anderss* has been. The isolated substance (*ca.* 10 mg) was identified with tricin by a mixed-melting-point determination, by co-chromatography, and by a comparison of its UV spectra with those of the authentic sample obtained from *Miscanthus sinensis Anderss.*

Experimental

All the melting points were uncorrected. The NMR spectra were measured at 60 MHz with a Hitachi R-20B H. R. NMR spectrometer. The chemical shifts were measured with tetramethylsilane as the internal standard. The high-resolution mass spectrum was determined by direct sample introduction using Hitachi RMS-4 and RMU-7 mass spectrometers.

Arthraxon hispidus Makino. *Extraction and Isolation*: Air-dried leaves and stems (approximately 70 kg) of the grass were treated as has been described in a previous arthraxin paper[1]; 2.85 g of arthraxin (**1**) were thus obtained. The ether solution (see Ref. 1) left after the arthraxin had been removed was concentrated to about one-third the volume and kept in a refrigerator. The deposited solid was recrystallized from acetone-benzene to give 1.95 g of aconitic acid (**2**) as colorless needles. The mother liquor of arthraxin and aconitic acid was concentrated almost to dryness. The residual substance was dissolved in 800 m*l* of boiling water and extracted with ether. The ether solution was then extracted three times with 300-m*l* portions of a saturated aqueous solution of sodium hydrogen carbonate and eight times with 300-m*l* portions of a 1% aqueous sodium carbonate solution. All the extracts were acidified with hydrochloric acid. The product from the hydrogen carbonate extract was recrystallized from alcohol-water to give 120 mg of luteolin-7-glucoside (**4**) as pale yellow micro-needles. The product from the carbonate extract was recrystallized from alcohol-water to give 260 mg of luteolin (**3**) as pale yellow needles.

Aconitic Acid (2): Recrystallization from acetone-benzene gave colorless needles; mp 190°C; λ_{max} (EtOH) 215 mμ; ν_{max} (KBr) 3030, 1730, 1690, 1420, 1285, 1220, 900, 850, and 740 cm^{-1}. The above data agreed with those obtained from authentic aconitic acid. Found: C, 41.37; H, 3.47. Calcd for $C_6H_6O_6$: C, 41.39; H, 3.47%.

Luteolin (3): Recrystallization from alcohol-water gave pale yellow micro-needles; mp 325°C dec., λ_{max} (EtOH) 255, 268 (inflection), 349 mμ, λ_{max} (EtOH+NaOAc) 269, 356 mμ; λ_{max} (EtOH+NaOAc+H_3BO_3) 260, 372 mμ; λ_{max} (EtOH+$AlCl_3$) 263, 277, 362, and 388 mμ; λ_{max} (EtOH+NaOEt) 275, 405 mμ. R_f value on Toyoroshi #51: 0.78 in *n*-butanol - acetic acid - water (4-1-2 by volume). The above results were the same as those reported for luteolin.[2-5] Found: C, 63.15; H, 3.61. Calcd for $C_{15}H_{10}O_6$: C, 62.94; H, 3.52%.

Luteolin-7-glucoside (4): Recrystallization from alcohol-water gave yellow needles; mp 255°C; λ_{max} (EtOH) 257, 268 (inflection), 353 mμ; λ_{max} (EtOH+NaOH) 273, 405 mμ; λ_{max} (EtOH+NaOAc) 261, 362 and 410 mμ; R_f value on Toyoroshi #51: 0.51 in *n*-butanol - acetic acid - water (4-1-5 by volume). The data agreed with the data reported for luteolin-7-glucoside.[5-7] Found: C, 56.43; H, 4.92. Calcd for $C_{21}H_{20}O_{11}$: C, 56.25; H, 4.50%.

Hydrolysis of the Glucoside: Compound (**4**) was hydrolyzed by refluxing with 25% sulfuric acid for 11 hr. The aglycone was collected by filtration and recrystallized from ethanol-water to give luteolin, which was identified by its melting point (325°C), R_f values, and UV spectra, as has been described above. The filtrate was neutrilized with barium carbonate and then concentrated; it was used for the determination of the sugar by paper chromatography, which was carried out on Toyoroshi #51 in four solvent systems: R_f 0.18 in *n*-butanol - acetic acid - water (4-1-5 by volume),

0.27 in *n*- butanol - ethanol - water (4-1-5 by volume), 0.39 in coridine saturated with water, and 0.41 in phenol saturated with water. Identical values were obtained with an authentic sample of glucose.

Misanthus tinctorius Hackel. Extraction and Isolation: The grass was collected in Shiga Prefecture in September, 1970. One kg of air-dried leaves and stems of the grass were treated by the procedure previously described for the isolation of arthraxin from *Arthraxon hispidus Makino*. The resulting product was recrystallized from ethanol-water to give 6 mg of luteolin (**3**). The original mother liquor, which was left after extraction with ether to isolate luteolin, was extracted with 300 m*l* of ethyl acetate. The extract was concentrated under reduced pressure to yield a brownish-orange solid, which was then dissolved in 50 m*l* of boiling water. The solution was then saturated with 50 m*l* of ethyl acetate and kept for a month in a refrigerator. A yellowish crystalline substance which separated at the boundary of water and ethyl acetate was recrystallized from ethanol-water to give 8 mg of luteolin-7-glucoside (**4**) as yellow needles. In this way, approximately 10 kg of the air-dried grasses were processed, yielding *ca.* 50 mg of luteolin and *ca.* 65 mg of luteolin-7-glucoside.

The remaining solution, from which luteolin was obtained, was evaporated to dryness. The residue was dissolved in 200 m*l* of dry acetone and was heated under reflux with 15 m*l* of dimethyl sulfate and 20 mg of anhydrous potassium carbonate for 56 hr, until the ferric chloride reaction became negative. After the inorganic salt has been removed by filtration, the filtrate was evaporated under reduced pressure. The residue was dissolved in a small portion of a mixture of acetone and benzene (1 : 4) and passed through a silica-gel (Kieselgel less than 0.08 mm, Merck) column. Elution was carried out successively with the following solvents: 500 m*l* of benzene, 1000 m*l* of benzene-ethyl acetate (1 : 1), 1000 m*l* of ethyl acetate, and 1000 m*l* of ethyl acetate-acetone (1 : 1). The fraction which was eluted with ethyl acetate-acetone (1 : 1) was evaporated, and the residue was recrystallized from ethanol to give *ca.* 120 mg of arthraxin penta methyl ether as colorless needles.

*Luteolin (**3**) and Luteolin-7-glucoside (**4**)*: The identifications of these compounds were based on the agreement of the melting points, R_f values, and UV spectra with those of the luteolin[2-5] and luteolin-7-glucoside[5-7] isolated from *Arthraxon hispidus Makino*.

Arthraxin Penta Methyl Ether: Recrystallization from ethanol gave colorless needles; mp 204°C; λ_{max} (EtOH) 247, 266, and 338 mμ; ν_{max} (KBr) 2905, 1635, 1590, 1510, 1410, 1395, 1315, 1255, 1200, 1120, 1040, and 835 cm^{-1}. This substance was identified with arthraxin penta methyl ether by a mixed-melting-point determination and by co-chromatography on tlc with authentic sample[1] obtained from *Arthraxon hispidus Makino*.

*Miscanthus sinensis Anderss and Phragmites communis Trinius. Tricin (**5**)*: Recrystallization from ethanol-water gave yellow needles; mp 282°C; Mass (high-resolution mass spectrum): M 330.0730, Calcd for $C_{17}H_{14}O_7$, M 330.0739; λ_{max} (EtOH) 245 (inflection), 270, 350 mμ; λ_{max} (EtOH+NaOAc+H_3BO_3) 272, 355 mμ; λ_{max} (EtOH+$AlCl_3$) 280, 305, 370, and 395 mμ; λ_{max} (EtOH+NaOEt) 262, 325, and 415 mμ. These data are nearly equal to those reported for tricin.[9-11]

The authors wish to express their thanks to Mr. Kyuzaburo Furuhashi, Tokyo Kyoiku University, for the microanalyses and the NMR measurements; to Mr. Hidetora Okuyama for sending a sample of *Arthraxon hispidus Makino* collected on Hachijo Island; to Mr. Tomohiko Takahashi for sending some grass of *Miscanthus tinctorius Hackel* collected in Shiga Prefecture, and to Dr. Tsuguo Tateoka, National Science Museum, for giving an expert opinion on the grass of *Miscanthus tinctorius Hackel*.

The Synthesis of Purine Nucleosides of L-Mycarose and L-Cladinose[1]

Shinkiti Koto, Shonosuke Zen, Satoshi Omura,* and Toju Hata*

School of Pharmaceutical Sciences, Kitasato University

** Kitasato Institute, Shirokane, Minato-ku, Tokyo*

(Received May 26, 1971)

Purine nucleosides of L-mycarose and L-cladinose, neutral branched-chain sugars of macrolide antibiotics, synthesized by a fusion method with the aid of dichloroacetic acid. The structure of these synthesized nucleosides was determined on the basis of the results of elemental analyses and the ultraviolet absorption and proton magnetic resonance spectra, as well as on the basis of the optical rotatory dispersion.

Since the first synthesis of cytotoxic nucleosides of branched-chain sugars by Walton *et al.*,[2] a number of synthetic studies of nucleosides of this class of sugars have been reported; some nucleosides exhibit considerable biological activity.[3] In the course of chemical studies of the macrolide antibiotics, the synthesis of purine nucleosides of the branched-chain sugar was carried out by the use of L-mycarose[4] and L-cladinose;[5] this was of chemical and biological interest. Recently, Howarth *et al.*[6] synthesized a purine nucleoside of arcanose.

As the base components, purine[7] and 6-chloropurine were used. The condensation of the above-mentioned dideoxy branched-chain sugars with these bases was performed by a fusion method,[8] using dichloroacetic acid[9] as the catalyst.

4-*O*-Isovaleryl-L-mycarose, obtained by an acid hydrolysis of leucomycin A_3,[10] was converted into 1-*O*-acetyl, 1-*O*-isovaleryl, and 1-*O*-*p*-nitrobenzoyl derivatives (I, II and III). In the case of the preparation of II, 1-*O*-isovaleryl derivatives of 4-*O*-*n*-butyryl and 4-*O*-acetyl-L-mycarose (II′ and II″), arising from the minor components[11] of the leucomycin complex were also isolated from the reaction mixture.

The fusion procedure was carried out by quickly heating a mixture of the appropriate 1-*O*-acyl derivative of L-mycarose, the base, and dichloroacetic acid at a moderately elevated temperature (95±3°C). 1,4-Di-*O*-Acetyl-L-cladinose was coupled with these bases in an essentially similar fashion. The amount of dichloroacetic acid used was relatively high in comparison with that of the ordinary fusion method.[8] Excess dichloroacetic acid seems to act excellently as a solvent to form a homogeneous melt or to aiding in the smooth mixing of the reaction mixture, even if it is somewhat heterogeneous. In the course of the reaction, the mixture was fused after heating for 1—2 min. A thin-layer chromatogram showed essentially a single spot with the exception of the remaining base, which was detectable under ultraviolet light. The yields of nucleosides were not substantially affected by changing the leaving group. In the coupling of the 1-*O*-nitrobenzoyl derivative of L-mycarose (III) and purine, the yield was slightly improved. In this fusion, *p*-nitrobenzoic acid was quickly deposited from the reaction mixture, thus making evacuation unnecessary, and the duration of the reaction was so diminished that an undesirable decomposition of labile branched chain sugar could

be depressed.

In these fusion reactions, only the β-nucleosides were obtained as fine crystals and no significant formation of their α-anomer was observed. The anomeric configuration of synthetic nucleosides was confirmed by the measurements of their proton magnetic resonance spectra. All the synthesized nucleosides showed a quartet peak of the H-1′ proton, typical of axial anomeric the protons of 2-deoxy sugar, and a doublet of H-4′ with a large splitting constant, indicating the $\mathbf{C}_4^1$ conformation for the sugar moiety. It should be noted that 4′-*O*-isovaleryl derivatives of β-L-mycarosyl nucleoside (IV and VI) show a rather abnormal H-1′ quartet signal, indicating a slight deformation of their pyranosyl ring system. The removal of their isolvaleryl group made them again show the normal quartet pattern.

The assignment of the β-L-configuration described above was also supported by the optical rotatory dispersion data. All the dispersion patterns of synthetic nucleosides showed features opposite of those of a group of β-D-purine nucleosides.[12,13] In each case, a positive Cotton effect was observed.

The position of the *N*-glycosyl bond was assigned by measuring the ultraviolet absorption spectra.[13] The nucleosides of purine showed spectra similar to those of nebularine.[14] The spectra of the nucleosides of 6-chloropurine also indicated the *N*-9 substitution.[15]

The attempt to de-*O*-acylate the nucleosides of 6-chloropurine (VI and XI) without affecting the chloro group was unsuccessful. Treating them with dilute barium methoxide in methanol afforded corresponding 6-methoxyl derivatives (VIII and XII).

Experimental

Generally, the crude products obtained were purified by column chromatography on silica gel (20 weights of raw product), followed by the examination of each fraction by thin-layer chromatography. The organic layer was dried over sodium sulfate. After the removal of the salt, the solutions were concentrated below 40°C under reduced pressure, unless otherwise stated. Thin-layer chromatography was performed using Silica Gel G (Merck) as the adsorbent. The proton magnetic resonance spectra were measured with a Hitachi H-6013 and, in part, Varian, S-60A apparatuses. The optical rotatory dispersion was measured with a Nihon Bunko spectropolarimeter, Model ORD/UV-5, at 24—25°C.

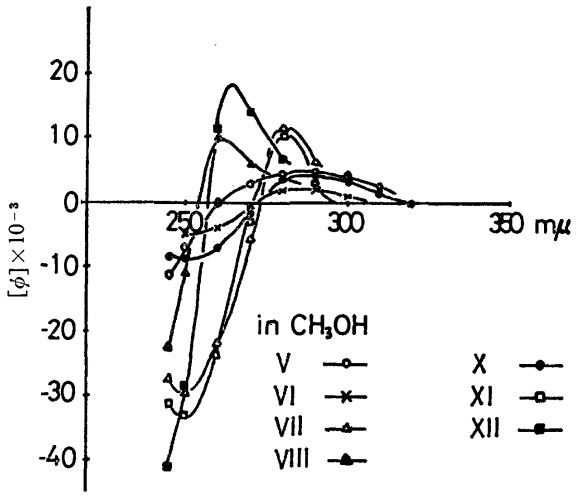

Chart B ORD Curves of Branched-chain Nucleosides

1-O-Acetyl-2,6-dideoxy-4-O-isovaleryl-3-C-methyl-β-L-ribo-hexopyranose (I). Acetic anhydride (3.0 ml) was added to a solution of crude 4-*O*-isovalery-L-mycarose[10] (carimbose) (0.32 g) in pyridine (1 ml). The solution was kept standing for 3 hr. Methanol (4 ml) was then added into the solution and the resulting mixture was kept standing at room temperature for 3 hr. It was concentrated below 55°C to afford a brown syrup (0.54 g), which was then subjected to column chromatography (benzene : 2-butanone=10 : 1). Five-gram fractions were collected. A combination of Fractions #4 and #5 afforded a syrup (0.27 g; 72%) which was then distilled to give an analytically pure acetate; mp 72—74°C, bp 133—135°C/0.01 mmHg, $[\alpha]_D^{25}-15°$ (*c* 1.1, chloroform). ν_{max}^{KBr} (cm^{-1}): 1761 (*O*-acetyl), 1738 (*O*-isovaleryl).

Found: C, 58.10; H, 8.56%. Calcd for $C_{14}H_{24}O_6$ (288.34): C, 58.32; H, 8.39%.

2,6-Dideoxy-1,4-di-O-isovaleryl-3-C-methyl-β-L-ribo-hexopyranose (II). Isovaleryl anhydride (3.3 ml) was added to a solution of crude 4-*O*-isovaleryl-L-mycarose[10] (4.0 g) in pyridine (40 ml), and the resulting mixture was left standing at room temperature for 18 hr. Additional anhydride (2 ml) was then added to the reaction mixture. After

standing for a further 25 hr, methanol (20 ml) was stirred into the mixture under cooling. The solution was allowed to stand overnight and was then concentrated *in vacuo* at 65°C (oil pump), followed by repeated co-evaporation with toluene to give a brown residue with a disagreeable odor. This was fractionated on a silica-gel column (150 g; benzene : 2-butanone=20 : 1; 100 ml fractions). The third and fourth fractions afforded Compound II (2.8 g; 52%). A pure product was obtained by a high-vacuum distillation (79% recovery); bp 155—158°C/0.002 mmHg, n_D^{20} 1.4552, $[\alpha]_D^{23}$ −20° (*c* 4.1, chloroform). ν_{max}^{film} (cm^{-1}): 1735 (*O*-isovaleryl).

Found: C, 61.33; H, 9.02%. Calcd for $C_{17}H_{30}O_6$ (330.43): C, 61.80; H, 9.15%.

The fifth fraction gave crude 4-*O*-*n*-butyryl-2,6-dideoxy-1-*O*-isovaleryl-3-*C*-methyl-β-L-*ribo*-hexopyranose (II′) (1.0 g; 20%), which was purified by high-vacuum distillation; bp 140—145°C/0.06 mmHg, n_D^{20} 1.4543 $[\alpha]_D^{23}$ −29° (*c* 3.9, chloroform). ν_{max}^{film} (cm^{-1}): 1738 (ester).

Found: C, 60.49; H, 8.83%. Calcd for $C_{16}H_{28}O_6$ (316.40): C, 60.74; H, 8.92%.

The seventh fraction gave 0.20 g (4.3%) of 4-*O*-acetyl-2,6-dideoxy-1-*O*-isovaleryl-3-*C*-methyl-β-L-*ribo*-hexopyranose (II″); bp 125—130°C/0.002 mmHg. The proton magnetic resonance spectrum of this compound (in $CDCl_3$ with TMS) had a singlet peak at δ 2.05 attributable to acetoxymethyl.

*2,6-Dideoxy-4-*O*-isovaleryl-*C*-methyl-4-*O*-p-nitrobenzoyl-β-*L*-ribo-hexopyranose (III).* *p*-Nitrobenzoyl chloride (1.28 g) was added stirred into a solution of 4-*O*-isovaleryl-L-mycarose[10] (1.53 g) in pyridine (10 ml), and the resulting mixture was stirred at room temperature for 16 hr. The mixture was moistured with water (0.5 ml), agitated for a while, diluted with a mixture of dioxane (50 ml) and water (5 ml), and then concentrated at 45°C *in vacuo* to give a cake. This was dissolved in benzene (100 ml), and the solution was washed successively with aqueous sodium bicarbonate (1.3%) and water, dried, and evaporated to dryness to afford a syrup (2.42 g), which was then crystallized with isopropanol; yield, 0.58 g (24%); mp 110—112°C. The mother liquor gave a further crop. Recrystallization from isopropanol gave analytical sample. Mp 112.5—114.5°C, $[\alpha]_D^{25}$ −19° (*c* 0.64, chloroform). $\lambda_{max}^{methanol}$ 259 mμ (ε, 13.1×10^3). ν_{max}^{KBr} (cm^{-1}): 1737 (ester), 1607, 1526, 1350, 725 (*p*-nitrophenyl).

Found: C, 57.56; H, 6.38; N, 3.56%. Calcd for $C_{24}H_{25}NO_8$: (395.42); C, 57.71; H, 6.37; N, 3.54%.

*9-(2,6-Dideoxy-3-*C*-methyl-β-*L*-ribo-hexopyranosyl)-purine (V).*
*A. From the 1-*O*-Acetyl Derivative*: A mixture of I (0.27 g), purine (0.11 g), and dichloroacetic acid (0.14 ml) were heated at 99°C for 3 min while being stirred well. A water aspirator vacuum (25 mmHg) was then applied, and the melt was stirred for more 10 min at the same temperature. The resulting greenish melt was quickly cooled with cold water and dissolved in ethyl acetate (20 ml). The solution was washed successively with aqueous sodium bicarbonate (1.3%) and water, dried, and evaporated to dryness to furnish a brown glass (0.27 g), which was then fractionated on a silica-gel column (benzene : acetone= 2 : 1; 5 g fractions). The product (0.14 g, 38%) obtained from Fractions #6 to #9 was dissolved in cold methanol (40 ml), and then chilled methanolic barium methoxide (1N; 5.3 ml) was showly added into the solution. After standing for 48 hr, the solution was carefully bubbled with carbon dioxide, quickly concentrated below 20°C, and purified by means of a silica-gel column (4 g, benzene : acetone= 1 : 1) to give homogeneous glass, 0.090 g (36% from I). Crystallization with diethyl ether (mp 197—199°C (colored)) and subsequent recrystallization from 2-butanone afforded colorless prisms; mp 215—216°C, $[\alpha]_D^{24}$ −25° (*c* 3.3, water). λ_{max}^{water} 265.5 mμ (ε, 6.9×10^3), $\lambda_{max}^{ethanol}$ 262.5 mμ (ε, 7.2×10^3). ν_{max}^{KBr} (cm^{-1}): 1595, 1584, 1497 (purinyl).

Found: C, 54.10; H, 6.12; N, 20.87%. Calcd for $C_{12}H_{16}N_4O_3$ (264.29): C, 54.53; H, 6.10; N, 21.20%.

*B. From the 1-*O*-nitrobenzoyl Derivative*: A mixture of III (0.20 g), purine (0.062 g), and dichloroacetic acid (0.07 ml) was heated in a test tube on a boiling-water bath for 3 min while being efficiently mixed by means of a glass rod. Then, the dark-colored mixture was quickly cooled by cold water and taken up with ethyl acetate (20 ml). The solution was treated as has been described above to give 0.17 g of a crude condensation mixture, which was then subjected to silica-gel column chromatography (5 g, benzene : acetone=2 : 1; 5 g each). The Fractions #3—#5 afforded a homogeneous syrup (0.07 g), which was then de-*O*-isovalerated with methanolic barium methoxide and subsequently treated in the above-described manner to give pure glass (0.049 g; 37% from III). Crystallization and recrystallization were carried out as above. The mixed melting point of this compound with the product from I was not depressed. The IR of the two were superimposable.

Found: C, 54.30; H, 6.16; N, 20.91% Calcd for $C_{12}H_{16}N_4O_3$ (264.29): C, 54.53; H, 6.10; N, 21.20%

*6-Chloro-*O*-(4′-*O*-isovaleryl-2′,6′-dideoxy-3′-*C*-methyl-β-*L*-ribo-hexopyronosyl)-purine(VI).* *A. From the 1-*O*-Acetyl Derivative*: A mixture of I (0.23 g), 6-chloropurine (0.20 g), and dichloroacetic acid (0.12 ml) was heated for 4 min at 95°C while being stirred well; the resulting melt was then stirred for a further 5 min under reduced pressure (25 mmHg, water aspirator) at the same temperature. The reaction was quenced by cooling, and the dark-colored mixture was diluted with 20 ml of ethyl acetate. After the recovery of the unreacted 6-chloro-purine (0.06 g) by filtration, the solution was treated as has been described above and then concentrated to furnish a heavy syrup (0.35 g), which was subsequently fractionated by means of a silica-gel column (benzene: 2-butanone=3 : 1; 5 g each). From Fractions #4 and #5, the product was obtained in a glassy state; yield, 0.11 g (36%). Crystallization and recrystallization were carried out with diisopropyl ether; colorless granular crystals; mp 130—131°C, $[\alpha]_D^{20}$ −28° (*c* 1.0, chloroform). $\lambda_{max}^{ethanol}$ 264 mμ (ε, 9.1×10^3). ν_{max}^{KBr} (cm^{-1}): 1737 (*O*-isovaleryl); 1599, 1567, 1499 (purinyl).

Found: C, 53.13; H, 5.89; N, 14.89%. Calcd for $C_{17}H_{23}O_4N_4Cl$ (382.85): C, 53.33; H, 6.05; N, 14.63%.

*B. From the 1-*O*-Isovaleryl Derivative*: 6-Chloropurine (0.15 g) and dichloroacetic acid (0.10 ml) were heated at 95°C for 2 min while being efficiently stirred, and then the reaction system was connected to a water aspirator while stirring and heating were continued for 2 min at the same temperature. From the resulting mixture, Compound VI was obtained after the above-mentioned treatment; yield, 0.10 g (27%). A mixed melting-point determination with the Compound VI obtained from I was not depressed. The IR of the two samples were superimposable.

Found: C, 52.95; H, 6.01; N, 14.77%. Calcd for $C_{17}H_{23}N_4O_4Cl$ (382.85): C, 53.33; H, 6.05; N, 14.63%.

*C. From the 1-*O*-p-nitrobenzoyl Derivative*: A finely-divided IV (0.20 g) and 6-chloropurine (0.08 g) were mixed well with dichloroacetic acid (0.05 ml) in a test tube with the aid of a glass rod and then heated on a boiling-water bath for 2 min while being efficiently mixed. After the reaction had been quenched, the mixture was subjected to the same treatment as above. The titled compound, 0.06 g (31%), was thus obtained; its melting point was not depressed by ad-

mixture with that from I. The IR of the two were superimposable.

Found: C, 53.14; H, 6.08; N, 15.05%. Calcd for $C_{17}H_{23}N_4O_4Cl$ (382.85): C, 53.33; H, 6.05; N, 14.63%.

6-Chloro-O-(4'-O-n-butyryl-2',6'-dideoxy-3'-C-methyl-β-L-ribo-hexopyranosyl)-purine (VII). A mixture of III (0.295 g), pulverized 6-chloropurine (0.15 g), and dichloroacetic acid (0.10 m*l*) was heated at 95°C at atmospheric pressure for 3 min and then *in vacuo* (23 mmHg). The recovering of the unreacted 6-chloropurine and the extraction of the acidic substances were carried out as has been described in the case of VI. The crude product thus obtained was fractionated on a column of silica-gel (benzene : 2-butanone=10 : 1—3 : 1; gradient elution), having been cut into five-gram portions. The main oily product (0.094 g, 27%) thus obtained was crystallized by trituration with diisopropyl ether. Two recrystallizations from the same solvent gave a pure sample as colorless prisms; mp 144—145°C; $[\alpha]_D^{23}$ −10° (*c* 0.72, chloroform): $\lambda_{max}^{ethanol}$ 264 mμ (ε, 10.1×10^3). ν_{max}^{KBr} (cm^{-1}): 1740 (*O*-*n*-butyryl); 1598, 1561, 1497 (purynyl).

Found: C, 52.21; H, 5.91; N, 15.01%. Calcd for $C_{16}H_{21}N_4O_4Cl$ (368.83): C, 52.12; H, 5.74; N, 15.19%.

6-Methoxy-9-(2',6'-dideoxy-3'-C-methyl-β-L-ribo-hexopyranosyl)-purine (VIII). VI (84 mg) was dissolved in 0.1 N methanolic barium methoxide (10 m*l*), and the resulting mixture was kept standing at room temperature for 4 days. After the careful bubbling in of carbon dioxide, the reaction mixture was quickly concentrated below 20°C under reduced pressure to give a residue which was then passed through a silica-gel column (2 g). By elution with a mixture of benzene and acetone (1 : 1), a product was obtained as a homogeneous glass (42 mg, 65%); it was twice crystallized from a mixed solvent of benzene, acetone, and diisopropyl ether (2 : 1 : 2) to give colorless needles; mp 211—213°C, $[\alpha]_D^{23}$ −18° (*c* 1.0, methanol). $\lambda_{max}^{methanol}$ 249 mμ (ε, 11.5×10^3). ν_{max}^{KBr} (cm^{-1}): 1604, 1581 (purinyl).

Found: C, 53.05; H, 6.16; N, 19.04%. Calcd for $C_{13}H_{18}N_4O_4$ (294.31): C, 52.89; H, 6.22; N, 18.94%.

9-(2',6'-Dideoxy-3'-C-methyl-3'-O-methyl-β-L-ribo-hexopyranosyl)-purine (X). 1,4-Di-*O*-acetyl-β-L-cladinose[16] (0.26 g) was fused and, after quick cooling to room temperature, was well mixed with purine (0.12 g) with the aid of dichloroacetic acid (0.18 m*l*). The mixture was heated with stirring at 98°C for 5 min under atmospheric pressure and then for a further 5 min under reduced pressure (water aspirator). After the quenching of the reaction by cooling with cold water, the greenish-colored mixture was diluted with 30 m*l* of ethyl acetate. The solution was washed and concentrated as in the case of the preparation of VI to afford an oily product (0.297 g), which was fractionated by a silica-gel column (5 g). The column was eluted with a mixed solvent of benzene and acetone (2 : 1). Five-gram fractions were collected. Fractions #3—#6 gave a main product (0.17 g) whose proton magnetic resonance spectrum did not show the presence of the α-anomer. This product was dissolved in methanol (30 m*l*) and treated with 4 m*l* of methanolic 1 N barium methoxide, as has been described in the preparation of V, followed by a similar working-up; it was then passed through a silica-gel column (4 g; benzene : acetone=3 : 2) to afford a glass (0.099 g, 35%). Two crystallizations and recrystallization from diisopropyl ether afforded colorless prisms; mp 155—156°C, $[\alpha]_D^{27}$ −10° (*c* 2.5, water). λ_{max}^{water} 262.5 mμ (ε, 7.2×10^3), $\lambda_{max}^{ethanol}$ 262.5 mμ (ε, 7.1×10^3). ν_{max}^{KBr} (cm^{-1}): 1596, 1581, 1499 (purinyl).

Found: C, 55.90; H, 6.48; N, 19.89%. Calcd for $C_{13}H_{18}N_4O_3$ (278.31): C, 56.10; H, 6.52; N, 20.13%.

6-Chloro-9-(2',6'-dideoxy-3'-C-methyl-3'-O-methyl-4'-O-acetyl-β-L-ribo-hexopyranosyl)-purine (XI). A mixture of 1,4-di-*O*-acetyl-β-L-cladinose[16] (0.26 g), pulverized 6-chloropurine (0.20 g), and dichloroacetic acid (0.13 m*l*) was heated for 4 min at 92—95°C with stirring in an open system and then *in vacuo* (25 mmHg) for 5 min to give a colored mixture; this mixture gave 0.36 g of an oily product after cooling, extraction, and concentration. This was subjected to silica-gel column chromatography (10 g, benzene : 2-butanone=5 : 1; 5 g each). Fraction #3 and #4 gave 0.10 g (28%) of a glass; this glass was subsequently crystallized with diisopropyl ether; mp 126—127°C. Two recrystallizations from the same solvent gave colorless prisms; mp 133—134°C, $[\alpha]_D^{25}$ −26° (*c* 2.5, chloroform). $\lambda_{max}^{ethanol}$ 264 mμ (ε, 9.5×10^3). ν_{max}^{KBr} (cm^{-1}): 1731 (*O*-acetyl); 1590, 1564, 1487 (purinyl).

Found: 50.73; H, 5.57; N, 15.63%. Calcd for $C_{15}H_{19}N_4O_4Cl$ (354.80): C, 54.53; H, 6.54; N, 15.79%.

6-Methoxy-9-(2',6'-dideoxy-3'-C-methyl-3'-O-methyl-β-L-ribo-hexopyranosyl)-purine (XII). XI (61 mg) was treated with 0.1 N methanolic barium methoxide (9 m*l*) for 3 hr, followed by neutralization with carbon dioxide and purification by means of a silica-gel column (5 g; benzene : acetone=2 : 1), to afford a colorless glass (53 mg, quant.). Three crystallizations from diisopropyl ether gave long, colorless needles; mp 179—180°C, $[\alpha]_D^{23}$ −15° (*c* 1.9, methanol), $\lambda_{max}^{methanol}$ 249 mμ (ε, 11.6×10^3), ν_{max}^{KBr} (cm^{-1}): 1608, 1582 (purinyl).

Found: C, 54.54; H, 6.63; N, 18.32%. Calcd for $C_{14}H_{20}N_4O_4$ (308.34): C, 54.53; H, 6.54; N, 18.17%.

This work was supported in part by the Grants-in-aid for cancer research from the Ministry of Education.

The authors wish to thank Dr. Shinichi Kondo and Mr. Seiji Shibahara, Institute of Microbial Chemistry, for the measurements of proton magnetic resonance spectra. We are indebted to Mr. Kazuo Yago for technical assistance.

The Reaction of Diaryl Disulfides with the Cyanide Ion

Kazuhiko TANAKA, Jun-ichi HAYAMI, and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 8, 1971)

The reaction of symmetrical disulfides with the cyanide ion in various solvents has been investigated. The reaction modes may be summarized as follows: (1) Dialkyl disulfides and diaryl disulfides with electron-withdrawing substituents react with the cyanide ion in DMSO or DMF to give the corresponding monosulfides. (2) Diaryl disulfides with electron-donating substituents react with DMSO to yield aryl methyl sulfides. (3) Diaryl disulfides are cleaved by the cyanide ion into thiolate anions and aryl thiocyanates, which then react with alcohol to afford alkyl aryl sulfides.

The scission of the sulfur-sulfur bond takes place when the attacking nucloeophile has a greater affinity for sulfur than the displaced group. This affinity for sulfur is called "*S*-nucleophilicity" or "thiophilicity".[1] The reaction of unsymmetrical disulfide with various *S*-nucleophiles was studied in detail by Parker and Kharasch.[2] The results indicate that the more stable (less basic) thiolate anion is displaced; the order of thiophilicity is found to be as follows:

$$C_2H_5S^- > C_6H_5S^- > CN^- > SO_3^{2-} > DNPS^- > N_3^- > SCN^-$$

The cyanide ion is a typical anthioanion which has a great affinity for sulfur to form thioanion (the thiocyanate ion).[3] The unsymmetrical disulfides with electron-withdrawing substituents on the aromatic nucleus were cleaved by the cyanide ion to displace thiolate anions at room temperature in aqueous alcohol.[2] Braun *et al.* found that bis(dialkylthiocarbamoyl) disulfides and bis(alkylarylthiocarbamoyl) disulfides react with potassium cyanide to give the corresponding monosulfides.[4] The analogous desulfurization of disulfides has been reported for dixanthyl disulfides,[5] bis(2-benzothiazolyl) disulfide, and dithiodiglycolic acid;[6] however, diphenyl disulfide,[5] bis(*p*-tolyl) disulfide,[6] and dibenzyl disulfide[6] do not react with the cyanide ion. We have previously found that dibenzyl disulfide reacts with the cyanide ion in dipolar aprotic solvents.[7] Therefore, we investigated the reaction of symmetrical disulfides with the cyanide ion in various solvents. We can now classify these reactions into three modes as follows:

$$\text{Mode A:}\quad RS\text{-}SR + CN^- \xrightarrow{\text{DMSO or DMF}} RSR + SCN^- \qquad (1)$$

$$\text{Mode B:}\quad RS\text{-}SR + CN^- + DMSO \rightarrow RSCH_3 \qquad (2)$$

$$\text{Mode C:}\quad RS\text{-}SR + CN^- + R'OH \rightarrow RSR' + RS^- \qquad (3)$$

Results and Discussion

Reaction Mode A. It has been reported that dialkyl disulfide does not react with the cyanide ion in alcohol,[1] since the alkanethiolate anion is a more powerful *S*-nucleophile than is the cyanide ion—*i.e.*, the equilibrium shown in Equation (4) lies to the left:

$$RS\text{-}SR + CN^- \rightleftharpoons RS^- + RSCN \qquad (4)$$

$$RS^- + RSCN \rightarrow RSR + SCN^- \qquad (5)$$

Since the cyanide ion reacts 5×10^5 times faster with methyl iodide in a dipolar aprotic solvent than in a protic solvent,[8] dialkyl disulfide can be expected to be cleaved by the cyanide ion in a dipolar aprotic solvent. Thus, dibenzyl sulfide was isolated in a 58% yield in the reaction of dibenzyl disulfide with the cyanide ion at room temperature in DMSO (Eq. (5)). This result shows that the cyanide ion is a more powerful *S*-nucleophile than is the alkanethiolate anion in the dipolar aprotic solvent. In a similar way, sulfides were obtained from disulfides in fairly good yields. The results are given in Table 1. Bis(*p*-nitrophenyl) and bis(*o*-nitrophenyl) disulfides were easily cleaved by the cyanide ion and gave the corresponding monosulfides in 60% and 76% yields respectively, while bis(*m*-nitrophenyl) and bis(*p*-tolyl) disulfides were not desulfurized to sulfides on treatment with the cyanide ion in DMSO.

Reaction Mode B. Diaryl disulfides, which have electron-donating substituents, were rapidly cleaved by the cyanide ion at room temperature; however, the corresponding monosulfides were not obtained, as has been cited above. When mixtures of diphenyl disulfide and sodium cyanide in DMSO were refluxed for 6 hr, a transparent oil was obtained in a 52% yield. The NMR spectra in CCl_4 exhibited singlet peaks at τ 7.63 (3H, S–CH_3) and at τ 2.66 (5H, aromatic), and the IR spectrum was identical with that of authentic methyl phenyl sulfide. The reaction process can reasonably be explained as follows; diphenyl disulfide was cleaved by the cyanide ion into phenyl thiocyanate and the benzenethiolate anion. Phenyl thiocyanate then reacts with the cyanide ion to afford the benzenethiolate

a) Diethyl sulfoxide was used instead of DMSO.

anion and cyanogen:[9]

$$ArSCN + CN^- \rightarrow ArS^- + (CN)_2 \quad (6)$$

Thus, when mixtures of phenyl thiocyanate and sodium cyanide in DMSO were refluxed for 6 hr, methyl phenyl sulfide was isolated in a 63% yield. The above data show that the thiolate anion, once formed, should react with DMSO to give aryl methyl sulfide. Thus, sodium p-toluenethiolate was treated with DMSO to afford methyl p-tolyl sulfide in an 80% yield. The results are shown in Table 3. The reaction of the thiolate anion with DMSO would form the I adduct, which might then thermally rearrange to aryl methyl sulfide.

$$ArS^- + CH_3\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}CH_3 \rightarrow \left[Ar\text{-}\overset{\overset{CH_3}{|}}{\underset{\underset{CH_3}{|}}{S}}\text{-}O^- \right] \rightarrow Ar\text{-}S\text{-}CH_3 + [CH_3SO^-] \quad (7)$$

a) Refluxing in alcohol.

Although the mechanism of this novel reaction is not yet clear, the *S*-methylation of thiols with DMSO is a useful method for preparing aryl methyl sulfides.

Reaction Mode C. Parker and Kharasch isolated phenyl thiocyanate in the reaction of 2,4-dinitrophenyl phenyl disulfide with sodium cyanide in the presence of 2,4-dinitrochlorobenzene.[2] We found that symmetrical diaryl disulfides were rapidly cleaved by the cyanide ion under refluxing in methanol, and that aryl methyl sulfides were isolated in high yields, as is shown in Table 4. The reaction can be explained by considering the initial formation of *O*-alkyl *S*-aryl thioiminocarbonate (II) from aryl thiocyanate and alcohol.[11] The intermediate (II) is in turn decomposed into the thiolate anion and alkyl cyanate. The nucleophilic attack of the thiolate anion on alkyl cyanate gave alkyl aryl sulfide, with the elimination of the cyanate ion.

The mechanism of the addition of alcohol to thiocyanate in the presence of the cyanide ion and the decomposition of the resulting *O*-alkyl *S*-aryl thioiminocarbonate will be described in detail elsewhere.

Conclusion

The reaction of disulfides with the cyanide ion may be summarized as follows:

i) Dialkyl disulfides and diaryl disulfides with electron-withdrawing substituents in the *ortho*- and *para*-positions give the corresponding monosulfides in dipolar aprotic solvents.

ii) Diaryl disulfides with electron-donating substituents react with DMSO to afford aryl methyl sulfides.

iii) Diaryl disulfides react with alcohol to give alkyl aryl sulfides.

Experimental

The melting points were determined on a hot-stage apparatus and were uncorrected. The NMR spectra were obtained in carbon tetrachloride with a JEOLCO 3H-60 spectrometer against internal TMS. The IR spectra were recorded with JASCO IR-S and DS-402G spectrophotometers, and glc was carried out using a Yanagimoto GCG-5DH gaschromatograph (Silicone DC-550, 3 m).

Material. The disulfides were prepared as has been described in the literature. The physical constants and the results of the elemental analysis of disulfides are listed in Table 5.

Reaction Mode A. General Procedure: Disulfide (0.05 mol) was dissolved in dry DMSO (100 m*l*) or dry DMF (100 m*l*) under stirring, and then powdered sodium cyanide (0.051 mol) was added. After a definite period (see Table 1), the colored solution (red to yellow) was poured into ice-cooled water. The resulting monosulfide was filtered (if solid), dried *in vacuo*, and then recrystallized. If the monosulfide was a liquid, the organic layer was extracted with ether three times, washed with water, and dried with anhydrous sodium sulfate. Distillation gave monosulfide as a transparent liquid. The physical data and the results of the analysis of the monosulfide which was formed by desulfurization are given in Table 6.

Table 6. Melting points and analytical data of monosulfides

Monosulfide	Mp °C (lit.)	Analysis Found (Calcd) C%	H%	S%
IIIb	46.5—47.5 (48.5[12])	78.72 (78.45)	6.60 (6.58)	14.68 (14.96)
VIIb	122—124 (122—123[19])	52.20 (52.17)	3.20 (2.92)	11.35 (11.61)
IXb	162.5—163.5 (160—161[20])	51.87 (52.17)	2.83 (2.92)	11.55 (11.61)
Xb	156.5—158.0 (149—150[21])	41.84 (41.76)	1.96 (1.75)	9.47 (9.29)

Reaction Mode B. General Procedure: A mixture of disulfide and sodium cyanide in DMSO was refluxed for 6 hr. After being cooled to room temperature, the reaction mixture was steam-distilled. The organic layer was extracted with *n*-hexane four times, washed with water, and then dried over anhydrous sodium sulfate. The evaporation of the solvent gave an oil, which was then distilled *in vacuo*. Methyl phenyl sulfide, by 86—87.5°C/20 mmHg (lit,[13] bp 84°C/18 mmHg); methyl *p*-tolyl sulfide, bp 100.8—103°C/19 mmHg (lit,[13] bp 104—105°C/20 mmHg). The NMR and IR spectra and the glc retention time of aryl methyl sulfide were identical with those of authentic samples.

The Reactions of Metal Acetylacetonates and Related Compounds with 2,2-Diphenyl-1-picrylhydrazyl[1)]

Kaku UEHARA, Kiyohiro KAMEI, Makoto TANAKA, and Niro MURATA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture: Sakai-shi, Osaka

(Received June 18, 1971)

Some metal acetylacetonates ($M(acac)_n$) were observed to react with the stable free radical 2,2-diphenyl-1-picrylhydrazyl (DPPH) in organic solvents. For the reaction of cupric 3-α-butenylacetylacetonate with DPPH in benzene and cyclohexane, the following rate equation was obtained: $R=k$[cupric chelate][DPPH]. The activation parameters of the reaction were remarkably dependent upon the nature of the substituent and the metal atom in $M(acac)_n$, and upon the solvent. The results of the kinetic studies and the analytical work suggested that $M(acac)_n$ reacted with DPPH to yield 2,2-diphenyl-1-picrylhydrazine (DPPH-H) *via* the reduction of the central metal of the $M(acac)_n$.

In a previous communication,[2)] it was reported that some metal acetylacetonates (M (acac)$_n$) reacted easily with 2,2-diphenyl-1-picrylhydrazyl (DPPH). The reaction will be described in more detail in this paper.

Although DPPH has been known as an efficient radical scavenger, it reacts with species other than radicals. For example, DPPH reacts with compounds having a labile hydrogen atom to produce a radical by the abstraction of the hydrogen atom.[3–13)] Furthermore, DPPH also reacts with some metal salts to form redox systems or complexes.[14–18)]

On the other hand, some $M(acac)_n$ are effective initiators of the radical polymerization of vinyl monomers.[19–22)] To elucidate the reaction mechanism of $M(acac)_n$ with DPPH, we carried out kinetic studies and a determination of the products.

Experimental

Materials. The cupric 3-alkylacetylacetonates were prepared from an aqueous solution of cupric acetate and an ethanol solution of 3-alkylacetylacetone which has been synthesized from sodium salt of acetylacetone and alkyl bromide in the manner reported by Morgan and Martin.[23,24)] The 3-α-butenylacetylacetone and other 3-α-alkenylacetylacetones were synthesized by the condensation of acetylacetone with *n*-butyraldehyde or other aldehydes in the presence of piperidine, according to the method shown in preceding papers.[21,25)] Their cupric chelates were prepared from an aqueous solution of cupric acetate and an ethanol solution of 3-alkenylacetylacetone. The $Cu(acac)_2$, $Fe(acac)_3$, $Mn(acac)_3$, $Co(acac)_3$, $Zn(acac)_2$, $Al(acac)_3$, and $Cr(acac)_3$ were G.R.-grade reagents and were used without further purification. A G.R.-grade sample of DPPH was recrystallized from benzene-ligroin; mp 137—138°C. The solvents were purified by the ordinary method and were distilled before use.

Apparatus and Procedure. The reaction was followed by photometric measurements of the DPPH concentration using a Hitachi recording spectrophotometer, Model EPS-3T. For the reaction in air at atmospheric pressure, aliquots of the reaction mixture were pipetted out at regular intervals from the stock solution in a test tube thermostatted at 25°C. The absorbance of this solution at 525 mμ (in benzene) was measured. For the reaction under a vacuum (10^{-5} mmHg), the following procedure was employed throughout this investigation. The reaction mixture was degassed by the use of the H-shaped tube illustrated in Fig. 1 because the conventional freeze-thaw cycle was unsuitable for this study, as will be described in the next paper.[26)] The solution of $M(acac)_n$ in A and the solution of DPPH in B were simultaneously frozen in liquid nitrogen, and the H-tube was joined to a high-vacuum line after the tube has been sealed at the (a) neck. Each solution was out-gassed by three freeze-thaw cycles under 10^{-5} mmHg, and then the H-tube was sealed at the (b) neck and separated from the vacuum line. The solutions in A and B were mixed thoroughly, and the resulting solution was transferred to the C section. The quartz cell, C, was immediately sealed at the (c) neck

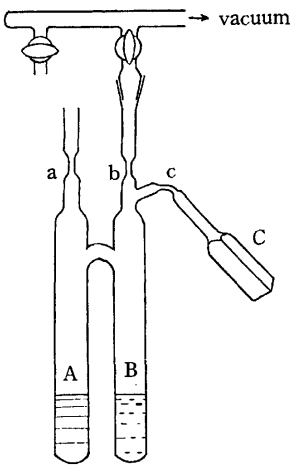

Fig. 1. Schematic drawing of the apparatus.

and separated from the H-tube. It was placed in the cell holder thermostatted at the desired temperature, and the optical density at 525 mμ was measured continuously.

The infrared spectra of the reaction products were measured on KBr disks by means of a Hitachi Model EPI-S2 infrared spectrometer. The mass spectra were recorded on a Hitachi Model RMU-6E mass spectrometer under the following conditions: ionization energy, 15 eV; total emission current, 80 μA; vacuum, 2×10^{-6} mmHg; sample temp., 250°C. The ESR spectra of cupric chelate in the presence of DPPH were measured by means of a Hitachi Model MES-4001 ESR spectrometer.

The isolation of products from the reaction mixture was carried out in the following way. Cupric 3-α-butenylacetylacetonate 1.2 g (0.0033 mol) was allowed to react with DPPH 0.87 g (0.0022 mol) in benzene under a vacuum for 48 hr. After the evaporation of the benzene, the cupric ion and 3-α-butenylacetylacetone were separated by twice extracting the resulting reaction mixture with 200 ml of disodium ethylenediaminetetraacetate (EDTA-2Na) on a hot plate. The residue after the extraction was a viscous brownish-red oil. By the recrystallization of the residue from methanol-water, an orange-brown powder (P) was obtained.

Results and Discussion

Most of the present studies were performed on cupric 3-α-butenylacetylacetonate because it has an appreciable solubility in nonpolar solvents and a high reactivity toward DPPH. Furthermore, this chelate is easily made and has been fairly well studied in our preceding papers.[25,27]

The effects of oxygen on the reaction of cupric 3-α-butenylacetylacetonate with DPPH in benzene are summarized in Table 1. The rate of the reaction

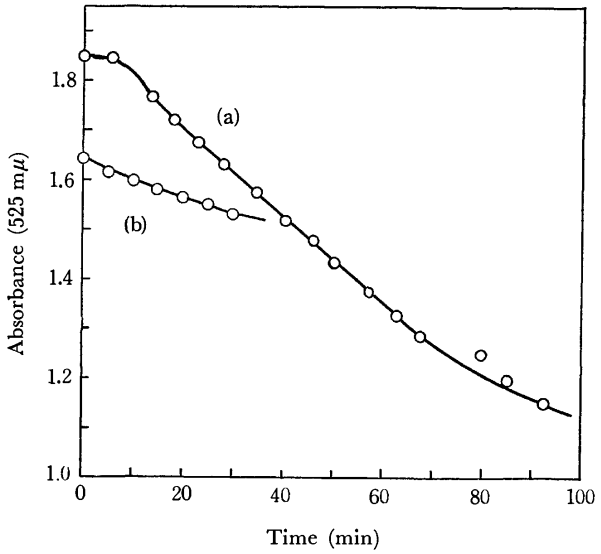

Fig. 2. The change of absorbance in the reaction of cupric 3-α-butenylacetylacetonate with DPPH at 25°C.

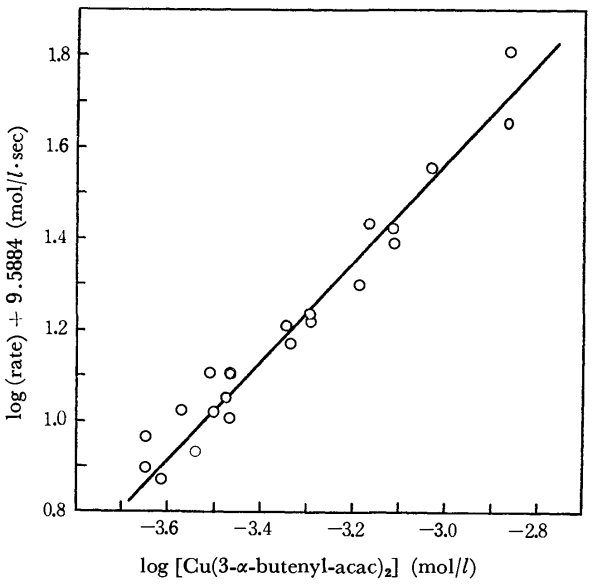

Fig. 4. Plot of log (rate) *versus* log [Cu(3-α-butenyl-acac)$_2$] at 25°C.
[DPPH] $=5.85\times10^{-5}$ mol/*l*

parent activation energy for the reaction was 9.2 kcal/mol *in vacuo* and 11.1 kcal/mol in atmospheric air. The relationships between the reaction rates and the initial concentrations of DPPH for a constant initial cupric chelate concentration *in vacuo* are shown in Fig. 3, from which the rate is found to increase with a 0.9 power[28] of the DPPH concentration. The dependencies of the rate of the reaction *in vacuo* on the concentration of the cupric chelate are shown in Fig. 4, from which the reaction rate is found to be first order with respect to the cupric chelate. In atmospheric air, the rate of the reaction (estimated from the portion of the initial straight line of the sigmoid curve) depended on the 1.4 power of the cupric chelate concentration and the 1.6 power of DPPH. These effects of air suggested that, in atmospheric air, oxygen virtually takes part in the reaction and complicates it. Therefore, to exclude the effect of oxygen, all subsequent experiments were carried out *in vacuo* (10^{-5} mmHg).

The solvent effects on this reaction are summarized in Table 2. In a few solvents the maxima of the absorption spectra of DPPH shifted to shorter wavelengths in the following order: benzene (525 mμ), dioxane (520 mμ), cyclohexane (513 mμ). It was found that the rate of the reaction in these solvents increased with a decrease in the λ_{max} of DPPH. The complex formation of DPPH with several solvents has been confirmed by means of elemental analysis[29] or X-ray diffraction data.[30] Recently, some investigators have reported that the formation of a charge-transfer complex between DPPH and benzene or dioxane was observed from the ESR spectra.[31,32] The solvent effect in the present reaction may be related in some way to the complex formation with these solvents.

While the activation energies of this reaction increase in the order: benzene<dioxane<cyclohexane, the frequency factors markedly increase in the same order. The net reaction rates observed reflect the fact that the unfavorable activation energies are more than compensated for by the higher frequency factors.

First-order kinetics for each reactant were observed in benzene and cyclohexane. Sutcliffe and Walkly[14] have also pointed out that the redox reaction of metal acetate with DPPH in acetic acid gives first-order kinetics for each reactant and that the rate is reduced by the addition of benzene.

The effects of the replacement of the hydrogen atom in the 3-position of acetylacetone are shown in Table 3. The styryl derivative, I, showing the largest rate among the derivatives studied here had the same activation energy as III or IV, but a much higher frequency factor. It has been reported that the type of substituent markedly affects the frequency factor rather than the activation energy in the radical polymerization of styrene.[25,33]

The effects of metal atoms of metal acetylacetonates on the reaction rate are shown in Table 4. The order of the reactivity of $M(acac)_n$ was as follows:

Mn(III)>Fe(III)>Zn(II)>Co(III)>Cu(II),
Al(III), Cr(III)

The observed reactivity order of $M(acac)_n$ was independent of their stability constants (in water) and of the ionization potentials or electronegativities of their central metals, as was pointed out in connection with the radical polymerization initiated by $M(acac)_n$.[22] The Mn(III) chelate was most reactive toward DPPH, which is in agreement with the activity in the radical polymerization of styrene[19] and methyl methacrylate.[22] On the other hand, the Co(III) chelate, which has a fairly high activity for the radical polymerization, was less reactive to DPPH. The lower reaction rate of $Co(acac)_3$ is attributable to its lower frequency factor.

Table 4. The reaction of DPPH with $M(acac)_n$ in benzene
([DPPH]$=0.545\times10^{-4}$ mol/l, [$M(acac)_n$]$=4.68\times10^{-4}$ mol/l)

$M(acac)_n$	Rete at 25°C mol/l·sec	Activation energy kcal/mol	Frequency factor l/mol·sec
$Mn(acac)_3$	9.8×10^{-10}	8.6	9.8×10^{4}
$Fe(acac)_3$	2.2×10^{-10}	15.3	1.4×10^{9}
$Zn(acac)_2$	1.9×10^{-10}	13.0	2.6×10^{7}
$Co(acac)_3$	0.9×10^{-10}	6.5	2.1×10^{2}
$Cu(acac)_2$	$<10^{-11}$	—	—
$Al(acac)_3$	$<10^{-11}$	—	—
$Cr(acac)_3$	$<10^{-11}$	—	—

The effects of solvents, substituents, and central metals showed that the reactivity of $M(acac)_n$ toward DPPH could not be explained only by the activation energy. The difference between the frequency factors, especially the low frequency factor, is noteworthy.

The ESR spectra of cupric 3-α-butenylacetylacetonate in benzene in the presence of DPPH are shown in Fig. 5. The reduction of the central metal, Cu(II)→Cu(I), is established from the decrease in the intensity of the ESR spectra of Cu(II) with the time.

In order to identify the reaction product (P) isolated

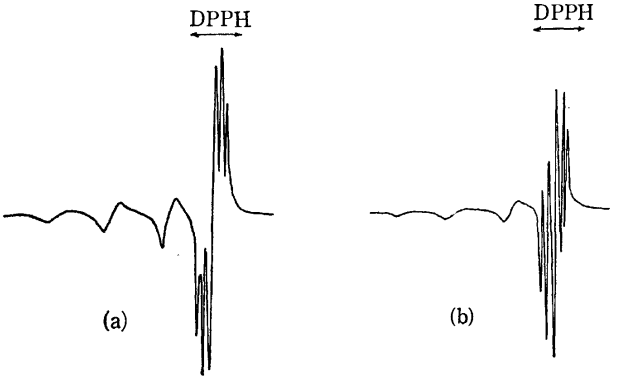

Fig. 5. ESR spectra of $Cu(3\text{-}\alpha\text{-butenyl-acac})_2$ in benzene in the presence of DPPH at room temperature.
(a) $t=0$ min (b) $t=60$ min

by the way described in the Experimental section, the following analyses were carried out. The infrared and ultraviolet absorption spectra of the product (P) agreed with those of an authentic sample of 2,2-diphenyl-1-picrylhydrazine(DPPH-H). The mass spectrum of (P) was closely analogous to that of DPPH-H. It showed the base peak at *m/e* 168 corresponding to that of $(Ar\text{-}NH\text{-}Ar)^+$, *m/e* 212 $(picryl)^+$ and *m/e* 227 $(picryl\text{-}NH)^+$. The value of the elemental analysis of this product also agreed with that of DPPH-H. Found: C, 54.70; H, 3.28; N, 17.28%. Calcd for $C_{18}H_{13}O_6N_5$: C, 54.68; H, 3.28; N, 17.71%.

Cupric 3-α-butenylacetylacetonate has two kinds of labile hydrogen atoms (H^a, H^b). In order to investigate which kind of hydrogen atom takes part in the reaction, the reaction rate of the styryl derivative I, which has no labile H^a was compared with that of the butenyl derivative IV (Table 3). The I derivative showed a higher reactivity than the IV derivative toward DPPH, and the product in this reaction was also DPPH-H. This fact suggests that H^a does not take part in the reaction. Gritter and Ratmore[34] have shown in a study of the site of attack with a *t*-butoxy radical,[34] that a hydrogen atom is abstracted from the 1-position of metal acetylacetonate (H^b). Therefore, it is plausible that labile H^b was abstracted by DPPH in the reaction.

II

Therefore, 3-α-butenylacetylacetone (ligand) was used in place of its cupric chelate in the reaction with DPPH (Table 5). It was found that the reaction rate is one order of magnitude smaller than that for its cupric chelate.

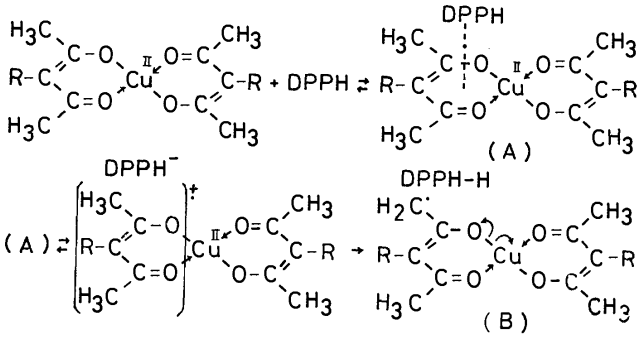
Table 5. The reaction of DPPH with 3-α-butenylacetylacetone (ligand)
([3-α-butenylacetylacetone] = 4.68×10^{-4} mol/l
[Cu(3-α-butenyl-acac)$_2$] = 4.68×10^{-4} mol/l
[DPPH] = 0.545×10^{-4} mol/l)

Reactant	Rate at 25°C mol/l·sec
3-α-butenylacetylacetone	0.35×10^{-9}
Cu(3-α-butenyl-acac)$_2$	3.1×10^{-9}

This lower reactivity of the ligand suggests that the electron transfer from the ligand to the central metal contributes to the reactivity of metal chelates.

As has been described in the Introduction, DPPH forms complexes with several kinds of organic solvents or metal salts. Therefore, it is probable that, in this reaction, the complex formation with M(acac)$_n$ promotes the internal electron transfer from the ligand to the central metal in the same manner as has been described for the system of Cu(acac)$_2$ and tetracyanoethylene.[35] This reaction involves the reduction of the central metal, but does not involve the oxidation of the metallic ion, as has been reported by Bawn and Verdin in the reaction of the ferrous ion and DPPH.[15] Furthermore, the complex formation is considered to lead DPPH to a favorable steric arrangement to abstract a hydrogen atom of the cupric chelate.

A possible mechanism embodying these ideas may be proposed for the reaction of M(acac)$_n$ with DPPH.



The mechanism is consistent with the observed kinetic results *in vacuo* and the products of the reaction. The internal electron transfer from the ligand to the central metal will facilitate the expulsion of a proton from a methyl group of metal acetylacetonate. The highest reactivity of cupric 3-styrylacetylacetonate (I) seems to result from phenyl group conjugated to the chelate ring, which would be expected to facilitate the internal electron transfer.[25]

Stereochemical Studies of Monoterpene Compounds. XIV.[1] The Rotational Conformation of the Acetyl and the Formyl Groups of Monoterpene α,β-Unsaturated Carbonyl Compounds

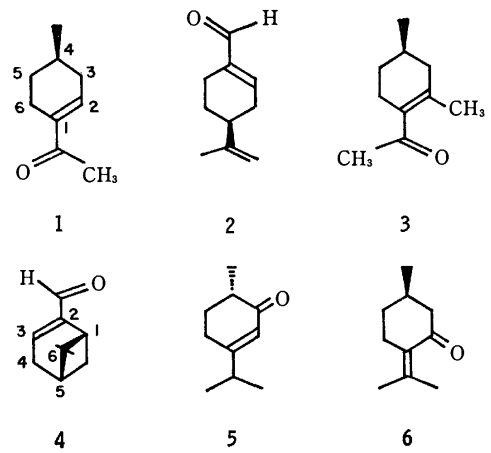
Takayuki SUGA, Kiyoshi IMAMURA, and Tsuyoshi SHISHIBORI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 21, 1971)

Temperature-dependent circular dichroism measurements in the *n*-π* transition enabled us to predict the preferred rotational conformation of the acetyl and the formyl groups of such monoterpene α,β-unsaturated carbonyl compounds as (+)-1-acetyl-4-methylcyclohexene (**1**), (−)-perillaldehyde (**2**), (+)-1-acetyl-2,4-dimethylcyclohexene (**3**), and (−)-myrtenal (**4**).

The geometry of α,β-unsaturated carbonyl compounds has been determined by means of studying the IR, the UV,[2] and the NMR spectra[3] and by dipole-moment measurements.[4] The temperature-dependent circular dichroism (CD) has recently been found to be useful for studying quantitatively the conformational alteration of optically-active, flexible cyclohexanone derivatives.[5] The conformational analysis of α,β-unsaturated carbonyl compounds, particularly flexible ones, is important, because the conformation of the compounds can be expected to affect their chemical reactivity and physicochemical properties. However, only one attempt[6] to make a conformational study of flexible α,β-unsaturated carbonyl compounds has been made. We now wish to deal with the rotational conformation of the acetyl and the formyl groups of four monoterpene α,β-unsaturated carbonyl compounds, (+)-1-acetyl-4-methylcyclohexene (**1**), (−)-perillaldehyde (**2**), (+)-1-acetyl-2,4-dimethylcyclohexene (**3**), and (−)-myrtenal (**4**). The present study was undertaken on the basis of the temperature-dependent circular dichroism and on the basis of the rule[7] of the correlation between the chirality of an enone system and its sign of a Cotton effect for the *n*-π* transition.



The absolute configuration of the α,β-unsaturated carbonyl compounds used.

Results and Discussion

For the compounds (**1**), (**2**), and (**3**), but not (**4**), both the conformational exchange of the cyclohexene ring and the rotational conformation of the carbonyl group are suspected to be important factors directly affecting the CD curve. However, since the cyclohexene ring substituted with the bulky group would exist in a stable half-chair conformation,[8] the change in the rotational strength depending on the temperature should be considered to indicate truly the equilibrium of the rotational conformation.

The acetyl group of the compound (**1**) can exist in the *s-trans* or the *s-cis* geometry, which may be stabilized by the orbital overlap interaction of the carbonyl and the ethylenic double donds. The geometry of α,β-unsaturated carbonyl compounds can be elucidated by means of the frequency difference and the intensity ratio between the C=O and the C=C stretching bands in the IR spectrum and by means of the molecular extinction coefficient of the π–π* transition in the UV spectrum. The compound (**1**) was identified as taknig preferentially the *s-trans* geometry on the basis of the similarity of its values to those of the representative, *s-trans* α,β-unsaturated ketone, (−)-carvenone (**5**) (Table 1). The CD curve of **1** exhibited a positive Cotton effect with a fine structure in the region of the *n*–π* transition (Fig. 1). The positive rotational strength was increased linearly with a lowering of the temperature. This observation can be explained in terms of the rotational conformations of the acetyl group. This group may be not coplanar with the ethylenic double bond, but may be rotated out of the plane. Accordingly, the compound (**1**) can exist in two possible rotational conformations, **1a** and **1b** (Fig. 2). Since the octant projection diagram predicts a positive Cotton effect for **1a** and a negative one for **1b**, the temperature-dependency of the CD curve indicated the predominancy of **1a** in the conformational equilibrium between **1a** and **1b**.

Fig. 3. The preferred rotational conformation of the formyl group of compound **2**.

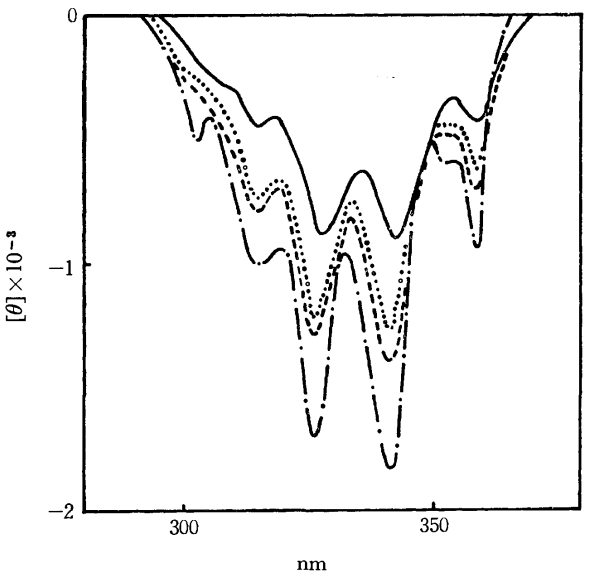

Fig. 4. CD curves of compound **2**: ——, at 25°C, ·····, at −25°C, ----, at −76°C, and —·—, at −115°C in MI solvent.

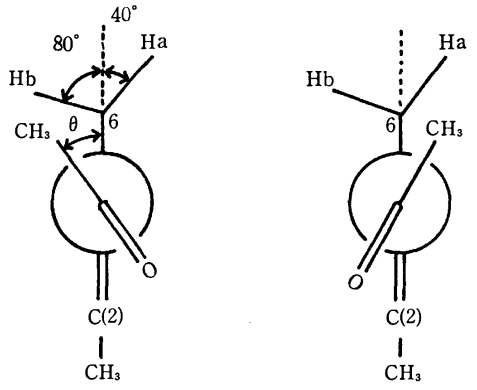
For the compound (**2**), the **2a** and **2b** conformations (Fig. 3) with the skewed *s-trans* geometry may be favored, as has been discussed above. The temperature-dependency of the CD curve (Fig. 4) showed the presence of the conformational equilibrium between **2a** and **2b**, with a negative and a positive Cotton effect respectively. The increase in the negative rotational strength with the lowering of the temperature indicated the predominance of the **2a** conformer.

According to the Dreiding Model, two allylic hydrogen atoms, (Ha) and (Hb), at the C-6 position are located dissymmetrically in relation to the plane of the ethylenic double bond, keeping the angles of 40 and 80° respectively (Figs. 2 and 3). For the **1b** and **2b** conformers, accordingly, the internuclear distance (2.4 Å) between the Ha and the oxygen atom of the

carbonyl group is shorter than the sum of the van der Waals radius[9] of the hydrogen atom (1.2 Å) and that of the oxygen atom (1.4 Å). On the other hand, the distance between the Hb and the oxygen atom is 2.8 Å for the **1a** and **2a** conformers. These conformers suffer no van der Waals interaction. Thus, the similarity of the temperature-dependent CD curve of the compound (**1**) to that of the compound (**2**) seems to indicate that the bulkiness of the alkyl group (the hydrogen atom or the methyl group) of the carbonyl side chain does not significantly affect the rotational conformation.

The similarity of the IR and the UV spectral data of the compound (**3**) (Table 1) to those of (+)-pulegone (**6**) with a *s-cis*, α,β-unsaturated ketone moiety suggests **3a** and **3b** with a skewed *s-cis* geometry (Fig. 5), as the preferred conformation of **3**. From the



3a **3b**

Fig. 5. The preferred rotational conformation of the acetyl group of compound **3**.

discussion, compared with the compound (**1**), it seems that the steric hindrance of the methyl group at C-2 could enable the compound (**3**) to take the preferred conformation with the *s-cis* moiety. According to the octant projection diagram, a positive Cotton effect can be predicted for **3a**, and a negative one, for **3b**. The CD curve of the compound (**3**) exhibited a weak negative Cotton effect at 25°C. However, with a lowering of the temperature, a strong positive curve appeared in the long-wavelength region at the expense of the negative one (Fig. 6). This result suggests the predominance of the **3a** conformer. This is supported by the fact that the dihedral angle, θ, of the the compound (**3**) between the plane of the ethylenic double bond and that of the carbonyl double bond is larger than that of the compounds (**1**) and (**2**), because the van der Waals radius of the methyl group (2.0 Å) is larger than that of the oxygen atom.

As is shown in Table 1, the IR and the UV spectral data of the compound (**4**), except for the value of the relative intensity, showed an intermediate value between those of the compounds (**5**) and (**6**). This seems to imply that the formyl group may exist in an equilibrium between the *s-trans* and the *s-cis* forms. For the compounds (**1**) and (**2**), however, the conformation with the *s-trans* geometry must be predominant over that with *s-cis*, as has been described above. In addition, it has been pointed out[10,11] that, for butadiene, the *s-trans* form is more stable than the *s-cis* one because of the unfavorable arrangement of the pi orbitals of the latter. Accordingly, the **4a** and **4b** conformations with the skewed *s-trans* geometry are favored for the compound (**4**) (Fig. 7). A positive

4a **4b**

Fig. 7. The preferred rotational conformation of the formyl group compound **4**.

Cotton effect can be predicted for the **4a** conformer and an opposite one for the **4b** conformer. Actually, the CD curve of **4** exhibited a positive Cotton effect at room temperature. This seems to indicate the preference of the **4a** conformer. However, the compound (**4**) showed unusual variable-temperature CD curves; with a lowering of the temperature, the positive rotational strength in the shorter-wavelength region increased, together with the negative one in the longer-wavelength region (Fig. 8). This indicates the existence of an equilibrium containing more than two rotational conformations, which is considered to show that the conformer population of **4a**, together

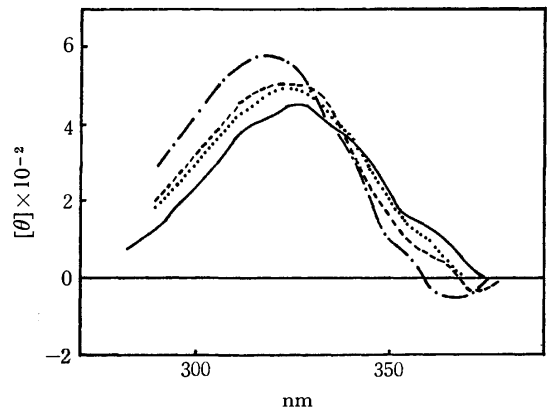

Fig. 8. CD curves of compound **4**: ——, at 25°C, ·····, at −27°C, ----, at −92°C, and —·—, at −184°C in MI solvent.

with that of **4b**, increased at the expense of the *s-cis* form. This can be explained by the symmetry of the spatial arrangement of the allylic carbon-carbon single bonds at the C-1 position to the planes of C-1, C-2, and C-3, a symmetry resulting from the insertion of a cyclobutane ring into the cyclohexene ring, as has been shown in the cases of **4a** and **4b**. Thus, the stabilities of the **4a** and **4b** conformers are nearly equal.

For the cyclohexene derivatives, thus, the predominance of the conformation has been concluded to depend on the dissymmetry on the allylic carbon of the ethylenic double bond.

Experimental

Measurements. The temperature-dependent CD curves were measured by means of a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a CD attachment in the MI solvent (methylcyclohexane - isopentane, 1 : 3 by volume) and in the EPA solvent (ether - isopentane - ethanol, 5 : 5 : 2 by volume), using a variable temperature CD cell designed and constructed by the authors.

Materials. (+)-*1-Acetyl-4-methylcyclohexene* (**1**): (−)-10-Nor-8-oxomenthol[12] was treated with a mixture of hydrochloric acid and ethyl alcohol (1 : 4 by volume) overnight to convert it to **1**. The crude oil was then refined by column chromatography over silica gel. The compound (**1**) (100% pure by analytical glc) thus obtained showed the following properties: bp 84.0—85.0°C/5 mmHg, n_D^{25} 1.4786, d_4^{25} 0.9384, $[\alpha]_D^{25}$ +184.4° (neat); NMR $\delta(CDCl_3$, 60 MHz) 0.98 (d, J=6 Hz, −CH−C$\underline{H}_3$), 2.15 (s, −CO−C$\underline{H}_3$), 6.64 ppm (m, −C=C$\underline{H}$−).

(−)-*Perillaldehyde* (**2**): A commercial sample was purified by distillation to give a 99.0% pure compound (**2**), which showed the following properties: bp 89.0—90.0°C/9 mmHg n_D^{25} 1.5036, d_4^{25} 0.9610, $[\alpha]_D^{25}$ −126.5° (neat).

(+)-*1-Acetyl-2,4-dimethylcyclohexene* (**3**): The compound (**3**) was synthesized from (+)-isopulegone (bp 96.0-96.5°C/14 mmHg, n_D^{25} 1.4715, d_4^{25} 0.9745, $[\alpha]_D^{25}$ +9.65° (neat); 90% pure by analytical glc) by the Grignard reaction, followed by ozonization and the dehydration with thionyl chloride. Column chromatography over silica gel impregnated with 15% (v/v) silver nitrate gave a compound (**3**) with the following properties: bp 64.0°C/4 mmHg, $[\alpha]_D^{25}$ +119.0° (*c* 0.185, ethanol); NMR $\delta(CDCl_3$, 60MHz) 0.96 (d, J=6 Hz, −CH−C$\underline{H}_3$), 1.80 (s, −C=C−C$\underline{H}_3$), 2.11 ppm (s, −CO−C$\underline{H}_3$).

(−)-*Myrtenal* (**4**): Following the method in the literature,[13] the oxidation of β-pinene, bp 164.0°C/760 mmHg, n_D^{25} 1.4782, d_4^{25} 0.8692, $[\alpha]_D^{25}$ −19.9° (neat), with selenium dioxide gave a crude compound (**4**), which was then subjected to column chromatography. The pure sample (100% pure by the analytical glc) showed the following properties: bp 58.5°C/4 mmHg, n_D^{25} 1.5002, d_4^{25} 0.9845, $[\alpha]_D^{25}$ −15.8° (neat).

The authors are indebted to the Takasago Perfumery Co., Ltd., and the Nippon Terpene Chemical Co., Ltd., for furnishing us with the samples of perillaldehyde, isopulegol, and β-pinene.

The Photochemical Reduction of Nitrobenzene and Its Reduction Intermediates. X. The Photochemical Reduction of the Monosubstituted Nitrobenzenes in 2-Propanol

Shizunobu HASHIMOTO and Koji KANO

Department of Applied Chemistry, Doshisha University, Kamikyo-ku, Kyoto

(Received July 9, 1971)

The photochemical reduction of the monosubstituted nitrobenzenes has been investigated in 2-propanol under a nitrogen atmosphere. The nitrobenzenes with electron-withdrawing groups on *meta*- and *para*-positions (*p*-NO_2, *m*- and *p*-CN, *m*- and *p*-$COOC_2H_5$, *p*-$COOCH(CH_3)_2$, and *m*- and *p*-COOH) were photoreduced to the corresponding anilines, and nitrobenzene and the *para*-substituted nitrobenzenes with electron-donating groups (*p*-CH_3 and *p*-OCH_3) were photoreduced to the corresponding phenylhydroxylamines. *p*-Nitroaniline and *p*-nitrophenol were unreactive toward the photoreduction. In the experiments on the determination of the quantum yields for the nitrobenzenes' disappearance upon irradiation with a 313- or 366-nm light, it has been found that there is a linear correlation between the log-values of the relative quantum yields of the substituted nitrobenzenes and nitrobenzene and the Hammett constants, and the ρ value was +1.5. The results obtained suggest that the hydrogen-abstraction reaction of the photoexcited nitrobenzenes may proceed electrophilically.

Hurley and Testa[2] have reported that the reactivity of the hydrogen abstraction of the protonated nitrobenzene triplet is greater than that of the unprotonated nitrobenzene triplet. Similar results have been obtained in the photoreduction of 1-nitronaphthalene in hydrochloric acid (HCl) -2-propanol (IPA) solutions.[3] These results obtained by Testa *et al.* are very interesting in clarifying the mechanism of the hydrogen abstraction of the photoexcited nitro aromatic compounds. On the other hand, we ourselves have previously reported that 4-nitropyridine is not photoreduced in IPA, whereas it is reduced photochemically in a HCl-IPA solution to form 4-hydroxylaminopyridine in a quantitative yield,[4] and that judging from the results of the quantum-yield measurements, the hydrogen abstraction of 4-nitropyridine in the n,π^* excited state may proceed electrophilically.[1] We have also found that, when the photoreduction of the *para*-substituted nitrobenzenes is done in IPA, there is a linear correlation between the log-values of the relative quantum yields for the substituted nitrobenzenes' disappearance and the nitrobenzene and the Hammett constants (ρ : +).[5]

In this paper, we wish to report in detail our findings on the photoreduction of the monosubstituted nitrobenzenes in IPA and to discuss the mechanism of the hydrogen-abstraction reaction of the photoexcited nitrobenzenes. Both the reporting and discussing were begun in a previous communication (Ref. 5).

Experimental

Materials. The *p*-nitrobenzonitrile[6] and phenylhydroxylamine[7] were prepared according to the procedures described in the literature. The monosubstituted anilines were prepared by the reduction of the corresponding substituted nitrobenzenes with zinc dust - HCl, or the reagent-grade anailines were purified prior to use. The monosubstituted phenylhydroxylamines were prepared according to the same procedures as were used in the preparation of phenylhydroxylamine.[7] The other materials, commercially obtained, were purified by recrystalization or distillation.

Identification of the Products. The identification of the photoreduction products was established by comparing the UV spectra with those of authentic samples. A Hitachi 124 spectrophotometer was used to follow the progressive spectral changes in the nitrobenzenes photochemistry.

Determination of Quantum Yields. The determination of the quantum yields for the nitrobenzenes' disappearance was undertaken according to the methods of previous papers.[1,5] The 366-nm light was isolated from a high-pressure 130-W mercury lamp with a Toshiba UV-D1B filter or with a combination filter of Toshiba UV-D1B and UV-35.

Results

Photoproducts of the Monosubstituted Nitrobenzenes. The progressive spectral changes were measured when 1 or 2×10^{-3} mol/*l* solutions of the nitrobenzenes in IPA were irradiated with an immersion-type 130-W high-pressure mercury lamp under a nitrogen atmosphere at room temperature. In most of the reaction, the isosbestic points were observed; therefore, it seems that the photoreaction of the nitrobenzenes in IPA proceeds quantitatively. The isosbestic points in each case were: *p*-NO_2; 233 and 294, *p*-CN; 225 and 242, *m*-CN; 265, *p*-$COOC_2H_5$; 230 and 269, *p*-$COOCH(CH_3)_2$; 231 and 268, *p*-COOH; 232 and 267, H; 244 and 288, *p*-CH_3; 253 and 302, *p*-OCH_3; 228, 266, and 366, *p*-OH; 215 and 264, and *p*-NH_2; 305 and 436 nm, respectively.

Meanwhile, the photoproducts were the corresponding substituted anilines in the photolysis of the *meta*- or *para*-substituted nitrobenzenes with electron-withdrawing groups, and were the corresponding phenylhydroxylamines in the photolysis of nitrobenzene and the *para*-substituted nitrobenzenes with electron-

donating groups, except for the *p*-NH_2 and *p*-OH derivatives. In the photolysis of *p*-chloronitrobenzene in IPA, no isosbestic points were observed in the UV spectrum; this suggests that the photoreaction of *p*-chloronitrobenzene proceeds in a complicated way. Therefore, we put off the photolysis of the halonitrobenzenes until a latter time.

Quantum Yields for the Disappearance of the Substituted Nitrobenzenes. The quantum yields for the nitrobenzenes' disappearance in IPA at 313 or 366 nm were measured. The photolysis was done under a nitrogen atmosphere at room temperature. The reaction conditions and the results obtained are summarized in Table 1.

TABLE 1. QUANTUM YIELD RESULTS FOR THE DISAPPEARANCE OF THE SUBSTITUTED NITROBENZENES IN 2-PROPANOL

$XC_6H_4NO_2$	Concn. $\times 10^3$ mol/*l*	Light nm	Product	Quantum yield
p-NO_2	1.00	366[a]	*p*-Nitroaniline	0.16
p-CN	1.03	313	*p*-Aminobenzonitrile	0.48[c]
m-CN	1.00	313	*m*-Aminobenzonitrile	0.34
p-$COOC_2H_5$	1.00	313	Ethyl *p*-aminobenzoate	0.15
m-$COOC_2H_5$	1.00	313	Ethyl *m*-aminobenzoate	0.11[c]
p-$COOCH(CH_3)_2$	0.25	313	Isopropyl *p*-aminobenzoate	0.15
p-COOH	1.00	313	*p*-Aminobenzoic acid	0.12
m-COOH	1.17	313	*m*-Aminobenzoic acid	0.18
H	1.10	313	Phenylhydroxylamine	0.03
p-CH_3	1.00	313	*p*-Hydroxylamino-toluene	0.07
p-OCH_3	0.25	313	*p*-Hydroxylamino-anisole	0.02
p-OH	0.50	313	—	0.00
p-NH_2	0.50	366[b]	—	0.004

a) A combination filter of Toshiba UV-D1B and UV-35 was used.
b) A filter of Toshiba UV-D1B was used.
c) In these cases, the quantum yields for the formation of the anilines were measured.

In the UV-spectrum measurements, the n,π^* absorption bands ($\log\varepsilon \leqq 2$) were observed in IPA in the 320—420 nm range for the *m*- and *p*-CN, *m*- and *p*-$COOC_2H_5$, *p*-$COOCH(CH_3)_2$, *m*- and *p*-COOH, H, and *p*-CH_3 derivatives; therefore, the reactivity of the n,π^* excited nitrobenzenes was measured by irradiation with the 313-nm light. On the other hand, since no n,π^* bands were observed in the UV spectrum for the *p*-OCH_3, *p*-OH, and *p*-NH_2 derivatives, the light which excites these compounds at the lowest energy was irradiated.

As Table 1 shows, the quantum yields for the disappearance of the *meta*- and *para*-substituted nitrobenzenes with electron-withdrawing groups ($\Phi_X > 0.1$) were greater than those of nitrobenzene and the *para*-substituted nitrobenzenes with electron-donating groups ($\Phi_X < 0.1$). Particularly, *p*-nitrophenol and *p*-nitroaniline were unreactive toward the photoreduction.

Solvent Effect on the Photoreduction of p-*Nitrobenzonitrile.* A solvent effect on the photoreduction of *p*-nitrobenzonitrile, which was most reactive toward the photoinduced hydrogen-abstraction reaction, was investigated. Table 2 shows the quantum yields for the *p*-nitrobenzonitrile disappearance (Φ_{CN}) upon irradiation with the 313-nm light under a nitrogen atmosphere at room temperature.

TABLE 2. SOLVENT EFFECT FOR THE PHOTOREDUCTION OF *p*-NITROBENZONITRILE

Concn. $\times 10^3$ mol/*l*	Solvent	Quantum yield
1.03	IPA	0.48
1.00	Ethanol	0.11
1.00	Cyclohexane[a]	0.00

a) It contained 10 vol% of IPA to dissolve *p*-nitrobenzonitrile.

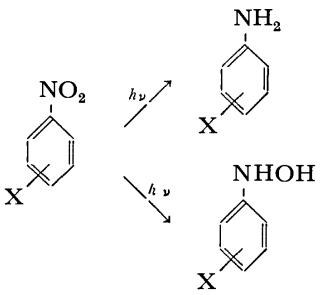
The quantum yields were influenced by the hydrogen-donating ability of the solvents. That is, the hydrogen-donating ability of the solvents in this photoreduction may classified, in decreasing order, as: IPA (secondary alcohol), ethanol (primary alcohol), and cyclohexane (parafine).

Oxygen-quenching Effect. The quenching effect by oxygen was studied in oder to clarify the state of the photoreduction.

The 1×10^{-3} mol/*l* solutions of *p*-nitrobenzonitrile and/or *p*-nitrotoluene in air-saturated IPA were irradiated with the 313-nm light at room temperature. In both cases, the photolysis of the nitro aromatic compounds was completely quenched by oxygen. The photoreduction of the nitrobenzenes, therefore, may proceed *via* excited triplet states.

Discussion

The Photoproducts of the Monosubstituted Nitrobenzenes. The photoproducts of the substituted nitrobenzenes were classified by substituent effects as is pictured below:



X; *p*-NO_2, *m*- and *p*-CN, *m*- and *p*-$COOC_2H_5$, *p*-$COOCH(CH_3)_2$, *m*- and *p*-COOH

X; H, *p*-CH_3, *p*-OCH_3

It has been established that nitrobenzene, [8,9] 1-

9) S. Hashimoto, J. Sunamoto, H. Fujii, and K. Kano, This Bulletin, **41**, 1249 (1968).

nitronaphthalene,[10] 4-nitropyridine 1-oxide,[11,12] and 4-nitropyridine[1,4] in hydrogen-donative alcohols are reduced photochemically to form the corresponding hydroxylamino compounds. However, little attention has been paid until recently to the substituent effect on the photoreduction of nitro aromatic compounds. Finnegan and Knutson[13] have reported that the photoreduction of the *meta*- and *para*-substituted nitrobenzenes in ethanol gives the corresponding anilines, as is summarized as follows:

ethyl *p*-nitrobenzoate →
ethyl *p*-aminobenzoate (32%)
ethyl *m*-nitrobenzoate →
ethyl *m*-aminobenzoate (24%)
t-butyl *p*-nitrobenzoate →
t-butyl *p*-aminobenzoate (52%)
p-nitroacetophenone →
p-aminoacetophenone (16%)
nitrobenzene →
aniline (13%)

Since authentic samples of the *meta*- and *para*-substituted phenylhydroxylamines with electron-withdrawing groups could not be obtained, we could not clarify the process of the aniline formation. However, the *m*- and *p*-$XC_6H_4NO_2H$ radicals may also be generated in the primary steps of the aniline formation, analogous with the nitrobenzene photochemistry.[2]

Correlation between the Quantum Yields and the Hammett Constants. Photoreduction Mechanism. The data on the quantum yields shown in Table 1 indicate a quantitative correlation between the quantum yields and the Hammett constants. A plot of the log-values of the relative quantum yields ($\log \Phi_X/\Phi_H$) of the substituted nitrobenzenes and nitrobenzene *vs.* the Hammett constants[14] is shown in Figure 1. Apparently, the Hammett plots gave a straight line, and the ρ value was + 1.5. The photochemical behavior of nitro compounds in hydrogen-donative solvents may be written as in the following sequence:

$$N + h\nu \rightarrow N^{*1} \quad \text{excitation to a singlet} \quad (1)$$

$$N^{*1} \xrightarrow{k_1} N \quad \text{radiationless decay} \quad (2)$$

$$N^{*1} \xrightarrow{k_2} N^{*3} \quad \text{intersystem crossing} \quad (3)$$

$$N^{*3} \xrightarrow{k_3} N \quad \text{radiationless decay} \quad (4)$$

$$N^{*3} + RH \xrightarrow{k_4} NH + R \quad \text{hydrogen abstraction} \quad (5)$$

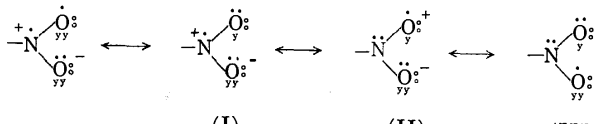
A steady-state approximation leads to this expression for the disappearance of nitro compounds:

$$\Phi = \frac{\Phi_T}{1 + [k_3/k_4(RH)]}$$

where Φ is the quantum yield for the disappearance of nitro compounds, Φ_T is the yield of the triplet, and (RH) is the concentration of the hydrogen-donative solvents. As is shown in the equation, Φ should be influenced by Φ_T, k_3, and (RH). However, our findings on the Hammett rule suggest that the only factor which governs the variation in the Φ is k_4(RH), and that the value of Φ_T and k_3 of the substituted nitrobenzenes is scarcely varied by the substituents. By the way, the electronic structure in the photoexcited states may be considerably different from that in the ground states; nevertheless, the Hammett relationship holds for the photoreduction of the nitrobenzenes in IPA. These findings suggest that the hydrogen-abstraction reaction of the photoexcited nitrobenzenes proceeds electrophilically and that the reactivity is governed by the electron density of the nitro groups in the ground states.

The photoreduction of the nitrobenzenes was quenched by oxygen; therefore, the photochemical hydrogen-abstraction reaction might proceed from the n,π^* triplet states (except for the *p*-OCH_3, *p*-NH_2, and *p*-OH derivatives).

The n,π^* transition of the nitro group may be pictured as follows:[15]



(I) (II) (III)

Ground state n,π^* Excited state
·: π electron; ○: *sp* electron; *y*: p_y electron

Structures (I) and (III) imply that a n,π^* excited state may be found to exhibit biradical properties. On the other hand, as Structure (II) shows, n,π^* excitation removes an electron from the oxygen atom and promotes it to the π^* orbital, which is then shared by the nitrogen and oxygen atoms, formally leaving a 1/2 positive charge on the oxygen. If Structure (I) or (III) participates in the photoreduction, the photoreduction of the nitrobenzenes is similar to the hydro-

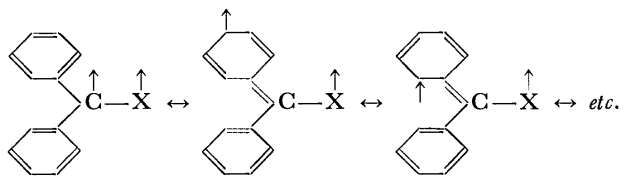
gen abstraction of the R·radical, which is well-known to proceed electrophilically. Meanwhile, if Structure (II) is an active species, our mechanism can be interpreted on the basis of this structure, because the electron affinity of the nitro groups increases in Structure (II).

The electrophilic hydrogen-abstraction mechanism is supported by the results on the photoreduction of 4-nitropyridine in the HCl-IPA solutions.[1]

It seems that the photoreduction mechanism of the nitrobenzenes is similar to that of the benzophenones. Porter *et al.*[16] have, on the basis of the quantum yields and spectroscopic data, reported that the hydrogen abstraction of the benzophenone triplet, the state of which are classified as n,π^*, π,π^*, and charge-transfer (CT) states, proceeds electrophilically. Meanwhile, Walling and Gibian[17] have found that the Hammett relationship holds for the photoreduction of benzophenone in substituted toluenes ($\rho=-1.15$).

On the other hand, Rosenberg and Servé[18] have reported that, judging from the results of the Stern - Volmer quenching studies, the rate constant for the triplet hydrogen abstraction of 1,1-diphenylethylene (DPE) in IPA is 1.4×10^9 mol^{-1} l sec^{-1}, which is considerably greater than the corresponding value reported for benzophenone, 10^6 mol^{-1} l sec^{-1}.[19] They have suggested that the electron repulsion between the unpaired electrons in the triplet states of DPE and benzophenone strongly induces the delocalization of one electron, so that the ability for the hydrogen abstraction of the two in the triplet states is similar to that of free radicals, such as alkyl and alkoxy radicals.[17,20] In other words, their interpretation means that the localization of one electron on the terminal carbon and/or oxygen atoms is important for the effective photoreduction.



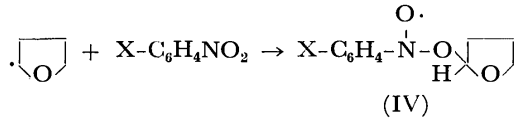
X=O, CH_2

Our results will be interpreted in terms of the mechanism postulated by Rosenberg and Servé. That is, the substituents on the *ortho*- and/or *para*-positions of the nitrobenzenes will facilitate the delocalization of one electron in the triplet states; therefore, the *ortho*- and *para*-substituted nitrobenzenes triplet may act as free radicals. In fact, the quantum yields for the disappearance of the *para*-substituted nitrobenzenes were greater than those of nitrobenzene (except for the *p*-OCH_3, *p*-NH_2, and *p*-OH derivatives). Particularly, the relative quantum yield of *p*-nitrotoluene ($\sigma=-0.170$) was 2.3. However, in the photolysis of the *meta*-derivatives with electron-withdrawing groups, the character of which as free radicals may be weaker than that of the *ortho*- and *para*-derivatives in their excited states, the quantum yields of the photoreduction are markedly greater than those of nitrobenzene. This suggests that the electron distribution of the nitro groups in the photoexcited states or ground states is an important factor in dominating the hydrogen-abstraction reaction of the photoexcited nitrobenzenes.

Hurley and Testa[2] have found that the nitrobenzene triplet is protonated in the higher acidity range, and that the reactivity toward the hydrogen abstraction of the protonated nitrobenzene triplet is greater than that of the unprotonated nitrobenzene triplet. This finding can be interpreted in terms of the electrophilic hydrogen-abstraction mechanism. That is, the positive charge of a proton which adds to the nitro group promotes it to one oxygen atom of the nitro group, so that the electron affinity of the nitro group is enhanced; the photoinduced abstraction of hydrogen may, therefore, effectively proceed. The photochemistry of 1-nitronaphthalene in the HCl - IPA solutions[3] may be understood in terms of the same interpretation.

$$C_6H_5NO_2H^{+*T} + (CH_3)_2CHOH \rightarrow C_6H_5N\dot{O}_2H + H^+ + (CH_3)_2\dot{C}OH$$

Meanwhile, Janzen and Gerlock[21] have reported, in their paper on substituent effects on the photochemistry of the nitro aromatic compounds in tetrahydrofuran, as studied by ESR spin-trapping techniques, that the photolysis of the substituted nitrobenzenes with electron-withdrawing groups gives the correspondingly-substituted nitroxide radicals (IV),



whereas most of the substituted nitrobenzenes with electron-donating groups do not give the (IV) radical except for *p*-phenyl-, *m*- and *p*-methyl-, *p*-ethyl-, *p*-isopropyl-, and *p*-phenoxynitrobenzenes. The results of the studies of the substituent effects by ESR seem to be connected with our findings: the quantum yields for the disappearance of the *meta*- and *para*-substituted nitrobenzenes with electron-withdrawing groups are greater than those of the *para*-substituted nitrobenzenes with electron-donating groups.

Photoreduction of p-*Nitroaniline and* p-*Nitrophenol.* *p*-Nitroaniline and *p*-nitrophenol were unreactive toward the photolysis in IPA; the quantum yields were 0.004 and 0.00 respectively.

The absorption maximum of *p*-nitroaniline at 322 nm ($\varepsilon_{max}=1.4\times10^4$) in *n*-hexane (containing 0.5 vol% of IPA to disolve *p*-nitroaniline) shifted to 377 nm ($\varepsilon_{max}=1.6\times10^4$) in IPA, and the solvent shift

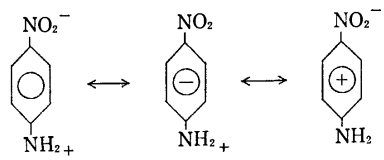
was +4500 cm^{-1} (the + sign means an increase in the polarity on excitation).[16] This enormous shift shows that the polarity of the molecule is greatly increased in the excited state, and it suggests that the absorption at 377 nm in IPA is an intra-molecular charge transfer (CT) band. In fact, the CT band of *p*-nitroaniline has been observed by Tanaka[22] and Godfrey.[23] The CT configuration of *p*-nitroaniline may pictured as follows:



Therefore, if the lowest excited energy level of *p*-nitroaniline is the CT triplet, the electron density of the nitro group may be greatly increased, so that the electrophilic attack will be made very difficult.

Therefore, the photolysis of *p*-nitroaniline in a HCl-IPA solution was carried out in order to clarify the state of the hydrogen abstraction.

A 5×10^{-4} mol/*l* solution of *p*-nitroaniline in a 2.4 mol/*l* HCl solution with 50% IPA-water was irradiated by a 366-nm light under a nitrogen atmosphere at room temperature. The quantum yield for the disappearance of *p*-nitroaniline was 0.004 in IPA, whereas it was 0.03 in the HCl-IPA solution. The increase in the quantum yield in the HCl-IPA solution suggests that the lowest excited state of *p*-nitroaniline hydrochloride is the n,π^* triplet, which is more reactive toward photoreduction than the CT triplet, or that the CT state of *p*-nitroaniline is protonated and has an increased reactivity. This photoreductive behavior of *p*-nitroaniline is similar to that of *p*-dimethylaminobenzophenone in an IPA and/or an IPA-HCl solution.[24] However, *p*-nitroaniline was unreactive in cyclohexane, and in this case, the quantum yield for the disappearance of *p*-nitroaniline was nearly zero.

By the way, *p*-nitrophenol was also completely unreactive toward the photoreduction in IPA. Proter and Suppan[16] have reported that *p*-hydroxybenzophenone in IPA is efficiently deprotonated in the excited singlet and triplet states, and that the lowest excited state of *p*-hydroxybenzophenone is the CT triplet; therefore, the abstraction of hydrogen occurs ineffectively in the photolysis of *p*-hydroxybenzophenone in IPA. The deprotonation of *p*-nitrophenol has not yet been investigated; however, it may be reasonable to conclude that the lowest excited state of *p*-nitrophenol in IPA is the unreactive CT state, because an absorption maximum at 289 nm in *n*-hexane (containing 0.05 vol% of IPA to dissolve *p*-nitrophenol) shifted to 312 nm in IPA, and the solvent shift was enormous (+2500 cm^{-1}).

Photochemical Partial Reduction of p-*Dinitrobenzene.* As has been described above, the *meta-* and *para*-substituted nitrobenzenes with electron-withdrawing groups were relatively reactive toward the photoreduction in IPA, whereas *p*-nitroaniline was unreactive. These findings may be useful for the photochemical partial reduction of *p*-dinitrobenzene to afford *p*-nitroaniline.

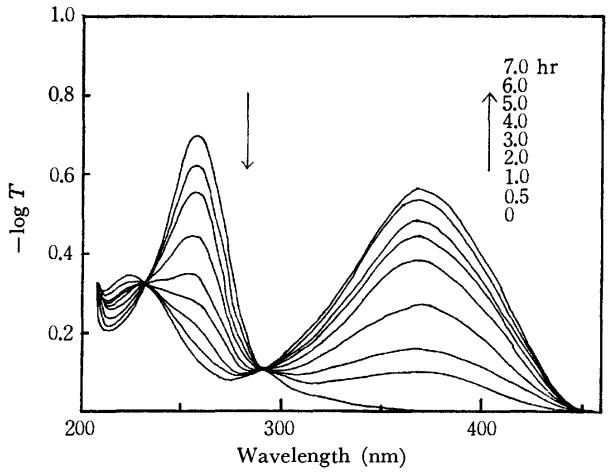


Fig. 2. Progressive spectral change of the photolysis of *p*-dinitrobenzene in IPA.

Figure 2 shows the progressive spectral change when a 2×10^{-3} mol/*l* solution of *p*-dinitrobenzene in IPA was irradiated with a high-pressure 130-W mercury lamp under a nitrogen atmosphere at room temperature. The absorption spectrum of *p*-dinitrobenzene decreased progressively in intensity, and a new absorption band of *p*-nitroaniline with its maximum at *ca.* 370 nm appeared. The isosbestic points were observed at 233 and 293 nm; therefore, the photochemical partial reduction of *p*-dinitrobenzene may proceed quantitatively.

Meanwhile, the n,π^* band of *p*-dinitrobenzene with a maximum at *ca.* 350 nm ($\varepsilon=100$) was observed in IPA. Then a 1×10^{-3} mol/*l* solution of *p*-dinitrobenzene in IPA was irradiated by a 366-nm light under a nitrogen atmosphere at room temperature; the quantum yield for the disappearance of *p*-dinitrobenzene was thus obtained as 0.16. This value (log Φ_X/Φ_H) greatly deviates from the Hammett plot, as is shown in Figure 1. This finding may be interpreted in terms of the inner-filter effect caused by *p*-nitroaniline. That is, the intense CT band with a maximum at 377 nm ($\varepsilon_{max}=1.6\times10^4$) of *p*-nitroaniline produced is absorbed near the 350-nm light, thus promoting the $n\rightarrow\pi^*$ transition of *p*-dinitrobenzene.

Synthesis of Chelating Agents. VIII. Synthesis and Acid Dissociation of 3,3-Dimethylbutane-1,2-dinitrilo-*N,N,N',N'*-tetraacetic Acid[1]

Yuzo YANAGIHARA,* Tairoku YANO, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received July 12, 1971)

3,3-Dimethylbutane-1,2-dinitrilo-*N,N,N',N'*-tetraacetic acid (BEDTA) has been synthesized by the carboxymethylation of 3,3-dimethylbutane-1,2-diamine (BEDA). The stepwise acid dissociation constants determined by the potentiometric method were found to be $pK_{a1}=6.26$ and $pK_{a2}=9.78$ for BEDA and $pK_{a1}=2.1$, $pK_{a2}=3.62$, $pK_{a3}=5.29$, and $pK_{a4}=11.6$ for BEDTA at 25°C and an ionic strength of 0.1 (KCl). The values were discussed in relation to molecular structures.

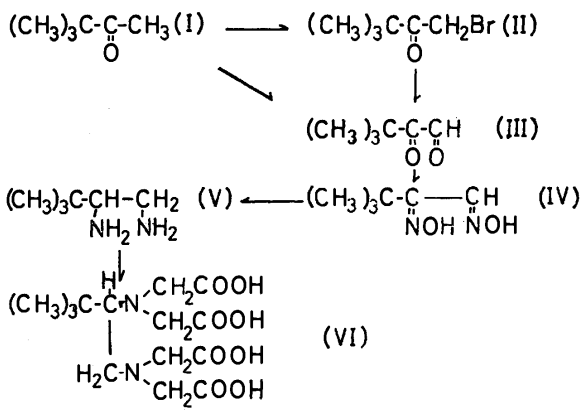
In previous papers we have reported on the effect of phenyl-substitution on either 1- or 2-carbons of ethylenedinitrilotetraacetic acid (EDTA) or both,[2] and on the effect of benzene ring fused to 4,5-positions of *trans*-cyclohexane-1,2-dinitrilo-*N,N,N',N'*-tetraacetic acid (CyDTA), on the chelating behavior of these ligands.[3] The major factors governing the chelate stability constant were found to be the ease of taking a *skew* conformation with respect to two nitrilodiacetate groups, as well as the inductive effect which may increase the basicity of nitrogen atoms of the nitrilodiacetate groups.

Introduction of alkyl groups on the ethylene bridge of EDTA would cause a steric effect favorable for chelate formation and also an electron-releasing effect to increase the basicity of nitrogen. Relatively higher chelate stability constants of propane-1,2-dinitrilotetraacetic acid (MEDTA)[4] and butane-2,3-dinitrilotetraacetic acid (BDTA)[5] can thus be understood.

From the results we were interested in the synthesis of EDTA derivatives, in which *t*-butyl groups were introduced on either 1- or 2-carbons of ethylene bridge in EDTA or both. Such bulky groups might cause a highly steric effect in favor of metal chelate formation.

This paper reports on the synthesis and acid dissociation behaviors of 3,3-dimethylbutane-1,2-diamine (BEDA) as well as 3,3-dimethylbutane-1,2-dinitrilotetraacetic acid (BEDTA).

3,3-Dimethylbutane-1,2-diamine (V), which was obtained as dihydrochloride, was synthesized from pinacolone (I) through *t*-butylglyoxal (III) and *t*-butylglyoxal dioxime (IV). 3,3-Dimethylbutane-1,2-dinitrilotetraacetic acid (VI) was synthesized by the carboxymethylation of the diamine (V). The acid dissociation behaviors of diamine (V) and tetraacetic acid (VI) were investigated by the potentiometric method, and the results were discussed in relation to their molecular structures.



Scheme

Experimental

IR spectra were measured with JASCO DS-301 and DS-403G spectrophotometers. NMR spectra were recorded on a Varian A-60 instrument using acetonitrile as an internal standard, its signal being set at 120 Hz downfield from TMS.

Synthesis of the Ligands. *t-Butylglyoxal (III)* was synthesized by two independent procedures.

(A) Oxidation of pinacolone with selenium dioxide.[6] *t*-Butylglyoxal was obtained in 47% yield according to the procedure in literature, bp 52—71°C/100 mmHg (lit, bp 114—115°C).

(B) Oxidation of bromopinacolone with dimethylsulfoxide. A solution of 78 g of bromopinacolone obtained by the bromination of pinacolone[7] in 400 m*l* of dimethylsulfoxide, was heated at 80—90°C for 3 hr and the reaction mixture was poured into 1 *l* of water. The aqueous solution was extracted with 200 m*l* ether several times. The combined ether extracts were washed with water, then dried over magnesium sulfate. After the solvent evaporated off, the residue was distilled under reduced pressure to give a fraction boiling at 45—50°C/55 mmHg. Yield was 9.3 g (29% from bromopinacolone). The purity of glyoxal (III) was a decisive factor on the yield of glyoxal dioxime (IV). The sample subjected to prolonged standing after the syntheses became inactive for oxime formation because of the hydration of glyoxal by atmospheric moisture. Furthermore, the dioxime from impure glyoxal crystallized with difficulty, resulting in a poor yield. Although procedure (A) gave better yield, procedure (B) was preferred because of a purer

product.

t-Butylglyoxal Dioxime (IV). To a solution of 12.6 g (0.18 mol) of hydroxylamine hydrochloride in 30 m*l* of water was added, successively a solution of 2 g (0.0175 mol) of freshly prepared glyoxal (III) in 10 m*l* of ethanol and a solution of 10.1 g of potassium hydroxide in 10 m*l* of water. The mixture was kept standing at room temperature for a few days. An oily layer separated and solidified gradually to afford a pasty mass, from which a solid product was collected by filtration under suction and was recrysrallized from ethanol-water, mp 101—102°C (lit, mp 101—102°C).[5] Yield was 1.3 g (51% of the theoretical). IR: ν_{OH}, 3200—3300 cm^{-1}, ν_{NO}, 950 cm^{-1}.

Found: C, 49.99; H, 8.44; N, 19.23%. Calcd for $C_6H_{12}O_2N_2$: C, 49.99; H, 8.39; N, 19.43%.

3,3-Dimethylbutane-1,2-diamine Dihydrochloride (V). Of the reduction methods including sodium in ethanol, aluminum lithium hydride, hydrogenation with Raney nickel or platinum oxide, tin-hydrochloric acid and zinc-acetic acid, the first one gave the best result in the preparation of diamine-(V) from dioxime(IV).

Metallic sodium (5.8 g) was added portionwise from the top of a condenser to a refluxing solution of 3.3 g of dioxime (IV) in 60 m*l* of ethanol. After the added sodium metal was consumed, 60 m*l* of water was added to the solution, and ethanol was distilled off through a fractionating column. The residue which separated into two layers was extracted with ether, and the ethereal layer was washed with a small amount of water and dried over anhydrous potassium carbonate. To the dried ether solution, dry hydrogen chloride gas was passed to precipitate the diamine dihydrochloride, which was then recrystallized from ethanol. Mp above 270°C. Yield: 1.8 g (42%). IR: $\nu_{NH_3^+}$ 2400—3300 cm^{-1}. NMR (τ in D_2O): 8.99(9H), 6.60—6.80(3H).

Found: C, 37.98; H, 9.49; N, 14.89; Cl, 37.57%. Calcd for $C_6H_{18}N_2Cl_2$: C, 38.10; H, 9.54; N, 14.81; Cl, 37.96%.

3,3-Dimethylbutane-1,2-dinitrilotetraacetic Acid (VI). A solution of 1.0 g (0.048 mol) of diamine dihydrochloride(V) in 3 m*l* of water, was neutralized with a calculated amount of 7 N sodium hydroxide solution. To this solution were added a solution of 3.7 g (0.267 mol) of bromoacetic acid in 5 m*l* of water, which had been neutralized to phenolphthalein with 7 N sodium hydroxide below 10°C, and 30 m*l* (0.21 mol) of 7 N sodium hydroxide solution. The mixture was heated at 100°C for 10 hours under carbon dioxide free atmosphere. The resulting solution was acidified with 6 N hydrochloric acid so that its pH was 1.8—2.0, and was kept in a refrigerator overnight to precipitate the crude tetraacetic acid. The white precipitates were collected by filtration and recrystallized from water. Mp 225°C (decomp.).

Yield: 0.42 g (23%). IR: ν_{COOH} 1763, 1730 cm^{-1}.

Found: C, 47.64; H, 6.60; N, 7.66%. Calcd for $C_{14}H_{24}N_2O_8$: C, 48.27; H, 6.94; N, 8.04%.

Determination of Acid Dissociation Constants. The same apparatus as that described previously was employed.[8] Measurements were carried out at 25.0±0.1°C in an aqueous solution under ionic strength, μ=0.10, with potassium chloride. For the determination of acid dissociation constants, 100 m*l* of 2×10^{-3} M of diamine(V) or of 1×10^{-3} M of tetraacetic acid (VI) was titrated with a solution of 0.1 N potassium hydroxide freed from carbonate ion.

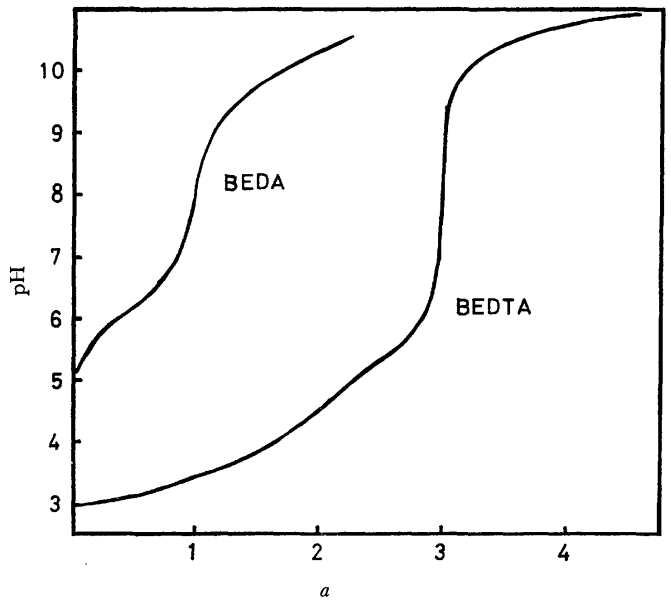

Fig. 1. The pH titration curves of BEDA and BEDTA at 25°C in 0.1 M KCl.

Calculation

The titration curves of BEDA dihydrochloride (V) and BEDTA (VI) are shown in Fig. 1. As the titration curve of BEDA dihydrochloride represents a typical curve of dibasic acid, it can be treated by the standard procedure of Schwarzenbach.[9] The final equations for the procedure are:

$$g + (g-1)[H^+]/K_{a2} + (g-2)[H^+]^2/K_{a1}K_{a2} = 0 \quad (1)$$

$$g = (2-a) + \{[OH^-]-[H^+]\}/C_A \quad (2)$$

where a represents the number of moles of alkali added per mole of the ligand, C_A the total ligand concentration, and K_{a1} and K_{a2} the first and second acid dissociation constants, respectively. In the neighbourhood of a=0.5, equation (1) can be simplified as

$$(g-1) + (g-2)[H^+]/K_{a1} = 0 \quad (3)$$

and in the neighbourhood of a=1.5 as

$$g + (g-1)[H^+]/K_{a2} = 0 \quad (4)$$

Thus, by computing each five sets of experimental values near a=0.5 and a=1.5 into Eqs. (3) and (4), the values of K_{a1} and K_{a2} were obtained, respectively.

As regards BEDTA (VI), the dissociation of the first three steps are clearly separated from the fourth step, as is shown in Fig. 1. Thus, the calculation of the acid dissociation constants can be carried out by the standard procedure of Bjerrum modified by McIntyre. The procedure is essentially the same as described previously.[3] The results of calculations on diamine (V) and tetraacetic acid (VI) are summarized in Tables 1 and 2, respectively, along with the values of related compounds.

Results and Discussion

Acid dissociation constants of diamines. As shown in Table 1, the characteristic of BEDA is its relatively low pK_{a1} value compared with those of other ethylenediamines. We see that the pK_{a1} value of the ethylene-

diamine homologue decreases with the increasing number of methyl groups introduced on ethylene carbons, and that pK_{a1} values of cyclohexanediamines are also relatively low.

The first dissociation step of 1,2-diammonium ion might be affected by the extent of electrostatic repulsion between the two ammonium groups as well as by the stereochemical ease of hydrogen-bond formation of the amine nitrogen resulting from the first deprotonation of an ammonium group with vicinal ammonium hydrogen. The effects can be evaluated by comparing pK_{a1} values or ΔpK_a ($=pK_{a2}-pK_{a1}$) values, since the pK_{a2} values of these diamines do not differ greatly.

In a bisprotonated stage of 1,2-diamines, in which the rotation of amino groups around the ethylene linkage is not restricted, the stable conformation will be a *trans* form with respect to the amino groups, relieving electrostatic repulsion between the vicinal ammonium groups. Ethylenediamine and *C*-methylated ethylenediamines can take this conformation. Thus, two ammonium groups of such diamines are so remote that less electrostatic repulsion operates between the ammonium groups, and dielectric interaction between the ammonium groups and polar solvent molecules favorably stabilize the highly polarized ammonium groups against the first deprotonation process. Thus the relatively higher pK_{a1} values or relatively smaller ΔpK_a values of ethylenediamine and propane-1,2-diamine can be explained. However, another effect might operate on highly methylated ethylenediamines, where the ammonium groups are embedded in nonpolar hydrocarbon moiety and the polar solvent molecules are restricted to gain access to the ammonium group. This effect would become more significant with the increasing number of methyl groups introduced on ethylene linkage.

In order to explain the significant difference between ΔpK_a values of *cis*- and *trans*-cyclohexane-1,2-diamines, Schwarzenbach[10] proposed the dielectric effect by polar solvent molecules which shielded electrostatic repulsion between the vicinal ammonium groups.

In highly methylated ethylenediamines the dielectric shielding of the ammonium groups by polar solvent molecules is less effective than in ethylenediamine, where the polar solvent molecules are easily accessible to ammonium groups. The effect is responsible for the relatively lower pK_{a1} values of highly methylated ethylenediamines, in spite of the fact that the distance between the two ammonium groups does not differ in both types of ethylenediamines.

In the case of BEDA, two ammonium groups can not take *trans* conformation due to the steric hindrance between *t*-butyl and ammonium groups, but take a stable *skew* conformation with respect to ammonium groups. Thus, the distance between two ammonium groups is comparable to those of cyclohexane-1,2-diamines. At the same time, since one of the ammonium groups is located in the close neighborhood of *t*-butyl group, the polar solvent molecules are less easily accessible. The electrostatic repulsion between two ammonium groups is, therefore, less effectively shielded in BEDA. Simultaneous operation of the conformational and dielectric shielding effects might

10) G. Schwarzenbach and R. Bauer, *Helv. Chim. Acta*, **39**, 722 (1956)
11) F. Basolo, R. K. Murmann, and Y. T. Chen, *J. Amer. Chem. Soc.*, **75**, 1478 (1953)
12) G. Schwarzenbach and G. Anderegg, *Helv. Chim. Acta*, **40**, 1773 (1957)

be responsible for the lower pK_{a1} value and higher ΔpK_a value of BEDA.

It is interesting to note in this connection that pK_{a2} of diamines do not differ greatly. Although the pK_{a2} value is expected to reflect the basicity of nitrogen atom, introduction of alkyl groups on nitrogen or adjacent carbon does not cause any appreciable increase of the value. The result might indicate that the inductive effect of alkyl groups plays a minor role in determining the pK_{a2} values of 1,2-diamines.

Dissociation Constants of BEDTA. In the acid dissociation of EDTA and related tetrabasic complexane-type ligands, deprotonation of the first two and last two steps correspond to the dissociation of carboxylic protons and ammonium protons, respectively. The pK_a values of BEDTA and some related ligands are shown in Table 2.

In previous papers,[2,3] we classified the complexane-type ligands into two groups. The first are those in which the rotation of nitrilodiacetate group is not hindered sterically and two nitrilodiacetates prefer a *trans* conformation due to electrostatic repulsion. This type is characterized by a relatively low $\Delta pK_{a(2-1)}$ value. The second are those in which two nitriloacetate groups sterically favor a *skew* conformation, and this group is characterized by a relatively high $\Delta pK_{a(2-1)}$ value.

The $\Delta pK_{a(2-1)}$ value for BEDTA clearly suggests that this ligand prefers a *skew* conformation with regard to the nitrilodiacetate groups. This can be ascribed to the steric effect by *t*-butyl group, and is in line with the preceeding discussion on BEDA.

The values of pK_{a3} and pK_{a4} are related to the deprotonations of ammonium nitrogens. Thus, a relatively lower value of pK_{a3} can be understood from the low pK_{a1} value of BEDA.

As regards the pK_{a4}, the potentiometric titration of 10^{-3} M solution of the ligand at high pH region might include a considerable error. Thus, the observed pK_{a4} value might not be accurate enough for quantitative discussion, however, pK_{a4} value of BEDTA is obviously higher than the other, the order of magnitude being comparable to that of *trans*-CyDTA ($pK_{a4}=12.35$).[13]

As discussed previously on the pK_{a2} values of methylated ethylenediamines, the introduction of alkyl groups on nitrogen or adjacent carbon does not appreciably contribute to increase of the basicity of nitrogen. The unusually high pK_{a1} value of BEDTA or *trans*-CyDTA might thus be related to some kind of steric and electrostatic effects of deprotonated species.

The authors are grateful to the Ministry of Education for financial support in this work.

Studies on Stable Free Radicals. VII.[1] The Mechanism for Cyclization Reaction of α-Amino Nitriles with Carbonyl Compounds

Toshimasa TODA, Syoji MORIMURA, and Keisuke MURAYAMA
Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received July 15, 1971)

Substituted 4-oxoimidazolidines were prepared by the condensation of α-amino nitriles with carbonyl compounds, or by the self-condensation of α-amino nitriles. The mechanism of the reaction was studied. The mass spectrum of the condensation product obtained by the reaction of cyclohexanone with 1-amino-1-cyano-^{15}N-cyclohexane (III) or by the self-condensation of III, and the ESR spectrum of corresponding nitroxide radical obtained by the oxidation of the respective condensation products served to elucidate the reaction mechanisms for these condensation reactions. The mechanism for the self-condensation of α-amino nitriles proposed previously was corrected from the spectral data of the reaction product. Possible mechanisms for these condensation reactions are proposed.

In a previous paper,[2] we reported that α-amino nitriles react with aldehydes or ketones to give substituted 4-oxoimidazolidines (I) in an alcoholic solvent and the resulting products yield corresponding stable nitroxide radicals (II) by oxidation.

On the other hand, Noland *et al.*[3] reported that the self-condensation of 1-amino-1-cyanocyclohexane afforded cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-1″-cyclohexane (IVa) in the presence of sodium ethoxide in ethanol containing a trace of moisture.

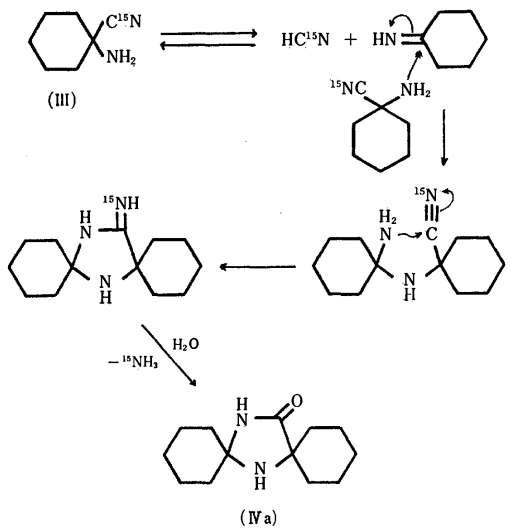

Chart 1.

They proposed for the mechanism of this self-condensation the sequence shown in Chart 1.

This paper deals with the mechanism for the cyclization reaction of α-amino nitriles with carbonyl compounds.

The reaction mechanism was clearly obtained from spectroscopic analysis of the product from the reaction of cyclohexanone with 1-amino-1-cyanocyclohexane (III) in which the nitrogen of cyano-group was replaced by ^{15}N.

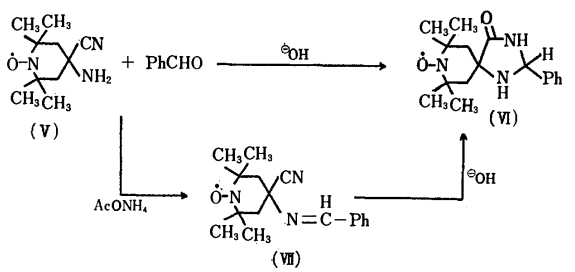
We will also discuss the reaction mechanism proposed by Noland *et al.*[3]

Results and Discussion

From our synthetic method for imidazolidinones (I), it was expected that the intermediate would be the Schiff base of an α-amino nitrile with a carbonyl compound.

In order to confirm this, the following reaction was carried out: The condensation of 4-amino-4-cyano-2,2,6,6-tetramethylpiperidine-1-oxyl (V) with benzaldehyde gave 1,3,8-triaza-2-phenyl-4-oxo-7,7,9,9-tetramethyl-spiro[4.5]decane-1-oxyl (VI) in the presence of a catalytic quantity of aqueous sodium hydroxide in ethanol solution, while the reaction of V with benzaldehyde yielded the Schiff base VII under reflux in benzene using ammonium acetate as a catalyst.

The Schiff base VII thus obtained, was treated under similar conditions as in the formation of VI from V, and VI was obtained in good yield.



From the results, we assumed the mechanism for cyclization reaction of α-amino nitriles with carbonyl compounds as shown in Chart 2.

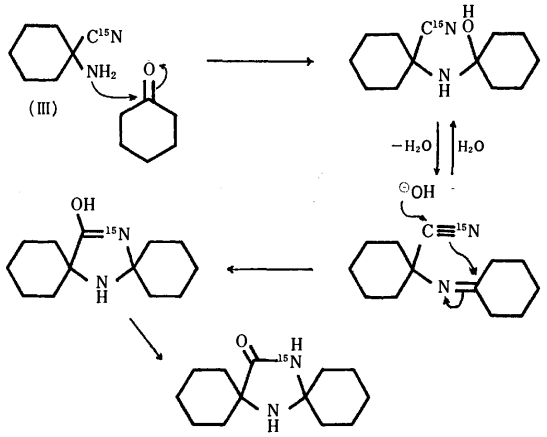


Chart 2.

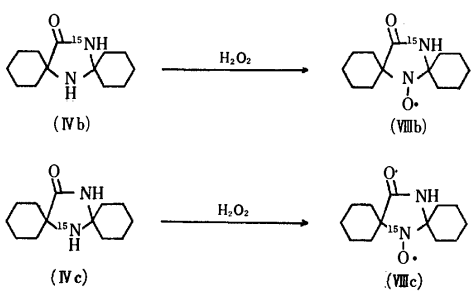
In order to confirm the assumption and the mechanism proposed by Noland and co-workers,[3] the following experiments were carried out.

The ^{15}N-substituted α-amino nitrile, 1-amino-1-cyano-^{15}N-cyclohexane (III) was prepared by the Strecker reaction of cyclohexanone with ^{15}N-sodium cyanide (95% ^{15}N content) and ammonium chloride. In a similar manner as reported previously,[2] we obtained product A by the reaction of III with cyclohexanone. Likewise, the self-condensation of III in the same way as reported by Noland *et al.*[3] afforded product B. The structures of these products A and B were both designated as cyclohexane-1-spiro-2′-[4′-oxoimidazolidine(3′-^{15}N)]-5′-spiro-1″-cyclohexane(IVb) from their IR spectra. The results are given below.

If the reaction of III with cyclohexanone follows the mechanism as shown in Chart 2, ^{15}N should be incorporated at the 3-position of the imidazolidine ring in product A.

Likewise, if the self-condensation of III proceeded as shown in Chart 1, product B would have no ^{15}N atom in the molecule.

The incorporation of ^{15}N in A or B, can be confirmed by mass spectra measurements; the position of ^{15}N in imidazolidine ring (IVb or IVc) can be determined by ESR measurements of tne corresponding nitroxide radicals (VIIIb or VIIIc) prepared by oxidation[4]



4) K. Murayama, S. Morimura, and T. Yoshioka, This Bulletin, **42**, 1640 (1969).

of A or B with hydrogen peroxide, since in the ESR spectrum triplet lines resulting from a ^{14}N nucleus are expected for VIIIb and doublet lines resulting from a ^{15}N nucleus for VIIIc, respectively.

In the high resolution mass spectrum of product A, the expected molecular ion peak at *m/e* 223.171 assigned to $C_{13}H_{22}ON^{15}N$, and a fragment peak at *m/e* 180.116 to $C_{10}H_{15}ON^{15}N$ were found, while in the case of the imidazolidinone IVa containing no ^{15}N, the corresponding peaks at *m/e* 222.277 ($C_{13}H_{22}ON_2$) and 179.119 ($C_{10}H_{15}ON_2$) were observed.

Oxidation of compound IVa by hydrogen peroxide afforded the corresponding nitroxide radical (VIIIa).[4] Similarly, oxidation of product A gave the nitroxide radical (VIIIb) which was given the following assignment.

Since triplet lines (a_N=14.1 gauss) were observed in the ESR spectrum of this oxidation product, the structure of product A was assigned to IVb. Thus, the mechanism shown in Chart 2 is plausible for the cyclization reaction of α-amino nitriles with carbonyl compounds.

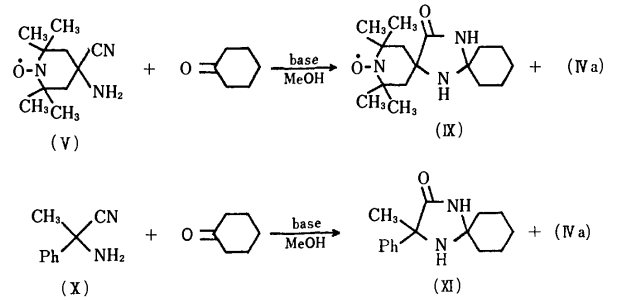
On the other hand, the structure of product B was also assigned to IVb from the mass spectrum of product B and ESR spectrum of the corresponding nitroxide radical.

This shows that the self-condensation reaction of α-amino nitrile does not follow the mechanism (Chart 1) proposed by Noland *et al.*,[3] but might proceed by a mechanism as shown in Chart 5 for the following reasons.

In the cyclization reaction of α-amino nitriles with carbonyl compounds, we found that imidazolidinone compounds I having different substituents from those expected from the mechanism (Chart 2) were obtained.

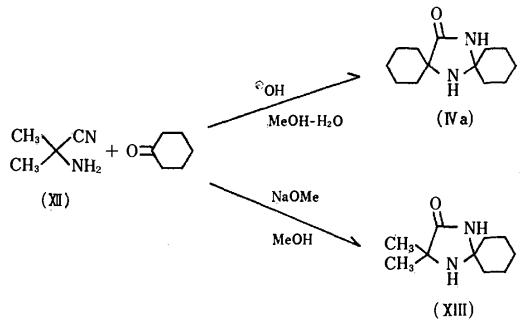
Treatment of amino nitrile V with cyclohexanone under the same conditions mentioned above gave the normal reaction product, cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-4″-(2″,2″,6″,6″-tetramethylpiperidine-1″-oxyl) (IX) and the abnormal reaction product with exchanged substituents IVa, in 44.5% and 36.0% yield, respectively.

Similarly, the reaction of α-amino-α-phenylpropionitrile (X) with cyclohexanone afforded the normal product 1,4-diaza-2-methyl-2-phenyl-3-oxo-spiro-[4.5]-decane (XI) and the same substituent-exchanged product IVa.



Further experiments showed that in these reactions, the presence of a small amount of water increased the yield of the substituent-exchanged product IVa.

The reaction of α-amino-isobutyronitrile (XII) with cyclohexanone in the presence of basic catalyst was carried out in water free methanol and in methanol containing a small quantity of water. In the former case the normal reaction product 1,4-diaza-2,2-dimethyl-3-oxo-spiro[4.5]decane (XIII) was obtained in 90% yield, while in the latter the substituent-exchanged product IVa in 80% yield.



Two possible processes are considered for these exchange reactions: iminopropane reacts with cyclohexanone to give iminocyclohexane (Chart 3); iminopropane is decomposed by water to acetone and ammonia (Chart 4). Cyclohexanone is then converted into 1-amino-1-cyanocyclohexane in the reaction system and the exchange reaction product IVa is formed by the mechanism shown in Chart 2.

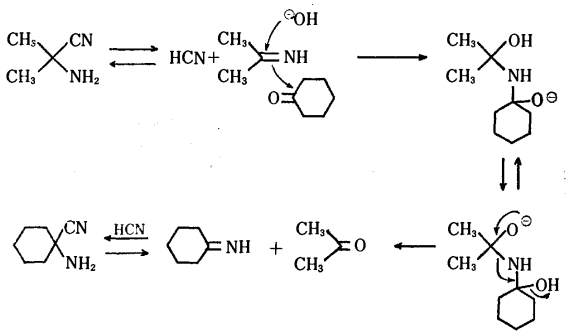


Chart 3.

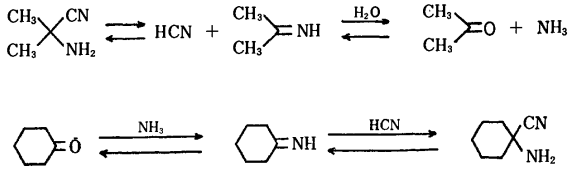

Chart 4.

The second assumption would be more reasonable in explaining the effect of water in promoting the formation of IVa.

In the case of the self-condensation of α-amino nitrile III, iminocyclohexane might also decompose into cyclohexanone and ammonia, and subsequently, the cyclohexanone thus formed would react with the amino nitrile III to give the imidazolidinone IVb by Chart 2 mechanism.

Consequently, the self-condensation reaction[3] of 1-amino-1-cyanocyclohexane might proceed by the mechanism shown in Chart 5.

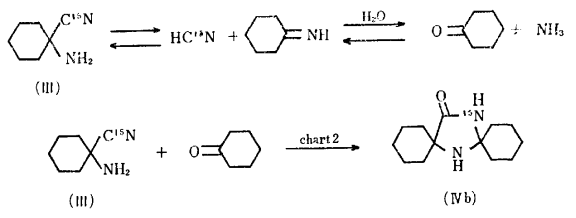

Chart 5.

Presumably the decomposition of iminopropane by water take place faster than that of iminocyclohexane, and cyclohexanone forms an α-amino nitrile more easily than other dialkyl ketones. This hypothesis can be supported by the fact that the reaction of the α-amino nitrile XII with methylisobutyl ketone gave only the normal product 2,2,5-trimethyl-2-isobutyl-4-oxoimidazolidine.[2]

Experimental

Melting points are uncorrected. The IR spectra were determined by means of nujol mulls and liquid films. The mass spectra were obtained using a JEOL-JMS-OIS mass spectrometer. The ESR spectra were recorded on a Hitachi MES 4001 type X-band spectrometer employing 100 kc modulation. Splitting constants were measured relative to the aqueous solution of Fermy's salt.

4-Cyano-4-benzilidenimino-2,2,6,6-tetramethylpiperidine-1-oxyl (VII). A solution of 2.0 g (10 mmol) of 4-amino-4-cyano-2,2,6,6-tetramethylpiperidine-1-oxyl (V)[2] and 1.1 g (10 mmol) of benzaldehyde in 50 m*l* of benzene containing 0.2 g of ammonium acetate was heated under reflux using a Dean-Stark water separator for 8 hr. The solution was cooled to room temperature, washed with water, dried over sodium sulfate and evaporated under reduced pressure to give 2.5 g (86.3%) of crude crystals VII. Recrystallization from benzene gave an analytical sample: mp 84.5°C. Found: C, 71.75; H, 7.82; N, 14.71%. Calcd for $C_{17}H_{22}ON_3$: C, 71.80; H, 7.81; N, 14.77%. IR (cm^{-1}): $\nu_{C\equiv N}$ 2230, $\nu_{C=N}$ 1648.

1,3,8-Triaza-2-phenyl-4-oxo-7,7,9,9-tetramethyl-spiro[4.5]-decane-8-oxyl (VI). (A) To a solution of 19.6 g (0.1 mol) of V[2] and 10.6 g (0.1 mol) of benzaldehyde in 30 m*l* of ethanol was added 1 m*l* of aqueous sodium hydroxide (40%) and the solution were stirred at room temperature for five days. After removal of ethanol under reduced pressure, the resulting crystalline solid was washed with water and dried in a vacuum. VI was obtained analytically pure by recrystallization from methanol: mp 184—185°C, yield 19.2 g (63.5%). Found: C, 67.46; H, 7.92; N, 13.81%. Calcd for $C_{17}H_{24}O_2N_3$: C, 67.52; H, 8.00; N, 13.90%. IR (cm^{-1}): $\nu_{C=O}$ 1703, ν_{NH} 3250 and 3350.

(B) A solution of 2.0 g (7 mmol) of VII and 1 m*l* of aqueous sodium hydroxide (40%) in 20 m*l* of methanol was stirred at room temperature for five days. A yield of 1.8 g (85.0%) of VI was obtained by a similar work-up to that mentioned above. The IR spectrum of the product was consistent with the authentic sample obtained in (A).

1-Amino-1-cyano-^{15}N-cyclohexane (III). A solution of 7.4 g (75 mmol) of cyclohexanone in 30 m*l* of methanol saturated with ammonia was added slowly to a stirred solution of 5.0 g of sodium cyanide-^{15}N (^{15}N content 95%)[5] and 9.3 g of ammonium chloride in 80 m*l* of aqueous ammonia (28%) at 0—5°C. Stirring was continued for 24 hr at room temperature. The resulting precipitate was removed by filtration and the methanol filtrates were evaporated under reduced pressure. The organic layer was extracted with 200 m*l* of diethyl ether, dried over potassium carbonate and evaporated under reduced pressure. The residual oil was distilled to give 5.5 g (64.6%) of III: bp 76—78°C/1 mmHg. IR (cm^{-1}): $\nu_{C\equiv N}$ 2200, ν_{NH} 3350, 3280, and 3200. Mass spectrum: M^+=125.

Cyclization Reaction of III with Cyclohexanone. To a solution of 1.5 g (12 mmol) of III and 1.4 g (12 mmol) of cyclohexanone in 10 m*l* of methanol was added 1 m*l* of a solution of sodium methoxide prepared by adding sodium (2.8 g) to 80 m*l* of methanol, with stirring at room temperature. Stirring was continued for 24 hr. After the solvent had been evaporated under reduced pressure, the resulting crystals were washed with water, dried *in vacuo*. Recrystallization from cyclohexane gave an analytical sample: mp 219—220°C, yield 2.2 g (79.1%). IR (cm^{-1}): $\nu_{C=O}$ 1687, ν_{NH} 3310, 3140, and 3010.

Self-condensation of III. To a solution of 3.8 g (30 mmol) of III in 15 m*l* of 98% (by weight) methanol was added 1 m*l* of a solution of sodium methoxide prepared as above, with stirring at room temperature. Stirring was continued for 24 hr. An analytical sample was obtained by a similar procedure as described above: mp 219—220°C, yield 2.8 g (80.0%). IR (cm^{-1}): $\nu_{C=O}$ 1687, ν_{NH} 3310, 3140, and 3010. Mass spectrum: M^+=223.173, $(M-C_3H_7)^+$=180.115.

Oxidation Reaction. (A) To a stirred solution of 0.6 g (27 mmol) of product A (IVb) in 4 m*l* of acetic acid was added 10 mg of ethylenediaminetetraacetic acid (EDTA) and 15 mg of sodium tungstate and then slowly 4 m*l* of aqueous solution of hydrogen peroxide (30%) at room temperature. The solution was stirred for additional 12 hr at room temperature. The resulting precipitate was separated by filtration, washed with water, and dried *in vacuo* to give 0.5 g (77.6%) of VIIIb: mp 227—228°C. IR (cm^{-1}): $\nu_{C=O}$ 1708, ν_{NH} 3160 and 3050. ESR (in benzene): a_N=14.1 gauss. (B). By a similar method to that described in (A), 0.5 g (77.6%) of VIIIb was obtained from 0.6 g (27 mmol) of the product B (IVb): mp 227—228°C. IR (cm^{-1}): $\nu_{C=O}$ 1708, ν_{NH} 3160 and 3050. ESR (in benzene): a_N=14.1 gauss.

Condensation of 4-Amino-4-cyano-2,2,6,6-tetramethylpiperidine-1-oxyl (V) with Cyclohexanone. A solution of 19.6 g (0.1 mol) of V[2] and 9.8 g (0.1 mol) of cyclohexanone and 1 m*l* of aqueous sodium hydroxide (40%) in 50 m*l* of methanol was stirred at room temperature for three days. After removal of methanol, 50 m*l* of benzene was added and the mixture was stirred at room temperature. After 1 hr, 8.0 g (36.0%) of crude crystals IVa separated; the precipitate was filtrated and washed with water. The crude material was recrystallized from ethanol to give a pure sample IVa which was confirmed by comparison of its IR spectrum with that of an authentic sample. The filtrate was dried over potassium carbonate, evaporated *in vacuo* to give 13.1 g (44.5%) of crude crystals IX. Recrystallization from petroleum ether gave an analytically pure sample: mp 201—202°C. Found: C, 65.22; H, 9.57; N, 14.26%. Calcd for $C_{16}H_{28}O_2N_3$: C, 65.27; H, 9.59; N, 14.27%. IR (cm^{-1}): $\nu_{C=O}$ 1705, ν_{NH} 3280.

Condensation of α-Amino-α-phenylpropionitrile (X) with Cyclohexanone. A mixture of 7.3 g (50 mmol) of α-amino-α-phenylpropionitrile (X) and 4.9 g (50 mmol) of cyclohexanone was heated at 50—60°C in the presence of

5) Available from the Institute of Physical and Chemical Research, Wako-shi, Saitama, Japan.

1 m*l* of sodium methoxide solution mentioned above. After 25 hr, 1.2 g (24.1%) of crude crystals IVa were separated by filtration, washed with water and dried *in vacuo*. By recrystallization from ethanol, IVa was obtained pure as shown by comparison of its IR spectrum and melting point with those of an authentic sample. The filtrate was dissolved in 50 m*l* of benzene, washed with water, dried over potassium carbonate and evaporated under reduced pressure. The residual oil was crystallized on adding petroleum ether to give 3.2 g (40.0%) of crude crystals XI. The crude material was recrystallized from petroleum ether to give an analytical sample: mp 130—131°C. Found: C, 73.69; H, 8.35; N, 11.21%. Calcd for $C_{15}H_{20}ON_2$: C, 73.77; H, 8.25; N, 11.21%. IR (cm^{-1}): $\nu_{C=O}$ 1695, ν_{NH} 3350, 3200 and 3095.

Condensation of α-Aminoisobutyronitrile (XII) with Cyclohexanone. (A). A solution of 8.4 g (0.1 mol) of α-aminoisobutyronitrile (XII) and 9.8 g (0.1 mol) of cyclohexanone and 1 m*l* of aqueous sodium hydroxide (40%) in 50 m*l* of 95% methanol (by weight) were stirred for three days at room temperature. A similar work-up as described above provided 17.8 g (85.0%) of IVa as shwon by comparison of its IR spectrum and melting point with those of an authentic sample. (B). The methanol used was distilled into a receiver containing dried anhydrous sodium sulfate and was used immediately. In a 100 m*l* flask was placed a solution of 8.4 g (0.1 mol) of α-aminoisobutyronirile (XII) and 9.8 g (0.1 mol) of cyclohexanone in 50 m*l* methanol and 1 m*l* of sodium methoxide solution was added. The flask was stoppered to exclude moisture and was heated at 40—50°C with stirring for 6 hr. After removal of methanol under reduced pressure, the resulting crystals were washed with water and dried *in vacuo*. Recrystallization from ethanol gave an analytical sample: mp 193—194°C, yield 16.4 g (90.0%). Found: C, 65.77; H, 9.84; N, 15.14%. Calcd for $C_{10}H_{18}ON_2$: C, 65.89; H, 9.96; N, 15.37%. IR (cm^{-1}): $\nu_{C=O}$ 1693, ν_{NH} 3190 and 3070.

The authors wish to thank Prof. Makoto Okawara, Tokyo Institute of Technology, for his valuable comments and Dr. G. Sunagawa, director of these laboratories, for his encouragement.

Studies on Mannan and Related Compounds. I. The Purification of Konjac Mannan

Noboru SUGIYAMA, Hideo SHIMAHARA,* and Tetsuo ANDOH*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

**Kabushikikaisha Shimizu Manzo Shoten, Laboratory, Onomichi, Hiroshima*

(Received July 22, 1971)

The preparation of pure konjac mannan is described. Its properties and purity are also studied.

A major component of the konjac flour, which is obtained from the tubers of *Amorphophallus Konjac* C. Koch (*Araceae*), is well known to be a glucomannan called konjac mannan. Traditionally, this flour has been used as the stuff of edible *konnyaku*.

We have succeeded in obtaining pure konjac mannan, which retains the most important intrinsic properties of konjac flour; it can make a transparent colloidal solution and can be used in making a *konnyaku* of good quality. The konjac mannan which are obtained by the methods of Ohtsuki[1-4] and Nishida *et al.*[5] do not exhibit these properties. Ohtsuki's method is to prepare the mannan from a colloidal solution of konjac flour by repeated precipitations with alcohol, while Nishida's method is to take the mannan out through the copper complex by treating the super-heated water extract of konjac flour with the Fehling solution. The latter method has been used up to the present as the general procedure for preparing material for chemical studies of konjac mannan.[6-8] The fact, however, that the mannan obtained by these methods lacks important intrinsic properties suggests that the molecular structure of this mannan suffers a kind of denaturing during the processing, as has also been observed in the case of amylose in an alkaline solution.[9] On the other hand, the retention of its intrinsic properties suggests that the mannan has received little or no denaturing effect.

The present method of purification is composed of extraction, dialysis, and lyophylization.

Results and Discussion

Properties. The purified konjac mannan is a light, voluminous, and white cotton-like product.[10] It readily dissolves in water to give a transparent viscous solution and has a *konnyaku*-forming ability. The viscosity of its colloidal solution is almost the samc as that of the mannan before purification. The IR (KBr) of the purified mannan showed bands near

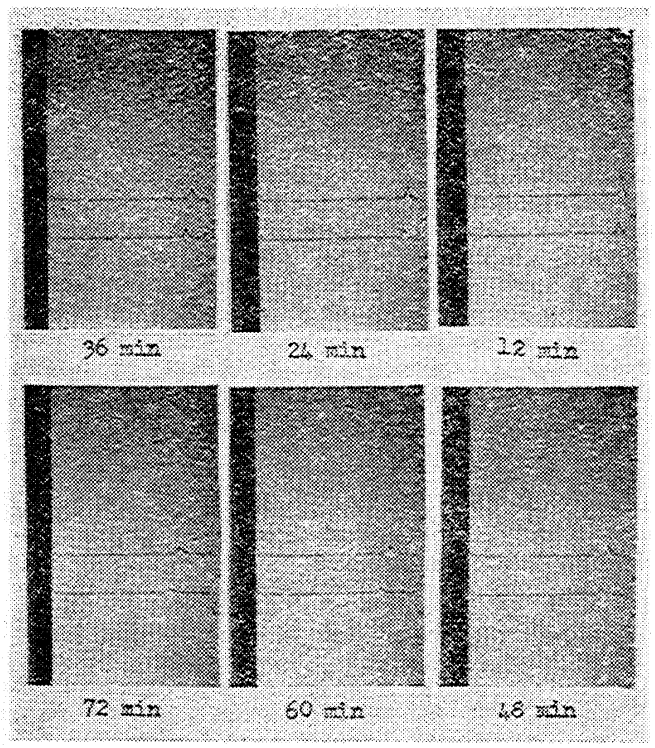

Fig. 1. Sedimentation patterns of purified konjac mannan. Sedimentation analysis was carried out under the following condition: 1.0 mg/m*l* konjac mannan, water, 20°C, 60000 rpm and phase plate angle 70°. Times after reaching the top speed is shown below each diagram. The upper and lower patterns in each diagram are traditional (Zairai-shu) and Chinese species (Shina-shu), respectively. Sedimentation is from light to left.

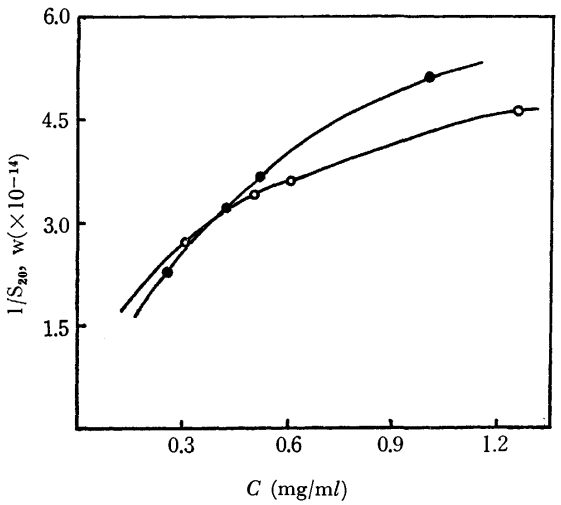

Fig. 2. The sedimentation coefficient as a function of concentration for purified konjac mannan: (○) Traditional species; (●) Chinese species.
Sedimentation analysis was carried out under the follwing condition: water, 20°C and 60000 rpm.

890 (β-glucosidic and β-mannosidic linkages), 1640, and 1720 cm^{-1}. Since the absorptions at 1640 and 1720 cm^{-1} are very weak in the IR chart, they cannot be attributed to uronic acid or the like; rather, it seems that they may be attributed to the trace of absorbed water[11] or to that of protein. However, no entirely reasonable explanation of these absorptions can be given at present. The sedimentation analysis of pure konjac mannan obtained from the traditional species (Zairai-shu) and from the Chinese species (Shina-shu) have been carried out. Each mannan showed only one peak at various intervals of time (Fig. 1). This fact indicates that the konjac mannan purified by the present method consists of ultracentrifugally homogeneous components. Generally, it is known that the linear polymer shows a high concentration dependence of the sedimentation coefficient. Since the purified konjac mannan also shows this phenomenon (Fig. 2), the shape of konjac mannan may be considered to be linear. The difference in the concentration dependence of the mannans suggests that there is some difference in the molecular weight[12] or in the shape of the molecule between the two kinds of mannans.

On complete acid hydrolysis, this purified konjac mannan gave only two spots, corresponding to D-mannose and D-glucose, on paper chromatography. The molar ratio of D-mannose to D-glucose was found to be 1.6 : 1.0 by measuring the spots with a densito-

meter. When the reducing sugar in this acid-hydrolysis mixture was determined by the Bertrand method as modified by Tomoeda, the total content of the reducing sugar was shown to be 96% as D-glucose.

The konjac mannan did not produce any precipitate during the process of the purifying dialysis. This fact and the negligible contents of nitrogen and ashes (Table 1 and Fig. 3) suggest that the inorganic substances and/or the nitrogen-containing substances are not bound with the mannan molecule, as has been mentioned by Kondo and Okimasu.[13]

Purity. This purity was confirmed by elemental analysis, by the ultracentrifuge pattenrs, the ash contentents, and the absence of any reaction of reducing sugars or of starch-iodine. These results are summarized in the above table.

Experimental

Purification Procedure. Ten grams of commercial konjac flour were extracted with three 50 m*l* portions of 50 v/v% ethanol at room temperature for three days. After extraction and filtration, a 50 m*l* portion of 80 v/v% ethanol was added to the residual flour. The flour was then collected and dried at 80—90°C to yield 7.80 g of flour apparently similar to the original flour.

Into 1000 m*l* of water were stirred 4.10 g of the above flour in small portions at room temperature; the stirring was continued for 2—3 hr until the mannan had been completely dissolved. The colloidal solution thus obtained was centrifuged at 15000 rpm for 30 min to remove the insoluble substances. The colorless and transparent supernatant liquid was dialyzed for 72 hr at 9—10°C through a cellulose membrane (VISKING) against running distilled water, and then lyophilyzed. We thus obtained 3.54 g of the purified product.

Preliminary Experiments for the Purification. The above purification procedure was established on the basis of the following experiments.

1) When the commercial konjac flour had been purified without extraction with an ethanol solution, as has been described above, the aqueous solution (0.176%) of the purified product became a slightly yellowish pink after a few days at 9—10°C. Therefore, it seems to have been contaminated with some substance. This substance was removed by extracting the starting flour with 50 v/v% ethanol.

2) The optimum concentration of the dialyzing solution and the necessary time of dialysis have been determined by measuring the ash contents of the lyophilyzed konjac mannan. Figure 3 shows the relationship between the ash content and the dialysis time at various concentrations. These results show that the more concentrated solution is dialyzed more effectively. Thus, the optimum conditions of dialysis were determined to be 0.411 w/w% and 72—96 hr.

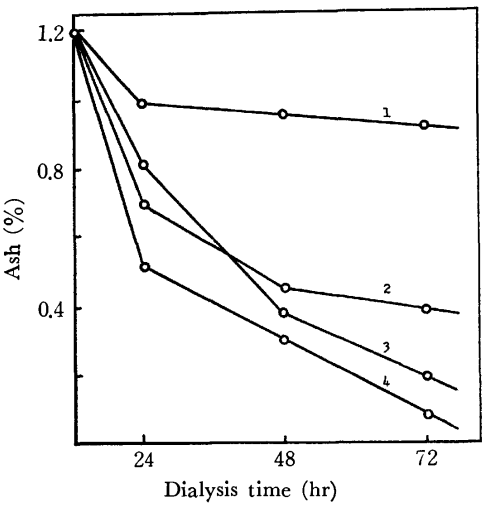

Fig. 3. The Effect of concentration on dialysis.
1: 0.085 2: 0.176 3: 0.252 4: 0.411 w/w%

Hydrolysis and Paper Chromatography. A mixture of 500 mg of the purified konjac mannan and 25 m*l* of N sulfuric acid was heated in a boiling water bath for 24 hr under reflux. According to the usual procedure, the hydrolyzate was paper-chromatographed (Toyo No. 50; *n*-butanol: ethanol : water 40 : 11 : 19; aniline-phthalic acid). The ratio of D-mannose to D-glucose was determined by measuring the area of each intensity integral by means of a densitometer.

The sedimentation patterns were obtained by the use of a Hitachi ultracentrifuge Model UCA-IA.

The authors are grateful to Mr. Koichi Kanna, Tokai Regional Fisheries Research Laboratory, for his measurement of the ultracentrifuge patterns and to Mr. Kyuzaburo Furuhashi, Department of Chemistry, Tokyo Kyoiku University, for the elemental analyses. Thanks are also due to Professor Yutaka Shimizu, Department of Fisheries, Kochi University, his helpful advice and continuous encouragement, and to Mr. Manzo Shimizu, the president of Kabushikikaisha Shimizu Manzo Shoten, for permission to publish this work.

Aroyl Arenesulfonyl Peroxides. III. Thermal Decomposition of *p*-Chlorobenzoyl *p*-Toluenesulfonyl Peroxide.[1]

Ryuki HISADA, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received July 21, 1971)

p-Chlorobenzoyl *p*-toluenesulfonyl peroxide was synthesized. Its spontaneous decomposition in benzene or in carbon tetrachloride did not follow a first-order rate equation because of the rate acceleration due to *p*-toluenesulfonic acid produced. When powdery magnesium oxide was suspended in benzene, isomerization to *p*-chlorophenyl *p*-toluenesulfonyl carbonate was completely inhibited, and the rate followed a first-order equation. The products of decomposition (*p*-chlorobiphenyl, *p*-chlorobenzoic acid, *p*-toluenesulfonic acid, phenyl *p*-toluenesulfonate, *etc*) were accounted for in terms of initial formation of *p*-toluenesulfonyloxy and *p*-chlorobenzoyloxy radicals. *p*-Toluenesulfonyloxy radical was found to be a very effective hydrogen-abstractor with little tendency to add to benzene.

The synthesis and decomposition of benzoyl *p*-toluenesulfonyl peroxide was described in a previous paper.[2] Spontaneous decomposition in benzene was mainly an acid-catalyzed isomerization to phenyl *p*-toluenesulfonyl carbonate (42 mol%), but when powdery magnesium oxide was added the extent of isomerization decreased (22 mol%) and products ascribable to phenyl radical[2,3] were found (biphenyl, 44 mol%).

Such facile isomerization is undoubtedly due to the strong electron-withdrawing tendency of the *p*-toluenesulfonyl group. Thus, it is expected that a substituted benzoyl *p*-toluenesulfonyl peroxide with an electron-withdrawing substituent on the benzoyl group may undergo completely homolytic decomposition yielding benzoyloxy radical and *p*-toluenesulfonyloxy radical. As an example of such peroxide, *p*-chlorobenzoyl *p*-toluenesulfonyl peroxide (CTP) was synthesized and its decomposition was investigated.

Results and Discussion

p-Chlorobenzoyl *p*-toluenesulfonyl peroxide (CTP) was prepared by a reaction between *p*-toluenesulfonyl chloride, *p*-chloroperoxybenzoic acid and potassium hydroxide at −22°C.

Spontaneous decomposition of CTP without any additives in benzene or carbon tetrachloride did not follow a first-order rate equation because of the rate acceleration due to the *p*-toluenesulfonic acid produced. However, when powdery magnesium oxide was suspended in the medium, the decomposition followed an ordinary first-order rate equation. Figures 1 and 2 show the rate of decomposition. The rate constants obtained are listed in Table 1. Arrhenius plots are shown in Fig. 3. In benzene with

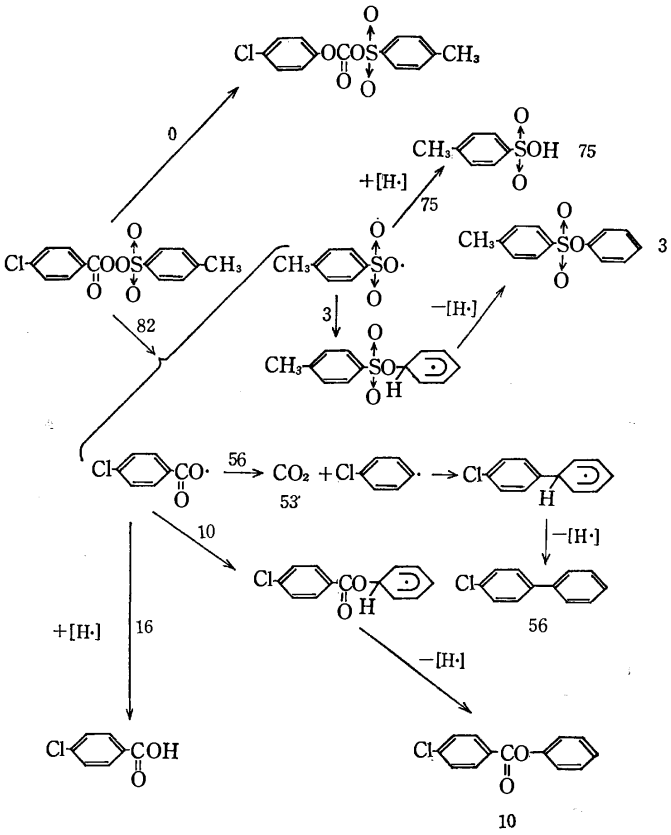
a) Temperature, 45°C; Reaction time, 20 hr. These data are the average of two experiments. Experimental errors are within ±2%.

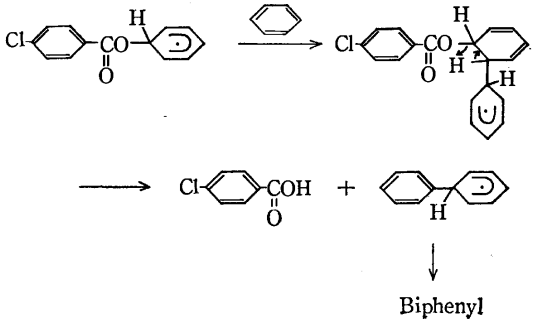
magnesium oxide, E_a was 25.5 kcal/mol and $\Delta S^{\neq}$ +1.0 e.u., whereas in carbon tetrachloride with magnesium oxide, E_a was 24.1 kcal/mol and $\Delta S^{\neq}$ −3.9 e.u.

Table 2 shows the products of decomposition of CTP in benzene and carbon tetrachloride in the absence and presence of magnesium oxide.

In the absence of magnesium oxide in benzene, isomerization to the mixed anhydride took place to a considerable extent (42 mol%), whereas in the presence of magnesium oxide isomerization was completely inhibited. The yields of various products in benzene can be summarized in the following scheme.



It is interesting to compare the behavior of three different radicals produced, namely, *p*-chlorophenyl, *p*-chlorobenzoyloxy and *p*-toluenesulfonyloxy radicals. Very reactive *p*-chlorophenyl radical almost exclusively adds to benzene molecules surrounding the radical (chlorobenzene was not detected), whereas the fate of *p*-chlorobenzoyloxy radical is 10 addition to benzene *versus* 16 hydrogen-abstraction from cyclohexadienyl radicals. *p*-Toluenesulfonyloxy radical must be a very effective hydrogen-abstractor, since its fate was 3 addition to benzene *versus* 75 hydrogen-abstraction from cyclohexadienyl radicals. The sulfonyloxy radical is stable enough to stay unreacted in the medium until it collides with cyclohexadienyl radicals (*p*-chlorophenyl-, *p*-chlorobenzoyloxy-, or *p*-toluenesulfonyloxycyclohexadienyl radicals.)



Decomposition of CTP in benzene with magnesium oxide produced unsubstituted biphenyl in 1.1 mol% yield. It was identified by gas chromatography, elution chromatography and infrared spectroscopy. A plausible mechanism of its formation is the above.

When CTP was decomposed in carbon tetrachloride, addition of magnesium oxide did not result in complete inhibition of rearrangement, and the mixed anhydride was produced in 7.4 mol% yield. However, formation of *p*-dichlorobenzene (58.7 mol%) and hexachloroethane (38 mol%) indicates that homolysis is a major reaction. A comparison of the yields of *p*-dichlorobenzene and hexachloroethane ($38\times2-58.7=17.3$) indicates that a part of trichloromethyl radicals arose from the Cl-abstraction of carbon tetrachloride by radicals other than *p*-chlorophenyl radical. *p*-Chlorobenzoyloxy radical may be responsible for this, but it was not possible to isolate *p*-$ClC_6H_4CO_2Cl$, the product of such Cl-abstraction.

Of the four different cases of decomposition of CTP, that in benzene with suspended magnesium oxide is the most interesting, the decomposition being completely homolytic. This paper seems to be the first to describe the formation of a sulfonyloxy radical without competing side reactions.

Experimental

Materials. Benzene, carbon tetrachloride and *p*-toluenesulfonyl chloride were purified according to procedures described previously.[2] *p*-Chloroperoxybenzoic acid was prepared by the method used for the synthesis of *p*-nitroperoxybenzoic acid;[4] yield, 84.1%; mp 110—112°C (lit,[5] 111—113°C). Powdery magnesium oxide was heated in a crucible, cooled and then used.

Preparation of p-*Chlorobenzoyl* p-*Toluenesulfonyl Peroxide (CTP).* This new peroxide could not be prepared by the method used for the synthesis of benzoyl *p*-toluenesulfonyl peroxide. It was synthesized as follows. A solution of *p*-tosyl chloride (9.6 g, 0.05 mol) in dichloromethane (200 m*l*) was cooled to −22°C in a four-necked round-bottomed flask equipped with a mechanical stirrer, a dropping funnel, a thermometer and a calcium chloride tube. Then, an aqueous 50% KOH solution (12 g) was added drop by drop with stirring. The temperature rose to some extent. After the solution was again cooled to −22°C, a solution of *p*-chloroperoxybenzoic acid (11.2 g, 0.06 mol) in dichloromethane (1 *l*) was added slowly while the temperature was kept below −20°C, it was washed with 10 *l* of ice water and dried over anhydrous magnesium sulfate. Evaporation of the dichloromethane under reduced pressure yielded a brownish residue, which gave colorless needles (9.3 g, 57%) upon recrystallization from ether. Recrystallization was repeated twice more and the crystals obtained were used for the experiments. They were stable for a long period at −20°C. Mp, 73—74°C (decomp). The main IR absorptions were observed at 1785, 1395, 1220, 1195, and 1180 cm^{-1}.

Found: C, 51.49; H, 3.17; Cl, 11.01; S, 9.68%. Calcd for $C_{14}H_{11}O_5ClS$: C, 51.46; H, 3.39; Cl, 10.85; S, 9.81%.

Kinetic Measurements. Rates of decomposition were measured by the procedure used for benzoyl *p*-toluenesulfonyl peroxide.[2] A 0.02 N $Na_2S_2O_3$ solution was used instead of a 0.05 N solution.

Analyses of Products of Decomposition. Products of decomposition of CTP were analyzed by a procedure essentially similar to that used in the case of benzoyl *p*-toluenesulfonyl peroxide. Since *p*-chlorophenyl *p*-toluenesulfonyl carbonate was found to decompose in a chromatographic column containing silica gel (Wako Gel Q22; 200 mesh), the reaction mixture was treated with aniline. When the mixture thus treated was subjected to elution chromatography, *p*-chlorophenyl *N*-phenylcarbamate produced was eluted with a hexane-benzene (1 : 2) mixed solvent.

Other products were determined by vapor phase chromatography. For determination of products from the decomposition in benzene, an Apiezon L column was used for *p*-chlorobiphenyl (internal standard, bibenzyl) and various esters (internal standard, *p*-tolyl benzoate). For determination of products in carbon tetrachloride, a silicone oil SE 30 column was used for *p*-dichlorobenzene and hexachloroethane (internal standard, *p*-dibromobenzene) and an Apiezon L column was used for various esters (internal standard, phenyl *p*-chlorobenzoate).

Preparation of p-*Chlorophenyl* p-*Toluenesulfonyl Carbonate.* *p*-Chlorophenyl chloroformate was prepared from *p*-chlorophenol and a 30% toluene solution of phosgene according to the method of Oesper *et al.*[6]; yield, 70.0%; bp 112.5—114°C/20 mmHg (lit,[6] 114°C/20 mmHg).

A solution of *p*-chlorophenyl chloroformate (2.8 g, 0.015 mol) and silver *p*-tosylate (4.2 g, 0.015 mol) in acetonitrile (50 m*l*) was refluxed for 10 hr. The silver chloride precipitated was filtered off, the acetonitrile was evaporated under reduced pressure, and recrystallization of the residue from ether-hexane yielded white crystals (3.1 g, 63.3%). Mp. 123—124°C. This mixed anhydride has not been reported in the literature. Its main IR absorptions were observed at 1785, 1395, 1245, and 1180 cm^{-1}.

Found: C, 51.37; H, 3.44; Cl, 10.58; S, 10.03%. Calcd for $C_{14}H_{11}O_5ClS$: C, 51.46; H, 3.39; Cl, 10.85; S, 9.81%.

The Reduction of Chlorodeoxy Sugars by Tributyltin Hydride

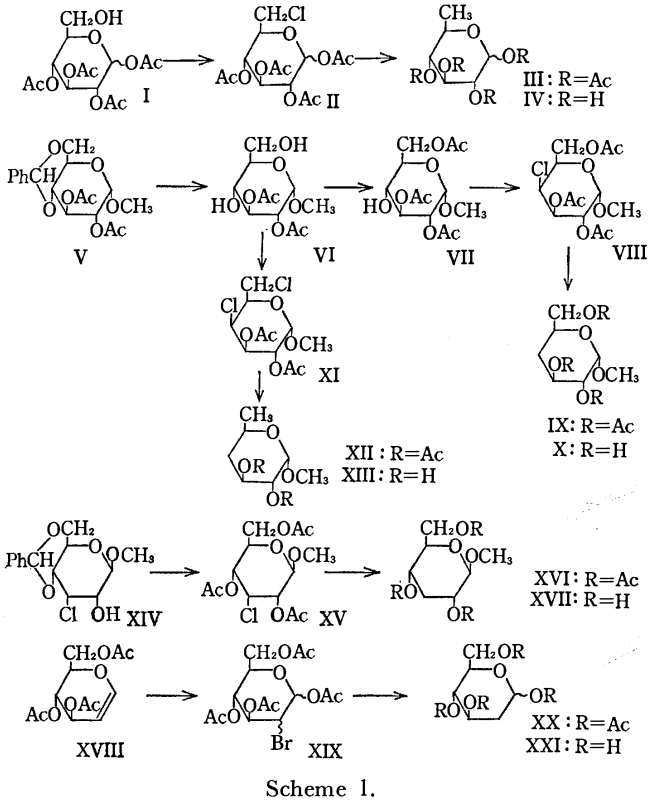
Hitoshi ARITA, Nobuhiko UEDA, and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University College of Science, Toyonaka

(Received July 23, 1971)

Acetylated chlorodeoxy sugars were prepared by the use of sulfuryl chloride. These chlorodeoxy sugars were then successfully reduced to deoxy sugars by the use of tri-*n*-butyltin hydride. α,α'-Azobis-isobutyronitrile, which has been known to be an effective radical initiator, was found to be indispensable for the reaction.

The deoxy sugars, long known as the components of many natural products, form an important class of carbohydrates. There have been many reports on the synthesis of deoxy sugars.[1] The reduction of deoxyhalo-sugars is one of the most important methods, and various effective reducing agents have been employed for this purpose. Lithium aluminum hydride or Raney nickel are excellent reagents, but they are not suitable for the reduction of sugar derivatives labile to alkali. To find milder reduction conditions, the present authors have investigated organotin hydride as a reducing agent of deoxyhalo sugars. Trialkyltin hydride[2] has recently been used for the selective reduction of organic halides. As reported in the previous paper,[3] we were successful in obtaining the 4'-deoxymaltose derivative in a fairly good yield by using organotin hydride and it was found that scarcely any by-product was produced during the course of the reaction. Therefore, this reagent will be useful for the synthesis of deoxy sugars. Jennings and Jones established that sulfuryl chloride could be used for the preparation of chlorodeoxy sugars.[4] We prepared *O*-acetylated chlorodeoxy sugars using this reagent. These *O*-acetyl-chlorodeoxy sugars were successfully converted to deoxy sugars by the use of organotin hydride under mild conditions. The structure of the deoxy sugars synthesized were confirmed by the NMR method and by gas-liquid chromatography. The reaction courses of the preparation of the deoxy sugars are represented in Scheme 1, while the retention times of the deoxy sugars thus obtained are summarized in Table 1.



Scheme 1.

TABLE 1. RETENTION TIMES (min) OF DEOXY SUGARS

Methyl 2-deoxy-arabinohexopyranoside	6.8
Methyl 3-deoxy-ribohexopyranoside	6.1
Methyl 4-deoxy-xylohexopyranoside	7.8 8.6
Methyl 6-deoxy-glucopyranoside	8.5 9.0

Gas chromatography was carried out at 185°C. Other conditions are described in the text.

Results and Discussion

Among the various tri-alkyltin hydrides, we chose tri-*n*-butyltin hydride because of its high reactivity and ease of preparation. The compound was stable at room temperature under a nitrogen atmosphere. During the course of this study, we found two important facts. The reduction of chlorodeoxy sugars by organotin hydride was unsuccessful if α,α'-azobis-isobutyronitrile was not present, also. By the addition of a small amount of the latter compound, though reduction proceeded smoothly under mild conditions. Menapace[5] proposed a radical mechanism for the reduction by the use of organotin hydride; in accordance with this proposal, the reduction of chlorodeoxy sugars also needed a radical initiator. The other point concerned the nature of the blocking groups of hydroxyls. We attempted to reduce methyl 4,6-*O*-benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (XIV)[6] without success, in spite of the co-existence of α,α'-azobis-isobutyronitrile. On the other hand, the reduction of methyl 3-chloro-3-deoxy-

2,4,6-tri-*O*-acetyl-β-D-allopyranoside (XV) proceeded smoothly. The reduction of methyl 4,6-dichloro-4,6-dideoxy-2,3-di-*O*-acetyl-α-D-galactopyranoside (XI) at 60°C gave methyl 4-deoxy-6-chloro-6-deoxy-2,3-di-*O*-acetyl-α-D-xylohexopyranoside[7] as the main product. The reactivity of primary and secondary halogenide agreed with the data presented by Menapace.[5] The yield of the reduction of each chlorodeoxy sugars was over 85%, and the separation of the product from the reaction mixture was complete and easy.

Experimental

General Methods. All the melting points are uncorrected. The nuclear magnetic resonance spectra were recorded at 60 MHz in chloroform-*d*, with tetramethylsilane as the internal standard. Thin-layer chromatography (tlc) was performed with silica gel G (Merck). The spots were detected by spraying with 5% sulfuric acid in methanol and by subsequent heating at 150°C. A Shimadzu gas chromatograph model GC-4A equipped with a 0.3×300 cm column of 5% SE-30 on chromosorb W (80—100 mesh) was employed. A sample was methanolyzed in a sealed glass tube with 1 N hydrogen chloride in methanol at 100°C for 2 hr. After the methanolysate had been dried up *in vacuo*, the residue was trimethylsilylated.[8]

Tri-n-butyltin Hydride. This reagent was prepared by the thermal decomposition of tri-*n*-butyltin formate according to the method of Okawara and Ohara.[9]

1,2,3,4-Tetra-O-acetyl-D-glucopyranose (I). Compound I was prepared by the detritylation of 6-*O*-trityl-1,2,3,4-tetra-*O*-acetyl-D-glucopyranose according to the method of Helferich and Klein.[10]

6-Chloro-6-deoxy-1,2,3,4-tetra-O-acetyl-D-glucopyranose (II). Compound I (14.5 g) was dissolved in 100 m*l* of anhydrous pyridine, and the solution was cooled in an ice-water bath. Into this solution was then stirred sulfuryl chloride (4.5 m*l*) and the mixture was kept at 4—5°C overnight. The excess sulfuryl chloride was destroyed by a few drops of water, and the mixture was extracted with chloroform (3×150 m*l*). The chloroform extracts were washed with water, 5% aqueous sulfuric acid, and finally with water. Evaporation *in vacuo* gave a reddish residue, which was decolorized with Norit A. Crystallization occurred in absolute methanol, and recrystallization in the same solvent gave 11.5 g of colorless needles. Mp 113—115°C, $[\alpha]_D = +113°$ (*c* 0.51, chloroform). Found: C, 45.43; H, 5.17; Cl, 9.87%. Calcd for $C_{14}H_{19}O_9Cl$: C, 45.85; H, 5.22; Cl, 9.67%.

6-Deoxy-1,2,3,4-tetra-O-acetyl-D-glucopyranose (III). Compound II (1.5 g) was dissolved in anhydrous toluene (10 m*l*), and to the solution were added tri-*n*-butyltin hydride (2.0 g) and α,α'-azobis-isobutyronitrile (15 mg) under a nitrogen atmosphere. The reaction was continued overnight under stirring in an oil bath kept at 80—90°C. On the evaporation *in vacuo* of the solution, crystals appeared immediately. They were washed with ligroin several times to remove the organotin compounds; subsequent recrystallization in methanol gave 1.3 g of colorless needles. Mp 141.5—142.5°C NMR data: δ1.1 (3-H d, C-CH_3), 2.0—2.1 (12-H $-COCH_3$). Found: C, 50.79; H, 6.15%. Calcd for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07%.

6-Deoxy-D-glucopyranose (IV). 6-Deoxy-1,2,3,4-tetra-*O*-acetyl-D-glucopyranose (III, 800 mg) was deacetylated in 0.1 M sodium methoxide in methanol. The solution was deionized with Dowex 50×8 (H^+) and dried up *in vacuo*. Crystallization cocurred in ethyl acetate, giving 380 mg of a colorless specimen. Mp 144—145°C, $[\alpha]_D^{24} = +78°$ (*c* 0.98, H_2O). A previous report[11] gave a mp of 146°C, $[\alpha]_D^{20} + 70°$. Found: C, 43.42; H, 7.23%. Calcd for $C_6H_{12}O_5$: C, 43.90; H, 7.37%.

Methyl 4,6-O-Benzylidene-2,3-di-O-acetyl-α-D-glucopyranoside (V). Compound V was prepared from methyl 4,6-*O*-benzylidene-α-D-glucopyranoside by acetylation with acetic anhydride and pyridine. Mp 108—109°C, $[\alpha]_D = +170°$ (*c* 0.5, chloroform). Found: C, 58.88; H, 6.04%, Calcd for $C_{18}H_{22}O_8$: C, 59.01; H, 6.05%.

Methyl 2,3,-Di-O-acetyl-α-D-glucopyranoside (VI). Compound V (17 g) was dissolved in 80% aqueous acetic acid (200 m*l*) and the solution was kept at 60°C for 2 hr. On the evaporation *in vacuo* of the solution, a syrupy product remained which showed a single spot on thin-layer chromatography.

Methyl 2,3,6-Tri-O-acetyl-α-D-glucopyranoside (VII). Compound VI (6.0 g) was dissolved in a mixture of pyridine (25 m*l*) and chloroform (15 m*l*), after which the solution was cooled in a dry ice-acetone bath. Acetic anhydride (2.25 m*l*) was then added carefully to the solution, and it was kept at −20°C for 24 hr. Subsequent evaporation *in vacuo* gave a syrupy residue, which was put on a silica-gel column; the column was then eluted with ethylacetate-toluene (1 : 1). Methyl 2,3,6-tri-*O*-acetyl-α-D-glucopyranoside (VII) was separated; it showed a single spot on tlc. Yield, 4.2 g.

Methyl 4-Chloro-4-deoxy-2,3,6-tri-O-acetyl-α-D-galactopyranoside (VIII). Compound VII (1.6 g) was dissolved in anhydrous pyridine (20 m*l*) and to this solution was added, drop by drop, sulfuryl chloride (0.7 m*l*) under cooling in an ice-water bath. The mixture was kept at room temperature overnight. The excess sulfuryl chloride was destroyed by the addition of a few drops of water, the reaction mixture was extratced with chloroform (3×50 m*l*), and the extracts were washed with 5% aqueous sulfuric acid and then with water. Evaporation *in vacuo* gave a reddish syrup, which was decolorized in methanol with Norit A. Crystallization occurred in ethanol-ligroin, and recrystallization in the same solvent gave 1.1 g of colorless needles. Mp 80—81°C, $[\alpha]_D^{24} = +180.7°$ (*c* 0.65, chloroform). Found: C, 46.11; H, 5.66; Cl, 10.67%. Calcd for $C_{13}H_{19}O_8Cl$: C, 46.09; H, 5.65; Cl, 10.47%.

Methyl 4-Deoxy-2,3,6-tri-O-acetyl-α-D-xylohexopyranoside (IX). Compound VIII (580 mg) was mixed with toluene (10 m*l*), tri-*n*-butyltin hydride (600 mg), and α,α'-azobis-isobutyronitrile (10 mg), and the reaction was continued overnight under a nitrogen atmosphere in an oil bath kept at 80°C. The reaction mixture was then dired up *in vacuo*, and a residual syrup was crystallized in ligroin. Recrystallization in the same solvent gave 453 mg of colorless crystals. Mp 74—75°C, $[\alpha]_D^{25} = +133.2°$. One previous report[7] gave a mp of 76—77°C, $[\alpha]_D + 134°$, and another[12] a mp of

74°C $[\alpha]_D$+135° (*c* 0.52, chloroform), Found: C, 50.79; H, 6.41%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.62%.

Methyl 4-Deoxy-α-D-xylohexopyranoside (X). Compound IX (300 mg) was deacetylated with 0.1 M sodium methoxide in methanol. Crystallization occurred in ethyl acetate, giving 160 mg of a colorless specimen. Mp 91—93°C, $[\alpha]_D^{25}$=+175.2° (*c* 1.0, water) Found: C, 47.32; H, 7.91%. Calcd for $C_7H_{14}O_5$: C, 47.18; H, 7.92%.

Methyl 4,6-Dichloro-4,6-dideoxy-2,3-di-O-acetyl-α-D-galactopyranoside (XI). Methyl 2,3-di-*O*-acetyl-α-D-glucopyranoside (VI, 5.5 g) was dissolved in anhydrous pyridine (65 m*l*) and the solution was cooled in an ice-water bath. To the solution sulfuryl chloride (5.1 m*l*) was then added and it was kept at 4°C overnight. The reddish-colored reaction solution was extracted with chloroform (7×50 m*l*), and the extracts were washed with water, 5% aqueous sulfuric acid, and finally with water. Evaporation *in vacuo* gave a syrup, which was then decolorized in methanol with Norit A. Crystallization in ethanol-ligroin gave 4.2 g of a colorless specimen. Mp, 103.5—105°C; $[\alpha]_D^{25}$=+162.9° (*c* 0.5, chloroform). Found: C, 42.07; H, 5.09; Cl, 22.55%. Calcd for $C_{11}H_{16}O_6Cl_2$: C, 41.92; H, 5.11; Cl, 22.50%.

Methyl 4,6-Dideoxy-2,3-di-O-acetyl-α-D-xylohexopyranoside (XII). Compound XI (1 g) was mixed with anhydrous toluene (20 m*l*), tri-*n*-butyltin hydride (2.8 g), and α,α′-azobis-isobutyronitrile (10 mg), and the mixture was refluxed overnight. Evaporation *in vacuo* gave 780 mg of a colorless syrup, which was purified by silica-gel column chromatography. The syrup thus obtained showed a single spot on tlc. NMR data: δ 1.1 (3-H, d, C-CH_3) 2.0—2.1 (6-H -$COCH_3$), 3.2 (3-H -OCH_3).

Methyl 4,6-Dideoxy-α-D-xylohexopyranoside (XIII). The deacetylation of Compound XII with sodium methoxide gave a colorless syrup, which crystallized on standing. Yield, 450 mg; mp, 106—108°C, $[\alpha]_D^{28}$=+168° (*c* 0.8, methanol). A previous report[13] gave a mp of 107—109°C, $[\alpha]_D$+171° (*c* 1.0 methanol). Found: C, 51.69 H, 8.61%.

Methyl 4,6-O-Benzylidene-3-chloro-3-deoxy-β-D-allopyranoside (XIV). Compound XIV was prepared from methyl 4,6-*O*-benzylidene-β-D-glucopyranoside according to the method of Jennings and Jones.[6] Crystallization occurred in ligroin-benzene. Mp 125.5—127°C, $[\alpha]_D^{25}$=−47° (*c* 1.02, chloroform). Found: C, 56.06; H, 5.74; Cl, 11.81%. Calcd for $C_{14}H_{17}O_5Cl$: C, 55.91; H, 5.70; Cl, 11.79%.

Methyl 3-Chloro-3-deoxy-2,4,6-tri-O-acetyl-β-D-allopyranoside (XV). Compound XIV (5 g) was dissolved in 60% aqueous acetic acid (60 m*l*), and the solution was refluxed for 10 min. After cooling, the solution was dried *in vacuo*. The residual syrup was consecutively acetylated with acetic anhydride and pyridine, giving 5 g of a syrupy product.

Methyl 3-Deoxy-2,4,6-tri-O-acetyl-β-D-ribohexopyranoside (XVI). Compound XV (2.5 g) was dissolved in anhydrous toluene (30 m*l*) and reduced by placing it in tri-*n*-butyltin hydride (2.5 g) and α,α′-azobis-isobutyronitrile (20 mg) at 80°C overnight. A syrupy product crystallized from ligroin in a refrigerator. The crystals were dissolved in methanol and treated with Norit A, and recrystallization in ligroin gave 1.8 g of colorless needles. Mp 64—66°C, $[\alpha]_D^{25}$=−45.3° (c 1.07, chloroform). NMR data: δ 2.0—2.1 (9-H -$COCH_3$) 3.24 (3-H -OCH_3). Found: C, 51.20; H, 6.66%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.62%.

Methyl 3-Deoxy-β-D-ribohexopyranoside (XVII). Compound XVI was deacetylated with sodium methoxide to Compound XVII. We thus obtained, a colorless syrup which crystallized on standing for a long period. A melting-point determination failed because of the high hygroscopicity of the crystals, $[\alpha]_D^{25}$=−49.5° (*c* 1.01, water). An earlier report[14] gave $[\alpha]_D^{20}$ −46°.

3,4,6-Tri-O-acetyl-glycal (XVIII). Compound XVIII was prepared from 2,3,4,6-tetra-*O*-acetyl-glucosyl bromide by the method of Fischer.[15]

2-Bromo-2-deoxy-1,3,4,6-tetra-O-acetyl-gluco(manno)pyranose (XIX). 3,4,6-Tri-*O*-acetyl-glycal (XVIII, 6.5 g) was dissolved in dichloromethane (25 m*l*), and to this solution was added bromine in dichloromethane until a slightly red color remained. The solution was then dried *in vacuo*, the syrupy residue was instantaneously dissolved in glacial acetic acid (120 m*l*), and mercuric acetate (12 g) was added to the solution. The mixture was then kept at room temperature overnight. The excess acetic acid was removed by evaporation *in vacuo*, and the residue was extracted with chloroform (3×100 m*l*). The extracts were washed three times with aqueous potassium bromide and finally with water. The chloroform layer was dried over calcium chloride and was evaporated *in vacuo*, giving 9 g of a syrup. Found: Br, 18.98%. Calcd for $C_{14}H_{19}O_9Br$: Br, 19.43%.

2-Deoxy-1,3,4,6-tetra-O-acetyl-D-arabinohexopyranose (XX). Compound XIX (1.5 g) was dissolved in anhydrous toluene (15 m*l*), together with tri-*n*-butyltin hydride (1.5 g) and α,α′-azobis-isobutyronitrile (10 mg) under a nitrogen atmosphere. The reaction was allowed to continue for 2 hr at 50—60°C. Subsequent evaporation *in vacuo* gave a colorless syrup, which was purified by silica-gel column chromatography. A syrup highly pure on thin-layer and gas-liquid chromatography was obtained; it weighed 1.1 g but failed to crystallize.

2-Deoxy-D-arabinohexopyranose (XXI). Compound XX (500 mg) was dissolved in cold 0.1 M barium methoxide in methanol and kept overnight in a refrigerator. The solution was then neutralized by adding 0.1 M aqueous sulfuric acid, and the barium sulfate which was thus precipitated was removed by centrifugation. The supernatant was treated with Dowex 50×8 (H^+) and dried up *in vacuo*. The residual syrup was extracted with acetone and crystallized in the same solvent. Mp 139—141°C. A previous report[16] gave a mp 142—144°C. The specimen was also identified by thin-layer chromatography (*n*-BuOH : EtOH : H_2O=3 : 1 : 1).

The authors are especially indebted to the Nitto Kasei Co., Ltd., for its gift of tri-*n*-butyltin oxide.

Stereochemical Studies of Monoterpene Compounds. XV.[1] A Conformational Study of Carvomenthone Derivatives by Means of Temperature-dependent Circular Dichroism[2]

Takayuki SUGA and Satoru WATANABE

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received August 5, 1971)

The conformations of (1*R* : 4*R*)-(−)-*p*-menth-8-en-2-one (**1**) and of diastereoisomeric pairs of (+)-1-hydroxy-*p*-menth-8-en-2-one, (**2**) and (**3**), (+)-1-hydroxy-*p*-menthan-2-one, (**6**) and (**7**), and (+)-1-hydroxy-8-bromo-*p*-menthan-2-one, (**10**) and (**11**), were examined by a combination of infrared spectra and temperature-dependent circular-dichroism (CD). Explanations are given mainly with regard to the epimeric pair, (**2**) and (**3**). It is demonstrated that α-hydroxyketone (**2**) exists in a conformational equilibrium among **2a**, **2b**, and **2c**. The **2a** conformer predominantly exists in a polar medium and at low temperatures, whereas the **2b** conformer is more stable than **2a** in a nonpolar medium. On the other hand, the epimer (**3**) exists preferentially in the **3a** conformation in both polar and nonpolar media and at low temperatures. The CD curves of compounds **6** and **7** exhibited the exactly same behavior as those in compounds (**2**) and (**3**) respectively. These results are interpreted in terms of the competition of the steric factor and the intramolecular hydrogen bonding.

Circular dichroism (CD) at different temperatures has been found to be very useful for investigating the conformational equilibrium in a flexible cyclohexanone structure.[3] α-Hydroxycyclohexanones provide interesting examples because, in addition to a possible conformational equilibrium, intramolecular hydrogen bonding between the hydroxyl and the carbonyl groups can be expected. Djerassi *et al.*[4] have recently demonstrated the conformational mobility in only (1*S* : 4*R*)-(+)-1-hydroxy-*p*-menthan-2-one (**6**), one of the C-1 epimers, on the basis of measurements of the variable temperature CD curves. This

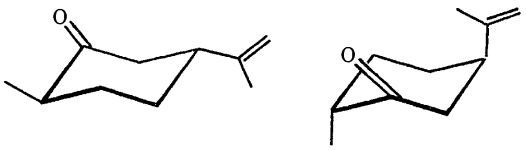
paper will deal with the conformational analyses of (1*R* : 4*R*)-(−)-*p*-menth-8-en-2-one (**1**) and the epimeric pairs of carvomenthone derivatives, (1*S* : 4*R*)- and (1*R* : 4*R*)-(+)-1-hydroxy-*p*-menth-8-en-2-ones (**2**) and (**3**), their acetates (**4**) and (**5**), (1*S* : 4*R*)- and (1*R* : 4*R*)-(+)-1-hydroxy-*p*-menthan-2-ones (**6**) and (**7**), their acetates (**8**) and (**9**), and (1*S* : 4*R*)- and (1*R* : 4R)-(+)-1-hydroxy-8-bromo-*p*-menthan-2-ones (**10**) and (**11**), all done by means of a combination of infrared spectra and temperature-dependent circular dichroism.

Results and Discussion

The CD curves of (1*R* : 4*R*)-(−)-*p*-menth-8-en-2-one (**1**) in MI and EPA exhibited a positive Cotton effect, and the rotational strength is almost temperature-independent over the range from 25 to −186°C. The menthenone (**1**) may exist in two interconvertible chair conformations, **1a**⇌**1b**. According to the



1a **1b**

octant rule,[5] the **1a** conformer should exhibit a positive Cotton effect, and the **1b** conformer, negative one. Therefore, the positive conformer **1a** is more stable than **1b** in respect to the energetic and steric requirements.

The CD curves of α-hydroxyketone (**2**) showed an inversion of the sign of the Cotton effect upon the change in the solvent polarity, as is shown in Fig. 1, in contrast with the corresponding dehydroxyketone (**1**). Such a phenomenon is interpreted in terms of the competition of the steric factor and the intramolecular hydrogen bonding. In the conformational equilibrium, **2a**⇌**2b**, the intramolecularly hydrogen-nonbonded conformer **2a** should exhibit a positive Cotton effect, and the hydrogen-bonded conformer **2b** a negative one. In a nonpolar solvent, the stabili-

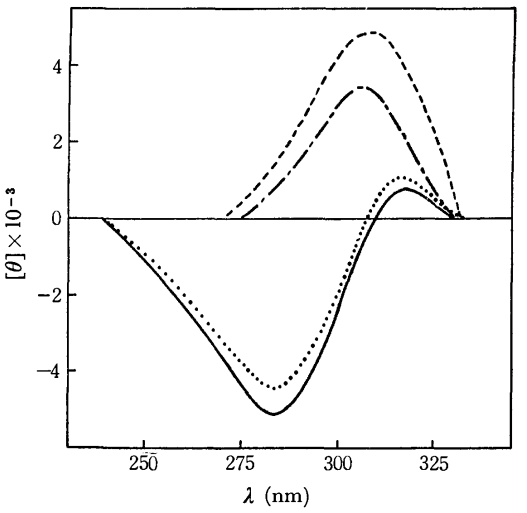

Fig. 1. CD curves of (1*S*: 4*R*)-(+)-1-hydroxy-*p*-menth-8-en-2-one (**2**) in selected solvents at +25°C: ····· in CCl_4, —— in isooctane, ——— in MeOH, and ---- in DMSO.

zation due to intramolecular hydrogen bonding overcomes the steric repulsion.[6] However, the stabilizing intramolecular hydrogen bond will be broken in a polar solvent, so that steric requirements mainly dominate the conformation of **2**. Therefore, the positively-rotating, nonbonded form, **2a**, is preferred in the polar solvents, and the negatively rotating, bonded form, **2b**, in the nonpolar solvents. The conformer populations were calculated[8] on the basis of the CD curves in selected solvents; the results are shown in Table 1.

Table 1. Population of **2b** in selected solvents

Solvent	$R_0^T \times 10^{40}$ (C.G.S.)	Population of **2b** (%)
Isooctane	−3.82	78
CCl_4	−3.67	77
Dioxane	+2.91	13
MeOH	+2.85	13
DMSO	+4.33	0

The predominant existence of the **2b** conformer in a nonpolar solvent, carbon tetrachloride, was further proved by a study of the infrared spectrum, which exhibited two bands, at 3612 (ε 29) and 3512 cm^{-1} (ε 41) (Fig. 2), resulting from a free hydroxyl group and an intramolecularly interacted hydroxyl group[9]

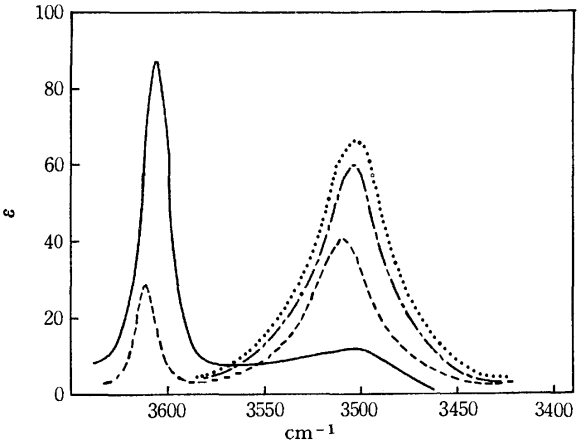

Fig. 2. IR spectra of α-hydroxyketones in carbon tetrachloride at +25°C: ---- for compounds **2**, ——— for **3**, —— for **10**, and ····· for **11**.

between the hydroxyl group and the lone-pair electrons of the carbonyl group. The influence of hydrogen bonding on the conformer population is further supported by the following two facts: (a) The CD curves of its acetate (**4**), in which the intramolecular hydrogen bond is inherently absent, exhibited only a positive Cotton effect, regardless of the solvent polarity, because of the loss of the stabilizing energy by hydrogen bonding. (b) The hydrobrominated compound **10** showed CD curves similar to those of the acetate (**4**) in both the polar and nonpolar solvents, because the positively-rotating, nonbonded conformer is stabilized by the anchoring effect[10] of the bulky 2-bromisopropyl group. This is supported by the infrared spectrum, in which the intensity of the free hydroxyl band of the hydrobrominated compound (**10**) at 3606 (ε 87) cm^{-1} increased greatly at the expense of the bonded peak at 3503 (ε 12) cm^{-1} (Fig.2), in contrast with the case of the parent compound (**2**).

The variable-temperature CD curves of the compound (**2**) in the MI solvent exhibited a double-humped Cotton effect which strikingly implies the temperature dependence of its conformation (Fig. 3). Such a double-humped Cotton effect arising from the n-π^* transition may be explained in terms of the solvational and/or the conformational equilibria. But, the blue-shifted band presumably due to an equilibrium between the solvated and nonsolvated species has been said[11,12] not to show any increase in apparent rotational strength at lower temperatures. Therefore, the double hump observed on the Cotton effect curves has been interpreted as being due to only the conformational equilibria involving the competition of the steric factor and the intramolecular hydrogen bonding. At 25°C, the intramolecularly-hydrogen-bonded form (**2b**) with the negative Cotton effect is preferred. However, the stabilizing intramolecular hydrogen bond will be broken as the tempera-

6) Assuming ΔG of the methyl, hydroxyl, and isopropyl groups to be 1.7, 0.7, and 2.0 kcal/mol,[7] respectively, a free energy difference ($-\Delta G$) for equilibria, **2a**—**2b** and **3a**—**3b**, on the basis of steric factor shows that conformers **2a** and **3b** would be energetically favored by *ca.* 1.0 and 3.0 kcal/mol. However, the **2a** conformer would be less favored and **3a** futher favored by an estimation of the hydrogen bond energy (2—5 kcal/mol). A clear-cut distinction between relative energies of **2a** and **2b** would be diffificult.

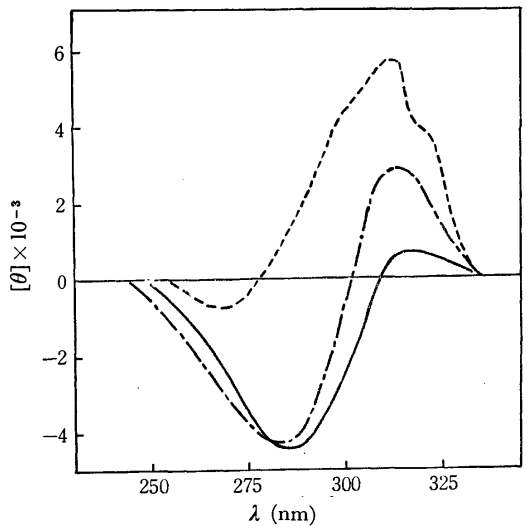

Fig. 3. CD curves of (1*S* : 4*R*)-(+)-1-hydroxy-*p*-menth-8-en-2-one (**2**) in MI: —— at +25°C, ---- at −74°C, and ---- at −186°C.

ture is lowered[4] so the steric requirements mainly dominate the **2a** conformer. The CD curves of **2** in EPA, incontrast with those in MI, showed only a positive Cotton effect with an increase in the apparent rotational strength as the temperature was lowered. This implies that the nonbonded conformer (**2a**) is also energetically preferred in EPA.

On the other hand, the CD curves of **2** in decalin (Fig. 4) exhibited an increase in the rotational strength in the short-wavelength band upon a change in the temperature from −74 to +25°C, and then a decrease from +25 to +150°C. These observations are not consistent with the simple equilibrium, **2a**⇌**2b**. At higher temperatures, the bonded form (**2b**) will diminish with an increase in the amounts of the nonbonded form (**2a**) and/or of the positively-rotating, twist form (**2c**), as has been suggested previously.[4]

Compound **3**, an epimer of **2**, may exist in two such interconvertible chair conformations as the positively-rotating, hydrogen-bonded conformer (**3a**)

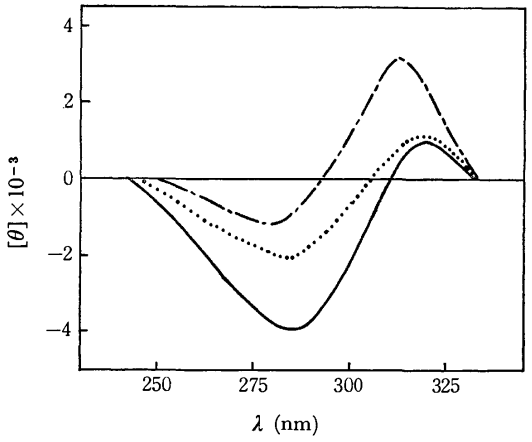

Fig. 4. CD curves of (1*R* : 4*R*)-(+)-1-hydroxy-*p*-menth-8-en-2-one (**2**) in decalin: ---- at −74°C, —— at +25°C, and ····· at +150°C.

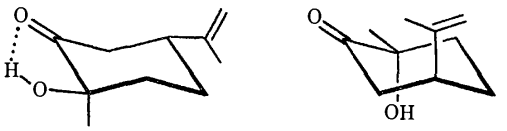
and the negatively-rotating, nonbonded one (**3b**).



3a **3b**

The compound (**3**) showed only a positive Cotton effect curve with a rotational strength which is almost independent of the solvent polarity. The CD curves of its acetate, **5**, and the hydrobrominated compound, **11**, also showed a solvent-independent, positive Cotton effect at 25°C. Consequently, the **3a** conformer, with an equatorial isopropenyl group, is predominant regardless of the presence of an intramolecular hydrogen bond. The conformer homogeneity of **3** in the nonpolar solvent was ascertained on the basis of infrared spectrum measurements. The spectrum (Fig. 2) in carbon tetrachloride exhibited only a band at 3508 cm^{-1} (ε 61) resulting from an intramolecular hydrogen bond[9] between the hydroxyl group and the lone-pair electrons on the carbonyl oxygen. The two compounds, (**7**) and (**11**), related to the compound (**3**) also exhibited only a similar band assigned to the intramolecular hydrogen bonding (Fig. 2).

The temperature-dependent CD curves of **3** in MI and EPA over the range from 25 to −186°C showed only a positive Cotton effect with a slightly increase in the rotational strength as the temperature was lowered. This implies that the positively-rotating, chair conformer (**3a**) is most stable from the steric and energetic[6] points of view. The compound (**3**) in decalin revealed a decrease in the rotational strength of its positive CD curves at both higher and lower temperatures. This indicates that the hydrogen-bonded conformer (**3a**) would diminish with an increase in the population of the nonbonded conformer when taken out of room temperature.

The saturated compounds **6**, **7**, **8**, exhibited the same phenomena in their CD curves as those in the cases of the corresponding unsaturated compounds, (**2**), (**3**), (**4**), and (**5**) respectively. All the CD data of the saturated compounds are presented in the Experimental section.

Experimental

Measurements. The CD curves were obtained by means of a Japan Spectroscopic Co., Ltd., automatically-recording spectropolarimeter, Model ORD/UV-5, equipped with a circular dichroism attachment, using a variable temperature CD cell designed and constructed by one of the present authors. The EPA solvent is composed of ether-isopentane-ethanol in the ratio of 5 : 5 : 2 by volume. The MI solvent is composed of methylcyclohexane-isopentane in the ratio of 1 : 3 by volume.

The infrared spectra in the hydroxyl-stretching region were measured with a Perkin-Elmer Model 621 Grating Infrared spectrometer at 25°C. A sodium chloride absorption cell (10 mm long) was used; the concentration of the solution was 0.005 mol/*l*.

The NMR, mass, IR, and UV spectra, although not

shown below, supported exactly the structure of the compounds on which the CD curves were measured. Only the methods of preparation of the compounds and the data on the CD curves are given below.

(*1*R : *4*R)-(−)-p-*menth-8-en-2-one* (**1**). The Jones' oxidation of (+)-neodihydrocarveol[13] produced (1*R* : 4*R*)-(−)-*p*-menth-8-en-2-one (**1**): n_D^{25} 1.4650; $[\alpha]_D^{25}$ −200° (MeOH, *c* 0.08); CD (max) in MI (*c* 0.134): $[\theta]_{295}^{+25°}$ +3251, $[\theta]_{300}^{+25°}$ +2955, $[\theta]_{304}^{-186°}$ +3944, $[\theta]_{299}^{-186°}$ +3944, $[\theta]_{309}^{-186°}$ +3199, in EPA (*c* 0.084): $[\theta]_{293}^{+25°}$ +3182, $[\theta]_{290}^{-186°}$ +3206, $[\theta]_{299}^{-186°}$ +2829, $[\theta]_{309}^{-186°}$ +1886.

(*1*S : *4*R)-(+)-*1-hydroxy*-p-*menth-8-en-2-one* (**2**) *and* (*1*R : *4*R)-(+)-*1-hydroxy*-p-*menth-8-en-2-one* (**3**). These compounds were the same as those prepared in the previous paper,[14] to which the physical properties are referred. Their acetates, (**4**) and (**5**) were prepared by the acetylation of **2** and **3** respectively with acetic anhydride in the presence of *p*-toluenesulfonic acid.

The compound (**2**): CD (max) in EPA (*c* 0.0589): $[\theta]_{307}^{+25°}$ +4329, $[\theta]_{307}^{-74°}$ +5101, $[\theta]_{300}^{-186°}$ +6515.

The compound (**3**): CD (max) in MeOH (*c* 0.1684): $[\theta]_{290}^{+25°}$ +10269, in DMSO (*c* 0.1332): $[\theta]_{294}^{+25°}$ +8992, in isooctane (*c* 0.1684): $[\theta]_{286}^{+25°}$ +11195, in decalin (*c* 0.0611): $[\theta]_{285}^{-74°}$ +10307, $[\theta]_{285}^{+25°}$ +9168, $[\theta]_{289}^{+150°}$ +7248, in EPA (*c* 0.0652): $[\theta]_{286}^{+25°}$ +8843, $[\theta]_{290}^{-74°}$ +8898, $[\theta]_{290}^{-182°}$ +10856.

The acetate (**4**): bp 55—56°C/30 mmHg; n_D^{25} 1.4688; $[\alpha]_D^{25}$ +4.81° (MeOH, *c* 0.1454); CD (max) in MeOH (*c* 0.1454); $[\theta]_{288}^{+25°}$ +2931, in DMSO (*c* 0.142): $[\theta]_{294}^{+25°}$ +2945, in isooctane (*c* 0.1644): $[\theta]_{292}^{+25°}$ +3021.

The acetate (**5**): bp 75—80°C/8 mmHg; $[\alpha]_D^{25}$ +61.58° (MeOH, *c* 0.1624); CD (max) in MeOH (*c* 0.1624): $[\theta]_{290}^{+25°}$ +6817, in DMSO (*c* 0.149): $[\theta]_{293}^{+25°}$ +6656, in isooctane (*c* 0.1648): $[\theta]_{294}^{+25°}$ +6534.

(*1*S : *4*R)-(+)-*1-hydroxy*-p-*methan-2-one* (**6**) *and* (*1*R : *4*R)-(+)-*1-hydroxy*-p-*menthan-2-one* (**7**). The reduction of the menthenones (**2**), (**3**), and (**5**) in methanol on 10%-palladium charcoal gave the corresponding saturated compcompounds, (**6**), (**7**), and (**9**).

The compound (**6**): n_D^{25} 1.4621; $[\alpha]_D^{25}$ +23.47° (MeOH, *c* 0.1704); CD (max) in MeOH (*c* 0.1704): $[\theta]_{272}^{+25°}$ −922, $[\theta]_{306}^{+25°}$ 1910, in DMSO (*c* 0.1692): $[\theta]_{308}^{+25°}$ +2255, in dioxane (*c* 0.172): $[\theta]_{276}^{+25°}$ −1566, $[\theta]_{310}^{+25°}$ +1827, in CCl_4 (*c* 0.151): $[\theta]_{282}^{+25°}$ −5201, $[\theta]_{316}^{+25°}$ +594, in isooctane (*c* 0.1686): $[\theta]_{280}^{+25°}$ −4881, $[\theta]_{307}^{+25°}$ +133, in decalin (*c* 0.156): $[\theta]_{282}^{-74°}$ −1827, $[\theta]_{310}^{-74°}$ +2166, $[\theta]_{282}^{+25°}$ −4819, $[\theta]_{318}^{+25°}$ +360, $[\theta]_{282}^{+72°}$ −4161, $[\theta]_{318}^{+72°}$ +371, $[\theta]_{284}^{+150°}$ −2089, $[\theta]_{318}^{+150°}$ +402, in MI (*c* 0.144): $[\theta]_{282}^{+25°}$ −5688, $[\theta]_{316}^{+25°}$ +312, $[\theta]_{274}^{-74°}$ −3072, $[\theta]_{306}^{-74°}$ +2513, $[\theta]_{305}^{-192°}$ +4758, in EPA (*c* 0.143): $[\theta]_{275}^{+25°}$ −1726, $[\theta]_{308}^{+25°}$ +3138, $[\theta]_{307}^{-192°}$ +4696, $[\theta]_{318}^{-192°}$ +3882, (*c* 0.172 at −74°) $[\theta]_{270}^{-74°}$ +683, $[\theta]_{307}^{-74°}$ +2904.

The compound (**7**): n_D^{25} 1.4593; $[\alpha]_D^{25}$ +97.23° (MeOH) *c* 0.1736); CD (max) in MeOH (*c* 0.1736): $[\theta]_{286}^{+25°}$ +2036, in DMSO (*c* 0.064): $[\theta]_{288}^{+25°}$ +7188, in dioxane (*c* 0.076): $[\theta]_{284}^{+25°}$ +9399, in CCl_4 (*c* 0.092): $[\theta]_{282}^{+25°}$ +9634, in isoocatne (*c* 0.0651): $[\theta]_{283}^{+25°}$ +9472, in decalin (*c* 0.06): $[\theta]_{282}^{-74°}$ +8270, $[\theta]_{282}^{+25°}$ +8041, $[\theta]_{282}^{+72°}$ +7341, $[\theta]_{284}^{+150°}$ +5431, in MI (*c* 0.06): $[\theta]_{282}^{+25°}$ +8840, $[\theta]_{284}^{-74°}$ +9596, (*c* 0.056, at −192°) $[\theta]_{286}^{-192°}$ +8828, in EPA (*c* 0.0524): $[\theta]_{284}^{+25°}$ +10706, $[\theta]_{288}^{-74°}$ +11403, $[\theta]_{291}^{-192°}$ +12815, $[\theta]_{298}^{-192°}$ +12132.

The acetate (**9**): n_D^{25} 1.4590; $[\alpha]_D^{25}$ +7.44°; CD (max) in MeOH (*c* 0.121): $[\theta]_{287}^{+25°}$ +7516, in dioxane (*c* 0.12): $[\theta]_{291}^{+25°}$ +7269, in isooctane (*c* 0.1176): $[\theta]_{290}^{+25°}$ +6008.

The acetate (**8**): (1*S* : 2*S* : 4*R*)-1,2-Dihydroxy-*p*-menthane, prepared from the corresponding dihydroxy-*p*-menth-8-ene by hydrogenation, was converted into the hydroxyketone **6** by oxidation with chromic acid-pyridine complex. Then, the hydroxyketone was acetylated in the same manner as above to produce the acetoxyketone, **8**: n_D^{25} 1.4555; $[\alpha]_D^{25}$ +35.47° (MeOH, *c* 0.296); CD (max) in MeOH (*c* 0.296): $[\theta]_{286}^{+25°}$ +1654, in dioxane (*c* 0.353): $[\theta]_{287}^{+25°}$ +753, in isooctane (*c* 0.345): $[\theta]_{290}^{+25°}$ +710.

(*1*S : *4*R)-(+)-*1-Hydroxy-8-bromo*-p-*menthan*-2-*one* (**10**). A benzene solution of the hydroxyketone **2** was treated with a hydrobromic acid-acetic acid solution. After the reaction mixture was then poured into ice water, it was worked up as usual to yield the hydrobrominated compound (**10**) as white crystals: mp 65.5—66.0°C; $[\alpha]_D^{25}$ +63.4° (MeOH, *c* 0.122); CD (max) in MeOH (*c* 0.122): $[\theta]_{304}^{+23°}$ +2825, in CCl_4 (*c* 0.092): $[\theta]_{311}^{+23°}$ +2591.

(*1*R : *4*R)-(+)-*1-Hydroxy-8-bromo*-p-*menthan*-2-*one* (**11**). The treatment of the hydroxyketone **3** in a manner similar to that above gave a hydrobrominated derivative (**11**): mp 61.5°C; $[\alpha]_D^{25}$ +64.4° (MeOH, *c* 0.114); CD (max) in MeOH (*c* 0.114): $[\theta]_{290}^{+23°}$ +5254, in CCl_4 (*c* 0.091): $[\theta]_{286}^{+23°}$ +6227.

The authors wish to thank the Takasago Perfumery Co. for its gift of limonene and Mr. Kiyoshi Imamura of our laboratory for his helpful assistance in the preparation of the hydrobrominated compounds.

A New Steroid with an Unnatural Configuration: 8α,14β-Progesterone

Fumikazu MUKAWA and Wataru NAGATA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received August 6, 1971)

A modified Wolf-Kishner reduction of certain 5α,8α,14β-11-oxo steroids gave the corresponding 11-deoxy steroids with the same stereochemistry, and the introduction of a double bond at C_4—C_5 leads to 8α,14β-progesterone. The structure and configuration of this compound are discussed on the basis of its physical properties. Its unnatural backbone stereochemistry was established by transformations from the 8α,14β-1,4-diene derivative to the known 8α,14β-estrone.

The demonstration by Westerhof of differences in the biological activity of steroids which feature unnatural backbone stereochemistry has led to the preparation of a variety of such compounds.[1] Although racemic 8α,14β-estrone[2] was prepared by the total synthetic method, no 8α,14β-steroid of the pregnane series has yet been reported on. In view of the current interest in progesterone analogs,[3] we would like to report the synthesis of 8α,14β-progesterone (**7**).

The reduction of 11-oxo-5α,8α,14β-spirostan-3β-ol[4] (**1a**) by a modified Wolf-Kishner procedure, developed in our laboratory[5] for the reduction of highly-hindered ketones, followed by acetylation, led to 8α,14β-spirostan 3β-acetate (**2a**, R_1=Ac). Side-chain degradation then gave the 16-pregnene derivative (**3a**, R=OAc), which, on hydrogenation over a palladium-charcoal catalyst, followed by saponification, yielded the 5α,8α,14β-pregnane derivative (**3b**, R=OH). Compound **3b** (R=OH) was also obtained using the technique described above for spirostan-series compounds, starting from the 11-oxo-8α,14β-pregnane derivative (**1b**, R_2=H).

The partial saponification of the 3β,20β-diacetoxy pregnane derivative, followed by the oxidation of the 3-hydroxyl derivative, provided the 3-ketone (**4a**, X_1,X_2=H). The subsequent introduction of the C_4–C_5 double bond was effected in the following way: the treatment of 2ξ,4ξ-dibromo-3-ketone (**4a**, X_1,X_2=Br) with lithium salts in *N*,*N*-dimethylformamide, and selective hydrogenation with the ruthenium complex[6]

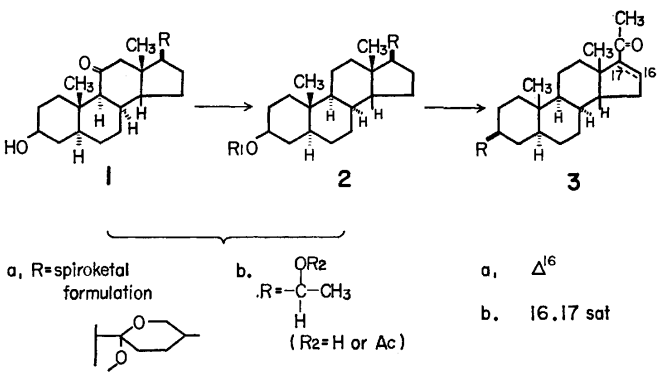

Fig. 1.

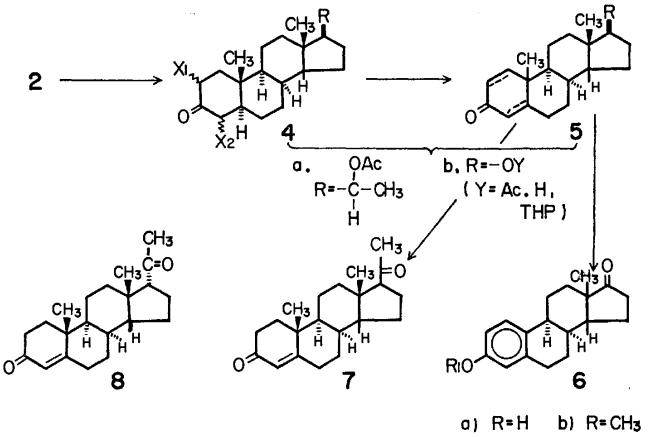

Fig. 2.

of the resulting 1,4-diene-3-ketone (**5a**, $\Delta^{1,4}$), gave the 20β-acetoxy-4-ene-3-ketone derivative (**5a**, Δ^4). This compound, on hydrolysis subsequent to its oxidation, led to the 17β-acetyl derivative (**7**) (predominating) and the 17α-isomer (**8**). These configurations were supported by the circular dichroism data (Table 1). In **7**, a positive Cotton effect appears at 288 nm, in agreement with the 17β-configuration of

TABLE 1. COTTON EFFECT OF UNNATURAL PROGESTERONE AND NATURAL PROGESTERONE

	Circular dichroism (Molecular ellipticity)
7	$[\theta]_{253}$ −12160, $[\theta]_{288}$ +8510, $[\theta]_{325}$ +5600
8	$[\theta]_{253}$ −11200, $[\theta]_{280}$ −3050, $[\theta]_{325}$ +7210
Progesterone	$[\theta]_{240sh}$ +18700, $[\theta]_{286}$ +13320, $[\theta]_{325}$ −4100

The spectra were measured in methanol.

the side chain of progesterone; **8** was shown to have the 17α-configuration by its negative Cotton effect in the same region.[7]

The positive Cotton effect for the n—π^* transition of the α,β-unsaturated ketone, at *ca.* 325 nm, and the negative effect for the π—π^* (253 nm) showed **7** and **8** to have identical 8α and 14β ring junctures. The natural configuration, as in progesterone, is characterized by a negative Cotton effect at 325 nm and a positive one at the π—π^* transition. This evidence indicates the stereochemistry of **7**, though it is not complete.

The Baeyer-Villiger oxidation of **3b** (R=OH) with trifluoroperacetic acid, followed by the oxidation of the C_3-hydroxy group with Jones's reagent, afforded **4b** (X_1,X_2=H, Y=Ac) after alkaline hydrolysis had given 17β-ol (**4b**, X_1,X_2=H, Y=H). This ketone was dibrominated with bromine in acetic acid, giving the dibromide, which, on subsequent treatment with lithium carbonate and lithium bromide, gave the 1,4-dien-3-one (**5b**, Y=H, $\Delta^{1,4}$). The corresponding tetrahydropyranyl ether (**5b**, Y=THP, $\Delta^{1,4}$) was obtained by the standard method. The reductive aromatization of **5b** (Y=THP, $\Delta^{1,4}$) by Dryden's method,[8] followed by the oxidation of 17-hydroxyl, provided 8α,14β-estrone (**6a**), identified with an authentic specimen of 8α,14β-estrone[2] by a comparison of the IR, mass, and NMR spectra. The methyl ether (**6b**) was also identical with an authentic specimen. Thus, we confirmed the assigned stereochemistry of 8α,14β in our synthetic compounds.

Experimental

The melting points are corrected. The UV spectra were obtained using a Hitachi EPS 3-T spectrophotometer, while a Nihon-Bunko DS-201B spectrophotometer was used for the IR spectra. The NMR spectra were obtained on a Varian A-60 spectrometer, with TMS as the internal standard, and the mass spectra were taken with a Hitachi RMU-6 spectrometer. The optical rotations were measured in 1% EtOH-$CHCl_3$ with a Perkin Elmer Polarimeter 141.

*1. (25R)-8α,5α,14β-Spirostan-3β-ol (**2a**, R_1=H).* A mixture of 1.0 g of (25*R*)-5α,8α,14β-spirostan-3β-ol-11-one (**1a**),[4] 9.5 g of 80% hydrazine hydrate, 1.8 g of hydrazine dihydrochloride, and 52 m*l* of triethylene glycol was heated at 130°C for 1.5 hr. After adding 4.5 g of potassium hydroxide pellets, the temperature was raised to 210°C by distilling the low-boiling material out. After 3.5 hr, the reaction mixture was diluted with water and extracted with methylene chloride. The methylene chloride solution was washed with water and dried, and the solvent was evaporated. The crystalline residue was then recrystallized from methanol to give **2a** (R_1=H) (0.73 g); mp 168—172°C. A pure sample melted at 169—173°C, $[\alpha]_D^{23}$ −95.5° (c 0.18); NMR τ: 9.21 (27-C$\underline{H_3}$), 9.05 (21-C$\underline{H_3}$), 8.98 (18-C$\underline{H_3}$), 9.13 (19-C$\underline{H_3}$).

Found: C, 77.7; H, 10.6%. Calcd for $C_{27}H_{44}O_3$: C, 77.8; H, 10.6%.

*2. 5α,8α,14β-Pregn-16-en-20-one 3β-Acetate(**3a**, R=-OAc).*[9] The 5α,8α,14β-tigogenine compound (**2a**, R_1=H) (0.75 g) was refluxed for 12.5 hr with 60 m*l* of acetic anhydride and 0.45 g of pyridine hydrochloride. The mixture was then cooled, diluted with 12 m*l* of acetic acid and 18 m*l* of water, and added to 0.3 g of chromic anhydride in 6 m*l* of 90% acetic acid while being stirred at 15—20°C. After standing at 25°C for 3 hr, the solution was treated first with 0.2 m*l* of 37% formaldehyde and then with 0.65 g of sodium acetate. The stirred suspension was then heated on a water bath for 1 hr, cooled, and diluted with water. After being extracted with ether, the ether solution was dried over anhydrous sodium sulfate and evaporated. The residue was chromatographed[10] on alumina (20 g, Wohlem activity II). Elution with benzene-petroleum ether (4 : 1) and benzene afforded 16-ene (**3a**, R=−OAc) (0.32 g) as plates (from acetone); mp 146—147°C, $[\alpha]_D^{21}$ +56.1° (*c* 0.3).

Found: C, 77.2; H, 9.6%. Calcd for $C_{23}H_{34}O_3$: C, 77.1; H, 9.6%. IR (CCl_4) cm^{-1}: 1745 (3β-acetate), 1670 (20-ketone), 1615 (Δ^{16}). NMR τ: 9.06 (19-C$\underline{H_3}$), 8.81 (18-C$\underline{H_3}$), 8.00 (3β-C$\underline{H_3}$COO), 7.75 (21-C$\underline{H_3}$), 3.40 (Δ^{16}-olefin, t, $J \fallingdotseq 4$ Hz).

*3. 3β-Hydroxy-5α,8α,14β-pregnan-20-one (**3b**, R=-OH).* A solution of 0.22 g of Δ^{16}-ene (**3a**, R=−OAc) in 20 m*l* of ethyl acetate was shaken with a 5% palladium-charcoal catalyst under a hydrogen atmosphere for 15 min. After the removal of the catalyst and the evaporation of the solvent under reduced pressure, a crude acetate was obtained. The saponification of this acetate with 0.2 g of potassium carbonate in ethanol, followed by recrystallization from ether-petroleum ether, gave 0.18 g of **3b** (R=-OH); mp 125—130°C. Analytical samples were recrystallized from methanol; mp 134°C, $[\alpha]_D^{21}$ +82.8° (*c* 0.3).

Found: C, 78.9; H, 10.8%. Calcd for $C_{21}H_{34}O_2$: C, 79.1; H, 10.8%. IR ($CHCl_3$) cm^{-1}: 3600 (3β-OH), 1700 (20-ketone). NMR τ: 9.16 (18-C$\underline{H_3}$), 9.06 (19-C$\underline{H_3}$), 7.91 (21-C$\underline{H_3}$). CD (*c* 0.009, MeOH): $[\theta]_{291}$+7630. Mass: 318 (M·).

*4. 3β,20β-Dioxy-5α,8α,14β-pregnane (**2b**, R_1, R_2=H).* In view of the facile alkaline isomerization at C-14 of 11-oxo-8-ene steroids, the preparation of 11-oxo-14β-pregn-8-en-3β-ol was carried out under Djerassi's conditions:[4] a solution of 12.7 g of 3β,20β-diacetoxy-5α-pregn-8-ene-11-one[11] was refluxed for 40 minutes with 1.2 *l* of 5% methanolic potassium hydroxide. After concentration *in vacuo*, dilution with water, extraction with methylene chloride, evaporation and recrystallization from methanol, we obtained 9.1 g of 11-oxo-5α,14β-pregn-8-en-3β,20β-diol with a mp of 198—202°C; $[\alpha]_D^{26.2}$+152° (*c* 1.0); UV λ_{max}^{MeOH} 248 nm (ε 9200); CD (*c* 0.01, CH_3Cl): $[\theta]_{385}$ 0, $[\theta]_{355}$ −1480, $[\theta]_{330}$ −1230, $[\theta]_{246.5}$ +25600; NMR ($CDCl_3$) τ: 8.88 (18-C$\underline{H_3}$ and 19-C$\underline{H_3}$), 8.81 (d, $J \fallingdotseq 7$ Hz, 21-C$\underline{H_3}$).

Found: C, 75.9; H, 9.6%. Calcd for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7%.

1b (R_2=H) (6.8 g) was reduced to the corresponding 11-deoxo derivative (**2b**, R_1,R_2=H) in a 79% yield by a modified Wolf-Kishner reduction, heating with 54 g of 80% hydrazine hydrate and 10.4 g of hydrazine dihydrochloride in 320 ml of triethylene glycol at 130°C for 1.5 hr. After adding 34.5 g of potassium hydroxide, the temperature was raised to 210°C, as in Exp. 1. After cooling, the reaction was worked up as usual. The recrystallization from acetone led to **2b** (R_1=H) (4.8 g) with a mp of 170—173°C. Three recrystallizations from acetone afforded an analytical sample with a mp of 185°C; $[\alpha]_D^{25.8}$ +28.1° (*c* 0.5); NMR τ: 9.10 (19-C$\underline{H}_3$), 9.03 (18-C$\underline{H}_3$), 8.85 (d, *J*≒7 Hz, 21-C$\underline{H}_3$).

Found: C, 78.9; H, 11.3%. Calcd for $C_{21}H_{36}O_2$: C, 78.7; H, 11.3%.

*5. 3,20-Dioxo-5α,8α,14β-pregnane (**3b**, R==O).* The oxidation of 0.70 g of **3b** (R=−OH) with 0.3 ml of Jones's reagent in 0.15 ml of acetone at room temperature produced **3b** (R==O) (0.54 g), with a mp of 133—135°C. Recrystallization from methanol then led to the analytical sample; mp 138°C; $[\alpha]_D^{29}$+115.5° (*c* 0.23); IR (CCl_4) cm^{-1}: 1705; NMR τ: 9.11 (18-C$\underline{H}_3$), 8.86 (19-C$\underline{H}_3$), 7.86 (21-C$\underline{H}_3$); CD (*c* 0.001, MeOH): $[\theta]_{325}$ −3926.

Found: C, 79.7; H, 9.9%. Calcd for $C_{21}H_{32}O_2$: C, 79.7; H, 10.2%.

The same product was obtained when the oxidation of **2b** (R_1,R_2=H) was carried out with stirred chromium trioxide-acetic acid; the mixed melting point and the IR spectra proved to be identical.

The 3,20-dioxo compound (**3b**, R==O) (0.18 g) obtained above was reduced by stirring with 20 mg of sodium borohydride in 20 ml of ethanol for 30 min at room temperature; the mixture was then treated as usual to afford 0.14 g of **2b** (R_1,R_2=H), which was identical with the sample of 3β,20β-diol obtained in Exp. 4.

*6. 3β,20β-Diacetoxy-5α,8α,14β-pregnane (**2b**, R_1,R_2=Ac).* The free 3β,20β-diol **2b** (R_1,R_2=H) (0.5 g) in 2.5 ml of acetic anhydride and 50 ml of pyridine was warmed on a water-bath for 1.5 hr. After dilution with water, filtration, and recrystallization from acetone, we obtained 0.44 g of the diacetate (**2b**, R_1,R_2=Ac) with a mp of 102—104°C; $[\alpha]_D^{26.8}$ +38.2° (*c* 0.9).

Found: C, 74.4; H, 9.8%. Calcd for $C_{25}H_{40}O_4$: C, 74.2; H, 9.9%. IR (CCl_4) cm^{-1}: 1735—1740; NMR τ: 9.16 (19-C$\underline{H}_3$), 9.08 (18-C$\underline{H}_3$), 8.83 (d, *J*≒7 Hz, 21-C$\underline{H}_3$), 8.00 (C$\underline{H}_3$COO).

*7. 20β-Acetoxy-5α,8α,14β-pregnan-3-one (**4a**, X_1,X_2=H).* The partial saponification of the diacetate (**2b**, R_1,R_2=Ac) in 120 ml of 90% methanol with 1.9 g of potassium carbonate gave, after stirring for 2.5 hr at room temperature and dilution with water, 3.5 g of **2b** (R_1=H, R_2=Ac) with a mp of 112—116°C. Further recrystallization from methanol afforded an analytical sample with a mp of 121°C; $[\alpha]_D^{26.8}$ +46.5° (*c* 0.52); IR (Chf) cm^{-1}: 3690, 3600 (3β-OH), 1725 (20β-acetate); NMR τ: 9.18 (19-C$\underline{H}_3$), 9.08 (18-C$\underline{H}_3$), 8.83 (d, *J*=7 Hz, 21-C$\underline{H}_3$), 8.00 (C$\underline{H}_3$COO).

Found: C, 76.1; H, 10.3%. Calcd for $C_{23}H_{38}O_3$: C, 76.2; H, 10.5%.

A mixture of Jones's reagent (1.2 eq.) was added to a solution of 3.2 g of the above 3β-ol **2b** (R_1=H, R_2=Ac) in 15 ml of acetone over a 3-min period, and then the whole mixture was immediately poured into a large volume of ice water. The precipitate was extracted with ether, washed, and dried, and the solvent was removed. Recrystallization from acetone then afforded 3.3 g of **4a** (X_1,X_2=H); mp 140—141°C; $[\alpha]_D^{26.9}$+71.9° (c, 0.12), IR (Chf) cm^{-1}: 1715 (3-ketone), 1735 (acetate); NMR τ: 9.13 (18-C$\underline{H}_3$), 8.88 (19-C$\underline{H}_3$), 8.81 (d, *J*=7 Hz, 21-C$\underline{H}_3$), 8.00 (C$\underline{H}_3$COO); CD (*c* 0.003, dioxane): $[\theta]_{330}$ 0, $[\theta]_{294}$+3635, $[\theta]_{250}$+117, $[\theta]_{218}$+5360.

Found: C, 76.7; H, 9.8%. Calcd for $C_{23}H_{36}O_3$: C, 76.6; H, 10.0%.

*8. 20β-Acetoxy-8α,14β-pregna-1,4-dien-3-one (**5a**, $\Delta^{1,4}$).* One gram of the 3-ketone (**4a**, X_1,X_2=H) was brominated in 70 ml of acetic acid (containing one drop of hydrogen bromide-acetic acid) with 950 mg of bromine in 20 ml of acetic acid. The color disappeared in 10 min, after which the solution was left to stand for 1 hr. The addition of water precipitated the crude 2ξ,4ξ-dibromo-3-ketone (**4a**, X_1,X_2=Br), which was dried and refluxed for 3 hr in 45 ml of *N*,*N*-dimethylformamide with 0.7 g of lithium bromide and 1.2 g of lithium carbonate, avoiding moisture. Most of the solvent was thus evaporated off, and the concentrate was diluted with 2 N-hydrochloric acid. After extraction with methylene chloride, the organic layer was washed with water, dried over anhydrous sodium sulfate, and evaporated. The residue was separated by tlc,[12] using benzene-ethyl acetate (9 : 1) as the developing solvent, to give 0.40 g of **5a** ($\Delta^{1,4}$). An analytical sample was recrystallized three times from ether - *n*-hexane; mp 165°C; $[\alpha]_D^{26.9}$ +220.2° (*c* 0.5); IR (Chf) cm^{-1}: 1730 (acetate), 1655, 1620, 1600 ($\Delta^{1,4}$-3-ketone); UV λ_{max}^{MeOH} 247 mμ (ε 12360); CD: (*c*, 0.001, MeOH) $[\theta]_{345}$+15200, $[\theta]_{320}$+7600, $[\theta]_{299}$+15200, $[\theta]_{273}$ 0, $[\theta]_{255}$−16000; NMR τ: 9.08 (18-C$\underline{H}_3$), 8.83 (d, *J*≒7 Hz, 21-C$\underline{H}_3$), 8.70 (19-C$\underline{H}_3$), 8.00 (C$\underline{H}_3$COO−), 3.96 (d. d., *J*≒2 Hz, C_4–H), 3.80 (d, *J*≒3 Hz, C_2–H), 3.00 (d, *J*≒10 Hz, C_1–H).

Found: C, 77.4; H, 9.1%. Calcd for $C_{23}H_{32}O_3$: C, 77.5; H, 9.0%.

*9. 20β-Acetoxy-8α,14β-pregn-4-en-3-one (**5a**, Δ^4).* 1,4-Diene-3-one (0.13 g) was hydrogenated with 0.1 g of the ruthenium complex in 20 ml of benzene at 40°C under an hydrogen pressure of 88 atm for 1 hr. The residue thus obtained was then separated by tlc, using benzene-ethyl acetate (4 : 1) as the developing solvent, to give 98 mg of **5a** (Δ^4). An analytica sample was recrystallized from ether-petroleum ether; mp 84°C; $[\alpha]_D^{27}$+145.3° (*c* 0.4); IR (Chf) cm^{-1}: 1725 (acetate), 1655, 1600 (4-en-3-one); NMR τ: 8.75 (19-C$\underline{H}_3$), 8.81 (d, *J*≒7 Hz, 21-C$\underline{H}_3$), 8.74 (19-C$\underline{H}_3$), 8.00 (C$\underline{H}_3$COO), 4.25 (t, *J*≒2 Hz, 4H); CD (*c* 0.003, MeOH): $[\theta]_{332}$+12660, $[\theta]_{316}$+8180, $[\theta]_{282}$+8310, $[\theta]_{262.5}$ 0, $[\theta]_{245}$−15510, $[\theta]_{229}$ 0, $[\theta]_{217}$+14800.

Found: C, 77.0; H, 9.5%. Calcd for $C_{23}H_{34}O_3$: C, 77.1; H, 9.5%.

*10. 8α,14β-Pregn-4-en-3-one (**7**) and 8α,14β,17α-pregn-4-en-3-one (**8**).* A solution of 0.90 g of 20β-acetyl-4-en-3-one (**5a**, Δ^4) dissolved in 40 ml of ether was added to a solution of 0.5 g of lithium aluminum hydride in 30 ml of ether, and the mixture was stirred at room temperature for 30 min. The mixture was then cooled, and the excess lithium aluminum hydride was decomposed by the addition of water. On a usual work-up, a syrupy residue was obtained. To a solution of 0.7 g of chromium trioxide in 20

12) For preparative and analytical tlc, silicagel G or GF (E. Merck Co.) was used as the adsorbent.

ml of pyridine, we then added, at 10—15°C, a solution of the syrupy residue in 13 ml of the same solvent. After the reaction mixture had been allowed to stand for 2 hr, the usual work-up gave 0.85 g of a mixture of **7** and **8**, which were separated by tlc. By using a developing solvent (benzene-ethyl acetate, 3 : 1), we obtained 0.71 g of **7** (recrystallization from ether-petroleum ether) with a mp of 78°C; $[\alpha]_D^{24}$+98°C (*c* 0.8). NMR τ: 9.10 (18-C$\underline{H}_3$), 8.75 (19-C$\underline{H}_3$), 7.90 (21-C$\underline{H}_3$), 4.25 (t, $J\doteqdot 2$ Hz, 4H).

Found: C, 80.0; H, 9.6%. Calcd for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6%.

We also obtained **8** (28 mg). It was recrystallized from acetone gave an analytical sample; mp 101°C, $[\alpha]_D^{23.5}$+38° (*c* 0.5). NMR τ: 8.78 (18-C$\underline{H}_3$), 8.68 (19-C$\underline{H}_3$), 7.86 (21-C$\underline{H}_3$), 4.25 (t, $J\doteqdot 2$ Hz, 4H).

Found: C, 80.3; H, 9.3%. Calcd for $C_{21}H_{30}O_2$: C, 80.2; H, 9.6%.

11. Oxidation of ***3b*** *(R=-OH) with Peroxytrifluoroacetic Acid.* Into a mixture of 0.20 ml of 90% hydrogen peroxide and 30 ml of methylene dichloride at 0°C, we stirred 1.5 ml of trifluoroacetic anhydride over a period of 10 min. The mixture was further stirred for five minutes and then transferred to a dropping funnel and stirred drop by drop, into an ice-cold solution of 1.2 g of **3b** (R=OH) in 60 ml of methylene chloride containing 3.8 g of disodium hydrogen phosphate. The mixture was allowed to stand at room temperature under stirring for 1 hr, and then water was added to dissolve the salt. An organic layer was separated and washed with 2 N sodium thiosulfite. After drying, the solvent was removed to give a crystalline residue, **4b** (X_1,X_2=H, Y=Ac); mp 121—123°C. An analytical sample showed a mp of 125°C, $[\alpha]_D$+79° (*c* 0.9).

Found: C, 75.7; H, 9.5%. Calcd for $C_{21}H_{32}O_3$: C, 75.8; H, 9.7%.

The saponification of 0.70 g of **4b** (X_1,X_2=H, Y=Ac) with 700 mg of potassium hydroxide in 16 ml of methanol for 30 min, followed by recrystallization from aq. methanol, produced 0.52 g of **4b** (X_1,X_2=H, Y=H); mp 138—141°C. Analytical sample: mp 142—143.5°C; $[\alpha]_D$+65° (*c* 0.5).

Found: C, 78.6; H, 10.4%. Calcd for $C_{19}H_{30}O_2$: C, 78.6; H, 10.4%.

*12. 8α,14β-Estrone (****6a****) and Its 3-Methyl Ether (****6b****).* The 1,4-dien-3-one (**5b**, $\Delta^{1,4}$) was prepared as has been described above. A solution of 0.20 g of **4b** (X_1,X_2 and Y=H) in 10 ml of acetic acid (containing one drop of hydrogen bromide-acetic acid) was treated with a solution of 0.10 g of bromine in 2.0 ml of acetic acid at room temperature for 20 min. After an additional 30 min's stirring at 45—50°C, the reaction mixture was diluted. The extract was made neutral by washing it with 2 N sodium bicarbonate and water; then it was evaporated to dryness to yield a crude dibromoketone. The dehydrobromination of the crude dibromoketone (0.21 g) with 0.17 g of lithium bromide and 0.21 g of lithium carbonate in 8.5 ml of refluxing *N,N*-dimethylformamide under a N_2 gas stream for 1.5 hr gave the 1,4-dien-3-one compound. The products were separated by tlc. Development with benzene - ethyl acetate (4 : 1) gave crystalline fraction (74 mg); repeated crystallizations from ether - petroleum ether gave **5b** (Y=H, $\Delta^{1,4}$); mp 92—93°C; $[\alpha]_D^{24}$+48° (*c* 0.7), IR (Chf) cm^{-1}: 1655, 1628, 1600 ($\Delta^{1,4}$-3-ketone). UV λ_{max}^{MeOH} 248 nm (ε 12100); CD (*c* 0.0004, MeOH): $[\theta]_{390}$ +13400, $[\theta]_{315}$ +4530, $[\theta]_{299}$+14310, $[\theta]_{268}$ 0, $[\theta]_{250}$−10410, $[\theta]_{225}$ 0; NMR τ: 9.03 (18-C$\underline{H}_3$), 8.70 (19-C$\underline{H}_3$), 3.98 (d, d., $J\doteqdot 2$ Hz, 4-H), 3.75 (d, $J\doteqdot 4$ Hz, 2H), 3.00 (d, $J\doteqdot 10$ Hz, 1H).

Found: C, 79.4; H, 9.4%. Calcd for $C_{19}H_{26}O_2$: C, 79.7; H, 9.2%.

A solution of 0.10 g of **5b** (Y=H, $\Delta^{1,4}$) in 4 ml of dihydropyran was treated with 0.5 ml of a dihydropyran-anhydrous hydrogen chloride solution (10%) by ice-cooling. After 1.5 hr, the mixture was poured into 30 ml of aq. saturated sodium bicarbonate and thoroughly extracted with ether. The organic layer was washed with water and evaporated *in vacuo* to give a residue, which was then purified by tlc. Development with benzene - ethyl acetate (9 : 1) gave 75 mg of the 17ξ-tetrahydropyranyl compound (**5b**, Y=THF, $\Delta^{1,4}$) as an oil. A solution of 60 mg of biphenyl and 0.1 ml of diphenylmethane in 2 ml of freshly-distilled tetrahydrofuran was refluxed under an argon stream with 30 mg of lithium metal with stirring. After this mixture had cooled, into the resulting dark-green solution the above **5b** in 1.5 ml of tetrahydrofuran was slowly stirred under an argon stream, after which the reaction mixture was refluxed for 15 min. The excess of lithium was then decomposed by the addition of methanol and acidified with diluted hydrochloric acid. After the hydrocarbon had been removed by steam distillation, the product was extracted with methylene dichloride. The organic layer was washed with water, dried over anhydrous sodium sulfate, and then evaporated to dryness. The residue was purified ay tlc (elution, benzene - ethyl acetate, 1 : 1) to give a phenolic substance (28.5 mg), which could not be crystallized. This was immediately oxidized with Jones's reagent (0.4 ml) in 4 ml of acetone; subsequent crystallizations from ethanol gave 20.4 mg of **6a** with a mp of 207—213°C. An analytical sample was recrystallized 2 times from ethanol; mp 215—219°C, $[\alpha]_D^{23}$ +11.5° (*c* 0.8). IR (Chf) cm^{-1}: 3600, 3000, 1730, 1605, 1500, 860, 820. (The IR coincided well with the IR of Rufer's sample); NMR τ: 8.85 (18-C$\underline{H}_3$), 3.44 (1H), 3.29 (3H), 2.97 (4H) ($\Delta\tau$ 1,4 ppm, 0.47).[13]

Found: C, 80.0; H, 8.20%. Calcd for $C_{18}H_{22}O_2$: C, 79.9; H, 82.0%.

*3-Methyl Ether (****6b****).* This was prepared by the dimethyl sulfate - 2 N potassium hydroxide treatment of **6a** and was crystallized from methanol; it exhibited a mp of 146—147°C; $[\alpha]_D^{23}$ +14.5° (*c* 0.8, dioxane).

Found: C, 80.1; H, 8.5%. Calcd for $C_{19}H_{21}O_2$: C, 80.2; H, 8.5%. IR (Chf) cm^{-1}: 2995, 2920, 2850, 1730, 1610, 1510, 845. Mass spectrum: 284 ($M^{\cdot}$), 256, 225, 199, 186, 173, 160, 140, 134. The samples of **6a** and **6b** were proven to be identical with authentic samples of *dl*-8α,14β-estrone and its 3-methyl ether (IR spectra, mass spectra, and thin-layer chromatographic behavior).

The authors are very grateful to Dr. C. Rufer (Schering AG) for kindly providing us with the authentic sample of *dl*-8α,14β-estrone.

13) The assignment of the B/C *cis* fusion in **6a** is supported by the small $\Delta\tau$ 1,4-value of 0.47 ppm in NMR (see W. Nagata, T. Terasawa, and K. Tori, *J. Amer. Chem. Soc.*, **86**, 3746 (1964).)

Studies on Geometrical Isomerism by Nulear Magnetic Resonance. V.[1] Stereochemistry of 5-Substituted 4-Alkoxycarbonyl-2-carbamoylimino-1,3-oxathiolanes[2]

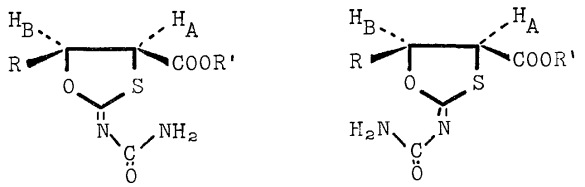
Toshio HAYASHI, Makiko AKANO,* Tetsuro YOKONO,** Jun UZAWA, Satoshi KAMBE,*** and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Wako, Saitama

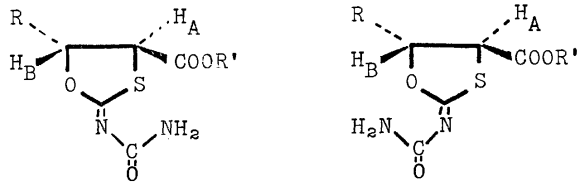
(Received August 9, 1971)

An equimolar reaction of thiocyanoacetic esters with aldehydes in the presence of potassium fluoride or carbonate leads to a stereoisomeric mixture of *cis* and *trans* isomers of 5-substituted 4-alkoxycarbonyl-2-carbamoylimino-1,3-oxathiolanes. Several of them were separated into two isomeric forms, whose geometrical configurations were determined by means of nuclear magnetic resonance technique. The vicinal coupling constant between the 4- and 5-protons is consistently larger for the *cis* forms than for the *trans*. In the case of the 5-aryl derivatives, the signals of the alkoxycarbonyl group appear at higher field for the *cis* isomers than for the *trans*. The composition ratios of *cis* and *trans* isomers of the oxathiolanes prepared are determined. Infrared data of the *cis* and *trans* oxathiolanes are also reported.

In a previous paper[3] we reported that the reaction of thiocyanoacetic esters (**1**) with aldehydes in the presence of potassium fluoride or carbonate, led to a mixture of 5-substituted 4-alkoxycarbonyl-2-carbamoylimino-1,3-oxathiolanes (**2**) and α,β-unsaturated esters. These oxathiolanes can exist in four isomeric forms, relative to arrangements of the alkoxycarbonyl group and 5-substituent about a single bond in the ring as well as to arrangement of the carbamoyl group about the C–N bond. In the course of study, it has been found that the oxathiolanes prepared in the present work consisted of *cis* and *trans* isomers, some of them being separated into two isomeric forms.[4] The present paper deals with configurational determinations of *cis* and *trans* isomers of the 1,3-oxathiolane derivatives by means of the nuclear magnetic resonance technique.



cis forms



trans forms

Results and Discussion

An equimolar reaction of methyl thiocyanoacetate (**1a**) with benzaldehyde in the presence of potassium carbonate, on standing overnight after removal of the catalyst, gave rise to predominant precipitation of the higher-melting isomer, mp 190—191°C (**6α**).[5] The reaction mixture, on further standing, gradually deposited the lower-melting isomer, mp 138—139°C (**6β**). The *cis* and *trans* isomers of the corresponding ethyl esters (**7α** and **7β**) were isolated similarly. The isomers showed essentially the same mass spectra. With the corresponding *t*-butyl ester only one form, mp 155—156°C (**8β**) was isolated pure.[6] The reaction of **1** with *p*-anisaldehyde, and *p*-chloro- and *p*-bromo-benzaldehydes gave exclusively one isomer. The physical properties of the oxathiolanes are summarized in Table 1. The NMR data for the *cis* and

1) Part IV: T. Hayashi, I. Hori, H. Baba, and H. Midorikawa, This Bulletin, **40**, 2160 (1967).

2) Presented in part at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

3) S. Kambe, T. Hayashi, H. Yasuda, and H. Midorikawa, This Bulletin, **44**, 1357 (1971).

4) Geometrical isomers of several imines were first isolated by Curtin and Hausser.[4a] This was the first unequivocal demonstration of the existence of stereoisomeric compounds in which a carbon atom was bonded to the imino nitrogen. Later, Marullo and Wagner[4b] showed that the isomerization rates of iminocarbonates were so fast that the stereoisomers could not be isolated. However, it was also shown that the isomerization rates are very sensitive to the group on the imino nitrogen. At present we prefer the explanation that the observed separation of the NH_2 signals in the 2-carbamoylimino-1,3-oxathiolanes (Figs. 2 and 3) is due to the existence of *syn* and *anti* isomers, and that the isomerization rates are too fast for isolation. This problem is now under investigation. a) D. Y. Curtin and J. W. Hausser, *J. Amer. Chem. Soc.*, **83**, 3474 (1961); b) N. P. Marullo and E. H. Wagner, *ibid.*, **88**, 5034 (1966).

5) The higher-melting isomers are denoted as α, and the lower-melting isomer, β. In the case where only one isomer was obtained, the isomer having the alkoxycarbonyl signals at higher field than those of the ordinary esters is denoted by C, while the isomer having the alkoxycarbonyl at almost the same field as the ordinary esters is denoted by T. Form C has *cis* configuration, and form T, *trans*.

6) The yield of the α-form was too low for purification. However, the stereoisomeric mixture which contained the α-form predominantly had a melting point higher than the β-form.

Table 1. Physical properties of *N*-carbamoyl-2-imino-4-alkoxycarbonyl-5-substituted 1,3-oxathiolanes

	Compound		Form	Mp (°C)	Formula	Calcd				Found

a) A differential shift between *trans* and *cis* isomers. b) *Cis* isomer. c) *Trans* isomer.

trans isomers of the oxathiolanes are summarized in Table 2. Assignments of two doublets responsible for the 4- and 5-protons were made by double irradiation technique. Of the doublets of the AB spin system the lines of the doublet at lower field are somewhat broader than those at higher field (Figs. 2 and 3). Irradiation of the benzene protons causes narrowing of the proton α (designated as H_B) to the irradiated group. Such coupling between aromatic and benzylic protons have been observed before in other classes of compounds.[7] The NH_2 signals of the carbamoyl group always appear at two positions, near 7.00 ppm and near 7.30 ppm, which might be due to the presence of *syn* and *anti* isomers.[4]

It can be seen from the Table that there is no clear relation between the electronegativities of the substituent on the benzene ring and the chemical shifts and vicinal coupling constants of the oxathiolane ring

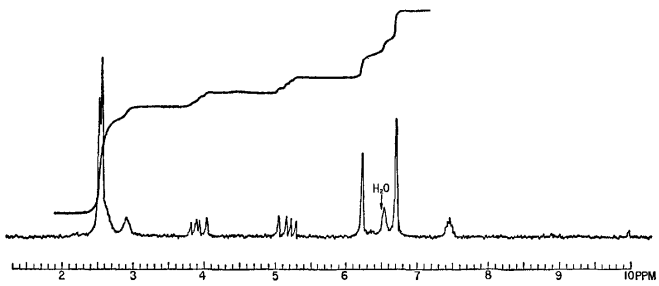

Fig. 1. NMR spectrum of a stereoisomeric mixture of *cis*- and *trans* isomers of *N*-carbamoyl-2-imino-4-methoxycarbonyl-5-phenyl-1,3-oxathiolane (**6**) (60 MHz).

protons. The observed coupling constants (J_{AB}) are in the range 6.0—6.4 Hz for the α-forms and 3.6—4.5 Hz for the β-forms, except for the *t*-butyl ester. It is a common assumption that in five-membered rings which cannot deviate appreciably from planarity, J_{cis} is always larger than J_{trans}[8] as expected from the Karplus rule.[9] However, several reports showed that in the absence of other information such conclusion were doubtful.[10] The Dreiding model indicates that the 1,3-oxathiolane ring should exist predominantly as a very slightly distorted envelope conformation with the oxygen as the "flap" atom. Recently X-ray diffraction studies[11] showed that in the crystal structure of cholest-4-one-3-spiro(2,5-oxathiolane) the oxathiolane ring exists in a slightly distorted envelope conformation with the methylene carbon adjacent to oxygen lying 0.5 Å out of the plane defined by the other four atoms and with a torsional angle of 34.3° between the two carbon atoms. Pasto and coworkers[12] and Bovey and coworkers[13] indicated from analysis of coupling constants for a series of 2-substituted 1,3-oxathiolanes that there is one highly preferred envelope conformation, but the latter concluded that rapid pseudorotation takes place. However, it was shown from an X-ray diffraction study of the structure of ethylene carbonate which is the oxygen analog of 2-imino-1,3-oxathiolane that the molecule has the half-chair C_2 conformation,[14] though 1,3-dioxolane which is the oxygen analog of 1,3-oxathiolane, possesses a slightly distorted envelope conformation.[15] Accordingly, it seems to be difficult to infer from available data the conformation of 2-carbamoylimino-1,3-oxathiolanes. Hence, in the present case the relative values of the coupling constants cannot be considered a reliable indication of the configuration of substituents.

It is interesting to note that with the 5-aryl derivatives the signals of the alkoxycarbonyl groups for the α-forms always appear at a higher field by *ca.* 0.5 ppm than those for the β-forms, while the signals for the β-forms are in almost the same positions as those for the derivatives not having the aryl group (near 3.72 ppm for the methyl and near 1.22 and 4.15 ppm for the ethyl signals). This means that the alkoxycarbonyl protons of the α-forms may experience the long-range shielding of the benzene ring. It should be noted that the H_A proton of the β-form resonates at higher field than that of the α-form, whereas the H_B proton of the former is located at lower field than

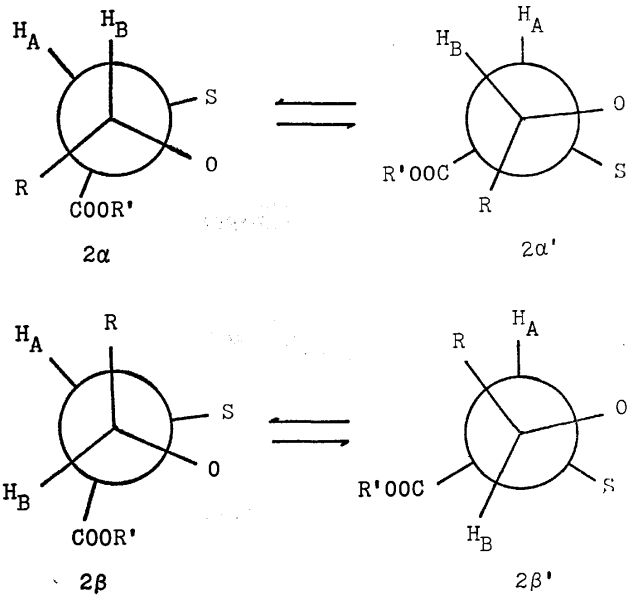
Table 3. Observed NOE and internuclear distance for H–H interaction

No.	Steucture	Proton irradiated	Proton observed	NOE (%)	Internuclear distance (Å)
6α		H_B	H_A	28	2.3—2.5
		H_A	H_B	19	
6β		H_B	H_A	7	2.7—3.1
		H_A	H_B	8	
8β		H_B	H_A	14	2.7—3.1
		H_A	H_B	11	

that of the latter. These differential shifts of the ring protons can be attributed to the long-range shielding of the benzene and alkoxycarbonyl groups.[16] The above facts suggest that the higher-melting α-forms possess the *cis* configuration, the lower-melting β-forms the *trans* arrangement.[17,18]

Conclusive evidence supporting these stereochemical assignments can be provided through studies of the nuclear Overhauser effect (NOE). The NOE results obtained when irradiating and observing protons are shown in Table 3, along with the internuclear distance as measured from Dreiding models on the assumptions of the slightly distorted envelope conformation in which rapid pseudorotation occurs. Recetly, Bell and Saunders[19] have shown that there is a linear relationship between the intramolecular nuclear Overhauser effect and the sixth power of the internuclear distance. Table 3 shows that the internuclear distance between the 4- and 5-protons is much shorter for the *cis* form than for the *trans*. Thus, a larger NOE would be expected for the α-form than for the β-form. The results are in good agreement with expectations.

On the assumptions of pseudorotation, one would expect that the molecule would assume the two limiting conformations **2α** and **2α'** for the *cis* isomer and **2β** and **2β'** for the *trans* one, whether in an envelope conformation or in a half-chair C_2 one. In the *cis*



forms, the difference in energy between the two conformations should not be large, because there is no 1 ; 3 diaxial interaction. However, in the *trans* forms, electrostatic repulsion between the two substituents may be larger in **2β'** than in **2β**. Since there is no 1 ; 3 diaxial interaction, conformation **2β** may be preferred to conformation **2β'**. This argument could explain the fact that J_{AB} is larger for the *cis* than for the *trans* isomer. However, since the introduction of the bulkier substituent into the 4- or 5-position should lead to an increase in population of **2β**, the *trans* isomer of *t*-butyl ester (**8β**) might be more heavily populated in **2β** than those of methyl and ethyl esters. This speculation leads to a contradiction to the fact that **8β** has an unusually larger J_{AB}, as compared with **6β** and **7β**. A plausible explanation for this is that the C=NCONH$_2$ group on the 2-position exerts some

16) Similar arguments have been made before in the case of cinnamic ester derivatives,[16a] 4,5-diphenyl-1,3-dioxolan-2-one,[16b] and 4,5-diphenyl-1,3-dithiolane-2-thione.[16b]; a) T. Hayashi, *J. Org. Chem.*, **31**, 3253 (1966); b) C. G. Overberger and A. Drucker, *ibid.*, **29**, 360 (1964).

17) Form C has *cis* configuration, form T, *trans*.

18) In the case of 1,3-dioxolanes[16b),18] and 1,3-dithiolane-2-thiones, the *cis* isomers always have melting points higher than the *trans*; F. A. L. Anet, *J. Amer. Chem. Soc.*, **84**, 747 (1962).

a) IR spectra were measured in KBr pellets (cm^{-1}). b) A stereoisomeric mixture of *cis* and *trans* isomers.

steric interaction on the 4- or 5-position, which shifts an equilibrium to the **2β′** side to that extent.

Although a stereoisomeric mixture of 5-alkyl substituted derivatives could not be separated, configurational assignments for the measurements of *cis* : *trans* ratios were made on the basis of the relative values of the coupling constants.[20]

The IR spectra are also useful for diagnostic purposes. The ester C=O stretching band for the *cis* isomers always appears at a higher frequency region than that of the *trans* one. The ester C=O band of **6α** exceptionally splits into a doublet (Fig. 4). It was also observed that the NH_2 stretching bands of the carbamoyl group are rather sharp doublet in the *trans* isomers, whereas the *cis* isomers showed broad absorption in the region between 3500 and 3000 cm^{-1} (Figs. 4 and 5).

The isomeric compositions of fourteen oxathiolanes, as evaluated from the integration of the area under the appropriate NMR signals, are given in Table 5. The reaction of **1** with benzaldehyde in the presence of potassium fluoride led to the predominant formation of the *cis* isomer. When potassium carbonate was used as a catalyst, the yield of the *trans* isomer inincreased. The reaction with *p*-anisaldehyde produced exclusively the *cis* isomer, whereas *o*-anisaldehyde afforded predominantly the *trans* isomer. On the contrary, the reaction with *p*-chloro- and *p*-bromobenzaldehydes provided exclusively the *trans* isomer, whereas

a) Potassium carbonate b) Potassium fluoride
c) Figures represent the average of at least three experiments.

20) Since a stereoisomeric mixture of 5-alkyl derivatives could not be separated, the NOE of the 5-methyl derivatives (**16**) was measured in a solution containing the *cis* and *trans* isomers (*ca.* 1 : 1). In this case the 5-methyl protons of the *cis* and *trans* isomers appeared at the same position. When the methyl protons were irradiated, the % area increase in the H_A proton signal was 7% for the *trans* isomer, and 0% for the *cis* isomer.

o-chlorobenzaldehyde resulted predominantly in the *cis* isomer. Furthermore, the reaction of acetaldehyde led to an almost equimolar mixture of the *cis* and *trans* isomers, while propionaldehyde and *n*-butyraldehyde predominantly produced the *trans* isomers. From the results it is difficult to observe any relationship between the electronegativities and steric requirement of the 5-substituent and the stereoisomeric compositions of the products. It was found that the *cis*(α) isomers are always produced more rapidly than the *trans*(β) forms. It was thought at first that the *cis* isomers are the kinetically-favored products and are thermodynamically unstable relative to the more slowly formed *trans* isomers. However, it was shown that under the conditions employed in the reactions the *cis* isomers did not isomerize into the *trans* ones. Under the more drastic conditions the *cis* isomer was converted into a higher-melting product, whose structure still remains undetermined.

Experimental

All melting points were uncorrected. NMR spectra were obtained with Varian HA-100D and JEOL C-60 spectrometers in deuterodimethyl sulfoxide solution using tetramethylsilane as an internal standard. The nuclear Overhauser effects (NOE) were measured as % area increase using the electric integrator of the instrument. The spectra were run as filtered (fine sintered glass) and carefully degassed CD_3SOCD_3 solutions, the concentration varying between 5 and 10%. A small amount of TMS was added as an internal lock.

IR spectra were determined in the KBr pellet using a Perkin-Elmer 521 spectrophotometer. Mass spectra were taken with a JMS-01S instrument operating at 75 eV.

*Reactions of Thiocyanoacetic Esters (**1**) with Aldehydes. General Procedure*: A solution containing thiocyanoacetic ester (**1**) (0.03 mol) and an aldehyde (0.03 mol) in 20 m*l* of moist ether was stirred mechanically in the presence of potassium carbonate or fluoride (5.0 g) at room temperature. The reaction required 3—4 hr, when the benzaldehydes having an electron-attractive substituent were used, and 7—8 hr, when the benzaldehydes having an electron-donating substituent were used. After the catalyst was removed by filtration and washed with 20 m*l* of ether, the filtrate and washings were combined and allowed to stand overnight in an open vessel. The precipitated crystals were collected on a filter and washed with ether, until the crystals became colorless. A small fraction of the crystals was subjected to NMR analysis for the measurement of isomeric ratios. The rest of the crystals were recrystallized from an appropriate alcohol, until the lower-melting isomer was removed (α-form).

The filtrate, from which the crude α-isomer was removed, was allowed to stand for several more days, until the formation of crystals ceased. The precipitate was washed repeatedly with ether and then a small fraction was subjected to NMR analysis. The rest of the precipitate was recrystallized from appropriate alcohol, until a pure lower-melting isomer was obtained.

cis *and* trans *5-Phenyl-4-methoxycarbonyl-2-carbamoylimino-1,3-oxathiolanes (**6α** and **6β**).* A mixture of methyl thiocyanoacetate (3.5 g) and benzaldehyde (3.5 g) in 20 m*l* of moist ether was stirred in the presence of potassium carbonate (5.0 g) for 6 hr. After the catalyst was removed by filtration, the filtrate was allowed to stand overnight at room

temperature. The resulting precipitate was collected on a filter and washed with ether, until the reddish yellow color was removed. After the crystals were weighed, a small fraction was subjected to NMR analysis. The rest of the precipitate was recrystallized from methanol. The crude product contained 80% *cis*-**6**.

The filtrate was allowed to stand for another three days and then the resulting precipitate was washed with ether repeatedly. After the precipitate was weighed, a small fraction was subjected to NMR analysis. The rest of it was recrystallized from ethanol. The crude product contained 40% *trans*-**6**. The *cis* isomer (yield 2.4 g) has mp 190—191°C, molecular ion peak at *m/e* 280. The *trans* isomer has mp 138—139°C, molecular ion peak at *m/e* 280.

cis *and* trans *5-Phenyl-4-ethoxycarbonyl-2-carbamoylimino-1,3-oxathiolanes (***7α** *and* **7β***).* A solution of ethyl thiocyanoacetate (3.5 g) and benzaldehyde (3.5 g) in 20 m*l* of ether was stirred in the presence of potassium carbonate (5.0 g) for 6 hr. The first precipitate was recrystallized from ethanol, giving 2.5 g of **7α**, mp 190—191°C, molecular ion peak at *m/e* 294. The second precipitate was recrystallized from methanol, giving 0.2 g of **7β**, mp 159—160°C, molecular ion peak at *m/e* 294.

Attempted Epimerization of **7α** *with Potassium Carbonate in Ethanol.* To 2.0 m*l* of ethanol were added 0.5 g of **7α** and 0.2 g of potassium carbonate and the mixture was refluxed for an hour and then allowed to stand for two days at room temperature. The solvent was removed in a vacuum. The resulting crystals proved to be the starting material by IR and NMR analyses.

Attempted Epimerization of **6α** *with Sodium Methoxide in Methanol.* In 30 m*l* of methanol was dissolved 0.05 g of sodium and then 0.2 g of **6α**. After the solution was allowed to stand at 50°C for 6 hr, the solvent was removed in a vacuum. The resulting solid product was recrystallized from ethanol. The crystals remained unmelted at 250°C.

The authors wish to express their thanks to Dr. Taro Hayashi of this Institute and Professor Tatsuo Takeshima of Chiba University for their interest and encouragement. Thanks are also due to Mr. Ko-ichi Iyama for his assistance in carrying out the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 584—587 (1972)

Reactions of 5*N*-(1,2,3-Triazol-1-yl)tropolones[1)]

Hiroshi HORINO* and Takashi TODA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 16, 1971)

The chemical properties of 5*N*-(1,2,3-triazol-1-yl)tropolones are investigated. The reactions of 5*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)tropolone methyl ether (I) with malononitrile and ethyl cyanoacetate gave the corresponding azulene derivatives, but with ethyl acetoacetate the reaction afforded a 1-oxaazulan-2-one derivative. The methoxyl group of I is replaced by aliphatic amines to form 2-aminotropone derivatives. Also, the reaction of I with guanidine and *o*-phenylenediamine gave a 1,3-diazaazulene derivative and a quinoxaline derivative respectively. The brominations of triazolyltropolones afforded the corresponding 3,7-dibromotropolone derivatives, while reactions with thionyl chloride gave 2-chlorotropone derivatives.

Only a few troponoid compounds which possess heterocyclic aromatics on their nuclei have been found, and even their chemical properties have not yet been investigated in detail.[2,3)] Triazole compounds have been known to be interesting, biologically-active substances;[4)] therefore, to synthesize troponoid compounds which possess a triazole ring as a substituent and to investigate their chemical and physiological properties are interesting and important problems. We investigated the reactions of 5-azidotropolones' methyl ethers with several active methylene compounds and obtained 5*N*-(1,2,3-tiazol-1-yl)tropolone methyl ethers.[5)] In this paper, several chemical properties of the triazolyltropolones thus obtained will be presented.

The treatment of 2-methoxy-5*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)tropone (I)[5)] with active methylene compounds, such as ethyl cyanoacetate and malononitrile, afforded the corresponding azulene compounds, diethyl 2-amino-6*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)azulen-1,3-dicarboxylate (II) and 2-amino-1,3-dicyano-6*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)azulene (III) respectively, in fairly good yields. However, the reaction of I with ethyl acetoacetate gave a crystalline substance (IV).

The results of elemental analysis, $C_{17}H_{15}O_5N_3$, and the UV and visible spectra of IV indicated that it is an oxaazulan-2-one type compund.[3)] Ethyl acetoacetate is a weak active methylene compound compared with malononitrile or ethyl cyanoacetate. That is why the second mole of the reagent does not

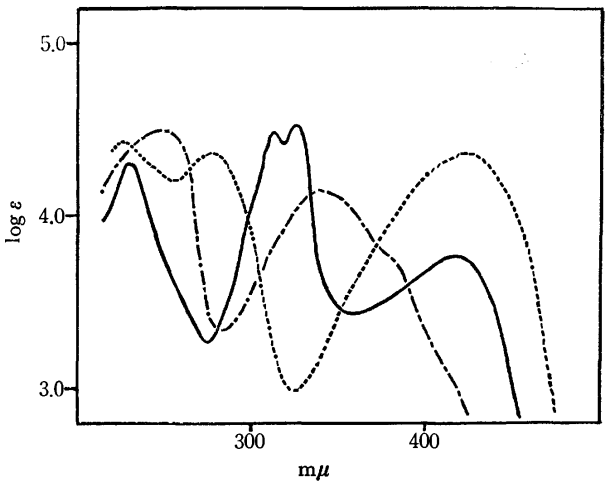

Fig. 1. Ultraviolet absorption spectra of III(——), IV(----) and XVII (------) in methanol.

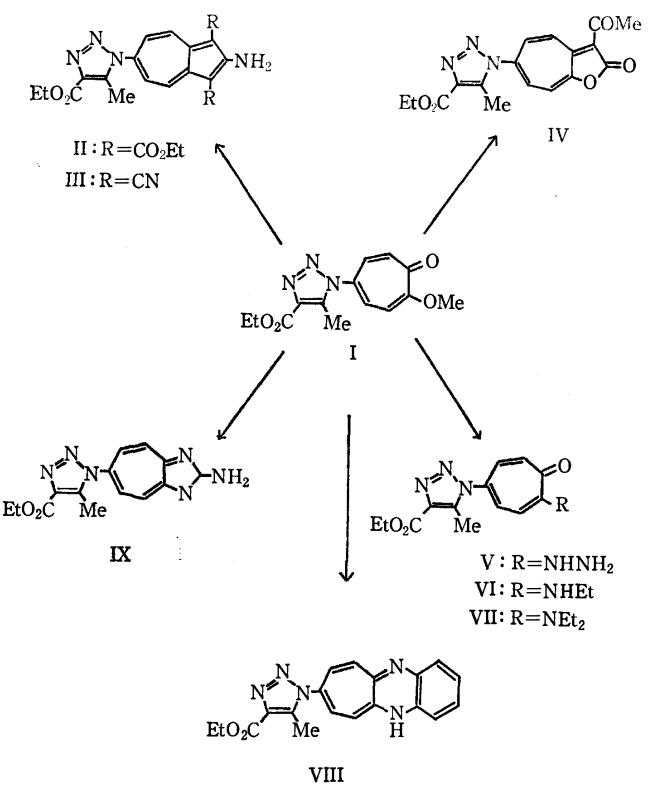
attack the formed oxaazulanone.

The reactions of I with nucleophilic reagents such as amine were also investigated. When reactions of I were carried out in alcohol with hydrazine, ethylamine, and diethylamine, 2-hydrazino-(V), 2-ethylamino-(VI), and 2-diethylamino-5*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)tropone (VII) were obtained respectively. The treatment of 5-azidotropolone methyl ether with aliphatic amines gave the corresponding 2-aminotropone derivatives, but with aromatic amines only the starting substance was recovered under the same reaction conditions.[5] However, I gave a quinoxaline derivative (VIII) in a reaction with *o*-phenylene diamine. This fact suggests that the azido group is a strongly negative one, but that it acts as an electron-donating group by means of its resonance contribution[6] and reduces the reactivity of tropolone nuclei toward nucleophiles.

On the other hand, the triazole ring acts only as an electron-withdrawing group. I afforded 2-amino-6*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl)-1,3-diazaazulene (IX) in a reaction with guanidine.

The properties are analogous to those of other tropolone methyl ethers.[7] The reactions mentioned above are summarized in the following chart:



Free triazolytropolones were prepared by the hydrolysis of the corresponding methyl ethers;[5] the tropolones thus obtained are listed in Table 1.

The decarboxylation of XIII and XV in quinoline gave 5′-methyl (XVII) and 5′-phenyl (XVIII) derivatives of 5*N*-(1,2,3-triazol-1-yl)-tropolone. The UV and visible spectra of the triazolyltropolones are analogous to those of other 5-substituted tropolones;[8] being especially similar to that of 5-phenyltropolone.[9]

However, those of XVI and XVIII are shifted to shorter wavelengths compared with those of XVII or 5-phenyltropolone. This phenomenon indicates that the phenyl group at the 5′-position of XVI and XVIII interacts with tropolone nuclei and that the triazole ring can not take a planar position with the tropolone ring. XIV and XVI possess a fairly big shoulder near 400 mμ (log ε, *ca.* 3.5). Signals appear at 2.44 ppm (3H, broad, singlet), 7.44 ppm (4H, tropolone b. s), and 7.60 ppm (1H, triazole b. s) in the NMR spectrum of XVII. Also, those of XVIII appear at 7.32 ppm (1H triazol). These values are in good agreement with the values of the chemical shifts of other known

tropolones.[10]

The bromination of 5-methyl-1,2,3-triazol or 1*N*-methyl-1,2,3-triazole takes place at the 4-position.[11] Thus, it is interesting to determine at which moiety (tropolone or triazole) of XVII or XVIII cationoid substitution reactions take place. The treatment of XVII with two moles of bromine gave a dibromide (XIX). The absorption at 861 cm^{-1} of XVII disappeared, and a new band appeared at 887 cm^{-1} in the IR spectrum of XIX. The former corresponds to two adjacent hydrogens, while the latter is an isolated hydrogen of tropolones.[12] The UV spectrum of XIX is analogous with those of 3,7-dibromo- and 3,5,7-tribromotropolones.[13] The NMR spectrum of XIX shows a methyl peak at 2.39 ppm (3H), a triazol hydrogen at 7.63 ppm (1H), and at 8.15 ppm (2H), tropolone hydrogens which shift down field compared with those of XVII under the influence of the substituted bromines. Therefore, the structure of XIX is 3,7-dibromo-5*N*-(5'-methyl-1,2,3-triazol-1-yl) tropolone. Also, the bromination of XIV and XVIII took place at the 3,7-positions of the tropolone moieties, (XX) and (XXI), as shown in Table 1.

These tendencies of the cationoid reactions of 5-triazolyltropolones are analogous to those of 4- and 5-phenyltropolones.[9] The reactions of XVII and XVIII with thionyl chloride afforded the corresponding 2-chlorotropone derivatives; their structures are proved by the results of their elemental analyses and their spectral data.

Experimental[14]

*Diethyl 2-Amino-6*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)azulen-1,3-dicarboxylate (II).* Into a mixture of ethyl cyanoacetate (130 mg) and sodium (12 mg) in absolute ethanol (1.5 m*l*), 2-methoxy-5*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)tropone (I) (150 mg) was stirred and then the mixture was allowed to stand overnight at room temperature. The solution yielded 260 mg of orange precipitates, which were then extracted with benzene to give 195 mg of II; mp 164—165°C, recrystallized from a benzene-cyclohexane mixture.

Found: C, 59.99; H, 5.41; N, 12.81%. Calcd for $C_{22}H_{24}O_6N_4$: C, 59.99; H, 5.49; N, 12.72%. λ_{max}^{MeOH}, mμ (log ε): 244 (4.60), 320 (4.77 sh), 332 (5.12), 410 (4.05).

*2-Amino-1,3-dicyano-6*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)azulene (III).* A suspension of (I) (150 mg) in a solution of malononitrile (76 mg) and triethylamine (115 mg) in absolute ethanol (2.5 m*l*) was stirred overnight. The precipitates thus formed were then separated to afford 222 mg of orange needles of III; mp 285°C, recrystallized from dimethylformamide.

Found: C, 62.45; H, 4.29; N, 24.28%. Calcd for $C_{18}H_{14}O_2N_6$: C, 62.42; H, 4.07; N, 24.27%. λ_{max}^{MeOH}, mμ (log ε): 231 (4.53), 314 (3.64), 327 (4.95), 410 (3.95).

*3-Acetyl-6*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)-oxazulan-2-one (IV).* Into a mixture of ethyl acetoacetate (100 mg) and sodium (12 mg) in absolute ethanol (155 m*l*), I (150 mg) was stirred and then the solution was allowed to stand overnight. Then the solvent was removed under reduced pressure, water was added, and the solution was extracted with ethyl acetate to give 47 mg of orange crystals of IV; mp 210°C, recrystallized from ethanol.

Found: C, 59.72; H, 4.72; N, 11.60%. Calcd for $C_{17}H_{15}O_5N_3$: C, 59.82; H, 4.43; N, 12.31%. λ_{max}^{MeOH}, mμ (log ε): 225 (4.41), 278 (4.34), 428 (4.32).

*2-Hydrazino-5*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)-tropone (V).* A solution of I (100 mg) and an 80% hydrazine hydrate solution (150 mg) in methanol (2 m*l*) was refluxed on a water bath for 5 min. The yellow precipitates thus formed were collected to give 73 mg of a sand-like crystal, V: mp 202°C, recrystallized from ethanol.

Found: C, 54.02; H, 5.22; N, 24.02%. Calcd for $C_{13}H_{15}O_3N_5$: C, 53.97; H, 5.23; N, 24.21%. λ_{max}^{MeOH}, mμ (log ε): 256 (4.40), 355 (4.27), 414 (4.03).

*2-Ethylamino-5*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)-tropone (VI).* A solution of I (200 mg) and an 70% aqueous solution of ethylamine in ethanol (2 m*l*) was stirred and then allowed to stand for 2 hr. The solution produced yellow crystals, which were collected to give 150 mg of VI; mp 142—143°C, recrystallized from ethanol.

Found: C, 59.57; H, 6.03; N, 18.35%. Calcd for $C_{15}H_{18}O_3N_4$: C, 59.59; H, 6.00; N, 18.53%. λ_{max}^{MeOH}, mμ (log ε): 252 (4.57), 350 (4.35), 415 (4.12).

*2-Diethylamino-5*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)tropone (VII).* A solution of I (100 mg) and diethylamine (1 g) in 2 m*l* of ethanol was allowed to stand overnight. The solution was then concentrated under reduced pressure without heating and extracted with benzene to afford 84 mg of a paste, which, with a saturated solution of picric acid in alcohol, gave 100 mg of a yellow picrate of VII; mp 163—164°C (dec.), recrystallized from ethanol.

Found: C, 49.49; H, 4.68; N, 17.38%. Calcd for $C_{23}H_{25}O_{10}N_7$: C, 49.73; H, 4.52; N, 17.53%.

*8*N*-(4'-Ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)benz(b)tropazine (VIII).* A solution of I (100 mg) and *o*-phenylenediamine (45 mg) in absolute ethanol (2 m*l*) was refluxed on a water bath for 2 hr. The solution was then concentrated to give 64 mg of crystals of VIII; mp 181°C (dec.), from ethanol.

Found: N, 19.77%. Calcd for $C_{19}H_{17}O_2N_5$: N, 20.16%. λ_{max}^{MeOH}, mμ (log ε): 240 (4.54), 340 (4.13).

*2-Amino-6*N*-(4'-ethoxycarbonyl-5'-methyl-1,2,3-triazol-1-yl)-1,3-diazaazulene (IX).* To a solution of guanidine hydrochloride (60 mg) and sodium (12 mg) in absolute ethanol (2 m*l*), I (150 mg) was added, after which the mixture was refluxed on a water bath for 15 min. The precipitate thus formed was collected and washed with chloroform to afford 135 mg of IX; mp 280°C.

Found: C, 56.33; H, 4.77; N, 28.25%. Calcd for $C_{14}H_{14}O_2N_6$: C, 56.37; H, 4.73; N, 28.18%.

*5*N*-(4'-Carboxy-5'-methyl-1,2,3-triazol-1-yl)tropolone (XIII).* A solution of I (150 mg) in an aqueous 2N sodium hydroxide solution (3 m*l*) was heated on a water bath for 10 min. The solution was then acidified with 2N hydrochloric acid to afford colorless crystals of XIII (127 mg); mp 212—213°C (dec.), recrystallized from ethanol.

Found: C, 53.15; H, 3.86; N, 16.78%. Calcd for $C_{11}H_9O_4N_3$: C, 53.14; H, 3.67; N, 17.00%.

The following substituted triazolyl tropolones were prepared as above.

*5*N*-(4'-Carboxy-5'-phenyl-1,2,3-triazol-1-yl)tropolone (XV).* Mp 177°C (dec.), recrystallized from an ethanol-benzene

mixture.

Found: C, 59.26; H, 4.13; N, 12.74%. Calcd for $C_{16}H_{11}O_4N_3 \cdot H_2O$: C, 58.71; H, 4.00; N, 12.88%.

5N-(4'-Benzoyl-5'-phenyl)-1,2,3-triazol-1-yl)tropolone (XVI). Mp 193°C, recrystallized from ethanol.

Found: C, 71.80; H, 4.38; N, 11.47%. Calcd for $C_{22}H_{15}O_3N_3$: C, 71.53; H, 4.09; N, 11.38%.

5N-(5'-Methyl-1,2,3-triazol-1-yl)tropolone (XVII). A solution of XIII (407 mg) in quinoline (2 m*l*) was heated on an oil bath until all the bubbles had evaporated. After it had cooled, the solution was diluted with benzene and extracted with a 2N sodium hydroxide solution, which was then acidified and extracted with chloroform. When the solvent had been removed, XVII was obtained as colorless needles (316 mg); mp 153°C, recrystallized from ethanol.

Found: C, 59.29; H, 4.53; N, 20.57%. Calcd for $C_{10}H_9O_2N_3$: C, 59.14; H, 4.46; N, 20.68%. λ_{max}^{MeOH}, mμ (log ε): 245 (4.10), 334 (4.17), 379 (sh). ν(KBr): 3205, 1672, 863, 849 cm^{-1}.

5N-(5'-Phenyl-1,2,3-triazol-1-yl)tropolone (XVIII). A solution of XV (132 mg) in quinoline (2 m*l*) was treated as above to give XVIII as colorless plates; mp 195°C, from ethanol.

Found: C, 67.80; H, 4.45; N, 15.70%. Calcd for $C_{15}H_{11}O_2N_3$: C, 67.91; H, 4.18; N, 15.84%. λ_{max}^{MeOH}, mμ (log ε): 228 (4.47), 233 (4.49), 334 (4.07), 398 (3.70), 415 (3.31). ν(KBr): 3135, 858, 849, 738 cm^{-1}.

3,7-Dibromo-5N-(5'-methyl-1,2,3-triazol-1-yl)tropolone (XIX). Into a solution of XVII (100 mg) and sodium acetate (82 mg) in acetic acid (1 m*l*), bromine (170 mg) in acetic acid (0.3 m*l*) was stirred at room temperature. The solution was concentrated under reduced pressure, water was added, and then the solution was extracted with chloroform. When all the solvent had been removed, 159 mg of XIX were obtained; they were subsequently recrystallized from ethanol; mp 189°C (dec.).

Found: C, 33.95; H, 2.23; N, 10.90%. Calcd for $C_{10}H_7O_2N_3Br_2$: C, 33.26; H, 1.95; N, 11.64%. λ_{max}^{MeOH}, mμ (log ε): 274 (4.63), 354 (4.17), 436 (4.03). ν(KBr): 2860, 906, 887, 819 cm^{-1}.

The following 3,7-dibromo-5*N*-triazolyltropolones were prepared in the same way as above.

3,7-Dibromo-5N-(4'-acetyl-5'-methyl-1,2,3-triazol-1-yl)tropolone (XX). Mp 170—171°C, recrystallized from ethanol.

Found: N, 10.51%. Calcd for $C_{12}H_9O_3N_3Br_2$: N, 10.42%.

3,7-Dibromo-5N-(5'-phenyl-1,2,3-triazol-1-yl)tropolone (XXI). Mp 230°C (dec.), recrystallized from benzene-ethanol.

Found: N, 9.87%. Calcd for $C_{15}H_9O_3N_3Br_2$: N, 9.93%.

2-Chloro-5N-(5'-methyl-1,2,3-triazol-1-yl)tropone (XXII). A solution of XVII (375 mg) and thionyl chloride (500 mg) in dry benzene (5 m*l*) was refluxed on a water bath until it showed negative ferric chloride test. The subsequent concentration of this solution gave 333 mg of colorless crystals of XXII; mp 169—170°C, recrystallized from benzene.

Found: C, 54.56; H, 3.67; N, 18.20%. Calcd for $C_{10}H_6ON_3Cl$: C, 54.19; H, 3.64; N, 18.96%. λ_{max}^{MeOH}, mμ (log ε): 245 (4.34), 328 (3.98).

The authors are very much indebted to Professor Tetsuo Nozoe for his kind encouragement and guidance during the course of our work.

The Synthesis of 2,3-Dimethyl-3-(5-bromo-2-methoxy-4-methylphenyl)-cyclohexene, a Potentially Useful Intermediate for the Syntheses of Aplysin and Related Sesquiterpenes

Kiyoyuki YAMADA, Hisatoyo YAZAWA, and Yoshimasa HIRATA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 18, 1971)

As a key intermediate for the syntheses of aplysin, **1**, a bromine-containing sesquiterpene isolated from *Aplysia kurodai*, and related sesquiterpenes, 2,3-dimethyl-3-(5'-bromo-2'-methoxy-4'-methylphenyl)cyclohexene, **2**, was synthesized, starting from an anisole derivative, **6**. The reactivity of the double bond in **2** towards oxidizing reagents was examined: the cyclohexene, **2**, reacted with ozone to give an epoxide, **12**, and a cyclohexanone, **13**, an isomerization product of **12**; **2** could be converted to the diol, **15**, with osmium tetroxide in the presence of pyridine.

The structure of aplysin, a bromine-containing novel sesquiterpene isolated from *Aplysia kurodai*, has been established as **1**.[1] The total synthesis of aplysin, **1**, was previously achieved in our laboratory, employing cyclopentanone as the starting material.[2] A different route for the synthesis of aplysin has since been projected *via* the title compound, **2**, as an important intermediate. A keto aldehyde, **3**, which can be derived from **2**, can possibly be cyclized to a conjugated aldehyde, **4**. The aldehyde, **4**, would then be utilized as an intermediate for the syntheses of aplysin, **1**, and related sesquiterpenes (*e.g.*, laurenisol, **5**[3]). We will describe here the synthesis of the cyclohexene, **2**.

Selective metallation at the C-6 position of the anisole, **6**, was carried out with phenyllithium in ether.[2] The lithium derivative of **6** was reacted with cyclohexanone to afford a cyclohexanol, **7**, the structure of which was confirmed by a study of the NMR

spectral evidence: two sharp singlets arising from aromatic protons were observed at δ 6.80 and 7.50, indicating that the condensation took place between the C-6 position of the anisole, **6**, and cyclohexanone. The dehydration of the cyclohexanol, **7**, was smoothly effected by heating it with oxalic acid to give a cyclohexene, **8**. Although the double bond of **8** was inert towards various peracids, the conversion of the cyclohexene, **8**, to a cyclohexanone, **9**, was effected by heating it in performic acid. Methylation at the benzylic carbon atom alpha to the carbonyl group in **9** was performed by treating the cyclohexanone, **9**, with sodium hydride in 1,2-dimethoxyethane and then with methyl iodide. The resulting cyclohexanone, **10**, was submitted to the Grignard reaction under forcing conditions to afford a cyclohexanol, **11**, (~30%) with the recovery of **10** (62%). The rather unreactive nature of the carbonyl group in **10** must be due to steric reasons: the cyclohexanone, **9**, gave the corresponding alcohol in a Grignard reaction in a good yield (~70%). The cyclohexanol, **11**, was dehydrated by heating it in benzene - 50% sulfuric acid to give the desired cyclohexene, **2**.

The double bond of the cyclohexene, **2**, was rather unreactive towards oxidizing reagents. When treated with ozone, the cyclohexene, **2**, afforded an epoxide, **12**, and a cyclohexanone, **13**, and no cleavage of the double bond of **2** occurred. The structures of the two products, **12** and **13**, were established by the spectral data and the following chemical evidence: the epoxide, **12**, was isomerized with 50% sulfuric acid at 80°C to **13**; the reduction of **13** with lithium borohydride yielded a cyclohexanol, **14**, which was then led to the starting cyclohexene, **2**, on treatment with sulfuric acid. The formation of the epoxide, **12**, from **2** suggests that the double bond of **2** is sterically hindered; there are precedents for the formation of an epoxide from a sterically-hindered olefin by ozone.[4] While the *cis*-hydroxylation of **2** with wet silver acetate - iodine[5] did not take place under any conditions, the cyclohexene, **2**, reacted slowly with osmium tetroxide, though only in the presence of pyridine, to afford a diol, **15**. This diol, **15**, was then cleaved by periodic acid to give an oily, rather unstable keto aldehyde, **3**.

Experimental

The melting points are uncorrected. The IR spectra were measured on a JASCO Model IRS spectrophotometer, and the UV spectra (methanol as solvent), on a Perkin-Elmer Model 202 spectrophotometer. The NMR spectra were recorded with a JNMC-60H spectrometer; only the prominent peaks are cited, while the chemical shifts are expressed in ppm downfield from TMS as the internal standard (δ); s, singlet; d, doublet; m, multiplet; the coupling constants are given in Hz. The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer, operating with an ionization energy of 70 eV. Thin-layer chromatography (TLC) was performed on silica gel GF_{254} (E. Merck, A. G., Germany), and column chromatography, on silicic acid (100 mesh, Millinckrodt, U.S.A.). The organic solutions were dried over anhydrous magnesium sulfate and evaporated by means of a rotary evaporator.

1-(5'-Bromo-2'-methoxy-4'-methylphenyl)cyclohexanol (7). A phenyllithium solution was prepared by stirring 16 g (2.28 mol) of metallic lithium into 176 g (1.1 mol) of bromobenzene in 900 m*l* of anhydrous ether under nitrogen. To the solution of phenyllithium, 200 g (1 mol) of the anisole, **6**, was then added, drop by drop, at room temperature. The mixture was stirred for 20 hr at room temperature and then refluxed for 10 hr. After cooling, 97 g (1 mol) of

cyclohexanone were added, and the mixture was stirred for 30 min and then refluxed for 5 hr. The mixture was poured into ice water, acidified with 10% hydrochloric acid, and repeatedly extracted with ether. The ethereal extracts were washed with water, dried, and evaporated to give a solid, the recrystallization of which from 95% ethanol afforded pure **7** (94.6 g, 32%); mp 118—119°C; UV 288 (ε 2000), 281 (ε 2000), 233 nm (ε 6700); IR (KBr) 3450, 1600, 1545 cm^{-1}; NMR ($CDCl_3$) 2.36 (3H, s), 3.88 (3H, s), 6.80 (1H, s), 7.50 (1H, s). Found: C, 56.40; H, 6.30; Br, 26.64%. Calcd for $C_{14}H_{19}O_2Br$: C, 56.23; H, 6.41; Br, 26.73%.

*1-(5'-Bromo-2'-methoxy-4'-methylphenyl)cyclohexene (**8**).* A solid mixture of 80 g (0.27 mol) of the cyclohexanol, **7**, and 40 g (0.44 mol) of anhydrous oxalic acid was kept at 210°C for 30 min. After cooling, water was added and the resulting mixture was repeatedly extracted with ether. The ethereal extracts were washed with a 10% sodium hydroxide solution and water, dried, and then evaporated to give a crystalline residue. Recrystallization from 95% ethanol afforded pure **8** (72 g, 96%); mp 51—53°C; UV 291 (ε 2800), 239 nm (ε 9300); IR (KBr) 1600, 1550 cm^{-1}; NMR (CCl_4) 2.35 (3H, s), 3.75 (3H, s), 5.70 (1H, m, vinyl H), 6.62 (1H, s), 7.20 (1H, s); mass, M^+ 282 and 280. Found: C, 59.90; H, 6.05; Br, 28.64%. Calcd for $C_{14}H_{17}OBr$: C, 59.84; H, 6.10; Br, 28.44%.

*2-(5'-Bromo-2'-methoxy-4'-methylphenyl)cyclohexanone (**9**).* To a stirred suspension of 18 g (0.064 mol) of the cyclohexene, **8**, in 60 m*l* of 85% formic acid, we added, drop by drop, 7.5 g of a 30% hydrogen peroxide solution under ice-bath cooling. The mixture was stirred at room temperature for 1 hr and at 90—95°C for 2 hr, and was then allowed to stand at room temperature overnight. The solid thus deposited was filtered and washed with water, a 10% sodium hydroxide solution, and water. The solid was subsequently chromatographed on silicic acid (80 g) with chloroform to give a crystalline material, the recrystallization of which from 95% ethanol afforded pure **9** (11.3 g, 60%); mp 174—175°C; IR (KBr) 1710, 1605, 1550 cm^{-1}; mass, M^+ 298 and 296. Found: C, 56.63; H, 5.55; Br, 27.01%. Calcd for $C_{14}H_{17}O_2Br$: C, 56.61; H, 5.77; Br, 26.91%.

*2-Methyl-2-(5'-bromo-2'-methoxy-4'-methylphenyl)cyclohexanone (**10**).* A mixture of 12 g (0.04 mol) of the cyclohexanone, **9**, and 1.2 g (0.05 mol) of sodium hydride in 160 m*l* of 1,2-dimethoxyethane was kept at 80°C for 2 hr with stirring under nitrogen. After the addition of 8 g (0.056 mol) of methyl iodide, the mixture was stirred at 80°C for 30 min, refluxed for 1 hr, and poured into ice water. The aqueous mixture was repeatedly extracted with benzene. The benzene extracts were washed with water, dried, and evaporated to give a residue, which was then chromatographed on silicic acid (25 g) with chloroform. The crude material thus obtained was recrystallized from 95% ethanol to afford pure **10** (4.9 g, 39%); mp 135—137°C; IR (KBr) 1700, 1602, 1550 cm^{-1}; NMR (CCl_4) 1.18 (3H, s), 2.34 (3H, s), 3.68 (3H, s), 6.64 (1H, s), 7.28 (1H, s); mass, M^+ 312 and 310. Found: C, 57.89; H, 6.08; Br, 25.73%. Calcd for $C_{15}H_{19}O_2Br$: C, 57.93; H, 6.16; Br, 25.70%.

*1,2-Dimethyl-2-(5'-bromo-2'-methoxy-4'-methylphenyl)cyclohexanol (**11**), and 2,3-Dimethyl-3-(5'-bromo-2'-methoxy-4'-methylphenyl)-cyclohexene (**2**).* A solution of methyl magnesium iodide was prepared from 1.7 g (0.07 g-atom) of metallic magnesium and 9.7 g (0.068 mol) of methyl iodide in 120 m*l* of anhydrous ether under nitrogen. The ether was then distilled off, and 120 m*l* of dried benzene were added. To the stirred Grignard solution, 8.5 g (0.027 mol) of **10** in 60 m*l* of benzene were added. The mixture was stirred at room temperature for 30 min, refluxed for 15 hr, and, after cooling, poured into a saturated ammonium chloride solution. The benzene layer was separated, washed with water, and dried. The subsequent evaporation of the benzene afforded an oily residue, which showed two spots on a TLC plate (chloroform as the solvent). The residue was chromatographed on silicic acid (120 g) with chloroform to give the starting ketone, **10** (5.3 g), and a colorless oil, **11** (2.7 g). A solution of 2.7 g of **11** in 27 m*l* of benzene was mixed with 5.5 m*l* of 50% sulfuric acid, after which the mixture was refluxed while being stirred for 3 hr. The benzene layer was separated, washed with a saturated sodium bicarbonate solution and water, and dried. The subsequent evaporation of the solvent afforded an oily product (2.2 g), which was chromatographed on silicic acid (40 g) with chloroform to give a crystalline material. Recrystallization from 95% ethanol afforded pure **2** (1.35 g, 43% from **10**: the yield was calculated from the amount of **10** actually consumed); mp 96—98°C; IR (KBr) 1600, 1550 cm^{-1}; NMR (CCl_4) 1.45 (3H, s), 1.48 (3H, d, J=2), 2.33 (3H, s), 3.76 (3H, s), 5.50 (1H, m, vinyl H), 6.64 (1H, s), 7.17 (1H, s); mass, M^+ 310 and 308. Found: C, 62.06; H, 6.72; Br, 25.89%. Calcd for $C_{16}H_{21}OBr$: C, 62.19; H, 6.85; Br, 25.86%.

*Oxidation of the Cyclohexene (**2**) with Ozone.* Ozone was passed through a solution of 150 mg of **2** in 5 m*l* of dichloromethane at −60°C. The progress of the reaction was examined by TLC. The excess ozone in the solution was flushed out with nitrogen at −60°C. The subsequent evaporation of the solvent afforded a residue, to which water was added. The mixture was allowed to stand at room temperature for 2 hr and was then extracted with benzene repeatedly. The benzene extracts were washed with water, dried, and evaporated to give a yellow oily residue (0.15 g), which showed three spots on a TLC plate. The residue was chromatographed on silicic acid (5 g) with chloroform. The starting material, **2** (35 mg), was thus obtained from the early fractions; the following fractions gave **13**, which was recrystallized from 95% ethanol to give pure **13** (22 mg, 15%); from the later fractions, the epoxide, **12**, was obtained, the recrystallization of which from ethanol afforded pure **12** (75 mg, 50%).

12: mp 116—118°C; IR ($CHCl_3$) 1640, 1600, 1490 cm^{-1}; mass, M^+ 326 and 324.

13: mp 121—122°C; IR (KBr) 1708, 1600, 1545 cm^{-1}; NMR (CCl_4) 0.65 (3H, d, J=7), 1.16 (3H, s), 2.33 (3H, s), 3.82 (3H, s), 6.66 (1H, s), 7.20 (1H, s); mass, M^+ 326 and 324. Found: C, 59.00; H, 6.71%. Calcd for $C_{16}H_{21}O_2Br$: C, 59.13; H, 6.51%.

*Conversion of the Epoxide (**12**) to the Cyclohexanone, (**13**).* A mixture of 19 mg of **12** in 1 m*l* of 50% sulfuric acid was heated at 80°C for 2 hr and then poured into ice water. After the mixture has been repeatedly extracted with benzene, the benzene extracts were washed with water, a saturated sodium bicarbonate solution, and water, dried, and evaporated to give 10 mg of crystalline **13**.

*Conversion of the Cyclohexanone (**13**) to the Cyclohexene (**2**).* A mixture of 15 mg of **13** and 5 mg of lithium borohydride in 2 m*l* of tetrahydrofuran was refluxed for 2 hr. After cooling, the mixture was diluted with water-acetic acid (9 : 1) and extracted with benzene. The benzene extracts were washed with a saturated sodium bicarbonate solution and water, dried, and evaporated to give 15 mg of the alcohol, **14**; IR (neat) 3450 cm^{-1}. A mixture of 15 mg of **14** in 2 m*l* of benzene and 0.1 m*l* of 50% sulfuric acid was refluxed for 2 hr and then poured into a saturated sodium bicarbonate solution. The benzene layer was separated, washed with water, dried, and evaporated, thus affording a crystalline residue. Recrystallization from 95% ethanol afforded 9 mg

of pure **2**.

*Oxidation of the Cyclohexene (**2**) with Osmium Tetroxide.* To a stirred solution of 633 mg (2.05 mmol) of **2** in pyridine (10 m*l*)-tetrahydrofuran (8 m*l*), we added, drop by drop, a solution of 510 mg (2.0 mmol) of osmium tetroxide in tetrahydrofuran (15 m*l*) at room temperature under nitrogen. After two weeks, the dark-red solution was concentrated under reduced pressure to give a residue, which was then taken up in 80 m*l* of 95% ethanol - chloroform (1 : 1). Hydrogen sulfide was passed through the dark-red solution for 10 min, and the resulting black precipitate was filtered. The filtrate was evaporated to afford a dark brown oil, which was chromatographed on silicic acid (60 g); fractions eluted with chloroform gave the starting material, **2** (*ca.* 70 mg), while fractions eluted with chloroform - methanol (v/v, 98 : 2) afforded the crude diol (460 mg), the recrystallization of which from hexane gave the pure diol, **15**; mp 145—146°C. Found: C, 55.88; H, 6.74%. Calcd for $C_{15}H_{23}O_3Br$: C, 56.02; H, 6.76%.

*Periodic Acid Oxidation of the Diol (**15**).* A solution of 106 mg of periodic acid dihydrate in water (1 m*l*) was added to a solution of 140 mg of **15** in tetrahydrofuran (4 m*l*)-water (2 m*l*), after which the mixture was stirred at room temperature for 4 hr. The mixture was then evaporated, neutralized with a sodium bicarbonate solution, and repeatedly extracted with ethyl acetate. The ethyl acetate extracts were washed with a saturated sodium chloride solution, dried, and evaporated to give a colorless oil, **3** (*ca.* 120 mg); IR ($CHCl_3$) 2730, 1725, 1710 cm^{-1}; NMR (CCl_4) 1.35 (3H, s), 1.78 (3H, s), 2.37 (3H, s), 3.73 (3H, s), 6.70 (1H, s), 7.30 (1H, s), 9.60 (1H, t, $J=3$); mass, M^+ 342 and 340.

Solvolysis of Organic Phosphates. V. Participation of the Neighboring Groups and Effects of Metal Ions in the Hydrolysis of 3-Hydroxy-2-pyridylmethyl Phosphate[1]

Yukito MURAKAMI, Junzo SUNAMOTO, and Hideyuki ISHIZU

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received June 15, 1971)

The spontaneous hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate was investigated at 60, 70, and 80°C over the $-\log[H^+]$ range from 1 to 10 in aqueous media with an ionic strength of 0.10. The reactions followed apparent first-order kinetics with respect to the unreacted phosphate species, and the maximum rate was observed at $-\log[H^+]$ 7—8. Reactive species in hydrolysis were neutral zwitterion, monoanion, and dianion species, the reactivity increasing in this order. This trend in reactivity order has not been observed previously. In a moderately acidic region ($-\log[H^+]<2.0$), kinetic data were consistent with the acid catalysis acting on the zwitterion species. Activation parameters provide an evidence for the unimolecular nature of the transition state in spontaneous hydrolysis and suggest the A1 process for the acid catalyzed reaction. The anomalously high reactivity of the dianion species was attributed to participation of the 3-hydroxy group in the reaction process: intramolecular transfer of the hydroxyl proton to the ester oxygen in a pre-equilibrium stage, followed by the P–O bond cleavage in the subsequent transition state to give the products. Hydrolysis was also carried out in the presence of copper(II), nickel(II), zinc(II), aluminum(III), iron(III), and thorium(IV) ions at 60°C and $\mu=0.10$ in a relatively lower pH range. Introduction of the 3-hydroxyl group to 2-pyridylmethyl phosphate resulted in a change of catalytic status of various metal ions. Only iron(III) and thorium(IV) ions accelerated the rate to a significant extent. Validity of the two requirements originally proposed for the bivalent metal catalysis was extended to the polyvalent metal catalysis.

Intramolecular catalysis in the ester hydrolysis is much interesting from a biochemical viewpoint. In the enzymic reaction, the enzyme-substrate complex is formed prior to the rate-determining catalysis reaction as represented by

$$E + S \rightleftarrows ES \rightarrow P \qquad (1)$$

Thus, the enzymic reaction follows first-order kinetics and the loss of entropy in the transition state is rather small. The geometry of the enzyme-substrate complex at the binding site is the major controlling factor for enzyme-specificity rather than the structural environment at the catalysis site. Such mechanistic criteria may also be applied in an analogous sense to the general organic intramolecular catalysis.[2] Recently, investigations of intramolecular catalysis in the ester hydrolyses, particularly in the hydrolyses of phosphates and sulfates, have been extensively carried out. Among them, hydrolyses of salicyl phosphate,[3] *S*-(2-carboxyphenyl)phosphorothioate,[4] and salicyl sulfate[5] are the cases of carboxyl group participation in the intramolecular general acid catalysis. Benkovic and Dunikoski have found the intramolecular acid catalysis by the imidazole-group participation in the hydrolysis of an imidazole substituted phenyl sulfate.[6] Meanwhile, we have actively investigated the

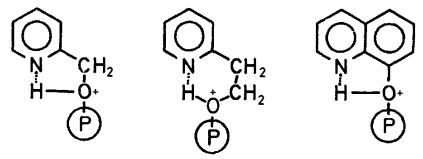
kinetics for the hydrolyses of aryl and alkyl phosphates containing a hetero-aromatic ring in their leaving alcohol groups. In this series of investigations, a unique intramolecular general acid catalysis has been confirmed in the hydrolyses of 2-pyridylmethyl,[7] 6-methyl-2-pyridylmethyl,[8] 2-pyridylethyl,[8] and 8-quinolyl phosphates.[9] We believe that the hydrolyses of the first three phosphates are the first examples of an intramolecular catalysis by the hetero-aromatic moiety in the hydrolyses of the open chain alkyl phosphates. The specific rate enhancement observed in the hydrolysis of these phosphates has been attributed to the participation of hetero-aromatic nitrogen. The intramolecular proton-transfer from pyridyl or quinolyl nitrogen to the ester oxygen seems to be facilitated in the pre-equilibrium step through a five- or six-membered chelate-ring formation, as illustrated by structures **1**, **2**, and **3**. In this work, we designed



1 **2** **3**

Ⓟ: phosphate moiety

a competing state of affair for the intramolecular general acid catalysis and investigated the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate which has an additional functional group, 3-hydroxy, to 2-pyridylmethyl phosphate in the proximity of a phosphate moiety. As a result, the present work clarifies which neighboring group, 1-pyridinium or 3-hydroxy group, provides more significant intramolecular catalysis in the hydrolysis.

We also studied the metal-ion catalysis in the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate. Previously, we investigated the metal-ion catalysis in the hydrolyses of pyridylmethyl phosphates,[7] and 3-pyridyl and 8-quinolyl phosphates.[10] From these studies, we have proposed two requirements for metal ions to yield catalytic efficiency.[7,10] (1) For preliminary chelate formation, the metal ion should form an appropriate chelate of significant stability with an organic phosphate prior to the hydrolysis reaction. (2) For transitional chelate formation, the metal ion should demonstrate an appropriate affinity for the ester oxygen in the transition state, which would give rise to formation of a chelate ring involving the ester oxygen.

3-Hydroxy-2-pyridylmethyl phosphate has three chelating sites. Thus, three kinds of structures for metal-chelate formation can be depicted as shown below by structures **4**, **5**, and **6**. The extent of catalysis due to these metal chelates is subject to the structural nature of the phosphate and the coordination affinity of a metal ion for the donor atoms. We qualitatively investigated the catalytic effects of various metal ions, *i.e.*, copper(II), nickel(II), zinc(II), aluminum(III), iron(III), and thorium(IV). Thus, the present work accumulates the kinetic and mechanistic data for confirmation of the above requirements established for the bivalent metal catalysis, and provides further mechanistic criterion for the polyvalent metal catalysis.[10]

Experimental

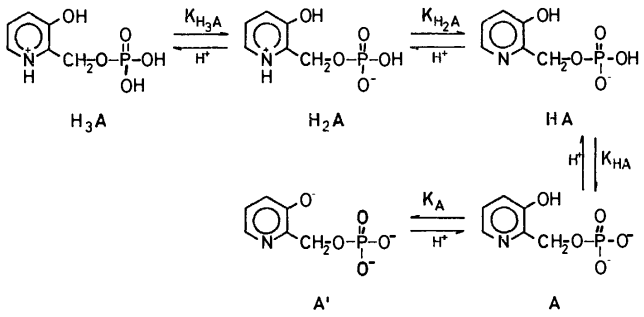
Materials. Preparation and purification of 3-hydroxy-2-pyridylmethyl phosphate have been described.[11] Other materials of analytical grade were commercially obtained and used without further purification. The stock solutions of metal ions were prepared from their nitrate salts. The solutions were standardized by means of the usual chelatometric titration.

Kinetic and Potentiometric Measurements. The apparatus and experimental procedures were essentially the same as those described previously.[9,10]

Determination of Acid Dissociation Constants and Specific Rate Constants. The overall rate constant k_0 is given by a summation of each product of a specific rate constant (k) and the corresponding mole fraction (X) over the all ionic species as represented by

$$k_0 = k_{A'}X_{A'} + k_AX_A + k_{HA}X_{HA} + k_{H_2A}X_{H_2A} + k_{H_3A}X_{H_3A} \quad (2)$$

To the present phosphate, the acid dissociation processes shown in Scheme 1 can be reasonably assigned.[11] The symbols suffixed to k's and X's in Eq. (2) (*i,e.*, A', A, HA,



Scheme 1

H_2A, and H_3A) stand for the ionic species shown in Scheme 1. A mole fraction of each ionic species was calculated by the aid of acid dissociation constants[11] which were determined by the pH-titration at low temperature (25°C) over the whole pH range (1—10.0). The results are illustrated by broken lines in Fig. 1. Thus, if all the acid dissociation constants at a given temperature are known, the specific rate constant for each ionic species can be easily evaluated by means of Eq. (2). However, the acid dissociation constants obtained by potentiometric measurements at higher temperatures (60—80°C) were suspected to involve a little uncertainty. These unavoidable errors might be caused by trace hydrolysis of the phosphate during the course of measurements. Thus, under the circumstances, the dynamic acid dissociation constants and the specific rate constants were simultaneously calculated from the kinetic data by the following procedures.

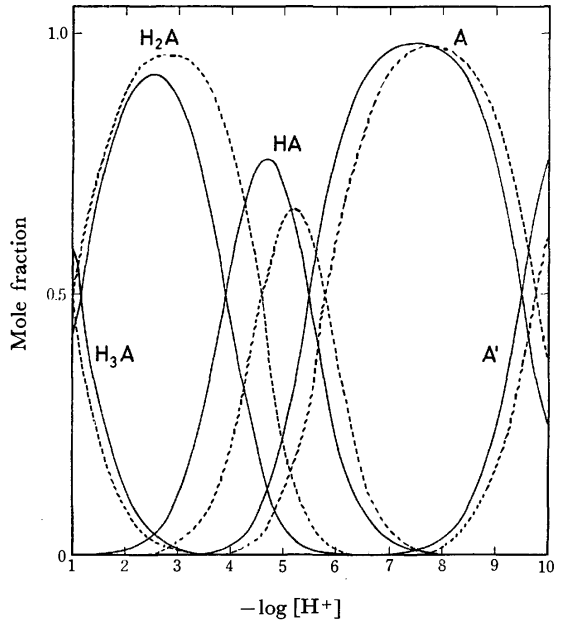

Fig. 1. Distribution of ionic species of 3-hydroxy-2-pyridylmethyl phosphate as a function of $-\log[H^+]$ at $\mu=0.10$, and at 25° (broken lines) and 60°C (solid lines). They were calculated using the pK_a values listed in Table 2.

1) Assumption is made that the trianionic species of the present phosphate (A′) is unreactive in the spontaneous hydrolysis over a pH-range 8.0—10.0 where only two species, trianionic and dianionic, are present. Then, the following relations are valid:

$$T_E = [A] + [A'] \tag{3}$$

$$k_{obs}T_E = k_A[A] \tag{4}$$

where T_E stands for the total concentration of the phosphate species and k_{obs} refers to the observed apparent first-order rate constant. The following equation is derived from Eqs. (3) and (4).

$$[H^+] = k_A\frac{[H^+]}{k_{obs}} - K_A \tag{5}$$

where K_A is the acid dissociation constant of the dianionic species. This equation indicates that a plot of $[H^+]$ *vs.* $[H^+]/k_{obs}$ should give a straight line. The slope of the line is equal to k_A and the intercept at $[H^+]/k_{obs}=0$ corresponds to K_A.

2) In a pH-range 6.0—7.5 where dianionic and monoanionic (HA) species exist exclusively, the following equations are applied to the system:

$$T_E = [HA] + [A] \tag{6}$$

$$k_{obs}T_E = k_{HA}[HA] + k_A[A] \tag{7}$$

where k_A value evaluated in Step 1 can be used. From Eqs. (6) and (7), the following relationship is given:

$$\frac{k_{obs}[H^+]}{k_A-k_{obs}} = k_{HA}\frac{[H^+]}{k_A-k_{obs}} + K_{HA} \tag{8}$$

The relationship between the left hand side and $[H^+]/(k_A-k_{obs})$ in the first term of the right hand side needs to be linear. Thus, k_{HA} and K_{HA} are to be obtained from the slope and the intercept at $[H^+]/(k_A-k_{obs})=0$, respectively.

3) For a pH-range 3.0—5.0, three phosphate species, neutral zwitterion (H_2A), monoanionic and dianionic forms, are to be taken into consideration. Then, the following equations can be given for this state of affair.

$$T_E = [H_2A] + [HA] + [A] \tag{9}$$

$$k_{obs}T_E = k_{H_2A}[H_2A] + k_{HA}[HA] + k_A[A] \tag{10}$$

where k_A and k_{HA} values evaluated in Steps 1 and 2, respectively, can be used. Combination of Eqs. (9) and (10) and the subsequent rearrangement give the following equations.

$$\frac{k_{obs}[H^+]^2}{(k_{HA}-k_{obs})[H^+] + (k_A-k_{obs})K_{HA}} = k_{H_2A}\frac{k[H^+]^2}{(k_{HA}-k_{obs})[H^+] + (k_A-k_{obs})K_{HA}} + K_{H_2A} \tag{11}$$

In a manner similar to those described in the preceding steps, k_{H_2A} and $K_{H\,A}$ are evaluated from the plots.

4) Finally, by using all the values already obtained in the preceding steps and the kinetic data covering a pH-range 1.0—3.0 where cationic, neutral zwitterion, and monoanionic species are considered to be present, we have

$$T_E = [H_3A] + [H_2A] + [HA] \tag{12}$$

$$k_{obs}T_E = k_{H_3A}[H_3A] + k_{H_2A}[H_2A] + k_{HA}[HA] \tag{13}$$

$$\frac{k_{obs}[H^+]^2}{(k_{H\cdot A}-k_{obs})[H^+] + (k_{HA}-k_{obs})K_{H_2A}} = k_{H\cdot A}\frac{[H^+]^2}{(k_{H_2A}-k_{obs})[H^+] + (k_{HA}-k_{obs})K_{H_2A}} + K_{H_3A} \tag{14}$$

k_{H_3A} and K_{H_3A} would be evaluated from the linear plots based on Eq. (14). In general, however, the neutral species of the alkyl phosphates[12] and the monocationic species of pyridylalkyl phosphates[7,8] show much less reactivity in their spontaneous hydrolyses. Therefore, for the present phosphate the kinetic analysis due to Step 4 was discarded. Instead, an acid catalyzed hydrolysis of the neutral zwitterion species was confirmed to proceed in such a moderately acidic region more significantly. The overall rate constant k_0 is, thus, consistent with the equation

$$k_0T_E = k_{H^+}[H^+][H_2A] + k_{H\,A}[H_2A] + k_{HA}[HA] + k_A[A] \tag{15}$$

Results

Spontaneous Hydrolysis. The specific rate constants evaluated by the preceding procedure and the acid dissociation constants are listed in Tables 1 and 2, respectively. Moreover, the agreement between the observed and the calculated rate constants at 60, 70, and 80°C is quite satisfactory as illustrated in Figs. 2, 3, and 4, respectively.

In our previous studies on the spotaneous hydrolyses of 2-, 3-, and 4-pyridylmethyl phosphates,[7] 6-methyl-2-pyridylmethyl,[8] 3-pyridyl, and 8-quinolyl phosphates,[9] the reactive species were always the neutral zwitterion and the monoanionic form, and rate-maxima in the pH-rate profiles were observed at —log[H+] 2—3 and 5—6 for all the phosphates. In the present case, however, the maximum rate in the pH-rate profile for the spontaneous hydrolysis appeared at —log[H+] 7—8 with a shoulder at 4.5. Consequently, the most reactive species was the dianionic form followed by the monoanion and then the neutral zwitterion in this order.

Activation Parameters. Each specific rate constant followed the Arrhenius law. The energy, enthalpy, and entropy of activation for each species are listed in Table 3. These values are quite similar in magnitude to those for the monoanions of organic phosphates previously reported,[13] and seem to indicate that all the reactive species of the present phosphate undergo hydrolysis through a unimolecular mechanism in which a pre-equilibrium proton-transfer process followed by P–O fission in the rate-determining step takes place.

Metal Ion Catalysis. In the presence of metal ions, the hydrolysis conditions were set at the upper limit pH and temperature in a range where no noticeable precipitates appeared and no partial hydrolysis of metal ions occurred. Consequently, a good homogeneous phase was maintained during the course of each run. All the reactions were carried out in the presence of equimolar amounts of a metal ion and the substrate at 60°C and μ=0.10 (KNO_3). The hydrolysis reactions in the presence of copper(II), nickel(II), zinc(II), and aluminum(III) ions followed ap-

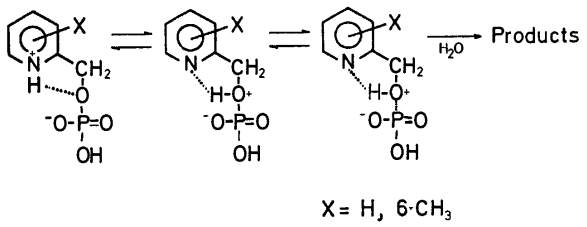
parent first-order kinetics with respect to the total concentration of the unreacted phosphate in homogeneous phase at pH's and metal concentrations studied. However, all the metal ions showed no significant catalytic effect. On the other hand, the presence of iron(III) and thorium(IV) ions resulted in a significant acceleration of rate, although the reactions did not follow the simple first-order kinetics and the hydrolysis rates were retarded as reactions proceeded further. During the course of reactions, no formation of insoluble materials was detected and a good homogeneous system was maintained. In particular, the thorium ion showed a profound rate enhancement. The catalytic efficiency of these metal ions is listed in Table 4. The catalytic status of the present metal ions with the exception of thorium(IV) is illustrated in Fig. 5 in reference to the spontaneous reaction.

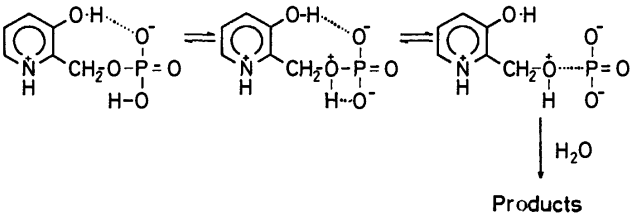
Discussion

Hydrolysis of Neutral Zwitterion Species. In the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate, the neutral zwitterion form (H_2A) was the least reactive of the three reactive species, H_2A, HA, and A. This behavior differs noticeably from other heteroaromatic phosphates studied previously.[7-9] Furthermore, for the hydrolyses of the zwitterion species of 2-pyridylalkyl phosphates and 8-quinolyl phosphate, a unique intramolecular general acid catalysis was observed upon participation of 1-pyridinium or 1-quinolinium proton which was transferred to the ester oxygen in the pre-equilibrium stage of reaction. The mechanistic aspect is shown in Scheme 2.



Scheme 2

Thus, for the zwitterion form of the present phosphate, the following two aspects of mechanistic criteria may be considered: (1) An intramolecular general acid catalysis played by the 1-pyridinium proton occurs and the 3-hydroxyl group provides only an electronic effect on the reaction rate as an electron-withdrawing group,[14] in a manner similar to the cases of 2-pyridylalkyl phosphates (Scheme 2). (2) An intramolecular hydrogen bonding of the 3-hydroxyl group to the terminal phosphate oxygen is formed and the phosphate proton is transferred intramolecularly to the ester oxygen, as seen in the usual hydrolyses of alkyl phosphate monoanions. Therefore, if the latter holds, the positive pyridinium group acts only as an electron-withdrawing group as illustrated in Scheme 3. If the driving force for the intramolecular proton



Scheme 3

transfer is due to a preliminary intramolecular hydrogen bonding, Scheme 3 may be more favorable for interpretation of the results than Scheme 2. Since an O–H···O bond is tighter in general than an N–H···O bond in hydrogen bonding strength, the phosphate moiety is to be fixed in space far away from the 1-pyridinium proton due to the intramolecular O–H···O bonding as shown in Scheme 3. Consequently, an intramolecular acid catalysis by the pyridinium group would not be expected, even though the present phosphate is one of 2-pyridylmethyl phosphates. Meanwhile, the absolute hydrolysis rate of the present phosphate is 2.3 times larger than that of 2-pyridylmethyl phosphate in zwitterion form at 70°C. Thus, the 3-hydroxyl group must participate in the reaction process so that the hydrolysis rate is enhanced due to its electronic effect and/or additional intramolecular interaction. As a result, there still remains some uncertainty in elucidating the hydrolysis mechanism. Further confirmation of the present mechanism waits studies of the linear free energy relationship on the hydrolysis of pyridylalkyl phosphates.

Linear free energy relationships (LFER) for the hydrolyses of phosphates and sulfates have been extended by Bunton,[15] Fendler,[16] and Kirby.[17] However, all the esters they studied were aryl esters. So far, the acidity of a leaving group (pK_{OH}) has been usually adopted as the structural parameter for LFER study of ester hydrolyses, where P–O or S–O bond cleavage is the rate-determining step. The pK_{OH} value of an alcohol is, however, generally very large (13—16)[18], even those of the alcohols having an aromatic moiety,[19] compared with those of the phenols (~10).[20] It is, therefore, difficult to determine the correct and reliable acid dissociation constants of alcohols, particularly at higher temperatures, by the usual techniques. Thus, it is quite important to establish some reliable structural parameters other than acid dissociation constants of the leaving alcohols for the LFER study of the hydrolyses of alkyl phosphates.

Activation parameters E, $\Delta H^{\neq}$, and $\Delta S^{\neq}$ for the

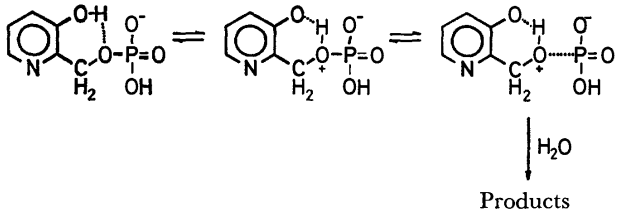
hydrolysis of the zwitterion species are quite similar in their magnitude to those for other pyridylalkyl phosphates,[7,8] 3-pyridyl and 8-quinolyl phosphates.[9] Thus, it may be reasonable to assume that the nature of the transition state is essentially the same as that discussed previously, where a unimolecular P–O bond cleavage to give an alcohol and HPO_3^- occurs, irrespective of the source of the transferable proton in the pre-equilibrium stage.

Hydrolysis of Monoanionic Species. Contrary to what would be expected from the previous studies,[7-9] the monoanionic species was more reactive than the neutral zwitterion. The anomalous behavior of the monoanion must be interpreted from two aspects: (1) a simple electron-withdrawing effect of the 3-group (similar to Scheme 3), and (2) an intramolecular general acid catalysis played by the 3-hydroxyl group (Scheme 4).



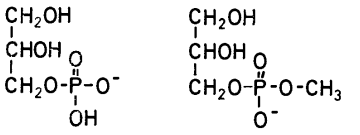
Scheme 4

If Scheme 3 is valid, the electronic effect of the 3-hydroxyl group for this species would be approximately in a similar magnitude to that expected for the zwitterion species. When the substituent effect due to the 3-hydroxyl group on the reaction rate is represented in terms of the ratio of reaction rates against 2-pyridylmethyl phosphate $k_{(3\text{-H-2-PMP})}/k_{(2\text{-PMP})}$, this value is about 2.3 for the hydrolysis of the zwitterion species. On the other hand, the rate ratio is 1.25×10^2 for the hydrolysis of the monoanionic species. This profound rate enhancement should be attributed to the additional proximity effect due to introduction of a hydroxyl group at the 3-position of 2-pyridylmethyl phosphate. Consequently, this neighboring group may be responsible for the intramolecular proton transfer in the transition state as seen in Scheme 4. The driving force for the proton transfer may be due to the preliminary intramolecular hydrogen bonding, primarily to the terminal phosphate oxygen, in which the hydroxyl group is brought about in the neighborhood of the ester oxygen. The hydrogen bonding is then switched to the ester oxygen in the pre-equilibrium stage prior to the transition state, where the stable six-membered ring is formed.

Activation parameters for the hydrolysis of the monoanion are consistent with a unimolecular mechanism accompanied with P–O bond cleavage.

Hydrolysis of Dianionic Species. Generally, the dianionic species of an organic phosphate is unreactive toward spontaneous hydrolysis, except for those of phosphate esters which have a strong electron-withdrawing group in a leaving alcohol moiety, *e.g.*, nitrophenyl and polynitrophenyl phosphates.[15,16] For the present phosphate, the dianionic species was the most reactive and the trianionic species was stable in alkaline media. This presents a unique case in which the dianionic species is more reactive than the zwitterion and monoanionic forms in the hydrolysis of alkyl phosphates. This interesting fact requires some characteristic explanation for the hydrolysis mechanism in reference to hydrolyses of the other ionic species of the present phosphate and of ordinary alkyl phosphates.

The profound rate enhancement must be ascribed to the participation of the 3-hydroxyl group situated in the proximity of the phosphate moiety. No work has been reported on the intramolecular participation of a hydroxyl group in the hydrolysis of alkyl phosphates or sulfates, which consequently gave out to some significant rate enhancement. Bender and Lawlor have shown that 8-hydroxy-1-naphthyl phosphate dianion hydrolyzed about 10-fold faster than the dianion of the 8-methoxyl ester.[3] They considered that this rate enhancement was due to the intramolecular proton transfer from the 8-hydroxyl group to the ester oxygen, although the extent of their investigation was rather limited. Glycerol-1-phosphate **7** was stable in alkaline media and had a rate maximum at around pH 4—5 in its hydrolysis in a manner similar to those observed for usual monoalkyl phosphates. Glycerol-1-methyl phosphate **8** was readily hydrolyzed in alkaline media to give a mixture of glycerol-

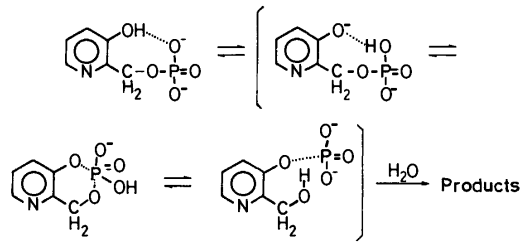


7 **8**

1- and -2-phosphates, no methyl phosphate being produced.[12] Kugel and Halmann have reported the hydrolysis of 1,2-propanediol-1-dihydrogen phosphate,[21] where the phosphate was also hydrolyzed with a maximum rate at pH ~4. In this pH region, the mole fraction of the monoanion reaches its maximum. As a whole, these studies indicate that an alcoholic hydroxyl group at the β-position and/or the γ-position to the phosphate group of alkyl phosphates does not bring about any significant rate enhancement in hydrolysis.

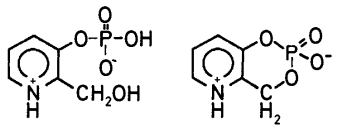
The profound rate enhancement due to the participation of the 3-hydroxyl group may be interpreted from two different aspects: (1) nucleophilic attack of the negatively charged phenoxide group at the phosphorus atom, and (2) intramolecular transfer of the hydroxyl proton to the ester oxygen. Scheme 5 demonostrates the nucleophilic attack of the phenoxide ion at the phosphorus atom forming a cyclic transition state (or a cyclic intermediate), which is followed by the intramolecular transfer of the phosphate group to the phenolic oxygen. A similar state of affair was confirmed in the hydrolysis of glycerol hydrogen

21) L. Kugel and M. Halmann, *J. Amer. Chem. Soc.*, **88**, 3566 (1966).



Scheme 5

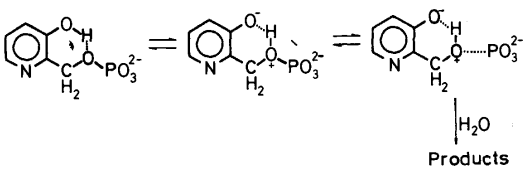
phosphates,[12] where a cyclic intermediate was formed and subsequently an intramolecular rearrangement of the phosphate group took place. We previously tried to isolate the cyclic phosphate **10** which would be derived from the present phosphate, and 2-hydroxymethyl-3-pyridyl phosphate under various conditions. However, the work failed to give these products, and gave 3-hydroxy-2-pyridylmethyl phosphate exclusively.[22] This suggests that the present phosphate, rather than



9 **10**

being the precursor of the cyclic phosphate **10** or of the intramolecularly rearranged phosphate **9** should be an intermediate in their hydrolytic decomposition. The dianionic species of 2-hydroxymethyl-3-pyridyl phosphate would not be as reactive as that of 3-hydroxy-2-pyridylmethyl phosphate toward hydrolysis, unless the 2-hydroxymethyl group would participate favorably in the reaction.

Thus, the alternative concept is adopted as the plausible mechanism for elucidation of the enhanced hydrolysis rate. As shown in Scheme 6, the hydroxyl



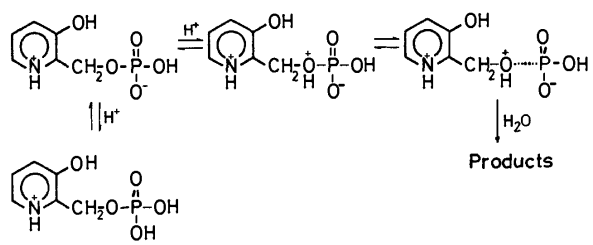
Scheme 6

proton is completely transferred to the ester oxygen in the pre-equilibrium stage, and the P–O bond is then weakened in the subsequent transition state to give the products. This mechanistic aspect is quite analogous to that employed for the hydrolysis of the monoanion as the most plausible mechanism. The six-membered ring formation would stabilize the pre-equilibrium stage in these hydrolytic pathways. For the dianionic species, however, an increase of negative charge on the phosphate moiety will make the proton transfer much more favorable. The small positive entropy of activation again suggests the unimolecular mechanism for the dianion hydrolysis.

Hydrolysis in Moderately Acidic Region. In the moderately acidic region, $-\log[H^+]$ 1.0—2.0, the hydrolysis rates of 8-quinolyl and 3-pyridyl phosphates increased in proportion to the stoichiometric concentration of acid,[9] while pyridylmethyl phosphates underwent no detectable acid catalyzed hydrolysis in a comparable acidic region.[7,8] We attributed the favorable acid catalysis for the former two aryl phosphates to the electron-withdrawing effect caused by the positively charged pyridinium or quinolinium group and also to resonance stabilization given to the generated alcohol of phenolic nature. For the present phosphate, the hydrolysis in a moderately acidic region was not subject to a marked acid catalysis along with the change of hydrogen ion concentration. Under these circumstances, two reaction mechanisms of kinetic equivalence are to be considered: (1) unimolecular spontaneous reaction of the monocationic species, and (2) acid catalyzed reaction of the zwitterion form.

If one assumes that the monocationic species is reactive in the hydrolysis of the present phosphate, the specific rate constants are $k_{H_3A}=0.368\times10^{-5}$, 1.33×10^{-5}, and 4.58×10^{-5} sec^{-1} at 60, 70, and 80°C, where $pK_{H_3A}=1.16$ (60°C), 1.08 (70°C), and 1.00 (80°C), respectively. From these kinetic data, the activation parameters may be estimated: $E=29.5$ kcal mol^{-1}, $\Delta H^{\neq}=28.8$ kcal mol^{-1}, and $\Delta S^{\neq}=+3$ e.u. The specific rate constants and the activation parameters cited here are not necessarily unfavorable to this mechanism. However, we can not show which one of the four protons may be transferred to the ester oxygen at the pre-equilibrium stage in this case.

Under consideration of the results previously obtained on the reactivity of the monocationic species,[7] this species should be much less reactive and the neutral zwitterion is subject to an acid catalysis in this moderately acidic region. The kinetic data and the corresponding activation parameters were evaluated from this aspect as listed in Tables 1 and 3. The entropy of activation in Table 3 suggests that the acid catalysis for the present phosphate proceeds through A1 process as shown in Scheme 7.



Scheme 7

Effects of Metal Ions. We proposed previously that the two successive interactions were required to yield the metal ion catalysis.[10] Thus, the hydrolysis reaction of 3-hydroxy-2-pyridylmethyl phosphate was investigated in the presence of various metal ions in order to examine the validity and applicability of the proposed mechanisms.

22) Y. Murakami, J. Sunamoto, K. Morooka, and H. Kondo, presented at the Local Meeting of the Chemical Society of Japan, Fukuoka, July, 1968.

3-Hydroxy-2-pyridylmethyl phosphate is related in structure to 2-pyridylmethyl phosphate. Therefore, it may be expected that the copper(II) ion would have a significant catalytic efficiency for the hydrolysis of the present phosphate. Contrary to what would be expected, the copper ion as well as other bivalent metal ions showed no detectable catalysis. When the reaction mixture prepared at pH above 4 in the presence of copper(II) was poured into a reaction vessel, a blue insoluble material appeared about ten minutes after the addition and simultaneously the pH value of the mixture decreased sharply. Apparently, a certain copper complex was produced with liberation of protons. The precipitates were insoluble in almost all of the polar and nonpolar organic solvents as well as in water. In order to examine the nature of the complex, we tried to prepare a complex of 3-hydroxy-2-pyridylmethanol with copper(II): equimolar amounts of the alcohol and copper nitrate were dissolved in water, pH was adjusted to 4—6 using 0.1 N-sodium hydroxide, and the resulting blue precipitates were isolated. The IR spectrum of this copper complex was compared with that of the complex produced during the course of hydrolysis. They differ from each other and the latter is more related to the spectrum of the substrate ester as shown in Fig. 6. As can be seen from Fig. 6-c, absorption bands assigned to the stretching vibration of P–O–C and P=O bonds (900—1200 cm^{-1}) are still observed in the spectrum of the complex formed in the hydrolysis. As a result, the complex is not the one with the hydrolysis product, but that with the unreacted substrate. With the knowledge obtained from the copper catalysis on the hydrolyses of 2-pyridylmethyl[7] and 8-quinolyl[10] phosphates, we can eliminate possibility of the formation of complexes **4** and **6**. If the copper chelate is primarily in structure **4**, the rate enhancement due to the copper ion must be necessarily obtained for the present hydrolysis. Thus, we may assign either **5** or **11** to the blue complex obtained

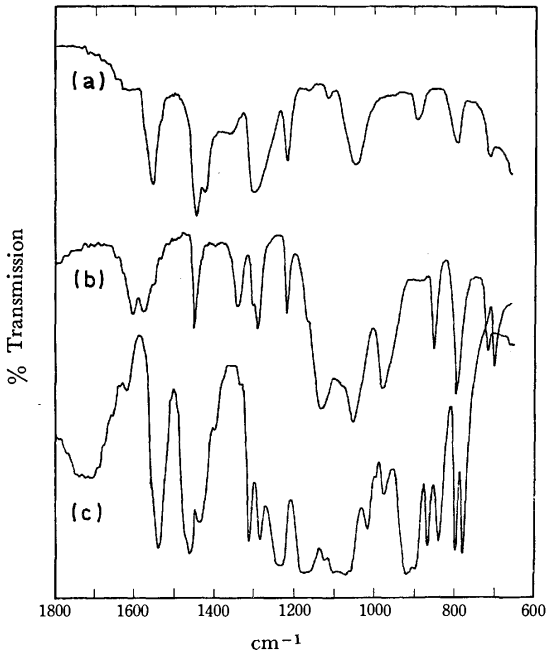


Fig. 6. Infrared spectra (KBr disk method): (a), the copper(II) complex of 3-hydroxy-2-pyridylmethanol; (b), the complex precipitated during the hydrolysis reaction of 3-hydroxy-2-pyridylmethyl phosphate in the presence of copper(II) (see text); (c), 3-hydroxy-2-pyridylmethyl phosphate.

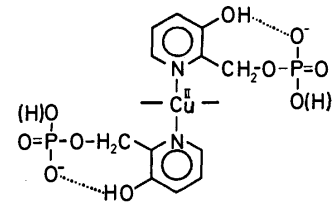
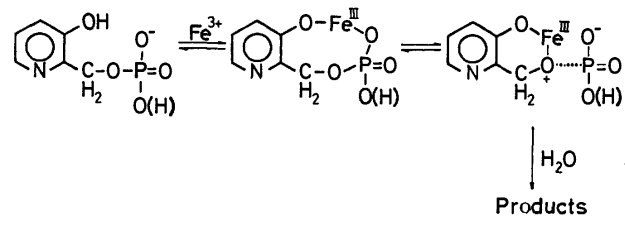


11

during the reaction on the basis of the affinity of the copper ion for nitrogen and/or oxygen donor atoms. There also remains possibility that the complex would be of polymeric nature. Although we are not ready to give a persuasible geometry for the complex, precipitation of the substrate-copper complex may also cause a catalytic inertness of the copper ion. The 3-hydroxy group controlled the geometry of the complex formed in the preliminary equilibrium stage, which resulted in null catalytic efficiency of copper(II) in this work.

For 2-pyridylmethyl[7] and 8-quinolyl[23] phosphoates, the iron(III) ion demonstrated a negative catalytic effect in both hydrolyses. On the other hand, the metal ion showed a large positive catalytic efficiency in the hydrolysis of salicyl phosphate.[24] We ascribed these opposite effects to the difference in affinity of the ferric ion for nitrogen and oxygen donor atoms.[25,26] The iron(III) ion usually demonstrates a larger affinity for an oxygen donor atom rather than for a nitrogen atom. The donor atom existing in the leaving alcohol group of the former two phosphates is nitrogen, while that of the latter phosphate is carboxyl oxygen. 3-Hydroxy-2-pyridylmethyl phosphate has donor atoms of both kinds, the 1-pyridinium nitrogen and the 3-hydroxyl oxygen. Thus, it is of quite interest to examine which donor atom is more effective for catalysis, in reference to the catalytic inertness of the copper ion which demonstrates a larger affinity for a nitrogen donor atom. We see from Fig. 5, that the iron(III) ion shows a positive catalytic effect although the reaction did not follow the strict first-order kinetics. At this stage, validity of the two requirements for the ef-



Scheme 8

fective metal ion catalysis, originally proposed for the bivalent metal ions, is extended to the trivalent metal ion catalysis and a reaction mechanism is put forward in Scheme 8. We take it for granted that this scheme is the most plausible mechanism for the iron catalyzed hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate.

The thorium(IV) ion demonstrated a profound catalytic effect in the hydrolyses of organic phosphates, irrespective of the nature of a leaving alcohol moiety.[10,25] We could, therefore, expect a significant catalysis also for the hydrolysis of the present phosphate. The reaction rate was progressively depressed and consequently deviated from the first-order plot. Nevertheless, a significant effect was observed by all means. For the thorium catalysis observed in the hydrolyses of 3-pyridyl and 8-quinolyl phosphates, the extent of catalytic efficiency in terms of k_c/k_0 was about 10^3 at $-\log[H^+]\sim 2.0$.[10] For the present phosphate, the hydrolysis rate was accelerated only by 30-fold. Although we are not ready to interpret this large difference in catalytic efficiency at present, there is no doubt as to the participation of the 3-hydroxyl group in the present thorium ion catalysis. Judging from the fact that this metal ion does not show a large substrate specificity in hydrolysis relative to other metal ions and possesses the large stability constants with inorganic phosphate,[27] we proposed previously that the catalytic site may be located at the phosphate moiety. The preliminary chelate formation may occur at the terminal phosphate oxygen atoms as illustrated by structure **6**. If this is the case, the relatively strong intramolecular hydrogen bonding between the 3-hydroxyl proton and the phosphate oxygen may interfere with the preliminary chelate formation, shown by structure **12**. Consequently the extent of the catalytic efficiency would be reduced. In addition, the steric hindrance and the inductive effect due to the presence of the 3-hydroxyl group may also affect this chelate formation. In conclusion, through our surveying studies on the polyvalent metal ion catalysis for the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate, we may advance a concept that the introduction of the 3-hydroxyl group to the 2-pyridylmethyl moiety influences to a great extent the metal ion catalysis and spontaneous hydrolysis due to its electronic and environmental nature.

The Rearrangement of 2α-Hydroxy-10β-pinan-3-one with Acetic Anhydride[1]

Toshifumi HIRATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September, 6, 1971)

The reaction of (+)-2α-hydroxy-10β-pinan-3-one (**1**) with acetic anhydride afforded (+)-2α-acetoxy-10β-pinan-3-one (**2**), (−)-carvone (**3**), (−)-4α-acetoxy-10α-pinan-3-one (**4**), (+)-4β-acetoxy-10β-pinan-3-one (**5**), and (−)-4β-acetoxy-10α-pinan-3-one (**6**). The three products, **4**, **5**, and **6**, were newly identified on the basis of a combination of chemical and physico-chemical methods. By examination using the ^{14}C-labelled acetate (**2**), the formation of **4**, **5**, and **6** was shown to arise from the intramolecular rearrangement of **2**. The mechanistic implications of the reaction are given.

In connection with studies of the stereochemistry and the reaction of pinane derivatives,[3,4] we have now found it necessary to examine the rearrangement of 2α-hydroxy-10β-pinan-3-one (**1**) with acetic anhydride. This paper will deal with the structures of some isomers of an α-acetoxyketone produced newly as well as with the mechanistic implications of the reaction.

Results and Discussion

The reaction of (+)-2α-hydroxy-10β-pinan-3-one (**1**) with acetic anhydride under reflux gave an oily reaction product, which was composed of (+)-2α-acetoxy-10β-pinan-3-one (**2**) (in 14% yield based on the sample taken), (−)-carvone (**3**) (1.3%), and three unknown acetates, **4**, **5**, and **6** (39, 17, and 20% respectively). The structures of the acetates, (**4**), (**5**), and (**6**), were established on the basis of the following evidence. The hydrolysis of the acetate (**4**) gave two unknown ketols, **7** and **8**. By acetylation, the former was returned to the acetate (**4**), whereas the latter was returned to a new acetate **9**. Furthermore, the lithium aluminum hydride reduction of the tosylate (**10**) derived from **7** gave two known compounds,

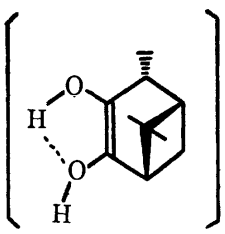
(−)-pinocampheol (**11**) and (+)-neopinocampheol (**12**).[5] These results showed the acetate (**4**) to be 4-acetoxy-10α-pinan-3-one. The ketol (**8**) was similarly confirmed to be 3-hydroxy-10α-pinan-4-one by the fact that its tosylate, **13**, was converted to (+)-neoverbanol (**14**)[5] on reduction with lithium aluminum hydride. It may probably be explained that the ketol (**8**) resulted from the isomerization of the ketol (**7**) through the intermediate (**15**) during the course



15

of the hydrolysis of the acetate (**4**). The acetate (**5**) was derived to (−)-neoisopinocampheol (**16**) and (+)-isopinocampheol (**17**)[5] on the reduction of the tosylate (**18**) derived from the hydrolyzed product, the ketol (**19**), of the original acetate (**5**) with lithium aluminum hydride. This indicates the structure of **5** to be 4-acetoxy-10β-pinan-3-one. It has been established[3,7–9] that, in the reduction of pinane derivatives with lithium aluminum hydride, the reagent approaches from the opposite side of the *gem*-dimethyl bridge and/or the polar group, because of the steric and/or the polar effects. The reduction of the hydroxyketone (**7**) with lithium aluminum hydride afforded *cis*- and *trans*-glycols, (**20**) and (**21**), in equal amounts. This can be ascribed to the competitive contribution between the *gem*-dimethyl and the hydroxyl groups to the reduction. Accordingly, the hydroxyl group of **7** should be *trans* to the *gem*-dimethyl group. On the other hand, the reduction of the acetate (**5**) with lithium aluminum hydride occurred stereospecifically to result in the formation of glycol, **22**. Therefore, the acetoxy group of **5** is surely *cis* to the *gem*-dimethyl group. This was also the case for the hydroxyketone (**8**), and **8** was converted to glycol, **23**. The acetate (**6**) was also derived to the glycol (**23**) on reduction with lithium aluminum hydride. This shows the structure of **6** to be 4β-acetoxy-10α-pinan-3-one. Consequently, all the structures of acetates, **4**, **5**, and **6**, together with those of ketol, **8**, and the diols, **20**, **21**, **22**, and **23**, were established, as is shown in the Schemes.

Reaction Mechanism. To clarify the mechanism of the formation of the acetates, (**4**), (**5**), and (**6**), from the hydroxyketone (**1**), the ^{14}C-labeled acetate (**2**), being active at the acetoxy carbonyl group, was treated with acetic anhydride in the same manner as above to give the acetates, (**4**), (**5**), and (**6**), in 21, 7, and 10% yields respectively; all of them retained the expected radioactivity. The treatment of the ^{14}C-labeled acetate (**5**) in the same manner as above yielded the radioactive acetates, (**2**), (**4**), and (**6**), in 2, 21, and 14% yields respectively. These findings suggest that the acetate (**2**) produced from the hydroxyketone (**1**)

5) These authentic samples were prepared in our laboratory by the reduction of the appropriate ketones.[3,6,7]

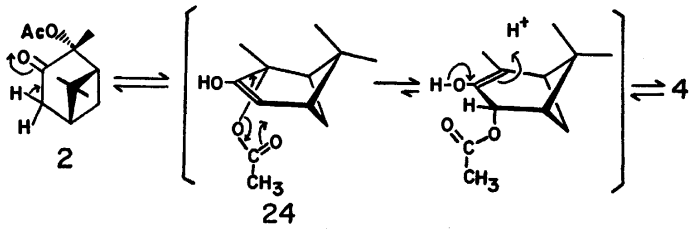

Scheme I

by acetylation suffers intramolecular rearrangements to form **4**, **5**, and **6**. The formation of the acetates is best explained by the initial formation of the acetate (**4**) through the formation of the enolic intermediate (**24**) of the acetate (**2**) by the subsequent intramolecularly-concerted migration of the acetoxy group, and finally by the isomerization of **4** to **5** and **6** through its enolic form, as is shown in Scheme I.

Experimental

The IR spectra were measured on a Perkin-Elmer, 621, Grating Infrared Spectrometer and a Hitachi, EPI-S, Infrared Spectrophotometer. The NMR spectra were recorded on a Varian Associates, HA-100, Spectrometer and a Hitachi Perkin-Elmer, R-20, Spectrometer, using tetramethylsilane as the internal standard. Vapor-phase chromatographic analyses were made on a Perkin-Elmer, F6-D, Gas Chromatograph. Mass spectral analyses were performed on a Hitachi, RMS-4, Mass Spectrometer, ionizing at the order of 80 eV. Radioassays were carried out by converting samples to carbon dioxide by Van Slyke-Folch oxidation,[10] followed by changing the resulting carbon dioxide to barium carbonate, and by counting on planchets at an infinite thickness and with a surface area of 5.0 cm^2 by means of an Aloka, LBC-1, Low-Background 2π-Gas Flow Countmeter. The counts were corrected for the background count, and the counting error was about ±3%.

*Reaction of 2α-Hydroxy-10β-pinan-3-one (**1**) with Acetic Anhydride.* A mixture of 22.0 g of (+)-2α-hydroxy-10β-pinan-3-one [mp 33—34°C, $[\alpha]_D^{25}$ +21.0° (*c* 4.6, EtOH), prepared from (−)-α-pinene following the literature method[11]] and 35.0 g of acetic anhydride was refluxed for 6 hr at 160°C. To the mixture, after cooling, we added 30 m*l* of water, and then it was heated for 30 min at 50°C in order to degrade the remaining acetic anhydride. The reaction mixture was then extracted with ether. The separated ether solution was washed with a dilute sodium bicarbonate solution and water, and then dried over anhydrous sodium sulfate. The removal of the solvent from the ether solution gave 22.9 g of an oily reaction product. The reaction product was chromatographed on a silica-gel column with a mixture of ethyl acetate and *n*-hexane (5 : 95 by volume) in order to separate five eluates.

The first eluate (0.4 g) was composed of complex minor components; it was further subjected to preparative gas chromatography. This resulted in the isolation of (−)-carvone (**3**): $[\alpha]_D^{25}$ −46° (*c* 0.45, MeOH); IR (liq.) 1677 (α,β-unsaturated C=O) and 1651 cm^{-1} (C=C). It was identified by a comparison of the IR spectrum with that of an authentic sample. The second eluate (3.2 g) was proved to be 2α-acetoxy-10β-pinan-3-one (**2**). The third eluate (13.5 g) consisted of two components in the ratio of 2 : 1; it was evaluated from the peak ratio of the C-4 proton signals on the NMR spectrum. A portion (5.0 g) was chromatographed twice on a silica-gel column with a mixture of ethyl acetate and *n*-hexane (1 : 99), but the complete separation was difficult. This procedure resulted in the separation of 4α-acetoxy-10α-pinan-3-one (**4**) (0.66 g) and 4β-acetoxy-10α-pinan-3-one (**6**) (0.11 g), and a mixture of **4** and **6** (4.05 g). The fourth eluate (3.9 g) gave a crystalline mass, which was then recrystallized from *n*-hexane to obtain (+)-4β-acetoxy-10β-pinan-3-one (**5**) (3.5 g). The fifth eluate (1.1 g) consisted of several compounds. One of the compounds was unchanged hydroxyketone (**1**) (0.8 g), but the others failed to separate.

*a) 2α-Acetoxy-10β-pinan-3-one (**2**)*: mp 38—40°C (from *n*-hexane), $[\alpha]_D^{25}$ +23.1° (*c* 0.26, MeOH); UV (MeOH) 300 nm (ε 29.5); IR (KBr) 1745 ($OCOCH_3$) and 1724 cm^{-1} (C=O); NMR (CCl_4) δ 0.86 (s, C_9-3H), 1.37 (s, C_8-3H), 1.49 (s, C_{10}-3H), and 1.92 ppm (s, $OCOCH_3$); mass *m/e* (rel. intensity) 210 (5, M^+), 192 (10), 168 (35) 153 (67), 150 (70), and 43 (100).

*b) 4α-Acetoxy-10α-pipan-3-one (**4**)*: $[\alpha]_D^{25}$ −78.1° (*c* 0.49, MeOH); UV (MeOH) 298 nm (ε 30.2); IR (liq.) 1744 ($OCOCH_3$) and 1728 cm^{-1} (C=O); NMR (CCl_4) δ 1.06 (s, C_9-3H), 1.07 (d, J=7,0 Hz, C_{10}-3H), 1.39 (s, C_8-3H), 2.02 (s, $OCOCH_3$), and 5.28 ppm (b.s, C_4-H); mass *m/e* (rel. intensity) 210 (1, M^+), 168 (2), 150 (7), 127 (16), 85 (56), 83 (25), 55 (30), 43 (82), and 28 (100).

*c) 4β-Acetoxy-10β-pinan-3-one (**5**)*: mp 100.5—101.0°C (from *n*-hexane - ethyl acetate), $[\alpha]_D^{25}$ +66.1° (*c* 6.0, EtOH); UV (MeOH) 292 nm (ε 27.7); IR (KBr) 1747 ($OCOCH_3$) and 1717 cm^{-1} (C=O); NMR (CCl_4) δ 0.93 (s, C_9-3H), 1.21 (d, J=7.0 Hz, C_{10}-3H), 1.33 (s, C_8-3H), 2.06 (s, $OCOCH_3$), and 5.26 ppm (b.s, C_4-H); mass *m/e* (rel. intensity) 210 (1, M^+), 168 (2), 150 (4), 127 (39), 85 (95), 83 (41), 55 (39), and 43 (100).

*d) 4β-Acetoxy-10α-pinan-3-one (**6**)*: $[\alpha]_D^{25}$ −8.5° (*c* 0.37, MeOH); UV (MeOH) 302 nm (ε 27.1); IR (liq.) 1745 ($OCOCH_3$) and 1727 cm^{-1} (C=O); NMR (CCl_4) 0.95 (s, C_9-3H), 1.14 (d, J=7.5 Hz, C_{10}-3H), 1.34 (s, C_8-3H), 2.04 (s, $OCOCH_3$), and 5.09 ppm (b.s, C_4-H); mass *m/e* (rel. intensity) 210 (4, M^+), 168 (2), 150 (7), 127 (20), 85 (25), 83 (20), 55 (11), 43 (25), and 28 (100).

*Hydrolysis of the Acetate (**4**).* To a stirred solution of 10 m*l* of 3 N methanolic potassium hydroxide, we added 2.00 g of **4**; the mixture was kept at room temperature overnight. The mixture was then diluted with 100 m*l* of water and extracted with ether. The removal of the solvent from the ether solution gave 1.40 g of an oily product, which was then chromatographed on a silica-gel column with a mixture of *n*-hexane and an increasing amount of ethyl acetate; we thus separated two components. The first eluate gave 419 mg of **7** and the second eluate, 208 mg of **8**.

*a) 4α-Hydroxy-10α-pinan-3-one (**7**)*: $[\alpha]_D^{25}$ −52.8° (*c* 0.55, MeOH); UV (MeOH) 285 nm (ε 29.7); IR (liq.) 1715 (C=O), and 1371 and 1387 cm^{-1} (*gem*-dimethyl);

10) D. D. Van Slyke and J. Folch, *J. Biol. Chem.*, **136**, 509 (1940).

NMR (CCl_4) δ 1.00 (s, C_9-3H), 1.06 (d, J=7.0 Hz, C_{10}-3H), 1.37 (s, C_8-3H), and 4.07 ppm (b.s. C_4-H). The acetylation of **7** with acetic anhydrade in pyridine gave the acetate (**4**); $[\alpha]_D^{25}$ −75.6° (*c* 0.37, MeOH). The acetate was identified by direct comparisons of its spectral data.

b) 3β-Hydroxy-10α-pinan-4-one (8): mp 44—45°C (from *n*-hexane), $[\alpha]_D^{25}$ −147.7° (*c* 0.27, MeOH); UV (MeOH) 282 nm (ε 36.9); IR (CCl_4) 1716 (C=O), and 1378 and 1391 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.74 (s, C_9-3H), 1.23 (d, J=7.0 Hz, C_{10}-3H), 1.37 (s, C_8-3H), and 3.70 ppm (d, J=6.5 Hz, C_3-H). The acetylation of **8** with acetic anhydride in pyridine gave the acetate (**9**); mp 38—39°C (from *n*-hexane), $[\alpha]_D^{25}$ −135.2° (*c* 0.49, MeOH); UV (MeOH) 284 nm (ε 54.9); IR (KBr) 1743 ($OCOCH_3$) and 1723 cm^{-1} (C=O); NMR (CCl_4) δ 0.81 (s, C_9-3H), 1.15 (d, J=7.0 Hz, C_{10}-3H), 1.38 (s, C_8-3H), 2.12 (s, $OCOCH_3$), and 5.12 ppm (d, J=6.5 Hz, C_3-H); mass *m/e* (rel. intensity) 210 (1, M^+), 168 (15), 150 (4), 135 (15) 95 (26), 83 (65), 55 (43), and 43 (100).

4α-Tosyloxy-10α-pinan-3-one (10). The tosylation of 350 mg of **7** with 500 mg of *p*-toluenesulfonyl chloride in 5 m*l* of pyridine at room temperaure for 5 days gave 545 mg of a crude product, which was then subjected to chromatography on a silica-gel column to give 453 mg of the tosylate (**10**); mp 68—69°C (from *n*-hexane - ethyl acetate); IR (KBr) 1722 (C=O) and 1595 cm^{-1} (C=C); NMR (CCl_4) δ 0.98 (s, C_9-3H), 1.05 (d, J=7.0 Hz, C_{10}-3H), 1.39 (s, C_8-3H), 2.44 (phenyl methyl), 4.80 (b.s, C_4-H), and 7.25—7.88 ppm (q, phenyl proton, 4H).

3β-Tosyloxy-10α-pinan-4-one (13). The treatment of 100 mg of **8** with 150 mg of *p*-toluenesulfonyl chloride in 3 m*l* of pyridine gave 137 mg of the tosylate (**13**); mp 118.0—118.5°C (from *n*-hexane - ethyl acetate); IR (KBr) 1740 (C=O) and 1598 cm^{-1} (C=C); NMR (CCl_4) δ 0.78 (s, C_9-3H), 1.26 (d, J=7.0 Hz, C_{10}-3H), 1.34 (s, C_8-3H), 2.44 (s, phenyl methyl), 4.73 (d, J=6.5 Hz, C_3-H), and 7.20—7.90 ppm (q, phenyl proton, 4H).

Reduction of the Hydroxyketone (7), To a stirred solution of 127 mg of **7** in 15 m*l* of ether, we added 100 mg of lithium aluminum hydride under ice-cooling, and then the mixture was refluxed for 2 hr. The mixture, after cooling, was treated with water and then dilute hydrochloric acid. The ether extract gave 120 mg of an oily product, which was separated by preparative thin-layer chromatography on silica-gel with a 3 : 7 mixture of ethyl acetate and *n*-hexane to give 60 mg of the *cis*-glycol, **20**, and 55 mg of *trans*-glycol, **21**.

a) 10α-Pinan-3α,4α-diol (20): mp 52—53°C (from *n*-hexane), $[\alpha]_D^{25}$ −1.0° (*c* 0.59, MeOH); IR (0.002 M CCl_4) 3627 (OH, free) and 3537 cm^{-1} (OH, intramol. bonded); NMR (CCl_4) δ 0.81 (s, C_9-3H), 0.97 (d, J=7.0 Hz, C_{10}-3H), 1.23 (s, C_8-3H), and 4.00 ppm (b.s, C_3- and C_4-H); mass *m/e* (rel. intensity) 170 (0.5, M^+). 152 (2), 137 (3), 85 (100), 43 (73), and 41 (54).

b) 10α-Pinan-3β,4α-diol (21): mp 146.0—146.5°C (from ethyl acetate), $[\alpha]_D^{25}$ −2.9° (*c* 0.14, MeOH); IR (0.002 M CCl_4) 3616 cm^{-1} (OH, free); NMR (pyridine) δ 0.98 (s, C_9-3H), 1.20 (d, J=7.0 Hz, C_{10}-3H), 1.22 (s, C_8-3H), 3.89 (d.d, J=7.0 and 6.0 Hz, C_3-H), and 4.42 ppm (b.d, J=6.0 Hz, C_4-H); mass *m/e* (rel. intensity) 170 (0.5, M^+), 152 (6), 137 (6), 85 (100), 43 (85), 41 (72), and 28 (87).

Reduction of the Hydroxyketone (8). A solution of 113 mg of **8** in 10 m*l* of ether was added to a strired suspension of 100 mg of lithium aluminum hydride in 10 m*l* of ether, and then the mixture was refluxed for 2 hr. After the degradation of the excess reagent, the mixture was extracted with ether to yield 110 mg of a crude product, which was subjected to preparative thin-layer chromatography on silica-gel with a mixture of ethyl acetate and *n*-hexane (3 : 7) to separate 91 mg of 10α-pinan-3β,4β-diol (**23**): mp 95.5—96.0°C (from a mixture of ethyl acetate and *n*-hexane), $[\alpha]_D^{25}$ −24.7° (*c* 0.11, MeOH); IR (0.002 M CCl_4) 3626 (OH, free) and 3547 cm^{-1} (OH, intramol. bonded); NMR (CCl_4) δ 1.00 (s, C_9-3H), 1.02 (d, J=7.0 Hz, C_{10}-3H), 1.19 (s, C_8-3H), 3.48 (m, C_3-H), and 4.10 ppm (b.s, C_4-H); mass *m/e* (rel. intensity) 137 (6), 85 (92), 43 (100), and 41 (77).

Reduction of the Tosylate (10). To a stirred suspension of 300 mg of lithium aluminum hydride in 15 m*l* of ether, we added a solution of 300 mg of **10** in 5 m*l* of ether at room temperature over a 30-min period, after which the mixture was further refluxed for 4 hr. The ether extract gave 139 mg of a reaction product, which was separated into two components by thin-layer chromatography on silica-gel with a mixture of ethyl acetate and *n*-hexane (3 : 7). The more eluted component (89 mg) was confirmed to be (−)-pinocampheol (**11**); mp 66—67°C (from *n*-hexane) (lit,[11] mp 67°C), $[\alpha]_D^{25}$ −57.2° (*c* 0.33, MeOH); IR (KBr) 3350 (OH), and 1370 and 1388 cm^{-1} (*gem*-dimethyl); NMR δ 0.92 (s, C_9-3H), 1.00 (d, J=7.0 Hz, C_{10}-3H), 1.21 (s, C_8-3H), and 3.56 ppm (d.t, J=9.0 and 7.0 Hz, C_3-H); the 3,5-dinitrobenzoate, mp 118—119°C (lit,[12] mp 118—119°C). The other component (21 mg) was found to be (+)-neopinocampheol (**12**); mp 26—27°C (from *n*-hexane) (lit,[11] mp 27°C), $[\alpha]_D^{25}$ +14.0° (*c* 0.15, MeOH); IR (Nujol) 3440 (OH), and 1370 and 1391 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.77 (s, C_9-3H), 0.93 (d, J=7.0 Hz, C_{10}-3H), 1.21 (s, C_8-3H), and 3.99 ppm (b.t, J=6.5 Hz, C_3-H). These physical properties and spectral data coincided with those of authentic samples.[5]

Reduction of the Tosylate (13). To a stirred suspension of 140 mg of lithium aluminum hydride in 5 m*l* of ether, we added a solution of 130 mg of **13** in 5 m*l* of ether at room temperature over a 10-min period. After refluxing for 3 hr, the treatment of the mixture in the usual manner gave 61 mg of a reaction product, which was chromarographed on a silica-gel column to separate 13 mg of the pinan-diol (**23**) (mp 95.5—96.0°C) and 42 mg of (+)-neovervanol (**14**); mp 78—79°C (from *n*-hexane), $[\alpha]_D^{25}$ +11.6° (*c* 0.17, MeOH); IR (KBr) 3340 (OH), and 1370 and 1389 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.88 (d, J=7.0 Hz, C_{10}-3H), 1.06 (s, C_9-3H), 1.21 (s, C_8-3H), and 4.14 ppm (m, C_4-H). The spectral data coincided with those of an authentic sample.[5]

Hydrolysis of the Acetate (5). To a stirred solution of 420 mg of **5** in 20 m*l* of methanol, we added 10 m*l* of 0.1 N methanolic sodium hydroxide at 15°C over a 10-min period. The mixture was further stirred for 20 min and then extracted with ether to give 292 mg of hydroxyketone, **19**; mp 67—68°C (from *n*-hexane), $[\alpha]_D^{25}$ +33.5° (*c* 0.25, MeOH); UV (MeOH) 288 nm (ε 29.8); IR (KBr) 1710 (C=C), and 1376 and 1390 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.86 (s, C_9-3H), 1.20 (d, J=7.0 Hz, C_{10}-3H), 1.32 (s, C_8-3H), and 3.98 ppm (b.s, C_4-H). This hydroxyketone was derived to the acetate (**6**) by acetylation.

4β-Tosyloxy-10β-pinan-3-one (18). The treatment of 200 mg of **19** with 300 mg of *p*-toluenesulfonyl chloride in 4 m*l* of pyridine at room temperature for 5 days gave 370 mg of the tosylate, **19**; mp 97—98°C (from *n*-hexane - ethyl acetate); IR (KBr) 1734 (C=O) and 1597 cm^{-1} (C=C); NMR (CCl_4) δ 0.92 (s, C_9-3H), 1.16 (d, J=7.5 Hz, C_{10}-3H), 1.35 (s, C_8-3H), 2.45 (s, phenyl methyl), 4.78 (b.s,

11) H. Schmidt, *Chem. Ber.*, **77**, 544 (1944).

12) T. Takemoto, G. Kusano, and H. Hikino, *Yakugaku Zasshi*, **86**, 1162 (1966).

C_4-H), and 7.20—7.90 ppm (q, phenyl proton, 4H).

*Reduction of the Acetate (**5**).* A suspension of 110 mg of **5** and 120 mg of lithium aluminum hydride in 50 m*l* of ether was refluxed for 7 hr under agitation, and then it was treated in the usual manner to give 80 mg of glycol, **22**; mp 79—80°C (from *n*-hexane); IR (0.0024 M CCl_4) 3634 (OH, free) and 3533 cm^{-1} (OH, intramol. bonded); NMR ($CDCl_3$) δ 1.10 (d, J=7.5 Hz, C_{10}-3H), 1.16 (s, C_9-3H), 1.20 (s, C_8-3H), and 4.35 ppm (m, C_3- and C_4-H); mass *m/e* (rel. intensity) 170 (1, M^+), 152 (1), 137 (7), 86 (92), 85 (100), 43 (54), and 41 (36).

*Reduction of the Tosylate (**18**).* To a stirred suspension of 300 mg of lithium aluminum hydride in 10 m*l* of ether, we added a solution of 290 mg of **18** in 15 m*l* of ether at room temperature over a 30-min period; this was followed by further refluxing for 3 hr. The mixture, after the usual treatment, gave 185 mg of a reaction product, which was subjected to column-chromatography on silica-gel with a mixture of *n*-hexane and an increasing amount of ethyl acetate to give 90 mg of (−)-neoisopinocampheol (**16**) [mp 50.5—51.0°C (from *n*-hexane) (lit,[11] mp 48°C), $[\alpha]_D^{25}$ −34.5° (*c* 0.75, C_6H_6); IR (KBr) 3340 (OH), and 1369 and 1388 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 1.05 (d, J=7.0 Hz, C_{10}-3H), 1.06 (s, C_9-3H), 1.18 (s, C_8-3H), and 4.35 ppm (d.t, J=5.0 and 10.0 Hz, C_3-H)], 20 mg of (+)-isopinocampheol (**17**) [mp 56—57°C (from *n*-hexane) (lit,[11] mp 57°C), $[\alpha]_D^{25}$ +29.0° (*c* 0.15, C_6H_6); IR (KBr) 3280 (OH), and 1372 and 1388 cm^{-1} (*gem*-dimethyl); NMR (CCl_4) δ 0.91 (s, C_9-3H), 1.08 (d, J=7.0 Hz, C_{10}-3H), 1.20 (s, C_8-3H), and 3.94 ppm (d.t, J=9.0 and 5.0 Hz, C_3-H)], and 18 mg of 10β-pinan-3β,4β-diol (**22**) (mp 79—80°C).

*Reduction of the Acetate (**6**).* A solution of 50 mg of **6** in 15 m*l* of ether was treated with 50 mg of lithium aluminum hydride under reflux for 1 hr to give 39 mg of the pinanediol (**23**); mp and mixed mp 95—96°C, $[\alpha]_D^{25}$ −21.0° (*c* 0.20, MeOH).

Preparation of Radioactive Acetic Anhydride. To a stirred suspension of 1-^{14}C-sodium acetate (3.50 g; 8620±80 dpm/mmol) in ether, we added acetyl chloride (4 m*l*) over a 5-min period at room temperature. The mixture was then further stirred for 3 hr. The distillation of the reaction gave acetic-1-^{14}C anhydride (2.82 g; 4462±40 dpm/mmol).

Rearrangement of Radioactive Acetate. 2α-(1-^{14}C-Acetoxy)-10β-pinan-3-one (**2**) and 4β-(1-^{14}C-acetoxy)-10β-pinan-3-one (**5**) were prepared by treating 2α-hydroxy-10β-pinan-3-one (**1**). The radioactive acetic anhydride in the manner as above. The radioactive acetates, (**2**) and (**5**), were then each treated with acetic anhydride in the manner to be shown below. The reaction product was purified by column-chromatography, followed preparative thin-layer chromatography or recrystallization. The proportion of products was evaluated on the basis of the gas chromatography and the peak ratio of the C-4 proton signals on the NMR spectra.

*a) Rearrangement of the ^{14}C-Acetate (**2**)*: A solution of 840 mg (0.004 mol) of the radioactive acetate (**2**) (187.3±2.0 dpm/mmol) in 1632 mg (0.016 mol) of acetic anhydride was refluxed for 5 hr. The usual treatment of the reaction mixture then gave 830 mg of an oily product, which was composed of 54 mg of the acetate (**4**) (119.2±2.0 dpm/mmol), 58 mg of the acetate (**5**) (97.3±2.0 dpm/mmol), 25 mg of the acetate (**6**) (104.6±2.0 dpm/mmol), and 257 mg of the unchanged acetate (**2**) (136.1±2.0 dpm/mmol).

*b) Rearrangement of the ^{14}C-Acetate (**5**)*: A sample of 1680 mg (0.008 mol) of the radioactive acetate (**5**) (182.4±2.0 dpm/mmol) was refluxed with 3264 mg (0.032 mol) of acetic anhydride for 5 hr. The ether extract of the mixture gave 1632 mg of an oily product, which was composed of 15 mg of **2** (126.5±2.0 dpm/mmol), 91 mg of **4** (138.7±2.0 dpm/mmol), 32 mg of **6** (131.4±2.0 dpm/mmol), and 660 mg of the unchanged **5** (170.2±2.0 dpm/mmol).

The author wishes to express his hearty gratitude to Dr. Takayuki Suga of Hiroshima University for his guidance and encouragement and to Dr. E. von Rudoloff of National Research Council of Canada, Saskatchewan, Canada, for measuring the NMR spectra with a Varian Associates, HA-100, Spectrometer.

Preparation of Cyclamenaldehyde by Selective Hydrogenation in Some Cobalt Carbonyl Complex Catalysts under Oxo Conditions[1]

(Received May 18, 1971)

Selective hydrogenation of *p*-isopropyl-α-methylcinnamaldehyde to cyclamenaldehyde in some cobalt carbonyl complex catalyst systems has been investigated under several oxo conditions. The yield of the aimed aldehyde was improved as much as 84 to 86.3% under controlled conditions. Selectivity of the hydrogen increased with the decrease of temperature and the increase of partial pressure of hydrogenation in a water gas. A maximum yield (84%) was obtained with solvents such as isopropyl ether and hexane when used in 2-fold volume for the cinnamaldehyde. A tris(2-bromoethyl) phosphite-substituted cobalt carbonyl complex catalyst gave the best yield (86.3%) as compared with catalysts unsubstituted and substituted with PR_3, $P(OR)_3$, and $PO(OR)_3$ (R=alkyl, aryl).

Cyclamenaldehyde, one of the principal aromatic chemicals, has been prepared industrially by two well known superior processes, *viz.*, dehydrogenation of the corresponding alcohol using a Cu-Zn catalyst[2] and hydrogenation of *p*-isopropyl-α-methylcinnamaldehyde over 5% Pd on a charcoal catalyst.[3-5]

Recently the hydrogenation of α,β-unsaturated carbonyl compounds to give saturated carbonyl compounds was reported on the following catalyst system; tri(triphenylphosphine)chlororhodium by Jardine and Wilkinson,[6] palladium boride by Kawai *et al*,[7] and cobalt hydrocarbonyl by Goetz and Orchin, who found that the saturated carbonyl compounds were produced at 25°C under one atmosphere of carbon monoxide, while the saturated carbonyl compounds formed were reduced very slowly into the corresponding alcohols.[8]

We found that dicobalt octacarbonyl and its complex substituted with tris(2-bromoethyl) phosphite were useful catalysts for selective hydrogenation to the double bond of *p*-isopropyl-α-methylcinnamaldehyde under oxo conditions.

Experimental

Materials. *p*-Isopropyl-α-methylcinnamaldehyde was prepared according to the Knorr method:[9] bp 117—120°C/2 mmHg, d_{20}^{20} 0.9986, n_D^{20} 1.4343.

The dicobalt octacarbonyl (mp 51°C) was prepared in a 51.4% yield according to the method in literature,[11] which involved the reaction between cobalt-hydroxide and a 150 kg/cm² water gas (H_2 : CO, 1 : 1, purchased from the Takachiho Commercial Co., Ltd.).

The complex of dicobalt octacarbonyl substituted with the following ligands in molar ratio of 1 : 2 were prepared in isopropyl ether under a purified nitrogen flow;[10] tiphenylphosphine, triphenyl phsphite, tributylphosphine, tributyl phosphite, tris(2-bromoethyl) phosphite, triphenyl phosphate, and tricresyl phosphate. They were of chemically pure grade and purchased from the Tokyo Kasei Co., Ltd.

Procedure. After *p*-isopropyl-α-methylcinnamaldehyde (18.8 g, 0.1 mol) and a solution of dicobalt octacarbonyl (0.56 g, 0.0016 mol) in 40 m*l* of isopropyl ether had been put into a 300 m*l* stainless steel autoclave equipped with an outlet tube for sampling, the air in the autoclave was flushed with nitrogen several times. The water gas was then charged at pressure from 60 to 80 kg/cm² at room temperature.

The autoclave was then heated up to the desired temperature with stirring. Aliquots of the reaction mixture were withdrawn from the autoclave at the prescribed time interval during the reaction, and submitted to glc.

Hydrogenation was continued until the peak of *p*-isopropyl-α-methylcinnamaldehyde disappeared, and the end point was detected from the gauge pressure-time relation. After the hydrogenation, the autoclave was cooled, purged, and then a solution of triphenylphosphine (1.7 g) in isopropyl ether (300 m*l*) was added. The insoluble precipitates (phosphine complex) were then filtered off. The resulting filtrate was neutralized with 200 m*l* of an aqueous solution of 5% sodium carbonate, and dried over sodium sulfate. After the removal of ether from the solution, an oily product obtained as a residue was distilled *in vacuo* to separate volatile products.

Identification and Analysis of Products. Cyclamenaldehyde and cyclamen alcohol were separated by the distillation of the products of Run 9 in Table 2 with a packed type rectifier, and identified by NMR spectra in carbon deuterium trichloride with tetramethylsilane as an internal standard on a JEOL 4H-100 spectrometer. Cyclamenaldehyde: bp 98—100°C/1 mmHg, d_{20}^{20} 0.9486, n_D^{20} 1.5080. NMR spectrum: 1.05 ppm (d) doublet (J=2.5) methyl 3H; 1.20 ppm (d) doublet (J=2.5) isopropyl methyl 6H; 2.64 ppm (m) multiplet methine H; 2.85 ppm (m) multiplet isopropyl methine H; 7.08 ppm (m) multiplet phenyl 4H; 9.26 ppm (s) singlet aldehyde H.

Cyclamen alcohol: bp 120—122°C/1 mmHg, d_{20}^{20} 0.9492, n_D^{20} 1.5080. NMR spectrum: 0.90 ppm (d) (J=3.0) methyl 3H; 1.21 ppm (d) (J=2.0) isopropyl methyl 6H; 1.80 ppm (bs) broad singlet hydroxy H; 1.91 ppm (m) methine H; 2.87 ppm (m) isopropyl methine H; 3.47 ppm (d) hydroxy methylene 2H; 7.09 ppm (m) phenyl 4H.

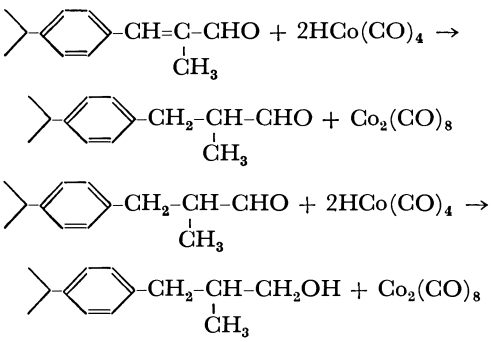
The composition of the products was determined by glc using a gas chromatograph (Kotaki GU-21) with a 2 m stainless steel column of KF 54 (5% by weight) on cellite 545 sk (60—80 mesh) at 180°C. Both of the above products were analyzed within a relative experimental error of ±1.5%. The standard materials cyclamenaldehyde and cyclamen alcohol were prepared by the following procedures.[2] Cyclamenaldehyde was prepared by dehydrogenation of cyclamen alcohol with a Cu-Zn catalyst (bp 110—112°C/4 mmHg, d_{20}^{20} 0.9498, n_D^{20} 1.5083), and cyclamen alcohol by the catalytic hydrogenation of *p*-isopropyl-α-methylcinnamaldehyde over a nickel-diatomaceous earth catalyst (bp 130—132°C/4 mmHg, d_{20}^{20} 0.9490, n_D^{20} 1.5076).

Results and Discussion

Hydrogenation of p-*Isopropyl-α-methylcinnamaldehyde Using Dicobalt Octacarbonyl Catalyst.* It is well known that cobalt hydrocarbonyl is formed by the reaction with dicobalt octacarbonyl and a water gas (H_2 : CO, 1 : 1) at 100°C under a pressure greater than 45 kg/cm².

From the results it is suggested that the hydrogenation of *p*-isopropyl-α-methylcinnamaldehyde into cyclamenaldehyde with a minor amount of $Co_2(CO)_8$ under oxo conditions proceeds by the repetition of the process given by the following equations.

$$Co_2(CO)_8 + H_2 \rightleftharpoons 2HCo(CO)_4 \quad (1)$$



$$\xrightarrow{2HCo(CO)_4}$$

$$\xrightarrow{Co_2(CO)_8}$$

$$\xrightarrow{2HCo(CO)_4}$$

$$\xrightarrow{Co_2(CO)_8} \quad (2)$$

However, it should be noticed that cyclamenalcohol may be formed simultaneously by the reaction of cyclamenaldehyde with $HCo(CO)_4$ at such a high temperature.

Increase in the partial pressure of carbon monoxide in the water gas would decrease the concentration of the cobalt hydrocarbonyl in the system (Eq. (1)), resulting in either a slower or a higher-temperature hydrogenation. The effect of solvents such as isopropyl ether and *n*-hexane upon the product distribution should also be examined under various conditions. The results obtained are summarized in Table 1.

1) Effect of the Amount of Catalyst Complex and Reaction Temperature. Increase in $Co_2(CO)_8$ from 5 to 18% (by weight) for the cinnam aldehyde served to shorten the reaction time, but the undesired cyclamen alcohol and resinous matter tended to increase it (Runs 1—3, Table 1).

A decrease in the catalyst from 5 to 1% (Run 5 and 6) was necessary to raise the reaction temperature, resulting in an increase in the above two compounds.

It was found that the increase of the partial pressure of hydrogen in a water gas at 55 kg/cm² lowered the reaction temperature, resulting in an increase in the yield of cyclamenaldehyde to 80.3% of the theoretical (Run 7, Table 1).

A higher molar ratio of carbon monoxide in a water gas at 45 kg/cm² (H_2 : CO, 1 : 2) raised the reaction temperature from 100—130°C to 140—145°C, giving greater amounts of cyclamen alcohol and resinous matter (Run 3 and 4, Table 1).

2) Solvent Effect. When isopropyl ether or *n*-hexane was used in 5—2-fold volume for the cinnam aldehyde, the reaction temperature was lowered from 100—130°C to 90—125°C, giving rise to an increase in the amount of cyclamenaldehyde as well as a decrease in that of the alcohol and resinous matter (compare Runs 10—12 with Run 8 in Table 1).

The higher molar ratio of hydrogen in the water gas, *e.g.* 65 kg/cm² water gas (H_2 : CO, 12 : 1) used instead of the 100 kg/cm² gas (H_2 : CO, 1 : 1) much lowered the reaction temperature from 90—125°C to 90—96°C and increased the yield of cyclamenaldehyde as much as 84.0% (Runs 11 and 12, Table 1).

By employing an 1.5-fold volume of isopropyl ether, the yield of the cyclamenaldehyde was lowered from 83.2 to 77.8%, accompanied by an increase of distillation residue from 8.9 to 13.6% (Runs 9 and 10, Table 1). From the results, the optimum conditions for yielding cyclamenaldehyde can be given as follows. *p*-Isopropyl-α-methylcinnam aldehyde is reduced at 90—96°C for 6.5 hr under stirring with a 65 kg/cm² water gas (H_2 : CO, 12 : 1) in a 2-fold volume of isopropyl ether with 3% (by weight) $Co_2(CO)_8$ for the cinnamaldehyde.

3) Effect of Ligand Substitution upon Selective Hydrogenation In order to improve the yield of cyclamenaldehyde, hydrogenation was carried out with ligand-substituted cobalt carbonyl complex catalysts. The ligand substitution (Table 2) was performed with the following compounds.

Tributylphosphine, triphenylphosphine, tributyl phosphite, tris(2-bromoethyl) phosphite, triphenyl phosphite, triphenyl phosphate, and tricresyl phosphate.[10] Hydrogenation with these complex catalysts was carried out in a 5-fold volume of isopropyl ether for the cinnamaldehyde at 122—180°C with a 100 kg/cm² water gas (H_2 : CO, 1 : 1). In the case of the tributylphosphine, tributyl phosphite, or triphenylphosphine complex, the reaction proceeded at higher temperature and the yield of cyclamenaldehyde was lowered, while the cyclamenalcohol increased in quantity as compared with the other cases.

The triphenyl phosphite complex catalyst, and triphenyl phosphate- or tricresyl phosphate-$Co_2(CO)_8$ catalyst gave a comparable yield of cyclamenadehyde and a product distribution similar to that given in

the $Co_2(CO)_8$ system unsubstituted (Run 4—7, Table 2).

Use of the tris(2-bromoethyl) phosphite afforded a maximum yield of cyclamenaldehyde (86.3%) (Runs 8—11, Table 2).

The increase in cyclamen alcohol can reasonably be interpreted in terms of the stability of the cobalt carbonyl phosphine and phosphite complexes, in which the scission of cobalt–carbon coordination in the π-oxapropenyl intermediate complex occurred at a relatively higher temperature. Hydridic character of the cobalt hydrocarbonyl complex persisted even at the higher temperature, and resulted in facilitating the hydrogenation of cyclamenaldehyde to cyclamen alcohol.

The increase in cyclamenaldehyde can be interpreted in terms of the fallen electron density of cobalt atom in the complex, which was caused by an electron-attracting effect of the 2-bromoethyl group and which favored the enhancement of the back donation of π-oxapropenyl intermediate as well as the transformation from σ- to π-intermediates of the complex.

The smaller yield in cyclamen alcohol may result from the difficulty in the formation of the cyclic transition state intermediate between the tris(2-bromoethyl) phosphite-substituted cobalt hydrocarbonyl complex and cyclamenaldehyde based on the steric effect of the complex.

The authors wish to express their thanks to Mr. S. Hasegawa, President of T. Hasegawa Co., Ltd, for his permission to publish this paper.

Metal Catalysts Supported on Zeolite. I. A Study on Platinum Particles Distribution

Toshihiko KUBO, Hiromichi ARAI, Hiroo TOMINAGA, and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 14, 1971)

Zeolite 13Y, loaded with platinum cations by ion exchange, was calcined in the air and subsequently reduced in a hydrogen stream. Hydrogen and carbon monoxide adsorption studies, together with an electron microscopic observation of the catalyst, revealed that the size distribution of platinum particles is controlled by the calcination temperature. The hydrogen chemisorption method gave the average particle diameters, which were in fairly good agreement with the observations made by means of an electron microscope on the catalyst with a platinum particle diameter larger than 20 Å, while trace amounts of hydrogen chemisorption were observed for platinum particles less than 20 Å.

In the preparation of metallic catalysts supported on carriers, the relationship between the size distribution of metallic particles and their adsorptive and catalytic activities has constituted one of the most interesting subjects of study. An incentive to the study from a practical point of view is the need for the efficient utilization of metals, especially of such highly priced ones as those in the platinum group. Several physicochemical techniques, such as X-ray diffraction-line-broadening, electron microscope, and gas chemisorption, have been developed for the dispersion state analysis of the metal. These studies involve the following: the influence of the platinum crystallite size on the selectivity of hydrocarbon reforming,[1] the crystallite size and the specific activity for benzene hydrogenation of platinum/silica catalysts,[2] the influence of the crystallite size on the infrared-active nitrogen adsorption on nickel, palladium and platinum,[3] the preparation of a highly dispersed platinum catalyst supported on silica gel,[4] X-ray adsorption edge study of zeolite supported platinum,[5] the adsorptive and catalytic properties of metal crystallites,[6] and some relations between the structural and catalytic properties of alumina-supported platinum.[7] Echigoya *et al.*,[8] and Shirasaki and Furuoya[9] reported that the temperature of calcining $Pd(NH_3)_4^{2+}$ on silica and silica-alumina in the air affected the size distribution of the palladium crystallites formed by subsequent hydrogen reduction. Further, they studied the dispersion state and the structure of palladium crystallites, in particular of the catalysts calcinined at rather high temperatures (>300°C), by X-ray diffraction-line-broadening, electron microscope, and carbon monoxide chemisorption techniques.

In the present study, we were especially interested in the catalysis of fine platinum particles, such as those less than 20 Å in diameter, on zeolite. The platinum

catalysts were prepared by ion exchange and subsequent calcination in the air, followed by reduction in hydrogen. Particularly, we attempted to establish a method of preparation by which to achieve a desired dispersion state of platinum crystallites, which were analyzed by electron microscope and also by hydrogen chemisorption techniques. The temperature of calcining ion exchanged zeolite in the air was found to be the key factor, whereby the particle size distribution after reduction is affected. The hydrogen chemisorption technique was shown to give an average diameter of particles which is in fairly good agreement with that obtained by electron microscopic examination of the catalyst with a platinum particle diameter of over 20 Å on the average.

Experimental

Catalyst Preparation. Platinum catalysts incorporated with a carrier, zeolite 13Y, were prepared by ion exchange, followed by calcination and reduction. The zeolite of Linde molecular sieves Y type SK-40 was employed. Its analysis indicated a chemical composition of SiO_2 63.5%, Al_2O_3 23.5%, Na_2O 13.0%, Cl 0.05%, and Fe 0.05% by weight.

The catalysts of the Pt-NaY type were prepared, in this work, according to the following procedure. The zeolite 13Y was degassed by stirring in deionized water, 20 times by weight, at 98—100°C for 2 hr. Then a given amount of aqueous solution of 0.01 mol/*l* $Pt(NH_3)_4Cl_2$ was added slowly, drop by drop; then the resulting mixture was stirred for another 3 hr at 98—100°C. The ion exchanged zeolite was obtained by filtration and washed thoroughly with deionized water until no chloro anion was detected in the filtrate. The zeolite was dried at 110°C for 3 hr, calcined in the air at a given temperature for 3 hr, and then, prior to use, reduced in a hydrogen stream at 500°C for 3 hr to give a zeolite-supported platinum catalyst.

The catalysts of the Pt-NH_4Y type were prepared in the same way except for the pretreatment of the zeolite 13 Y with aqueous NH_4Cl solution to replace the Na^+ with NH_4^+. This treatment was carried out before the ion exchange with $Pt(NH_3)_4^{2+}$.

The platinum contents in the catalysts were determined the colorimetric method proposed by Ayres and Meyer.[10]

Dispersion State Analysis. Electron microscopic observation and chemisorption experiments were carried out in order to characterize the platinum particle size distribution on zeolite.

The electron microscope employed was of Hitachi-HV·11·DS type. A lightly ground catalyst was dispersed in isopropanol; a drop of the suspension was then evaporated on a carbon film to get a specimen which was subjected to observation at a magnification of 108,000 x. Subsequent photographic enlargement to 324,000 x was practicable.

Conventional BET apparatus was used for the chemisorption experiment. The catalyst sample was allowed to stand in a vacuum system ($<10^{-3}$ mmHg) for 2 hr at 400°C. and then it was cooled to 25°C. A given amount of hydrogen was introduced in order to attain a pressure equilibration in 30—60 min at 25°C. Blank tests were made for the carriers, and a trace amount of hydrogen was found to be adsorbed at pressures ranging from 10^{-3} to 10^{-1} mmHg at 25°C. This might possibly be the result of the presence of iron in the zeolite (0.05%). Due calibration was made for the volume adsorption on carriers in order to obtain the net value of adsorption on platinum particles.

Carbon monoxide adsorption on platinum particles was measured by the same procedure as for hydrogen chemisorption.

Results and Discussion

Electron Micrographs. The electron microscopic observation of the catalyst revealed that the platinum particles supported on zeolite varied in their diameter sizes as a function of the calcination temperature in the air. These experimental results are summarized in Table 1.

Catalyst 1, the zeolite carrier, naturally showed no platinum particle. Catalyst 2 indicated only a few particles, ranging from 10 to 15 Å in diameter. Most of the platinum, therefore, would be dispersed in an atomic state and/or in fine particles less than 10 Å in diameter,[11] which is the limit of resolution of the electron microscope employed. It should be noted that 10 Å is close to the largest pore size of the zeolite 13Y. These findings are similar to the observations

TABLE 1. PLATINUM PARTICLE SIZE DISTRIBUTION AS A FUNCTION OF TREATING PROCEDURE

No.	Catalyst	Treating procedure			Platinum particle diameter range (Å)
		Calcination, 3 hr, at	Calcination in the air, at	H_2 reduction, 3 hr, at

11) P. H. Lewis[5] found that about 60% of the Pt of his Pt-CaY catalyst was soluble in HF. He attributed this to much smaller crystals, although it may have been due to incompletely reduced or reoxidized platinum.

reported by Benesi *et al.*[4] on silica gel-supported platinum catalyst made by ion exchange. Numerous tiny particles ranging from 15 to 55Å in diameter were found on the catalyst 4 (Fig. 1). These particles must exist on the external surface of the zeolite. In the case of the catalyst 6, bulky particles of platinum were noted; their size distribution was from 30 up to 680 Å (Fig. 2). These results suggest that the growth of platinum was accelerated by the temperature of calcination in the air prior to reduction in a hydrogen stream.

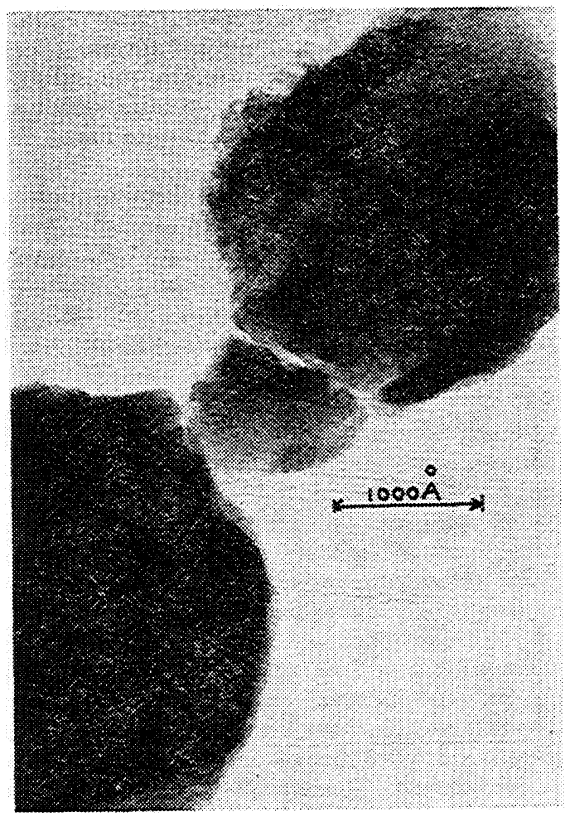

Fig. 1. Electron micrograph of the catalyst 4.

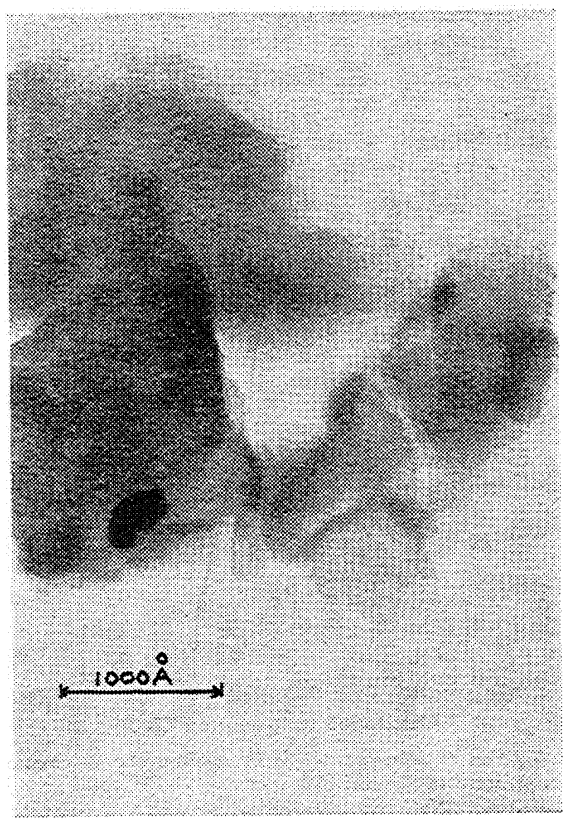

Fig. 2. Electron micrograph of the catalyst 6.

In the cases of the Pt-NH_4Y type catalysts, No. 10 to 12, the platinum particle size distribution seemed less sensitive to the calcination and a fairly good dispersion of platinum on the carrier was still maintained at temperatures ranging from 400 to 600°C. As an example, electron micrograph of the catalyst No. 11

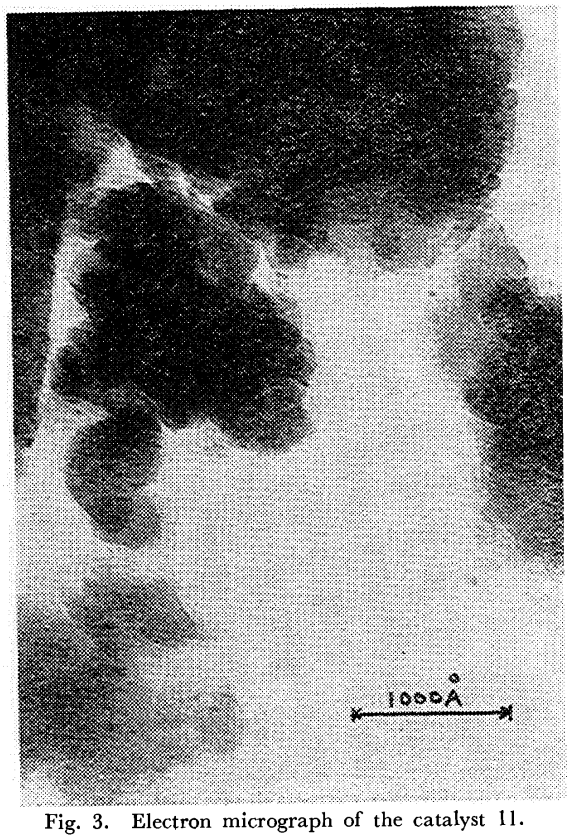

Fig. 3. Electron micrograph of the catalyst 11.

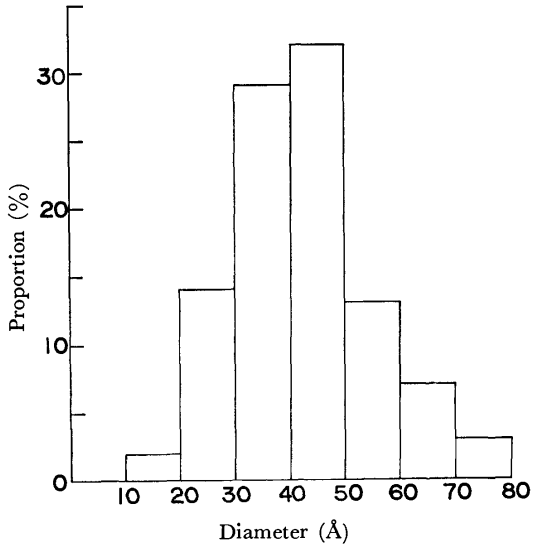

Fig. 4. Size distribution of platinum particles on the catalyst 11.

is shown in Fig. 3, while its particle size distribution is presented in Fig. 4.

The different susceptibilities to the calcining temperature between the Pt-NaY Type and the Pt-NH_4Y type supposedly has some connection with the changes in the crystal structure and electric field of the latter in calcination. That is, at temperatures near 300°C the ammonium ion decomposes into ammonia to leave a proton, while at higher temperatures, near 500°C water is eliminated by the combination of the hydroxyl group with the proton and a defect is formed in the lattice.[12] No definite explanation, however, has yet been developed to account for the above difference.

The pretreatment of ion exchanged zeolites, of both the Pt-NaY and Pt-NH_4Y types, before calcination in the air, by heating in a nitrogen stream (catalyst No. 13) or in a hydrogen stream (catalyst No. 14) respectively, was found to have an adverse effect on the growth of platinum particles in the subsequent calcination in the air. In these two cases, only a small number of tiny particles, 40—60 Å, were found on the carrier (Fig. 5).

Chemisorption. Hydrogen chemisorption on platinum catalysts was measured in the pressure range from 10^{-3} to 10^{-1} mmHg at 25°C. The results, shown in Figs. 6 and 7, indicate that Freundlich-type adsorption isotherms hold for both NaY and NH_4Y type catalysts. These figures also demonstrate that

the volume of hydrogen chemisorption is dependent upon the calcining temperature in the air. The dependency is shown more clearly in Fig. 8, where the number of hydrogen atoms chemisorbed per platinum atom loaded is plotted against the calcination temperature.

Based on the chemisorption data, the average diameter of the platinum particles was calculated. Two assumptions were involved in the calculation, that is, that the platinum particles are in a uniform sphere and that a hydrogen molecule dissociatively chemisorbs covering two platinum atoms. The average diameter is, consequently, given by $6V/S$, where V and S denote the total volume and the total surface area of platinum loaded respectively. S is given by the number of hydrogen atoms adsorbed times the unit area per platinum atom, namely, 8.09Å^2, which is the average the site densities of (100), (110), and (111) of the platinum crystal.[13]

Tables 2 and 3 present the calculated results. The diameters in parentheses, for catalysts 2, 3, 8, and 9, which were calcined at low temperatures, do not seem realistic because no such large particle as those calculated was found by electron microscope inspection. Rather, this could be regarded as meaning that the loaded platinum existed either near atoms or fine particles with diameters less than 10 Å which had little ability to chemisorb hydrogen. In this connection, an interesting fact has been reported by Van Hardeveld and Van Montfoort.[3] They carried out a study of infrared-active nitrogen adsorption on nickel supported on silica. The study consisted of an infrared spectroscopic investigation of the adsorbed nitrogen and of an electron microscopic determination of the metal particle size distribution. They found that the infrared-active adsorption was measurable only if the nickel crystallites were within the range of 15—70 Å. It was also stated that this applies not only to nickel but also to platinum and palladium.

Carbon monoxide adsorption on platinum particles was measured in the same way as hydrogen adsorption. The results are summarized in Figs. 9 and 10. In the case of the Pt-NaY type catalysts, the Freundlich-type adsorption isotherms were found to hold for carbon monoxide, the amount being dependent on the size of the platinum particles.

The gas adsorption behavior of hydrogen or carbon

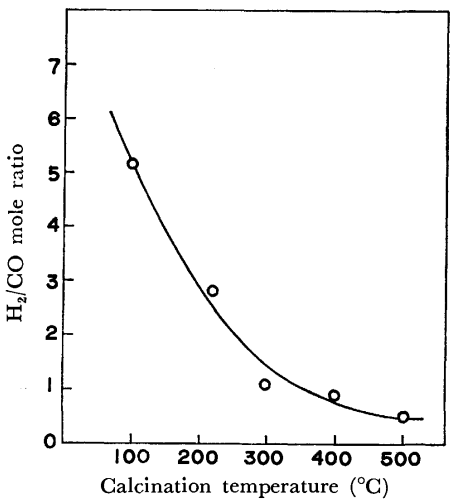

Fig. 11. The ratio of hydrogen and carbon monoxide adsorption on the platinum particles of the P-NaY type catalysts.

monoxide towards platinum particles may change according to their size distribution. This is suggested in Fig. 11, where the amount of hydrogen or carbon monoxide adsorption, at 10^{-1} mmHg and at room temperature, on the platinum supported on NaY zeolite is plotted against the calcining temperature, which has been shown to determine effectively the platinum particle size distribution. Those catalysts which are calcined at low temperatures, and which can consequently be supposed to have fine parparticles, adsorb larger amounts of hydrogen that of carbon monoxide, while those calcined at high temperatures, and having large particles, adsorb less hydrogen than carbon monoxide. The ratio of these two adsorption amounts is given in Table 4. Larger platinum particles, probably more than *ca.* 20 Å in diameter, are shown to have equal number of adsorptive sites for both of the gases by the fact, as is generally recognized, that hydrogen adsorbs in a dissociative fashion, while carbon monoxide does so in a linear form. This is shown by the fact that the ratio, H_2/CO in mole, in Table 4 approaches 0.5 with a rise in the calcining temperature. The reason why the catalyst calcined at a low temperature adsorbs much more hydrogen than carbon monoxide has not yet been made clear;[14] the fact, however, may be accepted that changes in the catalyst preparation procedure and/or conditions generally lead to a catalyst the surface of which is different in gas adsorption susceptibility as a result of some change in its physico-chemical properties, such as lattice defect and work function, in addition to merely physical properties, such as surface area.

TABLE 4. THE RATIO OF HYDROGEN AND CARBON MONOXIDE ADSORPTION ON THE PLATINUM PARTICLES OF THE Pt-NaY TYPE CATALYSTS

Cat. No.	Calcin. temp., °C	H_2/CO

3	220	2.9
4	300	1.2
5	400	0.9
6	500	0.5

a) The ratio is supposed to be slight reliable, because the amount of carbon monoxide on platinum is little.

14) G. C. A. Schuit and L. L. Van Reijen, "Advances in Catalysis," Vol. 10, ed. by Academic Press, New York and London (1958), p. 250.

On the other hand, the Pt-NH_4Y type catalysts were characteristically distinguished in their adsorptive properties from NaY type catalysts. Carbon monoxide on the carrier was extremely large. Figure 10 shows that the adsorption on the Pt-NH_4Y type carrier was also affected by the calcination temperature in the air.

In conclusion, dispersion state analysis by hydrogen chemisorption gives a result which is in virtual agreement with that obtained by electron microscopic observation with respect to the catalyst with an average particle size over approximately 20 Å in diameter. For the catalyst calcined at low temperatures, however, the hydrogen adsorption method possibly gives rise to a false result. This seems to suggest that the loaded platinum is dispersed in atoms or in fine particles which lose the metallic properties to adsorb hydrogen, supposedly in a more or less cationic state as a result of the pronounced effect of the surrounding oxygen atoms in zeolite. Carbon monoxide adsorption has generally been used to evaluate the metal surface and compared with the catalytic activity. However, the discrepancy between hydrogen and carbon monoxide adsorptions, observed in this study for the platinum fine particles, suggests that the hydrogen chemisorption method is more useful for predicting the catalytic activity, especially for reactions where hydrogen is involved.

These experiments have suggested that, for obtaining a properly dispersed platinum catalyst which has an excellent ability to chemisorb hydrogen, the temperature of calcining the ion exchanged zeolite is one of the most important key factors in the catalyst preparation.

The mechanistic interpretation of the action of oxygen in the calcination of $Pt(NH_3)_4^{2+}$ ion exchanged zeolite to promote the growth of platinum to form crystallites is an interesting subject; it is now under investigation in this laboratory.

For the catalysts calcined at low temperatures, the platinum particles dispersed in atoms or in fine particles, or both, lose their metallic properties to adsorb hydrogen, and supposedly gain a cationic character as a result of the pronounced effect of the surrounding oxygen atoms in zeolite.

A good parallelism that was found to exist between the amount of hydrogen adsorption, which depends on the dispersion states of platinum particles, and their catalytic activities of hydrogenation will be reported in the following paper.

The authors are indebted to Mr. S. Takagi and Mr. S. Takeda for their invaluable assistance in carrying out the electron microscopic study.

Metal Catalysts Supported on Zeolite. II. Dehydrogenation of Cyclohexane and Hydrodemethylation of Toluene over Zeolite-Supported Platinum Catalysts

Toshihiko KUBO, Hiromichi ARAI, Hiroo TOMINAGA, and Taiseki KUNUGI

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 14, 1971)

Correlations between the amount of hydrogen adsorption and the catalytic activities of the zeolite-supported platinum catalysts were interpreted in terms of the dispersion state of platinum particles. The activities for dehydrogenation of cyclohexane and hydrodemethylation of toluene were directly proprotional to the amount of hydrogen adsorption. The tiny platinum particles with diameters of less than 20 Å, which had little ability to chemisorb hydrogen, showed a poor activity in both reactions.

The correlation between the amount of hydrogen adsorption on metal particles and their catalytic activity for hydrogenation or dehydrogenation has been an interesting subject of catalytic study.[1-4] Our previous work[5] demonstrated that zeolite-supported platinum catalysts with a given dispersion state could be obtained by calcining the ion exchanged zeolite in the air and by subsequently reducing in a hydrogen stream. A pronounced effect was observed of the calcination in the air on the growth of the platinum to form particles. Low temperature calcination was found to give a catalyst which had supposedly tiny platinum particles with diameters below 20 Å that chemisorb very little hydrogen. The optimum size of the particles obtained by calcination at 300°C ranged from 20 to 50 Å in diameter and gave the largest hydrogen chemisorption per weight of platinum loaded.

The present paper will report a good parallelism between the amount of hydrogen chemisorption and the catalytic activity of the zeolite-supported platinum catalyst.

Experimental

Catalyst Preparation. The zeolite-supported platinum catalysts were prepared by ion exchange of zeolite 13 Y, followed by calcination in the air and reduction in a hydrogen stream. The catalysts of the Pt-NaY and Pt-NH_4Y types used in this study were prepared in just the same ways as those in the previous work. The catalyst of the Pt-CaY type were prepared in the same way as above except for the pretreatment of the zeolite 13 Y with $CaCl_2$ aqueous solution to replace Na^+ with Ca^{2+}. This treatment was carried out before the ion exchange of the zeolite with Pt-$(NH_3)_4^{2+}$.

Dehydrogenation of Cyclohexane. The experiment was carried out by the use of the pulse-technique. In the reactor (4 mm in diameter), 8 mg of powder of 0.24 wt% Pt-NaY, calcined at a specified temperature in the air, was placed and then reduced in a hydrogen stream at 500°C for 3 hr. After the catalyst temperature has been lowered to 280—320°C, 1 μl of cyclohexane was injected into the large amount of hydrogen stream that continuously flowed down the catalyst bed. The flow rate of hydrogen stream was 60 ml/min, and the pressure was 240 mmHg (gauge). The product stream was analyzed by gas chromatography (column: tricresyl phosphate on cellite, 2.0 m in length). The hydrogen was supplied from a commercial cylinder after purification over Deoxo catalyst and molecular sieve 5A.

For accurately evaluating the relative rate of a reaction by the use of the pulse technique, it is essential to avoid the use of a catalyst in a temperature range where a prolonged adsorption of the reactant or of the product on the carrier takes place. The preferred range of temperature was determined in the following way. Into a reactor with 8 mg of the zeolite 13Y (NaY type, no platinum loaded), 1 μl of cyclohexane or benzene was injected at temperatures ranging from 200 to 340°C; the changes in the height and width of the peak of gas chromatogram were then obtained as is shown in Fig. 1. This figure suggests that a reaction temperature higher than 280°C should be employed.

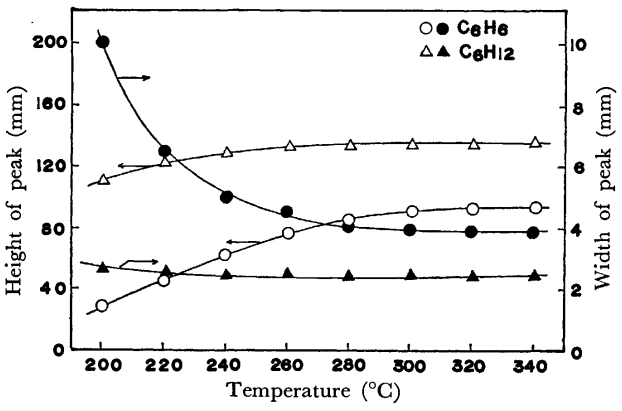

Fig. 1. Adsorption of cyclohexane and benzene on zeolite 13Y.

Hydrodemethylation of Toluene. In a reactor (8 mm in diameter), 0.1 g of a powdered catalyst was placed; 1 μl of toluene was then injected into a large excess amount of hydrogen stream, the flow rate of which was 40 ml/min and the pressure of which was 220 mmHg (gauge). The product stream was analyzed by gas chromatography (column: dinonyl phthalate on cellite, 1.0 m in length). The reaction temperature above 420°C was found to be preferred in the same way as in the cyclohexane experiment.

Results and Discussion

Dehydrogenation of Cyclohexane. The conversions of cyclohexane to benzene remained nearly constant for the first ten injections of cyclohexane at 10 min intervals. Therefore, the average of the conversions in the first ten injections was regared as indicating the catalyst activity. In Fig. 2 the cyclohexane de-

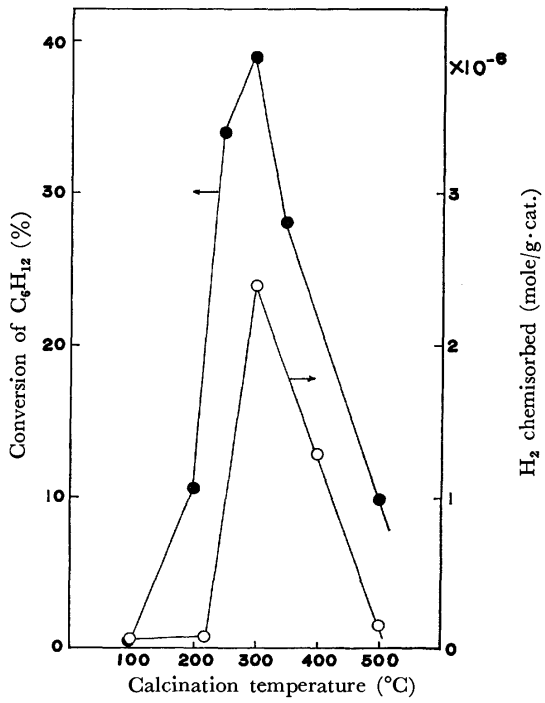

Fig. 2. Dehydrogenation of cyclohexane over 0.24wt% Pt-NaY at 300°C.

hydrogenation activities of the Pt-NaY catalyst at 300°C are plotted against the catalyst calcination temperatures in the air. The change in the amount of hydrogen adsorbed on the catalyst (at 25°C, 0.1 mmHg) is also plotted in the figure. This suggests that the active site for dehydrogenation of cyclohexane is closely connected with the adsorption site of hydrogen.

In our previous report,[5] it has been suggested that the amount of hydrogen adsorption on the zeolite-supported platinum catalyst depends upon the size of the platinum particles, which is a function of the calcination temperature of ion exchanged zeolite. These results show that the catalyst with fine platinum particles, which are less than 20Å in diameter and which have little hydrogen adsorptive capacity, have little activity to convert cyclohexane to benzene. Based on pseudo-first order kinetics with respect to the concentration of cyclohexane, apparent activation energies for the dehydrogenation were obtained for the different catalysts, as is shown in Table 1. All these activation energies were at 31±3 kcal/mol except for that over the catalyst calcined at 200°C in the air. Furuoya and Shirasaki[6] studied sintering mechanism of palladium on silica-alumina and found that the

(Reduction of the catalysts in a hydrogen stream was carried out at 500°C for 3 hr.)

Run No.	Calcination temp., °C	Activation energy, kcal/mol
1-1	100	—
1-2	200	19
1-3	250	29
1-4	300	31
1-5	350	34
1-6	400	29
1-7	500	32

lattice defect of palladium was mainly determined by the condition of hydrogen reduction and was independent of the condition of previous calcination in air.

In view of these findings, it is considered that the active sites of these catalysts are similar in their quality for dehydrogenation of cyclohexane, and that the difference in the catalytic activities can be attributed to the variation in the effective surface area of the platinum particle.

Hydrodemethylation of Toluene. Hydrodemethylation of toluene over zeolite-supported platinum catalyst of the Pt-NaY type was studied. The activity of the catalyst rapidly decreased with the first ten injections of toluene at 10 min intervals; then it reached a nearly constant level, as is shown in Fig. 3.

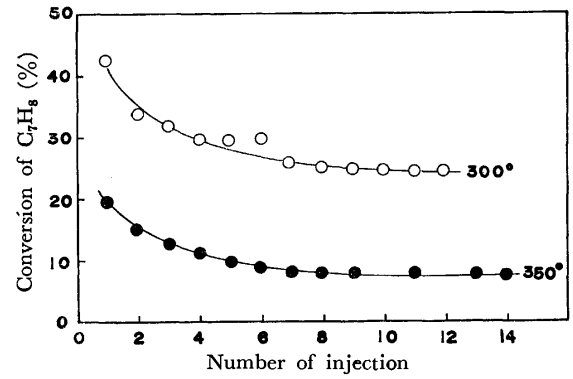

Fig. 3. Hydrodemethylation of toluene over 0.24wt% Pt-NaY at 500°C. Change of activity against the number of injection.
—○— Calcined at 300°C in the air
—●— Calcined at 350°C in the air

All of the catalysts of the Pt-NaY type used in this study showed a similar decline in their catalytic activities. This is considered to come from the deposition of carbonaceous materials on platinum particles because a grey color was found to develop over the catalyst used. After a constant conversion had been attained, the conversion of toluene was taken as a

6) I. Furuoya and T. Shirasaki, *Kogyo Kagaku Zasshi*, **72**, 1223 (1969).

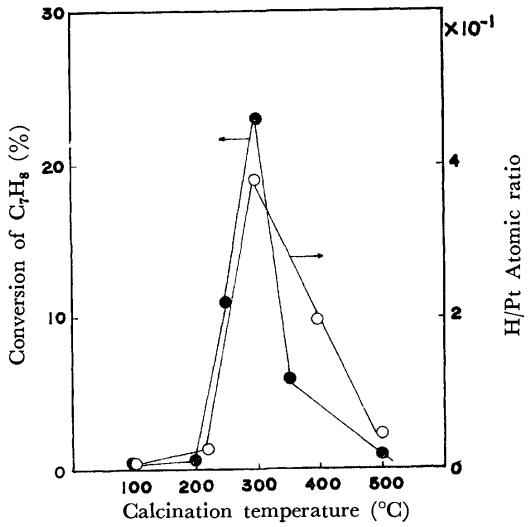

Fig. 4. Hydrodemethylation activity of 0.24wt% Pt-NaY at 500°C against the calcination temperature.

measure of the activity of the respective catalyst. This is plotted against the calcination temperatue in Fig. 4, where the amounts of hydrogen adsorption on the catalyst are also indicated.[5] The figure shows that hydrodemethylation activities of the catalysts are as well correlated with the amounts of hydrogen adsorption as are the cyclohexane dehydrogenation activities. The apparent activation energies for toluene hydrodemethylation were found to lie in the range from 38 to 41 kcal/mol.

Associated with the repeated injection of toluene, a decrease in the activities of the Pt-CaY type catalysts was observed as in the case of the Pt-NaY type catalysts. The hydrodemethylation activity, when a constant level was attained, of the Pt-CaY type catalyst at 500°C is shown as a function of the calcination temperature in the air in Fig. 5. The catalyst calcined at 200°C showed the maximum activity. The characteristic feature of the effect of the calcination temperature was similar to that on the catalysts of the Pt-NaY type.

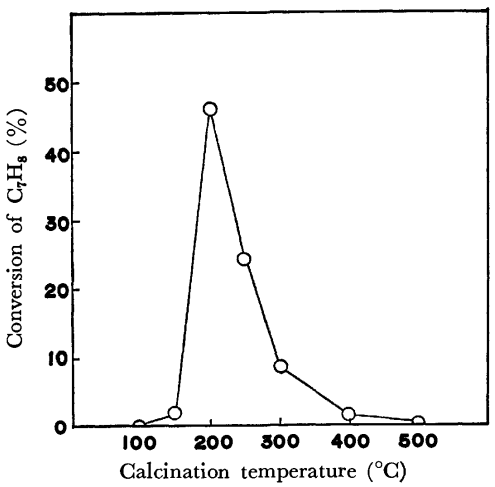

Fig. 5. Hydrodemethylation of toluene over 0.2wt% Pt-CaY at 500°C against the calcination temperature.

In the case of the Pt-NH_4Y type catalysts, no decrease in the initial activity was observed, as is shown in Fig. 6. This makes sharp contrast to the catalysts of the Pt-NaY and Pt-CaY types. The surface proton on the Pt-NH_4Y type catalysts, formed by the decomposition of ammonium ion, might accelerate the cracking of the carbonaceous materials, thus preventing their accumulation. Figure 7 shows the characteristic change in the catalytic activities of the Pt-NH_4Y type catalysts as a function of the calcination temperature. This should be discussed in view of the change in the structure of the zeolite during calcination in the air. That is, the NH_4Y zeolite is transformed by calcination into the decationized type through the HY type, while the structures of the NaY and CaY zeolites are unchanged. At any rate, a good parallelism between the amount of hydrogen

adsorption and the catalytic activity for hydrodemethylation is found to hold. The apparent activation energies for the respective catalysts are shown in Table 2. These experimental facts suggest that the growth of platinum is less favored in the decationized structure of zeolite.

Our previous study using electron microscope indicated that the presence of oxygen in the calcination procedure played an important role in the aggregation of platinum, and that the heating of ion exchanged zeolites in a non-oxidizing atmosphere, namely, in a nitrogen or hydrogen stream, had an adverse effect on the growth of platinum particles in the subsequent calcination in the air. The effect of this pretreatment on the Pt-NH_4Y type catalyst is shown in Fig. 8. The hydrodemethylation activity of the catalyst which was pretreated in a nitrogen stream before reduction in the air exhibited a slight activity. The platinum cation or atom may be stabilized on the zeolite by pretreatment in a nitrogen or hydrogen stream at 400—600°C and does not migrate on the surface during the subsequent calcination in the air to form platinum particles. Consequently, the platinum catalyst manufactured by reduction in a hydrogen stream has an ability for neither gas adsorption nor catalytic activity.

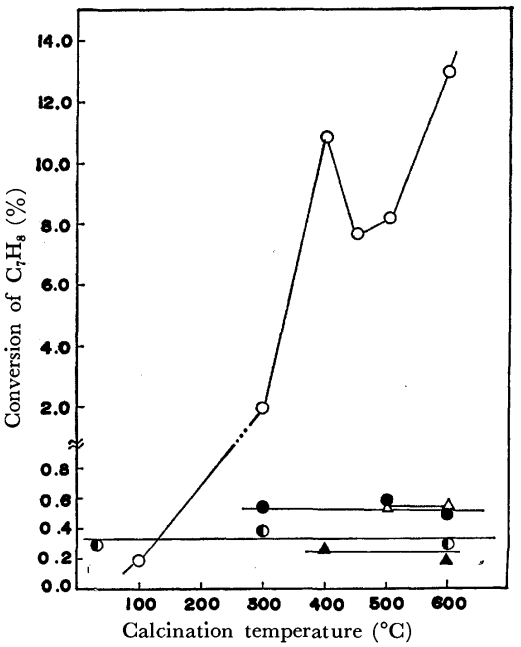

Fig. 8. The effect of pretreatment before calcination in the air and reduction in a hydrogen stream.
—○— Not pretreated.
—◐— Pretreated at 600°C in a nitrogen stream.
—●— Pretreated at 400°C in a nitrogen stream.
—△— Pretreated at 500°C in a nitrogen stream.
—▲— Pretreated at 500°C in a hydrogen stream.

The controlling factors were investigated in preparation of a zeolite-supported platinum catalyst active for hydrogen participating reactions. The most active catalyst, the platinum of which is properly dispersed on the carrier, can be obtained by calcining in the air at a specific temperature prior to reduction in a hydrogen stream. The catalytic activities are in good parallelism with their hydrogen adsorption abilities.

Structural Effects on the Properties of Nonionic Surfactants. I. The Synthesis and Some Surface Activities of Acetal Type Homogeneous Nonionics[1]

Tsunehiko KUWAMURA and Hideo TAKAHASHI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu

(Received July 26, 1971)

Higher aliphatic aldehydes (C_8—C_{16}) were treated in the presence of mineral acid with several pure polyoxyethylene glycols (m : 2—6), to give the corresponding acetals (AG types) with a general formula $RCH[O(C_2H_4O)_mH]_2$. These AG types are soluble in water, fairly stable in neutral and weakly basic aqueous solutions, and they exhibited the characteristic properties of nonionics. The hydration of the geminal polyoxyethylene (POE) chains are discussed on the basis of the data of unexpectedly low cloud points. Surface tension measurements on the aqueous solutions of AG types indicated that the critical micelle concentration (CMC) value decreases with an increment of oxyethylene units (m), and that the molecular area does not depend so greatly on m and is significantly smaller than that predicted from the data of conventional nonionics (S types) having one hydrophobic and hydrophilic chain each. For the gross effects of AG types, it has been found that the foam stability is considerably low and the dependence of the wetting power for canvas discs on m is larger than that of S types. The results are discussed on the basis of structural characteristics related to the unfavorable hydration and restricted configuration of the geminal POE chains. The acid-catalyzed hydrolysis of AG types in the micellar solution was significantly slower than that of acetaldehyde diethylacetal in water.

The preparation of pure polyoxyethylene alkanols and alkyl phenols has been described in many reports as thoroughly reviewed by Mulley.[2] In most cases two main methods have been used. (1) The mixture produced by ethylene oxide condensation is separated into individual compounds by distillation and (2) a pure POE glycol is joined to a hydrophobe by the Williamson ether synthesis. However, the yields are insufficient in both procedures. Introduction of two POE chains of definite length to a hydrophobe is, therefore, troublesome and has never been established hitherto.

In previous investigations,[3,4] several new type nonionic surfactants containing one to three hydrocarbon or POE chains have been synthesized from α,α'-glyceryl diethers and mono-, di-, and triethers of pentaerythritol by polyaddition of ethylene oxide, and the structural effects on their properties have been discussed. The role of the multi-chain type hydrophile in the behavior of these nonionics, however, could not be interpreted clearly because of the distribution of the POE chain length and the additional effects of the the joint parts in the surfactant molecules. In this investigation, a series of homogeneous nonionics in which two POE with the same chain length were attached to a hydrophobe by acetal linkage were synthesized and the effect of the multi-chain hydrophile on some surfactant properties was discussed. The reaction scheme and abbreviations are as follows.

$$RCHO + HO(C_2H_4O)_mH \xrightarrow{H^+} RCH\begin{matrix}O(C_2H_4O)_mH\\O(C_2H_4O)_mH\end{matrix}$$

R: C_nH_{2n+1} AG-$(n+1)(2m)$

It is of interest that AG types are easily hydrolyzable in the presence of acid, from the viewpoint of degradation after the utilization in an industrial process. Preliminary information on the hydrolysis of AG types is given in this paper.

Experimental

Materials. Commercially available aliphatic aldehydes were purified by distillation and then checked by gas-liquid chromatography (glc) for satisfactory purity (more than 99%). Pure POE glycols were obtained by fractional distillation of commercial products. The purity and the number of oxyethylene unit were checked and determined by glc, NMR, physical indices and analytical method.

Preparation of AG Acetals. To avoid the formation of diacetals by further condensation of acetal with unreacted aldehyde, a large excess of the glycol was used in each runs. In a 300 m*l* three-necked flask equipped with a reflux condenser, a thermometer, and a mechanical stirrer were placed 0.1 mol of aldehyde, 1 mol of the glycol and a catalytic amount of concentrated hydrochloric acid. The reaction mixture was maintained at room temperature with stirring for 1 hr and then gradually heated up to 60—80°C for 4—6 hr. The contents in the reaction vessel were immiscible and formed a suspension at the initial stage of the reaction. It gradually became homogeneous and produced a foam with the progress of reaction. The mixture was cooled, diluted with benzene and neutralyzed with powdered potassium carbonate. The inorganic salts were filtered off and benzene was then distilled off. Unreacted aldehyde and glycol were removed under reduced pressure. The residue was then dissolved again in benzene, warmed, and washed with a small amount of water several times to remove the remaining glycol and salts. Complete removal of benzene under a high vacuum gave a paste-like product in a high yield. Purity and structure of the products were confirmed by elementary and functional group analyses, paper and thin layer chromatographs and IR and NMR spectra. In paper chromatography, 10 mg of the sample was dissolved in an appropriate amount of benzene, spotted on filter paper (Toyo No. 50), developed by mixed solvents (*e.g.*, upper layer of the mixture of *n*-butanol : pyridine : water=

5 : 2 : 3) and detected by Dragendorff reagents. In the same way, thin layer chromatography was carried out on silica gel (Wakogel B-5).

Cloud point of the products was measured on a 0.5% aqueous solution.

Surface Activities Measurements. Aqueous surface tension of AG types were continuously measured by the vertical plate method, at 20±1°C using a Shimadzu ST-1 type tensiometer. Wetting power was evaluated by measurement of the sinking time of a canvas disc (diameter : 1 in.) at 40°C, according to the method described by Yano and Kimura.[5] To evaluate foaming properties, volume of the initial foam and foam remaining after 5 min were measured at 25±1°C according to the method by Yano *et al.*[6]

Hydrolysis. No reliable techniques by chemical or chromatographic analysis have yet been establisehd for the kinetic measurement of hydrolysis of AG type acetals in dilute aqueous solution. We have tried to follow the acid-catalyzed reaction through the measurement of cloud point, which might depend upon a concentration of the higher aldehyde produced and solubilized in aqueous solution during the hydrolysis of AG. The following facts are of use for this method. AG acetals are so stable in neutral and weakly basic aqueous solution that the cloud point of the solution was kept practically constant for periods more than 12 hr at 25—35°C as illustrated in Fig. 11. No appreciable depression of the cloud point was observed when a small amount of inorganic salt (less than 0.02 mol/*l*) was added to the solution.

The required calibration curve was obtained in the following way. Aqueous solutions containing three components (AG, the related aldehyde and POE glycol) were prepared at a definite total concentration, in the proportion corresponding to various extents of hydrolysis. Their cloud points were measured and plotted against the calculated % of conversion of AG as in Fig. 12.

Thus, the rate of hydrolysis at 30±0.2°C was measured on the acidic aqueous solutions of 0.5—1.0% initial concentration which are much higher than the CMC. Immediately after sampling, the catalyst in the sample solution was neutralized with a slight excess of alkali.

Results and Discussion

By the procedure mentioned above, a series of AG type homogeneous nonionics containing 8 to 16 carbon atoms in hydrophobe and 4 to 12 oxyethylene units in hydrophile were successfully prepared in one step from the corresponding aldehydes and glycols. Physical properties of the latter are listed in Table 1.

The adsorption band of IR spectra at 1600—1700 cm^{-1} of aldehyde carbonyl was not observed for all products. As an example IR spectrum of AG-12(6) is shown in Fig. 1. In Fig. 2, the strength ratios ($T_{1220/720}$) of IR adsorption bands at 1220 and 720 cm^{-1} and the refractive indices are given as a function of *m*. Deviation from these curves, indicating almost certainly the presence of impurity, was not observed as well as in some cases pointed out by Glassman,[7] Schüring,[8] and Wrigley[9] for S type nonionics. From chromatographic analyses, it was confirmed that the use of a large excess of glycol successfully prevented the formation of diacetal and that the unreacted glycol was almost completely removed by distillation and subsequent washing with water.

NMR spectra provided the proof on the structure of the products. The spectrum (in CCl_4) of AG-12(6) is shown in Fig. 3, where five bands are found at 0.88, 1.27, 3.10, 3.58, and 4.50 ppm in the proton ratio of 3 : 20 : 2 : 24 : 1. They can be ascribed to the protons on methyl, methylene in hydrophobe, hydroxyl, methylene in POE chains and methine groups, respectively. Physical properties, analytical data, and the yields of AG types are listed in Table 2. We see that

the method established in this investigation has the advantage of high yield in the preparation of homogeneous nonionics.

The cloud point of nonionics is a measure of the solubility in water and closely related with the hydrophile-lipophile balance (HLB). Smooth and characteristic curves were obtained by the plots of the cloud point *vs.* *m*. A representative example is shown in Fig. 4 for AG-12 series. It can be expected from the structural feature of AG having two terminal hydroxyl groups in a molecule, that the cloud point is higher than that of S types having one hydrophilic chain. On the contrary, the curve for AG lies close to that for S types provided by Schüring[8)] as can be seen in Fig. 4. When the cloud point was plotted against HLB value based on the "group numbers" proposed by Davies,[10)] the curve for AG was apparently shifted to the right side of that for S types as shown in Fig. 5. If the same group numbers are applicable to both type nonionics regardless of the variation in hydrophile structure, the curves for both types would be superimposable. The results suggest that hydration of the geminal POE chains, especially of the oxyethylene unit adjacent to hydrophobe, is significantly hindered and the hydration of two terminal hydroxyl groups in a molecule of AG is incomplete owing to the stronger intramolecular hydrogen-bonding. Such a characteristic hindrance to hydration for AG can be esti-

mated from Fig. 5 to be 1.5—2.0 in Davies's HLB value.

Measurement of surface activities for AG types gave some interesting results. Aqueous surface tension of AG considerably depends upon time as can be seen in Fig. 6. The equilibrium surface tension (γ), was thus taken at the time when the lowering of surface tension is no longer observed. The obtained γ was plotted against logarithm of the concentration and no minima in the γ-log C curves were found for all the AG types studied as shown in Figs. 7 and 8. Surface excess (Γ) and molecular area (A) at CMC were calculated from these γ-log C curves by applying the simple form of Gibbs' adsorption equation, and listed in Table 3. From the fact[12] that A of nonionics of polyglycol ether type is determined by the POE chain, it can be predicted that A of AG types (A_{AG}) is about twice as large as that of S types (A_S) containing the POE chain of the same length as in AG. As can be seen in Table 3, however, A_{AG} are considerably smaller than $2A_S$ and close to A_S.

a) Data in Ref. 11 for the homogeneous polyoxyethylene *n*-dodecanol, the number of oxyethylene unit is shown in parentheses.
b) Data in Ref. 12.

Concerning the surface film of nonionics, van Voorst Vader[13] has given a theoretical explanation for the fact that $A/m^{1/2}$ of S types is constant on the basis of a random coil configuration of POE chain. Fairly good agreement for $A/m^{1/2}$ has been obtained by many investigators as referred to by Lange in his review.[12] For AG-12 and AG-14 series, $A_{AG}/m^{1/2}$ were not constant but decreased with the increment of m, as can be seen in Table 3. Thus, it is suggested for the film state of AG types that two POE chains linked to the same carbon atom in hydrophobic chain never individually hold a random coil configuration but intertwisted with each other and penetrate into the solution.

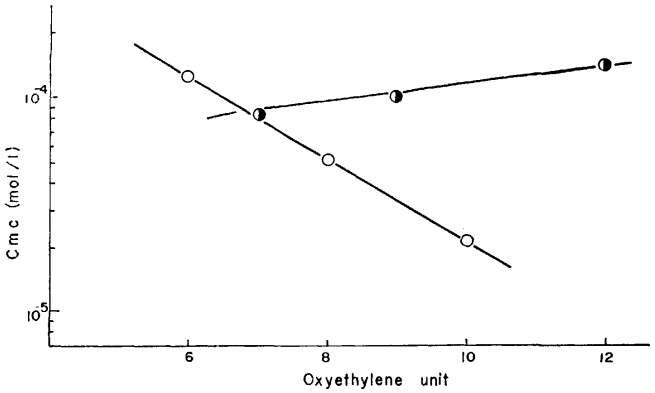

Fig. 9. Plots of log CMC *vs.* number of oxyethylene unit. ○; AG-12 series. ◑; S-12 series, based on the data in the following reference; H. Lange, Proc. Intern. Congr. Surface Active Substances, 3rd, Cologne, Vol. I, p. 279 (1960).

From the sharp inflection point of γ-log C curves in Figs. 7 and 8, CMC was determined and is listed in Table 3. Apparently, in the series of same m, the inflection point shifts to lower concentration region with an increase in the hydrocarbon chain length as shown in Fig. 7, while the CMC of the homologues with same hydrophobe shifts to higher with a decrease in m (Fig. 8) in contrast to S types. It is known that as a surfactant molecule becomes more hydrophilic, *i.e.*, as the POE chain length increases, the CMC increases, although a certain class of nonionics having a shorter hydrocarbon chain exhibits a reverse trend.[14,15] These relations have been quantitatively treated by applying the equation proposed by Hsiao,[16] ln $C_0 = a + bR$, where C_0 is a CMC, a and b are constants for a given hydrophobe and R is length of the POE chain. As shown in Fig. 9, a linear relation between log CMC and m was obtained for AG types. The slope is negative. It is still difficult to explain this anomalous trend from the present data. The phenomenon has been observed for AG series having shorter hydrophilic chains (m : 3—5), which are geminal POE chains unfavorable to hydration and hold a restricted configuration as regards the surface film state of AG. It seems that this configurational feature is closely related to the lowering of CMC with increasing m in a certain region of the smaller m.

a) Ethylene oxide condensate of *n*-dodecanol prepared by the base-catalyzed method. The average number of ethylene oxide added is shown in parentheses.

On the basis of Draves wetting data obtained for various commercial nonionics of POE monoether type, Komor and Beiswanger[17] reported that textile wetting is primarily dependent upon CMC, and indicated that the concentration dependence of sinking time becomes greater with an increase in CMC of surfactant. Wetting data for a series of AG types are shown in Fig. 10, where sinking time is plotted against concent-

ration. The slope, *i.e.*, the concentration dependence of sinking time, increases with decreasing m. This agrees with the result in which CMC becomes greater with decreasing m for a series of AG types studied.

In Table 4, the foaming properties of AG is presented in initial foam volume and after 1 and 5 min. The low foam stability of AG is more characteristic than the foaming ability, like that observed for other multi-chain type nonionics.[3,4,18]

The data of hydrolysis of AG-12(10) were obtained by the cloud point depression method. As can be seen in Fig. 13, they gave good first-order rate plots in the region of conversion below 40%. The plots of the pseudo-first-order rate constant against the concentration of acid also gave a straight line passing the origin with a slope k 5.5×10^{-3} $l$mol^{-1}sec^{-1}. The k value is significantly small in comparison with the specific rate constant 0.39 $l$mol^{-1}sec^{-1}, for acid-catalyzed hydrolysis of acetaldehyde diethylacetal in water.[19] On the acid-catalyzed hydrolysis of monoalkyl sulfates, it was reported that the reaction is strongly accelerated by the aggregation of the reactant anions into micelle.[20-22] However, the result for AG acetal is apparently the reverse. It seems significant that the acetal linkages in the micellar AG are covered by the dome of closely packed POE chains. Probably, the reaction centers compete with many ether linkages in the POE chains for protonation, and the hydrolysis is also subjected to steric hindrance.

Effects of $FeCl_3$ on the Graphitizability of Coal Tar Pitch

Sugio OTANI and Asao OYA

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received November 9, 1970)

For the purposes of raising the softening points (S.P.) of pitch materials or increasing the yields of cokes, raw pitch materials are conventionally distilled with some additives or by bubbling in an oxidizing gas, such as Cl_2 or air.[1] This manner, though, generally leads to a lowering of the graphitizability of the resulting carbonaceous materials. In an earlier paper,[2] however, it has been reported that the addition of $AlCl_3$ was remarkably effective in raising the S.P. of the residual pitch materials, but that it did not lower their graphitizability. Consequently, $AlCl_3$ is an interesting additive.

In order to clarify the action of $AlCl_3$ and to determine whether $AlCl_3$ is the only kind of additive having such effects, or whether three are some other additives with the same effects, it was thought advisable to investigate the effects of $FeCl_3$, which has a strong resemblance to $AlCl_3$ in character. The experiments described below deal with the effect of the addition of $FeCl_3$ as compared with that of the addition of Fe powder, and with the case of an entire absence of additives.

Experimental and Results

A mixture of 10 g of coal tar pitch and either 1 g of $FeCl_3$ or 0.5 g of Fe powder (under 100 mesh) was distilled with bubbling N_2 gas at desired temperatures below 550°C for 10 minutes. Coal tar pitch without any additives was also distilled as a reference. From the results shown in Fig. 1, it is clear that the S.P. of the residual pitch materials was more effectively raised by the addition of $FeCl_3$ than in the other two cases.

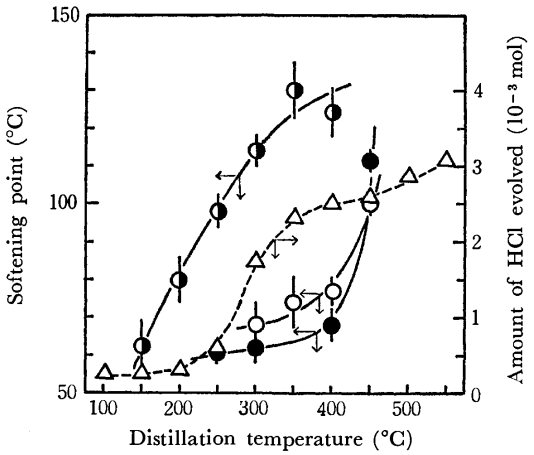

Fig. 1. Changes of softening point and amount of HCl evolved with distillation temperature.
S.P.: —○— no additive, —◑— $FeCl_3$ 10%, —●— Fe 5%, Amount of HCl, —△—

In order to measure the amounts of HCl evolved on heating, the mixture of 10 g of coal tar pitch and 1 g of $FeCl_3$ was heated with bubbling N_2 gas up to 550°C at the rate of 10°C/min, and the HCl thus evolved was absorbed in water and was estimated on the basis of titration with a NaOH solution at 50°C intervals. The evolution of HCl was accelerated at 250—350°C, as is shown in Fig. 1, it corresponded to only 17% of the amount of Cl atoms in $FeCl_3$, even after heating up to 550°C. It is the most characteristic fact that, in spite of the remarkable rise in the S.P. in the distillation temperature range below 250°C, the evolution of HCl in the same range is very small in amount.

In order to estimate the effects of additives on the graphitizability of residues, the following examinations were carried out. First, coal tar pitches were distilled at 550°C for 10 min under the conditions listed in Table 1. The resulting carbonaceous residues were heat-treated at the desired temperatures below 2400°C, and the graphitizability of the resulting carbons was examined by the X-ray diffraction technique.[2] All of the carbonaceous residues which were obtained by bubbling N_2 gas, regardless of the kinds and the amounts of additives, gave graphitizable carbons which show single and symmetrical (002) diffraction patterns upon graphitization. Figure 2 shows the changes in the interlayer spacing d_{002}, and the crystallite thickness, L_c, with

—○—: None, —◑—: $FeCl_3$ 2%, —●—: $FeCl_3$ 5%, —△—: $FeCl_3$ 10%, —▲—: $FeCl_3$ 50%, —▲: Fe 3.44%

1) S. Otani and A. Oya, *Kogyo Kagaku Zasshi*, **73**, 493 (1970).
2) S. Otani and A. Oya, *ibid.*, **73**, 1110 (1970).

the heat-treatment temperature. From the results shown in Fig. 2, it is evident that all the resulting carbons were typically graphitizable. On the other hand, when coal tar pitches were distilled with bubbling Cl_2 gas, all of the resulting carbonaceous residues, regardless of the kinds and the amounts of additives used in this study, gave non-graphitizable carbons which exhibited composite (002) diffraction patterns upon graphitization. It should be pointed out that, when $AlCl_3$ was added in our previous study,[2] the resulting carbonaceous residues gave graphitizable carbons.

Conclusion

The above results show that the addition of $FeCl_3$ is remarkably effective in raising the S.P. of residual pitch without any deterioration of the graphitizability of carbon obtained in the subsequent heating stage. At temperatures below 250°C, the evolution of HCl from the pitch with the addition of $FeCl_3$ is very small in amount in spite of the remarkable rise in the S.P. of the residue. On the other hand, the addition of Fe powder is not effective in raising the S.P. of the residues. Consequently, it seems reasonable to consider that such effects caused by the addition of $FeCl_3$ depend on the action of neither Cl nor Fe, which may be formed by a decomposition of $FeCl_3$ in the distillation stage, but depend on some action of the entire molecule of $FeCl_3$. Such effects of $FeCl_3$ were similar to those of $AlCl_3$ reported previously.[2] Therefore, the effects caused by the addition of $FeCl_3$ or $AlCl_3$ are thought to be due to a certain property, such as the acidic property, which is common to both the reagents.

The Electronic Spectra of the Anion Radical Salts Derived from 2,3-Dicyano-1,4-naphthoquinone

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 21, 1971)

Much attention has been paid to solid-ion-radical salts,[1-3] because the ion-radical molecules form, in themselves, a plane-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals.[4] In this case, since any individual radical molecule interacts through charge transfer most strongly with one or two other radicals, the electronic spectrum of the solid salt was found to be different from the monomer spectrum of the radical anion in solution and to show an intermolecular charge-transfer band in the low-energy region.[2,3] In this respect, it was interesting to examine the solid-state spectra of the anion-radical salts of 2,3-dicyano-1,4-benzoquinone and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.[3]

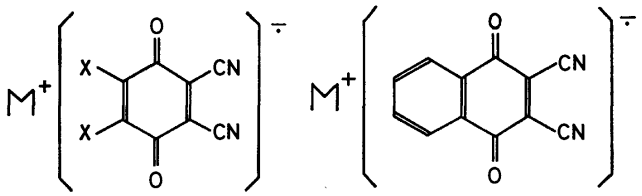

Fig. 1. The anion radical salts of (a) 2,3-dicyano-1,4-benzoquinone, (b) 2,3-dichloro-5,6-dicyano-1,4-benzoquinone and (c) 2,3-dicyano-1,4-naphthoquinone (DCNQ). M^+ represents a diamagnetic counter cation.

The present paper will describe the solid-state spectra, as well as the absorption spectra in solution, of some stable anion-radical salts derived from 2,3-dicyano-1,4-naphthoquinone (DCNQ). The following anion-radical salts were prepared according to the method of Reynolds and VanAllan[5]: Na^+ $DCNQ^-$, K^+ $DCNQ^-$, Rb^+ $DCNQ^-$, and Cs^+ $DCNQ^-$. The purpose of this paper is to show that the charge-transfer interaction between the DCNQ anion radicals also takes place in these solid anion-radical salts. It is interesting that the data indicate that the manner of the charge-transfer interaction is similar to those in the 2,3-dicyano-1,4-benzoquinone anion-radical salts.[3]

The Absorption Spectra in Solution

The absorption spectra of the anion-radical salts in an acetonitrile solution were measured at room temperature. The measurements were made at concentrations of the order of 1×10^{-4} mol/*l*, using a Beckman DK-2A spectrophotometer.

All of the DCNQ anion-radical salts dissolved in an acetonitrile solution appear red, and are quite

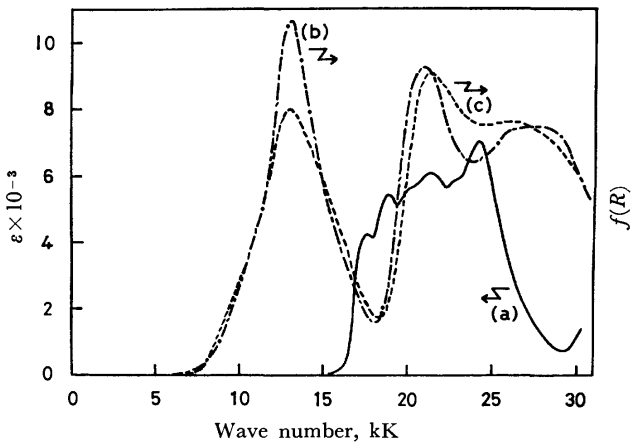

Fig. 2. The electronic spectra of the 2,3-dicyano-1,4-naphthoquinone (DCNQ) anion radical salts; (a) the absorption spectrum of K^+ $DCNQ^-$ in an acetonitrile solution, (b) the solid-state spectrum of Na^+ $DCNQ^-$ and (c) the solid-state spectrum of K^+ $DCNQ^-$.

stable at room temperature. As an example, the absorption spectrum of K^+ $DCNQ^-$ in an acetonitrile solution is reproduced in Fig. 2, Curve (a). It has absorption peaks at 17.6 kK and 18.8 kK, a peak at 21.3 kK with a shoulder around 20.3 kK, and a high-energy band at 24.1 kK with a slight shoulder around 22.7 kK. The spectrum does not change even when the counter cation of the salt is replaced. Since the concentrations are so dilute, the salts seem to be completely dissociated. The obtained spectrum is that of the DCNQ anion radical monomer, because the counter cations of the salts are simple alkali-metal cations.

The Solid-state Spectra

The electronic spectra of the solid DCNQ anion-radical salts were measured by the diffuse-reflection technique. The diffuse-reflection spectra were recorded on a Beckman DK-2A spectroreflectometer in the range from 4.0 kK to 30.8 kK at room temperature. The solid-state spectra were then obtained by plotting the diffuse-reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance. The experimental details were the same as those presented in previous papers.[2,3]

All of the DCNQ anion-radical salts were obtained as dark green polycrystals, and all were quite stable at room temperature.

The solid-state spectrum of Na^+ $DCNQ^-$ (Fig. 2, Curve (b)) shows a strong absorption at 13.1 kK, a band at 20.9 kK, and a broad high-energy band around 27.8 kK. This spectrum was found to be quite different from the monomer spectrum of the DCNQ anion radical in solution. The band at 13.1 kK characteristic of the solid salt appears in the low-energy region, where the anion-radical monomer does not absorb. This band has no vibrational structures, and its intensity is remarkably strong. It cannot be assigned to the charge-transfer transition from the anion radical to the counter cation, since its maximum position is scarcely shifted when the counter cation of the salt is replaced (see below). Although, at present, no experimental data on the charge-transfer absorption in the dimer of the DCNQ anion radicals are available for purposes of comparison, the low-energy band at 13.1 kK seems to be attributable to the charge-transfer transition between the DCNQ anion radicals in the solid state. This assignment is analogous to those for the anion-radical salts of the cyano-substituted *p*-benzoquinones,[3] where the charge-transfer band of Na^+ 2,3-Dichloro-5,6-dicyano-1,4-benzoquinone$^-$ has been reported to be located at 12.6 kK, while that of Na^+ 2,3-Dicyano-1,4-benzoquinone$^-$ is located at 10.7 kK with a shoulder around 14.3 kK.

The appearance of the strong charge-transfer band in Na^+ $DCNQ^-$ means that, in the solid state, the DCNQ anion radicals are stacked closely enough together for the half-filled molecular orbitals to make a large overlap. The DCNQ anion radicals seem to form, in themselves, a plane-to-plane stacking into columns; this feature of the crystal structure has also been found in a number of other ion-radical salts.[4] The charge-transfer absorption characteristic of the solid salt should be ascribed to the transition of the $\langle\cdots Q^-Q^-Q^-Q^-\cdots\rangle \rightarrow \langle\cdots Q^-Q^0Q^{2-}Q^-\cdots\rangle$ type, where Q denotes a quinone molecule. In this case, the π–π transitions of the DCNQ anion radical monomer will be perturbed in the field of the other anion radicals. This is shown as appreciable blue-shifts of the high-energy bands at 20.9 kK and 27.8 kK for the solid-state spectrum of Na^+ $DCNQ^-$, compared to the monomer absorptions of the DCNQ anion radical, shown in Fig. 2, Curve (a).

The solid-state spectra of K^+ $DCNQ^-$, Rb^+ $DCNQ^-$, and Cs^+ $DCNQ^-$, although the intensities of the low-energy charge-transfer bands depend slightly on the species of the counter cations, were found to be very similar to that of Na^+ $DCNQ^-$. As an example, the solid-state spectrum of K^+ $DCNQ^-$ is given in Fig. 2, Curve (c). Hence, the electronic structure in the solid DCNQ anion radical salts and the charge-transfer interaction between the DCNQ anion radicals are scarcely affected even though the counter cations of the salts are replaced in the present investigation. It is interesting to note that this situation coincides well with that previously reported for the cyano-substituted *p*-benzoquinone anion-radical salts.[3]

Studies on Salt Solution Aerosols. VI.[1] Droplet Size Determination of Aqueous Sodium Sulfate Solution Aerosols by Chemical Spot Method

Yasuo UENO and Isamu SANO

Department of Chemisty, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received November 20, 1970)

For the purpose of measuring the size distributions of aqueous sodium chloride solution aerosols, a new method based upon the chemical spot formation was developed.[2] One merit of the method is the easy preparation of a transparent film of polyvinyl alcohol containing the detecting reagent (silver nitrate) which reacts with the solution droplets to give spots of clear outlines. In addition a quantitative relationship holds between the size of the droplets and that of the spots impressed by them.

We have extended this technique to the size measurement of aqueous sodium sulfate solution aerosols. The results were analyzed in combination with those of aqueous sodium chloride solution aerosols.

Experimental

Materials. Ethanol used was of extra pure grade. Polyvinyl alcohol (PVA), obtained from Kurare Co., was 1700 in polymerization degree and 85% in saponification extent. Barium perchlorate was of chemical pure grade.

Preparation of the Reagent Film. To 100 g of an aqueous solution containing 4% by weight of PVA was added 200 m*l* of C_2H_5OH, and then a) 1 m*l*, b) 2 m*l* c) 3 m*l* and d) 4 m*l* of aqueous 40% $Ba(ClO_4)_2 \cdot 3H_2O$ solution was added separately to obtain four solutions of the detecting reagent in different concentrations. On dropping 10 μl of these solutions upon a dry glass slide[3] by means of a micropipette, the solvent (alcohol and water) rapidly evaporated off, leaving a circular transparent film of reagent, about 2.1 cm in diameter.

Generation of Droplets and Measurement of Size Distribution. An aqueous aerosol of 10% Na_2SO_4 solution was introduced into a mist chamber from an atomizer and was subjected to aging for various periods of time under agitation. The droplets were allowed to settle under the action of gravity onto the reagent film and an oil film[2] held on a glass slide. They were put side by side in the chamber. The size of the spots formed on the reagent film was measured with a phase microscope and that of the droplets suspended in the oil film with an ordinary microscope. Microphotographs of the spots and droplets were enlarged and their sizes were recorded with due precaution. The size of the droplets was in the range of about 0.3—12 μ in diameter.

Results and Discussion

Experimental Construction of the Calibration Curve. Both droplets and their spots have their own size distributions. Therefore, taking the volume average diameter D_d for the former and the surface average diameter d_s for the latter, the calibration curve was constructed for four films of varying $Ba(ClO_4)_2$ concentrations (Fig. 1, solid lines). We see that the spot diameter decreases with increasing reagent concentration in film.

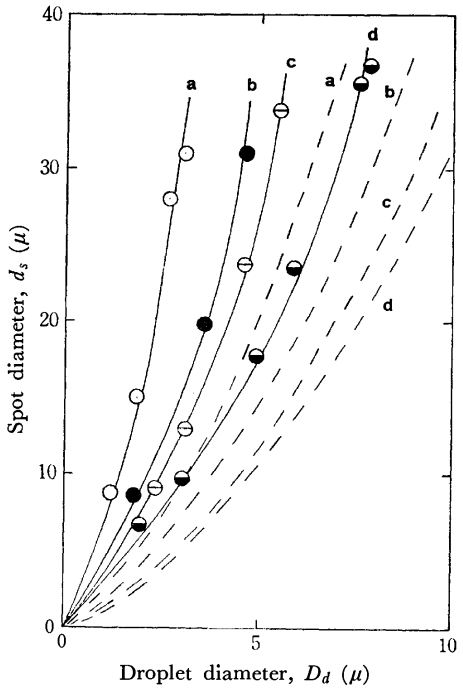

Fig. 1. Relation between the spot and droplet diameters. Solid lines refer to experimental curves and dashed lines calculated ones.
a : 1 m*l* $Ba(ClO_4)_2$ solution, b : 2 m*l* $Ba(ClO_4)_2$ solution
c : 3 m*l* $Ba(ClO_4)_2$ solution, d : 4 m*l* $Ba(ClO_4)_2$ solution

Calculation of the Calibration Curve. Assumptions similar to those of the former report[2] were made, *viz*, the spots of $BaSO_4$ formed are all of a cylindrical form whose height is equal to the film thickness. We thus obtain the relation

$$D_d^3 = 3/2\rho[\text{Film}]C[Ba(ClO_4)_2]M[Na_2SO_4]Hd_s^2/(\rho[Na_2SO_4]C[Na_2SO_4]M[Ba(ClO_4)_2]), \quad (1)$$

where ρ[Film]: density of film,
$\rho[Na_2SO_4]$: density of aqueous Na_2SO_4 solution,
$C[Na_2SO_4]$: concentration of aqueous Na_2SO_4 solution,
$C[Ba(ClO_4)_2]$: concentration of $Ba(ClO_4)_2$ in film,
$M[Na_2SO_4]$: molecular weight of Na_2SO_4,
$M[Ba(ClO_4)_2]$: molecular weight of $Ba(ClO_4)_2$,
H: thickness of film.

Since the concentration of the Na_2SO_4 solution used is known, Eq. (1) takes the form

1) Part V: Y. Ueno and I. Sano, This Bulletin, **44**, 908 (1971).
2) Y. Ueno and I. Sano, *ibid.*, **44**, 637 (1971).
3) cleaned beforehand in the same way as previously reported.[2]

Table 1. Estimated values of ρ[Film], H and $C[Ba(ClO_4)_2]$ and the values of ε.

Film	ρ[Film][a] (g/cm^3)	H[b] (μ)	$C[Ba(ClO_4)_2]$[c] (%)	$\varepsilon_{obs.}$	$\varepsilon_{calc.}$		
(a)	1.40	0.31_2	10.7	0.33	0.32[d]	0.33[e]	0.33[f]
(b)	1.48	0.33_1	19.0	0.42	0.41	0.40	0.40
(c)	1.55	0.34_9	25.7	0.45	0.46	0.46	0.46
(d)	1.61	0.36_8	31.2	0.52	0.51	0.51	0.51

a), b) and c) The values of ρ[Film], H and $C[Ba(ClO_4)_2]$ are calculated by the relations:

$\rho[\text{Film}]=(W[\text{PVA}]+W[Ba(ClO_4)_2\cdot 3H_2O])/(W[\text{PVA}]/\rho[\text{PVA}]+W[Ba(ClO_4)_2\cdot 3H_2O]/\rho[Ba(ClO_4)_2\cdot 3H_2O])$

$H=4(W[\text{PVA}]+W[Ba(ClO_4)_2\cdot 3H_2O]/\rho[Ba(ClO_4)_2\cdot 3H_2O])/\pi D_f^2$

$C[Ba(ClO_4)_2]=100W[Ba(ClO_4)_2\cdot 3H_2O]\cdot M[Ba(ClO_4)_2]/(W[\text{PVA}]+W[Ba(ClO_4)_2\cdot 3H_2O])M[Ba(ClO_4)_2\cdot 3H_2O]$

where W and ρ and the weight and density, respectively, of solid PVA or $Ba(ClO_4)_2\cdot 3H_2O$ in the film having a diameter D_f which is found to be 2.1 cm.

d) $k=1.0$, $\alpha=0.79_1$, $\beta=0.00015_5$. e) $k=2.0$, $\alpha=0.88_6$, $\beta=0.000056_3$. f) $k=5.0$, $\alpha=0.95_3$, $\beta=0.000019_4$.

$$D_d^3 = Kd_s^2 \tag{2}$$

where K is a constant given by

$$K = 5.82\rho[\text{Film}]HC[Ba(ClO_4)_2].^{4)} \tag{3}$$

According to Eq. (2), a plot of log D_d against log d_s should be linear, and this is actually the case, for all concentrations as shown in Fig. 2, the slope being 2/3 for all straight lines. The value of K is found from the intercept on the log D_d axis.

Theoretical curves calculated by Eq. (2) using the values listed in Table 1, are represented by dashed lines in Fig. 1. It is clear that the diameters of the spots found experimentally are larger than those calculated.

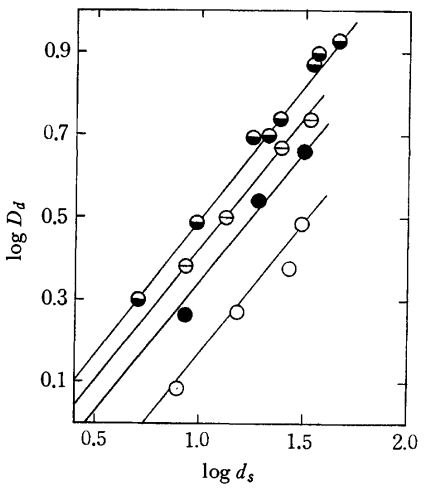

Fig. 2. Plot of log D_d against log d_s.
○: 1 m*l* $Ba(ClO_4)_2$ solution, ●: 2 m*l* $Ba(ClO_4)_2$ solution
⊖: 3 m*l* $Ba(ClO_4)_2$ solution, ◒: 4 m*l* $Ba(ClO_4)_2$ solution

Comparison between Theory and Experiment. It has been shown that for a given D_d[2)]

$$d_{s\ theor.}/d_{s\ exptl.} = (K_{exptl.}/K_{theor.})^{1/2} = \varepsilon \tag{4}$$

The values of ε determined by use of the values of $K_{exptl.}$ and $K_{theor.}$ in accordance with Eq. (4) are listed in Table 1 ($\varepsilon_{obs.}$). All of them are less than unity. For aqueous NaCl solution aerosols it has been shown[2)] that

$$\varepsilon = k(1-\alpha e^{-\beta C}) \tag{5}$$

where C is the concentration (%) of the detecting reagent ($AgNO_3$) in film. The applicability of Eq. (5) for aqueous Na_2SO_4 solution aerosols is shown in Table 1 ($\varepsilon_{calc.}$).

By combining the cases of $AgNO_3$[2)] and $Ba(ClO_4)_2$, we find that

$$\varepsilon = k(1-\alpha e^{-\gamma C/M}) \tag{6}$$

where M is the molecular weight of $AgNO_3$ or $Ba(ClO_4)_2$ and γ a constant.

4) The concentration of the dispersing solution is 10% by weight of Na_2SO_4. The term K, corresponding to $3/2\cdot M[Na_2SO_4]/(\rho[Na_2SO_4]C[Ba(ClO_4)_2]M[Ba(ClO_4)_2]$ in calculated to be 5.82, by replacing the values of 1.09 for $\rho[Na_2SO_4]$, 0.10 for $C[Na_2SO_4]$, 336.2 for $M[Ba(ClO_4)_2]$ and 142.0 for $M[Na_2SO_4]$. For the values of ρ[Film], H and $C[Ba(ClO_4)_2]$, *cf.* Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 628—630 (1972)

Studies on Photo-polarography. V. Theory of Photo-current and Reaction of Aquated Electrons with Scavenger[1]

Kazuo YAMASHITA and Hideo IMAI

Department of Chemistry, Faculty of General Education, Hiroshima University, Hiroshima

(Received December 28, 1970)

The existence of trapped electrons in gamma irradiated glass was directly substantiated by ESR studies[2]. The ESR technique, however, can not be applied to such a transient entity as solvated electrons in solution. On the other hand, the possible existence of free solvated electrons in solution at reasonably close proximity to the parent ion was suggested by spectrophotometric studies[3] using a matrix isolation technique. From kinetics and mass-transport studies[4,5] the reactive but transient entity of an electron in solution is known to be solvated. Accordingly, photo-detached electrons emitted into an aqueous electrolyte solution from an electrode irradiated by ultra-violet light are reasonably assumed to be aquated at a certain distance apart from the electrode surface, where electrons are thermalized. The aquated electrons e^-_{aq} then react with scavenger ions or molecules in solution, producing the photo-current in an electrolytic cell circuit.

The electrolytic photo-current is controlled by the diffusion of e^-_{aq} and its reaction rate with a scavenger. Barker *et al.*[6] gave an equation for the photo-current, but without details. A more generalized solution of this semi-infinite diffusion problem is presented in this paper on the basis of Hatta's theory on the absorption of gases in a reactive solution[7]. The validity of our theory was proved by the dependence of the photo-current on the scavenger concentration and by the Brønsted theory on an ionic reaction with special regard to the solvent effect on the rate process.[8]

Theory

According to Barker's model of the reaction the electrons emitted from the irradiated electrode partly return to the electrode by attraction. Some electrons, however, have sufficient kinetic energy to overcome the attraction,[9] and are thermalized at a distance δ where the attraction is equal to the thermal energy of an electron kT. In this process water molecules are repelled by a thermalized electron, and the liquid is dilated so that a cavity is created in the solution. The electron is then held in the cavity as an aquated electron (Eq. (1)), and enters into the chemical reaction with a scavenger ion or molecule S, as shown in Eq. (2). In this reaction it is assumed that the aquated electrons are wholly depleted through Reaction (2) except the self-decay (Reactions (3) and (4)).

These reactions are schematically shown in the following:

$$e^- + nH_2O \rightleftarrows e^-_{aq} \quad (1)$$

$$e^-_{aq} + S \xrightarrow{k_s} S^- \quad (2)$$

$$e^-_{aq} \rightarrow H_{aq} + OH^-_{aq} \quad (3)^{13}$$

$$2e^-_{aq} \rightarrow H_2 + 2OH^-_{aq} \quad (4)^{13}$$

When the self-decay of e^-_{aq} can be neglected in comparison with the rate of the scavenging reaction, the semi-infinite diffusion equation for the process given by Eqs. (1) and (2) is expressed as follows:

$$\frac{\partial C_e}{\partial t} = D_e \frac{\partial^2 C_e}{\partial x^2} - k_s C_e C_s \quad (5)$$

where C_e and D_e are the concentration and diffusion coefficient of the aquated electron, respectively, k_s the rate constant of Reaction (2), and C_s the scavenger concentration. Under a sufficiently high concentration of scavenger, C_s the scavenger concentration. Under a sufficiently high concentration of scavenger, $C_{s(t=0,x)} = C_{s(t=t,x)}$, we have

$$k_s C_e C_s = kC_e \quad (6)$$

Thus, Reaction (2) can be approximated as a pseudo-first order reaction.

At the stationary state of the diffusion and scavenging process $\partial C_e/\partial t = 0$, and we have from Eq. (5)

$$D_e \frac{\partial^2 C_e}{\partial x^2} = kC_e \quad (7)$$

The boundary conditions for Eq. (7) are

$$\left.\begin{array}{ll} \text{at} & x=0,\ C_e = C_e^s \\ \text{and at} & x=r,\ \dfrac{dC_e}{dx} = 0, \end{array}\right\} \quad (8)$$

12) V. P. Sharma, P. Delahay, G. G. Susbielles, and G. Tessari, *J. Electroanal. Chem.*, **16**, 285 (1968).

13) Whether the decay is to proceed in the first order reaction (Reaction (3)) or in the bimolecular decay depends upon the concentration of the aquated electrons formed on the deposition plane. For a review see F. S. Dainton, "The Chemistry of the Electron," Nobel Symposium 5, ed. by S. Claeson, Interscience Publishers, New York, N. Y. (1967), pp. 185—209.

where r denotes the distance where e_{aq}^-s are depleted.

The solution of Eq. (7) is given by Hatta[7] as in the following:

$$\frac{C_e}{C_e^\delta} = \frac{\cosh\left\{\sqrt{\frac{k}{D_e}}r\left(1-\frac{x}{r}\right)\right\}}{\cosh\left(\sqrt{\frac{k}{D_e}}r\right)} \quad (9)$$

The rate of electron depletion, v, through the scavenging reaction is expressed by the number of electrons diffusing away from the deposite plane during unit time, *i.e.*,

$$v = -D_e\left(\frac{dC_e}{dx}\right)_{x=0} \quad (10)$$

Thus, the photo-current can be expressed as follows:

$$i_p = -FD_e\left(\frac{dC_e}{dx}\right)_{x=0} = FD_eC_e^\delta\sqrt{\frac{k}{D_e}}\tanh\left\{\sqrt{\frac{k}{D_e}}r\right\} \quad (11)$$

When the reaction rate is sufficiently high, then $\sqrt{k/D_e}\cdot r \to \infty$, and $\tanh(\sqrt{k/D_e}\cdot r)$ can be approximated as unity. Thus, Eq. (11) leads to

$$i_p = FD_eC_e^\delta\sqrt{\frac{k}{D_e}} = FC_e^\delta\sqrt{k_sC_sD_e} \quad (12)$$

On the contrary, when the diffusion is sufficiently high in comparison with the reaction rate, the rate will be expressed simply as

$$v' = kC_e^\delta r \quad \text{and} \quad i_p' = FC_e^\delta k_sC_sr \quad (13)$$

It is noteworthy that Eq. (12) coincides well with the Barker equation[6].

Results and Discussion

In the following the validity of Eq. (12) is proved in relation to the dependence of photo-current on the scavenger concentration, ionic strength of the solution and on the static dielectric constant of the solution.

Field Effect on i_p. The field effect on the photo-current was first pointed out by Barker *et al.*[6] Delahay and Srinivasan applied Fowler's theory of photo-detached electrons *in vacuo* to the solution medium in question, and a quadratic relation of i_p to the electrode potential E was proved in the scavenging of e_{aq}^- by the hydrogen ion. Brodski and Gurevich[10] proposed an improved theory and proved a better linear relationship between i_p and $E^{5/2}$. In our experiment using polychromatic light (250—350 mμ) and nitrate as the e_{aq}^- scavenger[14] a better linear relationship of i_p *versus* $E^{5/2}$ was obtained as shown in Fig. 1.

Dependence of i_p on C_s. Eq. (12) shows a linear relationship between the photo-current and the square root of the scavenger concentration. The photo-current measured at the electrode potential of -1.6 V *vs.* S. C. E. showed a good linearity against the square root of the nitrate concentration as shown in Fig. 2. Even in 44% ethanol-water mixture the linearity was excellent in accordance with Eq. (12).

The Brønsted Theory Applied to the Reaction of e_{aq}^- with Nitrate. We assumed that the photo-current

Scavenger, NO_3^-.

flows as a result of Reaction (2) which proceeds in the solution phase at a distance δ apart from the electrode surface (for the reaction model proposed hitherto, *cf.* Ref. 6, 15, 16). The validity of our reaction model, which coincides with the Barker model, can be proved by a solvent effect on the activity coefficient of the reacting species. Thus the Brønsted theory on an ionic reaction was treated, and in the modified expression of the theory a plot of log i_p *vs.* $\sqrt{\mu}/(1+\sqrt{\mu})$ (μ : the ionic strength) should yield a straight line with slope of 0.51 Z_eZ_s, provided C_e and D_e are not significantly varied with changing μ. These data are shown in Fig. 3, which indicates that the values of both Z_e (the charge of the aquated electron) and Z_s (the charge of the scavenger) are univalent and negative.

The effect of the static dielectric constant of a solvent on the rate of an ionic reaction can be discussed in the same way. By combining the Brønsted-Christiansen-Scatchard equation[17,18] and Eq. (12) a plot

14) The scavenging reaction seems to proceed as follows:
$e_{aq}^- + NO_3^- \to NO_3^{2-} + aq \to NO_2 + 2OH^-$
(or $HNO_3^- + OH^-$)

of log i_p *versus* $(\sqrt{\varepsilon}-\text{const})/\sqrt{\varepsilon^3}$ (ε : the static dielectric constant) should yield a straight line for solutions constant μ. The data are shown in Fig. 4. The value of D_e was not corrected for the charge of the solution media in this plot. Nevertheless, it gives a fairly good straight line in accordance with the theory. From the plot the charge of an aquated electron is evaluated to be negative, and the rate-determining step of the photo-current is a reaction of an aquated electron with nitrate in the reaction layer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 630—632 (1972)

Formation of the Boron Chelates in the Sodium Borohydride Reduction of the Schiff Bases

Tsuguo TANAKA, Mitsue KOYAMA, Seiji IKEGAMI, and Masako KOGA
Department of Science and Technology, Saga University, Saga

(Received March 25, 1971)

Billman and Diesing[1] reported that the C=N bond of *o*- or *o'*-hydroxy Schiff bases could not be reduced with sodium borohydride in boiling methanolic solutions. Failure of the reduction was ascribed to the resonance stabilization of the Schiff bases (VIIa↔VIIb) in alkaline media. For the purpose of synthesizing the chelating reagents for the spectrophotometric determination of the metal ions,[2] the reduction of a number of Schiff bases with sodium borohydride in the methanolic solutions at 50°C, was attempted and the results are summarized.

When *o*- or *o'*-monohydroxy compounds are reduced, the expected benzylaniline derivatives are precipitated as crystals merely by the acidification of the reaction mixture with dilute acetic acid (procedure A). The Schiff bases having hydroxyl groups on *o*- and *o'*-positions such as Ig and Ih could also be reduced with sodium borohydride, as evidenced by the disappearance of the orange color of the Schiff bases. However, the expected product IIIg or IIIh does not crystallize upon the acidification of the reaction mixture with acetic acid. Therefore, the isolation of the soluble reaction products from the acidified solution was attempted, and the boron chelate *O,O,N*-(*o,o'*-dihydroxybenzylanilino)-borane (Va) was obtained as crystals by the evaporation of the solvents in a vacuum at room temperature (procedure C). The chelate Va was easily dehydrated to give VIa by sublimation in a vacuum at 130—135°C, indicating a weakly coordinated water molecule of Va. The mass spectral data of Va and VIa, and the structures of the ionic species involved are listed in Table 3. The structure of Va and VIa were proved by the *m/e* of 223 and other *m/e* values. Some differences were observed in the mode of fragmentation between Va and VIa.

The normal reduction products *o*-, *o'*-dihydroxybenzylaniline derivatives were also obtained by evaporating methanol from the reaction mixture prior to dilution and acidification (procedure B).

The IR spectra of IIIg, Va and Vb are given in Fig. 2. The 3600 cm^{-1} O-H stretching of Va was ascribed to the coordinated water molecule.[3] Two

Fig. 1.

IR peaks of 3490 and 3060 cm^{-1} seem to be due to the vibration related to the boron chelates. The peaks of 1470, 1280, and 1125 cm^{-1} of the boron chelate were ascribed to the B-N,[4] B-O,[5] and C-N stretching vibrations, respectively, in comparison with the IR spectrum of IIIg.

From the results, it was concluded that the isolation of the normal reduction products of Ig and Ih was prevented by the formation of soluble boron chelates in weakly acidic solutions.

The Schiff base II did not yield the boron chelate but gave the normal reduction product. The yellow color of II is also in contrast with the orange-red color of Ig and Ih. It is deduced that the naphthalene ring is prohibited by the steric hindrance from being in a plane containing the C=N double bond and the phenyl ring of II.

Experimental

Procedure A. To a solution of 100 mg of the Schiff base Id in 15 m*l* of methanol heated to 50°C, crystals of 50 mg of sodium borohydride were gradually added in small portions after frothing had subsided. The reaction mixture was then cooled, filtered, diluted with 12 m*l* of water, and acidified with dilute acetic acid. The solution became turbid and after a while white crystals separated out. Recrystallization from benzene gave 70 mg of IIId with a melting point 110°C (69.5%).

Procedure B. A solution of 1 g of Ig in 20 m*l* of methanol was treated with 114 mg of sodium borohydride as in procedure A. After the reaction was over, methanol was evaporated off in a vacuum at room temperature. The residual purple oil was dissolved in water, and the solution was acidified with dilute acetic acid. White crystals then separated out. Recrystallization from methanol gave 860 mg of IIIg with a melting point 88—90°C (86%).

Procedure C. A solution of 4.5 g of Ig in 150 m*l* of methanol was treated with 3.4 g of sodium borohydride as in procedure A. After the reaction was over, the reaction mixture was cooled and diluted with 120 m*l* of water, when the color of the solution turned green. The solution was then acidified with dilute acetic acid, and the color of the solution turned reddish brown. Evaporation of the solvent at room temperature in a vacuum, yielded 4.3 g of gray precipitate of Va (84.5%). UV, $\lambda m\mu$ (log ε); 203—5 (4.56), 207 (4.59), 244—5 (3.98), 277 (3.67),[8] 282 (3.70), 292 (3.59)[8] in ethanol; 218 (4.27), 230 (4.02), 275 (3.66),[8] 280 (3.70), 285 (3.66)[8] in cyclohexane.

One gram of Va was sublimed at 130—135°C in a vacuum (5 mmHg), to yield 570 mg of yellow crystals of VIa (61.3%). UV, λ mμ (log ε); 218—220 (4.10), 230 (3.92), 275 (3.53),[8] 280 (3.58), 284 (3.54)[8] in cyclohexane.

Low Frequency Vibrational Spectra of Triarylgermanium Pseudohalides

T. N. SRIVASTAVA and S. K. TANDON*

Department of Chemistry, Lucknow University, Lucknow, India

(Received April 13, 1971)

Infrared spectra of arylgermanium derivatives in the low frequency region have attracted attention of only a few workers[1-3] in recent years. We synthesized some triarylgermanium pseudohalides (Aryl= C_6H_5, p-$CH_3C_6H_4$, pseudohalide=CN, NCO, NCS) and recorded their spectra as KBr discs in the region 650—250 cm^{-1} using a Perkin-Elmer Model 521 Spectrophotometer. The results and fundamental absorption frequencies along with their assignments are given. The characteristic vibrations of pseudohalide groups are identified at the expected positions and have been discussed together with the preparation and purification of the compounds.[4]

Some vibrations of the aromatic rings bonded to germanium atom fall in the recorded range of the spectra. Whiffen's nomenclature[5] has been used throughout to designate various modes of aromatic ring vibrations. A mass sensitive ring stretching vibration t has been observed in all the compounds in the range 370—270 cm^{-1}.[3] It is known[1,3] that when more than one aryl group is present in the molecule, a splitting of this absorption occurs giving rise to a lower component t'. Accordingly we have identified two distinct bands in triphenyl and tri-p-tolylgermanium compounds, the position of the absorption in the former being slightly towards lower frequency side than the latter. The two absorptions have been described by some earlier workers as asymmetric and symmetric phenyl-metal stretching.[2,6-8] The two other mass sensitive aromatic ring stretchings q and r lie above the reported range of the spectra. However, in triphenylgermanium derivatives they have been identified at 1095±1 cm^{-1} vs and 669±1 cm^{-1} w, while in corresponding p-tolyl derivatives they lie at 1088±1 cm^{-1} vs and 702±1 cm^{-1} w respectively.

The strongest absorption in the whole of the spectra is a mass-sensitive out-of-plane ring bending mode which appears as a doublet[6] separated by about 10 cm^{-1} and distinguished by y and y'. Apart from its slight sensitiveness to the mass of the substituent atom,[3] it appears to be dependent on the nature of the substitution of the benzene nucleus. We[9] have identified this absorption in a large number of aryltin compounds and have observed that o-, m- or p- substitution on the benzene ring produces an appreciable change in its position. Some earlier workers[10,11] have mistaken this absorption to be a tin-phenyl stretch. The two other mass sensitive ring deformations u and x are expected to lie below the recorded range of the spectra, although some workers[3,12] have preferred to call the lower component of t by the mode u.

Gas Chromatographic Determination of Reversible Adsorption of Hydrogen. XI.[1] Reversible Adsorption of Hydrogen over Some Metal Oxides

Yoshiko SHIGEHARA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 5, 1971)

It has been shown that the rapid and reversible part of hydrogen adsorption can be measured by means of the gas chromatographic retention volume of deuterium in hydrogen carrier. This method has been applied to metals[2] and metal oxides.[3] It was found that the rapid and reversible adsorption of hydrogen is molecular at low temperature and atomic at higher temperatures. However, not many oxides can remain as oxide at high temperature in a hydrogen stream. The reversible adsorption of hydrogen was determined over some hardly reducible oxides at higher temperatures.

Experimental

The apparatus and procedure for gas chromatographic measurement were essentially the same as before.[2] A deuterium sample was introduced into the hydrogen carrier gas by means of a doser made of glass tubing, and was passed to the catalyst column and detecter.

Vanadium trioxide was obtained from Mitsuwa Chemicals Company, Limited. Chromia was prepared by thermal decomposition of ammonium dichromate. Manganous oxide and zinc oxide were prepared by thermal decomposition of manganous carbonate and zinc oxalate *in vacuo*. The gas chromatographic columns of these oxide samples were made from a glass U tube 10—20 mm in diameter. The amount of samples were as follows. The oxide sample was *in situ* pretreated with hydrogen at rising temperature up to 500°C, during which treatment the following amounts of hydrogen were absorbed as below.

Cr_2O_3	V_2O_3	MnO	ZnO
9.0 g	24.7 g	46.8 g	17.8 g

Results and Discussion

1. Chromia. The deuterium retention volumes are shown in Fig. 1 as a function of temperature. The isobar is independent of the direction of temperature variations. It appears that there is an activated adsorption of hydrogen starting from around 100°C.

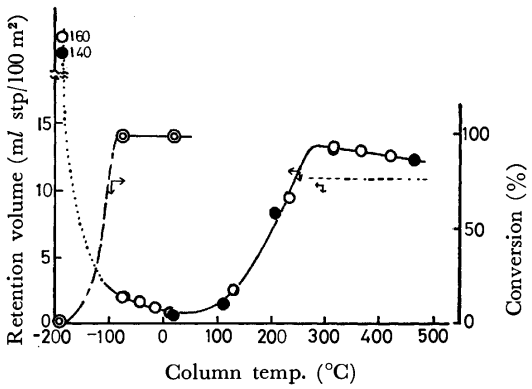

Fig. 1. Deuterium retention volumes and conversion of D_2 into HD by reduced chromia (9.0 g) at different temperatures.
—○— rising temperatures from −195 to 460°C,
—●— lowering temperatures from 460 to −195°C,
—◎— conversion of D_2,
------ difference between retention volume and activated adsorption.

Oxide	Cr_2O_3	V_2O_3	MnO	ZnO
Sorbed hydrogen	18 ml/100 m²	*ca.* 80 ml/g[a]	*ca.* 10 ml/100 m²	14 ml/100 m²
Color of oxide after H_2 treatment	gray	black	pale green	gray

a) This amont of hydrogen corresponds to 0.5 mol per mol of V_2O_3. However, X-ray analysis of hydrogen-treated sample showed only V_2O_3. The large amount of hydrogen consumed might be due to excess oxygen involved.

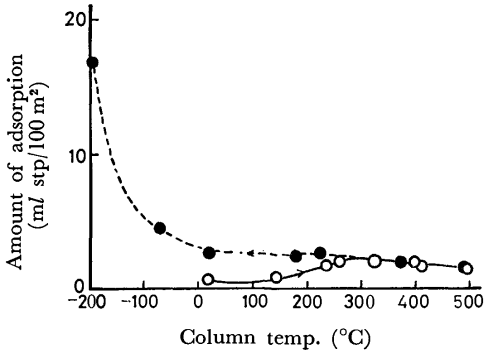

Fig. 2. Hydrogen adsorption isobar on reduced chromia.
—○— 20 → 500°C, —●— 500 → −195°C

In order to examine the contents of the deuterium retention, the static adsorption measurements were carried out on the same sample. The results are shown in Fig. 2. The activated adsorption of hydrogen is clearly demonstrated, but the amount is much less than that of deuterium retention. There must be another type of surface hydrogen which is incorporated into the deuterium retention through an exchange reaction. The amount of exchangeable hydrogen can be estimated by subtracting the activated adsorption from the deuterium retention. It is independent of temperature and is shown in Fig. 1 by the dotted line. Thus the exchangeable hydrogen would be the hydroxyl hydrogen. More than 80% of the deuterium retention accordingly seems to be caused by the surface hydroxyl.

The extent of conversion of D_2 into HD is 100% at above −75°C, while the activatedly adsorbed hydrogen is isotopically equilibrated with the flowing hydrogen above 300°C as shown in Fig. 1. This suggests that the exchange reaction between H_2 and D_2 is catalyzed by an active site other than the adsorption site for high temperature adsorption.

2. Vanadium, Manganese and Zinc Oxides. Three kinds of measurements were made on these oxides, for which activated adsorption of hydrogen is known.[4]

(1) Retention volume of deuterium sample.

(2) Extent of conversion of D_2 into HD in an eluted pulse.

(3) Static measurements of adsorption isobar of hydrogen (summarized in Fig. 3).

The retention volumes over these oxides are commonly null near room temperature, but increase above

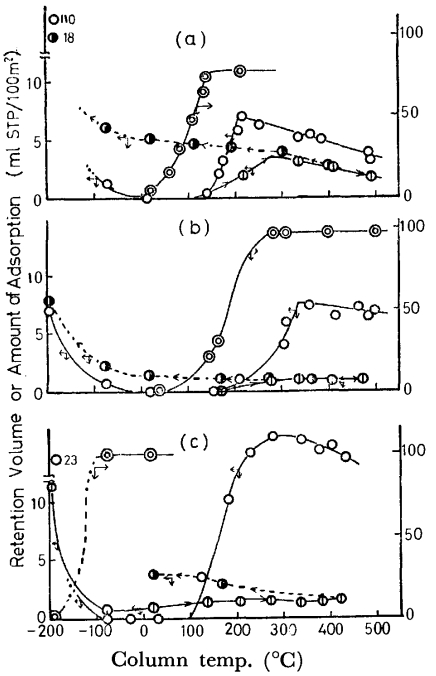

Fig. 3. Deuterium retention volume, amount of adsorption of hydrogen and conversion of D_2 into HD on vanadium (a), manganese (b) and zinc oxides (c).

Conversion, —◎—.

about 100°C up to respective maximums. In higher temperature ranges where the retention volumes decrease with rise in temperature, the rate of adsorption and exchange reaction would be fast enough to establish an isotopic equilibrium between gas and solid surfaces.

The extent of conversion of D_2 into HD begins to increase and reaches isotopic equilibrium[5] at a much lower temperature than the retention volume, particularly in the case of zinc oxide, where the conversion is 100% below 0°C. Thus the exchange reaction between H_2 and D_2 seems to be catalyzed by an active site other than the adsorption site for the high temperature adsorption.

The difference between the retention volume and the static adsorption must be due to the isotopic exchange between the adsorbed hydrogen and surface hydroxyl. The exchange is most extensive in the case of zinc oxide.

4) K. Tarama, and S. Teranishi, *Kogyo Kagaku Zasshi*, **55**, 316 (1952); H. S. Taylor, A. T. Williamson, *J. Amer. Chem. Soc.*, **53**, 2168 (1931); H. S. Taylor, S. C. Liang, *ibid.*, **69**, 1306 (1947). V. Kesavulu and H. A. Taylor, *J. Phys. Chem.*, **64**, 1124 (1960).

5) The equilibrium conversion to HD was lower than 100% in the case of V_2O_3 because of the small volume of the sample column of oxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 636—638 (1972)

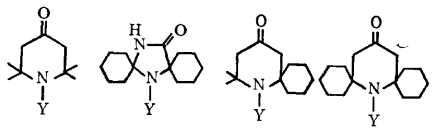
Studies on Stable Free Radicals. VIII.[1] The Synthesis and Oxidation of Hindered 4-Oxopiperidine Derivatives

Takao YOSHIOKA, Susumu HIGASHIDA, and Keisuke MURAYAMA

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received July 22, 1971)

It has been reported that a hindered amine, 2,2,6,6-tetramethyl-4-oxopiperidine (I), was easily oxidized with 30% aqueous hydrogen peroxide in the presence of EDTA and sodium tungstate to give a free radical, 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxyl (II), which was extremely stable in air at room temperature.[2] However, cyclohexane-1-spiro-2′-(4′-oxoimidazolidine)-5′-spiro-1″-cyclohexane (III)[3] did not give the corresponding *N*-oxyl IV (Chart I) and was quantitatively recovered under similar reaction conditions. The difference in the reactivities of I and III can be explained *a priori* by the following factors: a) the effect of the alkyl groups at *C*-2 and *C*-6 (or *C*-5 in imidazolidine ring), b) the character of a heterocyclic ring system. In order to establish the contribution of a), the monocyclohexane derivative V and the dicyclohexane derivative VI (Chart I)



I Y=H III Y=H V Y=H VI Y=H
II Y=O· IV Y=O· VII Y=O· VIII Y=O·

Chart I

were synthesized as is shown in Chart II; the relative ease of the oxidation of V and VI with 30% aqueous hydrogen peroxide into the corresponding *N*-oxyls VII and VIII respectively, was then qualitatively compared with that of I into II.[4] Utilizing a slight modification (in methanol) of the method of Rozantzev,[2] the oxidation of I and V with 30% aqueous hydrogen peroxide into II and VII respectively in good yields was successful, although the ease of the formation of the *N*-oxyl VII was observed to be slightly smaller than that of II. On the other hand, the oxidation of VI into VIII was unsuccessful under the same reaction conditions, and we recovered the starting amine VI. Thus, it was supposed that one of the major factors[4] influencing the rate of the oxidation of such amines is a steric effect. The synthesis of VIII in a good yield was achieved by the oxidation of VI with *m*-chloroperbenzoic acid(CPBA).

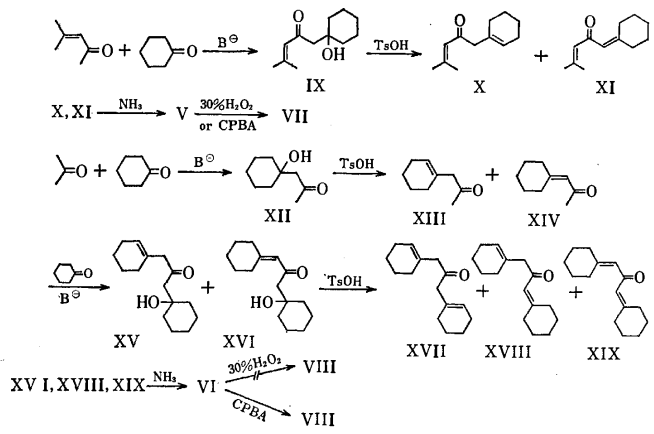


Chart II

Experimental

All the melting points are uncorrected.

Unless otherwise stated, the IR spectra were taken with a Hitachi EPI-S2 spectrometer (Nujol mull or liquid film); the NMR spectra, with a Varian A-60 apparatus, using tetramethylsilane as the internal reference; the mass spectra, with a JEOL-JMS-OIS apparatus, and the ESR spectra, with a Hitachi MES 4001-type X-band apparatus, employing 100-kHz modulation. Table 1 shows the formulae, molecular ion peaks, melting points, boiling points, yields and results of the elemental analysis of all the products, while the spectral data are shown in Table 2.

1-(1-Hydroxycyclohexyl)-4-methylpent-3-en-2-one (*IX*). Into a suspension of 1.00 mol of sodium ethoxide in 500 m*l* of toluene[5] was added slowly and dropwise a mixture of 100 g (1.02 mol) of cyclohexanone and 100.2 g (1.04 mol) of mesityl oxide at −55°C under nitrogen with stirring. After additional stirring for 30 min at −50°C, the reaction mixture was poured into a mixture of 101 g of 35% hydrochloric acid and 700 g of crashed ice. The resulting mixture was allowed to stand at 0°C for 1 hr and then at room temperature overnight. The organic layer was separated, and the aqueous phase was extracted with ether. The combined organic phases were washed three times with water saturated with sodium chloride, and then dried over anhydrous magnesium sulfate. The removal of the solvents and fractional distillation gave 150.3 g of IX.

1-(1-Hydroxycyclohexyl)propan-2-one (*XII*) was similarly prepared from acetone and cyclohexanone.

1-(Cyclohex-1-enyl)-3-(1-hydroxycyclohexyl)propan-2-one (*XV*) *Containing 1-(Cyclohexylidene)-3-(1-hydroxycyclohexyl)propan-2-one* (*XVI*). Similarly, a *ca.* 9 : 1 mixture of XV and XVI was prepared from cyclohexanone and the ketone, XIII, containing XIV.

XVI, A solution of ketols in benzene was refluxed for 1.5 hr in the presence of *p*-toluenesulfonic acid, using a Dean-Stark separator. After cooling the reaction mixture was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent and fractional distillation, IX gave a *ca.* 3 : 1 mixture of *1-(cyclohex-1-enyl)-4-methylpent-3-en-2-one* (*X*) and *1-cyclohexylidene-4-methylpent-3-en-2-one* (*XI*), identified on the basis of the signal intenisty in the NMR spectrum. Similarly, XII gave a *ca.* 85 : 15 mixture of *1-(cyclohex-1-enyl)propan-2-one* (*XIII*) and *1-cyclohexylidenepropan-2-one* (*XIV*) (NMR). Without the separation of XV and XVI, these were dehydrated to give a *ca.* 63 : 34 : 3 mixture of *1,3-(dicyclohex-1-enyl)propan-2-one* (*XVII*), *1-(cyclohex-1-enyl)-3-cyclohexylidenepropan-2-one* (*XVIII*) and *1,3-dicyclohexylidenepropan-2-one* (*XIX*) (NMR).

1-Aza-2,2-dimethyl-4-oxo-spiro[5.5]undecane (*V*). Without the separation of X and XI, these substances(8.7 g, 49.8 mmol) were treated with 12.4 g(730 mmol) of ammonia in 8.7 m*l* of water and 35 m*l* of methanol at 105—110°C for 17 hr in a pressure bottle (glass).[6,7] After the removal of the ammonia and the solvents, the reaction mixture was dissolved into petroleum ether and treated with active char-

6) D. Mackay and W. A. Waters, *J. Chem. Soc., C*, **1966**, 814.

7) It was inferable that the amine V or VI was produced by amination followed by cyclization of XI or XIX *via* isomerization of X or XVII, respectively, under the reaction conditions, although no isomerization was observed on the basis of the NMR and IR spectra under milder reaction conditions (80°C, 7 hr).

coal to give a colorless oil after the removal of the selvents. The oil was dissolved into acetone and diluted with water to give colorless needles of the monohydrate of V.

Cyclohexane-1-spiro-2'-(4'-oxopiperidine)-6'-spiro-1''-cyclohexane (*VI*). Similarly, a ketone mixture of XVII, XVIII, and XIX was treated for 24 hr. Almost pure crystals of VI separated out when the reaction mixture was cooled to room temperature.

Oxidation of Hindered Amine V with 30% Aqueous Hydrogen Peroxide in Methanol. The monohydrate of V(200 mg, 0.94 mmol) was oxidized with 0.5 g (4.41 mmol) of 30% aqueous hydrogen peroxide in 1 m*l* of methanol in the presence of EDTA and sodium tungstate at room temperature for 76 hr. After the removal of the methanol, 10 m*l* of benzene and 0.7 g of potassium carbonate were added to the reaction mixture; the resulting suspension was stirred at room temperature for 1 hr in order to decompose excess hydrogen peroxide. The potassium carbonate was filtered off; the subsequent evaporation of the benzene *in vacuo* gave *1-aza-2,2-dimethyl-4-oxo-spiro[5.5]undecane-1-oxyl* (*VII*) as an oil, which gave reddish needles upon recrystallization from *n*-hexane.
ESR: a triplet (10^{-3} M).

Oxidation of the Hindered Amine VI with 30% Aqueous Hydrogen Peroxide in Methanol. By the same procedures, the amine VI was recovered quantitatively. The oxidation of VI for 9 days gave a trace of the *N*-oxyl VIII, and most of the starting amine VI was recovered.

Cyclohexane-1-spiro-2'-(4'-oxopiperidine-1'-oxyl)-6'-spiro-1''-cyclohexane (*VIII*). A solution of 4.7 g (20 mmol) of the amine VI and 18.0 g (105 mmol) of CPBA in 120 m*l* of chloroform was stirred for 2 days at room temperature and washed with a 10% aqueous solution of potassium carbonate three times and then with water. The chloroform layer was dried over anhydrous magnesium sulfate and concentrated *in vacuo* to give a reddish oil, which solidified on being triturated in a small amount of petroleum ether. The crude product was dissolved into a small amount of benzene, after which petroleum ether was added to give reddish-orange prisms. ESR: a triplet (10^{-3} M).

The *N*-oxyl VII was also synthesized from V by similar procedures(CPBA).

The authors would like to thank Dr. Genshun Sunagawa, the director of these laboratories, for his encouragement and Mrs. Eiko Mori and Mr. Tsutomu Kanai for their technical assistance.

A Novel Synthesis of 3,4-Benzotropolone

Masaru SATO, Josuke TSUNETSUGU, and Seiji EBINE

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama

(Received July, 26, 1971)

3,4-Benzotropolone has been synthesized with difficulty from tediously-obtainable 2,3-benzosuberone.[1,2] We now wish to develop a method capable of synthesizing simply 3,4-benzotropolone.

There have appeared several examples of the reaction of diazo compounds with quinones. Diazomethane reacts with β-naphthoquinone (I) to afford a resinous product[3] or a dioxole derivative,[4] although it reacts with *p*-benzoquinone to give tropone derivatives in a few cases.[5-7] On the other hand, diazo compounds can react with quinones in the presence of Lewis acid to induce ring enlargement, thus affording troponoids.[8]

We examined the reaction of I with diazomethane in the presence of boron trifluoride etherate. To a methylene chloride solution of I and boron trifluoride etherate, we added an equal volume of an ethereal diazomethane solution. After working up as usual, followed by chromatographic separation, a bright yellow crystalline product (II) was obtained. II exhibited infrared absorption bands (KBr) at 1424, 1398, 1377, and 1329 cm^{-1} assignable to the chelated carbon-oxygen stretching absorption and at 1100 cm^{-1} due to the oxygen-boron stretching absorption.[9] The NMR spectrum ($CDCl_3$) of II showed only aromatic protons at δ 9.0 (1H) assignable to a benzene ring proton *peri* to the carbonyl group of a tropolone ring and at δ 8.0 (6H) for the other benzene and tropolone ring protons. These spectral data, as well as the complete agreement of the results of elemental analysis, indicated II to be a chelate compound of 3,4-benzotropolonoboron difluoride. The structure of II was established unequivocally by the fact that II was again formed in a high yield on the treatment of 3,4-benzotropolone (III) with boron trifluoride etherate.

The ring enlargement of I was examined under various conditions; the results are shown in Table 1. This reaction gave a very low yield in an ethereal solution but a fairly good yield (25.5%) in a 1 : 1 mixture of ether and methylene chloride. The use of an excess amount of boron trifluoride etherate resulted in no increase in the yield.

II was hydrolyzed with dilute sulfuric acid to afford III in an almost quantitative yield, the overall

a) The quinone (I) was recovered in 17% yield.
b) Calculated on the basis of *N*-nitrosomethylurea.

yield of III from I amounting to 24%. The present method for the synthesis of III involves a brief sequence starting with the easily-available I; it is markedly superior in its simplicity to another recently-reported method.[2)]

Experimental

Reaction of β-Naphthoquinone (I) with Diazomethane in the Presence of Boron Trifluoride Etherate. A distilled ethereal solution (50 m*l*) of diazomethane prepared from nitrosomethylurea (2.1 g, 0.005 mol) was rapidly added to a solution of freshly-prepared I (0.79 g, 0.005 mol) and 47% boron trifluoride etherate (1.5 m*l*, 0.005 mol) in methylene chloride (50 m*l*) under an atmosphere of nitrogen and with cooling in an ice bath. After having been stirred for 30 min, the mixture was poured into water and extracted with methylene chloride. The organic layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure at room temperature. To the residue we then added a small amount of methylene chloride (*ca.* 10 m*l*), and the insoluble crystals were filtered off. The filtrate and the washings were directly charged on a silica-gel column, which was then eluted with methylene chloride. The evaporation of the solvent from the eluate and the recrystallization of the product from benzene gave 3,4-benzotropolonoboron difluoride (II) as yellow crystals; mp 188—195°C. Yield, 0.281 g (25.5%). Found: C, 59.75; H, 3.21%. Calcd for $C_{11}H_7O_2BF_2$: C, 60.05; H, 3.20%.

This reaction was examined under various conditions; the results are given in Table 1.

Hydrolysis of 3,4-Benzotropolonoboron Difluoride (II). A mixture of II (122 mg), 2 N sulfuric acid (15 m*l*), and ether (10 m*l*) was refluxed for 0.5 hr. After the evaporation of the ethanol, the residue was diluted with water and extracted with cyclohexane. The subsequent removal of the solvent from the extract, after drying over anhydrous magnesium sulfate, gave a product (mp 82—85°C) which was sublimed at 130°C/20 mmHg to give pale yellow crystals of III (mp 85—86°C) in 94.3% yield. Admixture with an authentic sample[1)] showed no depression of the melting point.

Reaction of 3,4-Benzotropolone (III) with Boron Trifluoride Etherate. To a solution of III (30 mg) in absolute ether (3 m*l*) we added 47% boron trifluoride etherate (0.1 m*l*). The product, precipitated after the mixture had stood for 20 min, was collected by filtration and washed with ether to afford II (35 mg, 90% yield); mp 187—193°C (from benzene). The infrared spectrum of this compound was in complete agreement with that of the sample obtained by the ring enlargement of I.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 640—641 (1972)

The Formation of Ternary Complexes Involving Mercury(II) and Phenolphthalein Complexone

Toshiaki NOMURA, Kazuo WATANABE, and Sumio KOMATSU

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received August 6, 1971)

Organic reagents (R) with two iminodiacetate group in a molecule react with mercury(II) to give the corresponding mercury(II) complexes. These complexes then react with anions (X), such as cyanide, thiocyanate, iodide, bromide, and thiosulfate, to form the corresponding mixed-ligand complexes. The molar ratio of Hg(II) : R : X in these mixed-ligand complexes is found to be 1 : 1 : 1.[1,2] In the mixed-ligand complex of thymolphthalein complexone (TPC), the ratio is also 2 : 1 : 1.[2] In this paper phenolphthalein complexone (PPC), which has a structure analogous to TPC, will be discussed with regard to reactions with mercury(II) and anions.

Experimental

Reagents and Apparatus. All the reagents were of an analytical grade and were used without further purification. A PPC solution of 1×10^{-2} M was prepared by disolving Dotite PPC (121.7 mg) with small amounts of water, adding 100 m*l* of methanol, and diluting to 200 m*l* with water. This solution was diluted to a suitable concentration with water when used. Standard mercury(II) ($F=1.041$) and cyanide solutions of 1×10^{-2} M and a buffer solution were prepared as in a preceding experiment.[1]

The absorbances of the solutions were measured by means of a Hitachi Perkin Elmer 139-type spectrophotometer, while the absorption spectra were recorded by means of a Shimadzu Multipurpose Recording Spectrophotometer, MPS-50L type, with quartz cells of an optical length of 10.0 mm. The pH values were measured by means of a Hitachi-Horiba M-5-type pH meter.

Results and Discussion

Reaction of Mercury(II) with PPC. Absorption Spectra: At pH 10.8, a PPC solution showed a weak absorption spectrum with a peak at 565 mμ in the visible region (Fig. 1). When mercury(II) was added to the solution, it gave a strong absorption spectrum in which the peak was shifted to 574 from 565 mμ and in which a new absorption peak appeared at 384 mμ in the visible region. In view of these facts, it can be said that PPC reacted with mercury(II) to form a mercury (II) complex with a strong absorption in the visible region.

Effect of pH: The absorbances of the mercury(II) complex appeared adruptly from a neutral solution, and gave constant values between about pH 10.5 and 11.5.

Composition of the Mercury(II) Complex: The molar ratio of mercury(II) to PPC in the mercury(II) complex was found to be 1 : 2 by the use of the molar-ratio (Fig. 2) and continuous-variation methods. The apparent stability constant (K) of the complex ($Hg(PPC)_2$) was found to be 1.0×10^{11} at an ionic strength of $\mu=0.10$ and at pH 10.8 by the molar-ratio method.

Stability of the $Hg(PPC)_2$ and the PPC Solutions: The absorbance of the PPC solution (reagent blank) at pH 10.8 did not change for 2 hr. The absorbance of the mercury(II)-complex ($Hg(PPC)_2$) solution was constant for about 20 min, but it decreased at a rate of 1.0% an hour beyond this time.

Hg(II): 1×10^{-5} M, pH: 10.8, reference: water.

1) T. Nomura, This Bulletin, **43**, 104 (1970).
2) T. Nomura, R. Ikeda, and S. Komatsu, *Nippon Kagaku Zasshi*, **91**, 497 (1970).

Application for the Spectrophotometric Determination of Mercury(II): The above discussion shows that the spectrophotometric determination of mercury(II) with PPC was possible. Mercury(II) up to 60 μg could be determined with a good reproducibility by the following procedure, and the molar extinction coefficient was found to be 3.5×10^4.

Procedure: A mercury(II) sample solution containing up to 60 μg was treated with a buffer solution to adjust the pH to 10.5—11.5, 5 m*l* of a 2×10^{-4} M PPC solution were added, and then the mixture was diluted to 50 m*l* with water. The absorbance of the solution was measured after about 15 min at 574 mμ against the reagent-blank solution.

Reactions of $Hg(PPC)_2$ with Anions. Cyanide, iodide, and thiosulfate reacted with the mercury(II) complex to give the corresponding compounds, colored slightly. The molar ratio of the mercury(II) complex to these anions were determined by means of the molar-ratio (Fig. 3) and continuous-variation methods

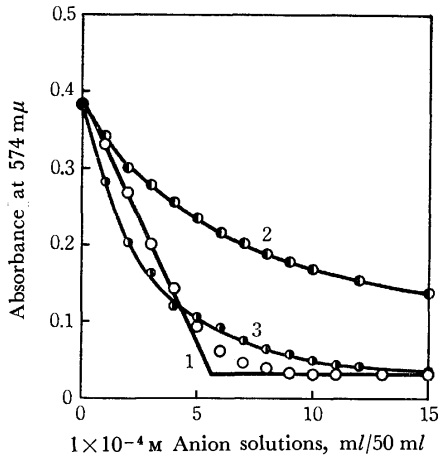

Fig. 3. Reactions of mercury(II) complex with anions. Hg(II): 1×10^{-5} M, PPC: 2×10^{-5} M, pH: 10.8, reference: water.
1) Cyanide ($F=0.928$). 2) Iodide ($F=1.001$).
3) Thiosulfate ($F=1.000$).

and by recording the absorption spectra of mercury(II)-complex solutions containing different amounts of the anions.

The absorption peak, at 574 mμ, of the mercury(II)-complex solution shifted linearly to 570 mμ with cyanide up to $CN^-/Hg(PPC)_2=1$. When an excess of cyanide was added, the absorption spectrum agreed with that of the PPC solution; the maximum absorption at 570 mμ shifted to 565 mμ, and the absorption peak at 384 mμ decreased. When an excess of iodide was added to the mercury(II)-complex solutions, the absorption peak at 574 mμ did not shift to 565 mμ, but to 569 mμ. From the results described above, it was found that cyanide and iodide (X_1) reacted with the mercury(II) complex as follows. When X_1 was added to the mercury(II) complex solution up to $Hg(PPC)_2/X_1=1$, a mixed-ligand complex (Hg-PPC-X_1) was formed and then the PPC was dissociated. When an excess of cyanide was added to the cyano mixed-ligand complex solution, the complex turned into mercury(II) cyanide and PPC. The iodo mixed-ligand complex, however, did not react with an excess of iodide to give mercury(II) iodide and PPC. From Fig. 3(1), it can be seen that the spectrophotometric determination of cyanide could be performed with the mercury(II) complex. This method was especially selective for cyanide because the only interfering anions were sulfide, thiosulfate, and iodide.

The mercury(II) complex reacted with thiosulfate in the molar ratio of 2 : 1. The absorption spectrum of this solution agreed with that of the PPC solution if an amount of thiosulfate about 3 times that in the molar ratio was added.

The absorption spectrum of the mercury(II)-complex solution did not change upon the addition of any other anions, such as fluoride, chloride, bromide, or thiocyanate. Therefore, it can be said that these anions did not react with the mercury(II) complex. The ammonium ion also did not react with this complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 642—644 (1972)

Some Reactions of Tetrafluorobenzyne with Halogens and Ethers, and with Alcohols

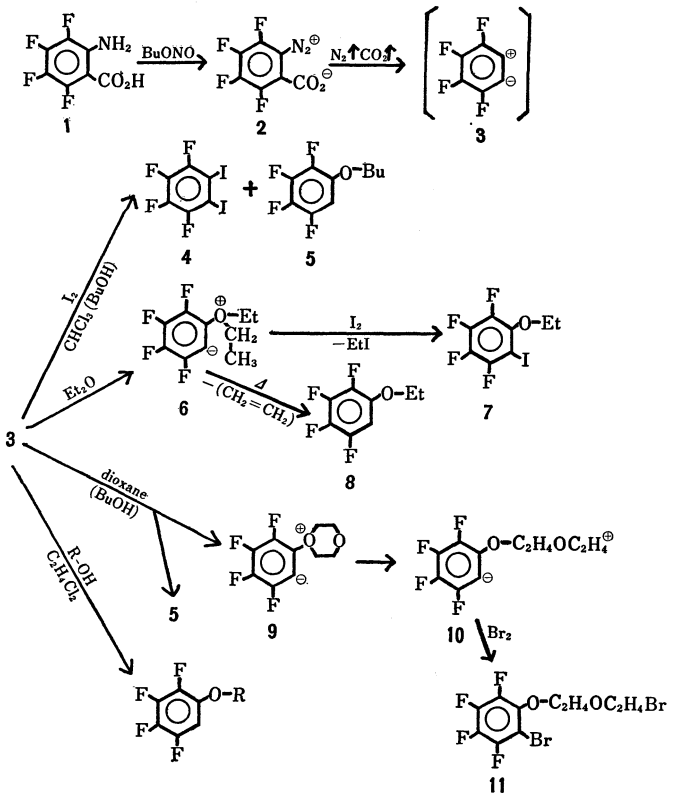
Seiichi HAYASHI and Nobuo ISHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received August 11, 1971)

As reported previously,[1] tetrafluorobenzyne generated from tetrafluorobenzenediazonium-2-carboxylate behaved as a potential electrophile, and it reacted even with diethyl ether to give 1-ethoxy-2,3,4,5-tetrafluorobenzene(**8**). In our continued studies of this subject, we have found that the tetrafluorobenzyne reacts with halogens and ethers, such as iodine and diethyl ether, or with bromine and dioxane, to give *o*-halogenoalkoxytetrafluorobenzenes.

When tetrafluoroanthranilic acid (**1**) was diazotized with *n*-butyl nitrite in chloroform and the resulting tetrafluorobenzenediazonium-2-carboxylate (**2**) was decomposed in the presence of iodine, two products were obtained : one was the expected 1,2-diiodotetrafluorobenzene (**4**) (15% yield), while the other was 1-butoxy-2,3,4,5-tetrafluorobenzene (**5**) (25% yield).



8 (R=Et)
5 (R=Bu)
12a (R=*i*-C_5H_{11})
12b (R=CH_2CH_2Cl)
12c (R=CH_2CH_2OH)
12d (R=CH_2CH_2OEt)

The latter compound was probably formed by the reaction of tetrafluorobenzyne and 1-butanol, which itself resulted from the diazotizing agent, *n*-butyl nitrite.

If the above reaction was carried out in diethyl ether, however, 1-ethoxy-2-iodo-3,4,5,6-tetrafluorobenzene (**7**) was obtained as the main product. In this case, it is evident that iodine reacted with the betaine intermediate **6**, prior to its intramolecular proton-withdrawing to ethoxytetrafluorobenzene (**8**) and ethylene.

Furthermore, if dioxane was used as the solvent and bromine was present in the reaction mixture, tetrafluorobenzyne reacted with both, thus affording 1-(β-(β'-bromoethoxy)ethoxy)-2-bromotetrafluorobenzene (**11**) as the main product. This reaction seemed to have started with the electrophilic attack of tetrafluorobenzyne on dioxane to form **9**, followed by the cleavage of dioxane molecule to **10** and the subsequent reaction of bromine on this betaine intermediate. This is probably the first example of the reaction of any benzyne with dioxane.

In the absence of bromine, however, the only product isolated was 1-butoxy-2,3,4,5-tetrafluorobenzene (**5**), which, as has been mentioned before, had been formed from tetrafluorobenzyne and butanol, which had itself come from *n*-butyl nitrite. In this case, no product which might be formed by the reaction between benzyne and dioxane was confirmed. We assume that this is because the intramolecular proton transfer in the betaine intermediate, **9** or **10**, is sterically more difficult than that in the case of **6**.

Our finding that, in the presence of halogen, dioxane is cleaved by tetrafluorobenzyne seems to be analogous to the facts, which have been reported recently, that tetrahydrofuran is cleaved by benzyne in the presence of water,[2] in the absence of it no product which might result from the cleavage of tetrahydrofuran is observed.[3]

As has been described above, tetrafluorobenzyne reacted with even a small amount of butanol present in the reaction mixture to give a considerable amount of butoxytetrafluorobenzene (**5**). Then, to generalize this reaction we effected the diazotization-decomposition of tetrafluoroanthranilic acid in various alcohols. As we had expected 1-alkoxy-2,3,4,5-tetrafluorobenzene was obtained in a rather good yield in every case. The structures of these compounds were clear from their ^1H and ^{19}F NMR spectra (Table 1).

a) Values calculated according to Bruce's formula[4] are: 2-F, 80; 3-F, 78; 4-F, 86; 5-F, 63 ppm.

Experimental

All the NMR spectra were run at room temperature, and CCl_4 was used as the solvent unless otherwise noted. The chemical shifts in ^{19}F NMR are shown by δ(ppm) from external CF_3CO_2H.

The Reaction of Tetrafluorobenzyne with Iodine in Chloroform. Into a solution of *n*-butyl nitrite (3.09 g, 0.030 mol) and iodine (7.62 g, 0.030 mol) in chloroform (20 m*l*), a solution of tetrafluoroanthranilic acid (**1**) (4.18 g, 0.020 mol) in chloroform (80 m*l*) was added drop by drop, at 50°C over a 40-min period. After refluxing for 6 hr, the solvent was distilled out in a vacuum and the residue was dissolved in diethyl ether. The ether solution was then treated with an aqueous solution of sodium sulfite to remove the excess iodine, and with a dilute aqueous sodium hydroxide solution to remove any alkaline-soluble matter. After subsequent washing with dilute hydrochloric acid and water, it was dried with magnesium sulfate. The solvent was evaporated, and the oily residue was distilled in a vacuum to give the following two products:

1) 1-*n*-butoxy-2,3,4,5-tetrafluorobenzene (**5**); bp 60—61°C/3 mmHg (1.1 g, 25% yield). Identified with **5** in Table 1 by means of its IR spectrum.

2) 1,2-diiodotetrafluorobenzene (**4**); bp 74°C/3 mmHg, mp 49—51°C (lit. mp 50—51°C[3]). IR: 1110, 1023 cm^{-1} (C-F). ^{19}F NMR (in Me_2CO): +24.7 (3,6-F), +71.7 (4,5-F) ppm.

The Reaction of Tetrafluorobenzyne with Iodine and Diethyl Ether. Into a boiling mixture of *n*-butyl nitrite (2.48 g), iodine (5.08 g), dichloromethane (20 m*l*), and diethyl ether (20 m*l*), a solution of **1** (4.18 g) in diethyl ether (20 m*l*) was added, drop by drop, during the course of 3 hr. The reaction was then run and after-treated in the manner described above; 1-ethoxy-2-iodotetrafluorobenzene (**7**) (bp 65—66°C/3 mmHg, 1.75 g) was thus obtained in a 27% yield.

Found: F, 23.6%; I, 39.5%. Calcd for $C_8H_5F_4IO$: F, 23.7%; I, 39.7%. NMR: ^1H, τ 5.85 q (CH_2), 8.52 t (CH_3); ^{19}F, +38.8 (3-F), +74.9 (6-F), +75.7 (5-F), +82.1 (4-F).

The Reaction of Tetrafluorobenzyne with Bromine and Dioxane. Into a solution of *n*-butyl nitrite (2.60 g) and bromine (3.80 g) in dioxane (30 m*l*), we added a solution of **1** (4.18 g) in dioxane (30 m*l*) at 55—65°C over a 2-hr period. Stirring was continued for 8 more hr at 94°C, and then the reaction mixture was treated as usual, giving 1-(β-(β'-bromoethoxy)-ethoxy)-2-bromo-3,4,5,6-tetrafluorobenzene (**11**) (bp 124—125°C/2 mmHg, 2.2 g) in a 28% yield.

Found: Br, 40.8%; F, 19.3%. Calcd for $C_{10}H_8Br_2F_4O_2$: Br, 40.4%; F, 19.2%. NMR: ^1H, τ 5.78 t (α CH_2) 6.08—6.37 m (β CH_2 and $\alpha'CH_2$), 6.60 t (CH_2Br); ^{19}F,

4) M. I. Bruce, *J. Chem. Soc., A*, **1968**, 1459.

+52.8 (3-F), +75.6 (6-F), +77.6 (5-F), +83.0 (4-F). IR: 1190 (Ar-O-C), 1080 (C-F).

When the above reaction was carried out without bromine, **5** was obtained as the main product (bp 93—94°C/19 mmHg, 1.4 g, 32% yield), as was confirmed by a study of the IR spectrum. The other fraction isolated (bp 120—136°C/3 mmHg, 1.0 g) was a mixture of more than three components, as was shown by gas chromatography; they could not be separated from each other.

*1-Ethoxy-2,3,4,5-tetrafluorobenzene (**8**).* Into a mixture of *n*-butyl nitrite (1.3 g), ethanol (10 m*l*), and 1,2-dichloroethane (10 m*l*), we added a solution of **1** (2.1 g) in ethanol (10 m*l*) at 50—60°C over a 1 hr period. After refluxing for 3 hr with stirring, the solvent was evaporated in a vacuum, and the residue was dissolved in diethyl ether. On treating with an aqueous sodium hydroxide solution to remove the alkaline-soluble matter and washing with dilute hydrochloric acid and then with water, the ether solution was dried on magnesium sulfate. The ether was evaporated, and the residue was distilled to give **8** (1.3 g), which was identified with an authentic sample.[1)]

The reactions with other alcohols were carried out in a similar manner (Table 1).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 644—645 (1972)

The Solvent Effect on the Visible Absorption Spectra of the Radical Anion and the Dianion of Anthraquinone[1)]

Masamichi FUJIHIRA and Shigeo HAYANO

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received August 14, 1971)

In a previous work,[2)] the half-wave potentials of anthraquinone were found to shift to more positive potentials with an increase in the water content in the DMF-alkaline water system. This behavior was interpreted in terms of the hydrogen-bonding of the radical anion or the dianion with water. On the other hand, the change in the hyperfine coupling constants in the ESR spectra of the radical anions[3–6)] has been interpreted also in terms of the hydrogen-bonding of the radial anions with hydroxylic solvents, and a quantitative treatment has been given by Fraenkel *et al.*[5)] The present work will deal with this hydrogen-bonding from the viewpoint of the solvent effect on the visible absorption spectra of the radical anion and the dianion of anthraquinone and with the correlation between the solvent shift of the visible absorption spectra of the anions and the change in the half-wave potentials.

Experimental

The radical anion and the dianion of anthraquinone in the DMF-alkaline water system were generated by controlled-potential electrolysis.[7)] The measurements of the visible absorption spectra of the anions were the same as have been described in a previous paper.[7)]

Results and Discussion

In DMF containing 0.1 N tetraethylammonium perchlorate (TEAP) as the supporting electrolyte, the absorption maxima of AQ^- were 390, 410, and 553 mμ[7)] and those of AQ^{2-} were 420 and 460 mμ. Every visible absorption maximum showed a strong blue shift with an increase in the water content, as is shown in Fig. 1. The results for the radical anion are consistent with the λ_{max} values of 410 and 555 mμ in DMF[8)] and with the λ_{max} values of 400 and 480 mμ in an ethylene glycol-alkaline water system.[9)] As the molar extinction coefficients for these visible absorption bands were of the order of 10^4,[7)] these intense

absorption bands are presumably due to the $\pi \rightarrow \pi^*$ allowed transition.[10,11]

The blue shifts are similar not only to the change in the hyperfine coupling constants in the ESR spectra,[12] but also to the change in the half-wave potentials.[2] The changes are sharp for small quantities of water, but they gradually level out. The changes in the transition energies of AQ^- and AQ^{2-} were compared with the changes in the half-wave potentials[2] of the first and the second waves respectively. There exists a linear relation between them, as is shown in Fig. 2. Such a relation suggests that both solvent shifts have the same cause, *i.e.*, hydrogen-bonding.

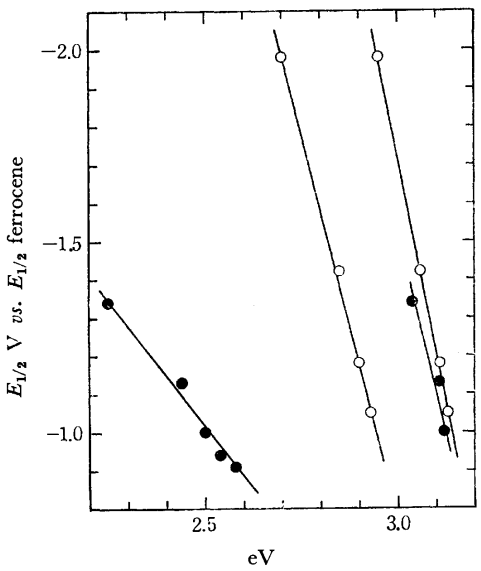

Fig. 2. Correlation between the solvent shifts of λ_{max} and those of $E_{1/2}$.
●, λ_{max} of AQ^- *versus* $E_{1/2}$ of the first wave.
○, λ_{max} of AQ^{2-} *versus* $E_{1/2}$ of the second wave.

The electronic structures of hydrocarbon mono- and dinegative ions have been studied considerably,[13] but no theoretical investigations of those of mono- and dinegative ions of quinones have ever been made except for that of the *p*-benzosemiquinone ion.[11] Thus, we performed the HMO calculations in order to interpret the behavior qualitatively. The oxygen atoms of the anions are expected to be more electronegative in protic solvents, such as water and alcohol, than in aprotic solvents.[5] The Coulomb integral for the oxygen atom was varied in the calculations, since the change in the electronegativity of the oxygen atoms corresponds to the variation in the Coulomb integral for the oxygen atoms.[5] The variations in the energy levels with the change in the values of the parameter, δ, in the $\alpha_o = \alpha + \delta\beta$ relation for the Coulomb integral of the oxygen atom are shown in Fig. 3. The highest occupied energy level of the mono- and dinegative ions of b_{3g}* is found to be lowered remarkably with an increase in the values of δ. Thus, it is clear from such a simple calculation that the blue shift of λ_{max} and the positive shift of $E_{1/2}$ with the increase in the water content can be interpreted in terms of the hydrogen-bonding.

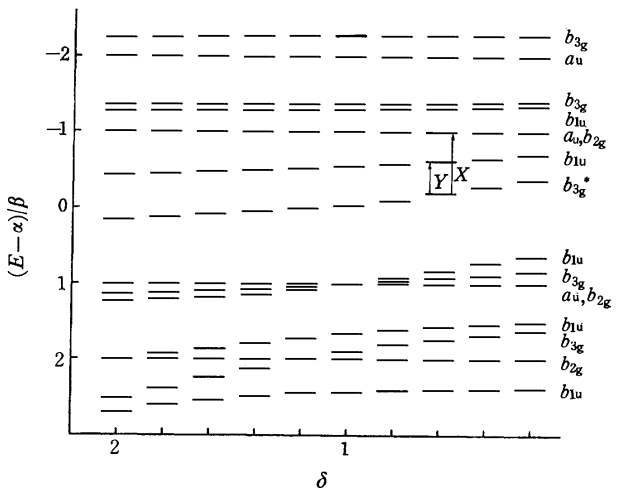

Fig. 3. Variations of the energy levels of anthraquinone with the change in the Coulomb integral for the oxygen atoms. The Coulomb and resonance integrals are assumed as follows:[14,15]

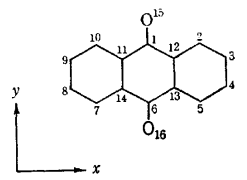

$\alpha_{12}=\alpha_2=\alpha_3=\alpha \quad \alpha_1=\alpha+0.2\beta$
$\alpha_0=\alpha+\delta\beta$

$\beta_{1-15}=\beta_{12-13}=\beta_{12-2}=\beta_{2-3}=\beta_{3-4}=\beta$
$\beta_{1-12}=0.8\beta$

14) A. Kuboyama, This Bulletin, **31**, 752 (1958).
15) Fraenkel *et al.*[5] adjusted α_o and β_{1-15} by varying the parameters δ and γ in the relations $\alpha_o=\alpha+\delta\beta$ and $\beta_{1-15}=\gamma\beta$ in an attempt to fit the proton splittings observed from the radical anions in ethanol - water system. The best values were found to be $\delta=0.9$ and $\gamma=1.4$. The HMO calculations were then performed in an attempt to fit the data for proton splittings in dimethylsulfoxide (DMSO) solution by adjusting the value of δ, while γ used for the ethanol - water system was left unchanged. The best value was found to be $\delta=0.4$ in DMSO. In the present work, other parameters except α_o were quoted from Ref. 9, because the tendency was not affected very much by the choice of parameters.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 646—647 (1972)

The Thermal *trans*-to-*cis* Isomerization of $[CrCl_2(en)_2]Cl$ in the Solid Phase

Choei SATO and Suekichi HATAKEYAMA

Department of Chemistry, Faculty of Science, Hirosaki University, Hirosaki

(Received August 30, 1971)

The *cis*↔*trans* isomerization reactions of transition metal complexes have been extensively studied in solution.[1] However, only a few studies have been recently reported on reactions in the solid phase,[2] and little is known about the mechanism of these solid-phase isomerizations. The thermal behavior of *trans*-$[CrCl_2(en)_2]Cl$ in the solid phase was studied by differential thermal analysis (DTA) and compared with that of the *cis*-isomer. *trans*-$[CrCl_2(en)_2]Cl$ showed an endothermic peak at 275°C and then an exothermic peak at 285°C, after which the sample turned reddish violet from gray green, accompanied by an appreciable bulk compression, and above 300°C it decomposed. On the contrary, the *cis*-form showed no peak up to 300°C, and above 300° it decomposed quite like the product obtained by heating *trans*-isomer up to 300°C. The *trans*-to-*cis* isomerization of $[CrCl_2(en)_2]Cl$ at 250—290°C was suggested and confirmed by measurements of the infrared and electronic spectra of the samples.

Experimental

Both *trans*-$[CrCl_2(en)_2]Cl$ and *cis*-$[CrCl_2(en)_2]Cl \cdot H_2O$ were prepared as has been described in the literature.[3] DTA studies were made using the Rigaku-Denki automatic recording DTA apparatus, in which the inert material was alumina, with a helium gas flow through the sample. A powdered sample of 100 mg sandwiched between alumina layers was used, and the heating rate was 5°C min^{-1}. The Rigaku-Denki differential scanning calorimeter (DSC) was also used for a more detailed inspection, with a 20-mg sample and a heating rate of 3°C min^{-1}. The infrared spectra were recorded as Nujol and hexachlorobutadiene mulls on a Model 601-F (4000—200 cm^{-1}) grating spectrophotometer of the Japan Spectro Co., Ltd. The electronic spectra of the samples in aqueous hydrochloric acid solutions were obtained on a Hitachi EPS-2U recording spectrophotometer.

Results and Discussion

The DTA curve obtained for the *trans*-$[CrCl_2(en)_2]Cl$ is given in Fig. 1, together with that of *cis*-$[CrCl_2(en)_2]Cl \cdot H_2O$. In the case of the former, an endothermic peak appears at 275°C and then an exothermic peak at 285°C, but in the case of the latter these peaks do not appear. Above 300°C both complexes decompose in almost the same way. In the heat treatment up to 300°C, the *trans*-complex shows only a slight weight loss (less than one percent), but in the above-peak region it changes in color to a dark-reddish violet from the initial gray green, and there is an accompanying appreciable bulk compression. This product, once obtained from the *trans*-form on being heated up to 300°C, shows no color change upon cooling and no peak in DTA curve when reheated to 300°C. To present the details of the thermal behavior of the *trans*-complex in the 230—300°C region, the DSC curve is shown in Fig. 2. It is noteworthy that small endothermic and exothermic peaks precede the principal peaks.

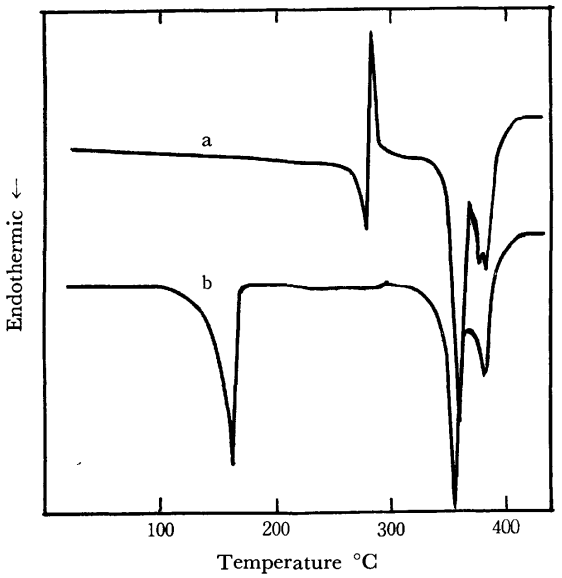

Fig. 1. The DTA curves of *trans*-$[CrCl_2(en)_2]Cl$ (a), and *cis*-$[CrCl_2(en)_2]Cl \cdot H_2O$ (b).

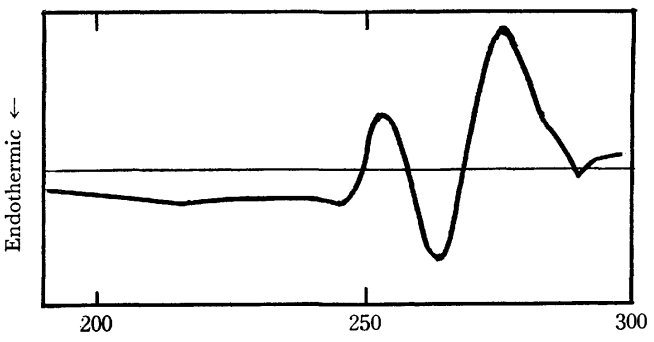

Fig. 2. The DSC curve of *trans*-$[CrCl_2(en)_2]Cl$.

These results suggest that *trans*-$[CrCl_2(en)_2]Cl$ may isomerize to the *cis*-form irreversibly on being heated in the temperature range of 250—290°C. This is confirmed by the results of the measurements

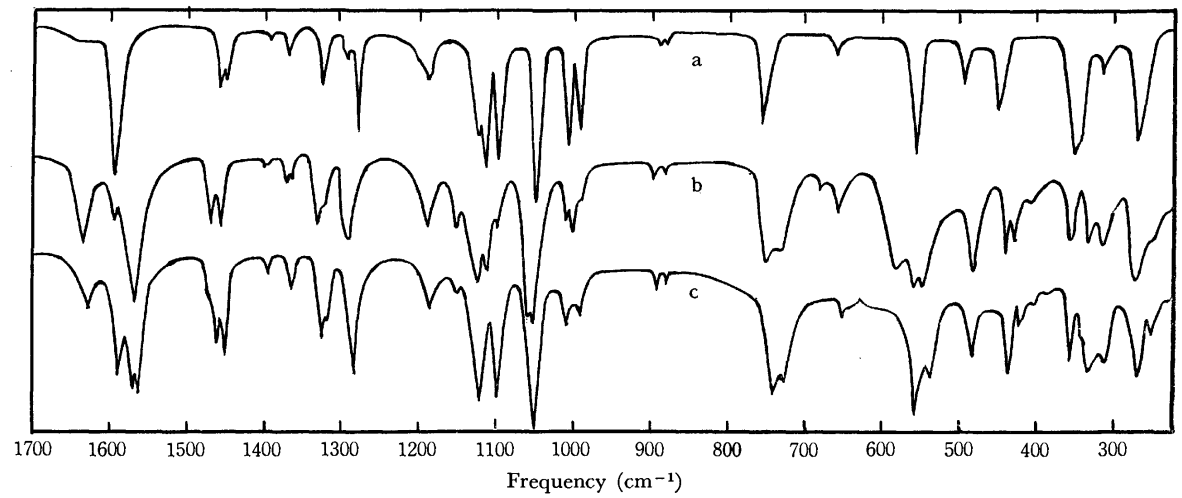

Fig. 3. Infrared spectra of *trans*-$[CrCl_2(en)_2]Cl$ (a), *cis*-$[CrCl_2(en)_2]Cl \cdot H_2O$ (b) and the product obtained from *trans*-form by heating up to 300°C (c).

of the electronic and infrared spectra. The resulting sample, when dissolved in an aqueous hydrochloric acid solution, exhibits absorption maxima at 528 mμ and 402 mμ, these values are in agreement with the values for the *cis*-form.[4] The point group of *trans*-$[CrCl_2(en)_2]^+$ is D_{2h}, on the contrary, that of the *cis*-form is C_2, and the infrared spectra differ appreciably in these two isomers.[5] This is ascertained in our measurements; the results are shown in Fig. 3, together with the results for the sample produced by heating the *trans*-complex up to 300°C. These results clearly indicate the *trans*-to-*cis* isomerization.

The above results suggest that, by the bond-breaking of a Cr-N linkage and the anation of Cl^-, *trans*-$[CrCl_2(en)_2]Cl$ may change first to *cis*,*trans*-$[CrCl_3(en)_2]$, in which one (en) behaves as an unidentate ligand, and may simultaneously melt and subsequently change to *cis*-$[CrCl_2(en)_2]Cl$ and resolidify. A similar type of *cis*↔*trans* isomerization, in which melting, isomerization and resolidification occur successively, has been reported in the case of *cis*-$[PtCl_4\{(C_2H_5)_2S\}_2]$, which isomerizes to the *trans*-form in the temperature range of 120—140°C.[6]

Reactions of Grignard Reagents with Chromium(IV) *t*-Butoxide: Unstable Organochromium(IV) Intermediates

Tetsuo TSUDA* and J. K. KOCHI

Department of Chemistry, Indiana University, Bloomington, Indiana, U.S.A.

(Received February 22, 1971)

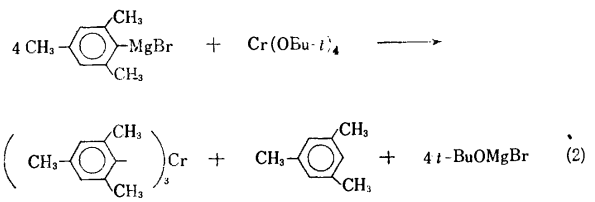
Several organochromium(III) compounds have been characterized[1] and others have been postulated as intermediates in reactions.[2] Chromium(IV) is less common and only a few compounds with this oxidation state are known.[3] We have examined the metathesis between chromium(IV) tetra-*t*-butoxide[4] [$Cr(OBu\text{-}t)_4$] and various Grignard reagents with the intention of

$$Cu^{IV}(OBu\text{-}t)_4 + n\text{RMgX} \longrightarrow \underset{\text{I}}{R_nCr^{IV}(OBu\text{-}t)_{4-n}} + n\ t\text{-BuOMgX} \quad (1)$$

probing the properties and stabilities of alkyl and arylchromium(IV) species, I.

Results and Discussion

Aryl Grignard Reagents and Cr(OBu-t)$_4$. Mesityl derivatives of chromium III and II are significantly more stable than their phenyl analogs.[1a,5] The reaction between mesitylmagnesium bromide and $Cr(OBu\text{-}t)_4$ in a 4: 1 molar ratio in tetrahydrofuran (THF) solution at 25°C was observed by following the disappearance of the visible absorption band of $Cr(OBu\text{-}t)_4$ at 630 nm as shown in Fig. 1. After 48 hr the visible absorption spectrum (λ_{max}=518 nm) and the electron paramagnetic resonance (EPR) spectrum ($\langle g\rangle$= 1.983) of the solution were the same as those of trimesitylchromium(III) prepared from mesitylmagnesium bromide and chromium(III) chloride.[5b] Addition of a solution of mercuric chloride in THF quantitatively converted mesitylchromium(III) and unreacted mesitylmagnesium bromide into mesitylmercuric salts,[5] which were separated and the resulting solution was analyzed. Quantitative gas chromatography indicated the presence of 1.11 mol of mesitylene per mol of $Cr(OBu\text{-}t)_4$, but only traces of bimesitylene. The partial stoichiometry of the reaction is:



(2)

The analogous reaction between phenylmagnesium bromide and $Cr(OBu\text{-}t)_4$ in a molar ratio of 4: 1 produced after 2 hr a yellow-green solution whose absorption spectrum (λ_{max}=473 nm) was similar to that of a red-brown solution (λ_{max}=445 nm) of triphenylchromium(III) generated from chromium(III) chloride. The presence of other phenylchromium species derived from Ph_2Cr was suspected, but this possibility was discarded by a negative qualitative test. Thus, Ph_2Cr is unstable and is transformed to a π-arene chromium complex which on treatment with sodium tetraphenylboride after aerial oxidation should have afforded a π-arenechromium(I) salt,[6] but none was found. Excess phenylmagnesium bromide also reacted with either $CrCl_3$ or $Cr(OBu\text{-}t)_4$ to afford a solution of phenylchromium(III) species absorbing at 408 nm. On standing both reactions gave rise to dark red-brown solutions showing the same visible absorption spectrum. These differences were attributed to various phenylchromium(III) complexes containing other ligands,[5d] and not to the presence of phenylchromium(II). Analysis of the reaction mixture indicated the presence of biphenyl according to the following stoichiometry:

$$4\text{PhMgBr} + Cr(OBu\text{-}t)_4 \longrightarrow Ph_3Cr + \frac{1}{2}\text{Ph-Ph} + 4\ t\text{-BuOMgBr} \quad (3)$$

Alkyl Grignard Reagents and Cr(OBu-t)$_4$. Ethylmagnesium bromide and $Cr(OBu\text{-}t)_4$ were mixed in a 4: 1 molar ratio in THF solution at −78°C. No reaction occurred until the temperature was raised to −55°C when the color changed abruptly from blue to brown, and a more of less equimolar mixture of ethane and ethylene (no butane) was slowly evolved. The EPR spectrum (g=1.993) of the solution taken at below −20°C was the same as that (g=1.994) of triethylchromium(III) prepared from ethylmagnesium bromide and chromium(III) chloride[1c,d,f] and shown to be relatively stable under these conditions. Approximately 1 mol of hydrocarbons was liberated from each mol of $Cr(OBu\text{-}t)_4$ between −55 and −25°C. We conclude that ethylchromium(IV) species (I, R=CH_3CH_2) are unstable between these temperatures.

$$Cr(OBu\text{-}t)_4 + 4CH_3CH_2MgBr \longrightarrow \underset{\text{I}}{[CH_3CH_2Cr^{IV}]}$$

$$I \longrightarrow (CH_3CH_2)_3Cr + [CH_3CH_3 + CH_2{=}CH_2] + 4\,t\text{-BuOMgBr} \quad (4)$$

Similarly methylmagnesium bromide and Cr(OBu-t)$_4$ reacted at less than −30°C and only methane (no ethane or ethylene) was liberated as the temperature was raised further to 25°C. The EPR spectrum (g=1.997) of the solution taken at −20°C was the same as that (g=1.995) of trimethylchromium(III) prepared for methylmagnesium bromide and chromium(III) chloride. Hydrolysis of the reaction mixture after completion produced only 65% of methane based on the methylmagnesium bromide used.

$$4CH_3MgBr + Cr(OBu\text{-}t)_4 \longrightarrow (CH_3)_3Cr + CH_4 + 4\,t\text{-BuOMgBr} \quad (5)$$

The latter reflected loss of methyl groups by attack on solvent, incontrast to the good material balance obtained withthe ethyl analog.

Organochromium(IV) Species. We conclude from these studies that alkyl and arylchromium(IV) species are rather unstable intermediates and readily converted to trialkyl and triarylchromium(III) under these conditions. During the slow conversion of Cr(OBu-t)$_4$ by mesitylmagnesium bromide shown in Fig. 1, a metastable species absorbing at approximately 600 nm could be seen after 1.5 hr. Analogous changes in the EPR spectrum of the solution were also observed. Thus, Cr(OBu-t)$_4$ showed only a weak and broad EPR spectrum (g=1.964) in THF solution. On reaction with mesitylmagnesium bromide a new species was found. The multiplet (g=1.983) absorption of this species slowly changed to one characteristic of trimesitylchromium(III). We associate both observations with an intermediate mesitylchromium(IV) species. It is, however, clear that organochromium(IV) species of the kind indicated by I are too unstable for isolation and should be compared with the recently reported trimethylsilylmethyl derivatives.[7a]

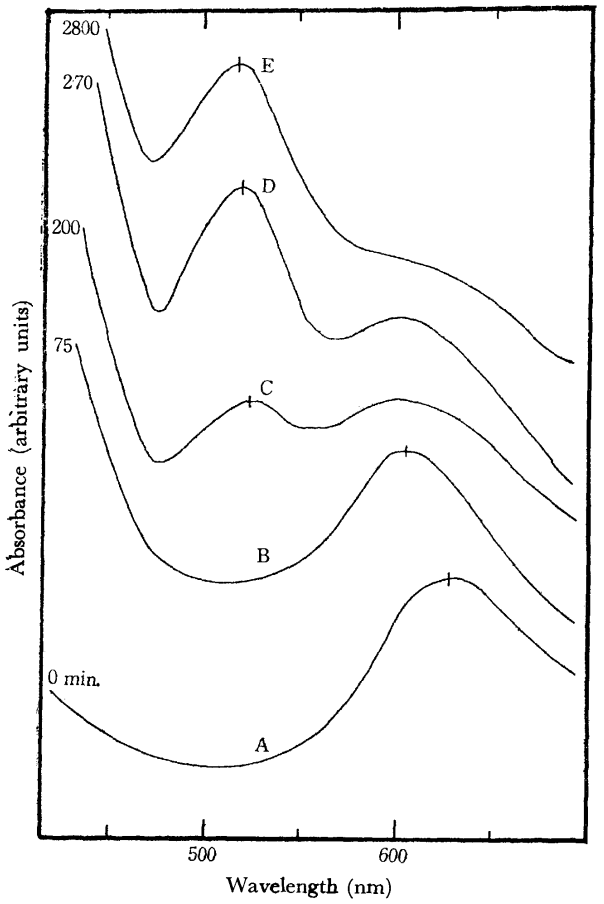

Fig. 1. Reaction of 0.039M Cr(OBu-t)$_4$ and 0.16M mesitylmagnesium bromide in THF at 25°C. A, mix; B, 75 min; C, 200 min; D, 270 min; E, 2800 min. A and E correspond to spectra of Cr(OBu-t)$_4$ and Mes$_3$Cr, respectively.

Experimental

Materials. Cr(OBu-t)$_4$ was prepared according to the reported procedure[8] from bis-benzene chromium[9] and di-t-butyl peroxide in benzene. The purity of Cr(OBu-t)$_4$ checked by iodometry was 95.0%. The Grignard reagents were synthesized under nitrogen by the conventional method. Tetrahydrofuran was refluxed and distilled over LiAlH$_4$ under nitrogen. CrCl$_3$ was used as purchased.

All operations described below were carried out under nitrogen atmosphere except the operation following the addition of HgCl$_2$.

The Reaction of Cr(OBu-t)$_4$ and Mesitylmagnesium Bromide. To the magnetically stirred solution of 4.25 ml THF containing 0.30 mmol Cr(OBu-t)$_4$ in a 100 ml flask, 0.75 ml THF solution containing 0.88 mmol mesitylmagnesium bromide was added at −78°C with a hypodermic syringe. The reaction mixture was gradually warmed to room temperature and kept at ambient temperatures for 50 hr. Of the reaction mixture, 1.80 ml was removed to a 50 ml test tube capped with a rubber septum, and 0.53 ml THF solution of 0.70 mmol HgCl$_2$ was added. After 20 hr the inorganic precipitate was removed by filtration and the resulting solution was analyzed for mesitylene by quantitative gas chromatography (6 ft DEGS on firebrick, durene as a marker).

The Reaction of Cr(OBu-t)$_4$ and Ethylmagnesium Bromide. To a 50 ml test tube capped with a rubber septum, 4.80 ml THF solution of 0.08 mmol Cr(OBu-t)$_4$ was added with a hypodermic syringe chilled to −78°C. Then 0.20 ml THF solution of 0.32 mmol ethylmagnesium bromide was added to this magnetically stirred solution, followed by the injection of 0.50 ml of methane marker gas. The reaction temperature was gradually raised by allowing the ice bath to stand at ambient temperatures. Quantitative gas chromatography analysis using a Porapak column for ethane and ethylene formation was carried out periodically at various temperatures. Standard mixtures of methane, ethane, and ethylene without substrate were calibrated under the same conditions.

EPR Spectra. EPR spectra of THF solutions of the organochromiums were obtained using a Varian E-4 spectrometer. Solutions of the organochromium species were prepared by mixing the degassed THF solutions of Cr(OBu-t)$_4$ and the Grignard reagents at the dry-ice temperature and transferring directly the resulting reaction mixture to an EPR sample tube cooled to dry-ice temperatures. g-Values were determined by calibration with DPPH powder.

The Infrared Spectra of the 1-Propynyl Anion

Isao KANESAKA, Kenji TAKEDA, and Kiyoyasu KAWAI
Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received August 31, 1971)

The structure of the 1-propynyl anion, whose electronic structure is anologous to that of acetonitrile $H_3C\text{-}C{\equiv}N:$, is represented by $H_3C\text{-}C{\equiv}C:^-$ (I) as a first approximation. Nest and Gremm[1] have measured the infrared spectra of the alkali acetilides of the R-C CM type, where R is H, CH_3 or C_6H_5 and where M is an alkali metal, in order to investigate the structure of those compounds on the basis of the C≡C stretching frequencies alone; they interpreted the decrease in the C C stretching frequencies from Li to Cs compounds in terms of an increase in the contribution of the $R\text{-}\overset{-}{C}=C:$ structure in the resonance hybride. If so, the contribution of the $H_3C\text{-}\overset{-}{C}=C:$ (II) structure in the 1-propynyl anion(I) would lead to a decrease not only in the C≡C stretching frequencies but also in the C–C stretching frequencies. Radionov *et al.*[2] have studied the infrared spectra of some lithium acetylides and observed the Li-C stretching frequencies in the 440–495 cm^{-1} region, suggesting the presence of a strong covalent character in the Li-C bond. The present paper will deal with the infrared spectra of the 1-propynyl sodium and potassium; except for the lithium compound, which is unsuitable, as has been shown above; we hope to obtain the normal frequencies and the force constants of the 1-propynyl anion and to obtain information concerning their structures.

The 1-propynyl sodium and potassium were prepared by the ordinary method. The infrared spectra were observed for both compounds in the region of 4000—200 cm^{-1} by Nujol or hexachloro-1,3-butadiene mull prepared in a gloved box. The observed frequencies were assigned on the basis of the C_{3v} symmetry; they are shown in Table 1. The C≡C stretching frequencies observed in both compounds differ slightly from that previously reported, *viz.*, 2032 cm^{-1} for the sodium salt and 2023 cm^{-1} for the potassium salt.[1] The normal frequencies of the 1-propynyl anion are listed in Table 2.

The force constants for the 1-propynyl anion were calculated on the assumption of the Urey-Bradley force field, in which F' (linear repulsive force constant) was assumed to be $-0.1\ F$(repulsive force constant), as usual. The atomic distances of the anion were assumed to be C–H=1.11 Å, C–C=1.46 Å, and C≡C=1.21 Å, while the valence angles were assumed to be tetrahedral for the CH_3 group and linear for the C–C C skeleton. For comparison, the force constants were also calculated, on the same assumption of force field, for acetonitrile and propyne, whose normal frequencies have been reported by Pace and Neo[3] and by Crawford[4] respectively, while the atomic

distances and valence angles have been reported by Costain.[5] The numerical calculation was carried out by means of computer program reported previously[6] using an electronic computer, HITAC 5020 E, of the Computer Center of Tokyo University. The force constants were fitted by the least-squares method; they are listed in Table 3. The calculated frequencies are in good agreement with the observed ones within the limit of ± 1 cm^{-1} in the two sets of the anion listed in Table 2, and also in the acetonitrile and propyne.

As is shown in Table 3, the C≡C stretching force constant of the 1-propynyl anion is considerably smaller than that of the propyne; it is possible that, because of the increase in the electronic repulsion and the decrease in the *s* character in the bonding, the C C bond in the 1-propynyl anion is less stable than that of the propyne, in which the *sp* hybridisation is postulated for the bonding in the C C bond.

One notices from Table 3 that the C–C stretching force constant of the 1-propynyl anion is larger than that of the acetonitrile or propyne, but that the C–H stretching force constant of the anion is smaller than that of the molecules. In acetonitrile, there is a significant contribution of the $H_3^+C=C=N:^-$ (III)[7] structure. For the 1-propynyl anion, however, we may not expect any important contribution of the $H_3^+C=C=C:^{--}$ (IV) structure in the resonance hybride because the uni-negative-charged carbon in the (I) structure is far less electronegative than the nitrogen atom in the acetonitrile and the distribution of the electronic charge in the (IV) structure is unfavorable. Accordingly, another important structure, $H_3^-C=C=C:$ (V), in which the negative charge is distributed among three hydrogen atoms, may be considered; its contribution may be more significant than that of the (III) structure in the acetonitrile.

The authors wish to express their gratitude to Professor Hiromu Murata for his kind advice.

SHORT COMMUNICATIONS

Formation of Ethylenic Compounds by the Decomposition of Cuprated Sulfur Compounds

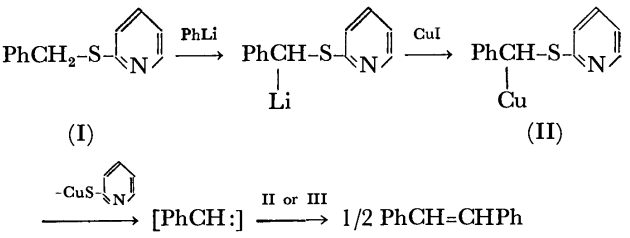
Teruaki MUKAIYAMA, Koichi NARASAKA, and Masayasu FURUSATO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 25, 1971)

It was found in our laboratory that bivalent sulfur compounds react easily with some nucleophiles in the presence of $CuCl_2$ to give the corresponding condensation products along with copper mercaptide.[1] A study of the decomposition of α-cuprated sulfides was thus initiated with the expectation that carbenes would be generated by the elimination of copper mercaptide from the α-cuprated sulfides.

α-Cuprated sulfides were prepared according to Gilman's method by the reaction of CuI with α-lithio derivatives of sulfides in tetrahydrofuran at −70°C.[2] Decomposition of the α-cuprated sulfides was then carried out by raising the temperature of the resulting mixtures to room temperature. As an example, a tetrahydrofuran solution of 0.01 mol of benzyl 2-pyridyl sulfide (I) was treated with 0.011 mol of phenyllithium in ether under nitrogen atmosphere at −30°C for 1 hr. After the addition of 0.01 mole of CuI at −70°C, the solution was slowly warmed up to room temperature and allowed to stand for 2 hr with stirring. After hydrolysis, the organic layer was chromatographed on silica gel to afford *trans*-stilbene in 86% yield. The result is explained as shown in Scheme 1; Carbene (III) is initially produced by the elimination of copper mercaptide from the α-cuprated sulfide (II), which changed to stilbene either by dimerization or reaction with the precursor (II).



Scheme 1

Similarly, diphenylmethyl and cinnamyl 2-pyridyl sulfides gave tetraphenylethylene and 1,6-diphenylhexatriene in 33% and 10% yields, respectively.

In the cases of sulfide, mercaptals and orthothioformates (IV) with phenylthio or ethylthio group, the reactions also proceeded easily as in the case of 2-pyridyl sulfides. *n*-Butyllithium was used instead of phenyllithium in order to facilitate the formation of lithium salts of IV. The corresponding ethylenic derivatives (V) were obtained in good yields by treatment of the lithium salts with CuI in the same manner as mentioned above (Table 1).

Studies of the Basic Sites of the Silica-Alumina Surface by Means of the Adsorption of Copper(II) Complexes with 2,2'-Bipyridine

Kazuto TAKIMOTO and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September 18, 1971)

The basic properties of the silica-alumina surface have been studied by means of the calorimetric titration and phenol-vapor adsorption methods,[1,2] but the nature and structure of its basic sites have not yet been revealed. On the other hand, the basic properties of alumina have been elucidated fairly well in comparison with those of silica-alumina.[3] We have found, from ESR measurements, that one or two OH^- ions coordinate to the copper (II) complex with 2,2'-bipyridine in the aqueous solution of the complex at pH values higher than 8. Such a phenomenon has also been observed in a basic methanol solution. In this paper, the properties of the basic OH groups on the silica-alumina and alumina surfaces will be presented and compared with the ESR spectra in these solutions.

Alumina, 50% silica-alumina, and silica gel were treated *in vacuo* at 300°C for 3 hr. The copper(II) complexes with 2,2'-bipyridine, $[Cu(bip)(OH_2)_4]SO_4$, $[Cu(bip)_2(OH_2)_2]SO_4$, were synthesized in methanol and recrystallized repeatedly from methanol. The water-free methanol solutions of these complexes were evacuated and introduced to the solids through a breakable seal. After the methanol had been eliminated, the ESR spectra were measured at 77°K. The chemical species were determined from the ESR spectra of the 1st and 2nd derivatives.

Figure 1 shows the ESR spectrum for the 1 : 1 complex adsorbed on the surface of 50% silica-alumina. This spectrum suggests the presence of only one chemical species. The $g_{//}$ and $A_{//}$ values of the spectrum were 2.268 and -172×10^{-4} cm^{-1} respectively. This chemical species is identified to that in which two basic OH groups on the surface coordinate to the 1 : 1 complex by means of a comparison with the ESR spectrum of the complex in an aqueous solution at pH>12.5. This is considered to be reasonable, since the axial symmetry of this spectrum is approximately maintained, much as in the solution. On the other hand, when the 1 : 2 complex was adsorbed on the surface, two chemical species were observed; one is the same as that described above, while the other possesses lower values of $g_{//}$ and $A_{//}$, 2.224 and -143×10^{-4} cm^{-1} respectively, than the former. Noack *et al.* have found the species corresponding to these values in 40% ethanol - 60% water and identified it as the *cis* isomer of the 1 : 2 complex.[4]

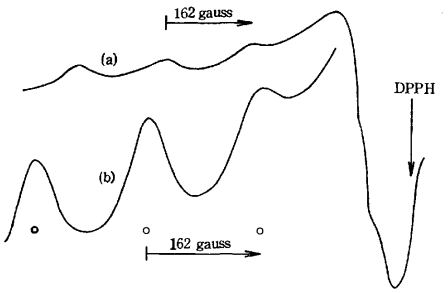

Fig. 1. ESR spectrum of the 1 : 1 complex adsorbed on the surface of 50% silica-alumina; (a) over-all spectrum, (b) parallel components of the spectrum magnified in the lower field region. ○: $g_{//}=2.268$.

The ESR spectrum for the 1 : 1 complex adsorbed on the surface of alumina is represented in Fig. 2. Three chemical species were observed. The species with the lowest value of $g_{//}$ (2.265) is the same as that of the 1 : 1 complex adsorbed on 50% silica-alumina. On the other hand, the species with the middle value of $g_{//}$ (2.306) is identified as that in which one basic OH group coordinates to the 1 : 1 complex by means of a comparison with the ESR spectrum of its aqueous solution in the 8—11 pH range, while the species corresponding to the highest value of $g_{//}$ (2.340) is still uncertain. It is of interest to note that the ESR spectrum of the 1 : 2 complex adsorbed on the surface of alumina was quite the same as in the case of the 1 : 1 complex.

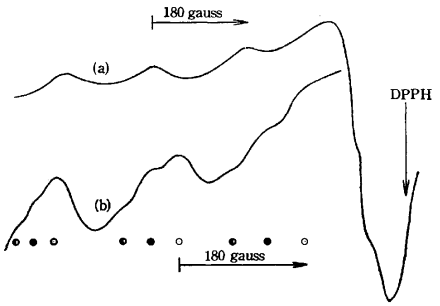

Fig. 2. ESR spectrum of the 1 : 1 complex adsorbed on the surface of alumina; (a) over-all spectrum, (b) parallel components of the spectrum magnified in the lower field region. ○: $g_{//}=2.265$, ●: $g_{//}=2.306$, ◐: $g_{//}=2.340$.

Though the negatively-charged oxygen ion and the OH group are present as basic sites, the effects of these sites on the ESR spectra are quite different; the OH group on $Ca(OH)_2$ and the O^{2-} group on CaO gave rise to different species. It was also found that the O^{2-} on the silica-alumina has a much smaller electron-donating ability than the OH group. The basic sites were thus clarified to exist on the surfaces of 50% silica-alumina and alumina, but they were not observed on the silica gel surface. The basic strength of the sites on the surfaces could also be revealed; the $g_{//}$ value decreases, and that of $A_{//}$ increases, with the electron-donating ability of the ligands. Thus, the adsorption of these complexes on the solid surfaces may be useful means for the elucidation of the basic properties.

p-Nitrophenyl Phosphate as a Phosphorylating Reagent in Nucleotide Synthesis

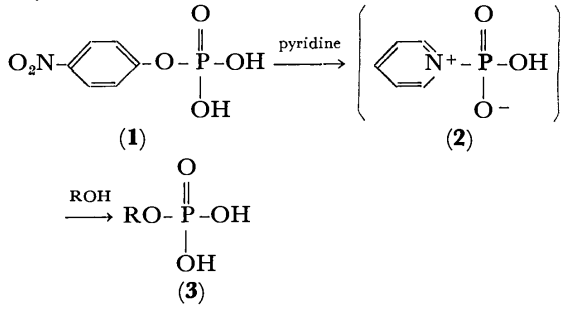
Tsujiaki HATA and Kyu-Jang CHONG

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 18, 1971)

It is known that tri-substituted esters of phosphoric acid such as triethyl phosphate are transesterified into the corresponding trialkyl phosphate by treatment with alcohol or sodium alkoxide.[1] In the case of mono-substituted phosphates, however, the interchange reaction proceeds very sluggishly and therefore can not be applied to the syntheses of desired monoalkyl phosphates. It was found that pyridine was a remarkably effective solvent for the ester-interchange reaction of *p*-nitrophenyl phosphate (**1**) with alcohols.[2] The reaction is of particular interest since it is an example of ester-interchange reaction, probably proceeding through a reactive *N*-phosphopyridinium intermediate (**2**) towards alcohols.

Phosphorylation of nucleosides by the use of **1** was investigated. When 2',3'-*O*-isopropylidene adenosine (0.3 mmole) was allowed to react with **1** (0.6 mmole) in dry pyridine (0.3 m*l*) at 110°C for two hours, 2',3'-*O*-isopropylidene adenosine 5'-phosphate was isolated by using DEAE cellulose column chromatography. After removal of the protecting group by treating 30% formic acid, adenosine 5'-phosphate was obtained in 85% yield.



Similarly, other nucleotides were obtained in high yields as shown in Table 1.

It is noted that the yields of nucleotides depend on the concentrations and the molar ratios of **1** to nucleosides. When a large excess of pyridine was employed, nucleoside polyphosphates were formed. 2',3-*O*-Isopropylidene adenosine (0.05 mmol) was treated with **1** (0.25 mmol) in 1.0 m*l* of dry pyridine at 110°C for four hours. After removal of the protecting group, adenosine 5'-diphosphate (ADP) and adenosine 5'-triphosphate (ATP) were obtained in 32% and 33% yields, respectively, along with adenosine 5'-phosphate (35%). These polyphosphates were isolated by means of DEAE cellulose column chromatography.

Phosphorylation of unprotected free nucleoside by the present method was attempted. When adenosine (0.1 mmol) was treated with **1** (0.7 mmol) in dry pyridine (3.0 m*l*) in the presence of tri-*n*-butylamine, adenosine 2',3'-cyclic phosphate (**4**) and adenosine 2'(3'),5'-diphosphate (**5**) were obtained in 43% and 39% yields, respectively. The cyclic phosphate (**4**) was converted with 0.1 N hydrochloric acid into adenosine 2'(3')-phosphate in quantitative yield. When **4** (0.1 mmol) was further treated with **1** (0.7 mmol) in dry pyridine (3.0 m*l*), adenosine 2',3'-cyclic phosphate 5'-phosphate (**6**) was obtained in 57% yield. Data on the chromatographic and spectral properties of these compounds (**4**, **5** and **6**) agree with those of authentic samples.[3,4]

Butadiene Formation from Ethanol over Silica-Magnesia Catalysts

Hiroo NIIYAMA, Saburo MORII, and Etsuro ECHIGOYA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 21, 1971)

Butadiene formation reaction from ethanol over various kinds of silica-magnesia having different MgO contents were studied from the standpoint of its acid-base catalysis. Maximum acidity was obtained at 50% MgO, while basicity increased with the MgO content. Silica-magnesia (85% MgO) having adequate acidity and basicity gave the maximum activity. The reaction mechanism and the roles of acidic and basic sites are discussed. The rate controlling step is the acetaldehyde formation catalyzed by basic sites.

Many investigations have been carried out on the reaction of butadiene formation from ethanol.[1,2,3] It was reported that active catalysts should have activities for both dehydration and dehydrogenation reactions. However, the roles of active sites were not clarified. In a previous paper,[4] dehydration and dehydrogenation of alcohols over acid-base bifunctional catalysts were described. It was concluded that the former took place on acidic and the latter on basic sites.

Since butadiene formation reaction includes dehydration and dehydrogenation reactions, acid-base properties of catalysts would be essential. In this paper, the correlations between acidity and/or basicity and the activity of SiO_2-MgO catalysts are given.

Experimental

Catalysts. SiO_2-MgO; A settled amount of magnesium hydroxide (Wako Pure Chem. Co.) and colloidal silica (Nissan Chem. Co.) was kneaded for 3 hr. The gel obtained was dried for 24 hr at 100°C in an oven and then calcined in an electric furnace at 600°C for 3 hr.

SiO_2; Colloidal silica was heated over a water bath. The obtained gel was dried in an oven and then was calcined at 600°C for 3 hr.

MgO; Magnesium hydroxide was calcined at 600°C for 3 hr.

Acidity measurements. Titration (Benesi's method) and gravimetric measurement of pyridine adsorption were used.

Titration was carried out as follows. Samples of the catalysts were calcined at 550°C for 1 hr and then degassed at 300°C under 10^{-5} mmHg. 0.1～0.5 g of the samples were taken in flasks containing water-free benzene. A known amount of *n*-butylamine in benzene solution (0.02N) was added. After four days, Hammett indicators were added and the color of the samples were compared visually with each other.

Adsorption of pyridine was carried out as follows. 0.15～0.3 g of the catalyst was taken in a basket made of quartz and evacuated *in situ* under 10^{-5} mmHg for 3 hr at 350°C. Pyridine was then introduced to the system up to 25 mmHg at 200°C. After adsorption equilibrium had been established (after 1～1.5 hr), desorption was started at the same temperature by trapping the remaining pyridine in the gas phase. The adsorbed amount was determined with a spring balance (sensitivity 10 μg/div.)

Basicity measurements. Titration by benzoic acid using phenolphtalein and nitroaniline[5] as indicators was carried out in order to measure the basicity. Some catalysts, however, showed abnormal color change, making the values obtained unreliable. In this study, the adsorbed amount of boron trifluoride was measured by the gravimetric method and was taken as the index of basicity. Pretreatments and procedures were almost the same as in the acidity measurements.

Infrared spectroscopy. A thin wafer, 1.2×2.0 cm, was prepared by compressing 0.02～0.03 g of the catalyst under 300 kg/cm^2. The infrared cell used was similar to that used by Little.[6] The cell could be attached to the conventional vacuum system and heated *in situ*. The infrared spectra were recorded on a Shimadzu IR spectrometer.

Reaction. Catalytic activities in butadiene formation from ethanol were measured by a conventional flow method. Ethanol and/or other reactants were stored in evaporators maintained at a constant temperature. They were introduced into the reactor with hydrogen, carrier gas. Vaporous products were taken out with a sampling tube and analyzed by gas chromatography.

Results and Discussions

Ethylene, ether, acetaldehyde, butadiene and water were found in the products when SiO_2-MgO catalysts were used. In the case of MgO catalyst, crotonaldehyde and other unknown products were also obtained. SiO_2-MgO catalyst (75 mol% MgO) was used in order to clarify the reaction mechanism.

The effects of contact time on the conversion to all the products were studied. A typical example is given in Fig. 1. Acetaldehyde formation decreased with increase of the contact time, while butadiene formation showed an induction period.[7] This suggests that acetaldehyde is an intermediate product and butadiene a final one in the consecutive reaction.

Several reactants considered[8] to be intermediate products were tested to confirm the reaction mechanism. The results are given in Table 1 and a typical example

in Fig. 2. Though neither acetaldehyde nor crotonaldehyde was converted into butadiene, butadiene was readily produced when either of them was fed with ethanol. Moreover, with *n*-propanol or isopropanol instead of ethanol, each produced butadiene with the corresponding dehydrogenated products (propionaldehyde or acetone). Under such reaction conditions, no acetone was found in the products when isopropanol alone was fed. It was also found that any combination of alcohols and ketones or aldehydes brings about hydrogen transfer reaction.[9]

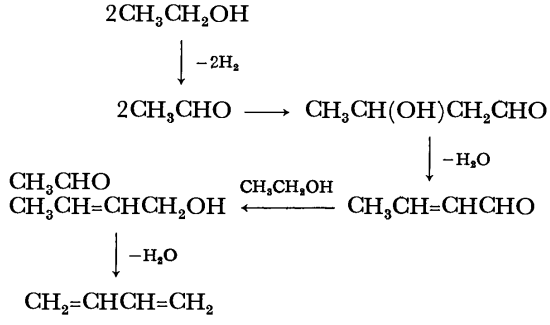
b) $\frac{\text{butadiene produced} \times 2}{n\text{-propanol fed}}$

c) $\frac{\text{butadiene produced} \times 2}{iso\text{-propanol fed}}$

Various mechanisms have been proposed for butadiene formation reaction. Most investigators considered acetaldehyde as a first intermediate product. Kagan[3] postulated that two acetaldehyde underwent an aldol condensation to form crotonaldehyde. Crotyl alcohol was then produced by the reduction of crotonaldehyde and converted into butadiene. The hydrogen atoms derived from the dehydrogenation of ethanol took part in the reduction. On the other hand, Quattlebaum *et al.* postulated[1] that the hydrogenolysis of crotonaldehyde took place *via* hydrogen transfer from ethanol to crotonaldehyde. 1-hydroxybutene or 1,3-butanediol produced from acetaldehyde and ethanol was also postulated as an intermediate product.[8]

Our results indicate that 1,3-butanediol can not be intermediate product (Table 1, run 4). 1-hydroxybutene is not appropriate, because acetaldehyde and isopropanol gave butadiene instead of isoprene or pentadiene. The mechanisms postulated by Kagan[3] could be rejected because isopropanol gave no dehydrogenated products under the reaction conditions. It was thus concluded that the mechanisms postulated by Quattlebaum *et al.*[1] is valid for this catalyst. This is schematically shown as follows.



9) H. Niiyama and E. Echigoya, This Bulletin, **45**, 938 (1972).

Table 2. Expected conversion based on the assumption that the first dehydrogenation step is rate determing

reactants	partial pressure	calculated conversion of alcohol	experimental value	run No. in Table 1
ethanol acetaldehyde	0.1 0.01	$0.11+0.10+\sum_{i=1}^{\infty}0.1\times2^{-i}=0.31$	0.31	5
ethanol crotonaldehyde	0.1 0.01	$0.11+0.10\times2+\sum_{i=1}^{\infty}0.1\times2^{-i}=0.41$	0.36	6
1-propanol crotonaldehyde	0.1 0.01	$0.10\times2=0.20$	0.18	7
2-propanol acetaldehyde	0.1 0.01	0.10	0.08	8

Determination of the rate controlling step. On the basis of this scheme and assuming that acetaldehyde formation is the rate controlling step, we can expect the conversion for run 5, taken as an example, in the following way. A mixture of acetaldehyde and ethanol (0.1 : 1) was fed. The relative amount of butadiene derived from ethanol independently of acetaldehyde addition was 0.11 (*cf.* run 1). Since the process after the dehydrogenation of ethanol was assumed to be very fast, all the added acetaldehyde was converted into butadiene. The amount of butadiene from the added acetaldehyde was thus 0.10. Hydrogen transfer between crotonaldehyde and ethanol took place and acetaldehyde was produced again. The secondary acetaldehyde formation was repeated infinitely. Thus the amount of butadiene derived from secondary produced acetaldehyde was $\sum_{i=1}^{\infty}0.1\times2^{-i}$, where i is the cycle number. The expected conversion was calculated as follows.

$$0.11 + 0.10 + \sum_{i=1}^{\infty}0.1 \times 2^{-i} = 0.31$$

The results for runs 5, 6, 7, and 8 are summarized in Table 2. There is a good agreement between the results and the calculated values.

Correlations between catalytic activity and acidity and/or basicity. The acidic properties determined by the Benesi's method and pyridine adsorption method, both of which show a similar tendency, are given in Table 3. The basicity is also given in the table.

The maximum acidity was obtained when MgO content reached 50%, while basicity increased with MgO content. Specific rates of butadiene formation increased with the MgO content up to 85%, but pure MgO showed little activity. This aspect was quite different from that of acidity and also of basicity.

Since the rate controlling step of this reaction was the dehydrogenation of ethanol catalyzed by basic sites,[4] the rate was expected to increase with the MgO content. This, however, was not the case. When MgO catalyst was used, crotonaldehyde was found in the products. This indicates that MgO has a catalytic activity in the aldol condensation reaction.[10] More-

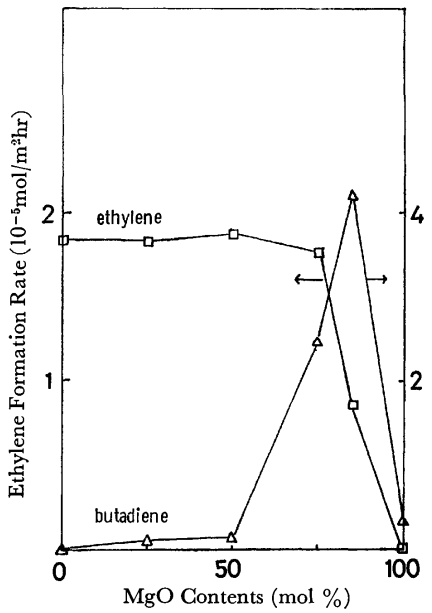


Fig. 3 Rate of production of butadiene or ethylene against MgO contents. temperature; 380°C, pressure of ethanol; 0.1 atm

Table 3. Acidity and basicity of the catalysts

Catalyst	Acidity: Benesi's method: Acidity $H_0>3.3$ 10^{-6} eq/m^2	Acidity: Benesi's method: maximum acid strength H_0	Acidity: Pyridine adsorption at 200°C 10^{-6} eq/m^2	Basicity BF adsorption at 300°C 10^{-6} eq/m^2
SiO_2	—	—	0.09±0.02	0.8±0.2

over, it showed considerable activity in the hydrogen transfer reaction.[9] Poor activity of MgO catalyst in the reaction could be attributed to the small dehydration activity for the final step catalyzed by acidic sites. It is thus concluded that both acidic and basic sites are necessary to increase the yield of butadiene.

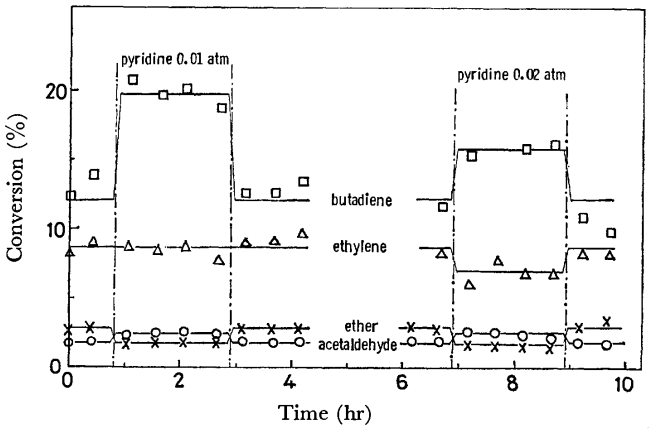

Fig. 4 The effects of pyridine addition. temperature; 380°C, pressure of ethanol; 0.1 atm, W/F=3.4 g hr/mol

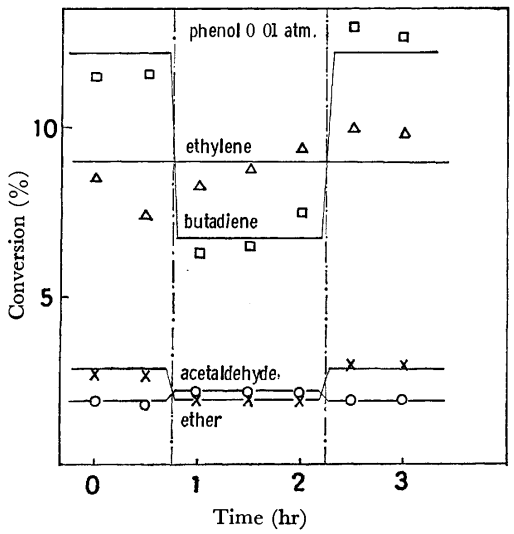

Fig. 5 The effects of phenol addition. temperature; 380°C, pressure of ethanol; 0.1 atm W/F=3.4 g hr/mol

Addition of acidic and basic materials. Pyridine and phenol were introduced into the reaction system in order to poison acidic and basic sites, respectively. The results are shown in Figs. 4 and 5. The addition of phenol brought a marked decrease in butadiene formation, but ethylene formation remained constant. Since the rate controlling step in butadiene formation is the first dehydrogenation catalyzed by basic sites, the effects of phenol are rational.

On the other hand, pyridine had a "promoter action" in butadiene formation. To understand the "promoter action" of pyridine the behavior of surface hydroxyl group was studied by infrared spectroscopy. As is shown in Fig. 6, four absorption bands were observed in 3400—4000 cm^{-1} region. They were assinged to OH stretching vibration bands since they could be exchanged with D_2O. Generally speaking, a hydroxyl group with higher stretching frequency has a basic nature.[11] It was observed that the bands around 3840 cm^{-1} and 3720 cm^{-1} remain while the band around 3650 cm^{-1} readily disappeared in contact with D_2O vapor. Since acidic OH is expected to undergo ex-

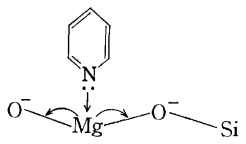
change more readily than neutral or basic OH, the band around 3650 cm^{-1} should refer to acidic OH. In other words, bands around 3840 cm^{-1} and 3720 cm^{-1} could be considered to have a basic nature as compared with 3650 cm^{-1} band.

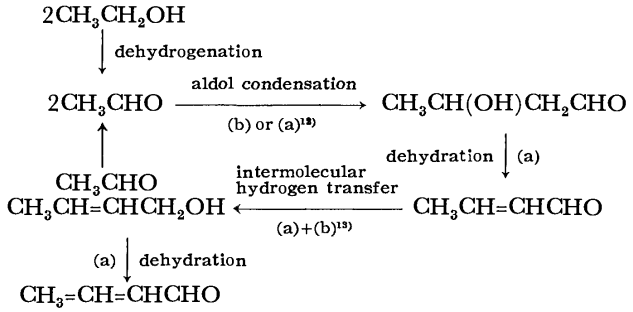
The effects of pyridine on the behavior of these surface hydroxyl group are shown in Fig. 7. Rehydration of the evacuated sample by traces of water (0.03 meq) made little change in the higher frequency bands. In the presence of pyridine, however, rehydration made the intensity of these bands increase. Evacuation at 100°C gave rise to the decrease of the intensity of these bands, with an accompanying decrease of a band around 2900 cm^{-1} assigned to CH stretching of pyridine. This suggests that basic sites are produced by adsorption of pyridine. This would be caused by the inductive effects of adsorbed pyridine.



When pyridine is adsorbed on acidic sites, the nearest oxide ions become rich in electron density. This will produce new basic sites available to catalyze the dehydrogenation of ethanol. A small amount of pyridine thus increases basicity accompanied with the increase of dehydrogenation activity. By excess addition, however, pyridine occupies more of the acidic sites than is necessary and makes the "promoter action" retarded.

Conclusion

The reaction mechanism and roles of acidic and basic sites in butadiene formation over silica-magnesia catalysts can be written as follows.



(a) and (b) represent acidic and basic sites, respectively. The rate controlling step over silica-magnesia catalysts is the dehydrogenation of ethanol catalyzed by basic sites. Thus activity increases with basicity. Over magnesia catalyst which has great basicity but no acidity, however, dehydration of crotyl alcohol hardly takes place and the activity is low. It is important to control the acidity and basicity in order to increase the yield of butadiene.

12) Both (a) and (b) are available in this step.[14]

13) This step was considered to take place in an acid-base concerted mechanism.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 659—664(1972)

Photodecomposition of Vinyl Iodide in Gas Phase

Shigeru YAMASHITA, Shigeo NOGUCHI, and Teruo HAYAKAWA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka

(Received March 20, 1971)

Photodecomposition of vinyl iodide has been studied at 313 and 254 mμ using a high intensity light source. Because of high concentration of the radicals formed primarily due to the high intensity of the light source, only the inter-radical reactions were taken into account in considering the secondary processes.

Both molecular and free radical processes have been observed in the primary process and the ratio of the contribution of molecular process to free radical process was found to be about 1 : 6 in the wavelength range studied. A slight energy dependence of k_d/k_c, the ratio of the rate of disproportionation reaction to that of combination reaction of vinyl radicals, was found in the secondary processes.

The primary process of the photochemical reaction has been studied by many investigators using various instruments for the detection of short-lived intermediates produced in the process.[1)]

In the case of photochemical studies carried out by means of a conventional static reactor and the analysis of the final products, there are ambiguities due to the contributions from so many secondary processes, most of which are the reactions between primary fragment radicals and reactant molecules since the concentration of the primary fragment is usually much lower than that of the reactant molecules.

By use of a high intensity light source in the study of photochemical reactions, the reaction scheme would be simplified even in the conventional static method

1) R. G. W. Norrish and G. Porter, *Nature*, **164**, 658 (1949). G. Porter, *Proc. Roy. Soc.*, **A200**, 284 (1950). G. Herzberg and D. A. Ramsay, *Proc. Roy. Soc.*, **A233**, 34 (1955). F. P. Phys.*, **48**, 18 (1968).

excluding radical-molecule reactions because of the high concentration of the reactive primary fragment radicals. In the photochemical studies of azoalkanes[2] and alkyl sulfides[3] using high intensity light sources, only the products from the reactions between the free radicals formed in the primary processes were observed. Since the products from the free radical-reactant molecule reactions were not detected in these works, the reaction schemes were rather simplified.

Although a number of data are available for the reactions of alkyl radicals, comparatively few studies have been carried out on the reactions of unsaturated free radicals.[4,5,6]

In the present work, direct photolysis of vinyl iodide in the gas phase at room temperature has been studied under high light intensity conditions. Photolysis of vinyl iodide was reported by Roberge and Herman.[7] However, the study was carried out in carbon tetrachloride solution with a light source of rather low intensity.

The purpose of the present paper was to find the primary process in the photodecomposition of vinyl iodide and to study the energy dependence of the primary and secondary processes by changing the wavelength of the exciting light.

Experimental

Vinyl iodide was prepared by the reaction of 1,2-diiodoethane with sodium ethoxide[8] and purified by vacuum distillation. Before every run, the sample was cautiously degassed at the temperature of liquid nitrogen. The absorption spectrum of vinyl iodide vapor is shown in Fig. 1. The reactor was a conventional drum-type quartz cylinder. The light source was a USH-500D 500W high pressure mercury lamp manufactured by Ushio Electric Co. and the light output was collimated in a housing fitted with condensing lens system and spherical mirror to obtain maximum intensity. The total light flux projected to the surface of the reactor was estimated by ferrioxalate actinometer[9] to be about 3×10^{18} quanta/sec, which is as high as the intensity of the light sources used by previous workers.[2,3]

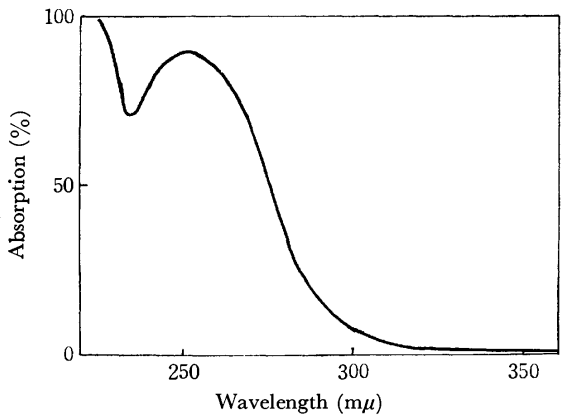

Fig. 1. Absorption spectrum of vinyl iodide vapor. Pressure; 60 torr. Path length; 50 mm.

The reactant gas was irradiated at room temperature in order to exclude thermal reactions. One series of the experiments was carried out using a Toshiba UV-29 filter which transmits a light of wavelength greater than 290 mμ. In the other series, the sample in the reactor was irradiated by a full arc with no filter.

In the UV-29 series experiments, the most abundant quanta absorbed by vinyl iodide are those from the 313 mμ output of the mercury lamp considering the absorption curve of vinyl iodide and other experimental conditions.

In the full arc series experiments, it was not easy to estimate the most effective radiation because of the lack of detailed energy distribution data of the lamp in the wavelength range smaller than 300 mμ. By rough estimation, however, the most effective wavelength in the full arc experiments seems to be 254 mμ line from the mercury lamp. The conversion of the reactant was less than 5% in all runs. Since the dissociation energy of C-I bond in vinyl iodide has been reported to be 66.5 kcal/mol,[10] the light quanta have enough energy for C-I bond rupture both in UV-29 and full arc series. Before the analysis of the reaction products, unreacted vinyl iodide and non-volatile products were condensed by a cold trap cooled at −79°C. The separated volatile products were analyzed by gas chromatograph with a column packed with dimethylsulfolane on alumina and by a Hitachi RMU-5 mass spectrometer.

Results and Discussion

The main products in both UV-29 and full arc series experiments were ethylene, acetylene and 1,3-butadiene. Hydrogen iodide in the reaction products was detected by mass spectrometry. Iodine formation was observed spectrophotometrically by dissolving a small amount of non-volatile products deposited on the reactor wall into *n*-hexane solution. Quantitative de-

termination of hydrogen iodide and iodine could not be achieved. The rather poor material balance of carbon and hydrogen in the reaction products might be caused by missing hydrogen iodide and a trace of polymeric products in the quantitative determination.

The results of the UV-29 series experiments at various initial pressures of vinyl iodide are shown in Table 1 and Fig. 2. In the pressure range lower than 20 torr, it is seen that the formation of C_2H_2 and C_2H_4 is proportional to the pressure of vinyl iodide and that of 1,3-butadiene to the square of vinyl iodide pressure. Saturation of the product formation takes place in high pressure range. This seems to be due to the fact that the transparency of the reactor wall decreases rapidly in the high pressure runs by the deposition of trace of opaque produsts, probably polymeric, on the reactor wall.

Light source; full arc of high pressure mercury lamp.
Irradiation; 4 min.

The results of the full arc series are shown in Table 2 and Fig. 3. The results were less reproducible than in the case of the UV-29 series.

These results of high intensity photolyses were expected to differ from those obtained by conventional low intensity light source.

The results obtained with the use of low intensity light source are shown in Table 3 together with those obtained with high intensity source for comparison. The composition of the two reaction products differs.

Table 3. Comparison of the composition of the products in high intensity photolysis of vinyl iodide with the results of low intensity photolysis

Light source for high intensity experiments was a USH-500 high pressure mercury lamp whose incident flux to the reactor was of the order 10^{18} photons/sec.
Light source for low intensity experiments was a SHL-100UV high pressure mercury lamp whose incident flux to the reactor was of the order 10^{16} photons/sec.
Filter; Toshiba UV-29 for both series experiments.
Irradiation time was adjusted for obtaining the products of the same order of amount in the two series.

In contrast to high intensity experiments, the predominant product in low intensity experiments is ethylene as reported by previous workers,[7] indicating that the hydrogen abstraction by vinyl radical-vinyl iodide molecule reaction is more predominant than radical-radical reaction in the low intensity condition because of the low concentration of vinyl radicals.

When nitric oxide was added to the reaction mixture, production of C_2H_4 and C_4H_6 was quenched completely whereas C_2H_2 formation was partly suppressed. The effect of nitric oxide suggests that C_2H_4 and C_4H_6 are formed from free radicals produced in a primary process. On the other hand, C_2H_2 seems to be produced by molecular process as well as by free radical process since its formation was not completely quenched by the addition of the free radical quencher nitric oxide.

It was confirmed that the rate of decomposition was proportional to light intensity as shown in Fig. 4, which means that the reaction rate is proportional to the number of quanta absorbed by the reactant molecules.

Thus, the primary steps of the photodecomposition of vinyl iodide under the conditions of the present work are supposed to be as follows:

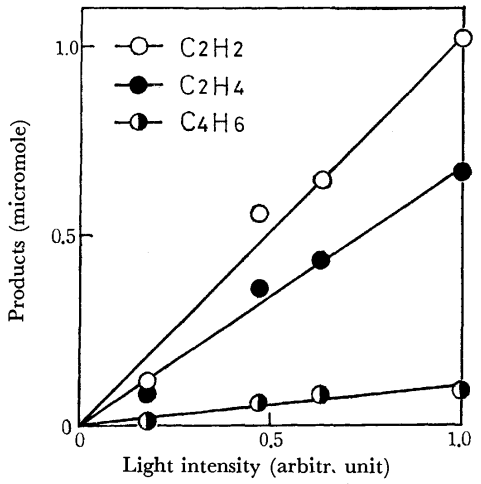

Fig. 4. The effect of light intensity on the products formation.

$$C_2H_3I + h\nu \longrightarrow C_2H_3I^* \quad (1)$$

$$C_2H_3I^* \xrightarrow{k_1} C_2H_3\cdot + I \quad (2)$$

$$C_2H_3I^* \xrightarrow{k_2} C_2H_2 + HI \quad (3)$$

where, the rate of process (1) is approximately expressed by $k_0I_0[C_2H_3I]$, which means that it is proportional to light intensity I_0 and to the pressure of the reactant $[C_2H_3I]$. Process (2) is a free radical process and process (3) a molecular process where the products are molecular species.

Because of the high intensity of the light source, radical-molecule reactions could be neglected in the secondary processes following the primary processes (1), (2), and (3).

The reaction scheme for the secondary processes can be proposed as follows:

$$2C_2H_3\cdot \xrightarrow{k_d} C_2H_2 + C_2H_4 \quad (4)$$

$$2C_2H_3\cdot \xrightarrow{k_r} C_4H_6^* \quad (5)$$

$$C_4H_6^* \xrightarrow{k_{-r}} 2C_2H_3\cdot \quad (6)$$

$$C_4H_6^* + M \xrightarrow{k_s} C_4H_6 + M \quad (7)$$

$$I + I + M \longrightarrow I_2 + M \quad (8)$$

where $C_4H_6^*$ denotes a vibrationally excited complex.

The study of mercury-photosensitized reaction of vinyl chloride in the gas phase by Gunning and his co-workers[6] is instructive for the present work although the reactants and the experimental conditions are different. The process of vinyl radical formation by the reaction of $Hg(6\ ^3P_1)$ atoms with vinyl halide can be ruled out for direct absorption excitation of the reactant molecule. Vinyl radical formation is given by process (2). The hydrogen-abstraction process

$$C_2H_3\cdot + C_2H_3I \longrightarrow C_2H_4 + C_2H_2I$$

can be ruled out because of the high concentration of C_2H_3 radicals since radical-radical reaction is much faster under such conditions. In contrast of the results of Gunning and co-workers the value of the ratio $[C_2H_4]/[C_2H_2]$ was time-independent. The reaction scheme is thus not incompatible with their results,[6] if we consider the difference in experimental conditions.

The contribution of the process

$$C_2H_3\cdot + I \longrightarrow C_2H_3I$$

was assumed to be negligible compared to reactions (4) and (5) by analogy with the fact that the rate constant of the recombination process

$$R\cdot + R\cdot \longrightarrow R\text{-}R$$

is about 10^2 times larger than that of the process

$$R\cdot + X \longrightarrow R\text{-}X$$

where R denotes alkyl radicals and X means NO molecule.[11] Assuming the short life of $C_2H_3I^*$ as in the case of CH_3Cl^*,[6] contribution of the process

$$C_2H_3I^* + M \longrightarrow C_2H_3I + M$$

might be smaller than processes (2) and (3).

The hydrogen-abstraction reaction by iodine atom could be excluded because of its low reaction rate.

Considering the dissociation energy of the C–I bond in vinyl iodide and the energy level of the lowest excited state of iodine atom which is known to be 21.7 kcal/mol,[12] contribution of the electronically excited iodine atom can not be excluded in UV-29 and full arc series while most of the excess energy at the C–I bond rupture would be distributed to the lighter fragment[13] $C_2H_3\cdot$.

Applying the steady state method, the rates of formation of C_2H_2, C_2H_4, and C_4H_6 are expressed as follows:

$$\frac{d[C_2H_2]}{dt} = \frac{I_0k_0k_2}{k_1+k_2}[C_2H_3I] + \frac{I_0k_0k_1k_d(k_s[M]+k_{-r})[C_2H_3I]}{2(k_1+k_2)\{(k_d+k_r)(k_s[M]+k_{-r})-k_rk_{-r}\}} \quad (9)$$

$$\frac{d[C_2H_4]}{dt} = \frac{I_0k_0k_1k_d(k_s[M]+k_{-r})[C_2H_3I]}{2(k_1+k_2)\{(k_d+k_r)(k_s[M]+k_{-r})-k_rk_{-r}\}} \quad (10)$$

$$\frac{d[C_4H_6]}{dt} = \frac{I_0k_0k_1k_rk_s[M][C_2H_3I]}{2(k_1+k_2)\{(k_d+k_r)(k_s[M]+k_{-r})-k_rk_{-r}\}} \quad (11)$$

Assuming the constancy of $d[C_2H_2]/dt$, $d[C_2H_4]/dt$, and $d[C_4H_6]/dt$ in the low conversion period, the following equation is obtained:

$$\frac{[C_2H_2]+[C_4H_6]}{[C_2H_4]+[C_4H_6]} = 1 + \frac{2k_2}{k_1} \quad (12)$$

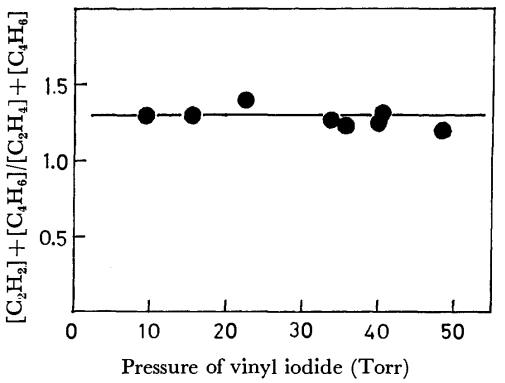

Fig. 5. Reaction product ratio $[[C_2H_2]+[C_4H_6]]/[[C_2H_4]+[C_4H_6]]$ obtained at various pressures of vinyl iodide. Filter; Toshiba UV-29.

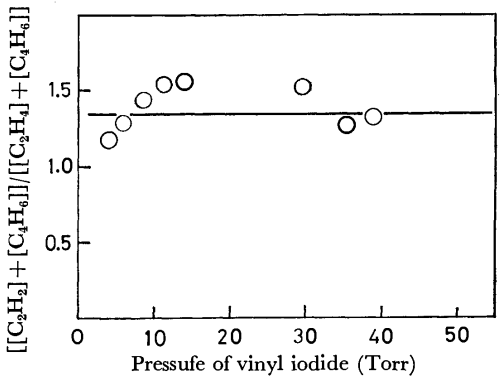

Fig. 6. Reaction product ratio $[[C_2H_2]+[C_4H_6]]/[[C_2H_4]+[C_4H_6]]$ obtained at various pressures of vinyl iodide when full arc was used without filter.

TABLE 4. CONTRIBUTION OF MOLECULAR AND RADICAL PROCESSES IN THE PHOTODECOMPOSITION OF VINYL IODIDE

Experiment	Molecular process	Radical process	k_2/k_1	Most effective wavelength for excitation
UV-29 series	13±2%	87±2%	0.14± 0.02	313 mμ (91 kcal/mol)
Full arc series	17±5%	83±5%	0.20± 0.07	254 mμ (112 kcal/mol)

The equation shows that the reaction product ratio $([C_2H_2]+[C_4H_6])/([C_2H_4]+[C_4H_6])$ is constant and k_2/k_1 value can be obtained.

It is seen in Figs. 5 and 6 that the ratio $[[C_2H_2]+[C_4H_6]]/[[C_2H_4]+[C_4H_6]]$ is constant in both UV-29 and full arc series although the results are rather scattered in the latter. Table 4 shows that the ratio k_2/k_1, ratio of the contribution of molecular process (3) to free radical process (2) in the primary processes, is about 1/6 and almost independent of the exciting energy in the range 91—112 kcal/mol.

The quantum yield for the sum of molecular and radical processes was found to be 0.26±0.2 in the UV-29 series.

In the low pressure range, where $k_s[M] \ll k_{-r}$, Eqs. (9), (10), and (11) are respectively reduced to

$$\frac{d[C_2H_2]}{dt} = \frac{(k_1+2k_2)k_0I_0}{2(k_1+k_2)}[C_2H_3I] \quad (13)$$

$$\frac{d[C_2H_4]}{dt} = \frac{k_0k_1I_0}{2(k_1+k_2)}[C_2H_3I] \quad (14)$$

$$\frac{d[C_4H_6]}{dt} = \frac{k_0k_1k_rk_sI_0}{2(k_1+k_2)k_dk_{-r}}[C_2H_3I]^2 \quad (15)$$

These equations explain the results in which, in the low pressure range, the rates of ethylene and acetylene formation are proportional to the pressure of vinyl iodide, while the rate of 1,3-butadiene formation is proportional to the square of vinyl iodide pressure.

From Eqs. (14) and (15) we obtain

$$\frac{[C_4H_6]}{[C_2H_4]} = \frac{k_rk_s}{k_dk_{-r}}[C_2H_3I] \quad (16)$$

This means that the product ratio $[C_4H_6]/[C_2H_4]$ is proportional to the pressure of vinyl iodide in the low pressure range as shown in Fig. 7.

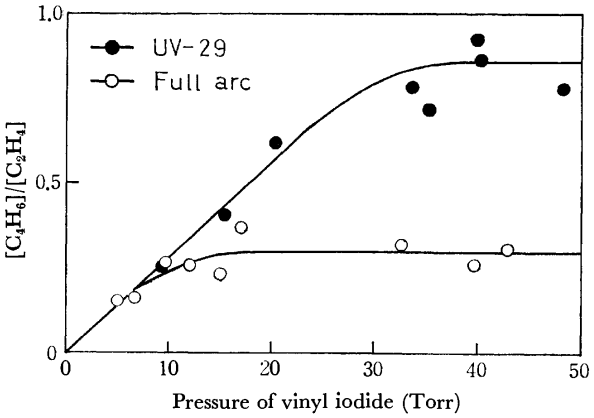

Fig. 7. Linear relation between the ratio $[C_4H_6]/[C_2H_4]$ and vinyl iodide pressure in low pressure range.

From Eqs. (10) and (11), the following equation is obtained:

$$\frac{[C_2H_4]}{[C_4H_6]} = \frac{k_d}{k_r}\left(1+\frac{k_{-r}}{k_s}\cdot\frac{1}{[M]}\right) \quad (17)$$

This shows the linear relation between the ratio $[C_2H_4]/[C_4H_6]$ and $1/[M]$ where [M] denotes the pressure of the reactant. Fig. 8 shows that the linear relation holds both for UV-29 and full arc series. From Fig. 8, the value of the ratio k_d/k_r is found to be 0.43 in UV-29 series and 2.5 for full arc experiments.

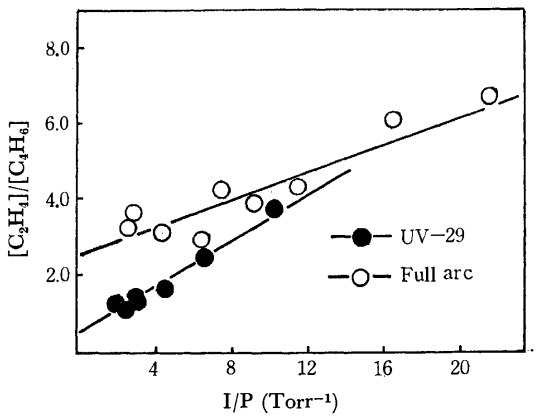

Fig. 8. Linear relation between the ratio $[C_2H_4]/[C_4H_6]$ and the reciprocal of vinyl iodide pressure.

TABLE 5. THE RATIO OF k_d/k_c FOR VINYL RADICAL PRESENTED BY DIFFERENT WORKS

k_d/k_c	Method	Investigators
0.4	Photodecomposition of vinyl iodide mostly at 313 mμ	S. Y. *et al.*
2.5	Photodecomposition of vinyl iodide mostly at 254 mμ	S. Y. *et al.*
1.1	Irradiation of the mixture of vinyl formate and acetaldehyde at a wavelength greater than 300 mμ	N. A. Weir; ref. 4
2	Decomposition of the mixture of vinyl iodide and vinyl bromide by sodium diffusion flame technique	D. J. LeRoy and A. W. Tickner; ref. 5
0.05	Photodecomposition of mercury divinyl by 220—260 mμ	A. G. Sherwood and H. E. Gunning; ref. 6

The value k_d/k_c which is usually used for the rate constant ratio of disproportionation to combination of the radical-radical reaction, is equal to the ratio k_d/k_r in the present paper. The values of k_d/k_c for vinyl radical reactions obtained by the previous and present workers are summarized in Table 5. The results of the present work and those of previous investigators are compatible except for the results of Sherwood and Gunning, although the vinyl radical sources and experimental conditions differ from each other.

Considering the results of photochemical study of Weir[4] and the present work, the value of the ratio k_d/k_c for vinyl radical seems to depend slightly on the exciting energy. When a molecule for free radical source is excited by absorption of quanta of shorter wavelength, the excess energy carried by the photofragment radical should be larger. The results in Table 5 suggest that the excitation by shorter wavelength light causes larger value of k_d/k_c in the case of vinyl radicals. It is difficult, however, to find a regularity from all the data in Table 5 taken from different studies since the conditions for vinyl radical formation differ.

It is generally accepted that recombination and disproportionation reactions of free radicals proceed with almost zero activation energy[14,15] as well as ion-molecule reactions.

It is also known that, in ion-molecule reactions, the "stripping" mechanism is predominant at high energy conditions whereas the "complex" mechanism is effective at low energy conditions.[16,17] In the reaction between CH_4^+ and CH_4, for example, H^+-stripping model was considered while the complex formation was assumed in low energy condition.[18]

$$CH_4^+ + CH_4 \begin{cases} \longrightarrow CH_3 + CH_5^+ & (H^+\text{-stripping}) \\ \longrightarrow C_2H_8^+ \longrightarrow CH_5^+ + CH_3 & (\text{complex}) \end{cases}$$

It might be suggested that the observation of the complex(combination) → disproportionation transition with increasing exciting energy in radical-radical reactions is phenomenologically analogous to the complex→ stripping transition with increasing energy found in ion-molecule reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 664—668(1972)

Interaction of Metal Porphyrins with Molecular Oxygen in Solutions

Kenichi YAMAMOTO and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received May 20, 1971)

The oxidation of divalent metal tetraphenylporphin complexes by molecular oxygen has been investigated in solutions. It was found that the one-electron oxidation of low-spin iron(II) complexes to yield high-spin iron-(III) does not take place, while a low-to-low conversion proceeds with ease. It is suggested that the ready oxidation is due to the delocalization of the d_π electrons of iron(II) to the vacant π-orbital of the porphin ligand. Oxidative mechanisms of manganese(II) and cobalt(II) tetraphenylporphins were also discussed.

It is well known that iron porphyrin complexes take part in oxygen-carrying, electron transfer (redox reaction) and in decomposing hydrogen peroxide in biological processes. These subtle functions may be ascribable to both the iron porphyrin and the axial-ligand environment (protein), and they are quite informative in regard to catalysis.

In the present work, a much simpler reaction system is undertaken; the interaction of synthetic iron tetraphenylporphin (abbreviated to TPP) complexes (Fig. 1) with molecular oxygen is investigated in chloroform solutions, mainly by means of an ESR technique, with special attention paid to the electron-spin configurations of the central metal ion and its ligand environment. Since the spin state of iron in the porphin ring is changeable according to the coordinating capability of the axial ligand, the redox behavior of the iron will be affected more or less by its surroundings. Previous works[1-3]

on cobalt phthalocyanine and cobalt TPP have, in fact, shown that the oxygenation and oxidation catalysis by these complexes are extensively influenced by the presence of axial ligands.

It is the purpose of the present paper to outline such a redox behavior of iron porphin complexes and to compare it with those of manganese and cobalt TPP complexes.

Experimental

Fe(III)-, Mn(III)-, and Co(II)-TPP complexes were prepared as usual[4] form metal(II) acetate and synthetic TPP. These complexes were dissolved in chloroform with or without a base which was expected to serve as an axial ligand (50—200 times or a saturated concentration). The axial bases used were tetrahydrofuran, quinoline, pyridine, 4-cyanopyridine, 4-methylpyridine, 4-aminopyridine, piperidine, imidazole, and benzimidazole.

Divalent iron and manganese complexes were prepared by reducing the corresponding trivalent metal TPP complexes with sodium dithionite($Na_2S_2O_4$). After the reduction treatment, the reducing reagent was removed from the solution by centrifugation. The concentrations of the metal complex usually ranged from 10^{-3} to 10^{-2}M. Throughout the procedure the complexes were kept in a dried nitrogen atmosphere.

The oxidation of metal(II) complexes was carried out by exposing their chloroform solutions to one atmospheric oxygen at room temperature. The ESR or optical absorption spectra were recorded before and after exposure to oxygen respectively. The ESR spectra were recorded at 77°K by means of a JEOL-P-10 (X-band) spectrometer with a 100-kcps field modulation.

Results and Discussion

Spin State of Iron(III) Complexes. Magnetic susceptibility measurements have served to provide information on the electronic configuration of ferrous or ferric ions. ESR methods have also provided supplementary information. Thus, theoretical analyses[5,6] have shown that high-spin iron(III) porphyrin complexes should exhibit ESR spectra with an axial symmetry at $g_\perp \sim 6$ and $g_{//} \sim 2$, while in low-spin complexes the anisotropic spectra of the three different g components are to be found near $g \sim 2$. The spin state of iron(III) porphin may thus be judged qualitatively from the shape of the obtained spectra.

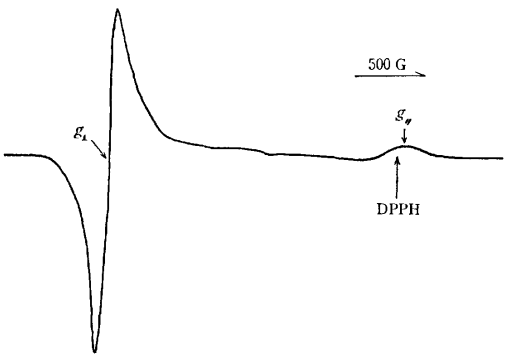

Fig. 2. ESR spectrum of Fe(III)-TPP-Cl in chloroform at 77°K. $g_\perp \sim 6$, $g_{//} \sim 2$.

A typical ESR spectrum of the Fe(III)–TPP complex in chloroform is shown in Fig. 2. It is apparent from the spectral shape of Fig. 2 that the complex is high-spin. The spin configuration is consistent with that determined by the magnetic susceptibility measurements.[7] When excess imidazole was added to this solution, the spectrum of Fig. 2 appeared to change greatly into that shown in Fig. 3 or into that characteristic of low-spin iron. The weak absorption around $g \sim 6$ is probably due to the contamination of high-spin iron.

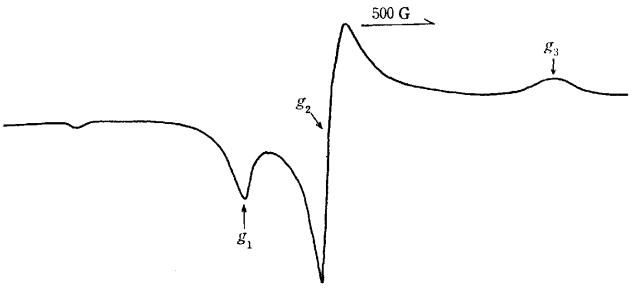

Fig. 3. ESR spectrum of [Fe(III)-TPP-2Im]Cl in chloroform at 77°K.
$g_1=2.98$, $g_2=2.31$, $g_3=1.52$.

A crystalline sample was then found to be isolable when repeated partial evaporation and centrifugation were carefully done. An elementary analysis of the isolated crystal indicated that its composition was consistent with [Fe–TPP–2Im]Cl(imidazole is abbreviated to Im); $C_{50}H_{36}N_8FeCl$, anal. (%), calcd., C: 71.47, H: 4.33, N: 13.34; found, C: 71.29, H: 4.47, N: 14.99. The sample redissolved in chloroform gave almost the same spectrum as that shown in Fig. 3. The diimidazole complexes may, hence, be regarded as stable in chloroform. Their formation may be expressed by:

$$\text{Fe(III)-TPP-Cl} + n\ \text{Im} \longrightarrow [\text{Fe(III)-TPP-2Im}]\text{Cl} + (n-2)\text{Im}$$

The ESR spectra of Fe(III)–TPP complexes coordinated with the other axial bases were further investigated; most complexes were found to be high-spin except that coordinated with 4-aminopyridine, which

Table 1. Electron spin states of Fe(III)-TPP complexes

Complex	ESR Spectra	Spin States
Fe(III)-TPP-Cl	$g_\perp=6.10$, $g_{//}=1.98$	high-spin
[Fe(III)-TPP-2B]Cl		
B: 4-cyanopyridine		
pyridine	$g \sim 6$	high-spin
4-methylpyridine		
4-aminopyridine	anisotropic	low-spin
B: imidazole	$g_1=2.98$, $g_2=2.31$, $g=1.52$	low-spin

was low-spin. The inspection of these spectra permitted us to confirm that a large basicity of the axial ligand favors a low-spin configuration of iron. The electronic features of the Fe(III) complexes are illustrated in Table 1. It is interesting to note in the Table that the dipyridine iron(III) complex[8] is high-spin, whereas the diimidazole complex is low-spin. This somewhat remarkable difference between pyridine and imidazole ligands can probably be ascribed to the stronger basicity[9] and π-donating capability of imidazole as compared with those of pyridine.[10]

Spin State of Iron(II) Complexes. Low-spin iron(II) complexes have six d electrons in the t_{2g} (d_π) orbital, hence, they are diamagnetic. The ESR absorption for high-spin iron(II) complexes is difficult to measure, probably because of the short spin-lattice relaxation time. Fe(II)-TPP coordinated with various bases has, in fact, shown no ESR spectrum, indicating that this technique is inadequate as far as ferrous iron is concerned.

On the other hand, magnetic susceptibility data were available for Fe(II)-TPP complexes,[7] as is illustrated below:

	μ Bohr magneton
Fe(II)-TPP	4.75
Fe(II)-TPP-2THF	2.75
Fe(II)-TPP-2Py	0

Accordingly, the dipyridine iron(II) complex can be said to be low-spin, while Fe(II)-TPP is high-spin. Unfortunately, no information is available on the diimidazole iron(II) complex. However, it seems very probable, in view of the stronger coordinating capability of imidazole as compared with that of pyridine, that the diimidazole iron(II) complex is also low-spin.

Interaction of Oxygen with Iron(II) Complexes. The oxidative behavior of Fe(II)-TPP complexes has been investigated in the light of both ESR and optical absorption spectra before and after exposure to oxygen at room temperature respectively. Generally speaking, the reactivity of Fe(II)-TPP complexes appeared to vary extensively from one complex to the other. Here, we shall confine ourselves to some extreme cases.

The high-spin Fe(II)-TPP was readily oxidized to yield Fe(III)-TPP upon exposure to oxygen, whereas this was not the case with the low-spin Fe(II)-TPP-2Py. Since the latter complex is hexacoordinated, the fact that oxidation did not occur for Fe(II)-TPP-2Py would, at first sight, indicate that the axial pyridine can not be displaced by oxygen. This interpretation is not correct, however; the hexacoordinated Fe(II)-TPP-2Im complex appeared to be readily and reversibly oxidized under exactly the same reaction conditions as in the case of Fe(II)-TPP-2Py. Such interesting oxidative behavior of Fe(II)-TPP complexes is compared below, together with their electron-spin states (in parentheses).

$$\text{Fe(II)-TPP (high)} \longrightarrow \text{Fe(III)-TPP (high)}$$

$$\text{Fe(II)-TPP-2Py (low)} \;-\!\!\times\!\!\rightarrow\; \text{Fe(III)-TPP-2Py (high)}$$

$$\text{Fe(II)-TPP-2Im (low)} \rightleftharpoons \text{Fe(III)-TPP-2Im (low)}$$

where $\longrightarrow$ indicates "oxidized", and $-\!\!\times\!\!\rightarrow$, "not oxidized". In other words, "oxidized" means the formation of a Fe(III) complex when the corresponding Fe(II) complex is brought into contact with oxygen, while "not oxidized" means no spectral change.

As is shown above, the diimidazole Fe(II) and Fe(III) complexes were both low-spin. On the other hand, the dipyridine Fe(II) was low, with its oxidized form high. The change in the spin state of iron is remarkable for the one-electron oxidation of the dipyridine Fe(II) complex when compared with that for the diimidazole complex. According to X-ray analysis,[11] there exists a substantial difference in structure between the low-spin-iron-porphyrin and high-spin-iron-porphyrin complexes. For high-spin iron porphyrins, the iron atom is known to lie 0.40—0.50 Å out-of-plane from the four porphin-nitrogens, whereas for low-spin iron porphyrins it lies nearly in-plane, hence bringing about rather long bonds between the iron and the porphin-nitrogen, for high-spin iron porphyrins. Thus, a large energy is required for the one-electron oxidation of the Fe(II) complex accompanied by a change in the spin state. The structural difference may arise from the electronic difference that two electrons must be transferred from the nonbonding $t_{2g}(d_\pi)$ to the antibonding $e_g(d_\sigma)$ orbital for the high-spin complex (Fig. 4).

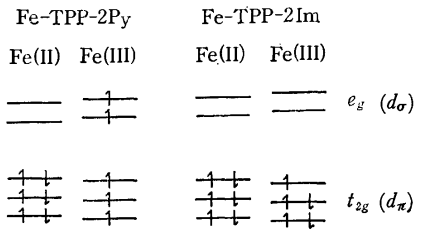

Fig. 4. Electron configuration of Fe-TPP complexes.

The ready oxidation of the diimidazole Fe(II) complex by molecular oxygen to yield Fe(III) is worthy of note, for the mechanism is perhaps associated with that in biological processes, for example, the effective electron transfer by hexacoordinated Cytochrome C. Mössbauer studies[12] of the Fe(II)-porphyrin bond has indicated that the electron of low-spin Fe(II) is extensively delocalized to the porphyrin ligand. Porphyrin itself is known to undergo facile reduction and

8) We were unable to isolate a crystalline dipyridine iron(III) because of some stickiness of the complex, unlike the case of diimidazole iron(III). On the other hand, the dipyridine protoporphyrin iron(III) complex has been isolated by us from a benzene-pyridine solution; $C_{44}H_{42}N_6FeCl$, anal. (%), calcd., C: 65.22, H: 5.24, N: 10.37; found, C: 64.71, H: 5.18, N: 9.69 (unpublished data). The ESR absorption lines of this complex were consistently explained if two pyridine molecules were assumed to be coordinated with the iron atom.[1]

9) pK_a-values: 5.18(pyridine), 1.80(4-cyanopyridine), 6.10(4-methylpyridine), 9.18(4-aminopyridine), 11.12(piperidine), 7.12-(imidazole).

oxidation thus forming a variety of molecular complexes.[13,14]

It may be suggested, therefore, that the oxidation of the diimidazole Fe(II) complex by molecular oxygen takes place by means of a *long-range* interaction mechanism. One electron of the $t_{2g}(d_\pi)$ orbital of Fe(II) is delocalized to the vacant π-orbital of the porphin ligand. Electrons may thus be transferred to molecular oxygen close to the porphin ligand, although the position of the oxygen is still undetermined.

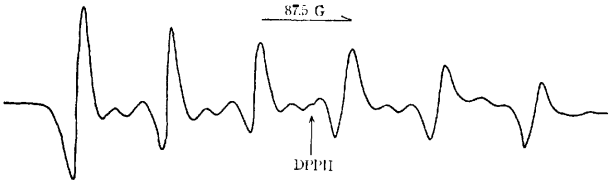

Fig. 5. ESR spectrum of Mn(II)-TPP in chloroform-imidazole solution at 77°K.

Interaction of Oxygen with Manganese(II) Complexes. The Mn(II)-TPP complex dissolved in chloroform gave rise to no ESR spectrum, but when excess amounts of imidazole are added it showed a resonance absorption near $g\sim2$. The spectrum consisted of six hf lines ($I=5/2$) and was characteristic of the high-spin state, provided that the zero field splitting parameters, D and E, are very small.[15,16] The signal is illustrated in Fig. 5. No ESR absorption was observed for most Mn(II)- and Mn(III)-TPP complexes on the addition of axial bases other than imidazole. However, since the magnetic moments have been reported to be in the range of 4.8—5.0 B.M. for a number of Mn(III) porphyrin complexes,[17] it would be highly probable that the Mn-TPP complexes are generally of the high-spin state.

No spectral change was observed when the imidazole Mn(II) complex was exposed to oxygen at room temperature, indicating that the complex was not susceptible to oxidation; we would expect the spectrum of Fig. 5 to disappear if the imidazole Mn(II) complex is oxidized. On the other hand, the Mn(II)-TPP complex was found to be readily oxidized in the absence of a base, because, on adding imidazole to the *oxidized* solution, we found no perceptible ESR spectrum; we should expect that type of spectrum (Fig. 5) to appear if the Mn(II)-TPP complex is not perceptible to oxidation.

Further observations were carried out on the Mn(II)-TPP complexes in the presence of other axial base, mainly by an optical technique. Some representative results are shown below. It is assumed that a dipyridine or diimidazole Mn(II)-TPP complex was formed in chloroform, although the complex was not isolated.

Mn(II)-TPP (high) ⟶ Mn(III)-TPP (high)

Mn(II)-TPP-2Py (high) —x→ Mn(III)-TPP-2Py (high)

Mn(II)-TPP-2Im (high) —x→ Mn(III)-TPP-2Im (high)

Interaction of Oxygen with Cobalt(II) Complexes. All of the Co(II)-TPP complexes coordinated with the axial ligand gave rise to ESR spectra characterized by eight hf lines, as is familiar in the case of cobalt ($I=7/2$). Some of them yielded three shf lines due to ligand nitrogen ($I=1$). The presence of the three shf lines suggests that the cobalt complex is coordinated with a *single* ligand molecule on its z-axis, unlike Fe(II)-TPP or Mn(II)-TPP

$$\text{Co(II)-TPP} + n\text{Py} \longrightarrow \text{Co(II)-TPP-Py} + (n-1)\text{Py}$$

A crystalline sample was isolated from the chloroform-pyridine solution on evaporation, and its composition was consistent with monopyridine complex, or $C_{49}H_{33}N_5Co$; calcd, C: 78.38, H: 4.44, N: 9.32; found, C: 78.38, H: 4.22, N: 9.63. This pentacoordinated form is probably due to the d^7 low-spin electronic configuration of Co(II).[3] The ESR spectrum for Co(II)-TPP coordinated with pyridine is shown in Fig. 6a.

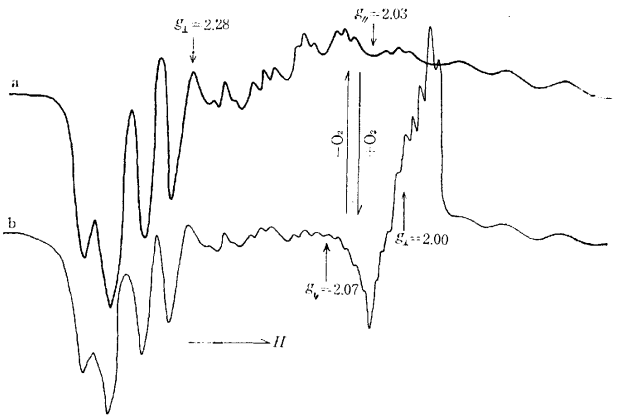

Fig. 6. ESR spectra of Co(II)-TPP-Py in chloroform at 77°K.
(a) evacuated; (b) exposed to O_2 for 10 min at room temperature.

When the Co(II)-TPP-Py complex was exposed to oxygen, the original signal due to Co(II) more or less decayed, while a new signal developed in the vicinity of $g\sim2$ (Fig. 6b). The spectral change was reversible as the oxygen pressures varied. The new signal near $g\sim2$ showed eight shf lines, suggesting that the molecular oxygen ion is formed and combined with cobalt.

An oxygenation took place irreversibly with the Co(II)-TPP coordinated with imidazole. In this case, no ESR signal was detectable after the irreversible oxygenation. The 3 d_{z^2} orbital energy of Co(II) rises especially when a strong base such as imidazole is coordinated. As a consequence, the unpaired electron of Co(II) may readily be transferred to the oxygenated cobalt complex, resulting in a diamagnetic, binuclear cobalt complex.[3] The complexing of oxygen is then no longer reversible.

Summary

So far we have dealt with the oxidation of tetra-, penta-, and hexacooridnated transition metal(II) complexes differing in the spin state. In order to bring about a rapid oxidation, (1) the complexes should provide empty sites for oxygen, and (2) the activation energy should be low. These conditions seem to be fulfilled at least in the oxidation of Mn(II)-TPP, Fe(II)-TPP, and Co(II)-TPP-Py. Conversely, the oxidation will be slow or will be inhibited if empty sites are not available and if significant energy is required for electron transfer. Such a case is the oxidation of Fe(II)-TPP-2Py. These examples are obviously two extreme cases.

We have found an *intermediary* situation in the oxidation of the Fe(II)-TPP-2Im complex, where no more empty sites are available, but where the activation energy must be low enough because of the rapid oxidation that takes place. We have presented a *long-range* interaction mechanism between oxygen and the Fe(II) ion through a conjugated porphin ring. Kinetic data for the oxidation were only qualitative, but the interpretation was consistent with the electronic and structural properties of the complex.

Electron transfer *via* the so-called outer-sphere activated complex has been observed in the electron exchange reaction for $[Fe(CN)_6]^{4-} \rightleftharpoons [Fe(CN)_6]^{3-}$, $[Fe(phenantroline)_3]^{2+} \rightleftharpoons [Fe(phenantroline)_3]^{3+}$, and so on.[18] A net chemical reaction is not involved here. The electron transfer reaction demonstrated above between oxygen and Fe(II)-TPP-2Im thus constitutes a new aspect of the problem of electron transfer.

The Intermolecular Potential of Hydrocarbon Dimers as Examined by the Perturbation Theory Including Exchange Energy in the PPP Approximation

Hiroko FUJITA and Akira IMAMURA

Biophysics Division, National Cancer Center Research Institute, Tsukiji, Chuo-ku, Tokyo

(Received June 5, 1971)

By using the perturbation method, including the exchange energy, the interaction potential curves for the intermolecular distances from 2.0 Å to 6.0 Å of the ethylene dimer, the butadiene dimer, the hexatriene dimer, and the benzene dimer were obtained. The matrix elements were evaluated in the Pariser-Parr-Pople approximation. Reasonable intermolecular potential curves were obtained for all the dimers studied. The analysis of the perturbation energy leads to the conclusion that the induction and dispersion energies and the exchange repulsion energy of the second order in the overlap integral give the potential minimum for the interaction of small molecules, such as ethylene or butadiene dimers, but for large molecules, such as benzene or hexatriene dimers, the exchange repulsion energy of the fourth order in the overlap integral should also be included in order to obtain the potential minimum. An important role of the charge transfer term was suggested for the chemical reaction; this was in agreement with the indications of previous researchers. The calculated depth of the potential minimum and the equilibrium molecular distance are in fairly good agreement with the experimental data.

The calculation of exact intermolecular potential curves for various large molecules is a very important but still unsolved problem. The relative geometries of charge-transfer complexes and the excimer or exciplex, the orientation of molecules in molecular crystals, and the conformation of such biopolymers as proteins and DNA are intimately related to the intermolecular potential energy between the corresponding molecules. Moreover, for the illustration of reaction mechanisms or the calculation of cross sections for the collisions of molecules, the intermolecular potential curves are indispensable.

The approaches to the evaluation of intermolecular force may mainly be classified into two types, according to whether the system is treated as one molecule or as a composite of two molecules. In the former type, variational methods, including configuration interactions or *ab initio* treatments, have been used. However, especially for large molecules, these methods are not reliable, since the contribution of ionic configurations is apt to be excessively included; hence, plausible intermolecular potential curves have been obtained for only small molecules or atoms.[1,2] In the latter, a difficult problem is the evaluation of the exchange repulsion energy, which heretofore has been treated only semi-empirically, when it has been taken into account at all.[3] One approach to this problem is the perturbation theories including exchange energy recently developed

1) G. Das and A. C. Wahl, *J. Chem. Phys.*, **47**, 2934 (1967).
2) G. H. F. Diercksen, *Chem. Phys. Lett.*, **4**, 373 (1969).

by many authors.[4-9] However, these theories have as yet been applied only to sets of small molecules or atoms.[10,11] On the other hand, for large molecules many phenomena have been studied, for example, the Diels-Alder reactions,[12,13] the excimer formations,[14-16] the spectra of the hydrocarbon dimers,[17] the charge-transfer complexes,[18,19] and the stacking energies of nucleic acid's bases.[20] However, in these calculations various types of approximations are employed, that is, the use of the iterative extended Hückel method, or the neglect of exchanges of electrons or a truncation of the expansion by excited levels.

In this paper, the intermolecular energies of the ethylene dimer, butadiene dimers, the hexatriene dimer, and the benzene dimer were calculated using the Pariser-Parr-Pople (PPP) approximation and by means of the perturbation method, including exchange energy, by Murrell *et al.*[4,5] The potential curves thus obtained are found to be reasonable, giving the potential minimum at an appropriate intermolecular distance. From the analysis of each term of the perturbation energy, it was found that the contribution of exchange energy due to the exchanges of two pairs of electrons, which corresponds to the fourth order term in the overlap integral, is very important for the interaction of large molecules.

Moreover, the contributions of the charge-transfer term is rather small for all the dimers studied except for the *trans*-butadiene-*cis*-butadiene dimer at short distances. The fact that this butadiene dimer has a remarkable contribution of the charge-transfer term is very interesting, since this dimer can be considered to become an activated complex of the Diels-Alder reaction. Those results correspond well with those obtained by Fukui and Fujimoto.[21] The comparison of the calculated intermolecular potential and the equilibrium intermolecular distance with those of the experimental data leads to the conclusion that the theoretical method in the present paper gives relatively reliable results.

Method

The perturbation theories recently developed[4-8] for intermolecular potentials including exchange integrals are multifarious in their formulas. This is because nonperturbed wave functions are not linearly independent of each other; hence, the expansion coefficients of these wave functions for an arbitrary function can not be uniquely determined, as has been pointed out by Lekkerkerker and Laidlaw.[9] However, the various formulas give almost the same results for the interaction energy between two atoms.[10,11] In the present paper, the formulas derived by Murrell and Shaw[4] were adopted for calculating all the intermolecular potential energies except for the charge-transfer term. For the charge-transfer term, the formula of Murrell, Randic, and Williams was employed.[5,22] The outline of the perturbation method will be given below.

The Shrödinger equations of the separated molecules, A and B, are:

$$H_A(i)A_r(i) = E_r^A A_r(i),$$
$$H_B(j)B_s(j) = E_s^B B_s(j). \quad (1)$$

Here, A_r and B_s are wave functions in ground or singly-excited configurations of the A and B molecules respectively.[23] Hereafter, the ground state will be denoted by the suffix '0', *i.e.*, A_0, B_0, *etc.* The Shrödinger equation of the total system is:

$$H\Psi = E\Psi, \quad (2)$$

where:

$$H = H_A(i) + H_B(j) + U,$$

and where U is the interaction potential:

$$U = \sum_s\sum_t e^2/r_{st} - \sum_a\sum_t Z_a^A e^2/r_{at} - \sum_b\sum_s Z_b^B e^2/r_{sb} + \sum_a\sum_b Z_a^A Z_b^B/r_{ab}. \quad (3)$$

Here s and t denote electrons in the A and B molecules respectively, and a and b, nuclei or cores in the A and B molecules. Z is the effective charge, and r represents the distance. The wave function of a configuration constituting the total wave function, Ψ, is constructed from the products of the wave functions of the separated molecules, allowing for exchanges of electrons; that is, for the ground state:

$$\Psi = \Psi_0 + \sum_{t\neq 0} b_t \Psi_t, \quad (4)$$

where:

$$\Psi_0 = \mathcal{A}A_0(i)B_0(j), \quad (5)$$
$$\Psi_t = \mathcal{A}A_r(i)B_s(j), \quad (6)$$

22) The charge-transfer term can not be treated together with other locally-excited terms by the perturbation method since the perturbed Hamiltonian for locally-excited terms is different from that for charge-transfer terms. Accordingly, after perturbed wave functions have been obtained for ground and locally-excited configurations, the variational method in which the wave function is represented by a linear combination of charge-transfer and locally-excited configurations (perturbed wave function) should be used. This treatment will give the total wave function for two interacting molecules.

23) Doubly-excited configurations are disregarded since the matrix element between the ground and doubly-excited configurations vanishes.

or:

$$\Psi_t = \mathscr{A}A_k^+(i')B_l^-(j'), \tag{7}$$

where $A_k^+B_l^-$ represents a charge-transfer configuration and where $\mathscr{A}$ is the antisymmetrizing operator, which allows for exchanges of electrons between the i and j sets (or i' and j'); *i.e.*:

$$\mathscr{A} = \{(2n)!(2m)!/(2n+2m)!\}^{1/2}(1+P_{ij}^1+P_{ij}^2+\cdots), \tag{8}$$

where $2n$ and $2m$ are the number of electrons of the i and j sets, respectively. P_{ij}^1 is the operator which exchanges one pair of electrons, accompanied by a change in the sign, while P_{ij}^2 is the one which exchanges two pairs of electrons with no change of the sign, and so on. The total energy for the ground state can be calculated by means of the perturbation method; that is, the substitution of the total energy and the total wave function of Eq. (4) into Eq. (2) yields the following Eqs. (9)—(13):[4,5,9]

$$E^{10} = U_{00}^{10}, \tag{9}$$

$$E^{20} = \sum_{t(\neq 0)} (U_{t0}^{10})^2/(E_0-E_t), \tag{10}$$

$$E^{12} = U_{00}^{12} - S_{00}^{02}U_{00}^{10}, \tag{11}$$

$$E^{22} = \sum_{t(\neq 0)} U_{t0}^{10}(U_{t0}^{12}-S_{t0}^{02}U_{00}^{10})/(E_0-E_t) - S_{00}^{02}E^{20}, \tag{12}$$

$$E^{CT} = \sum_{t(\neq 0)} (U_{t0}^{11}-S_{t0}^{01}U_{00}^{10})^2/(E_0-E_t), \tag{13}$$

where, for convenience, the interaction energies are classified according to the powers of U (the first upper index) and S, *i.e.*, the overlap integral by the electron exchange (the second upper index). E^{10} represents the electrostatic interaction energy between two molecules, A and B; E^{20}, the dispersion and induction energies; E^{12}, the exchange energy of the second order in the overlap integral; E^{22}, the exchange polarization energy, and E^{CT}, the charge-transfer energy. E_0 and E_t are:

$$\begin{aligned} E_0 &= E_0^A + E_0^B \\ E_t &= E_r^A + E_s^B. \end{aligned} \tag{14}$$

The matrix elements are as follows:

$$\begin{aligned} U_{00}^{10} &= \langle A_0(i)B_0(j)\,|\,U\,|\,A_0(i)B_0(j)\rangle, \\ U_{t0}^{10} &= \langle A_r(i)B_s(j)\,|\,U\,|\,A_0(i)B_0(j)\rangle, \\ U_{00}^{12} &= \langle P_{ij}^1A_0(i)B_0(j)\,|\,U\,|\,A_0(i)B_0(j)\rangle, \\ U_{t0}^{12} &= \langle P_{ij}^1A_r(i)B_s(j)\,|\,U\,|\,A_0(i)B_0(j)\rangle, \\ U_{t0}^{11} &= ((2m+1)/2n)^{1/2}\langle A_k^+(i')B_l^-(j')\,|\,U\,|\,A_0(i)B_0(j)\rangle, \\ S_{00}^{02} &= \langle P_{ij}^1A_0(i)B_0(j)\,|\,A_0(i)B_0(j)\rangle, \\ S_{t0}^{02} &= \langle P_{ij}^1A_r(i)B_s(j)\,|\,A_0(i)B_0(j)\rangle, \\ S_{t0}^{01} &= ((2m+1)/2n)^{1/2}\langle A_k^+(i')B_l^-(j')\,|\,A_0(i)B_0(j)\rangle. \end{aligned} \tag{15}$$

As we will show in the latter section, for large molecules the exchange energy up to the second order in the overlap integral, E^{12}, has a negative value at short distances; hence, the potential minimum can not be found. Accordingly we introduce E^{14}, the exchange energy of the 4*th* order in the overlap integral corresponding to the exchanges of two pairs of electrons. According to Murrell and Shaw,[4] the first-order correction for the energy is:

$$E^{(1)} = \langle\psi_0\,|\,U\,|\,\Psi_0\rangle/\langle\psi_0\,|\,\Psi_0\rangle, \tag{16}$$

where Ψ_0 is as given in Eq. (5) and where ψ_0 is:

$$\psi_0 = A_0B_0.$$

The expansion of Eq. (16) up to the 4*th* order in the overlap integral leads to the following formula:

$$\begin{aligned} E^{(1)} &= (U_{00}^{10}+U_{00}^{12}+U_{00}^{14})/(1+S_{00}^{02}+S_{00}^{04}) \\ &= U_{00}^{10} + (U_{00}^{12}-U_{00}^{10}S_{00}^{02}) \\ &\quad + (U_{00}^{14}-U_{00}^{12}S_{00}^{02}-U_{00}^{10}S_{00}^{04}+U_{00}^{10}(S_{00}^{02})^2). \end{aligned}$$

The second term as the right side of the above equation corresponds to E^{12} in Eq. (11), while the last term corresponds to E^{14} *i.e.*, the 4*th*-order term in the overlap integral:

$$E^{14} = U_{00}^{14} - U_{00}^{12}S_{00}^{02} - U_{00}^{10}S_{00}^{04} + U_{00}^{10}(S_{00}^{02})^2), \tag{17}$$

which can be rewritten as Eq. (18) for non-polar molecules since the U_{00}^{10} vanishes:

$$E^{14} = U_{00}^{14} - U_{00}^{12}S_{00}^{02}. \tag{18}$$

The applicability of Eq. (18) to polar molecules was confirmed numerically in the range of the equilibrium distances.

The ground-state wave functions of the separated A and B molecules were assumed to be antisymmetrized molecular orbitals (ASMO's). The coefficients of the atomic orbitals were obtained using the Pariser-Parr-Pople (PPP) method[24] for the π electron system. They can also be obtained by means of other molecular orbital methods such as the CNDO/2 method or *ab initio* calculation. The results by the CNDO/2 method is given in this paper only for the ethylene dimer. The E_t values in Eq. (14) were evaluated as follows: for locally excited configurations,

$$\begin{aligned} E_t &= E_0^A + E_0^B + \varepsilon_k^A - \varepsilon_i^A - J_{ik}^A + 2K_{ik}^A \\ &\quad + \varepsilon_l^B - \varepsilon_j^B - J_{jl}^B + 2K_{jl}^B, \end{aligned} \tag{19}$$

where J and K denote the Coulomb and exchange integrals respectively, and ε, the molecular orbital energies. On the other hand, for charge-transfer configurations,

$$E_t = E_0^A + E_0^B + \varepsilon_l^B - \varepsilon_k^A. \tag{20}$$

Mulliken's approximation was used for the atomic integrals between the different molecules. The two-center electron repulsion integrals (γ) were evaluated using Mataga and Nishimoto's approximation and the nuclear-repulsion potential, $Z_a^AZ_b^B\gamma_{ab}$, in the PPP approximation. The other approximations and parameters used are the same as those in Ref. 25 for the PPP method or in Ref. 26 for the CNDO/2 method. The matrix elements in Eq. (15) are given in terms of molecular orbitals in the Appendix.

Results and Discussion

1. Contribution of Each Term to the Total Interaction Energy. The total intermolecular potential curves in the PPP approximation for the ethylene dimer, the *trans*-butadiene dimer, the *trans*-hexatriene dimer, and the benzene dimer are shown, along with the E^{12}, E^{14},

and E^{20} values, in Figs. 1—4. In all these dimers, configurations of the sandwich type are assumed. In Tables 1—3, the values of all the terms are tabulated in more detail. The calculated intermolecular potential curves are reasonable, because the potential curves have a minimum point at an appropriate molecular distance and increase rapidly when two molecules come closer each other. However, the contributions of such terms as E^{10}, E^{20}, E^{12}, and E^{14} to the total energy differ from molecule to molecule. The electrostatic interaction (E^{10}) between two unsaturated hydrocarbons is very small or non-existent. The second-order term, E^{20}, contains the dispersion interaction energy, the dipole-induced dipole interaction energy, and so on. In the case of hydrocarbons, the former is dominant.

The magnitude of E^{20} depends upon the sizes of the interacting molecules; that is, this interaction energy is large in magnitude for the benzene dimer, small for the ethylene dimer, and intermediate for the butadiene dimer. The dependence of the magnitude of the dispersion force on the sizes of the molecules may easily be explained by the fact that large molecules have many energy levels. However, this interaction also depends upon the relative orientation between two interacting molecules (see Table 3 and Table 4). At any rate, the dispersion energies stabilize the interacting systems.

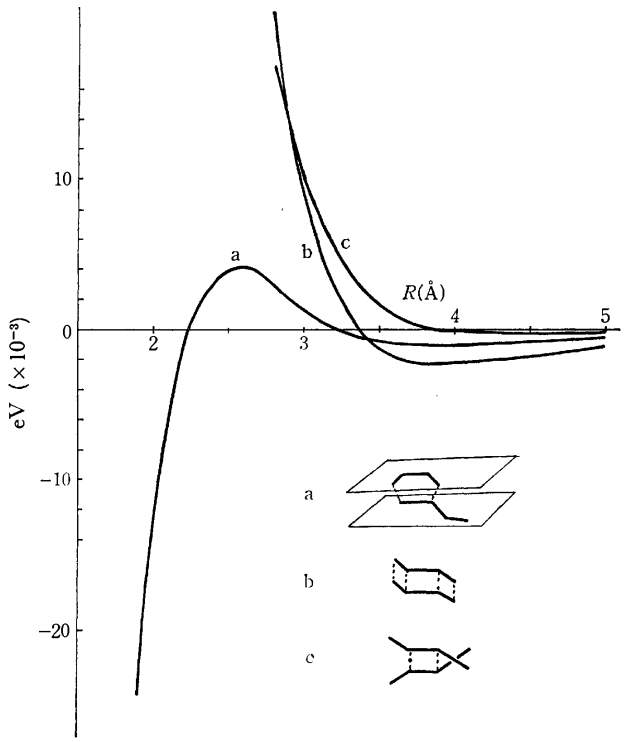

Fig. 5. The interaction energies of the *trans*-butadine-*cis*-butadine dimer (a), the *trans*-butadiene dimer type 1 (b), the *trans*-butadiene dimer type 2 (c).

The contribution of the charge-transfer interaction to the intermolecular potential is negligibly small for hydrocarbon dimers in sandwich-type configuration. On the other hand, the charge-transfer interactions of the *trans*-butadiene dimer in a type-2 configuration (Fig. 5 and Table 4) and of the *trans*-butadiene-*cis*-butadiene dimer (Table 5) are not negligible, especially at short distances. Moreover, among the three butadiene dimers in Fig. 5, only the *trans*-butadiene-*cis*-butadiene dimer has the potential maximum which comes from the remarkable increase in the stabilization energy caused by the charge-transfer interaction, while the other two dimers, the *trans*-butadiene dimer type 1 and type 2, give the increasing potential curves. Although these potential curves at short distances may not be reliable since the contribution of higher-order terms in the perturbation expansion and that of σ-electrons should be taken into account, these features of the potential curves can explain well the fact that the *trans*-butadiene-*cis*-butadiene dimer can bring about a Diels-Alder reaction, while the other two dimers can not. A similar approach to the chemical reaction by making use of the perturbation method has already been made by Fukui *et al.*,[21] emphasizing the importance of the charge-transfer interaction (delocalization interaction in Fukui's nomenclature). Our results are in complete agreement with theirs.

The other terms which depend upon the magnitude

of the overlap integral are the exchange interaction terms, E^{12}, E^{14}, and E^{22}. Among them, the exchange polarization term, E^{22}, is negligibly small for all the molecules studied. The most striking aspect of the results is the relative magnitude of the E^{12} and E^{14} terms at intermediate distances (~2.5 Å). That is, the absolute value of the term of E^{12} is much larger than that of E^{14} for the interaction between small molecules, such as ethylene and butadiene, while the reverse is true for the benzene dimer as well as for the hexatriene dimer. Moreover, E^{12} is negative and E^{14} is positive for large molecules, such as benzene and hexatriene. In other words, if the fourth-order term in the overlap integral is disregarded for the interaction of large molecules, the potential minimum can not be obtained and two molecules come closer to coalescing. Therefore, the inclusion of E^{14} term in the calculation of the intermolecular potential is indispensable for large molecules. However, the situation is different for small molecules; that is, here the potential minimim can be obtained without E^{14}. This characteristic behavior of the exchange interaction term can be ascribed to the fact that the overlap integral between molecular orbitals of the interacting molecules is quite large in magnitude for large molecules, but is relatively small for small

molecules, as is indicated in Table 7, although the value of the each atomic overlap integral is the same for all the dimers (Table 6). The signs of the terms of E^{12} and E^{14} are noteworthy since E^{12} is positive for the ethylene and butadiene dimers, except for very short distances, and negative for the hexatriene dimer, while E^{14} is positive for all the dimers. E^{12} is negative at short distances, but positive at the larger distances, for the benzene dimer (Table 3). The sign of E^{12} results from the nine terms with plus or minus signs in U^{12}_{00} given by Eq. (A-5); that is, the No. 1, 2, 3, 4, and 9 terms have negative signs, while the other terms, No. 5, 6, 7, and 8, positive signs. The values of each term for the ethylene and benzene dimers are listed in Tables 8(a) and 9(a) respectively. The dependence of each term on the size of the molecules is shown in Fig. 6. From this figure, it is apparent that the values of the terms, No. 4, 6, 8, and 9, increase rapidly with the increase in the size of the molecules, while the values of the other terms increase only slightly. This tendency can be explained by the number of sums

Table 8. E^{12} and E^{14}, and the values of each term in U^{12}_{00} and in U^{14}_{00} for the ethylene dimer at R=2.5 Å

included in each term in U^{12}_{00} (Eq. (A-5)); that is, the former terms are calculated by a fourfold summation, while, on the other hand, the summations for the latter terms are double or triple. From this tendency, the appearance of the negative sign of E^{12} for large molecules can easily be understood. These situations are the same for the terms of U^{14}_{00} except that each term of U^{14}_{00} has a sign opposite to the corresponding one of U^{12}_{00} because of the exchanges of two pairs of electrons. The values of each term in U^{14}_{00} or the ethylene and benzene dimers are listed in Tables 8(b) and 9(b) respectively. As has been mentioned above, all the terms of U^{12}_{00} and U^{14}_{00} have different signs, hence cancel each other out to make the exchange energy positive, as a whole, leading to the appearance of the potential minimum.

The importance of the term of E^{14} for large molecules was pointed out in a previous paragraph. In connection with this, the contribution of the E^{16} term should be investigated since this term probably has a sign different from that of E^{14}. However, the comparison of the magnitude of each term of U^{12}_{00} with that of U^{14}_{00} for the benzene dimer (Tables 9(a) and 9(b)) lead to a finding that each term in the equation of U^{12}_{00} is much larger in absolute magnitude than that of U^{14}_{00}, although the value of E^{14} is, as a whole, larger than that of E^{12}. Accordingly, it can resonably be

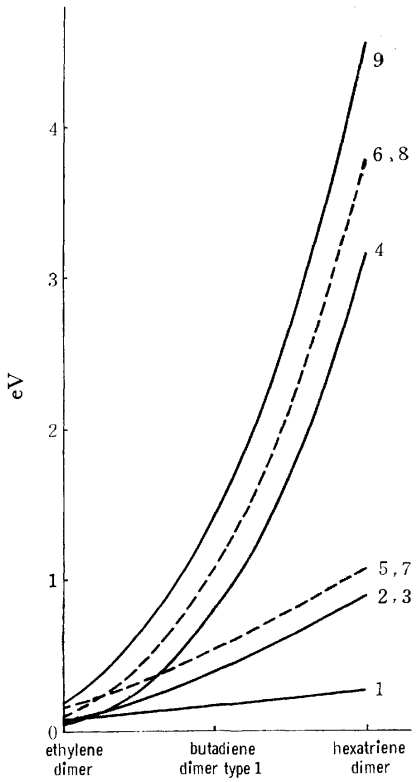

Fig. 6. The absolute value of the each term in U_{00}^{12} at R= 3.0 Å. The numbers represent the each term.———, negative value;--------- positive value.

expected that each term in U_{00}^{16} is too small in magnitude to contribute to the total intermolecular energy, even as a whole. In the present paper, other terms with a fourth order in overlap integrals such as E^{24} are completely neglected. This approximation is reasonable judging from the magnitude of E^{22}.

2. Comparison of the Calculated Values with the Experimental Values. It is very difficult to compare the calculated intermolecular potential and the equilibrium distance with those experimentally obtained, since the value obtained in the gas phase is an average of those of all possible geometries. The relative geometry of molecules in its molecular crystal gives some information, although the interactions between only two molecules are calculated in this paper.

The energy at the calculated potential minimum for both ethylene and butadiene dimers is much less than the thermal energy (0.026 eV at 300°K); hence these molecules have no ability to form stable dimers, a finding which is in accordance with the experimental results. Moreover, the calculated result that the ethylene dimer is more unstable than the butadiene dimer in a type-1 conformation is consistent with the relative stability of these molecules, which can be estimated from the boiling points if the entropic contribution is not serious. For benzene, the potential minimum becomes much deeper than the thermal energy. The experimental value derived from the viscosity (0.015 eV)[27] is very close to that obtained theoretically, although the experimental value corresponds to the average of various relative orientations. On the other hand, the intermolecular energy obtained from the heat of sublimation (0.40 eV) seems to be much larger. However, the difference between the experimental values from the heat of sublimation and the calculated value is not tremendous, since the heat of sublimation includes the interaction energies for all pairs of molecules in the crystal. As a whole, the calculated values of the intermolecular energies agree qualitatively fairly well with the experimental data, although the theoretical values should be calculated in more elaborate approximations in order to compare them with the experimental data quantitatively.

The calculated equilibrium molecular distances are noteworthy in connection with the geometry of the dimer of the molecular crystal. The equilibrium intermolecular distance for the ethylene dimer is located at about 4.5 Å (Fig. 1), which is comparable with the experimental values (4.2—4.8 Å) estimated from the value of viscosity or the second Virial coefficient.[27] On the other hand, the potential minimum for the benzene dimer in Fig. 4 is found at 2.9 Å, which seems to be slightly small in comparison with the value obtained for graphite (3.4 Å). This is because, for the ethylene dimer, the dispersion energy is reasonably balanced with the exchange energy, giving rise to a good agreement with the experimental results for the equilibrium intermolecular distance; on the other hand for the benzene dimer, the dispersion energy overcomes the exchange energy, leading to the slightly short intermolecular distance. From the results described above, we can conclude that the theoretical methods in the present paper are considerably reliable for the prediction of the intermolecular interaction energy and the intermolecular distance, though the quantitative agreement with the experimental data is not entirely satisfactory.

3. Discussion of the Method. In order to improve the present results, the use of a more exact atomic orbital and the explicit inclusion of σ electrons are important. As is well known, the SCF atomic orbitals for various atoms are considerably different form those of the usual Slater atomic orbitals, especially in the region distant from the atomic nucleus. Therefore, the improvement of the atomic orbital may be important for obtaining the exact intermolecular potential.[28] However, the use of the SCF atomic orbital, which is usually represented by the linear combination of several Slater-type atomic orbitals, is cumbersome in the expansion of the matrix elements into atomic orbitals. Instead of the SCF atomic orbital, the overlap matched atomic orbital (OMAO)[29] was employed in order to investigate the dependence of the result on the atomic orbitals used in the present paper. This orbital (OMAO) is a single Slater-type atomic orbital whose exponent was determined so as to reproduce overlap integrals calculated by SCF atomic orbitals. The value of the Slater exponent in OMAO[29] is 1.42, while the

27) J. O. Hirschfelder, C. F. Curtiss, and R. B. Bird, "Molecular Theory of Gases and Liquids", Wiley, New York (1954).

28) J. N. Murrell and G. Shaw, *Mol. Phys.*, **12**, 475 (1967).

29) L.C. Cusachs, B.L. Trus, D.G. Carroll, and P.S. McGlynn, *Int. J. Quant. Chem., Sympo.*, **1**, 423 (1967).

Slater rule gives 1.625 for the carbon atom. Obviously, OMAO has an overlap integral larger in magnitude. The intermolecular potential curves for the ethylene dimer and the butadiene dimer obtained by using OMAO are indicated in Figs. 1 and 2 in comparison with those obtained by the use of the Slater rule. The potential minimum obtained in OMAO is located at a distance longer by about 1 Å for both dimers, because of the increasing contribution of the exchange repulsion energy.

Table 10. The interaction energies in ONDO/2 approximation of the ethylene dimer (in eV)

R(Å)	E^{10}	E^{20}	E^{12}	Total
3.5	0.0051	−0.0150	0.0181	0.0081
4.0	0.0008	−0.0075	0.0030	−0.0037
4.5	0.0004	−0.0040	0.0004	−0.0032

Next, the explicit treatment of σ electrons was carried out in the framework of the CNDO/2 approximation for the ethylene dimer. In this calculation, however, the terms of E^{14}, E^{22}, and E^{CT} are neglected since these terms may not make large contributions to the equilibrium distance and since the calculation of these terms takes much computer time.[30] The results listed in Table 10 indicate that the inclusion of σ electrons increases the contribution of E^{20} because of the increase in the number of energy levels in the summation of Eq. (10). Since E^{20} is negative, the equilibrium distance obtained in the CNDO/2 approximation is shorter than that obtained in the PPP approximation. As a result of the above investigations, it can be concluded that the effects of the improvement of the atomic orbital and the explicit treatment of σ electrons cancel each other out to some extent, resulting in a relatively small correction for the equilibrium distance obtained in the PPP approximation using the usual simple Slater atomic orbitals. On the other hand, the magnitude of the interaction energy in the CNDO/2 approximation is much more than that in the PPP approximation because of the dominant increase in the contribution of E^{20}.

4. Comparison with Other Methods. The finding that the potential curves for the ground state have the minima shown in the present paper may be compared with the results by other authors. The results of the extended Hückel method show that, for example, for the ethylene dimer in Ref. 15 or the benzene dimer in Ref. 16, the potential minimum for the ground state does not appear, contrary to our calculations, while it does exist in the excited states, hence, they concluded that the excimer formations may be expected for these dimers. On the other hand, Chandra investigated the origin of the stability of aromatic hydrocarbon dimers using the Hückel-type π perturbation theory and showed that, in the ground state, the tilted configuration was stable, while the sandwich configuration was not.[17] However, our calculation for the benzene dimer in the sandwich configuration gives the potential minimum, although the magnitude is small because of the use of the π approximation. As was mentioned in the previous paragraph, the inclusion of σ electrons results in an increase in the interaction energy for the ethylene dimer; hence, it can probably be expected that, for the benzene dimer, the interaction energy involving the contribution of σ electrons is also larger by one order than that in the PPP approximation. Therefore, the intermolecular interaction energy obtained by the Hückel or the extended Hückel method, in which the electron-electron repulsion energies are not explicitly included, is substantially different from the results of the present paper with regard to the appearance of the potential minimum.

5. Summary. The method and the approximation used in the present paper give a satisfactory qualitative agreement with the experimental results for the intermolecular potential. In order to obtain a quantitative agreement, more elaborate and cumbersome approximations are required; that is, these must be an improvement in the atomic orbital and in the explicit treatment of σ electrons.

Appendix

The Matrix Elements. The matrix elements in PPP approximation are as followes.

(1)

$$U_{00}^{10} = \sum_a\sum_b Z_a{}^A Z_b{}^B \gamma_{ab}^{AB} - 2\sum_b Z_b{}^B \sum_i^{occ.} \langle \varphi_i{}^A(1) | e^2/r_{1b} | \varphi_i{}^A(1) \rangle$$
$$- 2\sum_a Z_a{}^A \sum_j^{occ.} \langle \varphi_j{}^B(1) | e^2/r_{1a} | \varphi_j{}^B(1) \rangle$$
$$+ 4\sum_i^{occ.}\sum_j^{occ.} \langle \varphi_i{}^A(1)\varphi_j{}^B(2) | e^2/r_{12} | \varphi_i{}^A(1)\varphi_j{}^B(2) \rangle$$
$$= \sum_a (Z_a{}^A - P_a{}^A) \sum_b (Z_b{}^B - P_b{}^B) \gamma_{ab}^{AB}, \qquad \text{(A-1)}$$

where $P_a = 2\sum_i^{occ.} (C_{ai})^2$.

(2) In evaluating the matrix element U_{t0}^{10}, the following cases are separately treated according to the configuration of $A_r(i)B_s(j)$.

(i) When the configuration is A_rB_0, where r denotes the $i \rightarrow k$ singly excitation,

$$U_{t0}^{10} = 2\sqrt{2}\sum_j \langle \varphi_k{}^A(1)\varphi_j{}^B(2) | e^2/r_{12} | \varphi_i{}^A(1)\varphi_j{}^B(2) \rangle$$
$$- \sqrt{2}\sum_b Z_b{}^B \langle \varphi_k{}^A(1) | e^2/r_{1b} | \varphi_i{}^A(1) \rangle$$
$$= -\sqrt{2}\sum_a C_{ak}^A C_{ai}^A \sum_b (Z_b{}^B - P_b{}^B) \gamma_{ab}^{AB}. \qquad \text{(A-2)}$$

(ii) When the configuration is A_0B_s, where s denotes the $j \rightarrow l$ singly excitation,

$$U_{t0}^{10} = -\sqrt{2}\sum_b C_{bj}^B C_{bl}^B \sum_a (Z_a{}^A - P_a{}^A) \gamma_{ab}^{AB}. \qquad \text{(A-3)}$$

(iii) When the configuration is A_rB_s, *i.e.*, both molecules are in excited states, where r denotes the $i \rightarrow k$, singly excitation and s does the $j \rightarrow l$,

$$U_{t0}^{10} = 2\langle \varphi_k{}^A(1)\varphi_l{}^B(2) | e^2/r_{12} | \varphi_i{}^A(1)\varphi_j{}^B(2) \rangle$$
$$= 2\sum_a C_{ak}^A C_{ai}^A \sum_b C_{bl}^B C_{bj}^B \gamma_{ab}^{AB}. \qquad \text{(A-4)}$$

(3)

$$U_{00}^{12} = -2\sum_i\sum_j \langle \varphi_i{}^A(2)\varphi_j{}^B(1) | e^2/r_{12} | \varphi_i{}^A(1)\varphi_j{}^B(2) \rangle \qquad 1)$$
$$-4\sum_l\sum_i\sum_j \langle \varphi_j{}^B(1)\varphi_l{}^B(2) | e^2/r_{12} | \varphi_i{}^A(1)\varphi_l{}^B(2) \rangle$$
$$\times \langle \varphi_i{}^A(3) | \varphi_j{}^B(3) \rangle \qquad 2)$$

30) The calculation of the intermolecular potential including these terms by using the CNDO/2 method is in progress; the results will be published in the future.

(when $l=j$, multiplied by 1/2)

$$-4\sum_{l}\sum_{i}\sum_{j}\langle\varphi_i^A(2)\varphi_l^A(1)\,|\,e^2/r_{12}\,|\,\varphi_l^A(1)\varphi_j^B(2)\rangle \times\langle\varphi_j^B(3)\,|\,\varphi_i^A(3)\rangle \quad 3)$$

(when $l=i$, multiplied by 1/2)

$$-8\sum_{m}\sum_{l}\sum_{i}\sum_{j}\langle\varphi_i^A(1)\varphi_j^B(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle \times\{\langle\varphi_i^A(3)\,|\,\varphi_m^B(3)\rangle\}^2 \quad 4)$$

(when $j=m$ or $i=l$, multiplied by 1/2)

$$+2\sum_{a}\sum_{i}\sum_{j}\langle\varphi_i^A(1)\,|\,Z_a^A e^2/r_{a1}\,|\,\varphi_j^B(1)\rangle \times\langle\varphi_j^B(2)\,|\,\varphi_i^A(2)\rangle \quad 5)$$

$$+4\sum_{a}\sum_{i}\sum_{j}\sum_{l}\langle\varphi_j^B(1)\,|\,Z_a^A e^2/r_{a1}\,|\,\varphi_j^B(1)\rangle \times\{\langle\varphi_i^A(2)\,|\,\varphi_l^B(2)\rangle\}^2 \quad 6)$$

(when $j=l$, multiplied by 1/2)

$$-2\sum_{a}\sum_{b}Z_a^A Z_b^B\gamma_{ab}^{AB}\sum_{i}\sum_{j}\{\langle\varphi_j^B(1)\,|\,\varphi_i^A(1)\rangle\}^2. \quad 9)$$

(A-5)

U_{00}^{12} is written down here only in terms of the molecular orbitals. In the calculation, if the value of overlap integral between a pair of atomic orbiatls is less than 10^{-4} in magnitude, the contributions of this term could be neglected. This cut off procedure was taken through the computation of any matrix elements including overlap integrals, *i.e.*, U_{00}^{14}, U_{t0}^{12} *etc.*

(4)

$$S_{00}^{02} = -2\sum_{i}\sum_{j}\{\langle\varphi_i^A(1)\,|\,\varphi_j^B(1)\rangle\}^2 = -2\sum_{i}\sum_{j}(\sum_{a}\sum_{b}C_{ai}^{A}C_{bj}^{B}S_{ab}^{AB})^2. \quad \text{(A-6)}$$

(5) The each term of U_{00}^{14} can be obtained by allowing the exchange of one pair of electrons in the electronic configuration of each term in U_{00}^{12}.

If $D_{fg}=\{\langle\varphi_f^A|\varphi_g^B\rangle\}^2$,

$$U_{00}^{14} = 1/2U_{00}^{12}S_{00}^{02}$$

$$+2\sum_{i}\sum_{j}\langle\varphi_i^A(2)\varphi_j^B(1)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle \times\sum_{\substack{f\\(\neq i)}}\sum_{\substack{g\\(\neq j)}}D_{fg} \quad 1)$$

$$+4\sum_{l}\sum_{i}\sum_{j}\langle\varphi_j^B(1)\varphi_l^B(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_l^B(2)\rangle \times\langle\varphi_i^A(3)\,|\,\varphi_j^B(3)\rangle\sum_{\substack{f\\(\neq i)(\neq l,j)}}\sum_{g}D_{fg} \quad 2)$$

(A-7)

(6) U_{t0}^{12} and S_{t0}^{02} can be classified as follows.

(i) When the configuration is A_rB_0, where r represents the $i\rightarrow k$ singly excitation,

$$U_{t0}^{12} = -\sqrt{2}\sum_{n}\langle\varphi_k^A(2)\varphi_n^B(1)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_n^B(2)\rangle -4\sqrt{2}\sum_{n}\sum_{m}\sum_{f}\langle\varphi_k^A(1)\varphi_n^B(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_n^B(2)\rangle \times\{\langle\varphi_f^A(3)\,|\,\varphi_m^B(3)\rangle\}^2$$

(when $m=n$ or $f=i$, multiplied by 1/2)

$$-4\sqrt{2}\sum_{f}\sum_{n}\sum_{m}\langle\varphi_f^A(1)\varphi_n^B(2)\,|\,e^2/r_{12}\,|\,\varphi_f^A(1)\varphi_n^B(2)\rangle \times\langle\varphi_k^A(4)\varphi_m^B(3)\,|\,\varphi_i^A(3)\varphi_m^B(4)\rangle$$

(when $m=n$ or $f=i$, multiplied by 1/2)

$$-2\sqrt{2}\sum_{m}\sum_{n}\langle\varphi_k^A(1)\varphi_n^A(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_m^B(2)\rangle \times\langle\varphi_m^B(3)\,|\,\varphi_n^A(3)\rangle$$

(when $n=i$, multiplied by 1/2)

$$-2\sqrt{2}\sum_{m}\sum_{n}\langle\varphi_n^B(2)\varphi_m^B(1)\,|\,e^2/r_{12}\,|\,\varphi_n^B(2)\varphi_i^A(1)\rangle \times\langle\varphi_k^A(3)\,|\,\varphi_m^B(3)\rangle$$

(when $n=m$, multiplied by 1/2)

$$-2\sqrt{2}\sum_{m}\sum_{n}\langle\varphi_n^A(1)\varphi_k^A(2)\,|\,e^2/r_{12}\,|\,\varphi_n^A(1)\varphi_m^B(2)\rangle \times\langle\varphi_m^B(3)\,|\,\varphi_i^A(3)\rangle$$

(when $n=i$, multiplied by 1/2)

$$+\sqrt{2}\sum_{a}\sum_{n}\langle\varphi_k^A(1)\,|\,Z_a^A e^2/r_{a1}\,|\,\varphi_n^B(1)\rangle \times\langle\varphi_n^B(2)\,|\,\varphi_i^A(2)\rangle$$

$$+2\sqrt{2}\sum_{m}\sum_{a}\sum_{n}\langle\varphi_m^B(1)\,|\,Z_a^A e^2/a_1\,|\,\varphi_m^B(1)\rangle \times\langle\varphi_k^A(2)\varphi_n^B(3)\,|\,\varphi_i^A(3)\varphi_n^B(2)\rangle$$

$$+\sqrt{2}\sum_{b}\sum_{n}\langle\varphi_n^B(1)\,|\,Z_b^B e^2/r_{1b}\,|\,\varphi_i^A(1)\rangle \times\langle\varphi_k^A(2)\,|\,\varphi_n^B(2)\rangle$$

$$+2\sqrt{2}\sum_{b}\sum_{n}\sum_{m}\langle\varphi_m^A(1)\,|\,Z_b^B e^2/r_{1b}\,|\,\varphi_m^A(1)\rangle \times\langle\varphi_n^B(2)\varphi_k^A(3)\,|\,\varphi_n^B(3)\varphi_i^A(2)\rangle$$

(when $m=i$, multiplied by 1/2)

$$+2\sqrt{2}\sum_{n}\sum_{m}\sum_{b}\langle\varphi_k^A(1)\,|\,Z_b^B e^2/r_{1b}\,|\,\varphi_i^A(1)\rangle \times\langle\varphi_m^A(3)\varphi_n^B(2)\,|\,\varphi_n^B(3)\varphi_m^A(2)\rangle$$

(when $m=i$, multiplied by 1/2)

$$-\sqrt{2}\sum_{n}\langle\varphi_k^A(2)\varphi_n^B(1)\,|\,\varphi_i^A(1)\varphi_n^B(2)\rangle \times\sum_{a}\sum_{b}Z_a^A Z_b^B\gamma_{ab}^{AB} \quad \text{(A-8)}$$

$$S_{t0}^{02} = -2\sqrt{2}\sum_{j}\langle\varphi_k^A(2)\varphi_j^B(1)\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle. \quad \text{(A-9)}$$

(ii) When the configuration is A_0B_s, where s represents the $j\rightarrow l$ singly excitation, the matrix elements U_{t0}^{12} and S_{t0}^{02} in this case are obtained from (i) by exchanging upper indices A and B and substituting j and l for i and k, respectively.

(iii) When the configurations A_rB_s, *i.e.*, both molecules are in excited states, where r represents the $i\rightarrow k$ singly excitation and s represents the $j\rightarrow l$,

$$\begin{aligned}U_{t0}^{12} = & -\langle\varphi_k^A(2)\varphi_l^B(1)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle\\ & -4\sum_n\sum_m\langle\varphi_n^A(1)\varphi_m^B(2)\,|\,e^2/r_{12}\,|\,\varphi_n^A(1)\varphi_m^B(2)\rangle\\ & \times\langle\varphi_k^A(3)\varphi_l^B(4)\,|\,\varphi_i^A(4)\varphi_j^B(3)\rangle\end{aligned}$$

(when $n=i$ or $m=j$, multiplied by 1/2)

$$\begin{aligned}& -2\sum_n\langle\varphi_n^A(1)\varphi_k^A(2)\,|\,e^2/r_{12}\,|\,\varphi_n^A(1)\varphi_j^B(2)\rangle\\ & \times\langle\varphi_l^B(3)\,|\,\varphi_i^A(3)\rangle\end{aligned}$$

(when $n=i$, multiplied by 1/2)

$$\begin{aligned}& -2\sum_n\langle\varphi_k^A(1)\varphi_n^A(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle\\ & \times\langle\varphi_l^B(3)\,|\,\varphi_n^A(3)\rangle\end{aligned}$$

(when $n=i$, multiplied by 1/2)

$$\begin{aligned}& -2\sum_n\langle\varphi_n^B(2)\varphi_l^B(1)\,|\,e^2/r_{12}\,|\,\varphi_n^B(2)\varphi_i^A(1)\rangle\\ & \times\langle\varphi_k^A(3)\,|\,\varphi_j^B(3)\rangle\end{aligned}$$

(when $n=j$, multiplied by 1/2)

$$\begin{aligned}& -2\sum_n\langle\varphi_l^B(2)\varphi_n^B(1)\,|\,e^2/r_{12}\,|\,\varphi_j^B(2)\varphi_i^A(1)\rangle\\ & \times\langle\varphi_k^A(3)\,|\,\varphi_n^B(3)\rangle\end{aligned}$$

(when $n=j$, multiplied by 1/2)

$$\begin{aligned}& -4\sum_m\sum_n\langle\varphi_n^A(1)\varphi_l^B(2)\,|\,e^2/r_{12}\,|\,\varphi_n^A(1)\varphi_j^B(2)\rangle\\ & \times\langle\varphi_k^A(4)\varphi_m^B(3)\,|\,\varphi_i^A(3)\varphi_m^B(4)\rangle\end{aligned}$$

(when $n=j$, multiplied by 1/2)

$$\begin{aligned}& +2\sum_a\sum_n\langle\varphi_l^B(1)\,|\,Z_a^Ae^2/r_{a1}\,|\,\varphi_j^B(1)\rangle\\ & \times\langle\varphi_n^B(3)\varphi_k^A(2)\,|\,\varphi_i^A(3)\varphi_n^B(2)\rangle\end{aligned}$$

(when $n=j$, multiplied by 1/2)

$$\begin{aligned}& +\sum_b\langle\varphi_l^B(1)\,|\,Z_b^Be^2/r_{1b}\,|\,\varphi_i^A(1)\rangle\langle\varphi_k^A(2)\,|\,\varphi_j^B(2)\rangle\\ & +2\sum_b\sum_n\langle\varphi_n^A(1)\,|\,Z_b^Be^2/r_{1b}\,|\,\varphi_n^A(1)\rangle\\ & \times\langle\varphi_k^A(2)\varphi_l^B(3)\,|\,\varphi_j^B(2)\varphi_i^A(3)\rangle\end{aligned}$$

(when $n=i$, multiplied by 1/2)

$$\begin{aligned}& +2\sum_b\sum_n\langle\varphi_k^A(1)\,|\,Z_b^Be^2/r_{1b}\,|\,\varphi_i^A(1)\rangle\\ & \times\langle\varphi_n^A(3)\varphi_l^B(2)\,|\,\varphi_j^B(3)\varphi_n^A(2)\rangle\end{aligned}$$

(when $n=i$, multiplied by 1/2)

$$-\langle\varphi_k^A(2)\varphi_l^B(1)\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle\sum_a\sum_bZ_a^AZ_b^Be^2/r_{ab} \tag{A-10}$$

$$S_{t0}^{02} = -2\langle\varphi_k^A(2)\varphi_l^B(1)\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle. \tag{A-11}$$

When $(U_{t0}^{10})^2/(E_0-E_t)$ is less than a critical value, the term including U_{t0}^{12} in E^{22}, *i.e.*, $U_{t0}^{10}U_{t0}^{12}/(E_0-E_t)$, can also be expected to be small in magnitude and hence the contribution of this term to E^{22} was neglected in order to save computation time. We found the critical value of 10^{-4} is sufficient for the result within the accuracy of 10^{-4} eV in total intermolecular potential.

(7)

$$\begin{aligned}U_{t0}^{11} = & \sqrt{2}\sum_j\langle\varphi_j^B(2)\varphi_l^B(1)\,|\,e^2/r_{12}\,|\,\varphi_k^A(1)\varphi_j^B(2)\rangle\\ & +4\sqrt{2}\sum_i\sum_j\langle\varphi_i^A(1)\varphi_j^B(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle\\ & \times\langle\varphi_l^B(3)\,|\,\varphi_k^A(3)\rangle\end{aligned}$$

(when $i=k$, multiplied by 1/2)

$$\begin{aligned}& -2\sqrt{2}\sum_i\sum_j\langle\varphi_i^A(1)\varphi_l^B(2)\,|\,e^2/r_{12}\,|\,\varphi_i^A(1)\varphi_j^B(2)\rangle\\ & \times\langle\varphi_j^B(3)\,|\,\varphi_k^A(3)\rangle\end{aligned}$$

(when $i=k$, multiplied by 1/2)

$$\begin{aligned}& -\sqrt{2}\sum_j\langle\varphi_j^B(1)\varphi_l^B(2)\,|\,e^2/r_{12}\,|\,\varphi_k^A(1)\varphi_j^B(2)\rangle\\ & -2\sqrt{2}\sum_a\sum_j\langle\varphi_j^B(1)\,|\,Z_a^Ae^2/r_{a1}\,|\,\varphi_j^B(1)\rangle\\ & \times\langle\varphi_l^B(2)\,|\,\varphi_k^A(2)\rangle\\ & +\sqrt{2}\sum_a\sum_j\langle\varphi_l^B(1)\,|\,Z_a^Ae^2/r_{a1}\,|\,\varphi_j^B(1)\rangle\\ & \times\langle\varphi_j^B(2)\,|\,\varphi_k^A(2)\rangle\\ & -\sqrt{2}\sum_b\langle\varphi_l^B(1)\,|\,Z_b^Be^2/r_{1b}\,|\,\varphi_k^A(1)\rangle\\ & -2\sqrt{2}\sum_b\sum_i\langle\varphi_i^A(1)\,|\,Z_b^Be^2/r_{1b}\,|\,\varphi_i^A(1)\rangle\\ & \times\langle\varphi_l^B(2)\,|\,\varphi_k^A(2)\rangle\end{aligned}$$

(when $i=k$, multiplied by 1/2)

$$+\sqrt{2}\sum_a\sum_bZ_a^AZ_b^Be^2/r_{ab}\langle\varphi_l^B(1)\,|\,\varphi_k^A(1)\rangle \tag{A-12}$$

$$S_{t0}^{01} = \sqrt{2}\langle\varphi_l^B(1)\,|\,\varphi_k^A(1)\rangle. \tag{A-13}$$

The matrix element of the charge transfer from B to A,

$$U_{t0}^{11} = (2n+1/2m)^{1/2}\langle A_l^-(i')B_k^+(j')\,|\,U\,|\,A_0(i)B_0(j)\rangle,$$

is obtained by exchanging upper indices A and B in Eq. (A-12).

The Abnormal Absorption Intensity of the C-H Stretching Vibration Band in Chloroform Vapor. I. The CNDO Calculation Involving the 3*d* Orbitals

Tomoo MIYAZAKI, Tsunehisa SHIGETANI, and Hiroshi YAMAMOTO

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo

(Received June 16, 1971)

By the CNDO calculation involving the 3*d* orbitals, the infrared absorption intensity of the C–H stretching vibration band in chloroform vapor has been discussed in comparison with those of methyl chloride and methylene chloride. The value of the 3*d* orbital exponent of the chlorine atom was estimated on the basis of calculations using different values of the 3*d* orbital exponent on methyl chloride. The absolute intensities of the fundamental and the first overtone bands were calculated from the values of the first and the second derivatives of dipole moments with respect to the normal coordinates. From the results of these calculations, it follows that the electrical properties of the vibrating bond are the most effective factors in bringing about the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor.

The CNDO method was applied by Segal and Klein[1] to the calculation of dipole-moment derivatives $\mu' = \partial\mu/\partial S_j$, where μ is the molecular dipole moment, and S_j, an appropriate symmetry coordinate. They concluded that the theory was reasonably successful in calculating both the magnitude and the sign of μ' for molecules composed of the first-row elements of the periodic table and/or hydrogen.

The CNDO method was extended to the treatment of molecules containing second-row elements by Santry and Segal.[2,3] In their papers, the importance of the 3*d* orbitals to the bonding in the molecule containing the second-row element was discussed and the CNDO parameters of the 3*d* orbitals necessary for calculation on molecules containing these elements were estimated.

The abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor is particularly interesting, since the fundamental band intensity is very weak and the first overtone band intensity is much stronger than that of the former.[4-6] Robinson *et al.* interpreted this experimental result in terms of the electrical properties of the vibrating bond.[4]

In view of the above situation, it appeared of interest to investigate the abnormal intensity of the C–H stretching vibration band in chloroform vapor by the CNDO calculation involving the 3*d* orbitals of the chlorine atom. However, the values of the parameter for the 3*d* orbitals of the second-row elements are not the most desirable.[2] Therefore, in the first step of the treatment in this work, we attempted to estimate the exponent, as a parameter, for the 3*d* orbitals of the chlorine atom by fitting the calculated molecular dipole moment of methyl chloride to the experimental one. By use of the appropriate value of the 3*d* orbital exponent of the chlorine atom, the dipole-moment derivatives referring to the C–H stretching vibration of chloroform have been calculated and the abnormal intensity of this vibration band has been discussed.

Methods of Calculation

The CNDO Calculation Involving the 3d Orbitals. The molecular orbital calculation used in this work followed the CNDO method proposed by Santry and Segal[2] except for the value of the 3*d* orbital exponent. To determine the appropriate value of the 3*d* orbital exponent of the chlorine atom, we adopted the approach of examining the comparative ability of molecular orbitals, as calculated by the various values of the 3*d* orbital exponent, to predict correctly the observed dipole moment of methyl chloride.

The CNDO approximation describes the molecular orbitals, φ_i, as linear combinations of valence atomic orbitals, χ_μ:

$$\varphi_i = \sum_\mu c_{i\mu}\chi_\mu, \tag{1}$$

where the coefficient, $c_{i\mu}$, are the eigenvectors of the Hartree-Fock matrix, $F_{\mu\nu}$. An important characteristic of the calculation in this work is that the 3*d* orbitals are considered to be members of the valence atomic orbital when the atom is a second-row element in the periodic table.

The coefficient of the molecular orbital and the energy can be obtained by solving the appropriate set of secular equations and corresponding secular matrix. The elements of the SCF energy matrix are given in this method by:

$$\begin{aligned} F_{\mu\mu}(\mathrm{S,S}) = &-\frac{1}{2}(I_\mu + A_\mu) + \left\{\left[P_{\mathrm{AA}}(S) - Z_{\mathrm{A}}\right] - \frac{1}{2}(P_{\mu\mu} - 1)\right\}\gamma_{\mathrm{AA}}(\mathrm{S,S}) + P_{\mathrm{AA}}(\mathrm{D})\gamma_{\mathrm{AA}}(\mathrm{S,D}) \\ &+ \sum_{\mathrm{B}\neq\mathrm{A}}\{[P_{\mathrm{BB}}(\mathrm{S}) - Z_{\mathrm{B}}]\gamma_{\mathrm{AB}}(\mathrm{S,S}), \\ &+ P_{\mathrm{BB}}(\mathrm{D})\gamma_{\mathrm{AB}}(\mathrm{S,D})\}, \end{aligned} \tag{2}$$

$$\begin{aligned} F_{\mu\mu}(\mathrm{D,D}) = &-\frac{1}{2}(I_\mu + A_\mu) + \left\{\left[P_{\mathrm{AA}}(\mathrm{S}) - \left(Z_{\mathrm{A}} - \frac{1}{2}\right)\right] \times \gamma_{\mathrm{AA}}(\mathrm{D,S})\right\} + \left[P_{\mathrm{AA}}(\mathrm{D}) - \frac{1}{2}P_{\mu\mu}\right]\gamma_{\mathrm{AA}}(\mathrm{D,D}) \\ &+ \sum_{\mathrm{B}\neq\mathrm{A}}\{[P_{\mathrm{BB}}(\mathrm{S}) - Z_{\mathrm{B}}]\gamma_{\mathrm{AB}}(\mathrm{D,S}) \\ &+ P_{\mathrm{BB}}(\mathrm{D})\gamma_{\mathrm{AB}}(\mathrm{D,D})\}, \end{aligned} \tag{3}$$

$$F_{\mu\nu}(\mathrm{S,S}) = \beta^0_{\mathrm{AB}}\mathrm{S}_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{\mathrm{AB}}(\mathrm{S,S}), \quad (4)$$

$$F_{\mu\nu}(\mathrm{S,D}) = \beta^0_{\mathrm{AB}}\mathrm{S}_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{\mathrm{AB}}(\mathrm{S,D}) \qquad (\mu \neq \nu), \quad (5)$$

$$F_{\mu\nu}(\mathrm{D,D}) = \beta^0_{\mathrm{AB}}\mathrm{S}_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{\mathrm{AB}}(\mathrm{D,D}), \quad (6)$$

where the suffix S refers to s and p orbitals, where D refers to the d orbital, and where γ_{AB} is the electron-repulsion integral calculated as a Coulomb integral involving valence s functions, which are divided into two sets, such as S (involving s and p orbitals) for those with exponents defined by Slater's rules and D (involving d orbital) for those with smaller exponents. In this calculation, the values of the orbital exponent were taken to be 6.1 and 5.5 for the S and D of the chlorine atom respectively. The $-\frac{1}{2}(\mathrm{I}_\mu+\mathrm{A}_\mu)$ term is the core integral, where I_μ and A_μ are the ionization potential and the affinity of the χ_μ orbital. The P_{AA} (S) term is the total charge density of the A atom in s- or p-type orbitals:

$$P_{\mathrm{AA}}(\mathrm{S}) = \sum_{\mu\in\mathrm{A}}^{\mu\neq\mathrm{D}} P_{\mu\mu}, \quad (7)$$

and P_{AA} (D) is the analogous charge density in $3d$ orbitals. The β^0_{AB} term is the resonance integral proportionality constant and is approximated as:

$$\beta^0_{\mathrm{AB}} = \frac{1}{2}K(\beta_{\mathrm{A}}{}^0+\beta_{\mathrm{B}}{}^0), \quad (8)$$

where $\beta_{\mathrm{A}}{}^0$ depends only on the A atom and where K is 0.75 if the A atom and/or the B atom is a second-row element, and 1 otherwise. The Z_{A} term is the core charge on the A atom. The $\mathrm{S}_{\mu\nu}$ term is the overlap integral between the χ_μ and χ_ν orbitals. The numerical values used in this calculation are listed in Table 1. The necessary overlap integrals were evaluated from the master formulas of Lofthus.[7] The electron–repulsion integrals involving s functions were theoretically evaluated from the master formulas, which were provided in the same way as in the derivation of Roothaan.[8]

Table 1. Parameter values (eV)

Atom	H	C		Cl		
Orbital	1s	2s	2p	3s	3p	3d
$1/2(I+A)$	7.176	14.051	5.572	21.591	8.708	0.977

The Dipole Moments and their Derivatives. The molecular dipole moments were calculated as a sum of three terms, μ_{Q}, μ_{sp}, and μ_{pd}, whree μ_{Q} is the contribution from net charge densities and where μ_{sp} and μ_{pd} are terms which arise from atomic polarization due to the mixing of s and p orbitals and that of p and d orbitals respectively. They can be calculated by means of the following equations:[9]

$$\mu_{\mathrm{Q}}(\mathrm{z}) = 2.5416\sum_{\mathrm{A}}^{\mathrm{atoms}} Q_{\mathrm{A}}z_{\mathrm{A}} \quad \text{(debyes)}, \quad (9)$$

$$Q_{\mathrm{A}} = Z_{\mathrm{A}} - P_{\mathrm{AA}},$$

where z_{A} is the appropriate Cartesian coordinate of the A atom.

$$\mu_{sp}(\mathrm{z}) = -2.5416\sum_{\mathrm{A}}^{\mathrm{atoms}}\left[\frac{10}{\sqrt{3}Z_s'(\mathrm{A})}P_{2s(\mathrm{A}),2p_z(\mathrm{A})} + \frac{21}{\sqrt{3}Z_s'(\mathrm{A})}P_{3s(\mathrm{A}),3p_z(\mathrm{A})}\right] \text{(debyes)}, \quad (10)$$

where Z'_s is the appropriate orbital exponent as defined by Slater's rules.

$$\mu_{pd}(\mathrm{x}) = -2.5416\sum_{\mathrm{A}}^{\mathrm{atoms}} M(\mathrm{A})\left[P_{3d_{xz}(\mathrm{A}),3p_z(\mathrm{A})} + P_{3d_{x^2-y^2}(\mathrm{A}),3p_x(\mathrm{A})} + P_{3d_{xy}(\mathrm{A}),3p_y(\mathrm{A})} - \frac{1^*}{\sqrt{3}}P_{3d_{z^2}(\mathrm{A}),3p_x(\mathrm{A})}\right] \text{(debyes)}, \quad (11)$$

$$\mu_{pd}(\mathrm{y}) = -2.5416\sum_{\mathrm{A}}^{\mathrm{atoms}} M(\mathrm{A})\left[P_{3d_{yz}(\mathrm{A}),3p_z(\mathrm{A})} + P_{3d_{xy}(\mathrm{A}),3p_x(\mathrm{A})} - {}^*P_{3d_{x^2-y^2}(\mathrm{A}),3p_y(\mathrm{A})} - \frac{1^*}{\sqrt{3}}P_{3d_{z^2}(\mathrm{A}),3p_y(\mathrm{A})}\right] \text{(debyes)}, \quad (12)$$

$$\mu_{pd}(\mathrm{z}) = -2.5416\sum_{\mathrm{A}}^{\mathrm{atoms}} M(\mathrm{A})\left[\frac{2^*}{\sqrt{3}}P_{3d_{z^2}(\mathrm{A}),3p_z(\mathrm{A})} + P_{3d_{xz}(\mathrm{A}),3p_x(\mathrm{A})} + P_{3d_{yz}(\mathrm{A}),3p_y(\mathrm{A})}\right] \text{(debyes)}, \quad (13)$$

$$M(\mathrm{A}) = \frac{5376[Z_s'(\mathrm{A})Z_{\mathrm{D}}'(\mathrm{A})]^{7/2}}{5^{1/2}[Z_s'(\mathrm{A})+Z_{\mathrm{D}}'(\mathrm{A})]^8}. \quad (14)$$

The numerical values required to discuss the intensities of the fundamental and the first overtone bands related to the C–H stretching vibration bands were obtained by fitting the calculated dipole moments to a cubic function with respect to the C–H distance and by taking the first and the second derivatives at the equilibrium distance. The dipole moments were calculated for the molecule distorted in the manner dictated by the symmetry coordinate including the C–H stretching modes. All the C–H bond stretching motions were calculated at intervals of ± 0.02 Å.

The Absolute Absorption Intensities of the Vibration Bands. The absolute infrared absorption intensity of the fundamental band, $(A^{*(k)}_{1\leftarrow 0})$, related to the normal coordinate, Q_k, was calculated from the following equation (15), which was derived, by Wilson *et al.*,[10] from a consideration of the 0→1, 1→2, *etc.* transitions, in the harmonic oscillator approximation:

$$A^*_{1\leftarrow 0} = A_{1\leftarrow 0} + A_{2\leftarrow 1} + A_{3\leftarrow 2} + \cdots$$

$$A^{*(k)}_{1\leftarrow 0} = \frac{\pi}{3C}\sum_{i=x,y,z}\left(\frac{\partial\mu_i}{\partial Q_k}\right)^2 [\mathrm{cm^2\cdot sec^{-1}\cdot molecule^{-1}}], \quad (15)$$

where C is the velocity of light and where μ_i is the i-component of the dipole moment of a system.

About the absolute intensity of the overtone band, $(A^{*(k)}_{2\leftarrow 0})$, in relating to the normal coordinate, Q_k, the

8) C. C. Roothaan, *J. Chem. Phys.*, **19**, 1445 (1951).

9) In this calculation, we made a few corrections in Equations (2-32) of the original paper[2]; the revised coefficients are marked by small stars.

10) E. B. Wilson, J. C. Decious, and P. C. Cross, "Molecular Vibrations," McGraw-Hill Book Company, New York (1955).

equation to be used in the calculation was obtained according to the approximation employed for the calculation of the fundamental band intensity by Wilson *et al*:

$$A_{2\leftarrow 0}^{*(k)} = \frac{\Theta^2(1-e^{-2U_k})}{\nu_k}\frac{h}{24\pi C}\sum_{i=x,y,z}\left(\frac{\partial^2\mu_i}{\partial Q_k^2}\right)^2$$

[cm²·sec⁻¹·molecule⁻¹], (16)

where Θ is the partition function for the Q_k vibration: $\Theta=(1-e^{-h\nu_k/kT})^{-1}$, $U_k=h\nu_k/kT$, ν_k is the normal frequency associated with the normal coordinate Q_k, k is Boltzmann's constant, h is Planck's constant, and T is the absolute temperature.

Generally, the dipole-moment derivatives related to the normal coordinates can be written as follows:

$$\frac{\partial\mu_z}{\partial Q_k} = \sum_i Ls_i^{(k)}\frac{\partial\mu_z}{\partial S_i},$$

$$\frac{\partial^2\mu_z}{\partial Q_k^2} = \sum_{i,j} Ls_i^{(k)}Ls_j^{(k)}\frac{\partial^2\mu_z}{\partial S_i\partial S_j}, \quad (17)$$

where Q_k is the kth normal coordinate and where the Ls's are the elements of the $\boldsymbol{L}$ matrix which relate the symmetry cooridnates to the normal coordinates.

As for the normal coordinates considered in this work, all the Ls values are negligibly small except for the Ls(CH) related to the C–H symmetric stretching coordinate, S_{CH}. In other words, it can be assumed that the normal modes considered in this work are approximately equal to the pure C–H symmetric stretching modes. Therefore, $(Ls(CH))^2$ is equal to $Gs(CH)$, where $Gs(CH)$ is the diagonal element of the $\boldsymbol{G}$ matrix related to the C–H symmetric stretching coordinate. Since the molecules lie along the z–axis, as is indicated in Fig. 2, the components of the dipole moments are all equal to zero except for the z–component; also, the derivatives of the x– and y–components of the dipole moments related to the C–H symmetric vibration are equal to zero.

For this reason, the absolute intensities of the fundamental and the first overtone bands of the C–H symmetric stretching vibrations in CH_3Cl, CH_2Cl_2, and $CHCl_3$ can be calculated approximately by the following equations:

$$A_{1\leftarrow 0}^{*(k)} = 3.49307\times 10^{-31}(Ls(CH))^2\left(\frac{\partial\mu_z}{\partial S_{CH}}\right)^2$$

[cm²·sec⁻¹·molecule⁻¹], (18)

$$A_{2\leftarrow 0}^{*(k)} = 2.93118\times 10^{-43}\frac{\Theta^2(1-e^{-2U_k})}{\nu_k}(Ls(CH))^4\left(\frac{\partial^2\mu_z}{\partial S_{CH}^2}\right)^2$$

[cm²·sec⁻¹·molecule⁻¹], (19)

where $\partial\mu_z/\partial S_{CH}$ and $\partial^2\mu_z/\partial S^2{}_{CH}$ are the numerical values calculated in [Debye/Å] and [Debye/Å²] respectively. In this calculation, the Ls(CH)'s were taken to be $1.00797\times\sqrt{N_A}$, $1.02183\times\sqrt{N_A}$, and $1.03698\times\sqrt{N_A}$ in $[gr^{-1/2}]$ units for CH_3Cl, CH_2Cl_2, and $CHCl_3$ respectively, where N_A is Avogadro's number. The value of $\Theta^2(1-e^{-2U_k})$ is practically equal to unity. The observed frequencies of the fundamental bands were used for the values of ν_k's: CH_3Cl[11] $2967.8\times C\,sec^{-1}$, CH_2Cl_2[4] $2989\times C\,sec^{-1}$, and $CHCl_3$[4] $3033\times C\,sec^{-1}$, where C is the velocity of light.

Results and Discussion

Figure 1 indicates the variation in the dipole moment of CH_3Cl in the observed geometry when the 3*d* orbital exponent of the chlorine atom is continuously changed from 0 to 6.1; here, the calculation with the zero 3*d* orbital exponent is equivalent to that without 3*d* orbitals, as has been referred to by Santry and Segal.[2] In this figure, it is obvious that the 3*d* orbitals of the chlorine atom play an important role in the molecular properties.

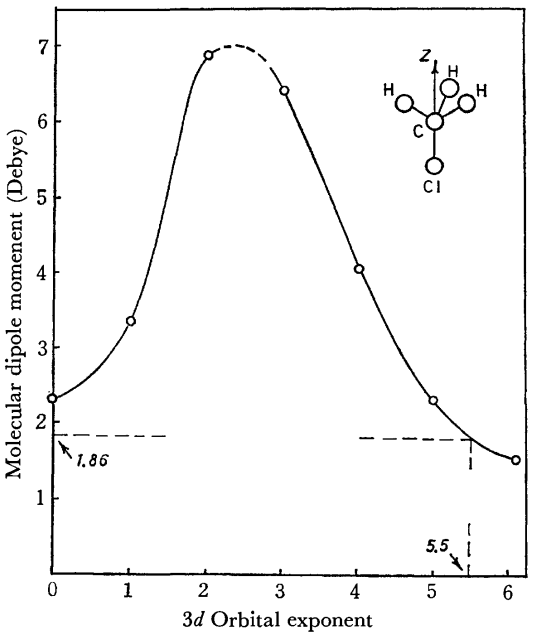

Fig. 1. The variation of dipole moment of CH_3Cl as a function of the 3*d* orbital exponent of chlorine atom.

The study of the results obtained from these calculations suggests that an optimum value of the 3*d* orbital exponent of the chlorine atom is 5.5. Table 2 records the calculated dipole moments of CH_2Cl_2 and $CHCl_3$ obtained by the use of this value. The theoretical dipole moments are in reasonable agreement with the experimental values.

From the results of the preliminary calculations, it is considered that the intensity of the vibration band in chloroform vapor can be discussed in comparison

with those of methyl chloride and methylene chloride. Figure 2 indicates the variations in the dipole moments of these compounds as a function of the C–H symmetric stretching coordinate. A cursory glance at this figure will show that the fundamental band intensity of the C–H stretching vibration in chloroform is weaker than those of other compounds. The numerical values of the $\partial\mu_z/\partial S_{CH}$ are indicated in Table 2. As for the molecules considered in this work, the absolute intensities of the fundamental bands can be calculated approximately from these numerical values, $\partial\mu_z/\partial S_{CH}$, as has been stated above. The calculated absolute intensities of the fundamental bands are summarized in Table 3. The calculated values indicate that the intensity of the fundamental band of the C–H vibration in chloroform vapor is much lower than those of methyl chloride and methylene chloride. As for these vibration bands, the intensity ratio of other compounds to chloroform are in fair agreement with those obtained experimentally, although there are some questions about the experimental absolute intensities because the absorption band of the symmetric C–H vibration is difficult to distinguish from that of the antisymmetric C–H vibration, *etc.*

The second derivatives, $\partial^2\mu_z/\partial S^2_{CH}$, necessary for the estimation of the first overtone band intensities are indicated in Table 2. The intensities of the fundamental and the overtone bands cannot be discussed in terms of a direct comparison of $\partial\mu_z/\partial S_{CH}$ and $\partial^2\mu_z/\partial S^2_{CH}$. In order to compare the intensity of the first overtone band with that of the fundamental band, the absolute intensity of the first overtone band should be calculated. The absolute intensities of the first overtone bands, as calculated from Eq. 5, are summarized in Table 3. The values show that the intensity of the first overtone band is stronger than that of the fundamental band in chloroform vapor, although the calculated first overtone band intensity is much weaker than the observed one. The

$A^*_{1\leftarrow0}/A^*_{2\leftarrow0}$ ratio in chloroform is indicated in Table 4, in which the ratios for other compounds are also predicted. From the results of these calculations, it was recognized that the electrical properties of the vibrating bond are the most effective factors in bringing about the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor. Since the calculated absolute intensity of the first overtone band in this work was much weaker than the observed one, the contribution of the mechanical anharmonicity to this abnormal absorption intensity should be examined, for it is a factor which cannot be overlooked.

Tables 5—7 indicated the constituent terms of the dipole moments and their derivatives. From these table, it is obvious that the relative intensity between these compounds and the abnormal intensity of the C–H stretching vibration band in chloroform cannot be ex-

plained by the values, such as $\partial\mu_Q/\partial S_{CH}$ and $\partial^2\mu_Q/\partial S^2{}_{CH}$, which are contributed by net charge densities alone. Atomic polarizations and their variations with the vibrating bonds are appreciably effective in determining the molecular dipole moment and the intensity of the vibration band. This is especially the case with the mixing terms of p and d orbitals.

Conclusion

The CNDO calculation involving the 3d orbitals of the chlorine atom was used in discussing the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor. The results of the calculations have suggested that the 3d orbitals play an important role in determining the molecular properties. The appropriate value of the 3d orbital exponent of the chlorine atom was 5.5. The absolute absorption intensities of the fundamental and the first overtone bands of the C–H symmetric stretching vibration in methyl chloride, methylene chloride, and chloroform were calculated from the dipole-moment derivatives. From the results of the calculations, it was recognized that the electrical properties of the vibrating bond are the effective factors in bringing about the abnormal absorption intensity of the C–H stretching vibration band in chloroform vapor. The contribution of the mechanical anharmonicity to this abnormal intensity will be the subject of future study.

The Magnetic Properties of $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$

Hirokazu MIYOSHI, Hiroaki OHYA-NISHIGUCHI, and Yasuo DEGUCHI*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto
**College of Liberal Arts and Science, Kyoto University, Kyoto*

(Received June 17, 1971)

From magnetic susceptibility and ESR measurements, it has been confirmed that polybis(μ-(2-picoline *N*-oxide)-chlorocopper(II)di-μ-chloro)diaquocopper, $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$, consists of alternating linear chains with diamagnetic $Cu_2Cl_4(C_6H_7NO)_2$ units and paramagnetic $CuCl_2 \cdot 2H_2O$ units joined by long Cu–Cl bonds. The two copper ions in the $Cu_2Cl_4(C_6H_7NO)_2$ unit are coupled together very strongly by antiferromagnetic exchange interaction and occupy almost entirely the diamagnetic singlet state below room temperature. This interpretation is appropriately supported by the observation of a half-field resonance near 1600 Oe in the ESR spectrum of the powdered sample. On the other hand, the copper ion in the $CuCl_2 \cdot 2H_2O$ unit isolated magnetically can account for the ESR spectrum due to $\Delta M = \pm 1$ transition and magnetic susceptibility, following the Curie law. The magnetic susceptibility of the dehydrate compound, $Cu_3Cl_6(C_6H_7NO)_2$, has also been measured.

There have been many reports on the physical properties of complexes formed between aromatic *N*-oxide and copper(II) halide compounds. They may be divided into general categories which reflect their chemical compositions and magnetic properties. One of them consists of magnetically subnormal substances which are composed of one aromatic *N*-oxide molecule and one $CuCl_2$ group (hereafter termed "1: 1 complexes"). Other well-known complexes with a normal magnetic moment belong to another category consisting of complexes which are formed between two aromatic *N*-oxide molecules and one $CuCl_2$ group ("2: 1 complexes").

Polybis(μ-(2-picoline *N*-oxide)-chlorocopper(II)di-μ-chloro)-diaquocopper, $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$, the

complex formed between 2-picoline *N*-oxide and copper(II) halide, is an exceptional compound ("2: 3 complex"). From the magnetic properties and the crystallographical analysis of this complex, it was confirmed by Watson and his co-workers[1,2] that the structure of this complex consists of infinite linear chains containing both five- and six-coordinated copper(II) ions bridged by either chlorine of oxygen atoms. The structure can be regarded as an alternating linear chain consisting of $Cu_2Cl_4(C_6H_7NO)_2$ units and $CuCl_2 \cdot 2H_2O$ units joined by long Cu–Cl bonds. Watson and his co-workers also proposed that the copper ions in the $Cu_2Cl_4(C_6H_7NO)_2$ unit interact antiferromagnetically through the bridging oxygens, while the copper ion in the $CuCl_2 \cdot 2H_2O$ unit does not interact with those of the $Cu_2Cl_4(C_6H_7NO)_2$ units through the bridging chlorine atoms. However, a central problem in this interpretation is whether or not the magnetic ions in the $CuCl_2 \cdot 2H_2O$ units really interact through the chlorine bridges.

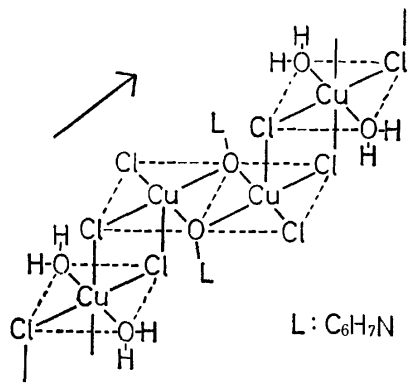

Fig. 1. Schematic crystal structure of $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$. The arrow shows the *c*-axis direction.

In the present study, the magnetic susceptibilities of this complex have been measured down to 1.6°K in order to obtain experimental data on the existence of the metal-metal magnetic interaction in this complex. The ESR spectrum of a single crystalline sample has also been observed at room temperature, and that of a powdered sample, at room temperature, 77°K and 4.2°K.

Experimental

$Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$ (I) was prepared following the procedure of Watson and his co-workers. From the results of a chemical analysis, thermal analysis, infrared and far-infrared spectra measurements,[3] we confirmed the identity of the compound with reference to the preceding data. Found: C, 22.22; H, 2.74; N, 4.38%. Calcd: C, 22.0; H, 2.73; N, 4.27%. The single crystals were grown by the spontaneous evaporation of the solvent from the unsaturated solution. When dried for 50 hr at 100°C, this complex lost two water molecules to its dehydrate, $Cu_3Cl_6(C_6H_7NO)_2$ (II). Found: C, 23.19; H, 2.26; N, 4.56%. Calcd: C, 23.19; H, 2.27; N, 4.51%. The dehydrate (II) has not been reported in the literature, but the identity of this compound was confirmed by a chemical analysis of II and a thermal analysis of I. This complex was a little hygroscopic and reverted to the hydrate after several months. We found some differences in the X-ray powder patterns between I and II.

Results and Discussion

Magnetic susceptibilities were measured in the temperature range from 1.6°K to room temperature by means of a magnetic torsion balance described elsewhere.[4] Mn-Tutton salt was used to calibrate the carbon resistor and the thermocouple. The usual Pascal diamagnetic correction was within the range of experimental error at low temperatures. The X_m-T curves for the two complexes are compared in Fig. 2.

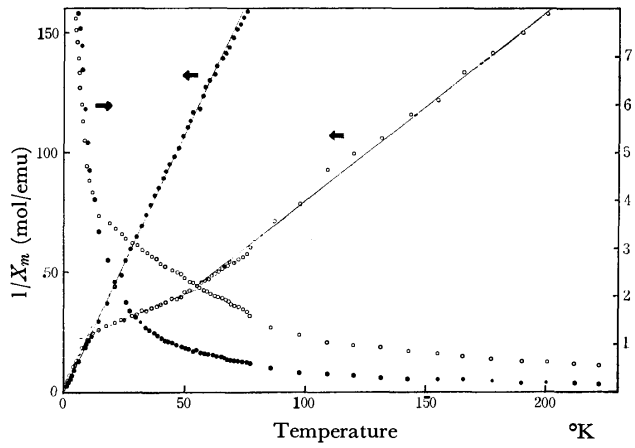

Fig. 2. Molar susceptibilities and their reciprocals as a function of temperature; ●: $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$, ○: $Cu_3Cl_6(C_6H_7NO)_2$.

Assuming that $X_m = xNg^2\beta^2 s(s+1)/3k(T-\theta)$, with $s=1/2$ and $g=2.15$, a parameter, x, obtained from the slope of the $1/X_m - T$ plots can offer information about the magnetic state of these complexes. Here the assumption about the *g*-value is consistent with the ESR data to be described later. The most remarkable features of the magnetic data of the compound (I) are that the data obey the Curie law, with $x=1.06$ from room temperature to 1.6°K, and that the molar magnetic susceptibilities can almost all be attributed to only one copper ion per molecule. On the other hand, the dehydrate (II) behaves very differently, as is shown in Fig. 2; this complex seems to be a magnetic trimer with mutual antiferromagnetic interaction.[5] It should be noted, in comparison with I, that the susceptibilities of the II have the values of three copper ions per molecule in the high-temperature range ($x=2.8_3$).

ESR measurements of the hydrate were carried out by using an X-band spectrometer. The hyperfine separation (429.4 Oe) and the *g*-value (2.000) of Mn(II) in MgO were used to calibrate the magnetic field, and DPPH was also used as the magnetic-field indicator. The ESR spectrum of the powdered sample at room

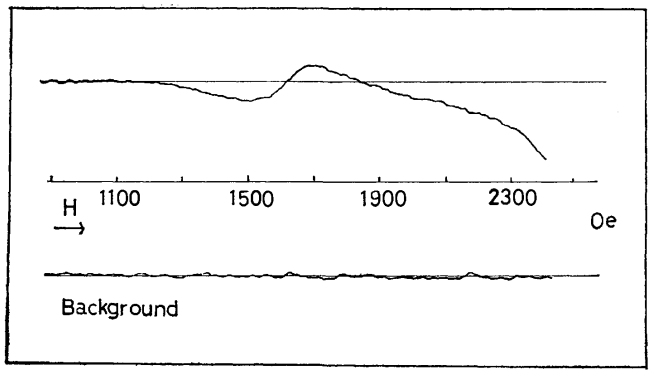

Fig. 3. Low field portion of the polycrystalline ESR spectrum of $Cu_3Cl_6(C_6H_7NO)_2 \cdot 2H_2O$ at room temperature.

temperature exhibited one broad, asymmetric line caused by the anisotropy of the g-value centered at about 3250 Oe, with one additional weak line at about 1600 Oe, as is shown in Fig. 3. The line-shape of the main absorption at 3250 Oe did not show any appreciable change, even at temperatures of liquid nitrogen and helium, implying that the magnetic environment of this complex changes little with the temperature.

Single-crystal studies were undertaken in this complex's three mutually perpendicular planes. The principal values of the g-tensor obtained from the single-crystal measurements are: $g_1=2.302\pm0.005$, $g_2=2.084$, and $g_3=2.032$. The experimental errors are mainly due to the uncertainty of the crystal mounting on the sample holder. The principal values of the g-tensor can be attributed to those of the copper ions, the site symmetry of which is rhombic or approximately orthorhombic and the orbital ground state of which is

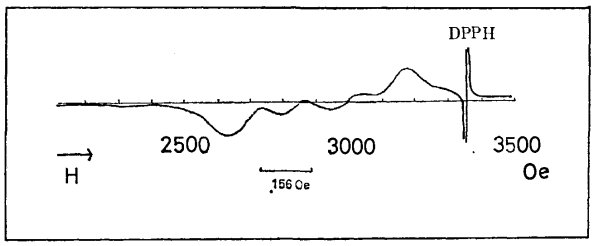

Fig. 4. ESR spectrum at a certain angle of $Cu_3Cl_6(C_6H_7NO)_2 2H_2O$ single crystal at room temperature.

$d_{x^2-y^2}$. This interpretation is supported by a crystallographic consideration of this complex.

The angular variation of the single crystalline ESR spectrum provides much interesting information about the electronic state of the paramagnetic copper(II) ion in this complex. At certain angles, for example, the sample gives an ESR spectrum with four hyperfine lines and a maximum separation between them are about 156 Oe, as is shown in Fig. 4. This splitting arises from copper ions with an electron spin of $s=1/2$ and a nuclear spin of $I=3/2$. The observation of the hyperfine splittings in the ESR spectrum of the single-crystal sample leads to the conclusion that this complex is similar to the magnetically diluted systems. This conclusion can be confirmed further from the results of the temperature variation of X_m with the values attributed to only one copper ion per molecule and with a Weiss constant nearly equal to zero. Other evidence of this consideration is that the dehydrate (II) shows the X_m values due to three copper ions per molecule in the high-temperature range. The absorption near 1600 Oe in the powder ESR spectrum is due to the $\Delta M=\pm2$ forbidden transition, which clearly indicates the existence of the dimer species in this complex, although its signal intensity is very weak. Therefore, it can be concluded that the copper ions of the $Cu_2Cl_4(C_6H_7NO)_2$ units are coupled together very strongly by antiferromagnetic exchange interaction and that they occupy almost entirely the diamagnetic singlet state below room temperature, while the copper ions of the $CuCl_2 \cdot 2H_2O$ units are isolated magnetically. Alternatively speaking, only the copper ions of the $CuCl_2 \cdot 2H_2O$ units diluted magnetically can account for the four hyperfine lines of the ESR spectrum and the molar susceptibilities due to one copper ion per molecule, while a few $Cu_2Cl_4(C_6H_7NO)_2$ units occupying the higher triplet state can give a half-field resonance. This conclusion is consistent with the invariability of the powder ESR line shapes in spite of the temperature variation.

The authors are much obliged to Professor H. Takaki for his continuous encouragement throughout this work and to Dr. M. Mekata for the susceptibility measurement and his helpful discussions.

Polarographic Studies on Substituted 2,2′-Bipyridyl *N*-Oxides[1]

S. S. KATIYAR,* M. LALITHAMBIKA, and R. P. SHUKLA
Department of Chemistry, Indian Institute of Technology, Kanpur-16, India
(Received February 19, 1971)

The polarographic behavior of 4-methoxy-2,2′-bipyridyl 1-oxide has been investigated in 20% dioxane-water solution. Two well defined reduction waves appear in the pH range 0.76—8.8, a third wave in pH 9.3—10.4, but only one wave in more alkaline solutions. The variation of $E_{1/2}$ with pH followed the relations $(E_{1/2})_1 = -0.37—0.10$ pH and $(E_{1/2})_2 = 0.84—0.065$ pH for waves 1 and 2, respectively. The diffusion current constant for the second wave decrease with increasing pH whereas for the first wave it remains constant upto pH 7.0 and decreases afterwards. Variation of diffusion current with temperature and reservoir height indicates the diffusion controlled nature. Wave 1 is produced by the 2 electron reduction of protonated *N*-oxide to 4-methoxy-2,2′-bipyridyl. This intermediate is further reduced, at more negative potentials, to 1,4′-dihydro-4-methoxy-2,2′-bipyridyl by consuming two more electrons and two hydrogen ions simultaneously. The third wave is presumably due to catalytic hydrogen evolution.

The polarographic behavior of pyridine *N*-oxides and purine *N*-oxides has been studied by several workers.[2-8] It has been found that these *N*-oxides give one or more reduction waves in buffered media. Pyridine *N*-oxide in various buffer solutions gives one wave[3,4,6] whose wave height decreases rapidly above pH 6, whereas adenine 1-*N*-oxide[2,7,9] gives a fundamental pattern of three polarographic waves over the pH range 1.4 to 5.6, the third wave being due to catalytic hydrogen evolution. It is also known that *N*-oxides such as nitrogen mustard *N*-oxide[10] and 2-azaadenine 1-*N*-oxide[7] are reduced polarographically to the corresponding amines. Alkaloid *N*-oxides such as narcotine *N*-oxide[3] have been reported to give three waves. It has been observed that the two-electron reduction waves of narcotine *N*-oxide are complicated by the adsorption at the electrode, the kinetic current of protonation and the reversible cleavage of lactone.

A detailed knowledge of the electrochemical behavior of *N*-oxides is of great interest in view of their biological importance, and the possible use of the electrolytic process of reduction for such *N*-oxides which give undesirable reduction products[11] when treated with conventional reductants like hydrogen and Raney nickel. Attempts have been made to correlate the herbicidal activity[12] of 2,2′- and 4,4′-bipyridyl salts to their redox potentials[13] as the herbicidal activity has been found to be dependent on the reversible reduction of the compound. Polarographic investigations on 2,2′-bipyridyl,[14,15] contain certain anomalies in that one report[14] states that it gives one wave while the other indicates that it gives three waves.[15] In view of the absence of polarographic data on substituted 2,2′-bipyridyl *N*-oxides and the existing anomalies in the data on 2,2′-bipyridyl it was considered desirable to investigate systematically the effect of concentration, pH, temperature and other factors on the polarographic reduction of substituted 2,2′-bipyridyl *N*-oxide.

Experimental

Apparatus. A sargent model XXI pen recording polarograph was used to record the current voltage curves. All the potentials were measured against saturated calomel reference electrode. An H-cell, one limb of which contained the calomel electrode and the other the test solution, served as the electrolytic cell. The capillary used had the following characteristics in 0.1M KCl in open circuit:
$m = 1.507$ mg sec^{-1}, $t = 3.38$ sec, $h = 75$ cm of mercury.
The cell was water jacketed and all measurements were made at 25±0.1°C with the help of an external thermostat.

pH measurements were carried out with an Elico pH meter. Ultraviolet spectra were recorded with a Beckman model DU spectrophotometer using 1 cm quartz cells.

Chemicals. The substituted 2,2′-bipyridyl 1-oxides were prepared by the methods given in literature.[16] They were recrystallized several times and checked for their purity by clemental analysis and melting point data. Dioxane used was always freshly distilled before use. All the chemicals used for preparation of buffers were of analytical grade. Buffer systems used in the present study were as follows: NaOAc+HCl (pH 0.65−1.24), KOOC–C_6H_4–COOK+HCl (pH 2.2−2.6), HOAc+NaOAc (pH 3.42−5.89), KH_2PO_4+NaOH (pH 6—8), KCl+H_3BO_3+NaOH (pH 8.5—10.0), Na_2HPO_4+NaOH (pH 11—13).
Nitrogen used for removal of oxygen from solutions was purified by passing through gas washing bottles containing

solutions of sodium salt of anthraquinone-2-sulphonic acid and $NaHSO_3$, alkaline pyrogallol, chromous sulphate in about 1N sulfuric acid, NaOH and distilled water in series.

Procedure. Stock solutions of *N*-oxides were prepared in pure dioxane. They were diluted with necessary amounts of water and buffer solutions so that the final volume of 10 m*l* of the test solution contained the desired concentration of *N*-oxide, 20% dioxane and 50% buffer. The final solution was thermostated till it attained a temperature of 25°C and during this time purified nitrogen was bubbled to remove the oxygen. The dropping mercury electrode was then introduced and the polarogram was recorded.

Results and Discussion

4-Methoxy-2,2'-bipyridyl 1-Oxide. 8.11×10^{-5}M solution of 4-methoxy-2,2'-bipyridyl 1-oxide was polarographed in 20% dioxane in various buffers over the pH range 0.85—13.0. A few typical polarograms in different buffers are shown in Fig. 1 and the other data are summarized in Table 1. From pH 0.76—8.8 two well defined and well separated waves were observed. At pH 9.3, 9.5, and 10.4 a third wave appeared which was clearly distinguishable from the second wave. However, in highly alkaline solutions (0.1N NaOH) only one wave was observed. The behavior of diffusion currents and half wave potentials with pH is shown in Figs. 2 and 3. It is of interest to note from Fig. 2 that $E_{1/2}$ becomes more and more negative with increase in pH of the solution. This indicates the participation of hydrogen ions in the electrode reaction. A similar variation of half wave potentials with

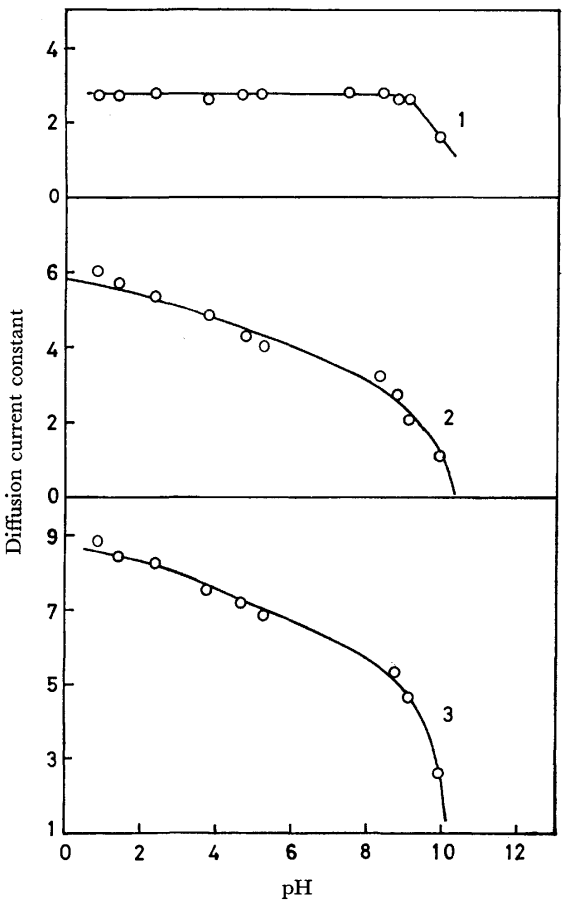

Fig. 3. Variation of diffusion current constant of *N*-oxide with pH. 1. First wave; 2. Second wave; 3. First and second waves.

pH has been reported[15] in the case of other heterocycles, *viz.* 4,4'-, 2,4'-, and 2,2'-bipyridyls, 4-cyanopyridine,[17] alloxan, alloxantin and dialuric acid.[18] The variation of $E_{1/2}$ of both the waves of 4-methoxy-2,2'-bipyridyl-1-oxide with pH is linear almost over the whole pH range investigated. The data for both the waves could be fitted to the following relationships:

$$E_{1/2} = -0.37 - 0.10\,\mathrm{pH}\ \text{(for wave 1)}$$

$$E_{1/2} = -0.84 - 0.065\,\mathrm{pH}\ \text{(for wave 2).}$$

However, for the second wave the half wave potentials appear to become more negative than required by the above relationship beyond pH 9.3. This is presumably due to the third wave which appears at pH 9.3 and almost merges with the second wave at higher pH thus making the accurate calculation of half wave potentials difficult. It can be clearly seen from Fig. 3 that the height of the first wave remains constant up to pH 7 and starts decreasing beyond it. However, the second wave shows a slight decrease in the diffusion current with increasing pH from pH 0.76—5.65 and a larger decrease after pH 7.0. The decrease in wave height with increasing pH has also been reported for pyridine *N*-oxide, 4-methylpyridine *N*-oxide.[4] It is not due to any structural change in 4-methoxy-2,2'-bipyridyl 1-oxide in acid or alkali as indicated by UV spectra of the *N*-oxide in neutral, acid and alkaline media. The spectra of *N*-oxide at various pH are shown in Fig. 4.

17) J. Volke and J. Holubek, *Coll. Czech. Chem. Commun.*, **28**, 1597 (1963).

18) W. A. Struck and P. J. Elving, *J. Amer. Chem. Soc.*, **86**, 1229 (1964).

It is clear from this figure that absorption maximum is at 266 nm in 0.1N NaOH and pH 7.0. Wave 1, for reasons subsequently discussed could be assigned to the reduction of protonated *N*-oxide functional group. It is, therefore, expected that in a medium deficient in protons, wave height should decrease and this is what we observed in buffers of increasing pH. This is further substantiated by the polarographic behavior of *N*-oxide in unbuffered media *viz.* neutral supporting electrolytes. The data is presented in Table 2. It can be seen that *N*-oxide gives three waves in KCl, LiCl, and $N(CH_3)_4Cl$. The first two waves appear at a more negative potential than those found in buffered medium of pH 7.0, while the third wave appears at almost the same potential at which the third wave is found in buffered media of pH greater than 9.3. Thus for example $(E_{1/2})_1$, $(E_{1/2})_2$, and $(E_{1/2})_3$ in 0.1M KCl corresponded to −1.17, −1.41, and −1.62 V *vs.* SCE whereas in buffer of pH 7.0 $(E_{1/2})_1$ and $(E_{1/2})_2$ corresponded to −1.07 and −1.24 V *vs.* SCE respectively. More negative half wave potentials in unbuffered solution further substantiate the observation that hydrogen ions are involved in the electrode process. It is instructive to find that the limiting currents for all the three waves in unbuffered media are very small compared to the values for the respective waves in buffer of pH 7.0. Even the total limiting current due to all the three waves in unbuffered media is substantially smaller than the total diffusion current of the two waves observed in buffer of pH 7.0. This observation strongly suggests that it is the protonated *N*-oxide which gets electroreduced, and in unbuffered media due to the paucity of hydrogen ions only a small fraction of *N*-oxide is electroreduced giving very low limiting currents.

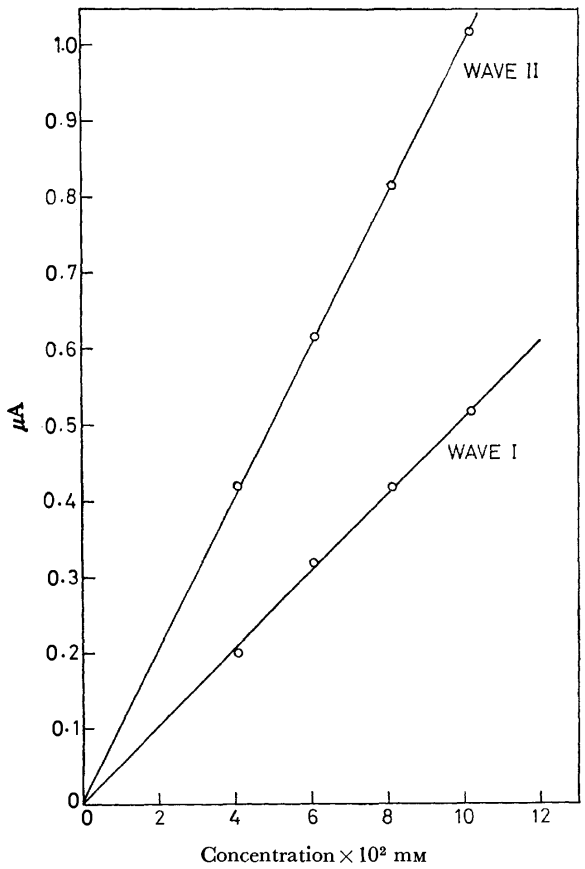

Fig. 5. Linear dependence of diffusion current of *N*-oxide on concentration at pH 0.85.

The characterization of the nature of the electrode process has been done by studying the effect of concentration of *N*-oxide, height of mercury reservior and temperature on the limiting current. The polarograms obtained at varying concentrations of 4-methoxy-2,2'-bipyridyl 1-oxide in the range $4.05-10.13\times10^{-5}$M at pH 0.85 were well difined and well separated. Plot of i_d against concentration gave a straight line as shown in Fig. 5. This indicates the absence of adsorption or catalytic character in both the waves and suggests that both waves are diffusion controlled. Heterocyclic compounds, especially those containing nitrogen, are known to exhibit pronounced adsorption effects at the mercury drop. Even adenine 1-*N*-oxide[2] and Narcotine *N*-oxide are reported to give adsorption waves. In our data we found no evidence for any adsorption wave in the reduction of 4-methoxy 2,2'-bipyridyl-1-oxide at the dme. However, the third wave which appears beyond pH 9.3 does not follow Ilkovic equation and is probably a catalytic wave.

A study of the effect of varying heights of the mercury

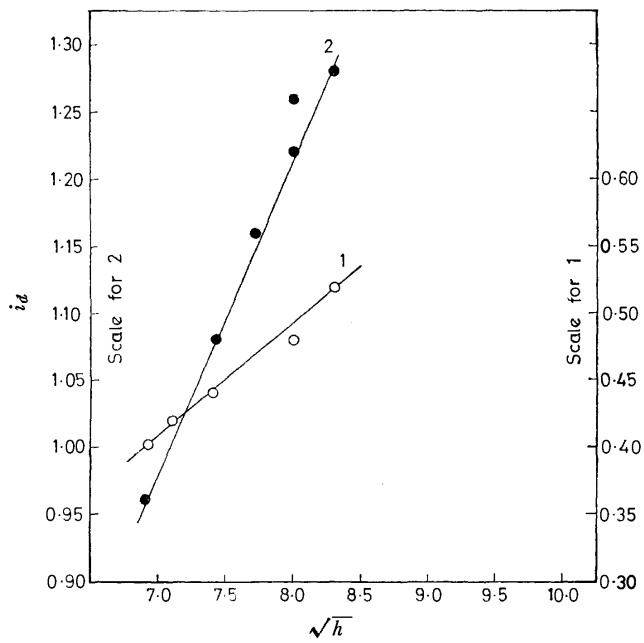

Fig. 6. Effect of mercury height on the diffusion current on *N*-oxide.

TABLE 3. EFFECT OF TEMPERATURE ON THE WAVE HEIGHTS pH=3.3

T °K	i_{d_1}	i_{d_2}	Temperature coefficient	
			Wave 1	Wave 2

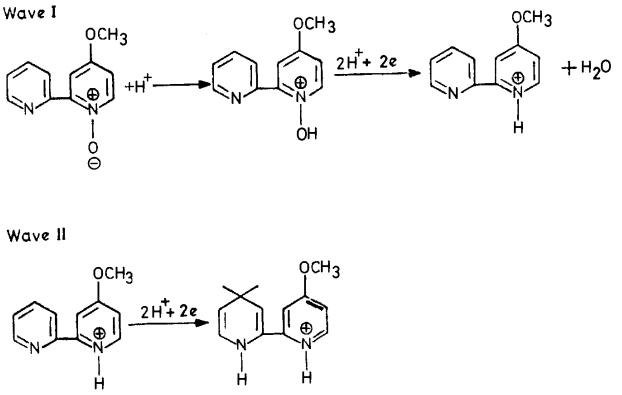
312.5	0.58	1.12	3.0	3.6
316.5	0.64	1.20	2.3	1.7
322.5	0.76	1.32	2.9	1.6

column on the diffusion currents as well as the determination of the temperature coefficient of both the waves indicates their diffusion controlled nature. The limiting currents are proportional to the square root of the mercury height as shown in Fig. 6, whereas the temperature coefficients are in the range 1.6—4.6% as summarized in Table 3. The diffusion controlled nature of the waves due to *N*-oxide function has also been reported for adenine 1-*N*-oxide by Elving.[2]

Mechanism of the Electrode Process. The observed polarographic behavior of 4-methoxy-2,2′-bipyridyl 1-oxide can be explained by the following reduction sequence:



Wave I is produced by the 2 electron reduction of protonated *N*-oxide to 4-methoxy-2,2′-bipyridyl. The *N*-oxide after reaching the electrode picks up two electrons and two protons simultaneously to form 4-methoxy-2,2′-bipyridyl, giving rise to the first two electron wave. 4-Methoxy-2,2′-bipyridyl thus formed as the intermediate is further reduced at more negative potentials to 1′,4′-dihydro-4-methoxy-2,2′-bipyridyl by consuming two more electrons and two hydrogen ions simultaneously, giving rise to the second two electron wave. The latter wave in addition to 4-methoxy-2,2′-bipyridyl reduction may have some contribution from a catalytic hydrogen reduction process. The evidence supporting the above mechanism is discussed below.

The value of diffusion current constant (I) is 3.7 for the first wave and is constant up to pH 7.0; its value is comparable with I value of 3.3 obtained for other *N*-oxide function by Warner and Elving.[2] The I value is also compatible with a two electron reduction process. In a macroscale electrolysis at the potential of the plateau of the first wave, 4-methoxy-2,2′-bipyridyl was detected in the solution.

The second wave is identical in behavior with that of the first wave of 2,2′-bipyridyl. The polarographic data for 2,2′-bipyridyl are summarized in Table 4. It is found that 2,2′-bipyridyl gives a single wave upto pH 3.4 and two waves in the pH range 3.6—10.5, the second wave becoming more and more drawn out in solutions of higher pH. The half wave potentials for the wave 1 of 2,2′-bipyridyl vary linearly with pH as shown in Fig. 7 and fit the relation

$$E_{1/2} = -0.81 - 0.066\,\mathrm{pH}$$

which is similar to that obtained for the second wave of *N*-oxide *viz.* $E_{1/2} = -0.84 - 0.065$ pH. Slightly more negative values obtained for $E_{1/2}$ of wave II of 4-methoxy-2,2′-bipyridyl-1-oxide are due to the presence of *p*-methoxy group in 2,2′-bipyridyl which has a σ value of -0.27.[19] The diffusion current constant for the second wave of *N*-oxide is ~7 (Table 1) which is comparable to the I value (~7) for the first wave of 2,2′-bipyridyl (Table 4). The value of diffusion current constant obtained by Pfeifer[20] for the 2-electron reduction first wave of 2,2′-bipyridyl in the pH range 3.46—7.0 has been reported to be 5.6. This is also in excellent agreement with the I values we obtained in a similar pH range as shown in Table 4. It is thus proved that the electrode reaction producing the second wave is due to the reduction of 4-methoxy-2,2′-bipyridyl.

Structure of the Vanadium-Potassium Catalyst during the Oxidation of Sulfur Dioxide and the Oxidation Mechanism

Akio KATO, Katsuhiko TOMODA, Isao MOCHIDA, and Tetsuro SEIYAMA
Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka

(Received July 3, 1971)

The structure of vanadium-potassium catalyst in gas mixtures of various compositions of SO_2, SO_3, and O_2 was investigated at 500, 550, and 600°C to elucidate the mechanism of SO_2 oxidation on the catalyst. It was found that in the catalyst 50—70% of V(IV) is in VO^{2+}-form, 10—15% of V(V) in VO_2^+-form and the rest of the vanadium forms large vanadium-oxygen networks. It was also found that both the reduction of V(V) with SO_2 and oxidation of V(IV) with oxygen are in equilibrium and the desorption of SO_3 from the molten catalyst into gas phase seems to be the rate-determining step in SO_2 oxidation. On the basis of this mechanism, the reaction rate of SO_2 oxidation can be formulated as follows,

$$dSO_3/dt = k'(SO_3) = kP_{SO_2} \cdot P_{O_2}^{1/2}.$$

For the sake of confirmation, the kinetics of SO_2 oxidation (below 10% conversion) over vanadium-potassium catalyst was measured by a flow method at 500, 550, and 600°C over gas compositions of SO_2=5~24% and O_2=10~36%. It was found that the rate expression was correct.

It is generally accepted for sulfur dioxide oxidation by vanadium-potassium catalyst that the active component of the catalyst forms a liquid phase under the reaction conditions[1-8], and that the reaction proceeds according to the reduction-oxidation mechanism.[8,9] However, the composition of the active component is not well established and various contradictory rate-determining steps are proposed for the oxidation. Tandy has suggested the reduction of pentavalent vanadium by sulfur dioxide to be the rate-determining step.[4] On the other hand, Mars *et al.* have proposed the following reduction-oxidation mechanism in which (1) is in equilibirum and (2) is rate-determining.[8]

$$2V^{5+} + SO_2 + O^{2-} = 2V^{4+} + SO_3 \quad (1)$$

$$2V^{4+} + 1/2O_2 = 2V^{5+} + O^{2-} \quad (2)$$

Simecek *et al.* have recently reported a similar mechanism.[9]

We noted that the reduction and oxidation of vanadium in molten salts are closely related to the basicity (activity of oxide ions) of the melts[7,10]. A quantitative estimation of the basicity of the catalyst is, therefore, necessary to elucidate the reaction mechanism of sulfur dioxide oxidation, although Mars and Simecek treated the reduction and oxidation of vanadium assuming a constant activity of oxide ions. The basicity can be estimated by means of the equilibrium relations for pyrosulfate formation:

$$O^{2-} + S_2O_7^{2-} = 2SO_4^{2-} \quad (3)$$

$$\text{or} \quad 2SO_3 + O^{2-} = S_2O_7^{2-} \quad (4)$$

We investigated the structure of potassium-vanadium catalyst under a SO_2-SO_3-O_2 mixture of various compositions, with the emphasis on the determination of the amount of pyrosulfate whose quantitative analyses have never been done. The reaction mechanism of sulfur dioxide oxidation was discussed from the viewpoint based on structural and kinetic investigations.

Experimental

Composition of Catalyst under SO_2-SO_3-O_2 Mixtures. About 0.5 g of V_2O_5–K_2SO_4 mixture was heated in a platinum boat (10×10×30 mm) in the fiowing atmosphere of SO_2(2—16%)–SO_3(3—14%)–O_2(5—40%)–N_2. The boat was placed in a 20-mm diameter quartz glass tube heated with an electric furnace. The temperature was controlled to within ±1°C. The gas mixtures were prepared from SO_2–O_2–N_2 mixture by oxidizing SO_2 partially with an industrial catalyst placed immediately before the catalyst sample. The composition of gas phase was determined by measuring SO_2 contents of the entering and outgoing gas mixtures by an iodimetric method with 0.2N iodine and 0.1N sodium thiosulfate solutions. Heating of catalyst sample in a given gas mixture was continued for 15 hr at 500, 550, and 600°C. The composition of catalyst samples was confirmed to be of steady state value after 8 hr. After the treatment of catalyst sample followed by rapid cooling, the weight change and chemical composition of the sample were determined and measurements of IR spectrum and X-ray powder pattern were carried out.

The concentrations of V(IV) and V(V) in the catalyst sample were determined by titration with ferrous sulfate solution using diphenylamine as an indicator. After dissolving the sample into 0.5N sulfuric acid, V(V) was titrated with 0.1N ferrous sulfate solution with one portion and total vanadium was titrated after oxidizing all vanadium to V(V) with potassium permanganate solution with the other portion. The amount of V(IV) was computed from the two values.

The concentration of pyrosulfate was determined as follows. About 200 mg of the catalyst sample ground was allowed to suspend in 60 ml of water on a water bath for an hour. By this procedure all the sulfate and pyrosulfate dissolved into water, together with some fractions of V(IV) and V(V). Since pyrosulfate hydrolyses to give HSO_4^- ions on dissolu-

tion, the amount of the former contained in the sample can be determined from that of acid formed. After filtration of the solution, a portion of the filtrate was titrated with 0.05N sodium hydroxide solution using phenolphthalein as an indicator. During the course of titration, V(IV) and V(V) ions undergo the following acid-base reactions or oxidation.[11]

$$VO_2^+ + 2H_2O = H_2VO_4^- + 2H^+ \quad (5)$$

$$2VO^{2+} + 3H_2O = HV_2O_5^- + 5H^+ \quad (6)$$

$$HV_2O_5^- + 1/2O_2 + 2H_2O = 2H_2VO_4^- + H^+ \quad (7)$$

In the indicator range of phenolphthalein, $H_2VO_4^-$ and $HV_2O_5^-$ ions are predominant species for V(V) and V(IV), respectively.[11] The amount of acid produced by reactions (5)—(7) during the neutralization can, therefore, be computed from the concentrations of V(IV) and V(V) before and after the titration with the sodium hydroxide solution. The amount of acid was corrected in the calculation of the amount of pyrosulfate from the consumption of the alkali. Most of V(IV) was oxidized to V(V) during titration.

The amount of SO_3 absorbed was calculated from the weight increase of catalyst sample after making a minor correction for the weight decrease due to the reduction of V(V) to V(IV). Sulfate is given as the difference between the total sulfur, the sum of initial potassium sulfate and SO_3 absorbed, and sulfur in pyrosulfate form.

IR spectra were measured by KBr method. Cu-K_α radiation was used for X-ray examination.

Oxidation Rate of Sulfur Dioxide. Catalysts used in the kinetic study were prepared by mixing the hydrochloric solution of V_2O_5 and K_2SO_4 with carborundum powder of 0.3—0.4 mm diameter and drying the mixture under stirring. The mole ratio K_2SO_4/V_2O_5 was 1(catalyst A) and 2(catalyst B). 42 mg of V_2O_5–K_2SO_4 mixture was supported on 1 g of the carborundum in both catalysts. The oxidation rate was measured by a flow method. Catalyst (0.2—0.3 g) was packed in 12 mm diameter quartz glass tube with quartz glass wool. Temperature was measured by a thermocouple inserted in the catalyst bed and controlled to within ±1°C. Analysis of gas phase was carried out by the iodimetric method.

Table 1. Composition of catalyst sample

Results and Discussion

Composition and Structure of Catalys tunder SO_2-SO_3-O_2 Mixture. The compositions of gas phase and catalyst are shown in Table 1. $V(V)_{aq}$ and $V(IV)_{aq}$ are water-soluble pentavalent and quadrivalent vanadiums, respectively, extracted into water phase. The amount of SO_3 absorbed can be obtained from the relation, $(SO_3) = 2(S_2O_7^{2-}) + (SO_4^{2-}) - (K_2O/V_2O_5)$ (in mol).

Some remarks are given on the melting of catalyst. Experiments were carried out at 450 and 470°C under the conditions given in Table 2. In runs 35 and 36, only a part of the sample appeared to melt.

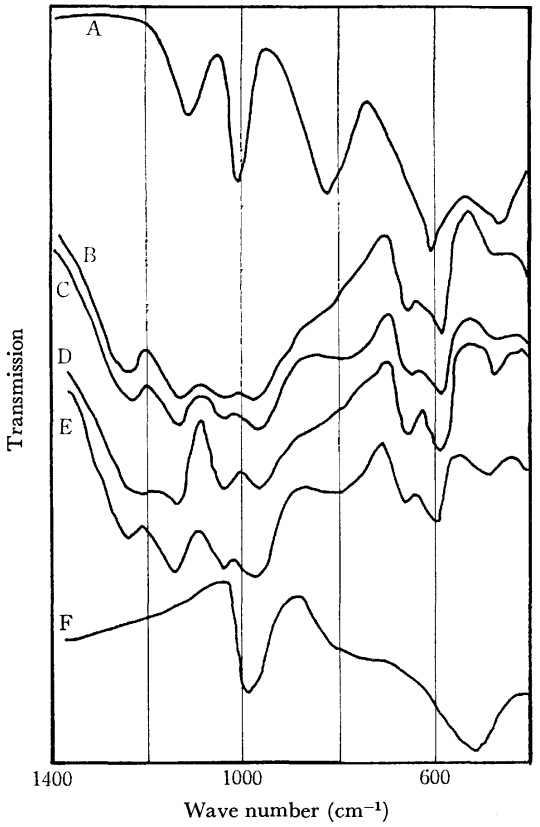

Fig. 1. IR spectra of catalyst samples.
A: Initial $2K_2SO_4$-V_2O_5 mixture, B: Run 7, C: Run 18, D: Run 24, E: Run 34, F: Water-insoluble residue in Run 32.

Even at 470°C, indication of incomplete melting was observed on samples treated under gas mixture of high SO_2/O_2 ratio as in runs 39—41. This casts a doubt on the homogeneity of the molten catalyst over 380—500°C at which the previous kinetic studies were carried out.[8,9] Above 500°C, all the samples had a glassy appearance and showed only a broad diffraction effect around $2\theta = 28°$ in X-ray examinations, indicating the complete melting of catalyst sample. The following discussions are restricted to the results on completely molten catalysts.

IR spectra of catalyst samples are shown in Fig. 1. As compared with the initial mixture of V_2O_5 and K_2SO_4 the sample treated under gas mixture showed complex spectra. IR spectra of the catalyst samples in other runs were very similar to the illustrated spectra of respective temperatures. Absorptions at 1050, 1150, and 1250 cm^{-1} in the spectra B to E can be assigned to ν_3 of SO_4^{2-} and SO_4-groups in $S_2O_7^{2-}$. There is a weak band near 800 cm^{-1}. The frequency coincides with that of asymmetric SOS stretching in $S_2O_7^{2-}$ [12], indicating the presence of pyrosulfate ions. Bands at 600—700 cm^{-1} are considered to be ν_4 vibration of SO_4-groups. Spectrum F of the insoluble residue of water-extraction has a band at 990 cm^{-1} which is assigned to the stretching vibration of double V–O bond.[13] The residue has a compsoition of $K_2O \cdot 1.2V_2O_4 \cdot 7.7 V_2O_5$ which is close to that of a vanadium bronze $K_2O \cdot V_2O_4 \cdot 8V_2O_5$ found in $V_2O_5 \cdot K_2SO_4$ system[6]. Spectrum F is also similar to that of the bronze. Water-insoluble residue in other runs showed very close spectra to F. Thus it seems that the insoluble vanadiums in the catalyst formed a network structure similar to those in vanadium bronzes.[14]

The oxygen atoms in the catalyst should be bound to either a vanadium or a sulfur atom. The compositions of the catalyst sample shown in Table 1 enable us to evaluate the limiting number of oxygen atoms bound to a vanadium atom. The lower limit is given when all sulfur atoms are assumed to be in the form of SO_4^{2-}. The calculated values for the limiting O/V ratio fall in the range 1.3—1.9. This means that each vanadium atom in the catalyst was bound with oxygen atoms on an average of more than 1.3—1.9 atoms. Although Mars *et al.* assumed V^{5+} or V^{4+} ions for vanadiums in vanadium-potassium catalysts under SO_2 oxidation, the present finding appears to be more reasonable considering high ratio of charge to radius of both ions.

The number of oxygen atoms bound a water-soluble vanadium atom is also of interest and can be estimated in a similar way. It was assumed that the ratio of oxygen atom to water-insoluble vanadium atom was 2.5 since the insoluble materials had a composition close to $K_2O \cdot V_2O_4 \cdot 8V_2O_5$, and that all sulfur atoms were in the form $S_2O_7^{2-}$. The second condition gives the upper limit of the ratio O/V_{aq} for water-soluble vanadiums. Caluculations revealed that the limiting O/V_{aq} ratio was in the range 1.3—1.7 for most catalyst samples with $K_2SO_4/V_2O_5 = 1$. Based on this value

12) A. Simon and H. Wagner, *Z. Anorg. Chem.*, **311**, 102 (1961).
13) J. Selbin, *Chem. Rev.*, **65**, 153 (1965).
14) H. G. Bachman and W. H. Barnes, *Z. Krist.*, **115**, 215 (1961).

for O/V_{aq} ratio and the analogy in the forms of vanadium atoms in acidic solution,[11] the water-soluble vanadiums in the catalyst are most likely to be present as VO^{2+} and VO_2^+ ions which will be coordinated with SO_3^{2-} or $S_2O_7^{2-}$ ions. Compounds consisting of K^+, SO_4^{2-}, and VO^{2+} or VO_2^+ ions such as $K_2SO_4 \cdot 2VOSO_4$, $K_2SO_4 \cdot VOSO_4$, and $K(VO_2)(SO_4)$ are highly water-soluble.[15] In the above pyrosulfate determination, the water-soluble vanadiums were thus assumed to be in VO^{2+} or VO_2^+-forms in the catalysts.[16]

From the above findings and compositions in Table 1, it might be concluded on the structure of vanadiums in vanadium-potassium catalysts under reaction conditions that 50 to 70% of V (IV) is in VO^{2+}-form, 10—15% of V(V) in VO_2^+-form and the rest of the vanadium forms large vanadium-oxygen networks.

Rate-determining Step in Sulfur Dioxide Oxidation. Sulfur dioxide oxidation proceeds by the reptition of the reduction of V(V) with sulfur dioxide and oxidation of V(IV) with oxygen. From the conclusions on the structures of vanadiums, the reduction and oxidation can be expressed as follows:

$$2(VO_2^+) + SO_2 = 2(VO^{2+}) + (SO_3) + (O^{2-}) \quad (8a)$$

$$(V(V)_nO_m) + SO_2 = (V(V)_{n-2}V(IV)_2O_{m-2}) + (SO_3) + (O^{2-}) \quad (8b)$$

$$2(VO^{2+}) + 1/2O_2 + (O^{2-}) = 2(VO_2^+) \quad (9a)$$

$$(V(V)_{n-2}V(IV)_2O_{m-2}) + 1/2O_2 + (O^{2-}) = (V(V)_nO_m) \quad (9b)$$

where, $V(V)_nO_m$ and $V(V)_{n-2}V(IV)_2O_{m-2}$ represent the V-O networks, and (8b) and (9b) show their reduction and oxidation, respectively. The desorption of sulfur trioxide formed in molten catalyst according to (8a) or (8b) completes sulfur dioxide oxidation.

$$(SO_3) = SO_3 \quad (10)$$

From the compositions of catalyst and gas phase given in Table 1, the rate-determining step in sulfur dioxide oxidation was examined as follows, where the reaction in molten phase

$$(SO_3) + (SO_4^{2-}) = (S_2O_7^{2-}) \quad (11)$$

$$[SO_3] = \frac{[S_2O_7^{2-}]}{K_{11}[SO_4^{2-}]} \quad (12)$$

was assumed to be in equilibrium and the equilibrium relation was used for the estimation of the concentration of (SO_3). We first examine whether reaction (10) is in equilibrium. If this is so, the ratio $[S_2O_7]/[SO_4^{2-}]$ should be proportional to P_{SO_3}. The observed value, however, was not in agreement with this expectation so that reaction (10) is considered to be not in equilibrium. When reaction (10) is rate-determining, reactions (8a) to (9b) are supposed to be in equilibrium. In this case, the following reaction should necessarily be in equilibrium.

$$SO_2 + 1/2O_2 = (SO_3) \quad (13)$$

The equilibrium conditions of reactions (12) and (13) lead to

$$\frac{[SO_4^{2-}]}{[S_2O_7^{2-}]} \cdot P_{SO_2}P_{O_2}^{1/2} = \frac{1}{K_{11} \cdot K_{13}} \quad (14)$$

When this relation is compared with the observed quantities, $1/K_{11} \cdot K_{13}$ shows no constant value. Flood *et al.*, however, have reported that the polarizing power of cations affects the stability of $S_2O_7^{2-}$ ions in molten state.[17] The inconstancy of $K_{11} \cdot K_{13}$ may be due to a similar effect of cations present. In the present study, correlations among observed quantities are found to be as shown in Fig.2 when $1/K_{11} \cdot K_{13}$ was assumed

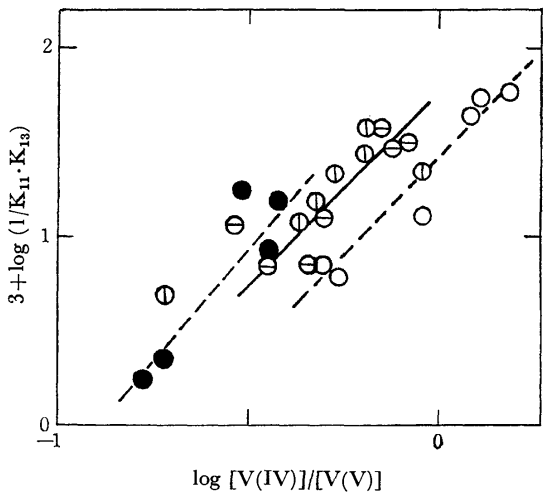

Fig. 2. Dependence of equilibrium constant $1/K_{11}K_{13}$ on the ratio V(IV)/V(V).
○: 500°C, $K_2O/V_2O_5=1$, ◑: 550°C, $K_2O/V_2O_5=1$,
⊖: 550°C, $K_2O/V_2O_5=2$, ●: 600°C, $K_2O/V_2O_5=1$.

to vary in proportion to the square of V(IV)/V(V). It should be noted that quantities observed on both catalyst samples with ratios $K_2SO_4/V_2O_5=1$ and 2 could be correlated by a common line. The dependence of $1/K_{11} \cdot K_{13}$ values on the ratio [V(IV)]/[V(V)] means the decrease in the stability of $S_2O_7^{2-}$ ions with increasing the ratio. This is presumably due to the polarizing effect of VO^{2+} ions on $S_2O_7^{2-}$ ions. The linear relations in Fig. 2 may be considered to support the view that reaction (13) is in equilibrium, although the ratio [V(IV)]/[V(V)] is introduced as a parameter. The effect of the ratio [V(IV)]/[V(V)] was also taken into account in the examination of equilibrium of reaction (10), but no reasonable correlation could be found between the ratio $[S_2O_7^{2-}]/[SO_4^{2-}]$ and P_{SO_3}.

When (SO_3) in the molten catalyst is formed by reactions (8a) to (9b), establishment of equilibrium of reaction (13) means that both reduction and oxidation of vanadiums are in equilibrium as described above. Accordingly, reaction (10) might be considered to be the rate-determining step for sulfur dioxide oxidation with respect to the catalyst at 500—600°C. In this

15) J. W. Mellor, "A Comprehensive treatise on Inorganic and Theoretical Chemistry". Vol. IX, Longmans, London. (1960) p. 818.

16) Although the upper-limit value of V/O_{aq} for catalyst samples with $K_2SO_4/V_2O_5=2$ was in the range 1.9—2.3, VO^{2+} or VO_2^+-forms were assumed in the pyrosulfate determination. A somewhat higher value for the ratio will be due to the relatively higher concentration of sulfate, all of which was assumed to be $S_2O_7^{2-}$ in the calculation.

17) H. Flood and T. Forland, *Acta Chem. Scand.*, **1**, 781 (1947).

this case, the following expression may be expected for the oxidation.

$$dSO_3/dt = k'[SO_3] = kP_{SO_2} \cdot P_{O_2}^{1/2} \quad (15)$$

Oxidation Rate of Sulfur Dioxide as a Function of P_{SO_2} and P_{O_2}. In order to examine the proceeding conclusion on the reaction mechanism, the rate of SO_2 oxidation was measured at 500, 550, and 600°C on vanadium-potassium catalysts. Conversion of SO_2 is shown as a function of contact time in Fig. 3, where

the contact time is expressed in terms of the ratio of weight of catalyst to the flow rate of reaction mixture (g·min/m*l*). The oxidation rates are constant up to almost 10% conversion of SO_2. We determined the oxidation rates as a function of P_{SO_2} and P_{O_2} below 10% conversion of SO_2.

The influence of P_{O_2} on the rate is shown in Fig. 4, where the rate R is expressed in m*l*. SO_3(stp)(*g*-catalyst)$^{-1}$ min^{-1}. All the correlations, at three different temperatures on catalyst A and at only one temperature on catalyst B, gives straight lines with a common slope. From the slope, the values 0.50 ± 0.05 can be obtained for the order of the reaction with respect to oxygen. The influence of P_{SO_2} on the rate is shown is Fig. 5, where the oxidation rate is first order with respect to sulfur dioxide.

In summary, the oxidation rate of sulfur dioxide on vanadium-potassium catalyst at 500, 550, and 600°C fits the rate expression (15), showing that the preceeding reaction mechanism concluded from the compositional consideration of catalysts under SO_2–SO_3–O_2 mixture may be valid.

It should be noted that catalyst B showed higher catalytic activity than catalyst A as seen in Figs. 4 and 5. The concentration of vanadium in catalyst A is 1.5 times larger than that in catalyst B. Since the ratio [V(IV)]/[V(V)] for both catalysts is supported to be close to each other from Table 1 and Fig. 2, concentrations of both V(IV) and V(V) will also be about 1.5 times larger in catalyst A than in catalyst B. If the rate-determining step is either the oxidation of V(IV) or reduction of V(V), the catalytic activity should be higher on catalyst A than on catalyst B. This is not the case in the present study. When the desorption of sulfur trioxide from the molten catalysts is rate-determining, a higher activity may be expected

for catalyst B, because the lower concentration of vanadium will give less viscous molten phase and make the desorption of sulfur trioxide from catalyst melt easier. Thus, the higher activity of catalyst B could be taken as another support of the conclusion on the rate-determining step.

Comparison of the Present Kinetics with the Literatures. The present rate expression $R=k\,P_{SO_2}\cdot P_{O_2}$ for the initial stage of SO_2 oxidation differs from the kinetics found in literature,[8] most of which were measured below 500°C. The difference may perhaps be due to that in the reaction temperatures. The lowering of reaction temperature may give two effects.

One is the variation of reaction mechanism. The temperature dependences of oxidation rate in Figs. 3, 4, and 5 give 6—10 kcal as the activation energy. This value is smaller than those obtained at lower temperatures.[8,9] The difference in activation energy suggests the change of the oxidation mechanism with temperature.

The second is the change in the solubility of vanadium component in the molten catalyst. $V_2O_5\cdot K_2SO_4$ mixture is not always a homogeneous melt below 500°C. The appearance of precipitates will influence the observed reaction kinetics and activation energy. This is true especially when the rate-determining step consists of the oxidation or reduction of vanadium. The phase diagram of $V_2O_5\cdot K_2SO_4$ system[6] and the present finding in Table 2 show that the limiting temperature at which the active component of catalyst changes from a homogeneous to a heterogeneous molten phase will depend upon the ratio V_2O_5/K_2O of catalyst and the composition of reacting gas phase. It should be noted that the temperature of the discontinuity in the Arrhenius plot depends on the composition of reaction mixture.[18]

The two effects may be partially responsible for the discrepancies between the present and other works and also for the discontinuity in the Arrhenius plot. To elucidate the reaction mechanism at lower temperatures, it is desirable to investigate the structure of catalyst and oxidation kinetics on catalysts with low V_2O_5/K_2O ratio. A low ratio is necessary to obtain a homogeneous molten catalyst.

The authors are grateful to Mr. T. Hayata for his help in kinetic measurement. A grant from the Matsunaga Science Foundation to A. K. is acknowledged.

The Calculation of the Rates of Intramolecular Nonradiative Transitions in Benzene

Noriyuki SHIMAKURA, Yuichi FUJIMURA, and Takeshi NAKAJIMA

Department of Chemistry, Tohoku University, Katahira-cho, Sendai

(Received August 16, 1971)

Intramolecular nonradiative transition rates for various interstates of benzene were calculated from the standpoint of the breakdown of the Born-Oppenheimer approximation. The electronic parts of the coupling matrix elements were explicitly evaluated. These parts vary in the range of $10^{-1}-10^{-3}$ Å^{-1}. The nonradiative transition rates for the $^1E_{1u}\rightarrow{}^1B_{1u}$, $^1B_{2u}$ transitions were predicted to be appreciable. The rate for the $^1B_{1u}\rightarrow{}^1B_{2u}$ transition vanishes as long as the geometrical structure of the $^1B_{1u}$ state is assumed to be of the D_{6h} symmetry. These results are compared with the experimental nonradiative transition widths recently reported by Jortner *et al.*

The ocurrence of intramolecular radiationless transitions in polyatomic molecules in the gas phase is now a well-established experimental fact.[1-10] Previous theoretical investigations concerning radiationless transitions have been based on the implicit assumption that the coupling between the molecule and the medium is essential for the occurrence of the nonradiative process. The theory for intramolecular radiationless transitions in an isolated molecule was set forward by Lin[11] and by Bixon and Jortner,[12] who derived the necessary restricting conditions for the occurrence of a radiationless transition in an isolated molecule in the gas phase from the standpoint of the breakdown of the Born-Oppenheimer approximation.

Information on the rates of the radiationless transi-

tions may be inferred from the linewidths in the absorption spectrum. In gas-phase spectra, it is difficult to determine the rates experimentally because of the trivial diffuseness of the linewidths as a result of the molecular rotation, the molecular vibration, and the sequence spectral congestion, but these difficulties are eliminated at low temperature in solid matrices. Recently Jortner *et al.*[13] have observed the linewidths in the absorption spectra of benzene at low temperatures in the rare-gas matrices and have estimated the line broadenings arising from the intramolecular radiationless decay in the lower three excited states ($^1B_{2u}$, $^1B_{1u}$, and $^1E_{1u}$) of benzene.

Our main purpose in this paper is to calculate the radiationless transition rates in the lower three $\pi\rightarrow\pi^*$ excited states of benzene on the basis of the theory for intramolecular radiationless transitions in an isolated molecule and to compare the results with the above experimental information reported by Jortner *et al.*

Robinson and Burland[14] have calculated the radiationless transition probabilities for the internal conversion between the $^1B_{2u}$ and $^1A_{1g}$ states and the intersystem crossing between the $^3B_{1u}$ and $^1A_{1g}$ states in benzene. In their treatment, however, the explicit forms of the perturbation terms which cause the zero-order states to be nonstationary were not given, and the physical meaning of the perturbation terms is somewhat obscure.

Our calculation of the radiationless transition rates in benzene is made on the basis of the following assumptions:

(1) The radiationless transition is regarded as the transition from the lowest zero-order Born-Oppenheimer vibronic level, Ψ_i, in the higher electronic state to a dense manifold of the (zero-order) vibronic levels, Ψ_f, corresponding to a lower electronic state, and the breakdown of the adiabatic approximation is taken as the perturbation which brings about the radiationless decay.

(2) The coupling matrix elements, v, between the Ψ_i and Ψ_f states are assumed to be constant, independent of the channels which connect the initial state with a manifold of the vibronic levels, Ψ_f.

(3) The density, ρ, of the zero-order vibronic states, Ψ_f, is sufficiently high to exceed the reciprocal of the vibronic coupling term, v. This is nothing but a condition for the statistical limit of the intramolecular vibronic coupling and is expressed as:

$$\rho v \gg 1. \tag{1}$$

(4) The vibrational wave functions are approximated by a product of the harmonic oscillator wave functions.

Method of Calculation

In the excited electronic states of a large molecule, the Born-Oppenheimer separability condition for electronic and nuclear motion breaks down, and the intramolecular coupling between the zero-order vibronic level, Ψ_i, and a dense manifold of vibronic levels, Ψ_f, corresponding to a lower electronic state, both of which are eigenstates of the Born-Oppenheimer Hamiltonian, H_o, is induced by the nonadiabatic interaction term (the nuclear kinetic-energy operator), V:

$$V = H - H_o \tag{2}$$

By considering the time evolution of a coherently-excited molecular state, which can be displayed as a time-dependent superposition of molecular eigenstates, each of which is a time-independent superposition of zero-order vibronic states, Bixon and Jortner showed that, with the statistical limits, the rate constant, k, for the nonradiative transition is given by:

$$k = (2\pi/\hbar)\rho v^2 \tag{3}$$

where v is the coupling matrix element and is expressed by:

$$v = \langle\Psi_f|V|\Psi_i\rangle. \tag{4}$$

The adiabatic (zero-order) molecular wave functions, Ψ, are represented in the simple product form:

$$\Psi_i = \Phi_b\theta_{b\beta} \tag{5}$$

and:

$$\Psi_f = \Phi_a\theta_{a\alpha} \tag{5'}$$

where Φ is the electronic wave function and where θ is the vibrational wave function. The non-adiabatic interaction term, V, is given explicitly by the following equation:

$$V\Psi_i = T\Phi_b\theta_{b\beta} - \Phi_b T\theta_{b\beta} \tag{6}$$

where T denotes the kinetic-energy operator for nuclear motion. The coupling matrix element, v, can now be displayed in terms of normal coordinates, Q_i:

$$v = -\hbar^2\langle\Phi_a|(\partial/\partial Q_i)|\Phi_b\rangle\langle\theta_{a\alpha}|(\partial/\partial Q_i)|\theta_{b\beta}\rangle \tag{7}$$

where the Condon approximation[15] has been employed.

We are now in a position to treat the electronic and vibrational parts of Eq. (7) separately. First, the reduction of the electronic part will be considered. Expanding the Hamiltonian in normal coordinates to the first order, we obtain:

$$H = H_o^o + H_{so}^o + \sum_i\{(\partial H_o/\partial Q_i)_o + (\partial H_{so}/\partial Q_i)_o\}Q_i \tag{8}$$

where H_{so} is the spin-orbit coupling Hamiltonian and where the two superscripts of H_o and H_{so} and the two subscripts of $(\partial H_o/\partial Q_i)$ and $(\partial H_{so}/\partial Q_i)$ indicate that the corresponding quantities should be evaluated at the ground-state equilibrium nuclear arrangement. Further, the Φ_a and Φ_b wave functions are expanded into the series of Φ_c^o, and the expansion coefficients, correct to the second order, can be determined using the second-order perturbation theory. We thus obtain for the internal conversion.

$$\langle\Phi_a|(\partial/\partial Q_i)|\Phi_b\rangle = \frac{\langle\Phi_a^o|(\partial H_o/\partial Q_i)_o|\Phi_b^o\rangle}{(E_b^o - E_a^o)}, \tag{9}$$

and for the intersystem crossing:

$$\langle\Phi_a|(\partial/\partial Q_i)|\Phi_b\rangle = \frac{\langle\Phi_a^o|(\partial H_{so}/\partial Q_i)_o|\Phi_b^o\rangle}{(E_b^o - E_a^o)} + \sum_{c\neq b}\sum_{c\neq a}\left\{\frac{\langle\Phi_a^o|H_{so}^o|\Phi_c^o\rangle\langle\Phi_c^o|(\partial H_o/\partial Q_i)_o|\Phi_b^o\rangle}{(E_a^o - E_c^o)(E_b^o - E_a^o)} + \frac{\langle\Phi_a^o|(\partial H_o/\partial Q_i)_o|\Phi_c^o\rangle\langle\Phi_c^o|H_{so}^o|\Phi_b^o\rangle}{(E_b^o - E_a^o)(E_b^o - E_c^o)}\right\}. \tag{9'}$$

13) B. Katz, M. Brith, B. Sharf, and J. Jortner, *J. Chem. Phys.*, **52**, 88 (1970).

14) D. M. Burland and G. W. Robinson, *ibid.*, **51**, 4548 (1969).

15) M. Lax, *ibid.*, **20**, 1752 (1952).

The problem is thus reduced to the calculation of the matrix element:

$$\langle \Phi_a^o | (\partial H_o/\partial Q_i)_o | \Phi_b^o \rangle.$$

According to Albrecht[16] and Liehr,[17] this matrix element is to be written as follows:

$$\langle \Phi_a^o | (\partial H_o/\partial Q_i)_o | \Phi_b^o \rangle = \sum_{f=1}^{3} \sum_{\sigma=1}^{N} (\partial \xi_\sigma^f/\partial Q_i)_o \times \int \rho_{ab}(p) (\partial H_{o,p\sigma}/\partial r_{p\sigma})_o (\partial r_{p\sigma}/\partial \xi_\sigma^f)_o dx_p \quad (10)$$

where σ runs over the N nuclei, where p denotes the pth electron, where ξ_σ^f is the coordinate of the nuclei in the Wilsonian type (Fig. 1), and where the integration of right-hand side of Eq. (10) is over the pth electron. $(\partial \xi_\sigma^f/\partial Q_i)_o$ is a matrix element which transforms the normal coordinates into the local cartesian coordinates, and $(\partial r_{p\sigma}/\partial \xi_\sigma^f)_o$ is the appropriate direction cosine of the vector, $r_{p\sigma}$, connecting the p electron and the σ nucleus with respect to the local cartesian coordinate, f. ρ_{ab} is the one-electron transition density given by:

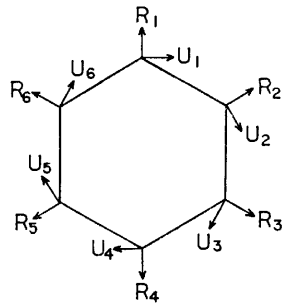

Fig. 1. Wilsonian type coordinate.
R: radial displacement of Wilsonian type coordinate
U: tangential displacement of Wilsonian type coordinate

$$\rho_{ab}(p) = n \int \Phi_a^o \Phi_b^o dx' \quad (11)$$

where n is the number of electrons and the integration is over all but the pth electron. It should be noted that $H_{o,p\sigma}$ is just $(-Z_\sigma e^2/r_{p\sigma})$, because the only nuclear dependent part of the Hamiltonian is the Coulomb potential between the electron and the nucleus. As an example, the electronic part $({}^1B_{2u} \rightarrow {}^1A_{1g})$ will be calculated in the Appendix.

Next, the vibrational part in Eq. (7) will be considered. The vibrational wave functions are approximated in terms of the products of the harmonic-oscillator wave functions, $\chi_{ami}(Q_i)$ and $\chi_{bni}(Q_i')$, where mi and ni correspond to the vibrational quantum numbers:

$$\theta_{bn} = \prod_i \chi_{bni}(Q_i') \quad (12)$$

and

$$\theta_{am} = \prod_i \chi_{ami}(Q_i) \quad (13)$$

where $Q_i' = Q_i + R_i$, R_i being the displacement of the equilibrium points of the its harmonic oscillator between the initial and final states. Using Eqs. (12) and (13), we get the following expression for the vibrational part of the coupling matrix element:

$$\langle \theta_{am} | \partial/\partial Q_i | \theta_{bn} \rangle = \langle \chi_{ami}(Q_i) | (\partial/\partial Q_i) | \chi_{bni}(Q_i') \rangle \times \prod_{j \neq i} \langle \chi_{amj}(Q_j) | \chi_{bnj}(Q_j') \rangle. \quad (14)$$

$\langle \chi_{ami}(Q_i) | (\partial/\partial Q_i) | \chi_{bni}(Q_i') \rangle$ is the non-adiabatic overlap integral; this term can also be expressed in terms of the usual overlap integrals as follows:[11,18]

$$\langle \chi_{ami}(Q_i) | (\partial/\partial Q_i) | \chi_{bni}(Q_i') \rangle = ni^{1/2} \langle \chi_{ami}(Q_i) | \chi_{b,ni-1}(Q_i') \rangle - (ni+1)^{1/2} \langle \chi_{ami}(Q_i) | \chi_{b,ni+1}(Q_i') \rangle \quad (15)$$

All the vibrational wave functions in the initial electronic state are assumed to correspond to the zero-quantum vibrational level.

In Eq. (14), we must take into consideration all the possible combinations of the vibrational overlap integrals under the constraint of the conservation of the excess electronic energy of the final state. Because of the difficulties of the above procedure, the first term on the right-hand side of Eq. (14), which corresponds to a non-adiabatic Franck-Condon overlap, is taken as the average value of the vibrational coupling matrix elements.

The evaluation of the vibrational part of the coupling-matrix element is thus reduced to the calculation of the overlap integral, $S_{mi,ni} (= \langle \chi_{ami}(Q_i) | \chi_{bni}(Q_i') \rangle)$. The analytical expression of $S_{mi,ni}$ as a function of the K_{mi} and K_{ni} constants and the displacement of the equilibrium point, R_i, is given as follows:

$$S_{mi,ni} = c \sum_{j=0}^{[mi/2]} \frac{(\alpha^2-1)^j}{j!} \sum_{k=0}^{ni} \frac{(2\alpha\beta)^{ni-k}(2\gamma)^{mi-2j-ni+k}}{(ni-k)!(mi-2j-ni+k)!} \times \sum_{L=0}^{[k/2]} \frac{(\beta^2-1)^L (2\delta)^{k-2L}}{L!(k-2L)!} \quad (16)$$

where:

$$c = (2^{mi+ni})^{-1/2} (mi!)(ni!) \sqrt{\frac{2K_{mi}K_{ni}}{(K_{mi}^2+K_{ni}^2)}} \times \exp\left\{ -\frac{K_{mi}^2 K_{ni}^2 r^2}{2(K_{mi}^2+K_{ni}^2)} \right\}$$

$$\alpha = \frac{2^{1/2}\rho}{(1+\rho^2)^{1/2}}, \quad \beta = \frac{\alpha}{\rho}, \quad \gamma = \frac{K_{mi} r}{1+\rho^2}, \quad \delta = -\rho r$$

$$\rho = \left(\frac{\nu_{mi}}{\nu_{ni}}\right)^{1/2}, \quad K_{mi} = \left(\frac{\mu \nu_{mi}}{\hbar}\right)^{1/2}, \quad K_{ni} = \left(\frac{\mu \nu_{ni}}{\hbar}\right)^{1/2}$$

where ν_{mi} and ν_{ni} are the vibrational frequencies for the initial and final states and where μ is the effective mass. This formula for $S_{mi,ni}$ applies only to a one-dimensional harmonic oscillator. For a two-dimensional case, we use the formula derived by Bell and Warsop.[19]

For the vibrational frequencies in both the ${}^1A_{1g}$ and ${}^1B_{2u}$ states of benzene, we employ the values proposed by Bernstein *et al.*[20] and by Garforth *et al.*[21] For the other states, the vibrational frequencies are unknown. Recently the differences in the zero-point vibrational energy between the ground state and excited states in benzene have been obtained by observing the deuteration effects on the transition energies.[13] We assume

that the vibrational frequencies for the $^1B_{1u}$ and $^1E_{1u}$ states can be estimated from these data.

Apart from the coupling matrix element, the remaining parameter determining the radiationless transition rate is the density, ρ, of the vibrational energy levels. The classical approximation[22-24] for the density of vibrational states is not sufficiently accurate, the main reason for the inaccuracy being the neglect of the zero-point energy. We adopt in this paper the semiclassical approximation proposed by Haarhoff,[25] where the density is expressed as follows:

$$\rho = [(E+E_z^o)^{n-1}/(n-1)!](\prod_i^n h\nu_i)^{-1} \quad (17)$$

and where ν_i is the frequency of the ith oscillator, n is the number of the vibrational freedom, E is the energy difference between the initial and final electronic states, and E_z^o is defined by the equation:

$$E_z^o = \sum_i^n (h\nu_i/2). \quad (18)$$

Results and Discussion

The nonradiative transition rates between the various states shown in Fig. 2 have been calculated by the method described in the preceeding section. The vibrational level densities calculated for the various electronic states are shown in Table 1. The calculated

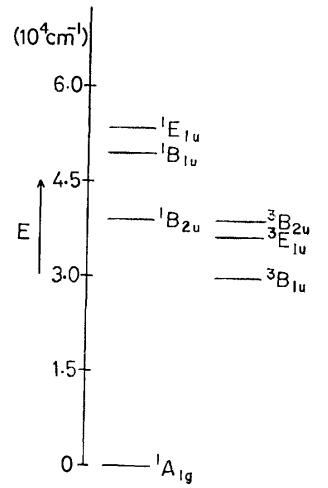

Fig. 2. Energy-level diagram showing the low-lying states of benzene.

matrix elements are summarized in Tables 2, 3, and 4. As can be seen from Table 3, the electronic parts of the vibronic matrix elements for the nonradiative transitions vary over a wide range, from about 10^{-1} to 10^{-3} (Å^{-1}). The electronic part for the $^1B_{1u}\rightarrow{}^1B_{2u}$ nonradiative transition vanishes, because all types of the transition density give zero. These results indicate that the electronic parts cannot be taken as constants in calculating the nonradiative transition rates. The calculated nonradiative transition rates are summarized in Table 4.

Table 1. Calculated level densities

Electronic state		Level density[a] $\frac{1}{\text{cm}^{-1}}$
Initial	Final	
$^1B_{2u}$	$^1A_{1g}$	9.26×10^{15}
$^1B_{1u}$	$^1A_{1g}$	1.13×10^{17}
$^1B_{1u}$	$^1B_{2u}$	6.50×10^{8}
$^1E_{1u}$	$^1A_{1g}$	4.25×10^{17}
$^1E_{1u}$	$^1B_{2u}$	9.60×10^{9}
$^1E_{1u}$	$^1B_{1u}$	1.17×10^{5}
$^1B_{2u}$	$^3E_{1u}$	2.25×10^{4}
$^1B_{2u}$	$^3B_{1u}$	1.90×10^{6}

a) The level densities are given by Eq. (17).

Table 4. Calculated nonradiative rate constants

Electronic state		Nonradiative rate constant
Initial	Final	k (sec^{-1})
$^1B_{2u}$	$^1A_{1g}$	1.1×10^{-27}
$^1B_{1u}$	$^1A_{1g}$	1.2×10^{-6}
$^1B_{1u}$	$^1B_{2u}$	0
$^1E_{1u}$	$^1A_{1g}$	5.5×10^{-6}
$^1E_{1u}$	$^1B_{2u}$	1.1×10^{-11}
$^1E_{1u}$	$^1B_{1u}$	1.7×10^{-15}

It is interesting to compare the calculated widths with the experimental ones. As the present results have been obtained on the basis of many assumptions which can be thought to be justified within the statistical limits, we cannot expect to reproduce the experimental widths exactly. Katz *et al.*[13] have experimentally determined the absorption widths of the $^1E_{1u}$, $^1B_{1u}$, and $^1B_{2u}$ excited states in solid rare-gas matrices and reported that they are about 300, 300, and 0 cm^{-1} respectively. The calculated width of the $^1E_{1u}$ state is about twenty times as large as the experimental one. This discrepancy between the calculated width and the experimental one may be ascribed in part to the evaluation of the level density by means of the semiclassical method. Frost *et al.*[26] have concluded, from a comparison of the semiclassical method with other methods, that the value of the level density based on the semiclassical method is about ten to twenty times as large as the true value in the case of a relatively low energy.

The calculated width of the $^1B_{1u}$ state is zero, in contrast to the experimental one. The width can be expected, from a consideration of the Franck-Condon factor, to have an appreciable order. The zero width stems from the basic assumption that the zero-order wave function, $\Psi(B_{1u})$, is constructed from the adiabatic wave function. In the present calculations, the vibronic coupling between the $^1B_{1u}$ and $^1E_{1u}$ states is not considered. It is well known [13,17,27,28] that the $^1B_{1u}$ state is subjected to the pseudo-Jahn-Teller interaction with the $^1E_{1u}$ state through vibrations of the e_{2g} symmetry. It can be expected, therefore, that, if $\Psi(B_{1u})$ is constructed by means of the configurational mixing, the calculated width will have a non-zero value. In a subsequent paper, the vibronic-coupling matrix element between the $^1E_{1u}$ and $^1B_{1u}$ states *via* e_{2g} vibrations will be evaluated on the basis of the crude adiabatic approximation.[29-31]

Table 5. Relative magnitudes of local cartesian coefficients $\xi_\sigma^R(b_{2u})$ and $\xi_\sigma^U(b_{2u})$ and relative magnitudes of electronic integrals $I_\sigma^R(B_{2u}, A_{1g}, b_{2u})$ and $I_\sigma^U(B_{2u}, A_{1g}, b_{2u})$

	1	2	3	4	5	6
R	O	O	O	O	O	O
U	x	$-x$	x	$-x$	x	$-x$

The width of the $^1B_{2u}$ state remains to be confirmed. It is shown in Table 4 that the calculated width of the nonradiative transition is negligibly small. We have calculated the width of the intersystem crossing from the $^1B_{2u}$ state to the $^3E_{1u}$ and $^3B_{1u}$ states. The results of the calculation are as follows:

$$\Gamma(^1B_{2u}\rightarrow{}^3E_{1u}) = 1.2\times10^{-6}\ cm^{-1},$$
$$\Gamma(^1B_{2u}\rightarrow{}^3B_{1u}) = 5.0\times10^{-13}\ cm^{-1}.$$

It may be concluded that the most favorable energy dissipation of the $^1B_{2u}$ state is the intersystem crossing to the $^3E_{1u}$ state. The width from other works gives 2.0×10^{-6} cm^{-1}.[7,32]

Appendix

The evaluation of the matrix element, Eq. (10), for the radiationless transition ($^1B_{2u}\rightarrow{}^1A_{1u}$) will be outlined as an example. Q_t should belong to the b_{2u} mode, judging from the selection rule for the nonradiative transition.

It is often convenient to symbolize the normal coordinate coefficient by $\xi_\sigma^f(b_{2u})$, and the electronic integral, by $I_\sigma^f(B_{2u}, A_{1g}, b_{2u})$, and to rewrite Eq. (10) as follows:

$$\langle\Phi(B_{2u})^o|\{\partial H_o/\partial Q(b_{2u})\}_o|\Phi(A_{1g})^o\rangle = \sum_f^3\sum_\sigma^N \xi_\sigma^f(b_{2u}) I_\sigma^f(B_{2u}, A_{1g}, b_{2u}), \quad \text{(A1)}$$

where:

$$\xi_\sigma^f(b_{2u}) = \{\partial\xi_\sigma^f/\partial Q(b_{2u})\}_o, \quad \text{(A2)}$$

$$I_\sigma^f(B_{2u}, A_{1g}, b_{2u}) = \int\rho(B_{2u}, A_{1g})(\partial H_{o,p\sigma}/\partial r_{p\sigma}) \times (\partial r_{p\sigma}/\partial\xi_\sigma^f)dx_p. \quad \text{(A3)}$$

All the types of the transition density, $\rho(B_{2u}, A_{1g})$, are shown in Fig. 3. Applying a group theoretical reduction[16] (Table 5) shows how Eq. (A1) may be greatly simplified. It is proven that the identical relationships holding among the $\xi_\sigma^f(b_{2u})$ values hold among the $I_\sigma^f(B_{2u}, A_{1g}, b_{2u})$ values, thus

32) J. W. Donovan and A. B. F. Duncan, *J. Chem. Phys.*, **35**, 1389 (1961).

permitting one to write:

$$\langle\Phi(B_{2u})^o|\{\partial H_o/\partial Q(b_{2u})\}_o|\Phi(A_{1g})^o\rangle = \sum_{f^*}\sum_{\sigma^*}\xi^{f^*}_{\sigma^*}(b_{2u})I^{f^*}_{\sigma^*}(B_{2u}, A_{1g}, b_{2u})\sum_{f}^{3}\sum_{\sigma}^{N}\gamma^2_{\sigma f}(b_{2u}, \sigma^*, f^*) \quad \text{(A4)}$$

where the sum over f^* and σ^* goes over a minimum number of atomic centers and the corresponding cartesian coordinates. The expression in brackets is group-theoretically determined, where:

$$\eta_{\sigma f}(b_{2u}, \sigma^*, f^*) = I_\sigma{}^f(B_{2u}, A_{1g}, b_{2u})/I^{f^*}_{\sigma^*}(B_{2u}, A_{1g}, b_{2u}) = \xi_\sigma{}^f(b_{2u})/\xi^{f^*}_{\sigma^*}(b_{2u}). \quad \text{(A5)}$$

Thus, we may write:

$$\langle\Phi(B_{2u})^o|\{\partial H_o/\partial Q(b_{2u})\}_o|\Phi(A_{1g})^o\rangle = 6\xi_1{}^U(b_{2u})I_1{}^U(B_{2u}, A_{1g}, b_{2u}). \quad \text{(A6)}$$

$I_1{}^U$ can be expanded as follows:

$$I_1{}^U = \beta[I_o(d_1)\cos(d_1, U_1) - I_o(d_2)\cos(d_2, U_1) + I_o(d_3)\cos(d_3, U_1) - I_o(d_4)\cos(d_4, U_1) + I_o(d_5)\cos(d_5, U_1) - I_o(d_6)\cos(d_6, U_1)] \quad \text{(A7)}$$

where d_1, d_2,$\cdots$and d_6 represent the distance between the atomic center, 1, and the six centers of the transition density. We assume that the geometry of benzene is a hexagon whose bond distance is 1.397 Å. The following values, which have been calculated by Liehr, are then substituted on the right-hand side in Eq. (A7):

$$\beta = 0.4367$$

$$\cos(d_1, U_1) = \frac{7}{2}, \qquad \cos(d_2, U_1) = \frac{21}{7},$$

$$\cos(d_3, U_1) = \frac{39}{26}, \qquad \cos(d_4, U_1) = -\frac{39}{26},$$

$$\cos(d_5, U_1) = -\frac{21}{7}, \qquad \cos(d_6, U_1) = -\frac{7}{2},$$

$$I_o(d_1) = I_o(d_6) = 0.8239, \quad I_o(d_2) = I_o(d_5) = 0.1834,$$

$$I_o(d_3) = I_o(d_4) = 0.0950.$$

Thus, we obtain:

$$I_1{}^U(\beta) = 0.5378/5.201 \text{ (eV/Å)}. \quad \text{(A8)}$$

There are two normal modes in b_{2u} species, whose vibrational frequencies are 1147.7 and 1306.7 (cm^{-1}) respectively. The $\xi_1{}^U$ value corresponding to each normal mode is obtained as follows:

$$\xi_1{}^U(b_{2u}-1306.8) = -0.10716$$
$$\xi_1{}^U(b_{2u}-1147.7) = 0.04894. \quad \text{(A9)}$$

By inserting Eq. (A8) and Eq. (A9) into Eq. (A1), we obtain $\langle\Phi(A_{1g})^o|(\partial/\partial Q_i)|\Phi(B_{2u})^o\rangle = 0.136$ and 0.0281 ($Å^{-1}$) for the modes of 1306.8 and 1147.7 (cm^{-1}) respectively.

The Heat of Adsorption from Solution. I. The Heat of Adsorption of Benzene on Silica Gel from the Benzene-Cyclohexane Solution

Tetsuo MORIMOTO and Hiromitu NAONO
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received August 23, 1971)

The sensitivity and reliability of the improved-flow micro-calorimeter have been examined by supplying given amounts of electric energy to the calibration heater inserted in the calorimeter. The detection limit of the heat amount was found to be 0.01 mcal, and its probable error to be ± 0.5 and $\pm 0.3\%$ at the heat evolutions of 10 and 40 mcal respectively. The heat of the adsorption of benzene on silica gel from a cyclohexane solution has been measured at 30°C by the calorimeter thus constructed. The adsorption calorimetry indicates that benzene is adsorbed reversibly on silica gel, and that the differential heat of the adsorption of benzene is independent of the amount of adsorbed benzene, but that it depends strongly on the pretreatment temperature of the silica gel. The heats of adsorption were found to be 1.2, 1.6, 2.0, and 3.8 kcal/mol on silica gel samples treated at 100, 300, 500, and 800°C respectively. The findings on the heats of adsorption have been elucidated in terms of the interaction between benzene molecules and silanol groups on silica gel.

The heat of adsorption from a solution is of great significance, since it is considered to be a measure of the interaction energy between the adsorbed molecules dissolved in the solution and the solid surface concerned.[1] Many reports have been published on the heat of adsorption from a solution, as calculated from the temperature dependence of the adsorption isotherm. The data obtained, however, seem to be lacking in reliability, because of such difficulties as the temperature effect on solubility and the uncertainties both in regard to the activity coefficient of the adsorbed molecules and in regard to the thickness of the adsorbed layer.[2,3]

So far, two direct calorimetric methods have been developed to measure the heat of adsorption from solu-

tion. Young *et al.*[4] have developed a method of measuring the heat of adsorption from solution by means of the technique of the heat of immersion. On the other hand, Groszek[5] has constructed a flow micro-calorimeter, in which the heat of adsorption was measured by injecting a solution of a known concentration into a solvent flowing through an adsorbent bed placed in the column.

In the present investigation, a flow micro-calorimeter has been constructed which is suitable for the exact measurement of a small heat evolution. By using this calorimeter, the heat of adsorption has been measured on a system of silica gel and the benzene-cyclohexane solution. Several investigators have reported the preferential adsorption of an aromatic hydrocarbon dissolved in an aliphatic hydrocarbon on the surface of silica gel.[6-11] However, the direct calorimetric measurement of the heat of adsorption has not yet been made in this system. Here, it will be reported that the direct calorimetric measurement by our improved flow micro-calorimeter can give a highly precise value of the interaction energy of adsorption in the same system.

Experimental

Materials. Silica gel was prepared by the hydrolysis of ethyl orthosilicate. The latter was purified by fractional distillation, and the fraction between the boiling points of 167.1 and 167.8°C was used. Two hundred grams of ethyl orthosilicate and 1015 g of redistilled water were mixed violently at 97—99°C for 4 hr in a 2-*l* flask. In this process, silica gel was produced by the hydrolysis reaction. After that, the excess water was evaporated out at *ca.* 80°C. The silica gel thus obtained was dried at 100°C in an air-bath for 24 hr, calcined at 500°C in the atmosphere for 15 hr, and treated in an agate ball-mill. The benzene and cyclohexane were purified by the usual method.[12] Glass beads of 65—100 mesh, used as a column bed of the flow micro-calorimeter, were treated with hot concentrated hydrochloric acid, washed thoroughly with distilled water, and then dried at 100°C in an air-bath.

Surface Area of Silica Gel. The specific surface area of the silica gel was determined by the BET method from the nitrogen adsorption at the temperature of liquid nitrogen. The surface areas of the samples pretreated *in vacuo* for 4 hr at 100, 300, 500, and 800°C were found to be 423, 422, 431, and 396 m^2/g respectively.

Flow Micro-calorimeter. The calorimeter was constructed by setting a heater circuit in the detection column of the liquid-column chromatograph manufactured by the Japan Electron Optics Laboratory Co., Ltd. The calorimeter, shown diagrammatically in Fig. 1, consisted of a constant flow pump, solvent and solution reservoirs, purification, reference and detection columns, exchange valves, and a metal thermostat. The flow rate was regulated by means of the constant flow pump. The thermistor was used as the temperature-sensitive element. A heater made of platinum wire with a diameter of 0.01 mm and a resistance of 12Ω was placed 1 cm above the thermistor in the detection column. The change in resistivity of the thermistor was amplified and recorded; it was caused by the temperature change due to the heat evolved by the adsorption on silica gel or by the electric current flowing through the heater. Furthermore, it should be noticed that this calorimeter performed excellently in several more points, *i.e.*, the method of injecting the solution, the temperature control of the metal thermostat, and the construction of the double-column system.

Adsorption Calorimetry. The primary purpose of the present adsorption calorimetry is to test the performance of the improved flow micro-calorimeter by applying it to the investigation of the interaction between the surface of silica gel and benzene molecules dissolved in cyclohexane. Silica gel (60—140 mg) was pretreated at a reduced pressure of 10^{-3} Torr for 4 hr at an elevated temperature and then placed in a bed at the same position as the calibration heater. In this case, care was taken so that the silica gel sample did not directly come in contact with the atmosphere. The silica gel bed, several millimeters thick, was sandwiched by glass beads (65—100 mesh) in the detection column. Both of them were similarly packed in the reference column. In the purification column, a large quantity of silica gel was used for the filteration of any impurities. At first, the cyclohexane used as a solvent was forced to flow through at the rate of 0.21 ml/min. The flow direction of cyclohexane is shown by arrows in Fig. 1. In order to reduce the fluctuation of the temperature in the detection column, the reference column

was connected with the flow circuit and was positioned close to the detection column in the metal thermostat. After the thermal equilibrium had been established in the measuring system, a stable base line with no slope was recorded; then the flowing liquid was replaced with a benzene solution of a given concentration by using the exchange valves. Thus, the temperature rise caused by the adsorption of benzene was recorded. During the flow of the benzene solution, the temperature rose initially, passed through maximum, and then went down to the same level as the original base line. This means that the adsorption equilibrium of benzene has been attained. The A curve in Fig. 6 is an example of such an adsorption peak. The desorption peak was obtained after exchanging the flow of the solution with that of the solvent by means of the exchange valves, as is shown in the B curve in Fig. 6. The calibration of the calorimeter was made with the aid of the calibration heater; the peak area recorded was plotted against the electric energy supplied by the heater.

Adsorption Measurement of Benzene on Silica-gel from the Benzene-Cyclohexane Solution. The amount of benzene adsorbed on silica-gel from the cyclohexane solution was obtained from the difference in the concentrations before and after the adsorption. In a 2-m*l* ampoule, silica gel (0.5—1.0 g) was pretreated under the same conditions as those described in the adsorption calorimetry. A known amount (*e.g.*, 2 g) of the solution of a given concentration was poured into the ampoule, and then it was sealed. In this case, precaution was taken so that the solid powder did not come into direct contact with the atmosphere by cutting off the top of the ampoule in the solution. The sealed ampoule was shaken for 15 hr at 30°C; this resulted in the attainment of the adsorption equilibrium. The concentration of benzene in the supernatant solution was determined by means of absorption spectroscopy at the wave length of 254.5 mμ by using a spectrophotometer of the Hitachi 139 type.

Results and Discussion

Reliability and Sensitivity of the Flow Micro-calorimeter. In Fig. 2, several calibration peaks are illustrated. These peaks are recordings of the resistivity change in the thermistor set in the detection column when different amounts of electric energy were supplied to the calibration heater at the heat-evolution rate of 4.60 mcal/min and at the flow rate of the solvent of 0.21 m*l*/min. Figure 3 presents the relation between the peak area and the electric energy supplied, which was obtained by varying the rate of the solvent flow and that of the heat evolution. It may be seen from Fig. 3 that the peak area is exactly proportional to the heat evolved and that the slope of the straight lines varies

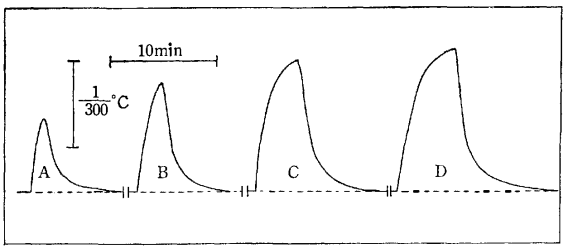

Fig. 2. Calibration peaks at 30°C.

with the flow rate of the solvent, independently of the heat-evolution rate. The slope for the straight lines in Fig. 3 increases with the flow rate of the liquid. This fact may be interpreted as follows: the heat generated in the detection column escapes in all directions of the column, but the enhanced flow rate of the liquid causes an increase in the heat sensitivity of the thermistor. Thus, it can be understood that, in flow calorimetry, it is necessary to operate the calorimeter at a constant flow rate.

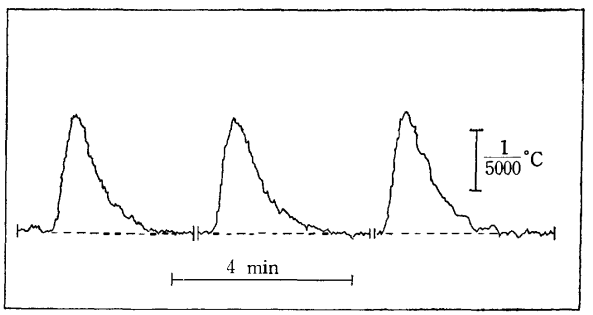

Fig. 4. Response of flow micro-calorimeter for 0.1 mcal at 30°C.
Solvent, cyclohexane; flow rate, 0.21 m*l*/min.

Next, the accuracy of the calorimeter was examined for the heat amounts of 10 and 40 mcal. Five measurements were repeated in each case. The peak area obtained gives probable errors of ± 0.5 and $\pm 0.3\%$ for 10 and 40 mcal respectively. The sensitivity of the calorimeter was also tested. Figure 4 shows the three peaks obtained for 0.1 mcal. Although there is appreciable noise, the peak area can be measured within an error of $\pm 5\%$, which corresponds to the detection limit

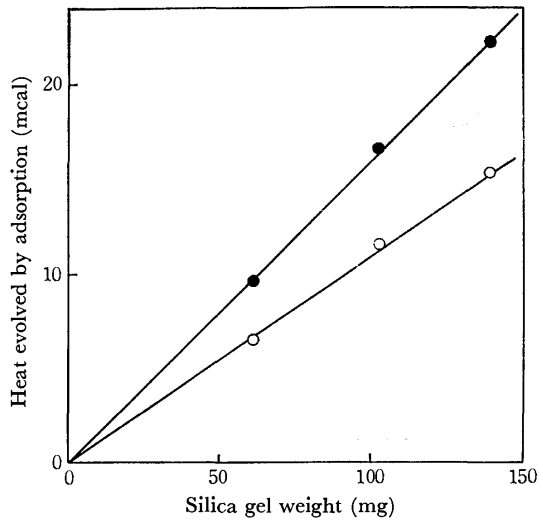

Fig. 5. Relation between heat evolved by adsorption of benzene and silica gel weight in flow micro-calorimeter. Pretreatment temperatrue of silica gel, 100°C; benzene concentration,
○: 0.050 molality, ●: 0.085 molality.

of the heat of 0.01 mcal.

Finally, the relation between the amount of the heat evolved by adsorption and the weight of the adsorbent used for the calorimetry was examined at a constant concentration of benzene. The results obtained are shown in Fig. 5, which indicates that the heat evolved by the adsorption of benzene is proportional to the weight of the silica gel used within the range of the present experiments. The above examinations prove that the present flow micro-calorimeter is useful for the measurement of the heat of adsorption from solution, especially for the investigation of a system with a weak interaction energy.

In comparison with the micro-calorimeter employed by Groszek,[5] the following points are improved in the present calorimeter: (1) the temperature of the metal thermostat is regulated within an error of $\pm 10^{-3}$°C, (2) the noise arizing from the fluctuation in the flow rate of the liquid and in the temperature of the metal thermostat is eliminated by adopting the double-column system, and (3) the solution in the reservoir is smoothly injected into the detection column by using the exchange valves. The sensitivity of his calorimeter was approximately the same as that of the present one. He reported that the slope was recorded by the base line, and that the peak areas are nearly linearly related to the heat produced by the heater up to 20 mcal. On the contrary, the present results give a straight base line, one with no slope over a prolonged period, and a good linearity between the peak area and the amount of heat supplied.

Heat of Adsorption of Benzene on Silica Gel from the Benzene-Cyclohexane Solution. Figure 6 shows the response of the flow micro-calorimeter, including both the exothermic peak due to the adsorption of benzene on silica gel and the endothermic one due to the desorption from silica gel. The silica gel samples used in the experiments in Fig. 6 were pretreated at 100°C *in vacuo*. In each sample of silica gel, no matter what the pretreatment temperature, the area of the adsorption peak is in good agreement with that of the desorption peak within the limits of experimental error. This agreement establishes that benzene molecules are adsorbed reversibly on the silica gel surface.

Taking into account the specific surface area of silica gel, the heat evolved by the adsorption of benzene, H, can expressed in calories per 100 Å^2 of silica gel. This is plotted in Fig. 7 as a function of the concentration. The silica-gel samples used were pretreated at 100, 300, 500, and 800°C *in vacuo*. It can be seen from Fig. 7 that the value of H increases with an increase in the concentration of benzene. Moreover, the H value

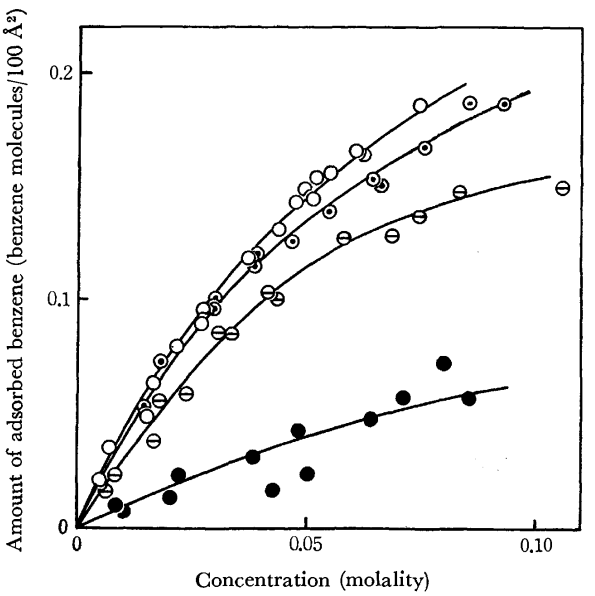

Fig. 8. Adsorption isotherm of benzene on silica gel at 30°C.
Pretreatment temperature of silica gel,
○: 100°C, ⊙: 300°C, ⊖: 500°C, ●: 800°C.

depends on the pretreatment temperature, *i.e.*, it increases in the order of 800, 100, 300, and 500°C treatment.

On the other hand, the adsorption isotherm of benzene on silica gel from the benzene-cyclohexane solution is as is shown in Fig. 8, where the amount of adsorbed benzene is expressed in benzene molecules per 100 Å² of silica gel. An appreciable fluctuation is observed in the experimental data on the amount of benzene adsorbed on the silica gel samples pretreated at 800°C, probably because of the remarkably reduced amount of adsorption. Taking the molecular area of benzene adsorbed in the close-packed state on graphitized carbon black to be 40 Å²,[13] it may be seen from Fig. 8 that only a small part of the silica gel surface is covered by benzene molecules within the concentration range examined here. Furthermore, it can be seen from Fig. 8 that the higher the pretreatment temperature of silica gel, the smaller the amount of benzene adsorbed.

From the smooth curves shown in Figs. 7 and 8, the relation between H and the amount of adsorbed benzene is obtained (*cf.* Fig. 9). A good linear relationship holds between them, and the slope increases with the pretreatment temperature of silica gel. Since the slope directly indicates the differential heat of adsorption, it can be seen from Fig. 9 that the differential heat of adsorption of benzene on silica gel from the cyclohexane solution is independent of the amount of adsorbed benzene within the concentration range examined. Therefore, we can conclude that the surface of silica gel is energetically homogeneous for the adsorption of benzene from the cyclohexane solution at a low coverage of benzene. Furthermore, it should be noticed that the heat of the adsorption of benzene depends greatly on the pretreatment temperature; the values are 1.2, 1.6, 2.0, and 3.8 kcal/mol on the samples pretreated at 100, 300, 500, and 800°C respectively. These values show that the interaction between the silica gel surface and benzene molecules is relatively weak compared to that between the same surface and polar molecules.[14]

In the present calorimetric measurements, the heat of dilution should be a factor in addition to the heat evolved by adsorption. In the benzene-cyclohexane system, the heat of dilution can be calculated from the heat of the mixing of benzene with cyclohexane. Ac-

cording to the data reported by Maagek *et al.*,[15] the heat of dilution is less than 5 cal/mol in the concentration range of benzene examined here; this is negligibly small compared with the heat of the adsorption of benzene.

So far, it has been clarified that the silanol groups play an important role in the interaction between the silica gel surface and aromatic hydrocarbon molecules, whether in the gaseous or in the liquid phase.[7,11,16,17] In the present investigation, the surface silanol groups were determined by an analysis of the active hydrogen atoms;[18] the results are presented in Fig. 10 as a function of the pretreatment temperature of silica gel. Figure 10 shows that the silanol content decreases remarkably with an increase in the pretreatment temperature. On the other hand, as is shown in Fig. 8, the amount of benzene adsorbed on the silica gel surface also decreases with an increase in the pretreatment temperature. These results suggest that benzene molecules are selectively adsorbed on silanol groups on the silica gel surface. Moreover, a benzene molecule may be considered to interact with a single silanol group on the basis of the following facts. Assuming that the surface silanol groups are distributed uniformly, the area of silica gel per silanol group can be calculated from the data in Fig. 10: the area are 38, 53, 100, and 320 Å^2 for the surfaces treated at 100, 300, 500, and 800°C respectively. Thus, the area per silanol group is almost equal to, or is larger than, the molecular area of benzene (40 Å^2) mentioned above.[13]

In order to examine the quantitative relationship between the amount of benzene adsorbed and the silanol content, the ratio of the former to the latter was replotted against the concentration of benzene (*cf.* Fig. 11). First, it may be seen from Fig. 11 that the ratio is always far less than unity over the concentration range of benzene examined; this indicates that the surface silanol groups are only partly covered by benzene molecules over the range of the amount of adsorbed benzene examined, in spite of a quite small population of silanol groups. Figure 11 also shows that the higher the pretreatment temperature, the larger the ratio. This latter fact implies that the silanol groups on the surfaces treated at higher temperatures can attract benzene molecules more strongly than those on the surfaces treated at lower temperature; this corresponds with the results in Fig. 9. The heat treatment of silica gel at higher temperatures may change the structure of the surface and make it feasible to adsorb benzene molecules.

A Chlorine NQR Study of Some Perchloro-compounds

Masao HASHIMOTO and Koichi MANO*

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe
**Research Institute for Atomic Energy, Osaka City University, Sumiyoshi-ku, Osaka*

(Received September 3, 1971)

The NQR frequencies of chlorines in seven perchloro-compounds were measured at 77°K and above. The assignments of the frequencies were made for each compound. It was found that the resonance frequency is considerably influenced by the electrostatic repulsion between chlorine atoms due to the close Cl···Cl distances. For several compounds, the resonance was found to fade out at rather low temperatures.

Several investigations of the nuclear quadrupole resonance, NQR, of the chlorine nucleus in perchloro-compound, C_mCl_n, have been reported.[1-4] Recently, West and his co-workers applied the NQR method to the determination of the molecular structure of some perchloro-compounds.[5-8] Their study constituets an important chemical application of the NQR technique. In order for this application to be reliable, however, it is necessary to establish the correlations between the molecular structure and the NQR frequencies. In the present work, we measured and assigned the NQR frequencies of chlorines in seven perchloro-compounds (Fig. 1) for which the crystal or molecular structures have been well established.

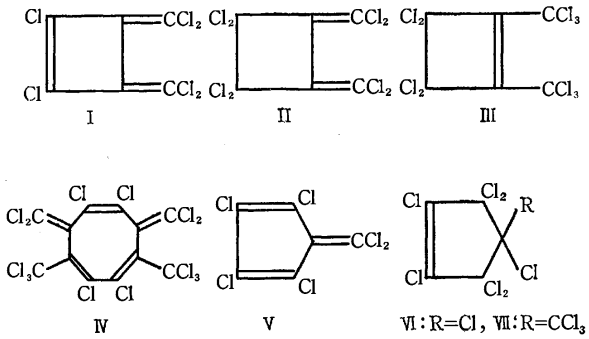

Fig. 1.

In perchloro-compounds, some of the chlorine atoms are expected to approach one another closely, because half or more than half of the atoms in the molecule are chlorine atoms. In fact, intramolecular and/or intermolecular Cl···Cl distances shorter than twice the van der Waals radius have been found in the crystals of some perchloro-compounds.[9-12] In this paper, we will report on the effect of the close Cl···Cl distance on the chlorine NQR frequency of perchloro-compounds. Agranat *et al.* have reported the effect of intramolecular interactions due to overcrowding on the NQR frequencies of chlorines in octachloropentafulvalene.[3]

Experimental

NQR Measurements. The NQR spectra were observed with an externally-quenched super-regenerative spectrometer; the absorption lines were displayed either on an oscilloscope or, when greater sensitivity was required, on a recorder after amplification by means of a lock-in amplifier. The frequencies were measured with a National VP-415 digital frequency counter. The accuracy of the frequency measurements was within ±2 KHz. The frequency measurements were carried out at 77°K (liquid nitrogen bath), at 198°K (dry ice-petroleum ether bath), and at room temperature. In some cases, the frequencies were measured at other temperatures by using a petroleum ether bath cooled by liquid nitrogen or dry ice. The temperature was determined by means of a copper-constantan thermocouple.

Materials. Perchloro-(3,4-dimethylenecyclobutene), I, was prepared by the dechlorination of perchloropropene with aluminum amalgam in ether.[13] This sample was purified by sublimation in a vaccum and by subsequent recrystallization from *n*-hexane under an atmosphere of nitrogen; mp 154—155°C.

Perchloro-(1,2-dimethylenecyclobutane), II, was prepared from I by means of chlorination with antimony pentachloride.[13] The sample of II was purified by chromatography on aluminum oxide. Recrystallization from acetone; mp 93°C.

Perchloro-(1,2-dimethylcyclobutene), III, was prepared from II by the same method as II. The product was purified by chromatography on aluminum oxide and by subsequent recrystallization from acetone; mp 153—154°C. The IR spectrum of this sample was identical with that of an authentic sample.[14]

Perchloro-(1,4-dimethyl-5,8-dimethylenecycloocta-1,3,6-triene), IV, was prepared from perchloro-(3,4,7,8-tetramethylenecyclooctadiene) by chlorination with liquid chlorine in a sealed tube.[13,15] It was then recrystallized from chloroform; mp 275°C.

Perchloro-(5-methylenecyclopentadiene), perchlorofulvene,[16] V, was obtained from perchloropropene by dechlorination with cuprous chloride in hydrous tetrahydro-

Results and Discussion

The NQR frequencies of ^{35}Cl in these perchloro-compounds are summarized in Table 1, together with the frequencies of ^{37}Cl at 77°K.

The intensities of the resonance lines of II, III, IV, VI, and VII were found to be much stronger than those of I and V.

The number of resonance lines found for II and III was equal to half the number of chlorines in the corresponding molecule. This indicates that these molecules must possess one or more symmetry elements in their crystals.

In order to minimize the effect of lattice vibrations on the resonance frequency, the observed frequencies were extrapolated to 0°K. The extrapolated values are listed in the last column of Table 1.

The assignments of the frequencies are shown in Fig. 2.

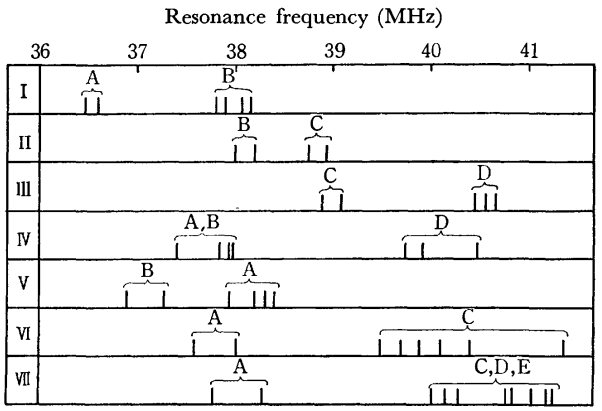

Fig. 2. Resonance frequencies extrapolated to 0°K. Vertical lines show the locations of the frequencies. The notations, A, B, C, D, and E, indicate the functional groups: A, =C–Cl: B, $=CCl_2$; C, $>CCl_2$, D, $-CCl_3$; E, $>\underset{|}{C}-Cl$.

The NQR spectrum of I consists of six resonance lines. Obviously these lines fall into two groups, one of two lines and one of four, centred at about 36.5 and 38.0 MHz respectively. From a structural point of view, the lower two lines may be attributed to the two vinyl chlorines attached to the cyclobutene ring, and the higher four lines, to the four chlorines in the two dichloromethylene groups. The frequencies of chlorines attached to the double bond in the cyclobutene ring are rather lower than those in the five- and eight-membered rings (see the spectra of IV, V, VI, and VII). Roedig *et al.* have reported unusually low resonance frequencies of vinyl chlorines on a cyclobutene ring, 35.53 and 35.95 MHz.[6] This supports our assignment above.

The NQR spectrum of II consists of two groups of lines. From a comparison of the spectrum of II with the spectra of III and I, it is evident that the two lines at about 38 MHz are assignable to the $=CCl_2$, and the other two lines at about 38.7 MHz, to the $>CCl_2$. Because of the conjugative effect, the frequency of an olefinic chlorine is somewhat lower than the frequency of a paraffinic chlorine.

The III molecule has two functional groups, $-CCl_3$ and $>CCl_2$. The three resonance lines at about 40.5 MHz were found to disappear gradually at about 210°K (the so-called "fade-out" phenomenon). This phenomenon has also occasionally been observed for compounds containing trichloromethyl groups, $-CCl_3$.[20,21] Therefore, the three lines at about 40.5 MHz are assignable to the $-CCl_3$, and the other two lines at about 39 MHz, to the $>CCl_2$.

At room temperature, Furusaki has investigated the crystal structure of IV and found that the symmetry of this molecule is C_2.[12] He also found that there were seven crystallographically-nonequivalent chlorine atoms in the unit cell, while, in our NQR study of IV, only four resonance lines were observed at room temperature. Since the frequencies of these four lines decrease monotonously with an increase in the temperature, this crystal seems to undergo no phase transition between 77°K and room temperature. Therefore, the experimental fact that seven resonance lines were observed at 77°K is consistent with this crystal structure. The NQR spectrum of IV consists of two groups: three lines appeared in the frequency region from 39.7 to 40.5 MHz, and four lines, in the region from 37.4 to 38.0 MHz. The higher three lines, ν_1, ν_2, and ν_3, were found to fade out at about 260°K; they are assigned to the $-CCl_3$.

The six resonance lines found for the V compound may be divided into two groups, four lines centered at about 38.2 MHz and two lines centered at about 36.9 and 37.3 MHz. Since this molecule has four olefinic chlorines adjacent to the double bonds in the cyclopentadiene ring and two chlorines in the $=CCl_2$ group, the four higher-frequency lines may be attributed to the olefinic chlorines adjacent to the five-membered ring, and the two lower-frequency lines, to the chlorines in the $=CCl_2$ group. This assignment requires some explanation. If the assignemnt mentioned above for V is correct, the resonance frequencies of the chlorines in the $=CCl_2$ of V are lowered by about 1 MHz below the frequencies of the chlorines in the $=CCl_2$ of I, II, and IV. The decrease in the resonance frequency may be due to the contribution of the following structure to the ground state of V.

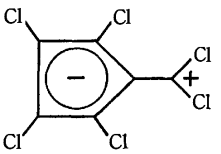

Fig. 3.

In this structure, the electrons of the p_π orbitals of chlorines in the $=CCl_2$ may be in part transferred to the adjacent carbon atoms. According to the theory of Townes and Dailey,[22,23] this decrease in the electron density of the p_π orbitals of chlorine atoms accounts for the decrease in the resonance frequency. Recently, Agranat *et al.* have suggested, in their study of dipole moments, a certain contribution of a dipolar structure to the ground state of V.[24] This supports the above

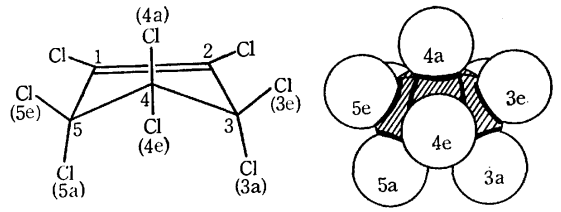

Fig. 4. Molecular model of perchlorocylcopentene, VI.

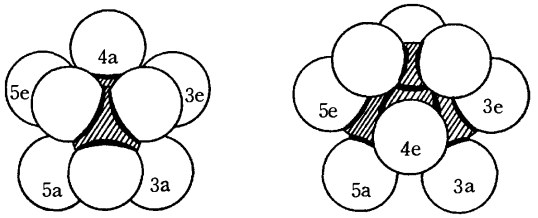
considerations.

In the NQR spectrum of VI, it is seen that one of the six frequencies of the geminal chlorines is considerably higher than the frequencies of the other geminal chlorines. This can be explained in terms of a strong electrostatic repulsion between the chlorine atoms. An examination of the molecular model of VI (Fig. 4) leads to the following results.

It can be seen in Fig. 4 that the distance between Cl (4e) and Cl(3a), and that between Cl(4e) and Cl(5a), are the shortest among those between the geminal chlorines. Thus, the equatorial chlorine, Cl(4e), is subject to a stronger electrostatic repulsion than any other geminal chlorine. The repulsive electrostatic interaction between chlorine atoms causes the migration of the electronic charge from the chlorine atoms to carbon atoms, and thus causes a diminution in the ionic character of the C–Cl bond. The decrease in the ionic character results in the shift of the resonance frequency to the higher-frequency side.[22,23] The highest frequency line, ν_1, of VI thus assignable to the equatorial chlorine, Cl (4e).



equatorial conformer axial conformer

Fig. 5. Two conformations of perchloro-(4-methylcyclopentene), VII.

The VII molecule has two possible conformations (Fig. 5). In either conformation, the degree of all the intramolecular Cl···Cl repulsive interactions may be larger than that in VI because of the extreme bulkiness of the $-CCl_3$ group. The ionic character of C–Cl bond in the $>CCl_2$ of VII is expected to be smaller than that of VI. This diminution of the ionic character accounts for the experimental fact that the average value of the resonance frequencies of VII shifts to a higher-frequency side compared to that of VI.

It should be noted that the average value of the resonance frequencies of the chlorines in carbon tetrachloride, CCl_4, is comparable to those of the chlorines in the $>CCl_2$ of VI and VII. According to the theory of Townes and Dailey,[22,23] the observed NQR frequency is related to the ionic and double-bond characters of the C–Cl bond and to the *s* character of the chlorine-bonding orbital. They also proposed that the amount of the *s* character was about 15% for the chlorine-bonding orbital in a C–Cl bond.[23] The double-bond character of the C–Cl bond in the $>CCl_2$ and CCl_4 may be neglected. Therefore, the ionic character of the C–Cl bond in the $>CCl_2$ of VI and VII is comparable to that of CCl_4.

Table 2. Resonance lines found to fade out and the temperatures, T_f, at which the resonance lines disappeared

No. of resonance lines	T_f (°K)
All lines of I	255
ν_1, ν_2, and ν_3 of III	210
ν_1, ν_2, and ν_3 of IV	260
All lines of V	255
ν_7 of VII	280

For several compounds, the fade-out phenomena were found at rather low temperatures. The temperatures, T_f, at which the resonance lines disappeared are summarized in Table 2. The fade-out of chlorine resonances has been reported for a number of compounds.[20,21,25,26] From the fact that the fade-out apparently occurs only in a solid where internal or molecular rotation is either definitely known to ocuur or is very likely to occur, it has been considered that such motions are responsible for the fade-out.[21] In the cases of III and IV, a similar mechanism may operate and the disappearance of the $-CCl_3$ chlorine resonances could results from the internal rotaion or rotational oscillation of the $-CCl_3$ group. This view is supported by the large X-ray temperature factors found for the chlorine and the carbon atoms in the $-CCl_3$ groups of IV.[12]

Furusaki, in his X-ray study of IV, has found close intermolecular Cl···Cl distances, 3.43, 3.56, and 3.58 Å for the $-CCl_3$ group.[12] Although the crystal structure of III has not yet been determined, the intramolecular Cl···Cl distances between the two $-CCl_3$ groups in this molecule are expected to be extremely short, for two bulky $-CCl_3$ groups are attached to either end of the C=C bond. However, the fade-out phenomena found for III and IV seem to suggest that the steric hindrance is not severe enough to prevent the internal rotation or rotational oscillation of the $-CCl_3$ group. Detailed studies of the mechanism of the fade-out phenomena found for I and V are now being undertaken by means of investigations of the crystal structures (at room temperature and at low temperatures), by thermal analysis (DTA and DSC), and by studying the temperature dependence of the dielectric constant and the electrical conductivity.

The authors wish to thank Professor Akira Fujino, Research Institute for Atomic Energy, Osaka City University, for his kind gift of the sample for identification. We also wish to thank Dr. Yoshio Kamishina, Faculty of Science, Kobe University, for his valuable suggestions.

Photoemission of Ion Radical Salts. Benzonitrile- and Triphenylene-Alkali Metal Complexes

Haruki KAWAMURA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 8, 1971)

The photoelectric emission of the benzonitrile-alkali metal salts were measured and compared with those of the hydrogen-chemisorbed samples. The adsorption of hydrogen onto the salt caused a decrease in the quantum yield of the photoemission at a higher energy region and also a decrease in the threshold energy. The threshold energies were 5.05±0.02 eV for the benzonitrile-rubidium ion radical salt and 4.95±0.02 eV for its hydrogen-chemisorbed sample. Further, the spectral response of the quantum yield of the photoemission for the triphenylene-cesium complex was measured. The threshold energies of the mono- and dinegative ions were 2.40 eV and 2.43 eV respectively, and the quantum yield of the mononegative salt was ten times than that of the dinegative one.

The photoemission from inorganic solids—metals and semiconductors —— has been studied by many workers. However, few studies have been reported on the photoemission from organic materials, especially for organic complexes. Suhrmann first showed that the efficiency of the photoelectric emission of alkali metals is enhanced by the evaporation of hydrocarbon, naphthalene, or anthracene onto sodium (or potassium) metal film;[1] this enhancement may arise from the formation of a complex between alkali metal and aromatic hydrocarbon.

Since this pioneer work, several studies of the photoemission from the aromatic-alkali metal salts have been made in order to clarify the mechanism of the charge-transfer process of the complexes.[2,3]

In this paper, we will present out results on the photoemission from the ion radical salts, benzonitrile-alkali metals and triphenylene-alkali metal. The effect of hydrogen adsorption onto the surface of the benzonitrile-alkali metal complex on the photoemission will be discussed. Further, the change in the photoemission efficiency from the triphenylene-alkali metal salt as a function of the valencies of the aromatic anion is reporsed.

Experimental

Preparation of the Thin Film of the Ion-radical Salt. Benzonitrile-alkali metal salts[4]: Commercial benzonitrile was refluxed with diphosphorous pentoxide in a sealed glass vessel to eliminate all traces of water, subsequently degassed by alternate boiling under a vacuum, and distilled repeatedly. Cesium and rubidium metals, the electron donors, were prepared from their chlorides by reduction with calcium metal in an evacuated glass vessel.[5] The sodium metal was purified by distillation *in vacuo*.

Both the preparation of the ion-radical salt and the measurement of the photoemission from the salt were carried out *in vacuo* (10^{-5}—10^{-6} Torr) because of the instability of the ion-radical salt in air; the purified alkali metal was first evaporated on the surface of a glass vessel, and then purified benzonitrile liquid was introduced into the vessel. By these operations, a dark red solution (excess benzonitrile acts as a solvent) was made. The coloured solution was then dropped onto a copper-disc cathode (emitter) 10 mm in diameter, and the excess benzonitrile was evaporated completely for about 20 hr to make the radical-salt thin film. Then, the copper disc with the deposited salt film was moved towards the centre of the glass photocell, the inside of which had been coated with evaporated gold thin film and which was used as collector. Figure 1 shows the delicate glass photocell.

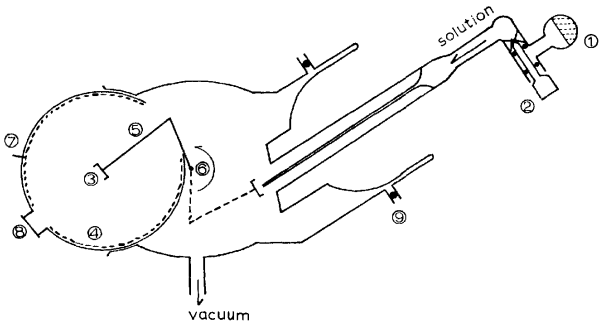

Fig. 1. The schematic diagram of the apparatus for photoemission measurement *in vacuo*. (1); The ion salt solution, (2); greaseless tap, (3); copper disc with the film, (4); Au evaporated film, (5); copper rod, (6); tungsten rod and moving apparatus, (7); collector lead (tungsten rod), (8); quartz window, (9); O-ring.

Triphenylene-cesium ion-radical salt: Commercial triphenylene was recrystallized several times from its alcohol solution and then sublimed in a vacuum. The triphenylene-cesium complexes, both mono- and dinegative ion salts, were prepared as precipitates from their tetrahydrofuran (THF) solution when the triphenylene in THF was brought in contact with Cs metal.[6] The THF solution, in which the radical salt had been suspended, was dropped onto the copper disc through a glass capillary, and then the THF was completely evaporated from the solution, during about a 4 hr period, to make a thin film.

Measurement of the Photoemission. An incident light from a hydrogen-discharge lamp was monochromatized with a Hilger-type monochromator with a quartz prism (for the benzonitrile salt) and also with a Shimadzu Baush-Lomb monochromator (for the triphenylene salt). The absolute measurement of the light intensity was made by means of an

Epply circular thermopile, the sensitivity of which was 0.3 μV/μW *in vacuo*. The output potential was applied from a Keithley 241 voltage supply; 10 V for the benzonitrile salt[8] and 50 V for the triphenylene salt. The photoemissive current was amplified and measured by means of a Cary 32 vibrating-reed electrometer, as a function of the wavelength of the incident light.

Results and Discussion

Benzonitrile-Alkali Metal Salts. The photoemissions from the benzonitrile-sodium, rubidium, and cesium ion-radical salts were measured as functions of the wavelength of the incident light; at first, the measurement of the photocurrent of the freshly prepared film was carried out, and then the salt film was placed in contact with purified hydrogen gas of 10 Torr for 100 min and then pumped up to 10^{-5} Torr. The photocurrent from the hydrogen-exposed film was measured and compared with that of the fresh one.[9] Figures 2, 3, and 4 show the photoelectric yield curves as functions of the photon energy.

In the present work, the quantum yield (in electrons/quantum unit) was measured only down to 10^{-6}; thereafter, the threshold energy, E_{th}, could not be determined by an extrapolation method.[10] Therefore, the value of the threshold energy had to be obtained another method. By analogy with the Fowler plots for the photoemission of metals, the quantum yield of the ion radical salts near the threshold energy may be subjected to the conventional power law:

$$Y \propto (E-E_{th})^n \qquad (1)$$

where Y is the quantum yield and E is the incident

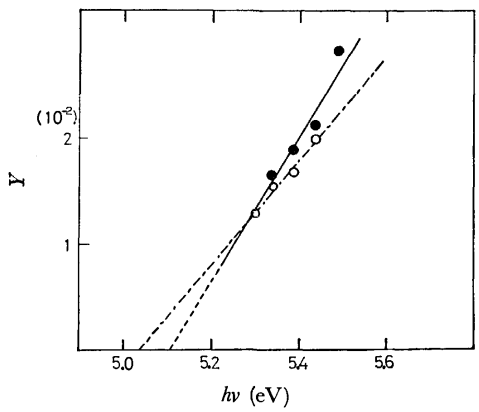

Fig. 5. The power-law fit for the photoelectric quantum yield near the threshold region (Cs-benzonitrile salt).
for the fresh film -●- and

10) The values of E_{th} are determined by extrapolation from a quantum yield of 10^{-7}—10^{-9} electrons per incident quantum.

photon energy. For the organic complexes, it has been shown empirically that a cube-root plot of the quantum yield ($n=3$) becomes almost linear as a funciton of the incident photon energy, as is illustrated in Fig. 5.[2,11] Table 1 summarizes the values of E_{th}. In Table 1, the accuracy of the work function of the salts is kept within the range of the resolving power of the monochromator for an incident light; the resolving power is 0.02 eV. The values of E_{th} thus obtained are, for example, 5.05 ± 0.02 eV for the benzonitrile-Rb ion radical salt and 4.95 ± 0.02 eV for the H_2-exposed sample. The energy differences, ΔE, between the fresh sample and the H_2-exposed one are 0.07—0.1 eV.

TABLE 1. THE THRESHOLD ENERGY in eV OF PHOTOEMISSION OF BENZONITRILE-ALKALI METAL ION RADICAL SALTS

Donor	Fresh	H_2-exposed	ΔE
Na	5.01	4.92	0.09
Rb	5.05	4.95	0.10
Cs	5.11	5.04	0.07

Generally, in the formation of the salt there is a sharp increase in the electronic conductivity and in the quantum yield photoemission in comparison with its components. The mobile electrons in the salt may originate from the excess charge which transfers from the donor, the alkali metal, to the acceptor, aromatics. The adsorption of hydrogen causes a decrease in the quantum yield in the higher energy region and also a decrease in the threshold energy, as is illustrated in Figs. 2—4. A similar phenomenon appeared in the behavior of the electronic conductivity; that is, there was a marked decrease in the conductivity with the chemisorpition of hydrogen onto the ion-radical salt.[12] The above findings suggest that the excess charge of the radical salt participates in forming a chemisorption-bond with hydrogen.

The quantum yield near the threshold energy of the H_2-exposed sample was larger than that of the fresh one, and the work function of the salt was decreased by the adsorption of hydrogen gas. It seems that the dcrease in the work function derives from the appearance of the surface state, located 0.07—0.1 eV[13] above the highest occupied level of the salt. When the hydrogen-exposed sample was pumped out for a week, the value of the quantum yield of the H_2-exposed sample recovered the value of the fresh sample. Figure 6 shows the time dependence of the photoemission for the benzonitrile-cesium complex under pumping.[14] This result shows that the hydrogen is chemisorbed onto the salt, but does not react.

Triphenylene-Cesium Complex. Figure 7 shows the quantum yield curve of photoemission for the triphenylene-cesium complex. The threshold energies of

for Tp^- film -●- and
for Tp^{2-} film --○--

the mono- and dinegative ion salts are 2.40 and 2.43 eV respectively. The quantum yield of the mononegative salt is ten times that of the dinegative one. In the case of the dinegative solid, there are many cesium ions surrounding the aromatic anion; therefore, it is more difficult for the electrons to jump out than in the case of the mononegative sample.

Some aromatic-alkali metal ion radical salts have been found to have a good catalytic activity for hydrogen-deuterium equilibration, $H_2+D_2=2HD$; this catalytic activity may arise from the excess charge, which participates in forming the chemisorotion bond with H_2 on the ion-radical salt in the solid phase.[15] This proposal is supported by these photoemission results.

On the other hand, we have already reported that the distinction of the valencies on the anion produces a large difference in their catalytic acitvity; the reaction rate for the dinegative ion salt was found to be ten times that of the mononegative ion salt at room temperature.[5,15,16] Although no quantitative correlation between the catalytic acitvity and the photoemissive character as functions of the valencies of the anion can be found, we

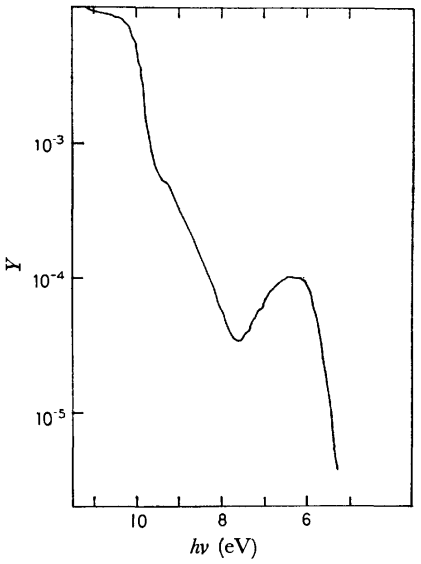

Fig. 8. The spectral response curve of the photoemissive quantum yield for triphenylene-cesium salt in the vacuum ultraviolet region.

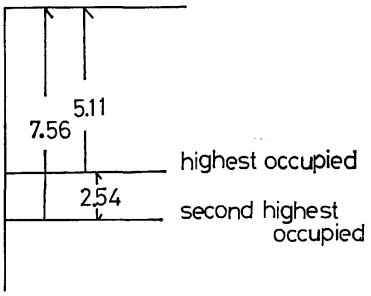
Appendix

The photoemission from the benzonitrile-Cs complex was measured in the vacuum-ultraviolet region. Figure 8 shows the spectral response curve of the photoemissive quantum yield. In the curve, a sharp minimum at the photon energy of 7.65 eV was found. The minimum may be the emission from the second-highest occupied level of the benzonitrile anion. This assumption is supported by the fact that the difference (7.65−5.11=2.54 eV) between the minimum (7.65 eV) and the threshold value (5.11 eV) agrees with the absorption peak of the anion, 490 mμ (2.54 eV), and corresponds to the transition between the highest occupied level and the second highest occupied level, as is shown in the following diagram.



BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 713—716(1972)

Magnetic Properties of Some Iminoxyl Polyradicals. III. Exchange Interaction in Iminoxyl Biradicals

Akira NAKAJIMA, Hiroaki OHYA-NISHIGUCHI, and Yasuo DEGUCHI*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

**College of Liberal Arts and Science, Kyoto University, Kyoto*

(Received September 11, 1971)

The EPR spectra of TEMPAD and Sulfite biradicals in a dilute solution have been reasonably interpreted in terms of the variation in the ratio of the intra-molecular exchange interaction to the ^{14}N hyperfine interaction. Comparing these spectra with the theoretical ones, the authors have estimated the intra-molecular exchange interactions as $10.0 \cdot A = 2 \times 10^{-2} k$ and $3.0 \cdot A = 5 \times 10^{-3} k$ respectively. The magnetic susceptibility of the TEMPAD biradical exhibits a broad maximum at a temperature of 16.5°K, while 50 and 75% TEMPAD diluted in corresponding diamine have no maximum in the temperature range measured. The magnetic susceptibility of the sulfite biradical also shows a broad maximum at 15.0°K, in spite of the weak intra-molecular exchange interaction. These results indicate that the origin of the short-range ordering is the inter-molecular exchange interaction between unpaired electrons in different molecules.

There have been a number of investigations with regard to the magnetic properties of organic, stable free radical solids; these investigations will be adequately introduced elsewhere.[1] In these works, some short-range ordering effects caused by the exchange interaction between unpaired electrons are of special interest. The mechanism of the exchange interaction, namely, intra- or inter-molecular exchange interaction, is also an interesting subject to us.[1]

Previously, the present authors reported the magnetic susceptibility of bis(2,2,6,6-tetramethylpiperidine-4) azine-1,1′-dioxyl (the TEMPAD biradical), which indicates a broad maximum at 16.5°K. In order to explain this result, we assumed a thermal equilibrium between the singlet ground state and the excited triplet

1) A. Nakajima, H. Ohya-Nishiguchi, and Y. Deguchi, This Bulletin, to be published.

state caused by the strong exchange interaction between the two unpaired spins in a molecule. On the basis of this model, one could estimate the exchange parameter as $J=-1.14\times10^{-3}$ eV;[2] however, we could find no evidence supporting the model.

On the other hand, recent EPR studies of other iminoxyl biradicals indicate fairly weak exchange interaction in a molecule which is of the same order as the hyperfine interaction.[3-5] These results are inconsistent with our estimation.

In order to clarify this discrepancy, one should take into account the existence of an inter-molecular exchange interaction in addition to an intra-molecular one. As for the experimental study of these two exchagne mechanisms, one must apply some techniques for the elimination of either intra- or inter-molecular exchange interaction. The present authors have made a couple of experiments along those lines: one of them was the dilution of TEMPAD in a diamagnetic matrix in order to decrease the inter-molecular exchange interaction, and the other was the study of other biradicals with a weak intra-molecular exchange interaction aimed at enhancing the inter-molecular exchange interaction.

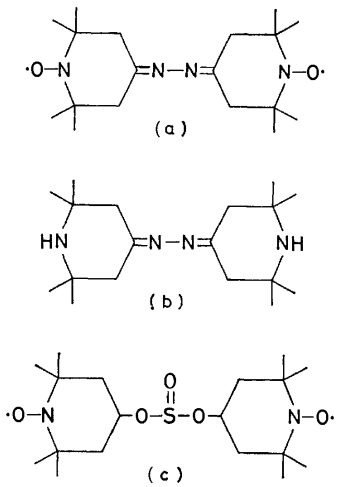


Fig. 1. Molecular structures of the TEMPAD biradical (a), the corresponding diamine (b), and the Sulfite biradical (c).

In this paper, the authors shall report the EPR spectra and the magnetic susceptibilities of the TEPMAD biradical (Fig. 1a) diluted in the corresponding diamine (Fig. 1b) and bis(2,2,6,6-tetramethylpiperidine-4)sulfite-1,1'-dioxyl (the sulfite biradical, Fig. 1c), which has a weak intra-molecular exchange interaction.[4]

Experimental

The TEMPAD biradical and the corresponding diamine were prepared from 2,2,6,6-tetramethyl-4-piperidone (triacetoneamine supplied by the Aldrich Chemicals Co.) following the method described by Rassat *et al.*[6] After purification by chromatography and recrystallization, pure diamine and TEMPAD (mp 139±0.5°C and 182±1.0°C) respectively were obtained. The sulfite biradical was prepared from the TANOL radical (2,2,6,6-tetramethyl-4-hydroxypiperidine-1-oxyl) obtained by the oxidation of the corresponding amine with hydrogen peroxide, following the process of Rozantsev *et al.*[4]

The EPR measurements were carried out using X-band spectrometers, JEOLCO's JES-3BX and JES-P-10, equipped with a 100-kHz field modulation. As a standard sample, peroxylamine disulfonate $[\cdot ON(SO_3)_2]^=$ ($A_N=13.0$ gauss, $g=2.00537$) was used. In all the EPR measurements, the samples were degassed and sealed in glass tubes *in vacuo*.

The static magnetic susceptibility measurements were performed with powder samples of about 50—100 mg over the temperature range of 1.8—273 °K and in magnetic fields of 8—9 kOe, using a torsion balance which has been described elsewhere.[7] The temperature of the samples was determined by means of a Au·Co-Cu thermocouple and a carbon resister set on samples which had been calibrated by means of a standard sample, Mn-Tutton's salt. All the data were corrected for the diamagnetic contributions calculated by the Pascal method, *i.e.* $\chi_{dia}=-2.37\times10^{-4}$ emu/mol for TEMPAD and $\chi_{dia}=-2.62\times10^{-4}$ emu/mol for the sulfite biradical.

Results and Discussion

EPR Spectra. The spin Hamiltonian applied by Lemaire and his co-workers to nitroxide biradicals is:[5,6]

$$\mathcal{H}=g\beta H\cdot S_z+A(S_{1z}I_{1z}+S_{2z}I_{2z})+2|J|(\boldsymbol{S}_1\cdot\boldsymbol{S}_2). \quad (1)$$

The Hamiltonian is expressed in units of h, and the three righthand terms correspond to the Zeeman, hyperfine, and exchange energies. The electron spin operators, $\boldsymbol{S}_i$ and $\boldsymbol{S}_{iz}$, refer to an electron spin wavefunction at the i-th side of the biradical; I_{iz} is the corresponding ^{14}N nuclaer spin operator, and $\boldsymbol{S}$ is the total electron spin operator. One can then show the eigen values of Eq. (1) as:

$$\begin{aligned}
E_{+1}(m_1m_2) &= g\beta H+|J|/2+(A/2)(m_1+m_2)\\
E_{\pm0}(m_1m_2) &= -|J|/2\pm(1/2)D\\
E_{-1}(m_1m_2) &= -g\beta H+|J|/2-(A/2)(m_1+m_2)\\
D^2 &= 4|J|^2+A^2(m_1-m_2)^2 \qquad (D>0)
\end{aligned} \quad (2)$$

and the theoretical EPR absorption energies and the relative intensities as:

i) $m_1\neq m_2$

$$\begin{aligned}
W_{1\pm}(m_1m_2) &= g\beta H+|J|+(A/2)(m_1+m_2)\mp(1/2)D\\
W_{2\pm}(m_1m_2) &= g\beta H-|J|+(A/2)(m_1+m_2)\pm(1/2)D\\
I_{t\pm} &= A^2(m_1-m_2)^2/(D^2+4|J|\cdot D)
\end{aligned} \quad (3)$$

ii) $m_1=m_2$

$$\begin{aligned}
W_3(m_1m_2) &= g\beta H+(A/2)(m_1+m_2)\\
I &= 1
\end{aligned} \quad (4)$$

The theoretical EPR absorption lines for different values $|J|/A$ are of shown in Fig. 2.

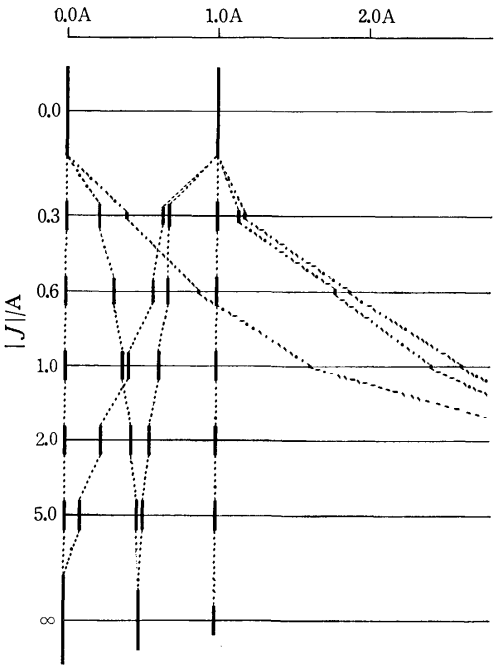

Fig. 2. The theroretical EPR absorption lines for the different values of $|J|/A$.

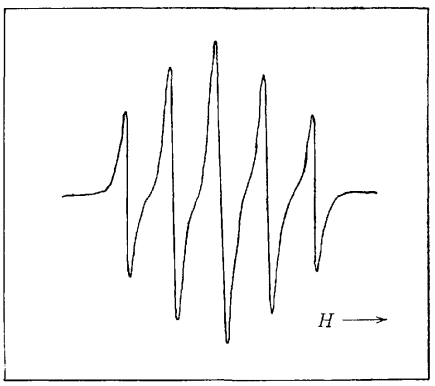

Fig. 3. The EPR spectrum of the TEMPAD biradical in THF solution.

biradical in a tetrahydrofurane (THF) solution at room temperature, as shown in Fig. 3, consists of five lines, with an intensity ratio of 1:2:3:2:1. This result implies that the spectrum corresponds to the case of $|J| \gg A$. The line-width of the center line, however, is considerably broader than that of the four side lines. This is caused by the incomplete superposition of the $W_{1\pm}(\pm 1, \mp 1)$, $W_{2\pm}(\pm 1, \mp 1)$, and W_3 (0, 0) lines. From the line-width of the center line, one can estimate the exchange parameter as $|J| \simeq 10.0 \cdot A = 2 \times 10^{-2} k$ (A= 15.0 gauss).

In the case of the sulfite biradical (see Fig. 4), the EPR spectrum consists seven lines, with an integrated intensity ratio of 1:2:1:1:2:1. This spectrum corresponds to the case of $|J| \sim A$; thus, the exchange energy can be estimated as $|J| \simeq 3.0 \cdot A = 5 \times 10^{-3} k$ (A= 15.6 gauss).

The magnitudes of the intra-molecular exchange interaction estimated from the EPR spectra are listed in Table 1 in units of the hyperfine energy, A. From

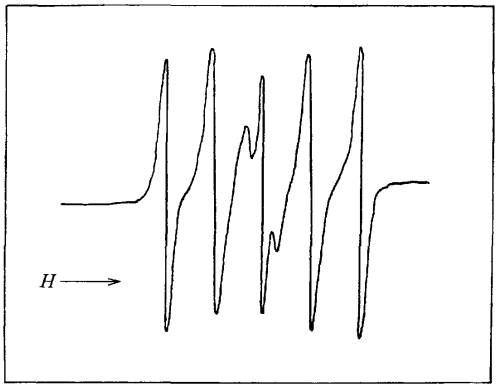

Fig. 4. The EPR spectrum of the Sulfite biradical in THF solution.

Table 1. Magnitude of the intra-molecular exchange interaction of some iminoxyl biradicals in the unit of the hyperfine energy, A.

Biradical	Solvent	Temperature	Magnitude	Reference
TEMPAD	THF	room temp.	10.0	our result
Sulfite	THF	room temp.	3.0	our result
	THF	20°C	2.8	4
Dimethyl-silicate	THF	20°C	1.7	4
Diphenyl-silicate	THF	20°C	6.0	4
Diallyl-silicate	THF	20°C	6.2	4
Carbonate	DMF	0°C	0.92	3
	DMF	−60°C	1.0	3
	n-Hexane	0°C	0.8	5
	CS_2	−100°C	1.1	5
Oxalate	CS_2	−60°C	0.15	5

this table, one can understand that the $|J|$ magnitudes of these biradicals range from 10^{-4} to $10^{-2}k$, that is, that their intra-molecular exchange interactions are fairly weak compared with those estimated from the susceptibility measurements.

Magnetic Susceptibility. The magnetic susceptibility of the 100% TEMPAD biradical *versus* the temperature[1] is shown in Fig. 5. From 273 to 77°K,

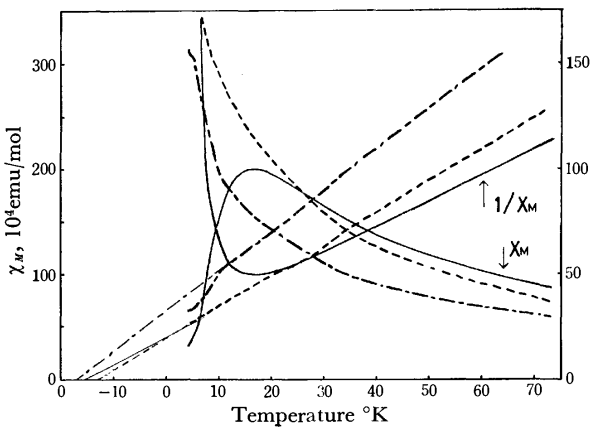

Fig. 5. Temperature dependence of the magnetic susceptibilities (χ_M) and their inverse ($1/\chi_M$) of the diluted TEMPAD biradical;
——: 100%, ----: 75%, and -·--: 50% TEMPAD.

χ_M increases paramagnetically with a decrease in the temperature and obeys the Curie-Weiss law: the Weiss constant is found to be about -15 ± 2°K. When the temperature is lowered further, the χ_M-T curve gradually deviates from the Curie-Weiss law and shows a broad maximum at the temperature of 16.5 ± 0.5°K. χ_M drops rapidly below that temperature. This behavior apparently suggests that a short-range ordering occurs as a result of the negative exchange interaction between unpaired electrons.

If one may apply some practical models, one can calculate the exchange interaction from three experimental values, *i.e.*, the temperature at the broad maximum, the value of χ_M at the broad maximum, and the Weiss constant. These values and the corresponding exchange parameters for the pair and the Ising linear-chain models are listed in Table 2.

The magnetic susceptibilities of 50 and 75% TEMPAD solid solutions diluted with the corresponding diamine, which are shown in Fig. 6, have been corrected for the diamagnetic contributions of the same value as that of the TEMPAD biradical. It should be noted that they show no maximum in the presently adopted temperature range and that their Weiss constants are nearly the same as that of 100% TEMPAD (-13°K for 75% and -16°K for 50%).

The diluted TEMPAD system, we can assume, will consist of two parts; inter-molecular dimers and isolated molecules. On this assumption, the paramagnetic susceptibility can be described as the superposition of these two parts; then, the Weiss constant obtained from the high-temperature region of the $1/\chi_M$-T curve may be to be contributed mainly by the intermolecular dimers. In the low-temperature region, these dimers almost entirely fall into the singlet ground state and the Curie constant is contributed to by only the isolated part. Our experimental results indicate these inclinations. The full details will be given in the following work.

TABLE 2. SOME MAGNETIC CONSTANTS OF 100% TEMPAD BIRADICAL AND CORRESPONDING EXCHANGE PARAMETERS FOR THE PAIR AND THE ISING LINEAR-CHAIN MODELS

	Experimental results	Exchange parameter J (°K)	
		Pair	Ising L-C
T (χ_{max})	16.5 ± 0.5°K	-13.4	-16.8
χ_{max}	$200\pm10\times10^{-4}$ emu	-15	-14
θ	-15 ± 2°K	-30	-15

θ: the Weiss constant

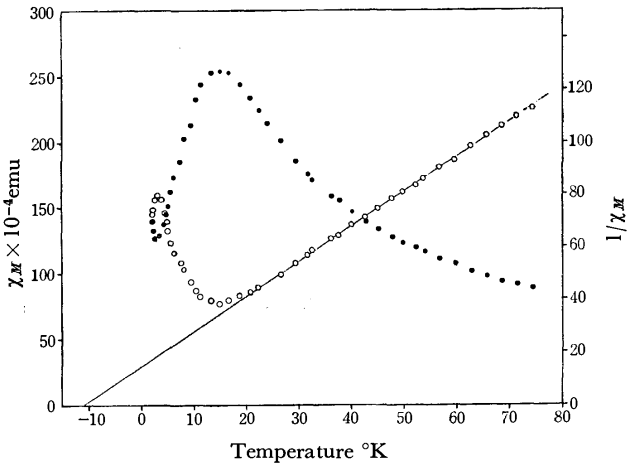

Fig. 6. Temperature dependence of the magnetic susceptibility of the Sulfite biradical;
●: χ_M, ○: $1/\chi_M$.

TABLE 3. SOME MAGNETIC CONSTANTS OF SULFITE BIRADICAL AND CORRESPONDING EXCHANGE PARAMETERS FOR THE PAIR AND THE ISING LINEAR-CHAIN MODELS

	Experimental results	Exchange parameter J (°K)	
		Pair	Ising L-C
T (χ_{max})	15 ± 1°K	-13	-15
χ_{max}	$254\pm10\times10^{-4}$ emu	-19	-18
θ	-11 ± 2°K	-22	-11

θ: the Weiss constant

The magnetic susceptibility of the sulfite biradical shows nearly the same behavior as that of 100% TEMPAD except for the rapid increase below 3°K. In order to explain this behavior, the pair model and the Ising linear-chain model can be applied. The exchange parameters of the models estimated from a comparison with the experimental results are listed in Table 3. Scince the intra-molecular exchange interaction of the sulfite biradical is fairly weak ($5\times10^{-3}k$), the large exchange interaction appearing in the magnetic susceptibility must be attributed to the inter-molecular exchange interaction.

The authors are very much indebted to Professor Hideo Takaki for his continuing guidance and encouragement through this work. They also wish to thank Professor Mamoru Mekata, Dr. Jun Yamauchi, and their collaborators for their helpful advice and discussions.

The Laser Photolysis of Methylene Blue in the Presence of *p*-Chlorophenylglycine

Kinichi Obi and Hiroshi Makino

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received September 20, 1971)

The photoreduction of methylene blue by a ruby laser light has been studied. The kinetic treatment and the measurement of the apparent activation energy show that, under the high-intensity irradiation, the excited triplet state of methylene blue plays a main role in the photoreduction by *p*-chloro phenylglycine. The apparent activation energy of the reduction of methylene blue is reduced from 7.4 to 2.8 kcal as the laser light energy increases from 23 to 530 mJ.

The photoreduction of methylene blue (MB) has been extensively studied by continuous irradiation[1-5] and by flash photolysis.[6-9] From these studies, it has become apparent that the photoreduction of MB by a reducing agent such as *N*-phenylglycines proceeds through the interaction between the lowest triplet state of MB and the reducing agent.

In a previous paper,[10] the saturation of the light absorption was observed using a giant-pulse ruby laser. Under such circumstances, the photoreduction of MB in the presence of dimethyl-phenylglycine (DMPG) has been proposed to take place through the excited triplet state of MB, which itself results from the subsequent photon absorption by the lowest triplet state.

The present paper is concerned with the reinvestigation of the excited triplet-state mechanism of MB using *p*-chloro-phenylglycine (*p*-CPG) as the reducing agent, for it is a mild reductant; the quantum yield of the photoreduction[2] of MB by *p*-CPG of an infinite concentration is 0.185, while that by DMPG is 0.388 at pH 7.0. Furthermore, new experimental proof of the excited-triplet-state mechanism was obtained from the apparent activation energies of the reduction of MB corresponding to two kinds of triplet states.

Experimental

The ruby laser head used in this work was the NEC model O-N583, which accommodates a ruby rod 8 mm in diameter and 150 mm long. The Q-switch accomplished by using an ethanol solution of cryptocyanine. The laser pulse 6943 Å was *ca.* 20 nsec in duration and had an energy of *ca.* 530 mJ, which corresponds to 1.85×10^{18} photons. The cross-sectional area of the laser beam was *ca.* 0.25 cm^2. Several neutral density filters, whose transmittance percentages were calibrated for the laser light, were used to reduce the light intensity. The quartz reaction cell used was cylindrical, 13 mm in diameter and 18 mm in path length.

Commercially available MB was obtained from the Koso Chem. Co. and was recrystallized from ethanol and water. The *p*-CPG was kindly offered by Professor Shiro Matsumoto. Dye solutions were prepared in borate buffer solutions in order to keep the pH at 8.0, at which the quantum yield of the photoreduction was at its maximum.[2,3] Degassing was carried out by freeze-pump-thaw cycles. The concentrations of MB were determined from the reported extinction coefficient[11] at the absorption peak ($\varepsilon=9.5\times10^4$ at 665 mμ). The energy of the laser pulse was measured by means of a TRG-100 thermopile. The temperature of the reaction cell was regulated by means of an electric furnace.

Results and Discussion

The transmitted light intensity (I_T) was measured as a function of the incident light intensity (I_0) for the MB solution without the reducing agent; the results are shown in Table 1. No reaction was observed under the laser-pulse irradiation. Using the value of 1.3×10^4 as the extinction coefficient of MB[11] at 6943 Å, the I_T/I_0 ratio was estimated to be 0.70 for the 6.6×10^{-6} M solution. However, the experimental results show a much higher transparency than the value estimated above. This indicates that the saturation of the laser light absorption is realized in the MB solution without the reducing agent. Since the radiative lifetime of the MB singlet-excited state is estimated to be 9.8 nsec from the spectral data[11], and since the fluorescence quantum yield is quite low,[12] the actual lifetime of this state is at least an order of magnitude smaller

Table 1. The transmittance of MB solution and the number of absorbed photons as a function of the dose light intensity

I_0 (mJ)	I_T (mJ)	I_T/I_0	$N_{abs.}$ (photons/molecule)

than the radiative lifetime. Actually, the fluorescence lifetime of MB has been directly measured to be 0.4 nsec using a mode-locked He-Ne laser.[13] This short lifetime indicates that the intersystem crossing rate is quite fast. Thus, in an early stage of the laser-pulse duration, almost all the MB molecules are probably stored in the lowest triplet state. As the absorption coefficient of the lowest triplet state is lower than that of the ground state[14] at 6943 Å, the saturation of the laser-light absorption results from the absence of the ground-state molecules in the pulse duration.

The last column in Table 1 shows the number of photons absorbed (N_{abs}) by each MB molecule. The number of photons absorbed increases with the light intensity; at 530 mJ, one MB molecule absorbs nearly 90 photons. This may be interpreted by the following repetitive process. An MB molecule in the lowest triplet state is excited to the higher triplet state by photon absorption, followed by relaxation to the lowest triplet state in its lifetime, that is, the order of 10^{-11} -10^{-12} sec; it may then absorb another photon. According to the repetitive process, the apparent lifetime of the excited triplet state is extended to 10^{-9} -10^{-10} sec at a high intensity of laser light.

When *p*-CPG was added to the MB solution as a reducing agent, the photoreduction of MB was observed by means of laser-light irradiation. Flash photolysis studies[7-9] have shown that the photoreduction of MB is accomplished through the lowest triplet state of MB. Therefore, the reaction scheme may be shown as follows:

where S_0, S_1, and T_1 are the ground state, the excited singlet state, and the lowest triplet state of MB respectively. According to this mechanism, the following equation is obtained:

$$\frac{1}{A} = \frac{1}{T}\left\{\frac{k_s}{k_1}\cdot\frac{1}{[p\text{-CPG}]} + \left(1+\frac{k_2}{k_1}\right)\right\} \quad (1)$$

where A is the quantity of MB reduced and T is total amount of MB converted to the triplet state. The plots of $1/A$ against $1/[p\text{-CPG}]$ fall on straight lines at various laser-light intensities, as is shown in Figs. 1 and 2 at 25 and 50°C respectively.

Equation (1) also indicates that the ratio of the intercept to the slope $(k_1+k_2)/k_s$ should be independent of the light intensity. Table 2 shows the values of $(k_1+k_2)/k_s$ for *p*-CPG, together with those for DMPG.[10] The values obtained with ordinary light[2] are also included. At a low intensity, this ratio is $1.1\times10^5\text{M}^{-1}$ for 8 mJ at 25°C and $4.7\times10^4\text{M}^{-1}$ for 23 mJ at 50°C.

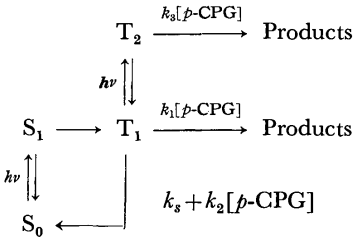
101 mJ		$14\times10^4\text{M}^{-1}$
45		5.7
4.4		2.8
Ordinary light[a]		40°
		$3.37\times10^4\text{M}^{-1}$

a) See Ref. 2

These values are compared with the value for the ordinary light given by Matsumoto.[2] However, this ratio increases with the dose intensity; in case of *p*-CPG, increases of 30 and 70% are observed with an increase in the dose energy from the lowest values to 530 mJ at 25 and 50°C respectively. These values are much smaller than that for DNPG, for which a five-fold increase was observed with the increase in the energy from 4.4 to 101 mJ.

In case of DMPG, the increase in the $(k_1+k_2)/k_s$ ratio with the laser-light intensity is interpreted as the result of the contribution of MB in the excited triplet state.[10] If this is the case for *p*-CPG, the reaction scheme can tentatively be written as follows:



According to the above mechanism, the following equation is obtained:

$$\frac{1}{A}=\frac{1}{T(1+a)}\left\{\frac{k_s}{k_1+bk_3}\frac{1}{[p\text{-CPG}]}+\left(1+\frac{k_2}{k_1+bk_3}\right)\right\} \quad (2)$$

where $a=[T_2]/[T_1]$ and $b=\int[T_2]\,dt/\int[T_1]\,dt$. At a low intensity, $a\to 0$, $b\to 0$, and Eq. (2) is identical with Eq. (1). From Eq. (2), it can be understood why the ratio of the intercept to the slope increases with the dose intensity.

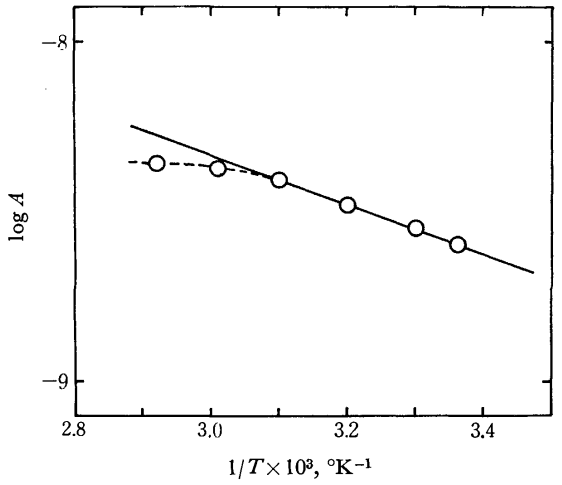


Fig. 3. The typical Arrhenius plot of the reduced MB at 530 mJ. The concentration of *p*-CPG is 10^{-4} M.

The photoreduction of MB was carried out at a rising temperature. Figure 3 shows a typical Arrhenius plot of the quantity of the reduced MB at the dose intensity of 530 mJ. At temperatures lower than 50°C, the plots give a straight line. The apparent activation energy is obtained from the straight part of the Arrhenius plots. It is not clear why the curve deviates from straight line in the temperature region higher than 50°C. The apparent activation energy of the reduction of MB was obtained by varying the laser-light intensity. The results are shown in Fig. 4. The curve shows a decline with an increase in the dose energy up to 270 mJ, while it becomes flat at energy higher than 270 mJ.

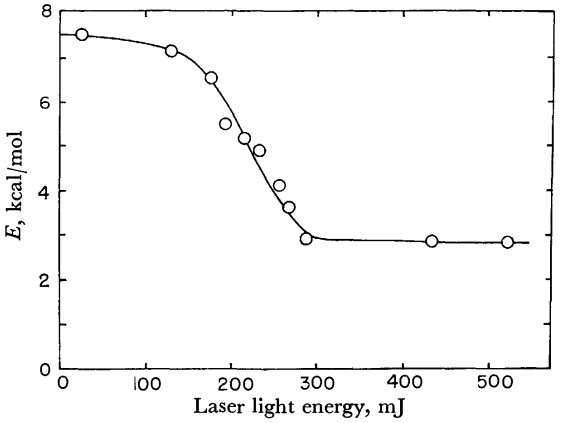

Fig. 4. The apparent activation energy *vs.* the laser light intensity. The concentration of *p*-CPG is 10^{-4}M.

It is supposed that the photoreductions through both the lowest triplet state and the excited triplet state contribute to the apparent activation energy. The activation energy extrapolated to zero light intensity should correspond to the activation energy for the lowest triplet state; it is estimated to be 7.4 kcal mol^{-1}. Since the apparent activation energy of the reaction through the excited triplet state is expected to be lower than that for the lowest triplet state, the decline in the activation energy with the laser intensity is thought to result from the contribution of the reduction of MB through the excited triplet state.

At energy higher than 270 mJ, the apparent activation energy is constant. This can be interpreted by the mechanism in which the reduction mainly occurs through the excited triplet state. Thus, the activation energy in this region would correspond to that of the reduction through the excited triplet state; it can be estimated from Fig. 4 to be 2.8 kcal mol^{-1}.

It is interesting to ascertain the nature of T_2, which was tentatively called the excited triplet state in the previous discussion. As has been mentioned above, the effective lifetime of T_2 is estimated to be 10^{-9}—10^{-10} sec in the absence of the reducing agent at the high-laser intensity, while it is estimated from the diffusion theory that a MB molecule collides with *p*-CPG molecules every 1.4×10^{-6} sec when the concentration of *p*-CPG is 10^{-4} M. This interval between collisions is much longer than the effective lifetime of the excited triplet state. Provided the photoreduction occurs as a result of direct interaction between the excited triplet states of MB and *p*-CPG, the reactionary radii must be about 100 times larger than the diffusional radii. However, if a molecular complex is formed between MB in the lowest triplet state and *p*-CPG, the MB in the excited triplet state may have a better chance to encounter *p*-CPG than would be expected from the simple diffusion theory. This may be the reason why the photo-

reduction occurs during the short effective lifetime of the excited triplet state.

An alternative interpretation of the nature of T_2 is as follows. When the MB molecule in the excited triplet state relaxes to the lowest triplet state, the electronic excitation energy is consumed in heating the solvent around the MB molecule. If the rate of the heat dissipation is slower than the rate of the heat formation by relaxation, the solvent around the MB molecule is locally heated by the repetitive photo-absorption: thus, the activation energy apparently decreases with a rise in the temperature. Since the apparent activation energy decreases from 7.4 to 2.8 kcal with an increase in the dose intensity, the average temperature of the reaction site is estimated to be 520°C.

At the present stage, it is not possible to determine which mechanism is operative in the photoreduction of MB. However, the long-range interaction proposed in the former case seems to be unreasonable in this case. Thus, we may suppose that the complex mechanism or the temperature effect is responsible for the reduction of MB.

The authors wish to express their thanks to Professors Ikuzo Tanaka and Yuji Mori for their helpful advice and support during the course of this work. They are also grateful to Professor Shiro Matsumoto for help in obtaining the compound used in this study.

(Received September 21, 1971)

Nanosecond time-resolved fluorescence spectra were measured at 77°K for pyrene and perylene crystals, and anomalous emissions which have lifetimes of ~8 nsec and are difficult to be found by the usual steady excitation, were observed at the higher-wave number sides of the usual excimer emissions. From the band position and the vibrational structure, the anomalous emission was interpreted as being due to monomer defects in each crystal. The analysis of the observed rise and decay curves of the monomer defect and excimer emissions shows that the excited states of both emissions are populated independently from the band level of each crystal excited by light irradiation. The temperature dependence of the emission indicates that a thermal activation of 0.035 eV is required for the excimer formation in a perylene single crystal, while no activation energy is required for the excitation of the monomer defect.

Excimer fluorescences from crystals of aromatic compounds were studied by various investigators[1-5] and were found to be observed for only dimeric crystals, such as pyrene and perylene, in which the molecules exist in pairs.[3] Birks, Kazzaz, and King[5] observed the time dependence of the excimer fluorescence of the pyrene crystal. According to their findings, the excimer is formed at 293°K within one nanosecond after the excitation. Beside the excimer band, a partially-structured anomalous emission band was observed with the microcrystalline layer of pyrene.[2,5] The band was assigned by Birks *et al.* to an emission from surface monomer defects excited by the encounter with excimer excitions.[5]

An anomalous fluorescence band with a vibrational structure was also observed by Tanaka for a single crystal of perylene at low temperatures below 50°K.[4] This band is very similar in position and shape to the monomeric perylene band and was assigned to a monomer emission. Tanaka assumed that the excimer state was populated *via* an excited monomer state and estimated the potential barrier of the process to be 285 cm^{-1} from an analysis of the observed temperature dependence of the excimer emission.[4] According to this mechanism, the excimer emission may be expected to have a rise time which corresponds to the decay time of the monomer emission.

Under these circumstances, we have undertaken to study, by the nanosecond time-resolved spectroscopy technique, the rise and decay processes of fluorescent states of pyrene and perylene, in order to clarify the nature of the anomalous fluorescence and the energy-transfer mechanism in both dimeric crystals.

sublimation of a synthetic material.[6] A single crystal of perylene was obtained by recrystallization from the toluene solution.

Nitrogen Gas Laser. A pulsed, coaxial-type nitrogen gas laser[7,8] was built as an exciting source. The discharge voltage of the laser is about 30 kV, and the pressure of nitrogen is approximately 4 Torr. Coaxial transmission lines are used as a condenser for the discharge. The wavelength of the laser emission is 3371 Å, and the laser pulse has a duration of approximately 3 nanoseconds, with a peak power of about 20 kW. The repetition rate is 20 Hz, and the oscillatory behavior is quite regular.

Fluorescence Measurements. Fluorescence spectra were measured by means of a Bausch and Lomb monochromator, being detected by an RCA 1P28 photomultiplier. By means of the repetitive operation of the laser, the sampling technique was used to measure the time-resolved spectra, a Tektronix 3S1 sampling oscilloscope being used. By setting the delay of a Tektronix 3T77A sampling sweep unit at a fixed time, a time-resolved spectrum was obtained by scanning the wavelength and recording the average photocurrent. The spectral response of the photomultiplier was not calibrated.

The laser light was attenuated by filters in order to prevent the excition-exciton interaction which causes a remarkable change in the decay characteristics of the fluorescences.[9-11]. A Toshiba UV-39 filter was set in front of the monochromator entrance slit in order to eliminate scattered laser light. For the purpose of analyzing the initial rise of emission, the exact pulse shape of the laser was measured by a Hamamatsu TV R317 biplanar photodiode and the sampling oscilloscope. The time resolution of the system was estimated to be about 0.5 nsec. A 3650 Å line from a high-pressure mercury lamp was used for the measurement of the fluorescence spectra by means of steady excitation.

Results and Discussion

Time-resolved Fluorescence Spectra and Lifetimes. Nanosecond time-resolved fluorescence spectra were measured at 77°K for perylene and pyrene single crystals; the results are shown in Figs. 1 and 2, respectively. Fluorescence spectra observed by the steady-excitation technique for both crystals are also shown in these figures for purposes of comparison. Furthermore, the fluorescence lifetimes measured for both crystals at 293°K and 77°K are listed in Table 1. This table also includes the wave numbers of the observed fluorescence maxima. Two fluorescence spectra with different lifetimes were observed at 77°K for each crystal: one is at shorter wavelengths and is short-lived, while the other is at longer wavelengths and is long-lived.

By the steady-excitation technique, the short-lived emission is difficult to be observed distinctly for the single crystals in the temperature range from 77°K to 293°K. This is because it has a relatively low fluorescence quantum yield in this temperature range. By the nanosecond time-resolved spectroscopy technique, however, we can observe separately each of the short-lived and long-lived components of the emission spectrum. For example, the fluorescence spectrum of the perylene single crystal, observed 4 nsec after the trig-

ger pulse, has an intense structured band at ~19000 cm^{-1} besides the band at ~17000 cm^{-1} which still remains in the fluorescence spectrum observed 20 nsec after the trigger pulse. The long-lived components are identified with the excimer fluorescences for the following reasons: (1) the lifetime of the emission at longer wavelengths of the pyrene crystal at 77°K, 180 nsec, is very close to that of the excimer emission obtained by Birks, Kazzaz, and King[5] (185 nsec); and (2) in both crystals, the time-resolved spectra of the long-lived emission coincide in their positions and shapes with the corresponding excimer fluorescence spectra obtained by the steady excitation.[1-5] The short-lived fluorescence at ~19000 cm^{-1} is very similar to that observed with the monomeric (β-type) perylene crystal and can safely be assigned to the excited monomer.[4]

Concerning the pyrene single crystal, in addition to the excimer fluorescence at 21500 cm^{-1}, the short-lived emission was observed at 25300 cm^{-1} in the spectrum 10 nsec after the trigger pulse. The latter is similar to the spectrum due to the monomer defect observed by Birks *et al.*[2,5] with a very thin film of pyrene.

The emissions at shorter wavelengths observed for both single crystals are anomalous in the sense that they are distinctly observed only by the nanosecond time-resolved spectroscopy technique at 77°K. On the other hand, when thin evaporated films are used instead of the single crystal, the anomalous emission can be observed by the steady-excitation technique for both aromatic hydrocarbons, even at room temperatures.

Examination of the Previous Mechanisms of the Anomalous Emissions. The two mechanisms were presented previously by Birks *et al.* and by Tanaka for the anomalous emissions observed for the pyrene and perylene crystals, respectively.

First, let us consider the mechanism presented by Birks *et al.*[5] If the anomalous emission of the pyrene crystal is assumed to originate from excited surface monomer defects which are populated by the encounter with excimer excitons,[5] the anomalous fluorescence should have a rise time comparable to the decay time of the excimer exciton. The time dependence of the anomalous emission observed with pyrene crystals at 25000 cm^{-1} at 77°K is shown in Fig. 3. The rise time of the anomalous fluorescence is very short compared with the decay time of the excimer fluorescence. This clearly contradicts the mechanism presented by Birks *et al.*

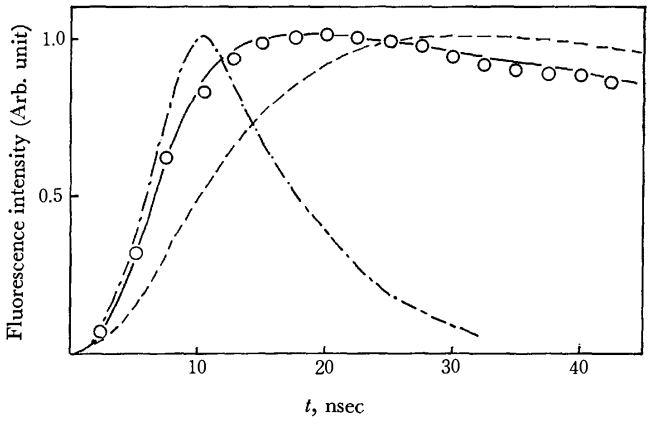

Fig. 3. Time dependence of the fluorescence of a pyrene crystal:——, calculated for the excimer fluorescence based on the present mechanism;----, calculated for the excimer fluorescence based on the mechanism presented by Tanaka; ·–·–, observed curve for the monomer defect fluorescence; –○– observed points for the excimer fluorescence at 77°K.

We will check, from the kinetic point of view, the mechanism presented by Tanaka, which is schematically shown as follows:

$$\mathrm{M} \xrightarrow[①]{h\nu} \mathrm{M}^* \xrightarrow[④]{\mathrm{M}} \mathrm{E}$$
$$②\swarrow \quad ③\searrow \quad ⑤\swarrow \quad ⑥\searrow$$

Here, processes ①, ②, ③, ④, ⑤, and ⑥ are respectively concerned with the excitation of the monomer M, the radiative and radiationless decay processes of the excited monomer, M*, the excimer formation process, and the radiative and radiationless decay processes of the excimer, E. According to this mechanism, the exciton concentrations of the monomer and excimer under pulse excitation may be represented as follows:

$$\mathrm{d[M^*]}/\mathrm{d}t = I(t) - (k_2+k_3+k_4[\mathrm{M}])[\mathrm{M^*}] \quad (1)$$

$$\mathrm{d[E]}/\mathrm{d}t = k_4[\mathrm{M^*}][\mathrm{M}] - (k_5+k_6)[\mathrm{E}] \quad (2)$$

Here, [M*], [E], and [M] represent the concentrations of the corresponding specimens, k_n is the rate constant for the above-mentioned process n, and $I(t)$ is the rate of the generation of singlet monomer excitons, which may be expected to be proportional to the intensity of an incident light pulse. Equations (1) and (2) can be solved as follows:

$$[\mathrm{M^*}] = \exp(-t/\tau_\mathrm{M})\int_0^t \exp(\xi/\tau_\mathrm{M})I(\xi)\mathrm{d}\xi \quad (3)$$

$$[\mathrm{E}] = \exp(-t/\tau_\mathrm{E})\int_0^t \exp((1/\tau_\mathrm{E}-1/\tau_\mathrm{M})\xi)\mathrm{d}\xi \times \int_0^\xi \exp(\eta/\tau_\mathrm{M})I(\eta)\mathrm{d}\eta \quad (4)$$

Here, τ_M and τ_E are the lifetimes of the monomer and excimer defined as $1/\tau_\mathrm{M}=k_2+k_3+k_4[\mathrm{M}]$ and $1/\tau_\mathrm{E}=k_5+k_6$, respectively. The monomer and excimer fluorescences are proportional to the concentrations of the monomer and excimer excitons, respectively. The equations were numerically integrated using the experimentally-determined shape of $I(t)$ and the measured lifetimes shown in Table 1. It is necessary to consider the distortion in the observed fluorescence time-dependence curve due to the inability of the measuring circuit to follow an extremely fast rise. The actual method for correcting the distortion by the aid of a simple theory of the four-terminal network will be described in the Appendix. The time dependence of the excimer fluorescence was evaluated by applying Eq. (4) to the perylene crystal at 77°K; the result is shown by a broken line in Fig. 4. In this figure, the observed result is also shown by open circles for the purpose of comparison. A marked discrepancy exists between the calculated and experimental results. A similar discrepancy was also found for the pyrene crystal, as clearly seen in Fig. 3.

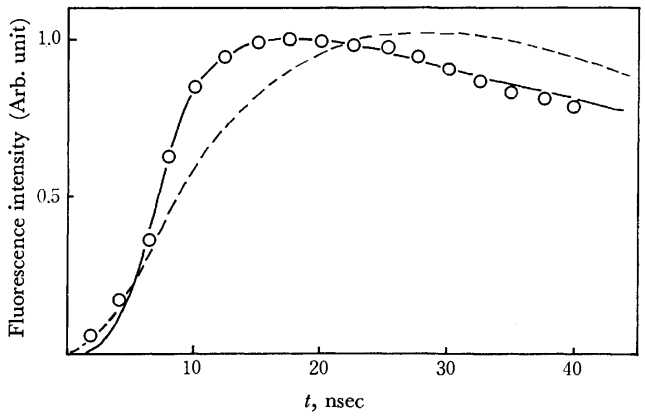

Fig. 4. Time dependence of the excimer fluorescence of a perylene crystal:—, calculated based on the present mechanism;----, calculated based on the mechanism presented by Tanaka; —○—, observed points at 77°K.

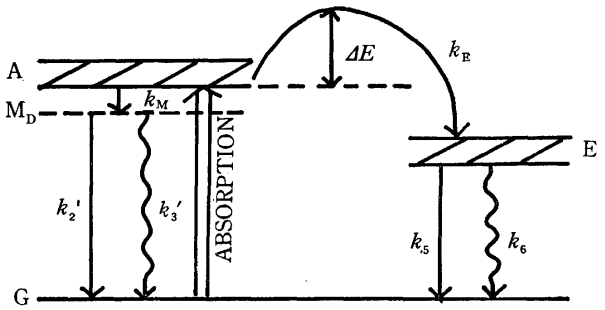

Fig. 5. Schematic diagram representing the mechanism of the excimer and the defect fluorescence of perylene and pyrene crystals.

It is obvious that neither of the two mechanisms presented previously can explain the rise and decay processes of the emissions of pyrene and perylene crystals.

A New Mechanism for the Excimer and Anomalous Emissions. Here, we propose a new mechanism for the appearance of the monomer defect and excimer fluorescences. (see Fig. 5). Crystals are excited to a band whose excitation energy corresponds to the photon energy of 29700 cm^{-1} of the nitrogen gas laser. After the excitation, a slight change in the orientation of paired molecules may take place in the formation of the excimer fluorescent state. The rate constant, k_E, for this process can be represented by $k_E=k_{EO}\exp(-\Delta E/kT)$, where ΔE is a potential barrier for this process and where k_{EO} is a temperature-independent constant. A relaxation to the monomer-defect states also takes place from the excited band level with the rate constant k_M, which has been experimentally determined to be temperature-independent. Actual dimeric crystals contains a number of defect sites occupied by "unpaired" molecules, particularly at the crystal surface. In the perylene crystal, the most intense component around 19000 cm^{-1} of the defect emission corresponds to the 0—1 band of the perylene-monomer emission, while the 0—0 band appears near 20000 cm^{-1} [12] and its intensity is considerably reduced by reabsorption.

12) K. Kawaoka and D. R. Kearns, *J. Chem. Phys.*, **45**, 147 (1966).

The following rate equations are obtained according to the new mechanism:

$$d\rho/dt = I(t) - (k_M+k_E)\rho \quad (5)$$

$$d[M_D]/dt = k_M\rho - (k_2'+k_3')[M_D] \quad (6)$$

$$d[E]/dt = k_E\rho - (k_5+k_6)[E] \quad (7)$$

Here, ρ is the exciton population in the excited band level, and the population of the monomer defect is represented by $[M_D]$. The rate constants k'_2 and k'_3 stand for those of the radiative and radiationless deactivations of the defect state, respectively, while k_5 and k_6 stand for those of the excimer state. Since k_M and k_E are much larger than k'_2, k'_3, k_5, and k_6, the stationary state condition may safely be applied to Eq. (5). Thus, the two concentrations $[M_D]$ and [E] can be expressed as:

$$[M_D] = k_M/(k_M+k_E)\exp(-t/\tau_M)\int_0^t \exp(\xi/\tau_M)I(\xi)d\xi \quad (8)$$

and

$$[E] = k_E/(k_M+k_E)\exp(-t/\tau_E)\int_0^t \exp(\xi/\tau_E)I(\xi)d\xi \quad (9)$$

Here, τ_M and τ_E are the lifetimes of the defect and excimer emissions, defined as $1/\tau_M=k'_2+k'_3$ and $1/\tau_E=k_5+k_6$. The rise curve of the excimer fluorescence was obtained by the numerical integration of Eq. (9) using the measured lifetime and the shape of the laser pulse. The curve obtained for the perylene crystal at 77°K is shown by a solid line in Fig. 4; it is in good agreement with the experimental results. The same mechanism was also applied to the pyrene crystal, with a good agreement between the calculated and observed rise curves, as is shown in Fig. 3. These results show that, in both crystals, the excimer excitons are not produced *via* the excited monomer; rather, both excited states are populated independently from the band levels of the crystals excited by the light irradiation.

Temperature Dependence of Emissions. According to our new mechanism, the intensity ratio of the excimer fluorescence to the anomalous fluorescence obtained by the steady excitation, I_E/I_M, can be written as:

$$I_E/I_M = k_Ek_5(k_2'+k_3')/k_Mk_2'(k_5+k_6) \quad (10)$$

The experimental value, τ_E^{-1}, can be expressed[5] by the sum of the temperature-dependent and temperature-independent rate constants:

$$\tau_E^{-1} = k_5 + k_6 = k_5 + k_6' + k_6^0\exp(-\Delta W/kT) \quad (11)$$

where k_6^0, k'_6, and ΔW are the frequency factor, the temperature-independent rate constant, and the activation energy. The plots of $\ln(\tau_E^{-1}-k_5-k'_6)$ *versus* $1/T$ give a linear relation, as shown in Fig. 6, with $k_5+k'_6=1.2\times10^7$ sec^{-1} and $\Delta W=680$ cm^{-1} for the perylene crystal. This may be compared with the value of $\Delta W=530$ cm^{-1} for the pyrene crystal given by Birks, Kazzaz, and King.[5] The results show that the exponential term may be disregarded in the temperature range below 100°K and that, therefore, k_5+k_6 may be regarded as temperature independent in this temperature range. Furthermore, the present experiment shows that the lifetime of the monomer-defect emission is temperature independent between 77—135°K within the limits of experimental error. Since the radiative

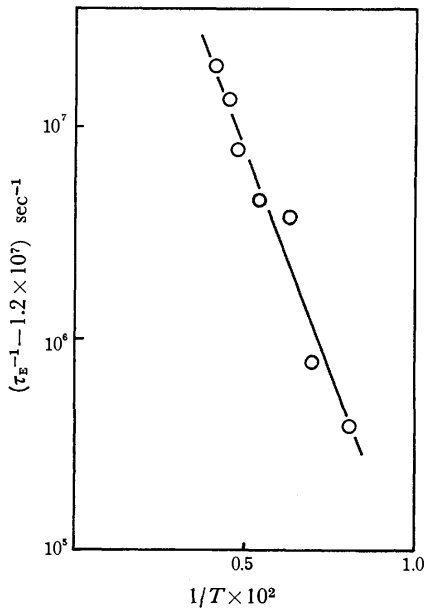

Fig. 6. Temperature dependence of the excimer fluorescence lifetime of a perylene crystal. Semilogarithmic plots of $(\tau_E^{-1}-1.2\times10^7)$ *versus* $1/T$.

rate constants may reasonably be assumed to be temperature independent, the temperature dependence of I_E/I_M given by Eq. (10) actually shows that of k_E/k_M.

To elucidate the natures of k_M and k_E, the temperature dependences of $k_E/(k_M+k_E)$ and $k_M/(k_M+k_E)$ were measured for the perylene crystal between 92—220°K and between 83—135°K, respectively. These values can be obtained by measuring the fluorescence intensity divided by the lifetime, *i.e.*,

$$I_E/\tau_E = C_1(k_E/(k_M+k_E))(k_5/(k_5+k_6))(k_5+k_6) = C_1k_Ek_5/(k_M+k_E) \quad (12)$$

In a similar way,

$$I_M/\tau_M = C_2k_Mk_2'/(k_M+k_E) \quad (13)$$

Here, C_1 and C_2 are temperature-independent constants. The fluorescence intensities, I_E and I_M, can be written as follows:

$$I_E = \int d\nu\int_0^\infty F_{E\nu}(t)dt \qquad I_M = \int d\nu\int_0^\infty F_{M\nu}(t)dt \quad (14)$$

where $F_{E\nu}(t)$ and $F_{M\nu}(t)$ are the time dependences of the excimer and monomer-defect fluorescences at a wave number, ν. The integrals for I_E and I_M with respect to the wave number are performed over the excimer- and defect-emission bands, respectively. Setting $F_{E\nu}(t)=F_{E\nu}^{t_0}\exp((t_0-t)/\tau_E)$ and $F_{M\nu}(t)=F_{M\nu}^{t_0}\exp((t_0-t)/\tau_M)$, where $F_{E\nu}^{t_0}$ and $F_{M\nu}^{t_0}$ are the fluorescence intensities at $t=t_0$, we can obtain:

$$I_E/\tau_E = \exp(t_0/\tau_E)\int F_{E\nu}^{t_0}d\nu \qquad I_M/\tau_M = \exp(t_0/\tau_M)\int F_{M\nu}^{t_0}d\nu \quad (15)$$

Therefore, the temperature dependence of $k_E/(k_M+k_E)$ was obtained by integrating each of the time-resolved spectra (at a fixed time, t_0) of the excimer observed at several different temperatures and by being multiplied by $\exp(t_0/\tau_E)$. Since, according to our experiment, the monomer-defect emission exhibits no change in its position and shape in the temperature range of 77—

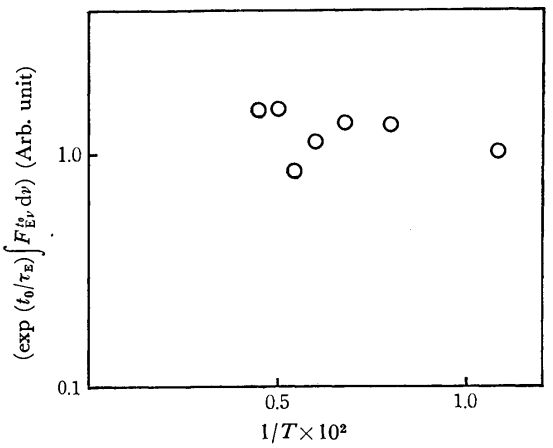

Fig. 7. Temperature dependence of the excimer fluorescence intensity of a perylene crystal obtained by the integration of time-resolved spectra at 20 nsec delay. Semilogarithmic plots of $(\exp(t_0/\tau_E)\int F_{E\nu}^{t_0}d\nu)$, $t_0=20$ nsec *versus* $1/T$.

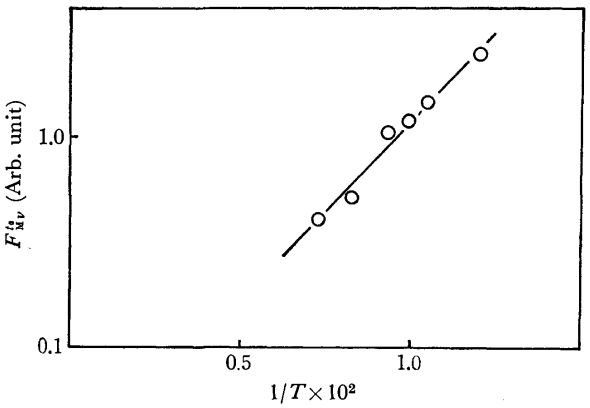

Fig. 8. Temperature dependence of the peak intensity of the defect fluorescence of a perylene crystal. Semilogarithmic plots of $F_{M\nu}^{t_0}$, $t_0=4$ nsec *versus* $1/T$.

135°K, the temperature dependence of $k_M/(k_M+k_E)$ was measured by observing the emission intensity 4 nsec after a trigger pulse at 19000 cm^{-1}. The results are shown in Figs. 7 and 8. The plots of $\ln(k_M/(k_M+k_E))$ *versus* $1/T$ in the temperature range of 96—135°K give a straight line, with an activation energy of $\Delta E=280$ cm^{-1}. On the other hand, $k_E/(k_M+k_E)$ is almost independent of the temperature within the range of 92—220°K. This directly indicates the inequality relation $k_E \gg k_M$ in this temperature range. The temperature dependences of $k_M/(k_M+k_E)$ and $k_E/(k_M+k_E)$ show that the monomer defect emission is intense at lower temperatures, while the excimer emission is almost constant at the temperatures above 90°K. This is in good agreement with the results obtained by the steady-excitation experiment. The results are also consistent with the fact that the quantum yield of the monomer defect emission is relatively small.

The activation energy thus obtained is in agreement with that obtained previously by the steady-excitation experiment,[4] but the mechanism of energy transfer should be reinterpreted according to the present mechanism.

Emissions from the Thin Films of Perylene and Pyrene. In a thin evaporated film which has a much higher concentration of the monomer defect relative to the regular site than a single crystal, the defect emission may be expected to be observed easily by the steady excitation at as high a temperature as 77°K. This is actually the case for a perylene evaporated film (thickness ~0.3 μm), and its peak intensity at 19000 cm^{-1} is comparable with the excimer fluorescence intensity at 77°K. The monomer-defect emission was also observed for a pyrene-evaporated layer.[2,5]

We wish to express our thanks to Dr. M. Geller of the U.S. Naval Electronics Laboratory Center for his kind suggestions about making a coaxial transmission line nitrogen gas laser. We are also greatly indebted to Professor S. Iwashima, Meisei University, and Professor H. Inokuchi, The University of Tokyo, for their kindness in providing us with synthetic materials. Our thanks are also due to Dr. M. Takami, The Institute of Physical and Chemical Research, and Mr. T. Kobayashi for their helpful discussions.

Appendix

The correction for the measured time dependence of the fluorescence was made as follows. An integration circuit assumed for the detector system including the photomultiplier and the oscilloscope, consists of a resistor, R, and a capacitor, C, as shown schematically in Fig. 9. From the theory of the four-terminal network, the ratio of the Fourier-transformed output signal, $G(\omega)$, to the input signal, $F(\omega)$, is given by:

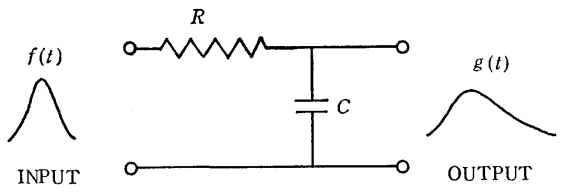

Fig. 9. A model circuit containing a resistor R and a capacitor C of the measuring system.

$$G(\omega)/F(\omega) = 1/(1+i\omega CR) \tag{A1}$$

where

$$F(\omega) = \int_0^\infty dt \exp(-i\omega t) f(t),$$

$$G(\omega) = \int_0^\infty dt \exp(-i\omega t) g(t), \tag{A2}$$

and $f(t)$ and $g(t)$ are the time dependences of the input and output signals, respectively. The output signal, $g(t)$, is obtained by an inverse transformation of $G(\omega)$ and by the aid of the equation (A1):

$$g(t) = (1/CR) \exp(-t/CR) \int_0^t f(\xi) \exp(\xi/CR) d\xi \tag{A3}$$

By the aid of Eq. (A3), the time constant, CR, can be determined in such a way that the integration of the experimentally-determined $f(t)$ fits into $g(t)$ as well as possible. Both $f(t)$ and $g(t)$ were obtained by observing the same laser pulse by a fast photodiode and a 1 GHz sampling oscilloscope, and by a photomultiplier and an 80 MHz oscilloscope, respectively. The actual integration of $f(t)$ fits well into $g(t)$ over a wide range of t with CR=3.5 nsec, suggesting that the original assumption is correct.

The Dye-sensitized Photooxygenation of Hexamethyleneammonium Hexamethylenedithiocarbamate by Xanthene Dyes

Toshihiro YAMASE, Hiroshi KOKADO, and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 5, 1970)

The photoelimination of hexamethyleneammonium hexamethylenedithiocarbamate (HMTC)[1] can be sensitized by xanthene dyes, such as rose bengal and eosine yellowish. In contrast to the direct photolysis results, the presence of HMTC in the dye-sensitized decomposition produces no carbon disulfide and consumes oxygen during the irradiation. The quantum yield of photoelimination in an aerated ethanol solution was measured. The quantum yield was almost unchanged on the variation of the xanthene dye concentration from 10^{-5} to 10^{-6}M. This is different from the former observation[2] that there was an apparent tendency for the quantum yield to decrease monotonously with an increase in the thiazine dye concentration. The singlet oxygen mechanism, in which the photochemical reaction is initiated by the interaction between the triplet dye and the ground-state oxygen molecules, has been inferred for the dye-sensitized photoelimination of HMTC. It has been explained in terms of the effect of 1,4-diazabicyclo [2.2.2] octane, β-carotene, and tetramethylethylene in reducing the quantum yield. The photooxygenation of HMTC by dyes seemed to be caused by attack of the singlet oxygen on the thiocarboxylion group, which has a rate constant of 10^{8}M^{-1}sec^{-1} in ethanol.

In the previous papers of this series,[2,3] the direct and thiazine-dye-sensitized chemistry of hexamethyleneammonium hexamethylenedithiocarbamate (HMTC) has been studied. In contrast to the direct photolysis results, the presence of HMTC in the dye-sensitized decomposition produces no carbon disulfide. It seems that the sensitization by thiazine dye takes place by means of the interaction of the triplet state of the sensitizing dye with dissolved oxygen. In this paper we will try to ascertain the role of oxygen in the dye-sensitized photoelimination of HMTC using xanthene dyes, further, we will describe how the dye-sensitization is not observed for nonionic dithiocarbamates, while it is observed for ionic dithiocarbamates such as HMTC.

Experimental

The HMTC was prepared by a method described previously,[2] Methyl dimethyldithiocarbamate[4] was obtained from Dr. Takeshi Nakai. The compound melted at 45°C and was used without further purification. The butyl ester of hexamethylenedithiocarbamic acid and 2,4-dinitrophenyl hexamethylenedithiocarbamate were prepared using the following general procedure.[5] 8 g of sodium hydroxide were dissolved in 80 m*l* of water, and the mixture was cooled to 5°C. 20 g of hexamethyleneimine and 15 g of carbon disulfide in small portions were stirred in well alternately. The sodium salt hexamethylene dithiocarbamic acid began to crystallize from the solution and was recovered as a white solid by the evaporation of the water and by drying at 110°C. 8.8 g of sodium hexamethylenedithiocarbamate were treated with 3.8 g of *n*-butyl chloride in 60 m*l* of ethanol, and then the mixture was kept at 50°C for 30 min. The sodium chloride thus precipitated was filtered off and the filtrate treated with water. The *n*-butyl ester of hexamethylenedithiocarbamic acid separated as a straw-colored liquid and was used without further purification. 44 g of sodium hexamethylenedithiocarbamate were treated with 40 g of 2,4-dinitrochlorobenzene in 300 m*l* of ethanol, and the solution was heated for 30 minutes at 50°C. The reaction mass was treated with water to dissolve the sodium chloride. The residue was crystallized from ethanol to form bright yellow needles of 2,4-dinitrophenyl hexamethylenedithiocarbamate which melted at 107.5°C.

The acetophenone, benzophenone, Michler's ketone, β-acetonaphthone, and naphthalene were purified by the methods described previously.[6]

The solvents and other reagents were of a GR grade (Tokyo Kasei Corp.), and they were used without further purification. The experimental procedure used in this study was almost the same as that described previously.[2] Degassing was carried out in the usual freeze-pump-thaw cycle at 10^{-5} mmHg. A 1-kW incandescent lamp was used as a source of actinic light for the dye-sensitization. Green light was isolated by means of an interference filter (KL-54) with a maximum in transmission at 546 nm and a transmitting glass filter which cut off light shorter than 520 nm. In most of the experiments, a heat-absorbing filter (HR 1-69) was also employed. The light intensities were measured by means of a Reinecke's salt actinometer. The concentration of oxygen in the ethanol solution was continuously measured using a dissolved-oxygen meter (Kyusuikagaku Kenkyusho D. O. Meter-TP) with a Galvanic electrode, and the output was recorded on a recorder with a 10-mV deflection. Overall, we estimate our absolute error to be within ±10%. For measuring the oxygen concentration, a glass reaction cell was used; it consisted of a cylinder 5 cm in diameter, with a total volume of 80 m*l*, and equipped with a stirrer.

Results

Participation of Oxygen. As was expected, the presence of oxygen was essential to the sensitization by xanthene dyes as well as to that by thiazine dyes,[2] as is shown in Table 1.

Dye Concentration Effects on Quantum Yields. Aerated ethanol solutions containing about 10^{-5}M xanthene

b) Deaerated condition.

dyes and 10^{-4}M HMTC were irradiated at 546 nm. The quantum yield for HMTC elimination was then determined by colorimetric analysis using copper acetate.[7)] The quantum yields obtained for different dye concentrations are tabulated in Table 2. The quantum yield was unchanged within the range of experimental uncertainty as long as all the factors were held constant. This forms a striking contrast with the case of the sensitization by thiazine dyes, where the reciprocal of the quantum yield changed linearly with the dye concentration.[2)]

Table 2. Dye concentration effects on quatum yields

Dye	$[HMTC]_{ini}$, M	[Dye], M	Quantum yield (η)
Erythrosine	3.7×10^{-4}	5.2×10^{-6}	0.222
		2.1×10^{-5}	0.226
		3.6×10^{-5}	0.228
		5.2×10^{-5}	0.263
Rose bengal	3.5×10^{-4}	9.2×10^{-6}	0.378
		3.7×10^{-5}	0.320
		5.5×10^{-5}	0.348
		7.4×10^{-5}	0.352
		9.2×10^{-5}	0.360

Effect of HMTC Concentration. Aerated ethanol solutions containing 10^{-5}—10^{-6}M xanthene dyes and various concentrations of HMTC were irradiated at 546 nm. The results are depicted in Fig. 1. As is represented there, a linear relation between the reciprocal of the quantum yield and that of the HMTC concentration holds for all of the dyes investigated. Apparently the efficiency of sensitization increased in the following order: eosine yellowish<phloxine<erythrosine<rose bengal. This order was the same as that of the dye-sensitized photolysis of 4-methoxy-α-naphthol[8)] or sodium *N,N*-dimethyldithiocarbamate,[7)] which have previously been reported by us.

Effect of the Reducing Agent, Allylthiourea. To examine if the dye-sensitized reaction is initiated by the semiquinone form of dye, allylthiourea was added as a reducing agent and the quantum yield was measured. Aerated ethanol solutions containing 9.2×10^{-6}M of rose bengal, 3.7×10^{-4}M of HMTC, and various concentrations of allylthiourea as a reducing agent were irradiated at 546 nm. Figure 2 shows the Stern-Volmer plots thus obtained. The value of the slope is of the order of 10^3M^{-1}, while it was of the order of 10M^{-1} in the case of thiazine dye. Allylthiourea did not increase, but

$[HMTC]_{ini}=3.7\times10^{-4}$M; [Rose bengal]$=9.2\times10^{-6}$M

decreased the efficiency of the sensitization. The present investigation suggests that a reducing agent is not necessary for dye-sensitization. It may be inferred that the sensitization does not take place *via* the semiquinone radical.

Effects of Singlet Oxygen Quencher and Trap. The fact that HMTC did not affect the fluorescence of the xanthene dye ruled out the excited-dye singlet as the sensitizing species under our conditions. From the essentiality of oxygen and the decreasing effect of allylthiourea on the quantum yield, the dye-sensitized photoelimination of HMTC may proceed by means of the singlet oxygen ($^1O_2$) formed by energy transfer from the triplet sensitizer, as was discussed in a previous paper.[2)] It therefore seems interesting to find out if an actual decrease in quantum yield is observed by adding

a $^1O_2$ quencher, such as 1,4-diazabicyclo[2.2.2.]octane (DABCO),[9] or efficient $^1O_2$ traps, such as tetramethylethylene (TME)[10] and β-carotene.[11] Aerated solutions containing 9.2×10^{-6}M of rose bengal, $2—4\times10^{-4}$M of HMTC, and various concentrations of DABCO, TME, or β-carotene in ethanol solvents were irradiated at 546 nm. The results are shown in Figs. 3, 4, and 5. The resulting quantum yields were reduced; the best fit of the data to the Stern-Volmer equation gave the slope values of 5.8×10, 2.7×10^2, and 7.0×10^4M^{-1} for DABCO, TME, and β-carotene respectively. This decreasing effect on the quantum yields supports the idea of the involvement of the singlet oxygen in the dye-sensitized photoelimination of HMTC.

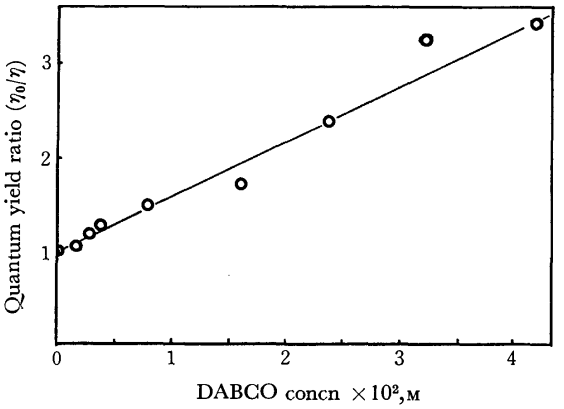

Fig. 3. Effect of DABCO on the quantum yield. η and η_0 indicate the quantum yields for the system with and without DABCO, respectively.
η_0=0.435, Slope=5.8×10 M^{-1}

b) The initial dye concentrations in all of the experiments were 4.0×10^{-5}M and 2.0×10^{-5}M for rose bengal and methylene blue respectively.

shows that the photooxygenation of HMTC took place. Furthermore, DABCO was found to be apparently unreactive toward $^1O_2$, yet to retard the oxidation of HMTC. This is identical with what Wilson had said regarding the effect of DABCO on the rubrene photooxygenation.[9] If the rate of oxygen consumption corresponds to the slope of the linear portion of the curve during the initial stage of the reaction in Fig. 6, the effect of the DABCO or HMTC concentration on the rate of oxygen consumption is also determinable. The results are given in Fig. 7.

Attempts at Dye-sensitization in Other Dithiocarbamates. Unfortunately, we encountered difficulty in identifying the photoproducts. Instead of the direct way of identification, therefore, we attempted to examine the sensitization in the variation of the dithiocarbamates. Esters of dithiocarbamic acid or thiuram sulfide show two strong ultraviolet bands in the 275—290 nm (N conjugation) and 245—260 nm (S conjugation) regions, both with log ε about 4, and another weaker absorption in the 325—360 nm region (log ε about 1.8), as well as HMTC, which represents a true ionic salt.[12] These dithiocarbamates were photolyzed by UV light.[13] In the course of the study we examined whether or not dye-sensitization takes place in these dithiocarbamates. Some representative results of sensitized photolysis in an aerated solution are presented in Table 3. No detectable dye-sensitized reaction occurred, though tetramethylthiuram disulfide (TMTD) was photo-sensitized by a few aromatic ketones possessing a high triplet energy. Furthermore, ethanolic solutions of these dithiocarbamates containing excess hydrogen peroxide were not oxidized by adding dilute aqueous sodium hypochloride.

Discussion

An attempt to check further the singlet-oxygen mechanism for the photooxidations by the action of H_2O_2 mixed with NaOCl, which is known to produce singlet oxygen, failed because HMTC was completely eliminated when NaOCl was injected into a HMTC ethanol solution in the dark. However, all the data presented here on the dye-sensitized photooxidation of HMTC are entirely consistent with a mechanism *via* the singlet oxygen. Because of the spin conservation, only a triplet-triplet transfer (Eq. 1) or a triplet-triplet annihilation (Eq. 2) can be responsible for the excitation of oxygen. Here, $^1D_0$, $^1D_1$, $^3D_1$, and $^3O_2$ represent the singlet ground state, the first excited singlet state, the lowest triplet state of the photosensitizing dye, D, and the ground state of oxygen respectively:

$$^1D_1 + {}^3O_2 \longrightarrow {}^3D_1 + {}^1O_2 \quad (1)$$

$$^3D_1 + {}^3O_2 \longrightarrow {}^1D_0 + {}^1O_2 \quad (2)$$

In dyes, the singlet-triplet splitting is very small.[18] Unfortunately, no literature on the energies of the triplet states of thiazine dyes is available except for thionine.[19] However, if the singlet-triplet splitting (ΔE_{ST}) is smaller than 10 kcal, as is the case with eosine and other xanthene derivatives, then the triplet-triplet transfer can not be responsible for the excitation of oxygen even to the lowest $^1\Delta_g$ state. This can be achieved only by the triplet-triplet annihilation (Reaction 2), in which the whole of the triplet energy of the sensitizer is available. This hypothesis is supported by the conclusion of Stevens and Algar[20] that the singlet oxygen is produced solely by energy transfer from the sensitizer triplet state, even when transfer from excited singlet state is spin-al-

lowed and exothermic. The reaction scheme which can explain the experimental data consists of the following steps:

$$^1D_0 + h\nu \xrightarrow{I_{abs}} {}^1D_1 \quad \text{Absorption} \quad (3)$$

$$^1D_1 \xrightarrow{k_1} {}^1D_0 \quad \text{Fluorescence and internal conversion} \quad (4)$$

$$^1D_1 \xrightarrow{k_2} {}^3D_1 \quad \text{Intersystem crossing to the triplet state} \quad (5)$$

$$^3D_1 \xrightarrow{k_3} {}^1D_0 \quad \text{Intersystem crossing to the ground state} \quad (6)$$

$$^3D_1 + {}^3O_2 \xrightarrow{k_4} {}^1D_0 + {}^1O_2 \quad \text{Formation of the singlet oxygen} \quad (7)$$

$$^3D_1 + \text{Red} \xrightarrow{k_5} D\cdot + \text{Red}\cdot \quad \text{Radical formation} \quad (8)$$

$$^1O_2 \xrightarrow{k_6} {}^3O_2 \quad \text{Deactivation of the singlet oxygen} \quad (9)$$

$$^1O_2 + H \xrightarrow{k_H} H\text{–}O_2\ ? \quad \text{Product formation} \quad (10)$$

$$^1O_2 + Q \xrightarrow{k_Q} \begin{matrix} Q + {}^3O_2 \\ Q\text{–}O_2 \end{matrix} \quad \text{Quenching or trapping of the singlet oxygen} \quad (11)$$

where Red, Red·, D·, H, and Q are, respectively, the reducing agent, the radical of Red, the semiquinone radical of D, HMTC, and the singlet-oxygen quenches or trap. If any reducing agent is rigorously excluded, the quantum yield (η) for HMTC photoelimination is given by:

$$\eta = \frac{k_2}{k_1+k_2}\cdot\frac{k_4[O_2]}{k_3+k_4[O_2]}\cdot\frac{k_H[H]}{k_6+k_Q[Q]+k_H[H]} \quad (12)$$

Under [Q]=0, the quantum yield (η_0) is given by:

$$\eta_0 = \alpha\cdot\beta\cdot\frac{k_H[H]}{k_6+k_H[H]} \quad (13)$$

where

$$\alpha = \frac{k_2}{k_1+k_2}, \qquad \beta = \frac{k_4[O_2]}{k_3+k_4[O_2]} \quad (14)$$

By dividing Eq. (13) by Eq. (12), we obtain the Stern-Volmer expression:

$$\frac{\eta_0}{\eta} = 1 + \frac{k_Q[Q]}{k_6+k_H[H]} \quad (15)$$

and a plot of η_0/η *vs.* [Q] should result in a straight line with a slope of $k_Q/(k_6+k_H[H])$. Such a plot is found to be linear for a quencher and two traps, as is shown in Figs. 3, 4, and 5. The value of k_H can be calculated as 1.5×10^8M^{-1}sec^{-1} from the $k_Q/(k_6+k_H[H])$ (7.0×10^4M^{-1}) obtained from Fig. 5, since k_6 and k_Q are 10^4 sec^{-1} and 5.0×10^9M^{-1}sec^{-1} respectively.[11,12] Using $k_H=1.5\times10^8$M^{-1}sec^{-1}, the k_Q values for DABCO and TME were calculated to be 5.3×10^6 and 1.6×10^7M^{-1}sec^{-1} respectively. The data obtained by the indirect kinetic approach are summarized in Table 4.[22]

Table 4. Rate constants for the process

Quencher or trap	$[HMTC]_{ini}\times10^4$, M	$k_Q/k_6+k_H[H]\times$M	$k_Q\times$M sec	$k_H\times$M sec
DABCO	4.48	5.8×10	5.3×10^6	
TME	2.80	2.7×10^2	1.6×10^7	1.5×10^8
β-carotene	3.35	7.0×10^4	5.0×10^9 [11]	

The rate of the oxygen consumption ($-d[^3O_2]/dt$) is given by:

$$-\frac{d[^3O_2]}{dt} = k_4[^3D_1][^3O_2] - k_{QD}[^1O_2][DO] - k_6[^1O_2] \quad (16)$$

where k_{QD} refers to the rate constant for DABCO (DO). Assuming the steady concentrations for $^1O_2$ and $^3D_1$,

$$[^1O_2] = \frac{k_4[^3O_2][^3D_1]}{k_6+k_H[H]+k_{QD}[DO]} \quad (17)$$

$$k_4[^3O_2][^3D_1] \approx \alpha I \quad (18)$$

since $k_4[^3O_2] \gg k_3$.[26] The substitution of Eqs. (17) and (18) into (16) gives the rate of oxygen consumption:

$$-\frac{d[^3O_2]}{dt} = \alpha I\cdot\frac{k_H[H]}{k_6+k_H[H]+k_{QD}[DO]} \quad (19)$$

Eq. (19) can be rewritten as:

$$1/-\frac{d[^3O_2]}{dt} = \frac{1}{\alpha\cdot I}\left(1+\frac{k_6}{k_H[H]}+\frac{k_{QD}}{k_H[H]}[DO]\right) \quad (20)$$

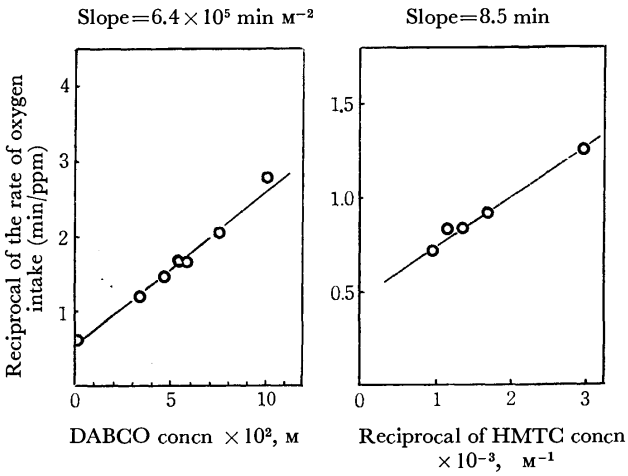

Fig. 8. Relationship between the rate of oxygen intake and DABCO or HMTC concentration.
[Rose bengal]=9.2×10^{-6} M

The best fit of the data in Fig. 7 to this equation gives $k_{QD}/\alpha I\cdot k_H[H]=6.4\times10^5$ min M^{-2} for the plot of $1/(-d[^3O_2]/dt)$ *vs.* [DO], with the [H] and αI constants, as shown in Fig. 8. Experimentally, the values of I and [H] were determined to be $4\text{—}5\times10^{-5}$ Einstein/l min and 1.0×10^{-3}M respectively. If k_{QD} is taken to be

21) P. J. Wagner and I. Kochevar, *J. Amer. Chem. Soc.*, **90**, 2232 (1968).

22) In the gas phase, k_Q for DABCO has recently been found to equal $1.2\pm0.1\times10^7$M^{-1}sec^{-1},[23] so the present value of $k_Q=5.3\times10^6$M^{-1}sec^{-1} seems reasonable. The value of k_Q obtained for TME is less than 10^8M^{-1}sec^{-1},[24] but greater than 10^5M^{-1}sec^{-1},[25] though these values were obtained in the gas phase.

23) E. A. Ogryzlo and C. W. Tang, *J. Amer. Chem. Soc.*, **92**, 5034 (1970).

24) S. J. Arnold, M. Kubo, and E. A. Ogryzlo, "Oxidation of Organic Compounds," Advances in Chemistry Series, No. **77**, American Chemical Society, Washington, D. C., 1968, p. 133.

25) W. S. Gleason, A. D. Broadbent, E. Whittle, and J. N. Pitts, Jr, *J. Amer. Chem. Soc.*, **92**, 2068 (1970).

$5.3\times10^{6}\text{M}^{-1}\,\text{sec}^{-1}$, as is shown in Table 4, then k_H can be calculated to be about $1—2\times10^{8}\text{M}^{-1}\,\text{sec}^{-1}$ from the value of the slope with 6.4×10^{5} min M^{-2}, since α and k_6 are about unity[27] and $10^{4}\,\text{sec}^{-1}$ [11] respectively. The value of k_H calculated here is in good agreement with that obtained by the plot of η_0/η *vs.* [Q]. As a further check, plots of $1/(-\text{d}[^3O_2]/\text{d}t)$ *vs.* 1/[H] were carried out for the data in Fig. 7; they gave a straight line, as is shown in Fig. 8. Then, k_H can be calculated to be about $5\times10^{7}\text{M}^{-1}\,\text{sec}^{-1}$ from the value of the slope with $k_6/\alpha I\cdot k_H=8.5$ min. The values of k_H obtained by different methods are in satisfactory agreement if one allows for the difference in reaction conditions and the errors included in the measurements. The best value of k_H is, therefore, probably around $10^{8}\text{M}^{-1}\,\text{sec}^{-1}$. These results illustrate the sensitivity of HMTC as a photometric detector of oxidation *via* $^1O_2$.

Considering the findings, shown in Table 3, that dye-sensitization did not take place for each dithiocarbamate representing a true nonionic structure, it may be suggested that the thiocarboxyl-ion group ($-C\overset{S}{\underset{S^{\ominus}}{<}}$) plays the important role in the dye-sensitized photooxygenation of HMTC. In connection with the involvement of the singlet oxygen, it was inferred that the singlet oxygen attacked the thiocarboxyl-ion group of HMTC with a rate constant of $10^{8}\text{M}^{-1}\,\text{sec}^{-1}$ in ethanol.[28]

Returning now to the dye reactions, the effects of the dye concentration and of allylthiourea delineated the differences between xanthene dyes and thiazine dyes (Table 2, Fig. 2).[2] As one conceivable mechanism to explain the differences, the D-D mechanism (Eq. 8′) may be mentioned:

$$^3D_1 + {}^1D_0 \xrightarrow{k_5'} D^+\text{–}D^- \qquad (8')$$

The occurrence of a D-D mechanism, in which the photochemical reaction is initiated by the interaction of the triplet-dye and the ground-state-dye molecules, is established for the ethanol solution of xanthene or thiazine dye.[29] When the rate constant of the D-D mechanism is represented by k_5', Eq. (15) can be rewritten to:

$$\eta_0'/\eta = 1 + \frac{k_5}{k_3+k_4[O_2]+k_5'[D]}[\text{Red}] \qquad (21)$$

with a η_0'=quantum yield under [Red]=0. Fig. 2 and a previous paper show that the concentration of allylthiourea, which reduces η to one-half of its original value, is of the order of 10^{-4}M for rose bengal and of 10^{-2}M for methylene blue. In connection with the fact that, on the quantum yield, there is a remarkable effect of the thiazine-dye concentration in comparison with the case of the xanthene dye, for rose bengal, k_5' must be smaller than that for methylene blue provided that k_3, k_4, and k_5 are of similar magnitudes for the two dyes. The above estimation suggests that the D-D mechanism easily occurs for the thiazine dye, resulting in a decrease in the rate of T-T annihilation. Further studies are necessary to examine the above possibility, however.

The Microwave Spectrum of *trans*-Ethylmethylsilane

Michiro HAYASHI and Chi MATSUMURA*

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima
**Government Chemical Industrial Research Institute, Tokyo, Honmachi, Shibuya-ku, Tokyo*

(Received July 14, 1971)

The microwave spectra of $CH_3CH_2SiH_2CH_3$ and $CH_3CH_2SiD_2CH_3$ in the *trans* form were studied. The rotational constants calculated from the spectra can be explained satisfactorily with a model which has structural parameters transferred with only a slight modification, from the values reported for dimethylsilane and ethylsilane. From the observed splittings of the spectra, the barrier to the internal rotation of the $SiCH_3$ group was calculated to be 1520 ± 30 cal/mol, assuming that the coupling effect of the torsional motions of the other groups can be ignored. From the Stark shifts, the dipole moment was determined to be $\mu_a=0.036\pm0.030$, $\mu_b=0.757\pm0.003$, and $\mu_{total}=0.758\pm0.005$ D, making an angle of 2°44′ with the *b* axis for the parent species, while it was determined to be $\mu_a=0.024\pm0.030$, $\mu_b=0.758\pm0.003$, and $\mu_{total}=0.758\pm0.005$ D, making an angle of 1°49′ with the *b* axis for the deuterated species. From these results, the orientation of the dipole moment in the molecule was concluded to be along the direction slightly inclined from the bisector of the CSiC angle toward the ethyl group in the molecule.

Ethylmethylsilane has been investigated by means of microwave spectroscopy as an expression of the current interest in rotational isomerism and in the barriers to internal rotation.

The infrared and Raman spectra of this molecule have also been previously investigated by one of the present authors[1]; they give evidence of the existence of two rotational isomers, which will be published separately. However, the observed microwave spectra were very weak, and assignments are possible for only the *trans* isomer at present.

Therefore, in the present paper, a brief consideration will be given of the structure, the barrier to the internal rotation of the $SiCH_3$ group, and the electric dipole moment of the *trans* isomer.

Experimental

The samples of $CH_3CH_2SiH_2CH_3$ and $CH_3CH_2SiD_2CH_3$ were prepared by the method of reacting CH_3CH_2MgBr with CH_3SiCl_3 in ethyl ether and by subsequently reducing the resultant $CH_3CH_2SiCl_2CH_3$ with $LiAlH_4$ or $LiAlD_4$ in *n*-butyl ether.[2]

The microwave spectra of the samples were measured in the region from 8000 to 36000 MHz with conventional sinu-

soidal and square wave Stark modulation spectrometers at the temperature of dry ice.

Results and Discussion

Spectra and Structure of the Molecule. Although *b*- and *a*-type transitions are expected for *trans*-ethylmethylsilane, the observation of the *a*-type spectra was impossible because of the small dipole moment component along the *a* axis.

As is shown in Table 1, the observed *b*-type spectra are doublets resulting from the internal rotation of the $SiCH_3$ group.

The "A" components of the doublets can be explained by an asymmetric rotor model with the rotational constants of A=15114.85, B=2703.34, and C=2463.25 MHz for the parent species and of A=12645.98, B=2656.80, and C=2415.73 MHz for the deuterated species, with reasonable centrifugal distortion contributions.

These rotational constants were determined by the least-squares technique from the observed frequencies of the "A" components of the doublets for the following six transitions; $1_{11}\leftarrow 0_{00}$, $1_{10}\leftarrow 1_{01}$, $2_{12}\leftarrow 1_{01}$, $2_{11}\leftarrow 2_{02}$, $3_{12}\leftarrow 3_{03}$, and $3_{13}\leftarrow 2_{02}$.

From these rotational constants, the unperturbed rotational constants were calculated by subtracting the contributions due to the internal rotation for the "A" sublevel.

As is shown in Tables 2 and 3, the moments of inertia obtained from the unperturbed rotational constants can be explained by a model (Model I in Table 3) which has structural parameters transferred from the reported values for $(CH_3)_2SiH_2$[3] and $CH_3CH_2SiH_3$.[4] Furthermore, a very good agreement is obtained between the calculated and the observed moments of inertia if the CCSi angle is increased by about 1° from the original value and if the CCH and SiCH angles are decreased by about 15′ (Model II in Table 3). Although the models described above should be tested further by

3) L. Pierce, *J. Chem. Phys.*, **34**, 498 (1961).

4) D. H. Petersen, Doctoral thesis, The University of Notre Dame (1961).

means of the observed rotational constants for other isotopic species which have not yet been measured, the agreement is so good and so reasonable that the structure of Model II may be proposed as the best structure for *trans*-ethylmethylsilane.

Internal Rotation of the $SiCH_3$ Group. The analysis of the fine structures of the observed spectra has been carried out by the principal-axis method.[5]

A preliminary analysis indicates that the doublet structures of the observed spectra originate mainly from the coupling of the over-all rotation and the internal rotation of the $SiCH_3$ group if the barriers are taken to be equal to the reported value for the similar molecules.

On the assumption that the coupling terms among the internal rotation of the $SiCH_3$ group, that of the CH_3CH_2 group and the skeletal torsion of the C–SiH_2–CH_2–C part of the molecule, can be neglected, the effective Hamiltonian for the v-th torsional state of the $SiCH_3$ group is given as;

$$H_{v\sigma} = H_r + F\sum_n W_{v\sigma}^{(n)}\mathscr{P}^n$$

$$H_r = AP_a^2 + BP_b^2 + CP_c^2,\ \mathscr{P} = \alpha P_a + \beta P_b$$

$$\alpha = \lambda_a I_\alpha/I_a,\ \beta = \lambda_b I_\alpha/I_b$$

$$F = \hbar^2/2rI_\alpha,\ r = 1 - \lambda_a\alpha - \lambda_b\beta$$

where I_α is the moment of inertia of the $SiCH_3$ group around the top axis and where the λ's are the direction cosines between the internal top axis and the principal axes of the entire molecule. σ stands for either the "A" or "E" sublevel.

I_α was calculated from the structural parameters of Model II, and the λ's were obtained on the assumption that the top axis coincides with the SiC bond.

According to the bootstrap method,[5] the perturbation coefficients, $W_{v\sigma}^{(n)}$, are simply proportional to a quantity, w_1, for a reasonably high barrier if the corrections due to the shape of the barrier are negligible.

By the least-squares technique, the w_1's were determined from the observed frequency splittings of the spectra, neglecting the terms higher than the fourth-order in the effective Hamiltonian for both parent and deuterated species. Then, the reduced barrier s's ($=4V_3/9F$) were obtained by the interpolation of the values of w_1 *vs.* s in the table.[6]

The barrier V_3's calculated from the interpolated s values are found to be 1522 and 1515 cal/mol, respectively, for the two species; the agreement between the two species is good within the limit of experimental error. The results are shown in Table 4.

As the analysis described above was made on the assumption that the coupling can be neglected among the torsional motion of the $SiCH_3$ group and those of the other groups, any comparison with the reported values for the similar molecules would be rather invalid. However, it is noticeable that the barrier of the $SiCH_3$ group in *trans*-ethylmethylsilane is lower than those of methylsilane[7] (1595 cal/mol), dimethylsilane[3] (1640 cal/mol), and trimethylsilane[8] (1830 cal/mol).

a) Root mean square deviation (MHz)

Dipole Moment. The electric dipole moments were quantitatively determined from Stark-effect measurements of $1_{11}\leftarrow 0_{00}$, $1_{10}\leftarrow 1_{01}$, and $2_{11}\leftarrow 2_{02}$ ($M=2$) transitions. For the deuterated species, very fast Stark shifts were found for $1_{11}\leftarrow 0_{00}$ and the $M=1$ lobe of $2_{11}\leftarrow 2_{02}$ transitions, since the energy levels of 1_{11}, 2_{02}, and 1_{10} are, accidentally in near degeneracy.

The spectrometer was calibrated with OCS[9] on the measurements.

The Stark shifts of the "A" and "E" components of the doublets were found to be essentially the same, and the averaged values were used for the calculations.

However, it was found that some of the observed Stark coefficients, $\Delta\nu/E^2$, show slight but regular variations with the field strength, E, beyond the limit of experimental error. This is probably due to the presence of the higher-order terms, since the second-order perturbation sums for the μ_a component are possibly considerably influenced by the contributions from the μ_b component as the field strength becomes stronger.

Considering the contributions from the higher-order terms as well as from the first-order term, which is especially significant for the $1_{11}\leftarrow 0_{00}$ transition of the deuterated species, the theoretical Stark shifts were calculated by the direct diagonalization of the energy

a) The measurements were made on the recorder at five or six different field strengths in the range from 0 to 600 V/cm except the $1_{11}\leftarrow 0_{00}$ transition of the deuterated species for which the range was from 0 to 150 V/cm.

b) In order to simplify the table, the observed and theoretical Stark coefficients are shown, though the frequency shifts were actually used for the determination of the diplole moments. These coefficients are the averaged values of the quantities $\Delta\nu/E^2$ for different field strengths.

matrices instead of by the usual perturbation calculation.[10)]

The energy matrices were truncated at the terms with $J=4$ and higher after the negligible influences of the truncation were confirmed.

Since more elaborate considerations are required for the application of the least-squares technique to this procedure, the dipole moments were determined by changing the magnitudes of the μ_a and μ_b components little by little until the minimum values of the $S=\sum_i(\Delta\nu_{i\text{obsd}}-\Delta\nu_{i\text{calcd}})^2$ quantity were obtained for each of the two species. The details of the procedures will be reported elsewhere.

As is shown in Table 5, the dipole moments were determined to be $\mu_a=0.036\pm0.030$, $\mu_b=0.757\pm0.003$, and $\mu_{total}=0.758\pm0.005$ D for the parent species, which makes an angle of 2°44′ with the b axis, while they were determined to be $\mu_a=0.024\pm0.030$, $\mu_b=0.758\pm0.003$, and $\mu_{total}=0.758\pm0.005$ D for the deuterated species which makes an angle of 1°49′ with the b axis.

The structural calculation indicates that the bisector of the CSiC angle makes angles with the b axis of 3°53′ for the parent species and 3°24′ for the deuterated species.

The values obtained from these observations lead to the conclusion that the orientation of the dipole moment of the molecule is along the direction making an angle of about 1°20′ with the bisector of the CSiC angle toward the ethyl group in the molecule.

As the reported value for dimethylsilane is 0.75 D[3)], the dipole moment of *trans*-ethylmethylsilane can be said to be equal to that for dimethylsilane.

One of the present authors (M.H.) especially wishes to thank Mr. Keiichi Ohno for his assistance in making the samples and Mrs. Hisae Imaishi for her assistance in calculating the theoretical Stark shifts.

Molecular Structures of Acetyl Chloride and Acetyl Bromide as Determined by Gas Electron Diffraction

Shuzo TSUCHIYA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 14, 1971)

The molecular structures of acetyl chloride and acetyl bromide have been investigated by the sector-microphotometer method of gas-phase electron diffraction. The thermal average distances, r_g, and the valence angles, φ_a, have been determined, with estimated limits of error, to be as follows: for acetyl chloride, r_g(C=O)=1.187±0.003 Å, r_g(C–Cl)=1.798±0.003 Å, r_g(C–C)=1.508±0.005 Å, φ_a(OCCl)=120.3°±0.6°, φ_a(CCCl)=112.2°±0.9°, and φ_a(CCO)=127.5°±0.9°; and for acetyl bromide, r_g(C=O)=1.184±0.004 Å, r_g(C–Br)=1.975±0.004 Å, r_g(C–C)=1.518±0.008 Å, φ_a(OCBr)=120.8°±0.9°, φ_a(CCBr)=109.5°±1.2°, and φ_a(CCO)=129.7°±1.1°. The C=O distances in these molecules are shorter than those in acetaldehyde and acetone by about 0.02 Å. This may be attributed to the effect of a highly electronegative halogen atom adjacent to the carbonyl group.

The interatomic distances of acetyl chloride and acetyl bromide were first investigated by the visual method of electron diffraction.[1-3] The purpose of the present study is to determine more accurate structure parameters of these molecules by the sector-microphotometer method.[4] Sinnott observed the microwave spectra of ten isotopic species of acetyl chloride and determined the r_s structure parameters from the rotational constants.[5] He showed further that, at the equilibrium conformation, a methyl hydrogen atom is eclipsed to the oxygen atom. The microwave spectrum of acetyl bromide was investigated by Krisher,[6] but the interatomic distances were not determined. These rotational constants are being used in our laboratory as additional information in a more complete and more accurate analysis of the structure parameters and the barrier to internal rotation. The results will be reported in a forthcoming paper.

Experimental

The samples of acetyl chloride and acetyl bromide were special-grade and extra-pure reagents respectively, obtained from commercial sources. The unit used in the present study has been reported elsewhere.[7] Both short (109.3 mm) and long camera lengths (244.3 mm) were used. Diffraction photographs were taken at room temperature (~16°C) with an r^3-sector. The experimental conditions were as follows: accelerating voltage, about 42 kV; sample pressure, about 60 Torr; exposure times, 25—35 sec; electron-beam current, 0.1—0.3 μA. The developing and photometric process were described in a previous work.[8] In order to calibrate the wavelength of the electron beam, carbon disulfide was used as the reference material.

Analysis

Reduction of the Molecular Intensity. The relation between the optical desity, D, and the scattering intensity, I, was previously estimated to be $I=D(1+0.03D)$ for the plates used in the present study (Fuji Process Hard).[9] The observed intensities were obtained from the optical densities by the use of this relation. The data adopted for analysis covered the range of q=30—130 for the short camera length and that of q=10—60 for the long camera length. After correction for the deviation of the sector shape from an ideal r^3-curve, the leveled total intensities, I_T, were obtained by dividing I by the theoretical background.[10] The experimental background was obtained by Karles' non-negativity criterion for the radial distribution curve.[11] The molecular intensity curves, $qM(q)^{obs}$, derived in this way and the experimental radial distribution curves for the short camera length are shown in Figs. 1 and 2.

Least-squares Analysis. The molecular parameters were determined by applying the least-squares method to the $qM(q)^{obs}$ with a conventional weight function.[9] The molecular model for the least-squares fitting was assumed as follows:

(i) An eclipse conformation for the H and O atoms;

(ii) r_a(C–H)=1.1070 Å (a value observed for ethane)[12] and the nonbonded distances related to the H atoms were fixed at calculated values, and

(iii) ∠CCH=110°21′ (Sinnott's r_s value) and the tilt angle of the methyl group=0°.

In addition to these assumptions, all the mean amplitudes were fixed at the values calculated from the spectroscopic data, since it was impossible to adjust the distances and the mean amplitudes simultaneously. The asymmetry parameters, κ, were estimated according to the equation given by Kuchitsu,[13] while the Morse parameters were assumed to be 2.0 Å^{-1} for the bonded atom pairs and zero for the nonbonded pairs. The elastic and inelastic scattering factors were obtained from the sources cited in a previous work.[9] It is not clear whether or not the H atom is eclipsed to the O atom in acetyl bromide. However, this ambiguity is not relevant to the present work, because the molecular intensity

structure parameters and the standard errors, σ_1 and σ_2,[14] derived are shown in Table 1. Table 2 shows the error matrices which were computed for the best-fit models, corresponding to the theoretical intensity curves for the short camera length depicted in Figs. 1(a) and 1(c).

Mean Amplitudes. The mean amplitudes of vibration used for the analysis were calculated by the normal coordinate treatment.[15] The force constants for the Urey-Bradley force field determined by Overend *et al.* were used for acetyl chloride.[16] The force constants for acetylbromide were transferred from those for acetyl chloride and methyl bromide, and adjusted by a trial-and-error method so as to reproduce the vibrational frequencies obtained from the infrared spectra.[17] The force constants thus determined and the vibrational frequencies of acetyl bromide are shown in Tables 3 and 4 respectively. Evans and Overend estimated[19] the out-of-plane bending force constant for acetyl bromide to be 0.39 mdyn·Å[20] from Taft's inductive and resonance substituent constants. This value is slightly smaller

than the constant, Θ, listed in Table 3. The calculated mean-square amplitudes, l, are shown in Table 5.

Estimation of Errors. The limits of error were estimated from 2.5 times σ_1 and from the systematic errors. The error due to the uncertainties in the fixed structure parameters was taken into consideration as one of the systematic errors. Yokozeki and Kuchitsu[21] treated this error by a Monte-Carlo technique. However, the present authors have dealt with it by a different and simpler method as follows:

(a) *Procedure*: It was assumed that a variation in one of the fixed parameters, Δ, caused a displacement in each adjusted parameter, δ, linearly proportional to the variation, and that such displacements were simply additive. A least-squares adjustment was carried out by varying only one of the fixed parameters at a time as much as its uncertainty. This procedure was applied to all the fixed parameters.

(b) *Uncertainties in the Fixed Parameters*: The uncertainties in the C–H and C···H distances were assumed to be 0.010 Å, while those for the other nonbonded distances related to the hydrogen atoms were assumed to be; r(O···H): 0.010 Å, and r(Cl···H): 0.010 Å for acetyl chloride, r(O···H): 0.010 Å and r(Br···H): 0.015 Å for acetyl bromide. The uncertainties in the mean amplitudes were assumed to be 10%.

By analogy with the estimation of errors in a previous work,[9] the uncertainties in the asymmetry parameters,

l(X···$H_{1,2}$)	−5	−5	0	+15	+2
$(\sum\delta_i^2)^{1/2}$	48	34	64	79	41
$\sum\|\delta_i\|$	97	67	88	104	61

Fixed parameter	Acetyl chloride δr(C=O)	Acetyl bromide δr(C=O)
l(C=O)	0	+6
r(C–H)	+5	−10
l(C–H)	−12	−10
$(\sum\delta_i^2)^{1/2}$	13	15
$\sum\|\delta_i\|$	17	26

a) Assumed uncertainties in the fixed parameters are described in text. The plus and minus signs indicate the directions of the displacements δ, when the variations $\Delta>0$.

κ, for the bonded atom pairs were considered to be insignificant. The κ of a nonbonded atom pair was estimated by Kuchitsu to be nearly equal to or less than that of a bonded atom pair.[22] Even if a large value of 100×10^{-7} Å^3 is used for the κ's of the nonbonded atom pairs, the resulting changes in the distances amount to only 0.0004 Å. Therefore, the errors due to the uncertainties in the κ values were ignored.

The results of the calculations are shown in Table 6, where only significant contributors to the error-estimation are presented. In general, the error in an adjusted distance due to the uncertainty in a fixed parameter is significant only if the adjusted distance and the fixed parameter are involved in the same peak in the radial distribution curve. The C=O distance was sensitive to only the uncertainties in the distance and mean amplitude of the C–H bond and in the mean amplitude of the C=O bond. For the C···O distance in acetyl bromide and the C–C and C–X distances, which have no close-by distances except for those which make very small contributions to the molecular intensity, the effect of the uncertainties in the fixed parameters was negligible. It is to be noted that more than about 80% of each error for the nonbonded distances comes from the uncertainties in the mean amplitudes for the C···X, C···O, and O···X pairs.

(c) *Error Estimation*: The last two entries, $(\sum\delta_i^2)^{1/2}$ and $\sum|\delta_i|$, in Table 6 are two possible estimates of the uncertainty in an adjusted parameter due to the uncertainties in the fixed parametes, where δ_i is the displacement due to the variation in the ith fixed parameter. Of the two estimates, $\sum|\delta_i|$ has been adopted as the systematic error to be included in the limits of error. Were the uncertainties in these fixed parameters perfectly random and mutually independent,—in other words, were the law of propagation of error valid in this case, then $(\sum\delta_i^2)^{1/2}$ instead of $\sum|\delta_i|$ might have been taken. However, it seems proper to adopt the latter larger value, unless the nature of the error is clear. The errors due to the uncertainties in the fixed parameters for r(C···X), r(O···X), and r(C···O in chloride) were four times as large as that of the scale factor and were nearly equal to 2.5 σ_1.

The errors in the scale factor were estimated to be 0.05% for acetyl chloride and 0.06% for acetyl bromide. Systematic errors due to the other sources were not included in the limits of error, for they were considered to be insignificant.[9]

Results and Discussion

The parameter, r_a, determined by the least-squares refinement was transformed to the thermal average distance, r_g, by the relation $r_g=r_a+l_a^2/r_a$.[23] The r_a parameter was evaluated by subtracting the harmonic and the centrifugal contributions from r_g, following the equation $r_a=r_g-(<\Delta x^2>+<\Delta y^2>)/2r_e-\delta r$.[24] Here, the third term, δr, was neglected. The angle, φ_a, composed of the thermal-average nuclear position[25] was calculated from the r_a parameters. The final r_g distances and the φ_a angles are listed in Table 7, together with the limits of error. The sums of the φ_a(OCX), φ_a(CCX), and φ_a(CCO) angles for acetyl chloride and acetyl bromide equal 359°56′ and 359°57′ respectively. These values are consistent with the planar structure of the CCOX skeleton. For a comparison of these results for acetyl chloride and acetyl bromide with those reported by Sinnott[5] and Krisher[6] respectively, it is necessary to take into consideration the corrections for the molecular vibrations, including internal rotation. The procedure for dealing with these systems and the results obtained will be reported in forthcoming papers.

Table 7. Thermal average distances r_g and φ_a angles of acetyl chloride and acetyl bromide (distances in Å units)

	CH_3COCl		CH_3COBr	
r_g(C=O)	1.1874	0.0028[a]	1.1840	0.0044[a]

a) Limits of error.

The interatomic distances, the stretching vibrational frequencies, and the force constants for carbonyl bonds in various compounds are compared in Table 8. The r_g distances were chosen as the interatomic distances except for the CH_3COF, COF_2, $COCl_2$, and CH_3COCN molecules, for which the r_g distances are not known. The r_g distance may be larger, by as much as about 0.01 Å, than the corresponding r_s (or r_o) value. Even so, it is evident that molecules with at least one halogen

atom attached to a carbonyl group have shorter r(C=O)'s and higher ν(C=O)'s than do molecules containing no halogen atom, as may be seen in Table 8. Since the carbonyl-stretching frequencies are relatively insensitive to variations in the masses of atoms or groups attached to the carbonyl groups, a relation between the stretching frequency and the distance was frequently discussed in the past by assuming the carbonyl frequency to be one of the characteristics of the carbonyl bond. Margoshes *et al.*,[49] for example, plotted the bond distances *versus* the stretching frequencies for the carbonyl groups and mentioned that the points lie on a smooth curve with average deviations of 0.013 Å from the curve, with the largest error being 0.05 Å. They adopted the distances of not only simple molecules in the gas state, but also complex molecules such as amino acids in the crystalline state. However, now that we have more accurate structures in the gas state, a similar plot may

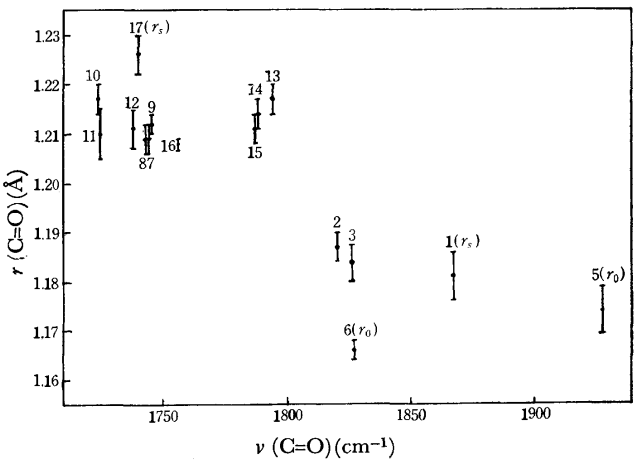

Fig. 3. Relation between bond length and stretching frequency for carbonyl groups. The numbers correspond to the compound numbers listed in Table 8 and the distances are entered in r_g unless remarked as r_s (or r_0). The vertical bars show the errors quoted in references.

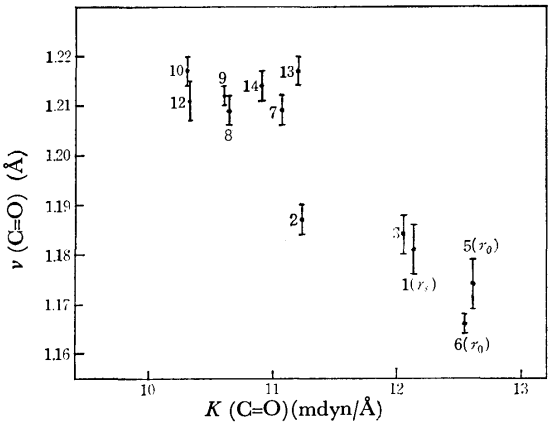

Fig. 4. Relation between bond length and force constant for carbonyl groups.

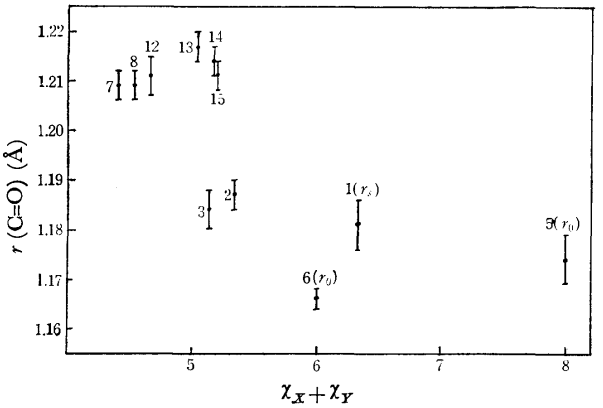

Fig. 5. Relation between the bond length of a carbonyl group and the sum of the electronegativity values of substituents for gaseous carbonyl-containing compounds. The electronegativity values of atoms are on the Gordy-Thomas scale[53] and those of the atomic groups, $-CH_3$, $-CH_2CH_3$, and -OH were evaluated by Kagarise's method.[52]

be made with the latest data (shown in Fig. 3). Roughly speaking, there exists a tendency for a molecule with a shorter r(C=O) to have a higher ν(C=O), as was pointed out by Margoshes *et al.* However, the plotted points can hardly be said to fall on a smooth curve in view of the accuracy of the current distance data.

The frequency-distance curve will serve for diagnostic purposes, but it is inappropriate for use in discussing the nature of the carbonyl bond, because the effect of the coupling between different normal modes of vibration is neglected. This has been particularly stressed by Overend *et al.*[16,44,50] A more physically significant quantity may be the force constant for the C=O bond. In Fig. 4, the r(C=O) values are plotted against the force constants, K(C=O), which, except for acetyl chloride, were calculated on the basis of the simple or a modified Urey-Bradley force field, with certain approximations where necessary. The value for acetyl chloride (Compound 2) is only an estimate made by Overend *et al.* by the use of the corresponding values for acetone and phosgene.[16] Since the calculated C=O stretching frequency for acetyl chloride is about 40 cm^{-1} smaller than the observed value, the best-fit force constant must be larger than this value, probably close to the force constants for acetyl bromide (Compound 3). The force constants for acids fall in the same region as those for the other compounds with no halogen atom. This is encouraging for the purpose of finding a relation between the force constant and bond length. However, the force constants listed in Table 8 have fairly large uncertainties, presumably ± 0.5 mdyn/Å on the average, and the r(C=O) values for the carbonyl halides cannot be compared directly with those for the other compounds. Nevertheless, it is clear, in surveying Table 8 and Fig. 4, that the halogen-containing compounds have the larger C=O force constants and the shorter bond lengths.

The shortening in the C=O bond length mentioned above may be considered to be partly due to the "*inductive effect*" and, perhaps, partly to the "*dipolar field effect.*"[51] Kagarise pointed out a linear relation between the sum of the electro-negativity values, χ_X and χ_Y, of the substituents, X and Y, and the carbonyl stretching frequencies for molecules of the X.CO.Y type, not including acids; *i.e.*, the higher the sum of the electronegativity values, the higher the frequency.[52] A plot of the sum of the electronegativity values against the r(C=O) bond length is shown in Fig. 5. The χ's for the $-CH_2CH_3$ and -OH groups were estimated to be 2.36 and 2.83 respectively, according to Kagarise's idea. The data for glyoxal, acrolein, benzaldehyde, oxalic acid, and acetyl cyanide were not plotted, since estimations of the χ's of the substituents, $-CH{=}CH_2$, $-C_6H_5$, and $-C{\equiv}N$, were difficult. However, since the χ's of the vinyl and phenyl groups are supposed to be similar to that of the H atom,[54] the data for acrolein and benzaldehyde would be in the region representing aldehydes, ketones, and acids on the electronegativity-distance map. It should be noticed that the sums of the electronegativity values for acids are nearly equal to those for acetyl chloride and bromide, while the r(C=O) distances for acids are much longer than those for the halides. This suggests that the C=O bonds in the halogen-containing compounds have partly a triple-bond character.[55]

Empirical relations between the bond lengths and the force constants for very simple molecules have been proposed by several workers.[56-58] Among them, Ladd *et al.*[58] have applied the relation for the carbonyl bond to amide molecules as well as to some of the molecules listed in Table 8, and have predicted the C=O stretching force constants. Their predicted values are generally reasonable. However, since the data of the bond

Electronic Spectra and Structures of Organic π-Systems. VI. Electronic States of Diazomethane, Ketene, Diazocyclopentadiene and Benzenediazonium Ion[1]

Zen-ichi YOSHIDA and Tsunetoshi KOBAYASHI*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received February 8, 1971)

The electronic states of diazomethane, ketene, diazocyclopentadiene and benzenediazonium ion were studied by the semi-empirical ASMO LCAO SCF CI method. Both π- and $\bar{\pi}$-systems were taken into consideration. Two types of approximations, Mulliken's formula and a new semitheoretical formula, were used in the evaluation of the core resonance integrals. The latter gives satisfactory results though it contains no arbitrary adjustable parameters. The longest wavelength singlet-singlet transition of diazomethane, ketene or diazocyclopentadiene is $^1\pi^*-{}^1\bar{\pi}$, and that of benzenediazonium ion $^1\pi^*-{}^1\pi$.

Cumulated systems such as diazomethane, ketene, diazocyclopentadiene and benzenediazonium ion are interesting from both physicochemical and organochemical view points. Orville-Thomas and Jones[2] treated diazomethane and ketene by the Hückel method. Hoffmann[3] treated diazomethane by his extended Hückel method. Evleth and Cox[4] treated benzenediazonium ion by the Hückel method and the free electron theory. Sukigara and Kikuchi[5] treated benzenediazonium ion by Pariser-Parr's ASMO LCAO CI method. Dixon and Kirby[6] treated ketene by the open shell SCFMO method. However, so far we have not come across the Pariser-Parr-Pople type SCFMO treatments of diazocyclopentadiene and benzenediazonium ion.

We wish to report on the study on the electronic states of diazomethane, ketene, diazocyclopentadiene, and benzenediazonium ion by the semiempirical ASMO LCAO SCF CI method. The $\bar{\pi}$-systems (in-plane π-systems) of these compounds are explicitly taken into consideration. In the evaluation of the core resonance integrals two types of approximations, Mulliken's formula and a new semi-theoretical formula containing no arbitrary adjusting parameters,[7] are used.

Method of Calculation

The self-consistent field molecular orbital theory[8] has been used to calculate the π-electronic charge distributions and the spectra of diazomethane, ketene, diazocyclopentadiene and benzenediazonium ion. Both

the π- and the $\bar{\pi}$-systems are considered explicitly.

The molecular structural data of diazomethane and ketene obtained by Cox, Thomas, and Sheridan[9,10] on the basis of the microwave spectral study were used. The molecular structure of benzenediazonium ion is assumed as that in benzenediazonium chloride determined by X-ray crystal analysis.[11] The molecular dimension of diazocyclopentadiene is assumed to be as shown in Fig. 1 using the structural data of benzenediazonium chloride and diazomethane. The five-membered ring of diazocyclopentadiene is assumed to be a regular pentagon. The carbon-carbon bond lengths of diazocyclopentadiene are assumed to be 1.40 Å.

The numberings of the atomic orbitals (in Arabic numerals) and the atoms (in Roman numerals) in the molecules are also given in Fig. 1.

The molecular orbitals (MO's), ϕ_i's, are taken as linear combinations of $2p_\pi$- and $2p_{\bar{\pi}}$-atomic orbitals (AO's), χ_r's.

$$\phi_i = \sum_r C_{ir}\chi_r \tag{1}$$

The total Hamiltonian, H, is given by

$$H = \sum_\mu H_\mu^{\text{core}} + \sum_{\mu<\nu}\frac{e^2}{r_{\mu\nu}} \tag{2}$$

$$H_\mu^{\text{core}} = -\frac{1}{2}A(\mu) - \sum_A \frac{e^2 Z_A}{r_{\mu A}} \tag{3}$$

where the Greek subscripts denote electrons, and Z_A the core charge of atom A left by removal of π-(and $\bar{\pi}$-) electrons.

For the closed-shell molecular species, the Roothaan SCF equation[8] is written as follows.

$$\sum_r C_{ir}(F_{rs} - S_{rs}\varepsilon) = 0 \quad (s = 1, 2, \cdots) \tag{4}$$

where

$$F_{rs} = H_{rs} + \sum_{t,u} P_{tu}\left[\langle rs\,|\,tu\rangle - \frac{1}{2}\langle rt\,|\,su\rangle\right]$$

$$S_{rs} = \int \chi_r\chi_s d\tau$$

$$H_{rs} = \int \chi_r(\mu) H_\mu^{\text{core}} \chi_s(\mu) d\tau_\mu$$

$$\langle rs\,|\,tu\rangle = \int \chi_r(\mu)\chi_s(\mu)\frac{e^2}{r_{\mu\nu}}\chi_t(\nu)\chi_u(\nu) d\tau_\mu d\tau_\nu$$

$$P_{tu} = 2\sum_i^{\text{occ}} C_{it}C_{iu}$$

For the sake of simplicity we used the Goeppert-Mayer and Sklar potential[12] and the so-called zero-differential overlap approximation.[13] We neglected non-neighbour core resonance integrals and penetration integrals of neutral atoms but not one-centre exchange integrals.

One-centre Coulomb repulsion integrals, $\langle rr|rr\rangle$'s, are evaluated using appropriate electron-transfer repulsions as proposed by Pariser.[14]

$$\langle rr\,|\,rr\rangle = I_r - A_r$$

where I_r and A_r denote the valence state ionization potential and the valence state electron affinity of the atomic orbital r, respectively. All the necessary values of I_r's and A_r's are taken from Hinze and Jaffé's tables.[15]

One-centre Coulomb repulsion integrals of the type $\langle rr|rr\rangle$'s are evaluated according to the formula

$$\langle rr\,|\,\bar{r}\bar{r}\rangle = \langle rr\,|\,rr\rangle - 6F_2^{\text{pp}}$$

where $\bar{r}$ and r are the $2p_\pi$-atomic orbitals of the same atom and orthogonal to each other. F_2^{pp} is the Slater-Condon parameter and the values of F_2^{pp}'s are taken from Pilcher and Skinner's table.[16]

One-centre exchange integrals are also evaluated using the Slater-Condon parameters as follows.

$$\langle r\bar{r}\,|\,r\bar{r}\rangle = 3F_2^{\text{pp}}$$

Two-centre Coulomb repulsion integrals $\langle tt|uu\rangle$'s and $\langle tt|\bar{u}\bar{u}\rangle$'s are evaluated using the parabolic formula when the distance R is shorter than 4 Å.

$$\langle tt\,|\,uu\rangle = \frac{\langle tt\,|\,tt\rangle + \langle uu\,|\,uu\rangle}{2} + aR + bR^2$$

$$\langle tt\,|\,\bar{u}\bar{u}\rangle = \frac{\langle tt\,|\,\bar{t}\bar{t}\rangle + \langle uu\,|\,\bar{u}\bar{u}\rangle}{2} + a'R + b'R^2$$

where the coefficients a, b, a', and b', are evaluated using the $\langle tt|uu\rangle$ values or the $\langle tt|\bar{u}\bar{u}\rangle$ values calculated at distances R=4 Å and 5 Å by the point charge approximation. When R is greater than 4 Å, $\langle tt|uu\rangle$'s and $\langle tt|\bar{u}\bar{u}\rangle$'s are evaluated by the point charge approximation.

The overlap integrals, S_{rs}'s, are evaluated according to Mulliken and coworkers' table.[17]

The H_{rr} term in Eq. (4) is given by

$$H_{rr} = \int \chi_r(\mu)\left(-\frac{1}{2}A(\mu) - \frac{e^2 Z_A}{r_{\mu A}}\right)\chi_r(\mu) d\tau_\mu - \sum_{B\neq A}\chi_r(\mu)\frac{e^2 Z_B}{r_{\mu B}}\chi_r(\mu) d\tau_\mu = \alpha_r + \sum_{B\neq A}\langle B\,|\,rr\rangle$$

where

$$\alpha_r = \int \chi_r(\mu)\left(-\frac{1}{2}A(\mu) - \frac{e^2 Z_A}{r_{\mu A}}\right)\chi_r(\mu) d\tau_\mu$$

$$\langle B\,|\,rr\rangle = -\int \chi_r(\mu)\frac{e^2 Z_B}{r_{\mu B}}\chi_r(\mu) d\tau_\mu$$

The core attraction integrals of the $\langle B|rr\rangle$ type are given as follows.

$$\langle B\,|\,rr\rangle_{B=1} = -\frac{Z_1}{2}\{\langle 11\,|\,rr\rangle + \langle 33\,|\,rr\rangle\}$$

$$\langle B\,|\,rr\rangle_{B=11} = -\frac{Z_{11}}{2}\{\langle 22\,|\,rr\rangle + \langle 44\,|\,rr\rangle\}$$

$$\langle B\,|\,rr\rangle_{B\neq 1,11} = -\langle rr\,|\,2P_{\pi_B}, 2P_{\pi_B}\rangle$$

a) Slater's orbital exponent.
b) See formulas (5), (6), and (7) in the text.
c) See formula (5) in the text.
d) See formula (3) in the text.
e) See formula (9) in the text.
f) See formulas (5) and (7) in the text.

α_r's are approximated as follows.

$$\alpha_{r_A}(r=1\sim4) = W'_{r_A} - (N_A-1)\langle rr|rr\rangle - (\bar{N}_A)\left\{\langle rr|\bar{r}\bar{r}\rangle - \frac{1}{2}\langle r\bar{r}|r\bar{r}\rangle\right\} \quad (5)$$

$$\alpha_r(r=5\sim10) = -11.16\,\text{eV}$$

where N_A and $\bar{N}_A$ in Eq. (5) are the numbers of electrons in the $2p_\pi$-atomic orbitals r and $\bar{r}$ of the atom A, respectively. Here the atomic orbital $\bar{r}$ is orthogonal to the atomic orbital r. $-W'_{t_A}$ is approximately equal to the first or second valence state ionization potential of the atomic orbital r. The values of α_r, W_r', N, $\bar{N}$, $<rr|rr>$, $<rr|\bar{r}\bar{r}>$ and $<r\bar{r}|r\bar{r}>$ are given in Table 1.

Two methods of approximations were employed in the evaluation of core resonance integrals, β_{tu}'s.

a) Mulliken's formula

$$\beta_{tu} = \frac{0.8676^7}{2} S_{tu}(W_t' + W_u') \quad (6)$$

The coefficient 0.86767 was evaluated using the empirical β_{CC}-value of benzene. This might be referred to as Eβ-approximation.

b) Theoretical formula

$$\beta_{t_Au_B} = \frac{S_{tu}}{2}\{W'_{t_A} + W'_{u_B} - \langle u|U_A|u\rangle - \langle t|U_B|t\rangle - \langle tt|uu\rangle(N_A+N_B-2) - \langle uu|\bar{t}\bar{t}\rangle(\bar{N}_A+\bar{N}_B)\} - \frac{1}{2}\{\langle t|T|u\rangle + \langle u|T|t\rangle\} \quad (7)$$

This might be referred to as Tβ-approximation. Formula (7) is derived as follows. We can easily obtain the following formula for the β_{tu} in the $\pi+\bar{\pi}$-systems as in the VI/2 method,[7] if the electron density change is taken into consideration.

$$\beta_{t_Au_B} = \frac{S_{tu}}{2}\{W'_{t_A} + W'_{u_B} - \langle u|U_A|u\rangle - \langle t|U_B|t\rangle - \langle tt|uu\rangle(P_{tt}+P_{uu}-2) - \langle uu|\bar{t}\bar{t}\rangle(P_{\bar{t}\bar{t}}+P_{\bar{u}\bar{u}})\} - \frac{1}{2}\{\langle t|T|u\rangle + \langle u|T|t\rangle\} \quad (8)$$

where W'_{t_A} is the orbital energy of the atomic orbital t_A and depends on the electron density of the atom in the molecule.

$$\langle u_B|U_A|u_B\rangle \fallingdotseq -\langle u_B|e^2Z_A'/r|u_B\rangle + n_{2s_A}\langle 2s_A 2s_A|u_Bu_B\rangle + n_{2p_{\sigma_A}}\langle 2p_{\sigma_A}2p_{\sigma_A}|u_Bu_B\rangle \quad (9)$$

$\langle u|e^2Z'_A/r|u\rangle$, $\langle 2s_A2s_A|u_Bu_B\rangle$, $\langle 2p_{\sigma A}2p_{\sigma A}|u_Bu_B\rangle$ and $\langle t|T|u\rangle$ are evaluated theoretically using the Slater atomic orbitals according to Roothaan.[18] Z_A' is the core-charge left by removal of electrons of principal quantum number 2 of the atom A. n_{2s_A} and $n_{2\sigma p_A}$ are the numbers of electrons in the atomic orbitals $2s_A$ and $2p\sigma_A$, respectively. If we put $P_{tt}=N_A$, $P_{uu}=N_B$, $P_{\bar{t}\bar{t}}=\bar{N}_A$ and $P_{\bar{u}\bar{u}}=\bar{N}_B$ in (8) we get (7).

For the sake of simplicity we used the fixed β_{tu}-values evaluated by (7) at certain limiting cases, where $P_{tt}=N_A$, $P_{uu}=N_B$, $P_{\bar{t}\bar{t}}=\bar{N}_A$ and $P_{\bar{u}\bar{u}}=\bar{N}_B$.

Two kinds of approximations were used in the evaluation of the atomic parameters of atom II: a) atom II is regarded as neutral (abbreviated as N-approximation) and b) atom II is regarded as positive (abbreviated as P-approximation). Thus all together four possible sets of approximations, NEβ, NTβ, PEβ, and PTβ, are used for each molecule.

The atomic parameters necessary in the calculation are given in Table 1.

The β_{tu}-values calculated by formulas (6) and (7) are given in Table 2.

The starting set of coefficients of MO's is obtained by the Hückel method. The eigenvalues and the eigenvectors are made self-consistent, and the electronic transition energies are then calculated by the configuration interaction (CI) method, all the singly excited configurations being taken into account.

The calculation has been carried out on a HITAC 5020 computer at the computation centre, the University of Tokyo, and on a FACOM 230-60 computer at the computation centre of Kyoto University.

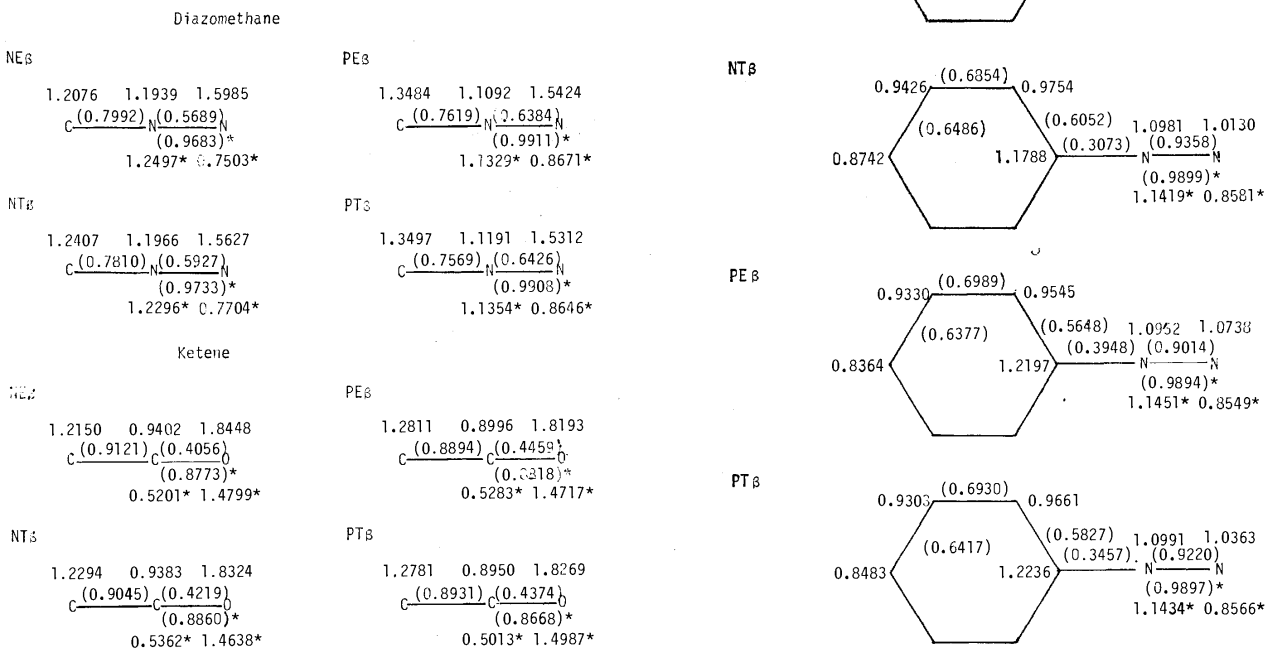
Results

The molecular diagrams of these compounds are given in Fig. 2.

The calculated and the observed transition energies are summarized in Table 3. CI coefficients are also given.

Discussion

As is shown in Table 2, with diazomethane β_{12}- and β_{45}-values calculated by formula (6) are slightly larger than those given by formula (7) in P-approximation. The same tendency is also observed with ketene, diazocyclopentadiene and benzenediazonium ion. In the cases of diazocyclopentadiene and benzenediazonium



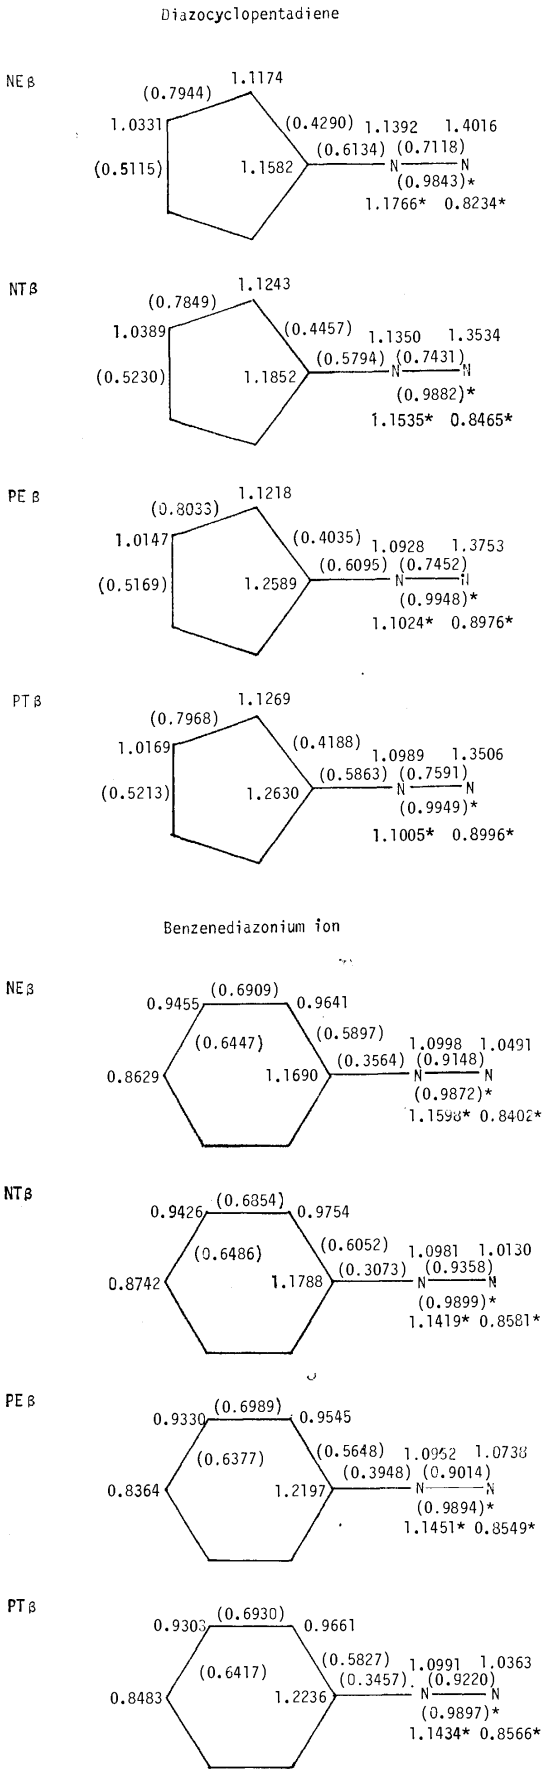


Fig. 2. Electron densities and bond orders (in parentheses).

a) The transition, indicated by i—j, refers to a one-electron excitation from orbital i to virtual orbital j. The second column gives the CI coefficient of the configuration i—j.

ion the β_{CC}-values calculated by formulas (6) and (7) are similar to each other.

In the case of diazomethane the four sets of approximations, NEβ, NTβ, PEβ, and PTβ, give similar eigenvector to one another. However, E_t-values obtained by P-approximation slightly differ from those given by N-approximation. Similar tendencies are also observed with ketene and diazocyclopentadiene. Estimated ionization potentials of diazomethane and ketene from SCF eigenvalues are 10.974—9.923 eV and 10.881—11.582 eV, respectively. The values are slightly larger than the observed ones, 8.99 eV (diazomethane[22]) and 9.607 eV (ketene[22]), respectively. Hoffmann[3] treated

diazomethane by his extended Hückel method. He obtained the value of −11.964 eV as the orbital energy of the highest occupied π-orbital. This is by about 1—2 eV smaller than ours. Dixon and Kirby[6] treated ketene by the PPP method. They made the π- and the $\bar{\pi}$-systems self-consistent independently. The eigenvectors they obtained are qualitatively similar to ours, but their eigenvalues differ from ours. Their orbital energy might lead to a large value of the ionization potential.

In the case of benzenediazonium ion the E_i- and the C_{ij}-values calculated by N-approximation differ slightly from those calculated by P-approximation.

The molecular diagrams of these compounds are shown in Fig. 2. In the case of diazomethane all the four sets of parameters give similar molecular diagrams. Every set of parameters suggests that nitrogen atom II bears a large positive charge and that the terminal carbon atom III and nitrogen atom I bear negative charges. The π-bond order of the nitrogen-nitrogen bond is 1.5—1.6. The molecular diagrams suggest that the carbon-nitrogen bond has a large double bond character.

In the case of ketene all the four sets of parameters give similar molecular diagrams and suggest that the central carbon atom II bears a charge of about +0.6 and the terminal oxygen atom a charge of about −0.3. The bond order of the carbon-oxygen bond is about 1.3. The bond order of the carbon-carbon bond is 0.9, suggesting that this bond has a large double bond character. Orville-Thomas and Jones[2] treated diazomethane and ketene by the simple Hückel method with and without π-hyperconjugation. The bond orders they obtained without hyperconjugation are similar to those shown in Fig. 2. The molecular diagram obtained from Dixon and Kirby's[6] SCF eigenvectors shows that the terminal oxygen atom is slightly positive and that carbon atom II is slightly negative in the ground state.

In the case of diazocyclopentadiene also the four sets of parameters give similar molecular diagrams. Nitrogen atom II bears a charge of about +0.7—0.8. This is larger than that of diazomethane. The terminal nitrogen atom I bears a charge of about −0.20——0.27. This is slightly smaller than that in diazomethane. The bond order of the nitrogen-nitrogen bond is about 1.7 and is larger than that in diazomethane. This suggests that the triple bond character of the nitrogen-nitrogen bond in diazocyclopentadiene is larger than that in diazomethane. The bond order of the carbon-nitrogen bond in diazocyclopentadiene is smaller than that of the corresponding bond in diazomethane. This suggests that the double bond character of the carbon-nitrogen bond in diazomethane is larger than that of the corresponding bond in diazocyclopentadiene. In the ground state a charge of about −0.5 is distributed over the five-membered ring. Thus it is anticipated that the contribution of the canonical formula $R^-–N_2^+$ to the ground state is not small. From the bond orders it can be anticipated that in the ground state the five-membered ring is not a regular pentagon but a slightly bond alternated pentagon in which the carbon(IV)-carbon(V) and the carbon(VI)-carbon(VII) bonds are slightly shorter than the carbon(III)-carbon(IV), the carbon(V)-carbon(VI), and the carbon(III)-carbon(VII) bonds.

In the case of benzenediazonium ion nitrogen atom II and terminal nitrogen atom bear charges of about +0.75 and +0.1 respectively. The carbon-nitrogen bond order is about 0.3—0.4 and smaller than that of diazomethane and diazocyclopentadiene. Thus the double bond character of the carbon-nitrogen bond in benzenediazonium ion might be smaller than that of diazomethane or diazocyclopentadiene. The nitrogen-nitrogen bond order is about 1.9 and is greater than that of diazomethane or diazocyclopentadiene, suggesting that the nitrogen-nitrogen bond has a greater triple bond character than that of diazomethane or diazocyclopentadiene. The greater part of the +1 charge of the cation exists on nitrogen atom II in the case of benzenediazonium ion.

From the above discussions the extent of contribution of the canonical formula $R^-–N_2^+$ or $R–N_2^+$ to the ground state might be in the order: diazomethane < diazocyclopentadiene < benzenediazonium ion. The triple bond character of the nitrogen-nitrogen bond might be in the order: diazomethane < diazocyclopentadiene < benzenediazonium ion. The double bond character of the carbon-nitrogen bond might be in the order: benzenediazonium ion < diazocyclopentadine < diazomethane. This is consistent with the observed nitrogen-nitrogen bond lengths and carbon-nitrogen bond lengths of diazomethane and benzenediazonium ion.

Evleth and Cox[4] treated benzenediazonium ion by the simple Hückel method. The π-electron densities ($P_{N_I}=0.706$, $P_{N_{II}}=1.340$) of nitrogen atoms I and II they gave differ from ours.

The calculated transition energies and the observed ones are summarized in Table 3. In the case of diazomethane, agreement between the calculated and the observed transition energies is best with PTβ-approximation. This is consistent with the molecular diagram. The observed 5.77 eV band can be assigned to $\pi—{}^1\pi^*$ transition. The observed 3.14 eV band is tentatively assigned to $\pi—{}^1\bar{\pi}^*$ transition. The calculated 2.417 eV $\pi—{}^1\bar{\pi}^*$ transition has the character of charge-transfer transition caused by electron migration from carbon III to the diazo-group. Hoffmann[3] assigned the longest wavelength transition to $\pi—\bar{\pi}^*$ by his extended Hückel method. This is consistent with our result.

In the case of ketene the observed bands can be assigned as in Table 3. Also in this case the long wavelength weak bands are π-${}^{1,3}\bar{\pi}^*$ transitions. From the MO coefficients it is anticipated that these two transitions have a large character of the intramolecular charge-transfer bands caused by the electron migration from carbon III to the CO-group. The strong band observed between 6.36—7.29 eV can be assigned to $\pi—{}^1\pi^*$. The transition energies calculated by Dixon and Kirby[6] are similar to ours. Knox, Norrish, and Porter[19] observed a weak band between 5.77—6.36 eV (max: 5.77 eV; log ε: 1.8). This band has been tentatively assigned to $\pi—{}^1\sigma^*$ by us[20] using the

ASMO-LCAO-SCF-CI method for the valence electron systems.

In the case of diazocyclopentadiene PTβ-approximation gives the best result as anticipated from the molecular diagrams. PEβ-approximation also gives a result similar to that given by PTβ-approximation. The 2.530 eV, 3.017 eV, 3.894 eV, and 4.346 eV transitions calculated by PTβ-approximation have the character of intramolecular charge-transfer bands caused by electron transfer from the five-membered ring to the diazo-group. The longest wavelength weak shoulder observed at about 2.70 eV is $\pi-{}^1\bar{\pi}^*$ transition.

In the case of benzenediazonium ion PEβ-approximation gives the best result. PTβ-approximation also gives a result similar to that given by PEβ-approximation. NEβ- and NTβ-approximations give unsatisfactory results. This is also anticipated from the molecular diagrams in Fig. 2. The 3.927, 4.245, and 4.395 eV transitions by PTβ-approximation have the character of intramolecular charge-transfer bands caused by electron migration from the benzene-ring to the diazo-group. In the case of benzenediazonium ion the longest wavelength singlet-singlet transition is $\pi-\pi^*$. On the other hand, as we have seen, the longest wavelength singlet-singlet transition is $\pi-\bar{\pi}^*$ in the case of diazomethane, ketene, and diazocyclopentadiene within $\pi+\bar{\pi}$-approximation. Sukigara and Kikuchi[5] have treated benzenediazonium ion by the PP type ASMO LCAO CI method taking the π-system only into consideration. They adjusted two parameters β_{NN} and ω (ω is the $\bar{\pi}$-electron density on nitrogen atom II) so as to reproduce the observed transition energies. They obtained -3.10 eV as β_{NN} and 1.05 as ω. The ω-value is close to the $\bar{\pi}$-electron density we obtained. This β_{NN}-value is slightly smaller than ours. They used $\beta_{CN}=-2.42$ eV and $\beta_{CC}=-2.39$ eV, which are similar to our values. The transitions they calculated by adjusting parameters β_{NN} and ω are similar to our results.

Conclusion

The molecular diagrams suggest that the triple bond character of the nitrogen-nitrogen bonds of these compounds is in the order, diazomethane < diazocyclopentadiene < benzenediazonium ion; and the double bond character of the carbon-nitrogen bonds in the order, benzenediazonium ion < diazocyclopentadiene < diazomethane. This is consistent with the observed carbon-nitrogen and nitrogen-nitrogen bond lengths of diazomethane and benzenediazonium ion. The extent of the contribution of the canonical formula $R^-\text{–}N_2^+$ or $R\text{–}N_2^+$ to the ground state may be in the order, diazomethane<diazocyclopentadiene<benzenediazonium ion.

The longest wavelength singlet-singlet transition is $\pi-\bar{\pi}^*$ in diazomethane, ketene, and diazocyclopentadiene and $\pi-\pi^*$ in benzenediazonium ion.

The semitheoretical formula (7) for the core resonance integral proposed in this paper gives satisfactory results though it contains no arbitrary adjustable parameters.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 749—753(1972)

Electronic Spectra and Structures of Organic π-Systems. VII. Electronic States of Benzoylium, Acryloylium, and Cinnamoylium Ions[1)]

Zen-ichi Yoshida and Tsunetoshi Kobayashi*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received February 8, 1971)

The electronic states of benzoylium, acryloylium and cinnamoylium ions have been studied by a semiempirical ASMO LCAO SCF CI method including both π- and $\bar{\pi}$-systems.

The results suggest that the contribution of the canonical formula $R^{-}-\overset{+}{C}O$ or $R-\overset{+}{C}O$ to the ground state in ketene should be smaller than that in benzoylium, acryloylium or cinnamoylium ion. The longest wavelength singlet-singlet transition of benzoylium or cinnamoylium ion is $\pi-{}^1\pi^*$ as in benzenediazonium ion, and that of acryloylium ion is $\pi-{}^1\bar{\pi}^*$ as in ketene, diazomethane and diazocyclopentadiene.

As a part of our investigations on the electronic states of cumulated systems, we reported on the electronic states of diazomethane, ketene, diazocyclopentadiene, and benzenediazonium ion.[2)] This paper deals with the electronic states of benzoylium (isoelectronic with benzenediazonium), cinnamoylium, and acryloylium ions. These systems called oxocarbonium ions are of

1) Presented at the Symposium on Molecular Structure, Fukuoka, October 1969.

2) Paper VI: Z. Yoshida and T. Kobayashi, This Bulletin, **45**, 742 (1972).

importance as the reaction intermediates in Friedel-Crafts type acylation.

The method used in this study is a semiempirical ASMO-LCAO-SCF-CI method in which π-systems are duly taken into consideration.

Method of Calculation

The method used in this study being the same as that used in the calculation of diazomethane, ketene, diazocyclopentadiene, and benzenediazonium ion,[2] its details are not given. Four types of approximations NEβ, NTβ, PEβ, and PTβ are used for each molecule.

For the sake of brevity the numberings of the atomic orbitals and the atoms in the molecules are given in Fig. 1.

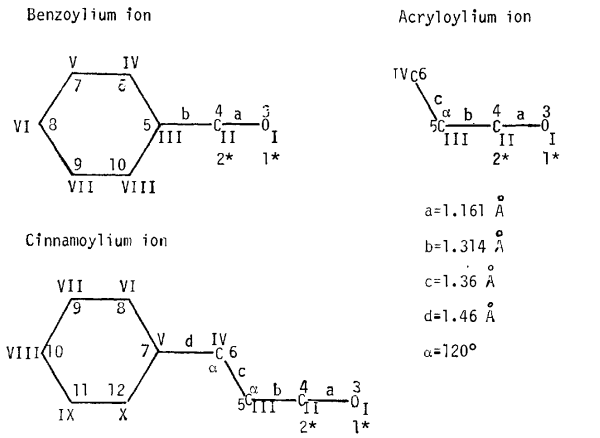

Fig. 1. Assumed structures and numberings of atoms (in Roman numerals) and numberings of atomic orbitals (in Arabic numerals) of benzoylium ion, acryloylium ion, and cinnamoylium ion. ('*' denotes an in-plane $2p_{\pi}$-atomic orbital.)

The molecular dimensions of these compounds are assumed to be as shown in Fig. 1. The carbon-oxygen bond length of methyloxocarbonium hexafluoroantimonate is 1.116 Å according to Boer.[3] This is slightly shorter than the carbon-oxygen bond length of ketene (1.161 Å) given by Kox, Thomas, and Sheridan.[4] We assumed the carbon-oxygen bond lengths and the carbon(II)-carbon(III) bond lengths of benzoylium ion, acryloylium ion, and cinnamoylium ion to be equal to those of ketene given by Kox and co-workers as shown in Fig. 1. This is because the CO-groups are in conjugation with other π-systems. The carbon(III)-carbon(IV) bond length of acryloylium ion or cinnamoylium ion is assumed to be 1.36 Å from the structural data of *trans*-acrolein.[5] The carbon(IV)-carbon(V) bond length of cinnamoylium ion is assumed to be 1.46 Å from the data of *syn-p*-chlorobenzaldoxime.[6] The benzene rings of benzoylium ion and cinnamoylium ion are assumed to be regular hexagons with the carbon-carbon bond lengths of 1.397 Å. Carbon (III), carbon(II), and the oxygen atom of each compound are assumed to lie on a straight line according to the structural data of methyloxocarbonium hexafluoroantimonate.[3,7]

The calculated core resonance integrals β_{tu}'s are summarized in Table 1.

The calculation has been carried out on a FACOM 230-60 computer at the computation centre of Kyoto University.

Results

The molecular diagrams of these compounds are shown in Fig. 2. The reported molecular diagrams of ketene are also given. The calculated and the observed transition energies are given in Table 2 together with CI coefficients.

Discussion

In the case of benzoylium ion, the β_{12}- and β_{45}-values calculated by PEβ-approximation are slightly larger than those calculated by PTβ-approximation as shown in Table 1. In N-approximation the β-values given by both methods NTβ and NEβ are similar to each other. The other β_{CC}-values calculated by formulas (6) and (7) in Ref. 2 are in good agreement with each other.

On the whole the four sets of parameters give similar SCF eigenvalues and eigenvectors. The eigenvectors of benzoylium ion are similar to those of benzenediazonium ion.

As is seen in Fig. 2, in the case of benzoylium ion carbon atom II carries a charge of about +0.7—+0.8 and the terminal oxygen I is nearly neutral. The bond

order of the carbon(II)-oxygen bond is about 1.6. The bond order of the carbon(II)-carbon(III) bond is about 0.54—0.60. A charge of about +0.7 exists on the CO-group. If we compare the molecular diagrams of

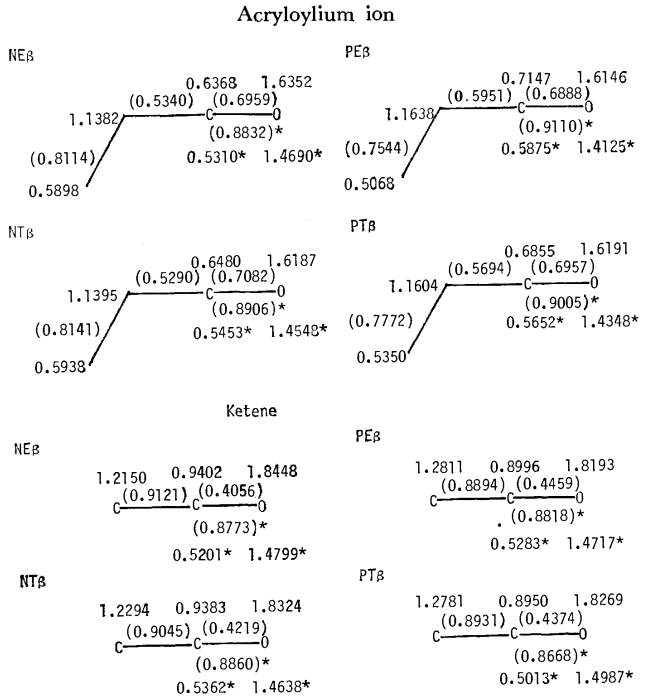

Fig. 2c. Electron densities and bond orders (in parentheses) of acryloylium ion and ketene.

ketene with those of benzoylium ion, the CO bond of benzoylium ion can be anticipated to have a larger triple bond character than the CO bond of ketene, and the C_{II}–C_{III} bond of ketene, a larger double bond character than the C_{II}–C_{III} bond of benzoylium ion. The electron density on the oxygen or carbon atom (I) in ketene is greater than that of the corresponding atom of benzoylium ion. On the whole the extent of contribution of the canonical formula $R–C^{+}\equiv O$ or $R^{-}–C^{+}\equiv O$ to the ground state may be greater in the case of benzoylium ion than in ketene.

In the case of acryloylium ion carbon atom II carries a charge of about +0.7—0.8 as in benzoylium ion. The terminal oxygen is nearly neutral as in benzoylium ion. The bond orders of the carbon(II)-oxygen bond and the carbon(II)-carbon(III) bond are about 1.6 and 0.53—0.60, respectively. These values are similar to those of benzoylium ion. The CO-group in acryloylium ion bears a charge of about +0.73—0.67. The extent of contribution of the canonical formula $R–C^{+}\equiv O$ to the ground state of acryloylium ion might be nearly equal to that in benzoylium ion.

In the case of cinnamoylium ion carbon atom II bears a charge of about +0.7—0.8 as in benzoylium ion and acryloylium ion. The terminal oxygen is nearly neutral also in this system. The bond order of the carbon(II)-oxygen bond is about 1.53 which is slightly smaller than those in benzoylium ion and acryloylium ion. The bond order of the carbon(II)-carbon(III) bond is about 0.61—0.67 which is slightly larger than those of acryloylium ion and benzoylium ion. The results suggest that the triple bond character of the carbon(II)-oxygen bond is slightly smaller than those of benzoylium ion and acryloylium ion, and the double bond character of the carbon(II)-carbon(III) bond is slightly larger than those of the other two com-

pounds. The bond order of the carbon(III)-carbon (IV) bond in acryloylium ion is 0.75—0.80 which is greater than that of cinnamoylium ion, 0.61—0.69. This suggests that the double bond character of the carbon(III)-carbon(IV) bond of acryloylium ion is larger than that of cinnamoylium ion. The CO-group of cinnamoylium ion bears a charge of about +0.58—0.64. The value is smaller than those in benzoylium and acryloylium ions. On the whole the triple bond character of the carbon(II)-oxygen bond of benzoylium ion, acryloylium ion or cinnamoylium ion is more enhanced than that of ketene. The double bond character of the carbon(II)-carbon(III) bond of ketene may be larger than those of benzoylium, acryloylium, and cinnamoylium ions. Contribution of the canonical formula $R^-–\overset{+}{C}O$ or $R–\overset{+}{C}O$ to the ground state of benzoylium ion, acryloylium ion, or cinnamoylium ion might be larger than in ketene.

Calculated transition energies are summarized in Table 2. In the case of benzoylium ion P-approximation gives better results than the other. This is consistent with the molecular diagram. Calculated 4.788 eV and 5.910 eV transitions (PTβ-approximation) are $\pi—{}^1\bar{\pi}^*$ transitions and are the so-called intramolecular charge-transfer transitions. The character of the transitions of this system is similar to that of benzenediazonium ion.

In the case of acryloylium ion P-approximation gives a better result as in the case of benzoylium ion. This is also consistent with the molecular diagrams. The calculated 5.052 eV transition has the character of the so-called intramolecular charge-transfer transition. This is $\pi—{}^1\bar{\pi}^*$ transition.

In the case of cinnamoylium ion the four methods give similar results but P-approximation gives slightly better results. The calculated 4.423 eV transition by PTβ-approximation has the character of the so-called intramolecular charge-transfer transition, and is $\pi—\bar{\pi}^*$ transition.

Conclusion

The triple bond character of the CO bond of benzoylium ion, acryloylium ion or cinnamoylium ion may be larger than that of ketene. The double bond character of the carbon(II)-carbon(III) bond of ketene may be larger than that of acryloylium ion, cinnamoylium ion or benzoylium ion. The contribution of the canonical formula $R^-–\overset{+}{C}O$ (or $R–\overset{+}{C}O$) to the ground state in ketene may be smaller than in benzoylium ion, acryloylium ion, and cinnamoylium ion.

The longest wavelength singlet-singlet transitions of benzoylium and cinnamoylium ions are $\pi—\pi^*$ as in benzenediazonium ion, and that of acryloylium ion is $\pi—\bar{\pi}^*$ as in diazomethane, ketene, and diazocyclopentadiene.

The Benzene-photosensitized Decomposition of Carbonyl Sulfide in a Cyclohexane Solution

Shin SATO, Hiroshi MIYAMOTO, Shun-ichi HIROKAMI, and Shigeru TSUNASHIMA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received July 27, 1971)

The decomposition of carbonyl sulfide photosensitized by benzene in the solution of cyclohexane has been investigated at room temperature. The quantum yield of CO formation, ϕ_{CO}, at an infinite concentration of COS was estimated to be 1.0. The COS concentration dependence of ϕ_{CO} corresponded well to that of the quenching efficiency of COS on benzene fluorescence. These results suggest that, of the two possible photosensitization processes:

$$C_6H_6(^1B_{2u}) + COS \longrightarrow C_6H_6 + CO + S(^1D)$$

and

$$C_6H_6(^3B_{1u}) + COS \longrightarrow C_6H_6 + CO + S(^3P),$$

the former is responsible for the formation of CO. The very small yield of cyclohexanethiol may be explained by the fact that benzene is an efficient catalyzer for the transition process, $S(^1D) \rightarrow S(^3P)$.

When electronically excited at around 5 eV, carbonyl sulfide has two energetically-possible decomposition channels. The one is through an excited singlet state:

$$COS = CO(^1\Sigma^+) + S(^1D) \qquad \Delta H = 98.8 \text{ kcal/mol}$$

the other is through a triplet:

$$COS = CO(^1\Sigma^+) + S(^3P) \qquad \Delta H = 72.4 \text{ kcal/mol}$$

Therefore, the benzene-photosensitized decomposition of carbonyl sulfide at 2537 Å, if it occurs, has two possible processes. The reaction mechanism may be described as follows:

$$C_6H_6 + h\nu \longrightarrow C_6H_6^*(^1B_{2u}) \quad (1)$$

$$C_6H_6^* \longrightarrow C_6H_6 + h\nu_f \quad (2)$$

$$C_6H_6^* \longrightarrow C_6H_6^{**}(^3B_{1u}) \quad (3)$$

$$C_6H_6^{**} \longrightarrow C_6H_6 \quad (4)$$

$$C_6H_6^* + COS \longrightarrow C_6H_6 + CO + S(^1D) \quad (5)$$

$$C_6H_6^{**} + COS \longrightarrow C_6H_6 + CO + S(^3P) \quad (6)$$

This report will be mainly concerned with which process, Reaction (5) or (6), is more important for the decomposition of carbonyl sulfide.

The gas-phase photolysis of carbonyl sulfide was extensively investigated by Gunning and Strausz.[1] Regarding the liquid-phase, Gollnick and Leppin reported several important observations.[2] When COS is photolyzed at 2537 Å in liquid alkanes such as cyclohexane and cyclopentane, the quantum yield of CO formation is 0.9 and that of mercaptan is in the range of 0.3—0.5. They also showed that methyl, ethyl, and isopropyl alcohols and acetonitrile efficiently catalyze the transition process, $S(^1D) \rightarrow S(^3P)$.

Recently, we showed that COS molecules act as effective electron scavengers in the radiolysis of benzene.[3] Consequently, the benzene-photosensitized decomposition of COS has become an urgent problem to be solved.

Experimental

The COS was a product of the Merck Company. Further purification was not made except for bulb-to-blub distillation, with the rejection of the head and tail fractions. The cyclohexane (Tokyo Kagaku Seiki Co., spectro grade) was passed through a 1 m silica-gel column before use. The benzene (Tokyo Pure Chemical Co., spectro grade) and ethylene (Takachiho Chemical Co.) were used as supplied.

A low-pressure mercury resonance lamp containing 5 Torr Ne was used for irradiating solutions at room temperature in a 30 m*l*, 1 cm thick, cylindrical quartz vessel. The solution was stirred with a magnetic stirrer in order to maintain the homogeneity of the solute concentration. The irradiating light was passed through a Toshiba UV-25 glass filter to cut off the wavelengths shorter than 2000 Å. The reaction vessel was irradiated horizontally to let the gas produced escape from the reaction zone.

In order to estimate the light intensity, the mercury-photosensitized decomposition of ethylene was carried out in a reaction vessel of exactly the same size. The quantum yield of hydrogen at 45 Torr of ethylene was assumed to be 0.203.[4]

The benzene fluorescence spectra were measured using a Hitachi PMF-2A fluorometer. The exciting light was set at 2537 Å. The cell used for the measurement was modified so as to evacuate it and to introduce a quencher gas.

The gas noncondensable at the temperature of liquid nitrogen was collected and measured by means of a Toepler pump. After passing the gas through a cuprous oxide furnace at 390°C, the noncondensables at the temperature of dry ice-methanol were again collected and measured. Cyclohexanethiol and benzenethiol were analyzed, using a Hitachi 023 gas chromatograph equipped with a FID detector and a 1 m tricresylphosphate column at 80°C. Bromobenzene was used as a reference to estimate the absolute yield because its elution time is close to that of cyclohexanethiol.

The solubility of carbonyl sulfide in cyclohexane and in benzene was measured by a technique already reported.[5] Ostwald's coefficients obtained at 20°C are 8.0 in cyclohexane and 13 in benzene.

Results

Benzene-photosensitized Decomposition of COS. A rather high concentration of benzene (0.43 mol/l) was used to prevent the direct photolysis of COS ($\varepsilon_{2537} \approx 10\ l\,mol^{-1}cm^{-1}$).[6] At this concentration, more than 99% of the impinging light at 2537 Å is absorbed in the solution. The quantum yield of CO is listed in Table 1 as a function of the COS concentration. The values of ϕ_{CO} may be a little overestimated, because the resonance line absorbed by mercury at room temperature is sharper than that emitted by the light source and because benzene molecules can absorb the foot of the resonance line. No gas noncondensable at 77°K other than CO could be obtained.

Table 1. The quantum yield of carbon monoxide in the benzene-photosensitized decomposition of carbonyl sulfide in the solution of cyclohexane

Benzene consentration is 0.43 mol/l

Concentration of COS 10^{-2} mol/l	Quantum yield of CO ϕ_{CO}
0.22	0.17
0.24	0.19
0.26	0.21
0.37	0.25
0.41	0.27
0.42	0.30
0.44	0.35
0.53	0.42
0.65	0.40
0.75	0.40
0.87	0.47
1.09	0.48
1.21	0.64
2.17	0.73
2.84	0.82
3.09	0.76

Gas-chromatographic analysis showed that cyclohexanethiol is the only product in the liquid. The formation of benzenethiol could not be detected. As the yield of cyclohexanethiol was very small, the benzene concentration dependence was checked. The results are shown in Fig. 1. Obviously, the presence of benzene severely prevents the formation of cyclohexanethiol. In the absence of benzene, the light is absorbed by COS and the [cyclohexanethiol]/[CO] ratio obtained is in agreement with that reported by Gollnick and Leppin.[2]

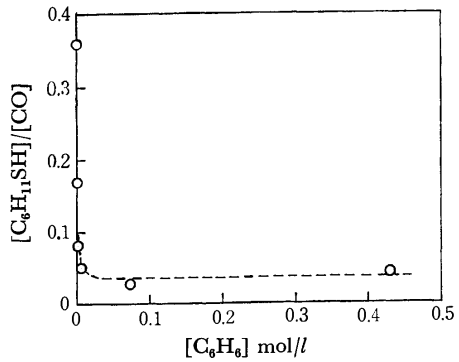

Fig. 1. The relative yield of cyclohexanethiol as a function of the concentration of benzene.

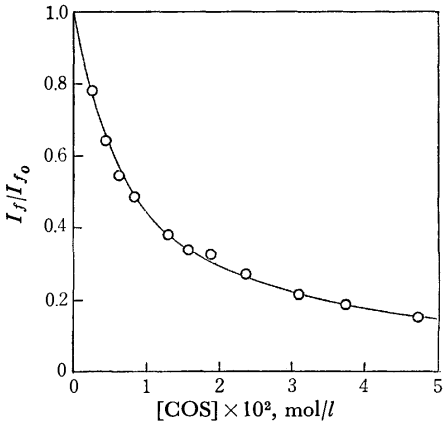

Fig. 2. The relative intensity of the benzene fluorescence as a function of the concentration of carbonyl sulfide.

Quenching of Benzene Fluorescence by COS. The benzene fluorescence was measured at 2800 Å, where the spectrum showed its maximum. In Fig. 2, the relative intensity of the fluorescence is plotted as a function of the concentration of COS. Exactly the same quenching curve was obtained by using the fluorescence intensity at a different wavelength (2950 Å). The benzene concentration used was 0.43 mol/l; the value was the same as that used for the photosensitized decomposition.

Discussion

The steady-state-treatment of the reaction mechanism described in the Introduction gives the following Stern-Volmer equation:

$$I_{f_0}/I_f = 1 + k_5\tau[COS] \qquad (I)$$

Here, I_{f_0} and I_f denote the fluorescence intensity in

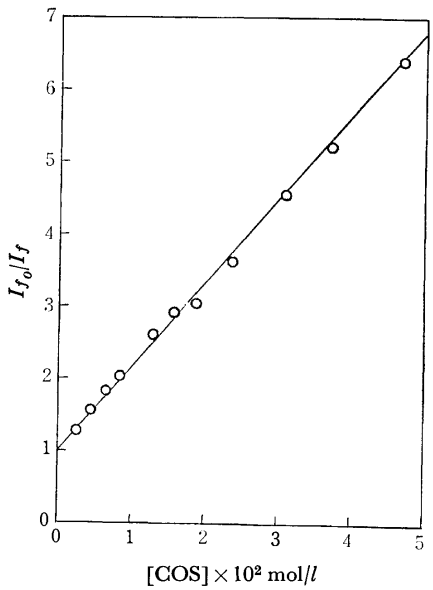

Fig. 3. The Stern-Volmer plot on the benzene fluorescence. The quencher is carbonyl sulfide.

6) K. Gollnick and E. Leppin, *Mol. Photochem.*, **2**, 179 (1970).

the absence and in the presence of the quencher, COS, respectively. k_5 is the rate constant of Reaction (5), and τ is the lifetime of the $^1B_{2u}$ benzene in this solution. From the linear relationship shown in Fig. 3, the $k_5\tau$ value could be calculated to be 110 ± 10 l/mol by the least-squares method. This value may be compared with 300 l/mol, the value which was obtained in the gas phase.[7]

Since the CO formation has two possible channels, the quantum yield of CO has a somewhat complicated dependence on the concentration of COS.

$$\phi_{CO}^{-1} = \left(1+\frac{1}{k_5\tau[COS]}\right)\left(1+\frac{k_3k_6}{k_5k_6[COS]+k_5/\tau'}\right)^{-1} \quad \text{(II)}$$

Here, τ' is the lifetime of the $^3B_{1u}$ benzene in the solution. If only one of the two possible channels is operative for the formation of CO, Eq. (II) can be simplified as follows:

$$\phi_{CO}^{-1} = A^{-1}\left(1+\frac{1}{B[COS]}\right) \quad \text{(III)}$$

In the case of the channel through the singlet-excited state, $A\leq1$ and $B=k_5\tau$, while in the case of the channel through the triplet state, A cannot exceed the quantum yield of the intersystem crossing, ϕ_{SC} and $B=k_6\tau'$. Figure 4 shows the reciprocal of the yield of CO as a function of the reciprocal of the COS concentration. Although the plots are a little scattered, the least-squares method gives $A\approx1.0$ and $B=80\pm30$ l/mol. This value of B roughly agrees with the $k_5\tau$ value obtained by the measurement of the fluorescence quenching.

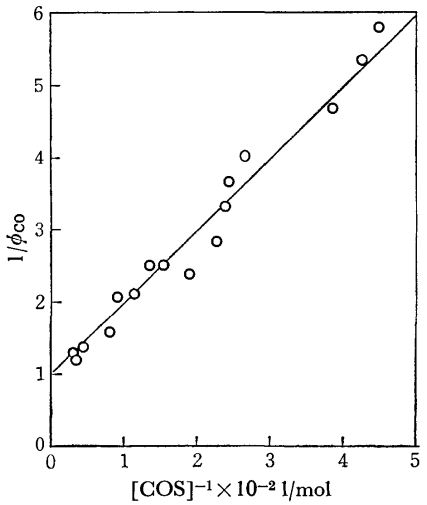

Fig. 4. The reciprocal of the quantum yield of carbon monoxide as a function of the reciprocal of the concentration of carbonyl sulfide.

The lifetime of the $^1B_{2u}$ benzene in cyclohexane at room temperature is reported to be 29 nsec, where the concentration of benzene is 3.4×10^{-2} mol/l.[8] Ludwig and Amata observed that the lifetime in n-nonane is a little dependent upon the concentration of benzene, but its value is not smaller than 26 nsec, even in pure benzene.[9] In the present discussion, therefore, τ may be assumed to be 29 nsec.

The situation is very obscure for the lifetime of the $^3B_{1u}$ benzene. Cundall *et al.* estimated that the lifetime in pure benzene is of the order of 10 nsec.[10] In a previous paper, we investigated the benzene-photosensitized isomerization of butene-2 in a solution of cyclohexane and estimated the lifetime of the $^3B_{1u}$ benzene to be of the order of 0.1 μsec at 5×10^{-4} mol/l of benzene.[11]

Consequently, the agreement between the B value and the $k_5\tau$ value obtained in the fluorescence measurement cannot establish that Reaction (5), the singlet-singlet energy transfer, is responsible for the formation of CO. If the triplet-triplet energy transfer, Reaction (6), is responsible for this process, however, the A value should be equal to or less than ϕ_{SC}. Our previous paper showed that ϕ_{SC} is less than 0.25, while Cundall *et al.* estimated that ϕ_{SC} in pure benzene is 0.6. The present experiment obviously shows that the quantum yield of CO at an infinite concentration of COS is much higher than 0.6. As stated in the Results section, the quantum yields obtained in the present experiment may be a little overestimated. The error is probably within 10%, however, because the quantum yield of cyclohexanethiol in the absence of benzene is in good agreement with that reported by Gollnick and Leppin.[2]

Thus, the discussion of the B factor could not distinguish whether Reaction (5) or Reaction (6) is responsible for the formation of CO, but that of the A factor strongly suggested that Reaction (5) is responsible. It may be concluded, therefore, that the CO formation in the benzene-photosensitized decomposition of COS in cyclohexane results from the singlet-singlet energy transfer. As has been stated above, the $k_5\tau$ value is 80—110 l/mol. The k_5 value, therefore, is $3.3\pm0.6\times10^9$ l/mol sec. This value suggests that Reaction (5) is diffusion-controlled.

As was shown in the Results section, the presence of benzene severely hindered the formation of cyclohexanethiol. This is probably because benzene molecules effectively catalyze the transition process, $S(^1D)\rightarrow S(^3P)$. In the benzene-photosensitization, the following process may be operative:

$$C_6H_6(^1B_{2u}) + COS \longrightarrow C_6H_6\cdots S + CO$$
$$\longrightarrow C_6H_6 + S(^3P) + CO$$

Here, $C_6H_6\cdots S$ represents the intermediate complex.

Since the benzene concentration used in the present experiment is high, the formation of the benzene singlet excimer cannot be ruled out. If the excimer formation is included in the reaction mechanism, the steady-state-treatment becomes a little more complicated. However, the conclusion of the singlet-singlet energy transfer cannot be altered regardless of whether or not the

excimer is quenched by COS.

In this work, the presence of the $^3E_{1u}$ state (4.5 eV) of benzene is completely ignored because its property is unknown. If the property becomes apparent, the inclusion of this state in the reaction mechanism can be easily done.

Amino Wagging of the *tert*-Butylamine in $\tilde{A}$ Electronic State

Akiko Y. Hirakawa, Hideyuki Miyazaki, and Masamichi Tsuboi

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received August 24, 1971)

Ultraviolet absorption spectra of two isotopic *t*-butylamines, $(CH_3)_3CNH_2$ and $(CH_3)_3CND_2$, have been observed in their gaseous state in the spectral region 2000—2500 Å. There is an electronic band, whose 0—0 band peaks are observed respectively at 2351.2 and 2334.9 Å. The vibrational structure of the band, caused by the amino wagging vibration, was analyzed. On the basis of the observed energy levels, the potential function of the excited molecule along the amino wagging coordinate was determined; it is nearly harmonic with a small positive quartic term. The dependence of intensity on the vibrational quantum number and the intensity ratio of the fundamental and the hot bands indicate that the equilibrium structure of the amino group is the same as that of methylamine; the angle between the C–N axis and the HNH plane has been determined to be $51\pm4°$.

Every aliphatic amine has a strong electronic absorption band in the 2300 Å region. We have examined previously the vibrational structure of the bands of four isotopic methylamines.[1] The result indicated that the amino group has a plane structure in the lowest excited electronic state ($\tilde{A}$), while in the ground state ($\tilde{X}$) it has a pyramidal structure.[2] Along the amino wagging coordinate there are two potential minima separated by a barrier of 1688 cm^{-1} in height in the $\tilde{X}$ state,[3,4] whereas in the $\tilde{A}$ state the potential function is nearly harmonic up to tenth vibrational quantum states. The ammonia molecule is also planar in the lowest excited electronic state according to the result of an analysis[5] of the rovibronic spectrum of ND_3. In the work reported here we have examined the corresponding band of *t*-butylamine and its amino deuterated compound in an attempt to elucidate the effect of an adjacent bulky group on the amino wagging potential. As will be detailed below, the amino group of *t*-butylamine is also found to be planar in the lowest excited electronic state. It has been shown, however, the potential function along the amino wagging coordinate is appreciably different from that in methylamine.

Experimental

t-Butylamine was purchased from Tokyo Kasei Company. *t*-Butylamine-d_2 gas was obtained from deuterated *t*-butylamine hydrochloride by adding concentrated D_2O solution of NaOD. $(CH_3)_3CND_2\cdot DCl$ was obtained by the exchange reaction of $(CH_3)_3CNH_2\cdot HCl$ with D_2O. NaOD used was obtained by the reaction of metallic sodium with D_2O vapor at lower temperature. All the procedures for deuteration were carried out in a vacuum line.

Ultraviolet absorption measurements of these two isotopic *t*-butylamines in the 2000—2500 Å region were made by the use of a Hitachi EPS-3T spectrometer with a quartz prism. The calibration was made by the absorption lines of the γ system of nitric oxide in the region from 1955 to 2270 Å.[6] The relative position of each vibrational peak has been determined with an experimental error of about ±0.5 Å.

A gas cell with quartz windows and with 10 cm path length was used. The pressure of the gas was in the range

of 0.5—1.5 mmHg to obtain spectra of suitable absorption intensity. In Figs. 1 and 2, the absorption curves of two isotopic *t*-butylamine obtained at 300°K are given. To distinguish the hot bands (v'←1) from the fundamental bands (v'←0), the spectra at 350°K were also examined and are given in Fig. 3.

Experimental Results and Analysis of the Spectra

The ultraviolet absorption spectrum of *t*-butylamine in the 40000—50000 cm^{-1} region consists of a few sets of long progressions of bands. First of all, the 0–0 band of each isotopic molecule was determined. The intensities of the peaks at 2397.0 and 2356.8 Å of $(CH_3)_3CNH_2$ increase as the temperature is elevated. Therefore, these peaks are assigned to hot bands and the peak at 2351.2 Å, whose intensity decreases as the temperature is raised, is assigned to the 0–0 band of A–X electronic transition. The frequency difference between the 0–1 band (the peak at 2397.0 Å) and the 0–0 band is 813 cm^{-1}, and this agrees with the frequency of the amino wagging vibration, 811 cm^{-1} observed in the infrared absorption spectrum.[7] Similarly, for $(CH_3)_3CND_2$, the temperature effects on the spectrum show that the peaks at 2408.3, 2372.3, 2338.9, and 2306.1 Å are hot bands and the peak at 2334.9 Å is assignable to the 0–0 band. The frequency difference between the 0–1 band (the peak at 2372.3 Å) and the 0–0 band, 675 cm^{-1}, is equal to the infrared absorption frequency, 673 cm^{-1} [7] within the experimental error.

In the analysis of the bands now in question, every detail of the observed structures should be regarded to be caused by the vibrations of the molecules. The rotational structure should not appear, because even if the rotational lines form a P or R head it should be located within 15 cm^{-1} from each band center, *i.e.* at a smaller distance than the resolution (25 cm^{-1}) of the spectrometer used. For both isotopic *t*-butylamines, all the observed vibronic bands are explained in terms of four vibrational frequencies, ν'_1, ν'_2, ν'_3, and ν'_4, of the excited state and one vibrational frequency ν''_1 of the ground state. The observed frequencies of the bands with their peak heights are given in Tables 1 and 2. Every observed frequency can be assigned to one of the calculated frequencies

$$\nu_{00}+v_1'\nu_1'+v_2'\nu_2'+v_3'\nu_3'+v_4'\nu_4'+f(v_1', v_2', v_3', v_4')-v_1''\nu_1''.$$

The assignment are shown in Tables 1 and 2 in terms of a set of vibrational quantum numbers v_1', v_2', v_3', v_4', and v_1''. The values of ν_{00}, ν'_1, ν'_2, ν'_3, ν'_4, ν''_1 and $f(v_1', v_2', v_3', v_4')$ are derived as shown in the follwing paragraphs and are given in the footnotes of Tables 1 and 2. In the bands of *t*-butylamines, there are a few long progressions of v_1'. The vibrational frequencies of the members of these progressions are given by

$$\nu(v_1') = \nu_{obs}(v_1', v_2', v_3', v_4', v_1'') - \nu_{obs}(v_1'=0, v_2', v_3', v_4', v_1''). \quad (1)$$

These frequencies $\nu(v_1')$ are given in Tables 3 and 4.

The vibrational structure of the band of the undeuterated species $(CH_3)_3CNH_2$ looks slightly complicated, because there is a short progression of v_2' as well as the long progression of v_1'. In other words, there is a progression of progression. The intensities and frequencies of peaks crowded in the 2270 Å region, those in the 2235 Å region, those in the 2200 Å region, and those in the 2160 Å region are all well explained by considering such a progression of progression. The frequencies $\nu(v_1')$ of the members of this progression of progression are given in the second, third, and forth columns of Table 3. In addition, there are two progressions of weaker bands, whose frequencies $\nu(v_1')$ are given in the fifth and sixth column of Table 3. In the seventh column the frequencies $\nu(v_1')$ of the members of a hot band progression are given. The observed $\nu(v_1')$ values presented in the second, third, and fourth columns of Table 3 can be reprodced by an empirical formula.

$$\nu(v_1') = 702.5v_1' + 5.64(v_1')^2 - 1.0(v_1')(v_2'). \quad (2)$$

The $\nu(v_1')$ values calculated from Eq. (2) with $v_2'=0$ are given in the last column of Table 3. The cal-

a) The values v_1', v_2', v_3', and v_4' are given in parentheses (in cm^{-1}).
b) $v(v_1')$ given by Eq. (1).
c) Calculated values by Eq. (3).

culated values are in an agreement not only with the observed values of the main progression, but also with those of the two progressions of v_2' progression, because the cross term between v'_1 and v_2', ($x_{12}=-1.0$) is negligibly small. The cross terms (x_{13} and x_{14}) between v_1' and v_3' and between v_1' and v_4' are considered to be a little larger than x_{12}. They are estimated to be -7.5 and -13 respectively.

The vibrational structure of the band of the deuterated species $(CH_3)_3CND_2$ is simpler. There is a main progression whose members are markedly strong and easily picked out. Their frequencies are given in the second column of Table 4. Three other progressions of weak bands, whose frequencies are given in the third, fourth, and fifth columns of Table 4, are also easily found out. In the sixth column of Table 4, the frequencies $v(v_1')$ of the members of a hot progression are given. The observed $v(v_1')$ values of the main progression (second column of Table 4) can be reproduced by an empirical formula

$$v(v_1') = 601.1v_1' + 27.0(v_1')^2. \quad (3)$$

The $v(v_1')$ values calculated from Eq. (3) are given in the last column of Table 4. The cross terms x_{12}, x_{13}, and x_{14} are estimated to be -4.4, -4.5, and -14 respectively.

Amino Wagging Potential for the Upper State

The energy value of the vibronic levels for the upper state of the main progression is now found to be expressed in the form

$$\nu = \nu_e + \omega_1\left(v_1'+\frac{1}{2}\right) + x_{11}\left(v_1'+\frac{1}{2}\right)^2. \quad (4)$$

On the basis of the empirical formula (2) and (3), ν_e= 41771, ω_1=696.9, and x_{11}=5.64 cm^{-1} for the undeuterated species and ν_e=42528, ω_1=598.4, and x_{11}=2.70 cm^{-1} for the deuterated species. The frequency appearing in the main progression (with the suffix 1) is assigned to the amino wagging vibration. This assignment is based upon its frequency (696.9 cm^{-1}), the isotope effect on its frequency (598.4 cm^{-1} for the ND_2 compound), and the character of the electronic band now in question. The band is considered to be caused by a transition in which one of the lone pair electrons on the nitrogen atom is taken up from its original orbital onto the 3*s* orbital of the nitrogen atom.[8] For such a transition, the most pronounced change in the geometrical structure of the molecule is expected

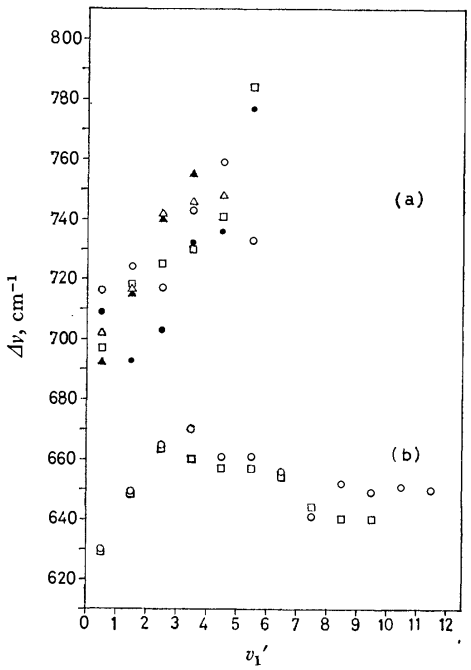

Fig. 4. Spacing of the adjacent vibronic bands in the progression of the amino wagging vibration in the $\tilde{A}$-$\tilde{X}$ band plotted against the vibrational quantum number v_1' for this vibration. Fig. 5. Similar plotting to that in Fig. 4 for (a) $(CH_3)_3CND_2$ and (b) CH_3ND_2. For (a), ○(for the main progression), △(for the $v_2'=1$ progression), □(for the $v_3'=1$ progression) and ●(for the $v'_4=1$ progression). For (b), ○(for the main progression) and □(for the $v_2'=1$ progression).

to take place along the amino wagging coordinate, as in the case of methylamine.[1] Therefore, the amino wagging vibration is expected to form the main progression in the vibrational structure of the band. Thus, Eq. (4) is regarded to give the energy levels of the amino wagging vibration of the *t*-butylamine molecule in the $\tilde{A}$ electronic state. It is noteworthy that the interval of the adjacent levels increases with increasing v_1'. In this respect, *t*-butylamine is similar to ammonia,[9] but it presents a contrast to methylamine, for which the interval is almost independent of v_1'. This contrast is demonstrated in Figs. 4 and 5. This fact indicates that the potential function along the amino wagging coordinate involves a positive quartic term for *t*-butylamine, whereas the function is nearly harmonic for methylamine.[1]

Let us now assume that the potential function along the amino wagging coordinate, θ (the external angle between the HNH plane and the C–N bond), has the form,

$$hcV = \frac{1}{2}k\theta^2 + j\theta^4. \tag{5}$$

The potential constant k and j are related to the observed ω_1 and x_{11} as

$$\omega_1 = \frac{1}{2\pi c}\sqrt{\frac{k}{\mu}} \tag{6}$$

and

$$x_{11} = \frac{3h^2}{32\pi^4\omega_1{}^2\mu^2c^2}\,\frac{j}{hc} \tag{7}$$

where μ is the reduced moment of inertia (amu·Å^2), h the Planck's constant, and c the light velocity. A transformation, leads to the potential function,

$$Q = \sqrt{\mu}\theta, \quad (\text{in amu}^{1/2}\text{Å}) \tag{8}$$

leads to the potential function,

$$hcV = \frac{1}{2}KQ^2 + JQ^4, \tag{9}$$

where

$$K = k/\mu^2 \tag{10}$$

and

$$J = j/\mu^2. \tag{11}$$

By the use of the observed values of ω_1 and x_{11}, we obtain the potential functions,

$$V(\text{cm}^{-1}) = 7200Q^2 + 1610Q^4 \quad \text{for } (CH_3)_3CNH_2 \tag{12}$$

and

$$V(\text{cm}^{-1}) = 5310Q^2 + 567Q^4 \quad \text{for } (CH_3)_3CND_2. \tag{13}$$

The potential fuction for the excited state of *t*-butylamine -d_2 is shown graphically in Fig. 6 (a).

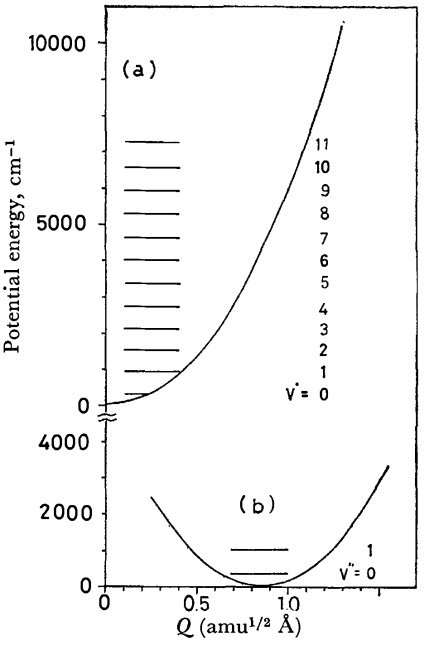

Fig. 6. Potential functions and vibrational energy levels of the amino wagging vibration of *t*-butylamine-d_2. (a) in the first excited electronic state $\tilde{A}$ and (b) in the ground state $\tilde{X}$.

Position of the Potential Minimum in the Lower State

The amino-wagging potential just described indicates that the *t*-butylamine molecule in the upper state has a planar amino group in its equilibrium conformation. It is probable, on the other hand, the amino group of *t*-butylamine is pyramidal in its ground electronic state as it is usually so in any aliphatic primary amine. In other words, the potential minimum in the lower state is considered to be greatly shifted along the amino wagging coordinate from that in the upper state as is shown in Fig. 6. The amount of shift (or the position of the potential minimum in the ground state, Q_{min}) can be estimated from the intensity distribution among the members of each of the progressions mentioned above.

Thus, according to the Franck-Condon principle, the

9) A. D. Walsh and P. A. Wasrop, *Trans. Faraday Soc.*, **57**, 345 (1961).

integrated intensity I of each vibronic band $v'\leftarrow v''$ is given by

$$I = \int \varepsilon(\nu)\mathrm{d}\nu = (8\pi^2 N\nu_{v'\leftarrow v''}/3\boldsymbol{h}c)\,|R_e|^2|S_{v'v''}|^2, \quad (14)$$

where N is the population in the lower state, R_e is the electronic transition moment of the band in question, and $S_{v',v''}$ is the overlap integral,

$$S_{v'v''} = \langle\phi_{v'}(Q)\cdot\phi_{v''}(Q)\rangle, \quad (15)$$

in which $\phi_{v'}$, (Q) and $\phi_{v''}(Q)$ are the vibrational eigenfunctions of the upper and lower states, respectively. In an approximation, both of these vibrational eigenfunctions are assumed to be those of harmonic oscillators, so that

$$\phi_{v'}(Q) = N_{v'}\exp[-(\gamma'/2)Q^2]H_{v'}(\sqrt{\gamma'}Q) \quad (16)$$

and

$$\phi_{v''}(Q) = N_{v''}\exp[-(\gamma''/2)(Q-Q_{\min})^2] \times H_{v''}[\sqrt{\gamma''}(Q-Q_{\min})]. \quad (17)$$

Here, $N_{v'}$ and $N_{v''}$ are the normalization factors, $\gamma' = 4\pi^2\omega'/\boldsymbol{h}$, and $\gamma'' = 4\pi^2\omega''/\boldsymbol{h}$. ω' and ω'' are the harmonic frequencies of the amino wagging vibrations in the upper and lower states respectively. In Eq. (14), all the fraction except $|S_{v'v''}|^2$ in the expression of the integrated intenisty are considered to be practically independent of v'. We therefore calculated $|S_{v'v''}|^2$ as a function of v' by the use of various assumed values of $Q_{\min}$, and compared the results with the observed intensities.

The relative value of absorbance determined at the peak of each vibronic band is given in Tables 1 and 2. In determining the intensities of the bands from these values a possibility of the superposition of the absorptions caused by the second electronic transition $\tilde{B}\leftarrow\tilde{X}$ must be taken into account. In each of Figs. 1 and 2, is shown by a line (b) what is considered to be the upper limit of such background absorption. In other words, the background absorption is considered to be some where between the lines (a) and (b) in Fig. 1 or 2. By subtracting this background absorption from the observed peak height, we can estimate the peak intensity of each band. The integrated intensity is considered to be proportional to the square of the peak intensity because each vibrational band should have the similar rotational structure, therefore, it has a similar contour to another.

The integrated intensities of the members of the v_1'-progressions, thus estimated, are given in Figs. 7 and 8. Each vertical line indicates a range of ambiguity caused by the difficulty of estimating the background absorption, and each range given by the line coresponds to the range (a) to (b) of the background absorption (Figs. 1 and 2).

In Figs. 7 and 8, are also shown the calculated intensities, *i.e.* the calculated values of $|S_{v'v''}|^2$ for a few different assumed values of $Q_{\min}$. The calculations were made by the use of a HITAC 5020E computer in the Computer Centre of the University of Tokyo. A comparison of the observed and calculated intensities indicates that $Q_{\min}=0.65\pm0.05$ amu$^{1/2}$ Å for $(CH_3)_3CNH_2$ and $Q_{\min}=0.85\pm0.05$ amu$^{1/2}$ Å for $(CH_3)_3CND_2$.

An estimation of the $Q_{\min}$ value can also be made

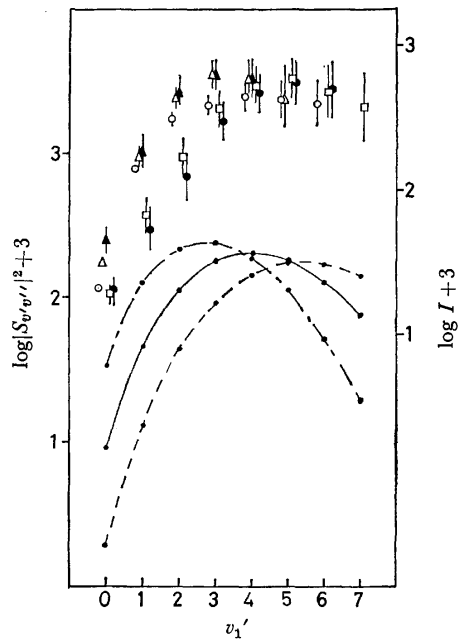

Fig. 7. The relative intensities of the vibronic bands in the progression of the amino wagging vibration of $(CH_3)_3CNH_2$, plotted against the vibrational quantum number v_1'. The points connected with curves represent the calculated values for $Q_{\min}=0.75$ amu$^{1/2}$ Å (---), for $Q_{\min}=0.65$ amu$^{1/2}$ Å (—) and for $Q_{\min}=0.55$ amu$^{1/2}$ Å (—·—·). The observed integrated intensities are shown by ○(for the main progression), △(for the $v_2'=1$ progression), ▲(for the $v_2'=2$ progression), □(for the $v_3'=1$ progression) and ●(for the $v_4'=1$ progression). The vertical line indicates the range of ambiguity of the observed intensity, which corresponds to the range of the background absorption defined by (a) and (b) in Fig. 1.

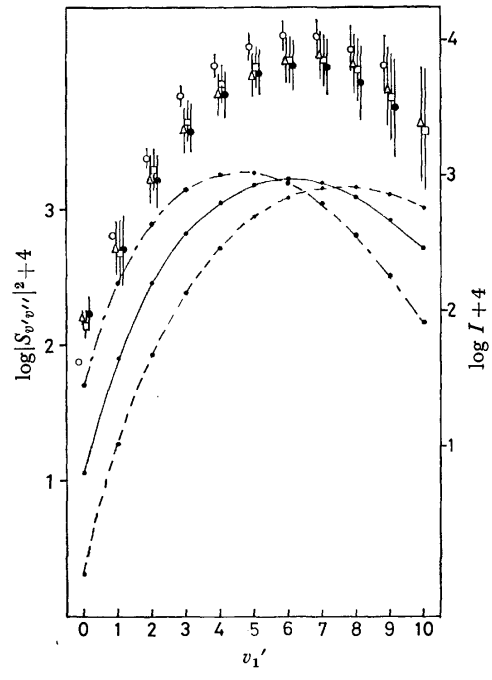

Fig. 8. Similar plotting to that in Fig. 7 for $(CH_3)_3CND_2$. The calculated values for $Q_{\min}=0.95$ amu$^{1/2}$ Å (---), for $Q_{\min}=0.85$ amu$^{1/2}$ Å (—) and for $Q_{\min}=0.75$ amu$^{1/2}$ Å (—·—·) are shown. The observed integrated intensities are shown by ○(for the main progression), △(for the $v_2'=1$ progression), □(for the $v_3'=1$ progression), and ●(for the $v_4'=1$ progression).

from the observed integrated intensity ratio (R) of the $(v'=1)\leftarrow(v''=1)$ band *versus* $(v'=0)\leftarrow(v''=0)$ band or of the $(v'=2)\leftarrow(v''=1)$ band *versus* $(v'=1)\leftarrow(v''=0)$ band. In general, a pair of bands $(v'+1)\leftarrow 1$ and $(v')\leftarrow 0$ come close to each other, and therefore in estimating the intensity ratio (R) of these bands the ambiguity caused by the background absorption is relatively small. On the other hand, the intensity ratio R should be sensitive to the $Q_{\min}$ value. A calculation has been made of the theoretical values of R for a few assumed values of $Q_{\min}$ by the use of Eqs. (15), (16), and (17). In Figs. 9 and 10, the observed and calculated intensity ratios (R) of such pairs of bands are given. In comparison, it is shown again that $Q_{\min}=0.65$ amu$^{1/2}$ Å for $(CH_3)_3CNH_2$ and $Q_{\min}=0.85$ amu$^{1/2}$Å for $(CH_3)_3CND_2$.

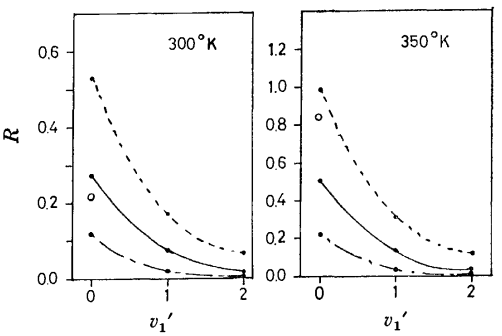

Fig. 9. Intensity ratio of the $v_1'\leftarrow 0$ band *versus* $v_1'+1\leftarrow 1$ band of *t*-butylamine plotted against v_1' at 300 and 350°K. The points connected with curves represent the calculated values for $Q_{\min}=0.75$ amu$^{1/2}$ Å (---), for $Q_{\min}=0.65$ amu$^{1/2}$ Å (—), and for $Q_{\min}=0.55$ amu$^{1/2}$ Å (—·—·). Circles represent the observed values.

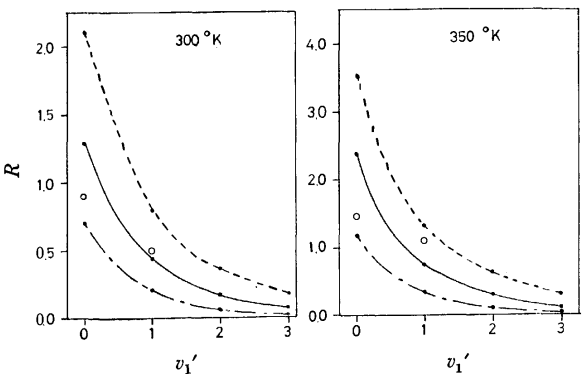

Fig. 10. Intensity ratio of the $v_1'\leftarrow 0$ band *versus* $v_1'+1\leftarrow 1$ band of *t*-butylamine-d_2 plotted against v_1' at 300 and 350°K. The points, connected with curves, represent the calculated values for $Q_{\min}=0.95$ amu$^{1/2}$ Å (---), for $Q_{\min}=0.85$ amu$^{1/2}$ Å (—) and for $Q_{\min}=0.75$ amu$^{1/2}$ Å (—·—·). Circles represent the observed values.

Discussion

From our analysis of the bands, an amount of information has now been obtained on the potential function along the amino wagging coordinates of upper and lower states of *t*-butylamine and *t*-butylamine-d_2. The values of potential constants obtained are given in Table 5.

The position of potential minimum in the ground state has been estimated to be at $Q=0.65\pm0.05$ and 0.85 ± 0.05 amu$^{1/2}$ Å respectively for $(CH_3)_3CNH_2$ and $(CH_3)_3CND_2$. These values are equal to the corresponding values (0.655 and 0.845 amu$^{1/2}$ Å, respectively) of methylamine.[4] If we know the reduced moment of inertia μ we can estimate the equilibrium angle θ by Eq. (8). Let us assume that the value of μ is equal to the inverse of the diagonal element of the G matrix (inverse kinetic energy matrix) corresponding to the wagging coordinate of the planar amino group. Then $\mu=0.540$ amu Å^2 for $(CH_3)_3CNH_2$ and $\mu=0.885$ amu Å^2 for $(CH_3)_3CND_2$. With these values of μ, the equilibrium θ value should be $50.7\pm4°$ for $(CH_3)_3CNH_2$ and $51.7\pm3°$ for $(CH_3)_3CND_2$. Both of these are practically equal to the known value of θ (=51.3°) of methylamine.[2] Thus, the equilibrium conformation of the amino group for *t*-butylamine in the ground state is now found to be quite similar to that for methylamine.

Table 5. Estimated potential constants of amino wagging motion for *t*-butylamine and *t*-butylamine-d_2 in $\tilde{X}$ and $\tilde{A}$ electronic state

$(CH_3)_3CNH_2$		
	ground ($\tilde{X}$)	excited($\tilde{A}$)

x_{11}(cm^{-1})	—	5.6$_4$
$Q_{\min}$(amu$^{1/2}$Å)	0.65±0.05	0
θ(degree)	50.$_7$°±4°	0
$(CH_3)_3CND_2$		
	ground ($\tilde{X}$)	excited ($\tilde{A}$)
ν_1(cm^{-1})	675	601.$_1$
ω_1(cm^{-1})	—	598.$_4$
x_{11}(cm^{-1})	—	2.7$_0$
$Q_{\min}$(amu$^{1/2}$Å)	0.85±0.05	0
θ(degree)	51.$_7$°±3°	0

The potential function in the upper state for *t*-butylamine, on the other hand, has been found to be somewhat different from that for methylamine. As has been demonstrated in Figs. 4 and 5, the potential function is nearly harmonic in methylamine, while in *t*-butylamine the potential rises up more steeply as the wagging angle of the amino group increases. As a possible cause of the difference it may be proposed to consider the repulsive force between the bulky *t*-butyl group and the amino group. To test this proposal, a calculation of the repulsive potential has been made for various positions (θ) of the amino group in both of these amines on the basis of a probable set of bond lengths and bond angles and on the basis of potential functions for the non-bonded C···H and H···H atom pairs given by Hendrickson[10] or those given by Bartell.[11] The result indicated that at least a part of the observed difference is explained by the extra repulsive potential caused by the bulkiness of the *t*-butyl group.

Lastly, a brief discussion will be made of the observed vibrational frequencies of the undeuterated and deu-

terated *t*-butylamines in the excited states. The frequency 1000 cm^{-1} of the former is considered to correspond to the frequency 991 cm^{-1} of the latter, and 1119 cm^{-1} to 789 cm^{-1}. The two frequencies 697 and 823 cm^{-1} of the undeuterated species are considered to be caused by a strong vibrational coupling. The intrinsic amino wagging frequency of the undeuterated species should be 765 cm^{-1} if it is 598 cm^{-1} in the deuterated compound. This vibration may couple with the 735 cm^{-1} vibration and may split into the 697 and 823 cm^{-1} vibrations. It is probable that the 735 cm^{-1} vibration which takes place in both deuterated and undeuterated molecules is a skeletal stretching vibration on the basis of a normal vibration calculation of isobutane[12] and of a comparison with the frequencies of *t*-butylfluoride (750 cm^{-1}),[13] *t*-butylalcohol (748 cm^{-1}) and *t*-butylalcohol-d (744 cm^{-1}).[14]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 764—769(1972)

Laser Photolysis Studies on the Formation of Solvated Ion Radicals in the Pyrene—*N,N*-Dimethylaniline System in Various Solvents

Yoshio TANIGUCHI, Yasuzo NISHINA, and Noboru MATAGA*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received August 27, 1971)

Formation of solvated ion radicals in the pyrene-*N,N*-dimethylaniline (DMA) system (which is a typical one showing heteroexcimer (HE) fluorescence) in various solvents has been studied by means of the laser photolysis and transient photoconductivity as well as transient absorption measurements. Ion radical formation due to the encounter collision between an excited pyrene and DMA in moderately as well as in strongly polar solvents has been established. This result is quite important in explaining the experimentally observed relation between the solvent dependent HE fluorescence quantum yield and decay time.

In relation to the electron transfer mechanism of fluorescence quenching in solution, somewhat detailed studies concerning the solvent effects on the HE fluorescence have been carried out.[1,2] According to those investigations, the fluorescence yield as well as fluorescence decay time of HE decrease as the solvent polarity is increased, where the solvent dependence of the fluorescence yield is much stronger than the decay time. One of the present authors (N.M.)[1] has interpreted this result as due to the decrease of the radiative transition probability and the increase of the radiationless transition probability of HE as the solvent polarity is increased. On the other hand, Weller and coworkers[2] have proposed an alternative interpretation for this phenomenon. They assumed the competition of the following two processes for an aromatic hydrocarbon (acceptor) and an aromatic amine (donor) system

$$A^* + D \xrightarrow{k_C} (A^- \cdot D^+)^*$$

$$A^* + D \xrightarrow{k_I} (A_s^- \cdots D_s^+)$$

where $(A^- \cdot D^+)^*$ is the fluorescent HE and $(A_S^- \cdots D_S^+)$ represents solvent-shared ion-pair which is non-fluorescent. It is assumed that the rate of process k_I increases with the increase of the solvent polarity, while process k_C is independent of the solvent polarity.

In order to examine the validity of the assumption of the existence of the non-fluorescent ion-pair state in a solvent which is not very polar, we have undertaken nsec laser photolysis studies on aromatic hydrocarbon-amine system in various solvents. If the dissociation of the ion-pair $(A_S^- \cdots D_S^+)$ into the solvated ion radicals $(A_S^- + D_S^+)$ occurs to some extent in a solvent which is more or less polar, it may be possible to confirm the existence of the dissociated ions by means of the nsec laser photolysis and conductivity measurements. Of course, it may be also possible to observe the non-fluorescent ion-pair and/or the solvated ion radicals by means of the nsec laser photolysis and the measurement of absorption spectra of ions as well as time variations of absorption intensities. However, the sensitivity of the detection by photoconductivity measurements may be higher than that by the absorption spectral measurements. Accordingly, the method of the nsec laser photolysis and conductivity measurement appears to be quite suitable for the detection of ion radicals of rather small concentration in the solvent which is not very polar.

In the following, we show the results of our measurements on the ion radical formation in the pyrene-*N*, *N*-dimethylaniline (DMA) system in various solvents with different polarities.

Experimental

We have used a Q-switched ruby laser (Japan Electron Optics, JLR-O2A) with the out-put power of about 1.5 joule.

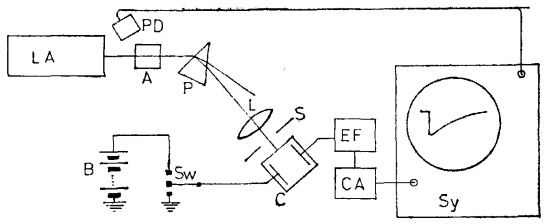

Fig. 1. Schematic diagram of the apparature for the transient photoconductivity measurement. LA: Q-switched ruby laser, PD: photo-diode, A: ADP frequency doubler, P: prism for separating the 694 and 347 nm beams, L: lense, S: slit, C: cuvette, B: battery, SW: switch, EF: emitter follower amplifier, CA: cascade amplifier type CA-2, Sy: Tektronix 585A oscilloscope.

The exciting light pulse of 347 nm was produced through the ADP frequency doubler with conversion efficiency of about 8%. The light pulse has a duration of 15—20 nsec.

The optical arrangement for the photocurrent measurments is shown in Fig. 1. The position of the quartz cuvette for the measurement of photocurrents or transient spectra was settled by using the light beam of a He-Ne gas laser which reproduced the optical path of 347 nm pulse. The optical path of the 347 nm beam was recorded by burned spots on coloured paper produced by irradiating with the 347 nm pulse.

The quartz cuvette for the photocurrent measurments contains two 9 mm × 10 mm Ni plate electrodes spaced each other by 7 mm. The direct irradiation on the electrodes was avoided by putting an optical slit on the front face of the cuvette. The supplied D.C. voltage between electrodes was adjusted in the range from 90 V to 540 V. Current signal obtained was converted to voltage signal through a 50Ω resister or home-made emitter follower amplifiers, the frequency characteristics of which covered the range from about 2 kHz to 150 MHz. The input impedance of our emitter followers was 13.2, 4.12, and 0.887 kΩ, respectively. Some weaker signals of photocurrent were measured by using Iwatsu cascade amplifier type CA-2. The time constant of the electronic circuit was less than 5 nsec when a 50Ω resister was used. In the other cases where the amplifiers were used, the time constant of the electronic circuit increased because of stray capacities of the cuvette and cables. The DC dark current was omitted by using the AC coupling of an emitter follower as well as the AC coupling of an input of Tektronix 585 A oscilloscope. For examining the effect of the exciting light intensity on the photocurrent, the intensity of the laser pulse was varied by using neutral filters composed of wire gauzes.

Transient absorption spectra of ion radicals produced by laser photolysis were measured by means of the methods explained in detail elsewhere.[3] The absorption spectra of ion radicals were photographed by using laser breakdown sparks in O_2 and Xe gases as spectroflashes. On the other hand, the spectra as well as time variations of their intensities were measured by using a Xe flash lamp as a monitoring light source.

Acetonitrile was refluxed repeatedly over phosphorus pentoxide, distilled into potassium carbonate and fractionally distilled. Merck spectrograde *n*-hexane, toluene, ethylether, monochlolobenzene, ethylene dichloride, methylethylketone, and acetone were used without further purification. Pyrene was chromatographed on activated alumina and silica gel, and extensively zone-refined. DMA was refluxed with acetic anhydride, washed with water, dried over potassium hydroxide, and distilled in vacuum several times. All the solutions measured were deaerated completely by repeated freeze-pump-thaw cycles.

Results and Discussion

Generally speaking, the photocurrent density may be given by,

$$i(t) = \sum_j z_j e n_j(t) \mu_j E_{eff} \quad (1)$$

where $z_j e$, μ_j and $n_j(t)$ represent an electric charge, the mobility of j-th carrier and its number in unit volume, respectively. E_{eff} is an effective electric field working on the carriers.

In the case of three compoment system of pyrene-DMA-solvent, the charge carriers may be mainly pyrene anions and DMA cations. We have confirmed the simultaneous production of these anions and cations by means of the laser photolysis and the measurement of the transient absorption spectra. For example, the spectra observed in acetonitrile and pyridine are indicated in Fig. 2 where the absorption bands appearing in the region from 440 to 510 nm can be ascribed to those of pyrene anion and DMA cation and those around 400 nm are due to the T-T absorption of pyrene.[4]

The effective electric field may be given by, $E_{eff} = E_{app}/\varepsilon$, where E_{app} is an applied electric field and ε is

the static dielectric constant of solution. Accordingly, Eq. (1) can be reduced to the following.

$$i(t) = en(t)(\mu_{\text{anion}}+\mu_{\text{cation}})E_{\text{app}}/\varepsilon \qquad (2)$$

For the actual evaluation of the concentrations of produced ions in various solvents from the observed photocurrent, the value of the mobility of ion radicals in each solvent is necessary. Because the concentration of ions is rather low, we assume here that the mobility is independent of the ion concentration and is inversely proportional to the viscosity η of the solvent.[5] Then, the concentration of ions may be proportional to the product of (photocurrent) $\times\eta\times\varepsilon$.

In the case of the three component system, the ion radicals may be produced by the encounter collision between A* and D, and the produced ions may decay mainly due to the recombination reaction, *i.e.* electron transfer from anion to cation. Since the concentration of DMA in the present study is approximately 10^{-2}—10^{-1} M, the formation of ion radicals seems to occur very rapidly during nsec time region. Actually, we have confirmed that the formation of ion radicals is quite rapid and the rise curve of the photocurrent is the same as that of a time-integrated function of a 347 nm pulse. As an example, the rise curve of photocurrent and that of the optical absorption at 493 nm (pyrene anion) of the pyrene-DMA-acctonitrile system are indicated in Fig. 3 together with the shape of an exciting light pulse.

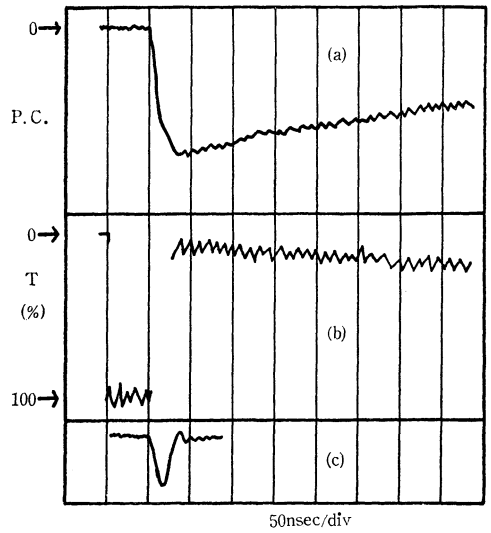

Fig. 3. The rise curve of photocurrent and that of the optical absorption of pyrene anion in the case of pyrene-DMA-acetonitrile system. Concentrations of pyrene and DMA are the same as those in Fig. 2.
(a) photocurrent. (b) transmittance at 493 nm. (c) shape of an exciting light pulse.

Since the concentration of the produced ion radicals may be rather small, the rate of the disappearance of ions due to the recombination reaction will be much slower compared to the rate of their production. We have confirmed that the photocurrent as well as the absorbance due to the ions decay slowly during times

(a) photocurrent (b) transmittance at 493 nm.

of μsec. As an example, the observed results for pyrene-DMA-acetone system are shown in Fig. 4.

If the decay of ions is mainly due to the bimolecular reaction between the acceptor anion and the donor cation radicals, both of the reciprocal of the photocurrent and that of the absorbance due to the ions should be proportional to time. This requirement is well satisfied as it is indicated in Fig. 5 for the same system as in Fig. 4. The difference in the slope between (a) and (b) in Fig. 5 can be ascribed to the difference in the initial concentrations of produced ions.

Now, because the formation of ion radicals is quite

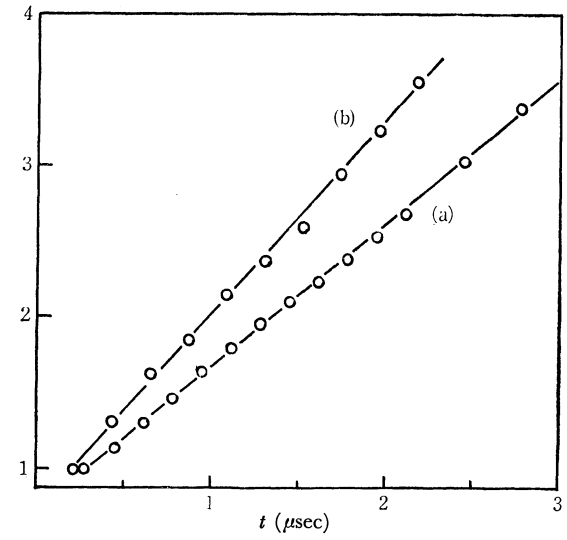

Fig. 5. The reciprocal of the photocurrent *vs.* time relation (a) and the reciprocal of the absorbance *vs.* time relation (b). The same system as indicated in Fig. 4.

rapid while they decay slowly during times of μsec as it is described above, the value of the peak photocurrent obtained immediately after the excitation appears to be proportional to the concentration of dissociated ions. However, there is another problem to be taken into account for the evaluation of ion concentrations in various solvents. Since the light pulse in the present work is fairly strong, it may be possible that the ionization of pyrene due to the double photon absorption occurs and that we are observing the photoconductivity due to pyrene cations and solvated electrons. In order to examine this problem, we have investigated the effect of the exciting light intensity on the peak photocurrent. As an example, the result for pyrene-DMA-acetonitrile system is indicated in Fig. 6, from which one can see that the ionic dissociation in this case is a one photon process. Therefore, in these systems of pyrene-DMA-solvent, the most predominant process leading to the photoionization appears to be the encounter collision between DMA and excited pyrene molecule followed by one electron transfer from DMA to pyrene.

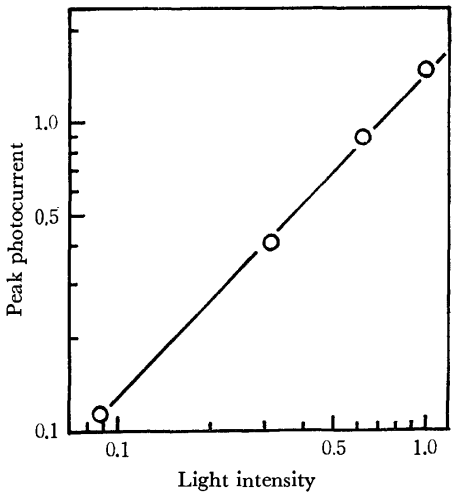

Fig. 6. The effect of exciting light intensity on the peak photocurrent of pyrene-DMA-acetonitrile system. Concentrations of pyrene and DMA are the same as those of Fig. 2, respectively.

In the actual experimental measurements, we have checked not only the photocurrent of the pyrene-DMA system in a solvent but also that of the two component system, pyrene or DMA in the same solvent, as well as that of the pure solvent. We have confirmed that the laser induced photoconductivity of a DMA-solvent system and also that of the pure solvent are negligibly small compared with that of the pyrene-DMA system in the same solvent. However, the photocurrent of pyrene-solvent two component system was not negligible compared with that of the three component system, especially in the case of less polar solvent. For example, the observed value of photocurrent of pyrene-acetonitrile system was *ca.* 5% of that of pyrene-DMA-acetonitrile system. The percentage of the photocurrent of pyrene-solvent system to that of the corresponding three component system becomes larger as the dielectric constant of solvent is decreased. Namely, it is 10% in acetone and pyridine, 30% in methylene dichloride, 50% in monochlorobenzene, and almost 100% in ethylether. These results indicate that the photoionization of pyrene-DMA-solvent system is affected by the solvent polarity more strongly than that of pyrene-solvent two component system.

The laser induced ionization of two component system is not limited to the case of pyrene-solvent systems. Although the details of our studies on the laser induced ionization of various aromatic molecules in organic solvents will be published elsewhere, some fundamental points will be given here.

According to our investigations, this photoionization is mainly caused by a biphotonic process which is a direct two quantum absorption by the ground state to give a high energy state which ionizes. Our studies have indicated further that the photoionization is partially due to mono-photonic absorption process, where the electron transfer from the excited Franck-Condon state of the solute to the solvent molecules seems to occur. At any rate, the laser induced ionization of the pyrene-solvent system is a very rapid process (faster than the encounter collision between A* and D). Therefore, in a rough approximation, the amount of ion radicals produced by the encounter collison between A* and D may be given by subtracting the value of photocurrent of two component system from that of the corresponding three component system. In this way, we have evaluated the relative concentrations of ions given in Table 1.

Although it was not possible to observe the ion radical formation due to the encounter collision between A* and D in *n*-hexane by means of the photocurrent measurements, we have observed transient absorption bands quite similar to those of pyrene anion in the case of pyrene-DMA-*n*-hexane system. The decay curve of the transient absorption at 719 nm is shown in Fig. 7

Table 1. Observed relative concentration of ions, I_C, free energies of HE state, ΔF(HE), the solvated ionpair state, $\Delta F(A_S^- \cdots D_S^+)$, and the dissociated ion radical state, $\Delta F(A_S^- + D_S^+)$, above the gound state, A+D. Free energies are given in units of eV.

Solvent	ε	ΔF (HE)	ΔF $(A_S^- \cdots D_S^+)$	ΔF $(A_S^- + D_S^+)$	I_C[a]
Acetonitrile	37.5	3.02	2.80	2.86	1.0

Chlorobenzene	5.62	3.06	3.12	3.48	0.004
n-Hexane	1.89	3.28	3.84	4.93	—

a) Strictly speaking, not only the dependence of mobility on the solvent viscosity but also its dependence on the degree of solvation of ions should be taken into consideration in the evaluation of I_C values. The mobility will be smaller in the case of stronger solvation in polar solvents, leading to the stronger dependence of I_C value on the solvent polarity than indicated here.

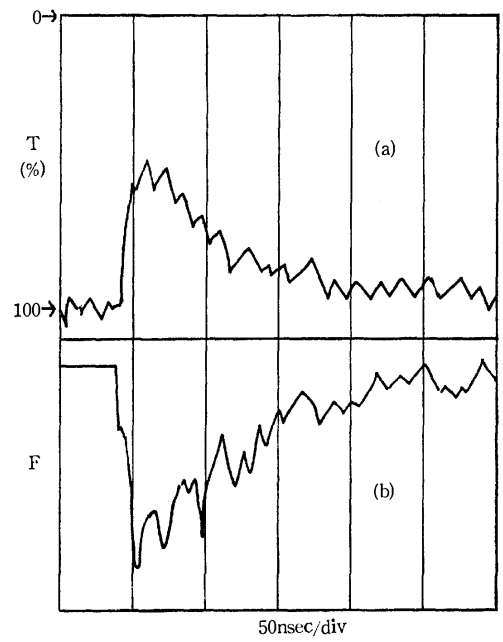

Fig. 7. Rise and decay curves of absorption at 719 nm (a) and those of pyrene-DMA HE fluorescence (b) in the case of *n*-hexane solution. Concentrations of pyrene and DMA are the same as those of Fig. 2, respectively.

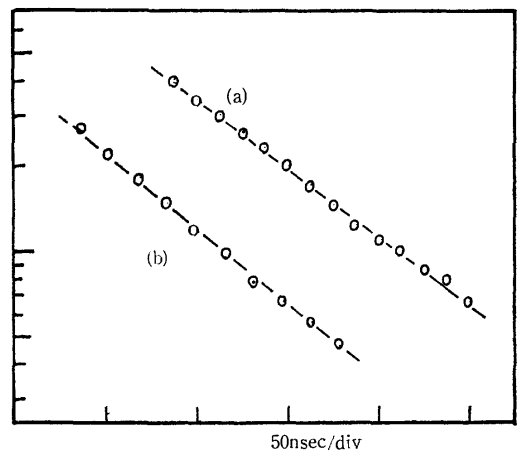

Fig. 8. Semilogarithmic plots of decay curves of Fig. 7. (a) absorption (b) fluorescence

together with the fluorescence decay curve of the pyrene-DMA HE. Semi-logarithmic plots of these decay curves are indicated in Fig. 8. One can see clearly from Fig. 8 that both decay curves are single exponential and they have approximately the same decay constant. Accordingly, the transient absorption bands similar to those of pyrene anion can be assigned to those of pyrene-DMA HE. Thus, the pyrene-DMA HE seems to have a quite polar electronic structure even in the *n*-hexane solution.

Now let us return to the discussion on the results given in Table 1. In Table 1, free energies of the HE state, ΔF(HE), the solvated ion-pair state, $\Delta F(A_S^- \cdots D_S^+)$, and the dissociated ion radical state, $\Delta F(A_S^- + D_S^+)$, respectively above the ground state, A+D, in various solvents are given together with the relative yield of the dissociated ions, I_C. ΔF(HE) has been evaluated by means of the relation,

$$\Delta F(\mathrm{HE}) = \Delta F(\mathrm{A}^* + \mathrm{D}) + \Delta F_c(\varepsilon) \quad (3)$$

where $\Delta F(A^* + D)$ has been estimated to be 3.346 eV, the excitation energy of pyrene to the fluorescent state, and $\Delta F_C(\varepsilon)$ is the free energy change associated with the formation of the HE in a solvent with dielectric constant ε, which can be calculated according to,

$$\Delta F_c(\varepsilon) = \Delta F_c(n\text{-hexane}) - \left(\frac{\varepsilon-1}{2\varepsilon-1} - 0.186\right)(\vec{\mu}_c^2/a^3) \quad (4)$$

The first term denotes the free energy change in *n*-hexane which has been estimated to be about −0.066 eV[6] and the second term the difference in solvation free energy of the complex with dielectric constant ε and *n*-hexane. a and $\vec{\mu}_C$ in the second term represent respectively the cavity radius in Onsager's theory of reaction field and dipole moment of the HE, and the value of $(\vec{\mu}_c^2/a^3)$ has been estimated to be 0.8 eV[7] by applying the equation,

$$h c \bar{\nu}_f \approx -\left(\frac{2(\varepsilon-1)}{2\varepsilon+1} - \frac{n^2-1}{2n^2+1}\right)(\vec{\mu}_c^2/a^3) \quad (5)$$

for the observed values of fluorescence wave numbers. (n is the refractive index of the solvent). $\Delta F(A_S^- \cdots D_S^+)$ can be calculated according to,

$$\Delta F(A_s^- \cdots D_s^+) = (E^+ - E^-) - (e^2/\varepsilon R_0) + \Delta F_s \quad (6)$$

The first term represents the difference between the oxidation potential of the donor and the reduction potential of the acceptor in acetonitrile, the second term the Coulomb attraction energy between the ions A_S^- and D_S^+ separated by the distance R_0 (assumed to be 7 Å), and the third term denotes the difference of the free solvation energies of ions in acetonitrile (ε=37.5) and a solvent with dielectric constant ε. ΔF_S can be calculated with the aid of Born's equation,

$$\Delta F_s = (e^2/2)\left(\frac{1}{R_+} - \frac{1}{R_-}\right)\left(\frac{1}{\varepsilon} - \frac{1}{37.5}\right) \quad (7)$$

where we have assumed $R_+ \approx R_- \approx 3.5$ Å. Finally, ΔF-$(A_S^- + D_S^+)$ is given simply by

$$\Delta F(A_s^- + D_s^+) = \Delta F(A_s^- \cdots D_s^+) + e^2/\varepsilon R_0 \quad (8)$$

The calculated ΔF values and the observed I_C values are plotted against ε values in Fig. 9 for convenience's sake.[8]

One can see clearly from Fig. 9 that the I_C value increases strongly and the $\Delta F(A_S^- + D_S^+)$ as well as $\Delta F(A_S^- \cdots D_S^+)$ values are lowered remarkably as the solvent dielectric constant is increased. The increase of the I_C value is especially notable for the range of $\varepsilon \gtrsim 10$. Thus, in these rather polar solvents with ε values larger than 10, the existence of the dissociated ions has been clearly proved by the present study. In the range of $\varepsilon \approx 5$—10, although the experimental errors for the

8) Quite similar plots of ΔF(HE) and $\Delta F(A_s^- \cdots D_s^+)$ against ε value have been given already by Weller. A. Weller, in Nobel Symposium 5, Fast Reactions and Primary Processes in Chemical Kinetics (S. Claesson, ed.,) Almqvist and Wiksell, Stockholm (1967), p. 413.

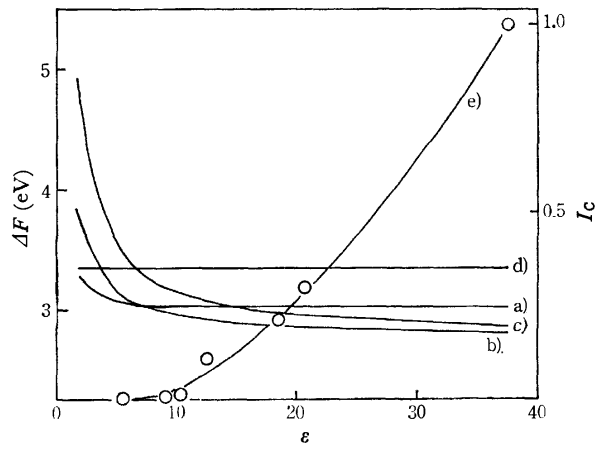

Fig. 9. Plots of ΔF values and I_C values given in Table 1 against ε values of solvents.
(a) ΔF(HE) (b) $\Delta F(A^-_S \cdots D^+_S)$ (c) $\Delta F(A^-_S + D^+_S)$
(d) $\Delta F(A^* + D)$ (e) I_C

determination of I_C values are rather large, the existence of a small quantity of dissociated ions produced by the encounter collision seems to be certain. However, the formation of such ions was not observable in the range of ε smaller than 5.

Of course, the precursor of the dissociated ions is the solvated ion-pair ($A^-_S \cdots D^+_S$) which is formed by the electron transfer process in the encounter complex. Then, the reaction scheme of the dissociated ion radical formation may be written as

$$A^* + D \rightleftarrows A^* \cdots D \rightleftarrows A_s^- \cdots D_s^+ \rightleftarrows A_s^- + D_s^+ \quad (9)$$

However, the difference, $\Delta F(A^-_S + D^+_S) - \Delta F(A^-_S \cdots D^+_S)$, is much larger than the thermal energy at room temperature even at $\varepsilon \approx 10$. Accordingly, it might be possible that the dissociation occurs in the non-relaxed state of the ion-pair immediately after the electron transfer, competing with the relaxation process to the equilibrium solvation state of the ion-pair and/or the relaxation process to the ground state, (A+D). At any rate, since the formation of solvated ion radicals in solvents, which are not very polar and where the HE fluorescence is fairly strong, has been proved in this work, the reaction scheme of the competition of the exciplex formation process with the electron transfer process in the encounter complex seems to be more suitable than the assumption of the continuous structural change of HE with the change of solvent polarity. Of course, there should be more or less structural change of HE induced by the solute-solvent interactions, in principle. However, this effect may play rather small role[9] in explaining the experimentally observed relation between the solvent dependent HE fluorescence quantum yield and decay time, in the case of moderately polar solvents.

As we have described already, the formation of dissociated ion radicals was not observable in *n*-hexane. The circumstance was the same also in toluene. One may see from Fig. 9 that not only the formation of the dissociated ions but also the formation of the solvated ion-pairs, $A^-_S \cdots D^+_S$, seems to be rather difficult in *n*-hexane and toluene (ε=2.38). However, according to the experimental results, the HE fluorescence yield in toluene is only one third of that in *n*-hexane, while the HE fluorescence decay time in toluene is practically the same as that in *n*-hexane.[1] It seems to be rather difficult to explain this result by assuming only the reaction of Eq. (9) which competes with the HE formation process, if the relations between the free energies in Fig. 9 are approximately correct.

Possible explanations for the observed results in toluene solution may be as follows. (a) Toluene molecules will make a specific short range interaction with the ions in the solvated ion-pair ($A^-_S \cdots D^+_S$) in addition to the long range dielectric interactions. This short range interaction (for which the π-electron system of toluene might be playing some role) may lower the $\Delta F(A^-_S \cdots D^+_S)$ value in toluene solution more strongly than indicated in Fig. 9, which makes possible the reaction of Eq. (9) to occur considerably. This is a kind of structural change of the complex involving the surrounding solvent molecules. (b) Owing to a specific interaction of excited molecules with π-electron systems of toluene, there arises some quenching process in the course of HE formation reaction *i.e.* in the encounter complex, as follows.

$$A^* + D \rightleftarrows A^* \cdots D \longrightarrow (A^- \cdot D^+)^* \xrightarrow{\text{solvent}} A + D \text{ or } A^*(T) + D$$

where A*(T) represents the triplet state of pyrene. The quenching process which competes with the HE formation in the encounter complex has been assumed also by Ottolenghi and co-workers[10] in order to interpret quite efficient and very rapid intersystem crossing in some aromatic hydrocarbon-DEA (*N*,*N*-diethylaniline) systems in several solvents. However, it seems to be rather difficult, at the present stage of investigation, to determine the true mechanism of the above described solvent effects on the HE fluorescence in almost non-polar solvents.

The Diffuse Reflection Spectra of Bentonites Colored with Various Aromatic Compounds and Related Ion-radical Salts

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 9, 1971)

Bentonites colored with each of the following aromatic compounds were examined by the method of diffuse reflection in the range from 4 to 30 kK: benzidine, 4,4'-dihydroxybiphenyl, 4,4'-dimethoxybiphenyl, perylene, tetrathiotetracene, and phenothiazine. By comparison with the spectra of the related ion-radical salts, the oxidation of the aromatic compounds to the mono- and/or di-valent cations could be proven in all of them. Except in the case of phenothiazine, the species in the colored clays was found to be drastically modified by moisture. In addition, the spectra of the copper-arene complexes recently reported by Mortland *et al.* were measured. The oxidation of perylene, tetrathiotetracene, and phenothiazine was found to proceed to a greater extent in the copper-exchanged clays.

Earlier we examined the coloration of acid clay upon the addition of benzidine and related aromatic diamines and showed that the diamines are oxidized to the mono- and di-valent cations.[1] The former cations were found to be in various modes of intermolecular interaction, depending on the kind and amount of the liquid. For instance, acid clay colored with benzidine is blue when moistened with water and yellow when dried. The spectrum of the wet sample consists of bands at 7.5, 12.0, 17.0, and about 27 kK, and closely resembles that of the solid benzidine bromide, where the monovalent diamine cations are supposed to be in a strong, more-than-by-pairs interaction.[2] The spectrum displayed by the dried sample has only one absorption maximum, located at 22.5 kK. Between these two situations, a pattern with maxima at 9.5, 14.5, and 26 kK and a shoulder at 16 kK can be observed by carefully controlling the amount of water. This spectrum can be more easily developed by moistening with methanol instead of water. Finally, when benzene is added to the dried sample, absorption maxima appear at 11.5, at 15.2, and somewhere around 27 kK. The last is similar to that of the dimeric cation in solution and is assigned to the cations in a pair-by-pair interaction.

Bentonite, a clay of the montmorillonite type, has been well known to be colored with aromatic amines;[3-5] therefore, it seemed interesting to study the spectra of bentonites colored with benzidine and to compare them with those of the colored acid clay. In recent years, the formation and stabilization of the monovalent cation from aromatic compounds by contact with silica-alumina and synthetic zeolite has been extensively examined by several workers.[6-10] On the other hand, a limited amount of work has been done on the coloration of natural clays with aromatic compounds other than amine. Takahashi observed that acid clay turns green upon the addition of 4,4'-dihydroxybiphenyl dissolved in aqueous ethanol.[5] Recently Mortland *et al.* reported that the color of well-dried copper(II) bentonite changes from a pale blue to dark red when exposed to benzene vapor.[11,12] Similarly, toluene forms a bright green complex, and xylene, a dark purple complex. In the present work, the following were selected in order to cover various types of aromatic compounds: benzidine, 4,4'-dihydroxybiphenyl, 4,4'-dimethoxybiphenyl, perylene, tetrathiotetracene, and phenothiazine. The ion-radical salts derived from most of these compounds are available, so that the spectra of the colored bentonites can be compared with those of the oxidized forms. The cupric ion has been found necessary to the coloration with benzene; the effect of the cation exchange was examined with perylene, tetrathiotetracene, and phenothiazine.

Experimental

Materials. Natural bentonite supplied by the Koso Chemical Co., Ltd., was refined by repeated elutriations. The colored clays were prepared by grinding an organic compound and the clay together in a ratio of 1 : 99 by weight. If the color was not well developed by this technique, a small amount of chloroform was added to the mixture. The copper exchange was carried out following the procedure given by Yariv *et al.*[13] As this clay was found not to be intensely colored with benzene, the copper-exchanged clay prepared from Wyoming bentonite was mostly employed in the rest of the work.

Van Alphen's 4,4'-dimethoxybiphenyl dinitrate was obtained by the addition of a mixture of fuming nitric acid and carbon tetrachloride to the compound dissolved in carbon tetrachloride.[14] The sodium salt of *p*-diphenosemiquinone was made by the oxidation of 4,4'-dihydroxybiphenyl dissolved in aqueous sodium hydroxide with ferricyanide ions, as has been described by Willstätter and Kalb.[15] The solid

salts of the mono- and di-valent tetrathiotetracene cations were prepared according to the methods of Marschalk and Niederhauser.[16]

Measurements. The spectra were recorded on a Beckman DK 2A spectrophotometer with the aid of a reflectance attachment.[1] The colored clays were moistened by leaving them in a desiccator containing water, while they were dried in a desiccator containing silica gel. If stable, the clays were dried in an oven kept near 100°C.

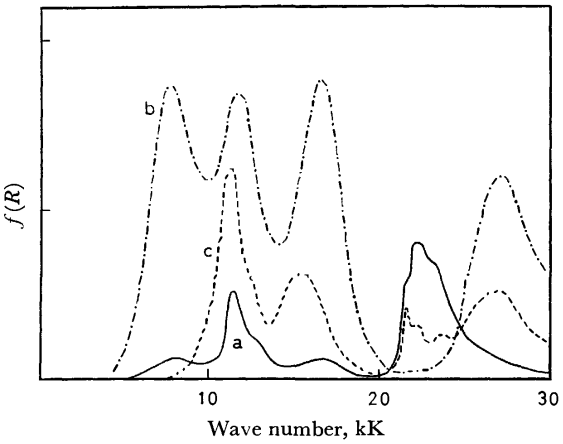

Fig. 1. Diffuse reflection spectra of benzidine-bentonite; (a) prepared by grinding, (b) moistened with water, (c) moistened with benzene.

Results and Discussion

Benzidine-bentonite (Fig. 1). When benzidine and the clay are ground together, absorption bands appear at 11.5, about 13, 21.6, 22.2, and about 23 kK. This spectrum, Curve a in Fig. 1, is in good agreement with that of the monovalent benzidine cation in an ethanolic solution at room temperature. The latter is known to have bands at 11.6 and 13.3, a shoulder at 14.3, and a strong band with a vibrational structure around 22 kK. Therefore, the cation formed at this stage is essentially free from intermolecular interaction. Upon moistening with water, a pattern with bands 7.8, 11.7, 16.6, and 27.3 kK is developed (see Curve b). The locations are close to those in the B-1 pattern which is observed in the wet benzidine-acid clay, as was reported in our earlier paper. The same pattern can be seen as the background of Curve a. However, the band at 7.8 kK becomes relatively less intense when the sample is partially dried. This observation leads to the conclusion that the spectrum given by Curve b is a superposition of the spectra of two species. The sample moistened with benzene exhibits bands at 11.3, 15.5, and 27.0 kK and a shoulder around 12.4 kK. This pattern can well be compared with the B-3 pattern recorded with the colored acid clay moistened with the same solvent. As this spectrum is similar to that of the dimeric form of the benzidine cation observed in a cold ethanolic solution,[17] the monovalent cations here may be supposed to be essentially in a pair-by-pair interaction. The spectrum shown by Curve b may be explained as a superposition of the B-1 and B-3 patterns. As was mentioned in our previous paper, the cations exhibiting the former pattern are likely in a more-than-by-pairs interaction, and this fraction is apparently increased by the presence of water. The band with some structure appearing in the range from 21 to 24 kK of Curve c indicates that the monomeric cations are left in this sample. Because of the presence of isosbestic points at 20.7 and 24.7 kK among the a, b, and c Curves, it may be concluded that the species giving the spectra shown by Curves b and c are in equilibrium with the monomeric cations.

Although a broad background, possibly arising from some decomposition products, appears upon drying, the pattern of the monomeric action reappears. It must be noted that this behavior is quite different from that found in the benzidine-acid clay. In the latter case, the dried sample is yellow and its spectrum has only one absorption maximum, at 22.5 kK which has been assigned to the divalent cation, the quinoidal form in Hasegawa's nomenclature.[1,18] This species is consumed in the development of the blue color in the acid clay upon moistening. From these observations, it can be argued that the mean oxidation state of benzidine in the bentonite complex is lower than that in the acid clay complex.

Dihydroxybiphenyl- and Dimethoxybiphenyl-bentonites (Figs. 2 and 3). 4,4'-Dihydroxybiphenyl, which has an isoelectronic structure with benzidine, gives a green-colored complex with bentonite.[5] A relatively weak band at 14.0 kK and a strong one at 24.2 kK are generated in the moistened sample. Both of them disappear when dried. The behavior of the dimethoxybiphenyl complex is essentially the same as has been described above (compare Curves a and b in Fig. 2). No cation-radical salt derived from dihydroxybiphenyl is known; however, salts of the $OC_6H_5 \cdot C_6H_5O^-$ anion, which is isoelectronic with the $HOC_6H_5 \cdot C_6H_5OH^+$ cation, are available. Figure 3 presents the spectrum of the solid sodium salt as well as the spectrum in an

ethanolic solution. The former exhibits absorption maxima at 11.5 and 19.0 kK, and the latter, at 12.2, at 13.8, and around 22 kK. As to dimethoxybiphenyl, the blue-colored dinitrate prepared by van Alphen has been reported by Buck *et al.* to show an ESR absorption.[19] This observation may be considered as an indication that the salt contains a monovalent cation rather than a divalent one; therefore, we will examine the spectrum of this dinitrate (see Curve c of Fig. 3).

As this compound is not stable, especially when diluted for the spectral measurements, the recorded spectrum is distorted because of the fading during the measurement. A comparison with the spectrum recorded without dilution suggests that the band at 7.4 kK is as intense as that at 27.5 kK. Among the spectra presented in Fig. 3, only the spectrum of *p*-diphenosemiquinone ion dissolved in ethanol bears some resemblance to those of the colored clays. However, the intensity ratio of the low-energy band to the high-energy one in the monovalent anion is far larger than that observed with the colored clay. In addition, the former spectrum is shifted to the low-energy side as much as several kK compared to the latter.

Hydroquinone and 1,4-dimethoxybenzene, closely related to the present compounds, have been known to be converted into monovalent cations upon being dissolved in concentrated sulfuric acid.[20] Therefore, the measurements of the spectra of dihydroxybiphenyl and dimethoxybiphenyl in sulfuric acid were attempted. The spectra recorded immediately after the dissolution are similar to each other, as is shown in Fig. 2. These species are transitory. In the case of dimethoxybiphenyl, the band at 22.2 kK is considerably increased on standing. As we may expect on the basis of their isoelectronic structures, the spectrum of the dihydroxybiphenyl cation is similar to that of the monovalent anion given in Fig. 3. Nevertheless, the general shift to the high-energy side and the enhancement of the high-energy band make the spectrum closer to that of the bentonite complex. Thus, it is very likely that the species in the colored clays are the monovalent cations derived from these compounds.

It should be noted that, although the spectrum of the *p*-diphenosemiquinone ion in ethanol is essentially the same as those of the tetrahalo derivatives reported earlier, the solid-state spectrum is markedly different from those of the derivatives. For example, the sodium salt of 3,3',5,5'-tetrachloro-*p*-diphenosemiquinone shows a solid-state spectrum composed of three bands located at 6.8, 15.5, and 26.4 kK.[21] This feature is rather similar to that of the spectrum of the dimethoxybiphenyl dinitrate, which consists of bands at 7.4, 17.4, and 27.5 kK. In accordance with the results of the ESR measurement made by Buck *et al.*, this spectral similarity and the presence of an absorption maximum as low as 7.4 kK strongly suggest that the cation in the dinitrate is monovalent rather than divalent, and that it is in a more-than-by-pairs interaction. The tetra-*n*-propylammonium salt of tetrabromo-*p*-diphenosemiquinone has been found to show a spectrum consisting of bands located at 11.5, 15.2, and 24.5 kK. Because these locations nearly correspond to those in the dimeric form of the benzidine cation (12.4, 16.4, and 28 kK), the monovalent anions in this ammonium salt have been assumed to be in a pair-by-pair interaction.[21] Although the location of the middle band in the spectrum of the sodium salt of unsubstituted *p*-diphenosemiquinone does not agree with the corresponding band in the above-mentioned ammonium salt, the semiquinone ions here might also be in a pair-by-pair interaction.

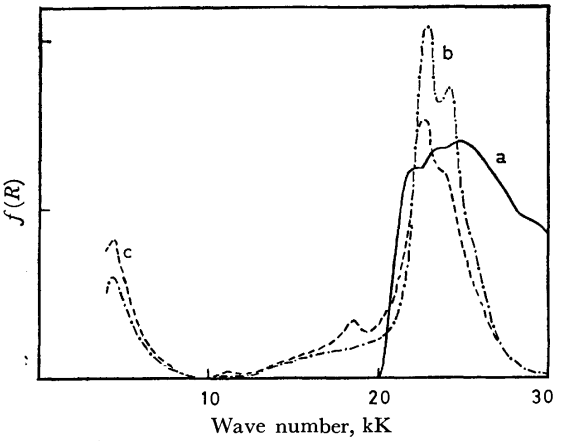

Fig. 4. Diffuse reflection spectra; (a) perylene, (b) perylene-bentontie, dried, (c) the same, moistened.

Perylene-bentonite (Fig. 4). The dried sample is yellow, but it is darker than the hydrocarbon itself because of the presence of a tail extending into the near-infrared region. In addition, the presence of a band at 4.4 kK must be noted. Upon moistening, this low-energy band is intensified and the bands corresponding to those of perylene are weakened (compare Curves b and c in Fig. 4). Furthermore, the appearance of a little peak is observed at 18.5 kK, where the well-known

monovalent cation exhibits a strong sharp absorption.[22-24] The weak absorptions in the range from 12 to 20 kK may be considered as a part of the spectrum of the perylene cation. In the solid-state spectrum of perylene perchlorate reported by Sato *et al.*, the low-energy band is found at 7.7 kK;[25] it arises from the interaction between the cations. On the other hand, the band appearing at 4.4 kK in the colored clay may be attributed to the interaction between the cation and the neutral molecule. Very recently Chiang *et al.* reported the preparation of (perylene)$_2$ ClO_4,[26] where

such an interaction may be expected to be observed. Unfortunately, though, no spectrum was given for this ion-radical salt.

Tetrathiotetracene-bentonite (Figs. 5 and 6). When a mixture of tetrathiotetracene and clay is moistened with chloroform, it turns dark red and then yellow. The red color reappears easily when it is dried in an oven. This color change is reproducible and can be observed even after storage for over a year. As may be seen by a comparison of Curves a and b in Fig. 5, the spectrum is a superposition of two patterns. One of them consists of three weak bands in the range from 7 to 11 kK and two strong ones located at 17.0 and 21.4 kK. The other has a sharp band at 20 kK and a rather broad one around 22 kK. As will be mentioned in the next paragraph, the former pattern can be ascribed to the monovalent cation, and the latter, to the divalent cation. Both of them seem to be free from intermolecular interactions. The equilibrium between these two species moves to the divalent cation upon the addition of moisture, as is shown in Fig. 5. In addition, the measurements of the spectrum in the range from 100 to 150°C, which is selected to avoid the effect of moisture, revealed the movement of the equilibrium towards the monovalent cation upon an elevation of the temperature.

Since the preparation of dark green-colored tetrathiotetracene, it has been discovered to be easily oxidized to the red-colored monovalent cation and the yellow-colored divalent cation. Several pairs of the salts of these two cations have been isolated by Marschalk and Niederhauser.[16] Moreover, tetrathiotetracene forms ionic molecular complexes with many strong electron-acceptors.[27] The spectra of the solid monobromide and the *o*-chloranil complex have been measured, and their red color has been attributed to bands appearing around 20 kK. To elucidate the species in the colored clays, the spectra of (tetrathiotetracene$^+$)$_2SO_4$ and tetrathiotetracene^{2+}$(HSO_4)_2$ were examined in both the solid and dissolved states. The former salt exhibits absorption maxima at 6.3, 9.5, and 18.4 and a shoulder at 21 kK. On the other hand, the spectrum of the monovalent cation in ethanol is characterized by the presence of three weak maxima, at 8.0, 9.5, and 10.7 kK, and a strong maximum at 17.3 kK. It must be noted that the bands in the near-infrared region are very much more widened and intensified in the solid state than in the dissolved state. The spectrum of the brown-colored bisulfate is rather similar to the above-mentioned in the visible region; that is, the maxima are found at 18.0 and 20.8 kK. However, no absorption is detected in the infrared region. When dissolved in dilute acid, the absorption bands become sharper and are shifted to 20.7 and 23.6 kK respectively. Furthermore, a shoulder at 22.7 kK can be observed (see Curve d in Fig. 6). Apparently the spectra of the colored clays are close to those of the cations in the dissolved state. We also examined the solid-state spectra of tetrathiotetracene$^+$ $Cl\cdot H_2O$, tetrathiotetracene$^+$ Br, and tetrathiotetracene$^+$ NO_3. They are similar to the above-mentioned spectrum; however, the intensity ratio

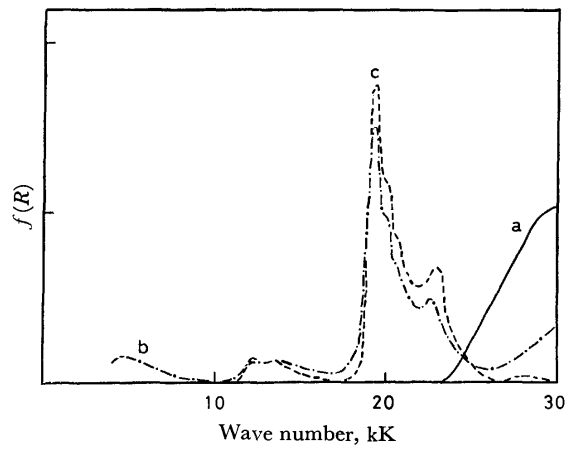

Fig. 7. Diffuse reflection spectra; (a) phenothiazine, (b) phenothiazine-bentonite, (c) phenothiazine-Cu bentonite.

between the band in the infrared region and that in the visible region depends markedly on the kind of anion; that is, it is 0.76: 1 in the chloride, 0.65: 1 in the bromide, 0.60: 1 in the sulfate, and 0.20: 1 in the nitrate.

Phenothiazine-bentonite (Fig. 7). The spectrum of this colored clay in the region between 10 and 25 kK is in good agreement with that of the monovalent cation in solution.[28] However, there are extra absorptions — a weak one in the infrared region and a relatively strong one above 25 kK (see Curve b in Fig. 7). The former may be due to the interaction between the cation and the neutral molecule, for the latter agrees well with that of phenothiazine itself. As was reported earlier, the solid semiquinoid bromide may show an absorption in the infrared region.[29] Nevertheless, the possibility that the weak absorption with a maximum at 4.7 kK in the colored clay is due to the interaction between the cations may be ruled out, because the spectrum of the colored clay between 10 and 25 kK is far from the solid-state spectrum of the bromide. No clear effect of moisture is noted in this case.

Mortland's Copper-arene Complexes (Fig. 8). It has been reported by Donor and Mortland that the benzene complex of copper(II)-exchanged Wyoming bentonite is green or gray when partially hydrated and dark red when well dried.[11] On the basis of the vibrational spectra, Mortland and Pinnavaia have concluded that the green form of coordinated benzene possesses a D_{6h} local symmetry, while the red form does not.[12] It has been suggested that a reduction in the symmetry of the benzene ring occurs if the copper(II) ion is bonded to an edge of the ring, as in the copper(I) complex C_6H_6-$CuAlCl_4$. As no electronic spectrum has been reported by them except for the statement that a very broad intense absorption extends from 1.7 to beyond 4.0 kK, the diffuse reflection spectra of these two forms of the benzene complex as well as those of the toluene and *p*-xylene complexes were measured.

The spectrum of the red form of the benzene complex has a broad maximum located at 19.4 kK and a shoulder around 23 kK in the visible region, and a very intense maximum at 4.4 kK. The electronic absorption mentioned by Mortland and Pinnavaia must be the tail of the last-named one. When this sample is exposed to ambient temperatures and humidity for a while, it turns gray. Contrary to the remarkable change in the vibrational spectrum reported by Mortland, the only change found in the electronic spectrum is the appearance of an additional strong band at 26.7 kK. The low-energy band of the green toluene complex is located at about 10 kK, and that of the purple *p*-xylene complex, at about 9 kK. Compared to the low-energy band of the benzene complex, they are appreciably weaker and at higher energies.

Perylene-Cu Bentonite (Fig. 9). After drying in an oven, the color is a bluish violet. The spectrum between 10 and 20 kK is essentially that of the monovalent cation (see Curve a). Nevertheless, the band in the infrared region and the one at 22.6 kK cannot be assigned to this ion. Upon moistening, the absorptions due to the cation become less intense, while the other two become more intense. The latter pattern is different from both the spectrum of the dimeric perylene cation, which has been shown by Kimura *et al.* to have bands at 10 and 20 kK,[30] and the spectrum of the

solid cation-radical salt studied by Sato *et al.*[25] Therefore, the species to which the new pattern is assignable may be the divalent cation or the neutral molecule. The electronic spectra of the alternant hydrocarbon cation and anion of the same valency may theoretically be expected to be practically identical.[31] As the spectrum of the divalent anion of perylene reported by Balk *et al.* bears no resemblance to the above-mentioned pattern,[32] it is not likely that a hitherto-unknown divalent cation is the major species in the moistened sample. The absorption at 22.6 kK may be attributed to the neutral molecule, and that in the infrared region, to the interaction between the monovalent cation and the neutral molecule. If this interpretation is correct, the effect of moisture on the equilibrium is in the direction opposite to that observed with the perylene-unexchanged bentonite. Finally, it must be added that the coexistence of perylene and its monovalent cation has been noted in experiments on the oxidation of this hydrocarbon by silica-alumina.[8,9]

Tetrathiotetracene-Cu Bentonite. The only species found in this sample is the yellow-colored divalent cation (see Curve c in Fig. 5).

Phenothiazine-Cu Bentonite. The spectrum is presented in Fig. 7 (see Curve c). There are no absorptions but those arising from the monovalent cation. Contrary to the case of phenothiazine-bentonite, the oxidation appears to be complete. The same tendency has already been noted in the other two cases discussed above.

As the species in the colored bentonites are mono- and/or di-valent cations, one may expect that the ionization potentials of these aromatic compounds correlate with the degree of the oxidation by bentonite, as has been demonstrated with silica-alumina.[33] The energy of the charge-transfer absorption generated by mixing with *p*-chloranil in chloroform is 1.52 eV for phenothiazine, 1.64 eV for perylene, 1.81 eV for benzidine, and 2.20 eV for dimethoxybiphenyl.[34] The ability to donate an electron should decrease in this order. The solid-state ionization potentials of perylene and tetrathiotetracene have been estimated to be 5.33 and 4.42 eV respectively by the photoemission method.[35] Thus, tetrathiotetracene is the best electron-donor among the compounds examined and, in fact, is the only compound to form the divalent cation when added to bentonite. The presence of the neutral molecule is noted in the cases of phenothiazine and perylene. In accordance with the order of the ionization potential, the latter spectrum is more dominated by the unionized component than is the former. The coloration of bentonite with the poorest donors, dihydroxybiphenyl and dimethoxybiphenyl, is very faint. Possibly only a small part of the added compound is oxidized to the monovalent cation. However, benzidine does not seem to show the tendency observed above. The absorption to be assigned to benzidine, 30.0 kK in the solid state, is absent in Fig. 1. This anomaly may be due to the protonation. If so, the absorption is not in the range covered by the present work. It should be pointed out that all the monovalent cations except the benzidine cation are found to be essentially free from mutual interaction. Apparently this observation cannot be explained by the difference in the concentration of the monovalent cation.

The author wishes to express his thanks to Professor Hiroshi Takahashi of the University of Tokyo for his gift of the sample of Wyoming bentonite.

The Electric Conductivity of the H_2O-B_2O_3 Melt

Hiroshi KODAMA, Toshio YOKOKAWA,* and Kichizo NIWA*

National Institute for Research in Inorganic Materials, 29-3, 2-chome, Honkomagome, Bunkyo-ku, Tokyo

**Faculty of Science, Hokkaido University, Sapporo*

(Received September 20, 1971)

Electric conductivity was measured over the whole composition range of H_2O–B_2O_3 in the liquid state. A peculiar conductivity-temperature relation was observed in a low B_2O_3-to-intermediate composition. The equivalent conductance of H_3BO_3 increases with its content in this range. Both the concentration of proton and its mobility through the proton-jump mechanism seem to change with the composition. The comparison of the results in the B_2O_3-rich range with those of alkali borates indicates a low extent of the dissociation of the –B–O–H group.

Various physico-chemical properties of binary metal borate melts have been investigated by many workers,[1] and it has been made clear that the addition of such metal oxides as Li_2O, Na_2O, K_2O, and PbO to B_2O_3 causes a variation in the coordination state from BO_3 to BO_4, that those binary borates completely dissociate into ionic liquids, and that the metal ion is the sole charge carrier in an electric field. Recently, Ag_2O has been shown to behave similarly, as determined from both the solubility of Ag_2O in Na_2O-B_2O_3 melt[2] and the electric conductivity.[3] H_2O-B_2O_3 provides another interesting system if its behavior is compared with that of the other borates. Considering such experimental evidence as the B–OH absorption band and the dependence of the solubility of water on its partial pressure,[4] the dissolution can be expressed by the following equation:

$$>B\text{–}O\text{–}B< + H_2O = 2>B\text{–}O\text{–}H \qquad (1)$$

Thus, the water molecule modifies the network as do the alkali metal oxides. The solubility of water in the alkali borate melt decreases with the alkali content. Water can be regarded as a basic oxide of the R_2O type, the basicity being quite weak. A recent study related to the density of H_2O-B_2O_3 suggests a change in the coordination number of oxygen around the boron atom in the composition range between $3B_2O_3 \cdot H_2O$ and $B_2O_3 \cdot H_2O$.[5]

The purpose of the present study is to make clear the conduction mechanism and to get structural information about this system through the whole composition range.

Experimental

The procedures used to prepare sample melts with desired compositions and to determine the melts' composition were similar to those used in the density measurements for this system.[5] Four types of cells, shown in Figs. 1, 2, 3, and 4, were used, depending on the compositions of the melts. The type of cell shown in Fig. 1(cell A) was used in the composition range from 0.5 to 2.5 mol% B_2O_3. The B and C cells in Fig. 3 were used in the range from 5.0 to 25.4 and from 33.3 to 80.5 mol% respectively. Each type of cell was sealed and set up as is shown in the b sections of Figs. 1, 2, and 3.

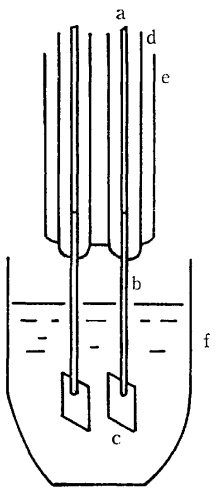

Fig. 4. Cell D used at the concentration of about 99.6 mol % B_2O_3.
a: W wire, b: Pt wire, c: Pt plate, d,e: quartz tube, f: Pt crucible.

For the glass-to-lead wire seal, we used tungsten wire. The last type of cell, the open cell (cell D), was used only in the range of a dilute water content (about 0.1 wt% H_2O). The platinum plate electrodes were platinized by the standard procedure.

Above the liquidus temperature, the vapor pressures of H_2O and HBO_2 become high in the intermediate composition range. The sealed cells, B or C, were so set in a autoclave that the stress due to pressure difference could be moderated. A diagramatic sketch of the apparatus is given in Fig. 5. Nitrogen gas was introduced into the autoclave to compensate the internal pressure of the cell. The data reported by Von Stackelberg[6] and F. Kracek *et al.*[7] were used for doing so.

The cell constant of each cell was calibrated with a 0.1 or 0.01 F KCl aqueous solution prior to the measurement. The cell constant of the A cell was independent of the depth

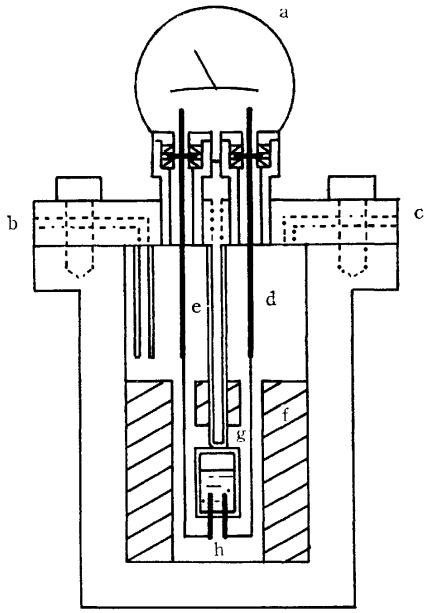

Fig. 5. Autoclave with cell B.
a: pressure gauge, b: gas inlet, c: gas outlet, d: lead wire(Cu), e: thermocouple seath, f: Cu-cylinder, g: cell, h: Pt electrodes.

if the Pt plate electrodes were more than 3 cm below the liquid level. The cell constant of the B cell was also independent of the depth provided that the tips of the electrodes were 5 mm from the liquid level. The corresponding values of the C and D cells depended on the liquid level and had to be calibrated according to its function. The resistance was measured by means of the AC method. A Kohlraush bridge (Y.H.P. type 4255A) was employed. A variable capacitor was coupled when effective. Since the resistance was shown to be independent of the frequency between 1 Hz and 10 kHz, except in the range of intermediate composition, an AC current of 1 kHz was used throughout the experiments.

Since the measured resistance was several hundred Ω and over, any error due to the solution-electrode interfacial capacitance seems to have been small.[8] The measurement with the A cell of a dilute aqueous solution of H_3BO_3 was carried out in an oil bath, its temperature being kept constant within ± 0.05°C. Electric-resistance furnaces were used for the rest of the measurements. The temperature was controlled within ± 0.2°C. The use of the autoclave made the region of homogeneous temperature shorter and the temperature reading somewhat ambiguous. However, the final uncertainty of the conductivity is estimated to be less than 5%, except when the C cell was employed in which case the uncertainty was estimated to be 10%.

Results

The results obtained in the present investigation are shown in Figs. 6, 7, and 8, in which the logarithm of the specific conductivity is plotted against the reciprocals of the absolute temperature.[9] One may note that the Arrhenius linear relation does not hold for most of the compositions. In a solution with an extremely

small B_2O_3 content, the specific conductivity increases with the temperature. With the rise in B_2O_3 content, however, the temperature coefficients of the specific conductivity fall to negative values. The temperature coefficient, strangely enough, returns to positive values beyond a 50 mol % B_2O_3 melt.

Discussion

In ionic conductors, the specific conductivity is given by the following equation:

$$K_{sp} = n_i \times |z_i| \times eu_i \qquad (2)$$

where n_i, z_ie, and u_i are the number of ions per cubic centimeter, the charge, and the mobility of the ion respecitively. Any change in the conductivity can be attributed to a change in either the carrier's concentration or its mobility, or both. The present experimental results indicate that: (1) an Arrhenius-type linear relation does not hold in the H_2O-rich region and (2) the fact that the apparent activation energy is negative in the intermediate range must be interpreted in accordance with the above equation. It is convenient to divide the whole system into ranges from H_2O to H_3BO_3 (25 mol % B_2O_3) and from H_3BO_3 to B_2O_3. The former will be considered as a aqueous solution, and the latter, as a B_2O_3 melt containing H_2O.

H_2O-H_3BO_3 range. H_3BO_3 dissociates into four ionic species, H^+, $H_2BO_3^-$, HBO_3^{2-}, and BO_3^{3-}. Among these species, the numbers of the last two ions are negligible compared with the other two over all the composition ranges in the present measurements. The first dissociation constant (pK) of H_3BO_3 is 9.234 at 25°C. Although there are nearly equal numbers of H^+ and $H_2BO_3^-$ in the solution, the mobility of the hydrogen ion is considerably greater than that of the other. The electric current must be carried mostly by the hydrogen ion.

The mobility of the hydrogen ion in an aqueous solution does not increase steadily with an increase in the temperature. For example, the conductivity of the hydrochloric acid solution has been throughly studied by Owen and Sweeton[10] over a wide range of concentrations and temperatures. They measured the mobilities of the hydrogen and chloride ions separately and found that the absolute temperature coefficient, $(\partial\lambda_-/\partial T)_c$, of the anoin increases from 1.405 at 5°C to 1.753 at 45°C. This increase is about 20%. Under the same conditions, the $(\partial\lambda_+/\partial T)_c$ for H^+ decreases about 18%. This decrease at higher temperatures can be partly explained by the proton-jump mechanism[11,12], since the rate of the proton jump is closely related with the liquid structure, especially the ordering. However, the decreases in the specific conductivity in the present work can not be interpreted only in terms of the decrease in the mobility resulting from the increase in the disorder with the rise in the temperature, for the temperature at which disordering becomes effective may vary from system to system. Further, since the information of the dissociation constant is available at present only for extremely dilute solutions, no firm conclu-

sion can be reached as to the reason for the negative temperature coefficient. However, the present authors feel on the basis of the following data that the variation in the dissociation constant with the temperature must lead to the variation in the hydrogen ion concentration.

In 1934, Harned and Embree,[13] surveying all the data on aqueous solutions, found a remarkable generality in the dissociation of acids. When a parabola of the form

$$\log K = \log K_m - P(T-\theta)^2 \qquad (3)$$

was applied to a set of data for each system, a single value of P, namely $P=5\times10^{-5}$, was found to fit all the data very well. Here θ is the temperature at which the dissociation constant reaches its maximum value, K_m. This phenomenon is related to the temperature dependence of the dielectric constant of water, which plays a decisive role in an acid's dissociation. Only in the case of boric acid do the results appear to be anomalous; there, P is 8×10^{-5} [14]. Although alternative equation,[15] which are thermodynamically more reasonable, have since been proposed, the simpler Eq. (3) is serviceable for the present discussion. For a dilute boric acid solution, the value of θ lies at 77.0°C.[16] In Fig. 9, the logarithmic specific conductivity is plotted against the temperature. These curves may be regarded as parts of a parabola. These results suggest that the concentration of the charge carrier plays an important role in the change of the specific conductivity with the temperature of the present system. As a matter of fact, the relation of the specific conductivity to the concentration was found to be puzzling. In Fig. 10, log K is plotted as a function of log $C_{H_3BO_3}$ at 144°C, where C denotes the number of moles per cubic cm. An almost linear line is obtained up to 25 mol % H_3BO_3. The slope was found to be 1.76, while it should be 0.5 if H_3BO_3 dissociates only at the first step and if the activity coefficients of the species are constant. This extra increase in conductivity with the H_3BO_3 content may be attributable to the change in mobility. In accordance with this the equivalent conductance of H_3BO_3 shown in Fig. 11 reaches a maximum at 25 mol % H_3BO_3. The proton jump mechanism may still be operative in the solution incorporated with the boric acid molecule. One must also note the decrease in the equivalent conductivity with the concentration in an extremely dilute solution, which is not shown in Fig. 11.

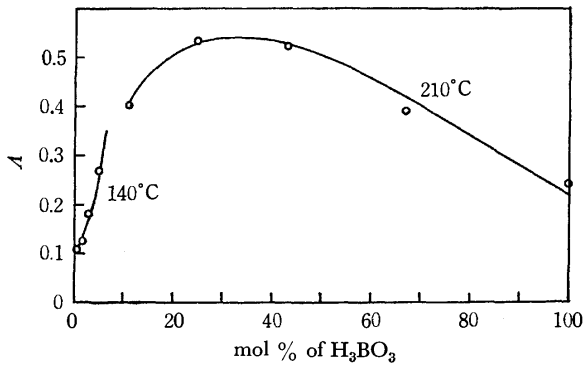

Fig. 11. Equivalent conductance of H_3BO_3 as a function of composition at 140 and 210°C in H_2O-H_3BO_3 range.

H_3BO_3-B_2O_3 Range. In the intermediate range of composition, the experimental data are not enough to allow a quantitative analysis because of the experimental difficulties. However, one may note that the temperature coefficient of the specific conductivity changes in sign near the composition of 50 mol %.

Finally, as is shown in Fig. 8, an Arrhenius-type equation is obtained in the melt of 0.1 wt % (0.4 mol %) water. The apparent activation energy is about 32 kcal/mol. Mackenzie[17] has measured the electric conductivity of B_2O_3 containing a small amount of water (0.1 to 0.2 wt %). He reported a value of about 25 kcal/mol for the activation energy in the region from 850 to 1300°C. The absolute value of the specific consuctivity is $1.9\cdot10^{-6}$ at 850°C, while the extra-

polation of the present results gives $4.5 \cdot 10^{-6}$ at this temperature. Since the specific conductivity and its temperature coefficient are sensitive to the content of water and any impurities, the agreement seems to be satisfactory.

The activation energy for alkali borates, as measured by Shartsis *et al.*,[18] is about 20 kcal at 800°C, which is of an order of magnitude similar to that of the present system. The equivalent conductance of the alkali-metal ions is about unity at a high dilution and increases with the concentration (10 at 20 mol % alkali oxide) at 900°C, while the corresponding H value of the present system varies, being $1.5 \cdot 10^{-4}$ (0.4 mol % water, 560°C), $2.2 \cdot 10^{-4}$ (19.5 mol %, 407°C), and $1.3 \cdot 10^{-3}$ (25.7 mol %, 429°C). Considering the higher mobility of the proton compared with that of any other cation, we may consider that the extent of the dissociation of the –B–O–H group is quite small. The rather perculiar tendency for the equivalent conductance to increase with the concentration is common to both systems, it must be related to the disintegration of the network. No appreciable influence of the coordination change from BO_3 to BO_4 was observed. It is highly desirable to measure the mobility and the concentration of the proton separately.

Conclusion

Electric conductivity was measured over the whole composition range of H_2O–B_2O_3 in the liquid state. The previous data on the dilute aqueous solution of H_3BO_3 and on the B_2O_3 melt with a trace of water are in good agreement with the present results. A perculiar conductivity-temperature relation was observed in the intermediate composition range. As to the conduction mechanism, the proton-jump mechanism and the usual ionic migration seem to be operative in the H_2O-rich and B_2O_3-rich ranges respectively. In the B_2O_3 melt, water behaves in the same manner as do alkali metal oxides except for a partial dissociation of the –B–O–H group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 780—785(1972)

The Characterization of the Electronic Spectra of Heterocyclic Amine *N*-Oxides by Means of the Non-Aqueous Oxidation and Reduction Potentials and the Substituent Effects on Them

Hiroshi MIYAZAKI, Tanekazu KUBOTA, and Masumi YAMAKAWA
Shionogi Research Laboratory, Shionogi and Co., Ltd., Fukushima-ku, Osaka

(Received September 20, 1971)

The half-wave potentials of the voltammetric oxidation and the reduction of various heterocyclic amine *N*-oxides have been measured in CH_3CN by the technique of a rotating platinum electrode. The reversibility of the electrode process was particularly examined for the oxidation reaction by analyzing the oxidation wave and by recording the ESR spectra. Then, the mutual relationship between the electronic spectra of these *N*-oxides and the values of the oxidation-reduction potentials was discussed in detail; we found that this kind of treatment is very useful in assigning the spectra. Finally, a good linear relation between the oxidation potentials of substituted pyridine *N*-oxides and the Hammett σ^+ (Brown-Okamoto) constants was demonstrated and discussed.

It is well known that the polarographic reduction and the oxidation potentials of organic compounds are closely correlated with the molecular orbital energies or with the total energy difference between the starting molecule and the product (free radical) after electrolysis.[1-6] That is, the oxidation ($E_{1/2}^{oxd}$) and the reduction ($E_{1/2}^{red}$) potentials are in a linear relation to the highest occupied molecular orbital (HOMO) and the lowest vacant orbital (LVMO) energies respectively. In other words, the $E_{1/2}^{oxd}$ and the $E_{1/2}^{red}$ seem to be a good measure of the ionization potential and the electron affinity of solvated organic molecules.[7,8] Keeping in mind these facts it can easily be expected that the oxidation and the reduction potentials are correlated quite well with the ultraviolet (UV) absorption spectra of organic compounds if the effect of the configuration interaction is small, and that a singly-excited configuration from HOMO to LVMO contributes mainly to these UV spectra. Typical examples of this kind previously reported are the charge-transfer (CT) ab-

sorption bands of CT complexes,[9-11] which are in a good linearity with the half-wave potentials of the polarographic reduction and the voltammetric oxidation of the electron acceptor and the electron donor respectively.

We will in this paper be concerned with an examination of the mutual relation between the half-wave reduction and oxidation potentials and the UV spectra of heterocyclic amine *N*-oxides; it is believed that the results obtained here will be quite useful in characterizing the UV absorption bands of the *N*-oxides, which were extensively studied hitherto in our laboratory. In connection with these dicussions, we will also study what kind of substituent effect on the oxidation and reduction potentials can be expected.

Experimental

Measurements. A Yanagimoto polarograph, Model P8-AP, was used to record the DC and AC polarograms. This instrument uses the three-electrode system, so that the potential due to the so-called *IR* drop term arising from the resistance of the cell circuit is automatically corrected. In the case of polarographic reduction, the details of the experimental technique for obtaining the accurate values of reduction potential have already been reported elsewhere.[4] The capillary used for the dropping mercury electrode was: $m=0.855$ mg/sec and $t=5.17$ sec at $h=70$ cm in distilled water at an open circuit. On the other hand, the half-wave potential of the oxidation voltammogram has been measured using the rotating platinum electrode illustrated in Fig. 1. This electrode has a platinum rod 1 mm in diameter, which was sealed in a soft glass tube with a diameter of ~6.5 mm, as may be seen in Fig. 1. Just before the use of this electrode, we polished the plane head of the rotating platinum electrode with very fine emery paper in order to keep the platinum surface always fresh. This simple technique gave reproducible results.[12] To record the voltammogram, a combination of the above rotating platinum electrode (600 rpm) and a Yanagimoto polarograph, Model P8-AP, was employed, a saturated calomel electrode (SCE) being

used as the reference electrode. Usually all the experiments were made at 25±0.1°C in a CH_3CN solvent containing 0.1 M tetra-*n*-propylammonium perchlorate (TNPAP) as the supporting electrolyte, the sample concentration being ~5×10^{-4} mol/*l*. As typical examples, the oxidation voltammograms of 1,4-dimethoxybenzene and 9,10-diphenylanthracene have been recorded; they are compared with the values in the literature[13,14] where the experimental conditions were the same as ours. The observed values of $E_{1/2}^{oxd}$ (in volts) are 1.310 (1.34) for the former and 1.241 (1.22) for the latter; here, the values in parentheses are those reported in the literature.[13,14] The agreement of the values seems to be good. Finally, the electron-spin-resonance measurements of the anion and the cation radicals of the compounds studied have been carried out by using a technique reported in a foregoing paper.[15]

Samples and Solvents. The samples used are listed in Tables 1 and 2 along with the experimental results. The preparation, the purification, and the physical constants of these samples have been described in our previous papers.[4,16] The supporting electrolyte, TNPAP, was synthesized in the usual manner[17] and was recrystallized several times from a CH_3CN–H_2O mixture. Acetonitrile has been employed as the solvent throughout the present electrode reaction of oxidation and reduction. Spectrograde CH_3CN was rectified carefully after dehydration with CaH_2. Dimethylformamide (DMF) was also used for comparing the data with those in CH_3CN in the case of voltammetric or polarographic reduction, the quality of DMF being the same as has been described elsewhere.[4]

Results and Discussion

Half-wave Potentials, $E_{1/2}$'s, of the Voltammetric Oxidation and Reduction. It is worthy of note that the electrode reactions of the aromatic amine *N*-oxides used are not all the same. An examination of the oxidation voltammograms shows that some compounds exhibit a reversible electrode reaction due to the cation-radical formation of a mother compound, while other compounds give an irreversible reaction. A typical example of the former is phenazine di-*N*-oxide, whose oxidation and reduction voltammograms are shown in Fig. 2. The high value of the first wave peak-height of alternating-current (ac) voltammograms should be noted; it indicates a reversible electrode reaction. In fact, the ESR spectra of the cation and of the anion radicals of phenazine di-*N*-oxide were observed by controlled potential electrolysis at the first wave of the oxidation and the reduction voltammograms respectively.[4,15,18] The following oxidation voltammetric data on phenazine di-*N*-oxide also support the above interpretation: (i) the temperature dependence of the limiting current, i_l (μA), is 0.87%, as computed by the compound-interest method; (ii) the plotting of i_l *vs.* the concentration gave a good straight line through the point of origin, and (iii) the value of 0.063 V of the log-plot (the value of $\Delta E/\Delta\log[i/(i_l-i)]$ indicates a one-electron oxidation process.

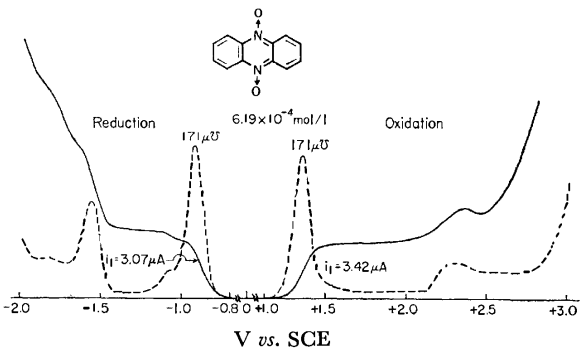

Fig. 2. DC (solid curve) and AC (dotted curve) voltammograms obtained by rotating platinum electrode for oxidation and reduction of phenazine di-*N*-oxide. The absolute value of current is taken at the ordinate for the convenience's sake.

On the other hand, the oxidation voltammograms of quinoxaline mono-*N*-oxide, *etc.*, which have nitrogen lone-pair electrons in a molecule, are typical examples of an irreversible electrode reaction. The participation of the lone-pair electrons in the process of electrode oxidation is the main reason for these irreversible reactions, where the voltammograms change with repeated runs of the measurements unless the platinum electrode is kept on the fresh surface before each recording.

Tables 1 and 2 list the data on the oxidation voltammograms of all the samples used in this report. The *n* value shown in Table 1 stands for the electron number entering in the reaction; it was determined by comparing the wave height with that (standard) of tetramethyl-*p*-phenylenediamine recorded under the same condi-

18) The interpretation and the assignment of the hyperfine coupling constants of these radicals, and also the non-aqueous polarographic data on the electrode reduction, have already been reported in detail.[4,15]

tions. The oxidation voltammogram of tetramethyl-*p*-phenylenediamine is typical of those due to the one-electron oxidation process.[19]

As was mentioned above, the reversibility of the electrode oxidation reaction is more or less different and depends on the compounds. Nevertheless, we have adopted the $E_{1/2}^{oxd}$ values obtained here for the following discussions, since it may be assumed that the effect of the reversibility on the half-wave potential value is not severe. The circumstances as to the $E_{1/2}^{red}$ values are somewhat similar to those presented above in the oxidation voltammogram. However, generally speaking, the reversibility in the electrode reduction process seems to be better than in the case of the oxidation process for many compounds. The polarographic behaviour of various aromatic *N*-oxides has already been reported in detail.[4,15,20] The results of the present reduction voltammetric study are quite similar to, and well reproduce those of the previous polarographic investigation,[4] so in this report we will not discuss these experimental results further. Since the values of $E_{1/2}^{oxd}$ and $E_{1/2}^{red}$ yielded under the same conditions are most reasonable for checking the theoretical treatment (*vide infra*), the $E_{1/2}^{red}$ values observed by using the rotating platinum electrode in CH_3CN solvent are included in Table 1.

The Mutual Relation between UV Spectra and the Half-wave Oxidation and Reduction Potentials. It is well known that the HOMO and the LVMO are in a linear relation to the $E_{1/2}^{oxd}$ and the $E_{1/2}^{red}$ values respectively.[1-8,21,22] Also, the electronic spectra are intimately correlated with the energy difference between the electron-occupied orbitals and the vacant orbitals, so we can except a reciprocal correlation, which would be useful in the assignment of the electronic spectra, of the electronic spectra to the half-wave oxidation and reduction potentials.[23]

If we let ε_{ho} and ε_{lv} be the orbital energies for the highest occupied and the lowest vacant orbitals respectively, Eqs. (1) and (2) are satisfied:

$$E_{1/2}^{red} = k_1\varepsilon_{lv} + k_2 \quad (1)$$

$$E_{1/2}^{oxd} = k_1\varepsilon_{ho} + k_3 \quad (2),$$

where k_1, k_2, and k_3 are all constants. It is assumed here that the electrode reaction is a reversible one-electron process, such as ($R+e \rightleftharpoons R^{\dot{-}}$) or ($R-e \rightleftharpoons R^{\dot{+}}$), and that the difference in diffusion coefficients, activity coefficient, and entropy terms between R and $R^{\dot{-}}$ or $R^{\dot{+}}$ can be disregarded because the values[2] are similar. The left-hand-side terms of Eqs. (1) and (2) can now be expressed by $\Delta F/\mathcal{F}$, where ΔF is the free-energy change for the above electrode process in an non-aqueous solution and is related mainly to the electron affinity[24] for the formation of $R^{\dot{-}}$ or to the ionization potential[24] for the formation of $R^{\dot{+}}$, and also to the solvation-energy change (ΔF_{solv}) between R and $R^{\dot{-}}$ or $R^{\dot{+}}$.[2] Accordingly, the slope, k_1, in Eqs. (1) and (2) becomes $1/\mathcal{F}$. Because $\mathcal{F}$ in a Faraday constant (1 eV/1 V), $|k_1|$ is equal to 1 when an electron volt is taken as the energy unit. The ΔF_{solv} term would be constant under the same experimental conditions in a series of similar compounds (see also later discussions), and would contribute greatly to the k_2 and k_3 terms in Eqs. (1) and (2). We can now write Eq. (3) by taking account of the difference between Eqs. (1) and (2) (here k_4 is a new constant):

$$(E_{1/2}^{red} - E_{1/2}^{oxd}) = k_1(\varepsilon_{lv} - \varepsilon_{ho}) + k_4 \quad (3)$$

In turn, the singlet energy corresponding to a one-electron transition from HOMO to LVMO is given by[25]:

$${}^1E_{ho\to lv} = \varepsilon_{lv} - \varepsilon_{ho} + 2K_{ho\cdot lv} - J_{ho\cdot lv} \quad (4)$$

The excited state pertinent to the transition energy, ${}^1E_{ho\to lv}$, may be mixed with the other excited states having the same symmetry, so that the ${}^1E_{ho\to lv}$ should be changed by the amount of the configuration interaction energy, ${}^1E_{CI}$. The observed energy, $E_{ho\to lv}^{UV}$, attributable mostly to the HOMO→LVMO transition, is thus written as $E_{ho\to lv}^{UV} = \varepsilon_{lv} - \varepsilon_{ho} + 2K_{ho\cdot lv} - J_{ho\cdot lv} + {}^1E_{CI}$. $K_{ho\cdot lv}$ and $J_{ho\cdot lv}$ are, respectively, the well-known two-electron exchange and the Coulomb repulsion integrals[25] pertaining to the two MO's given in the suffixes. The combination of the above equations leads to Eq. (5):

$$(E_{1/2}^{red} - E_{1/2}^{oxd}) = k_1[E_{ho\to lv}^{UV} + J_{ho\cdot lv} - 2K_{ho\cdot lv} - {}^1E_{CI}] + k_4 \quad (5)$$

The linear relation between the experimental values of $(E_{1/2}^{red} - E_{1/2}^{oxd})$ and $E_{ho\to lv}^{UV}$ may be obtained under the binding conditions that in a series of similar compounds, (i) the effect of ${}^1E_{CI}$ on the ${}^1E_{ho\to lv}$ is small or is considered to be constant throughout the compounds, and (ii) the magnitude of the electron repulsion terms ($J_{ho\cdot lv} - 2K_{ho\cdot lv}$) may be put constant in all the samples. In these cases, we can simply write Eq. (6):

$$(E_{1/2}^{red} - E_{1/2}^{oxd}) = k_1 \cdot E_{ho\to lv}^{UV} + k_5 \quad (6)$$

Previously we reported detailed Pariser-Parr-Pople (P.P.P.)-type SCF MO calculations of many aromatic tertiary amine *N*-oxides for use in interpreting the electronic spectra and the electronic structures.[26] These calculation results can be used to check Eqs. (3) and (6). For the compounds whose P.P.P. calculations have not yet been reported, the calculations have been newly carried out here using the same method as in

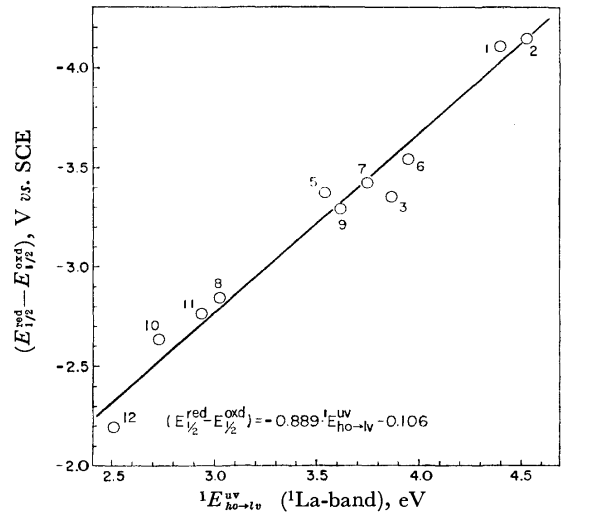

Fig. 4. The relationship between observed values of ^1L_a ($^1E^{uv}_{ho\to lv}$) band and $(E^{red}_{1/2}-E^{oxd}_{1/2})$ for heterocyclic amine *N*-oxides. See Table 1 for the numbering of each compound.

foregoing papers.[26,27] The calculation results are listed in Table 1.

Let us now focus attention on the intramolecular charge-transfer band (^1L_a band) of the amine *N*-oxides,[26] which is mainly due to an electron transition from HOMO to LVMO, where the effect of the configuration interaction is small except for the case of isoquinoline *N*-oxide (0.394 eV). On the basis of the calculation results made hitherto, we may say that the values of $^1E_{CI}$ and $(2K_{ho\cdot lv}-J_{ho\cdot lv})$ are within the maximum variation of 0.11 ± 0.10 eV and -2.21 ± 0.80 eV respectively, and that, except for a few exceptional cases, these values may be seemed to be nearly constant. Therefore, the linear relation of Eqs. (3) and (6) can reasonably be expected to be as is given in Figs. 3 and 4. The mutual correlations are very good. That the slope of the straight line obtained in Figs. 3 and 4 is less than, but near, the |1| should be noted. It can safely be said that the previous conclusion[26] that the ^1L_a (or CT) band of aromatic *N*-oxides arises mainly from a one-electron transition from HOMO to LVMO has been supported by the electrochemical study illustrated in Figs. 3 and 4. From the other standpoint, one can also discuss as follows. It may be remembered that, of the methods employed for analyzing the electronic spectra of a series of similar compounds, the so-called spectroscopic β method is a useful technique[28,29]; here the exchange integral, β, is taken to be a constant applied only to absorption bands which belong to electronic transitions similar in character (*i.e.*, for the ^1L_a and ^1L_b bands the β (^1L_a) and $\beta(^1L_b)$ values are separately assigned). In principle, the β value may be considered as a value including the electron repulsion terms pertinent to the electronic transitions in the same species; it is taken as a constant throughout the series of absorption bands in question, so that the assumptions used in deriving the present equation (6) (except for the discussion of the $^1E_{CI}$ term) and in estimating the spectroscopic β value seem to be similar to each other. Thus, the experimental results shown in Figs. 3 and 4 confirm the usefulness of the above-mentioned spectroscopic β method.

Next, let us discuss the slope of the straight lines shown in Figs. 3 and 4, which is less than the theoretical value of |1|. In previous discussions, we assumed that there was no change in the solvation energy of a variety of cation or anion radicals. The *N*-oxides used, however, can be roughly grouped in three groups by size; *i.e.*, the substances range from monocyclic to tricyclic *N*-oxides, so that the effective ion radii of the cation or anion radicals fall in three groups. As may be understood from Born's equation,[30] these may turn out to be different solvation energies, which would more or less destroy our first assumption. In the present case, we may say, in general, that as the molecular size increases, the values of $|E^{red}_{1/2}-E^{oxd}_{1/2}|$, $(\varepsilon_{lv}-\varepsilon_{ho})$, $^1E^{uv}_{ho\to lv}$, and *the solvation energy* of the anoin or cation radical ions, decrease, which may lead to the slope smaller than |1| that is found for the data obtained *in vacuo*. The following experimental data can also account for the deviation from the ideal linear relationship of Eqs. (3) and (6). That is, the reversibility of the electrode process may be a little different between the reduction and oxidation voltammograms, since, in general, the heterocyclic compound producing the corresponding stable anion radical brings about a lesser stability in the corresponding cation radical, and *vice versa* (see also the first section of "Results and Discussion").

Finally, we would like to discuss the relationship between the ^1L_b bands of the *N*-oxides and the $(E^{red}_{1/2}-E^{oxd}_{1/2})$ values. Generally speaking, the ^1L_b band has a very different character from that of the ^1L_a (or CT) band; not only is the contribution from the HOMO→

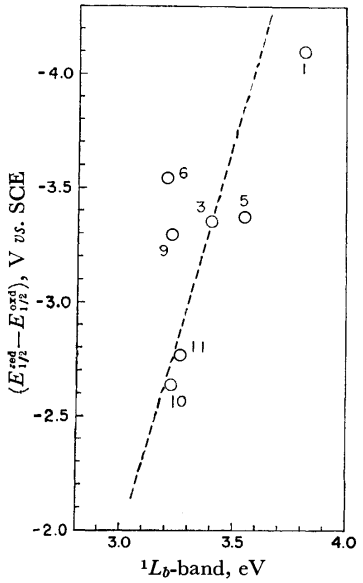

Fig. 5. Plot of the observed values of $(E^{red}_{1/2}-E^{oxd}_{1/2}$ against the observed ^1L_b band energies for heterocyclic amine *N*-oxides. See Table 1 for the numbering of each compound.

LVMO transition very small (if one considers the C_{2v} molecule, the contribution is zero), but also the effect of the configuration interaction on that band is quite large. Accordingly, we can not expect a linear relationship as in Eq. (6). For some *N*-oxides we plot (Fig. 5) the values of $(E^{red}_{1/2}-E^{oxd}_{1/2})$ against the ^1L_b band positions, whose assignment has already been reported.[26] It is now clear that there is no good linear relation and that, roughly speaking, the ^1L_b band position is quite independent of the values of $(E^{red}_{1/2}-E^{oxd}_{1/2})$, so the slope of the dotted line in Fig. 5 is very much larger than |1| and is theoretically unreasonable. Conversely speaking, we can say that the bands employed in Fig. 5 can not be assigned to the ^1L_a (or CT) and that the experimental test of Eqs. (3) and (6) is quite usefull in confirming the band assignment.

Substituent Effect on the Oxidation Potentials of Pyridine N-Oxide Derivatives. In our previous papers, we have already reported a good linear correlation between the $E^{red}_{1/2}$ values and Hammett's σ constants on pyridine *N*-oxide derivatives[4,16] and discussed the physical meaning of this. Here, we have tested whether or not such a correlation holds in the case of the $E^{oxd}_{1/2}$ values, also. Fig. 6 shows the correlation of the $E^{oxd}_{1/2}$ values, which are listed in Table 2, with the Brown-Okamoto σ^+ constants.[31] A good linear relation, written as $E^{oxd}_{1/2}=0.565\ \sigma^+ + 1.745$, with a root mean-square deviation equal to ± 0.066, is found to hold. It should be noted that, in the present case, if one adopts usual Hammett's σ or σ^- values[4,16] we can not find, in particular for the case of larger electron-donating substituents, a good linear relation such as is found in Fig. 6. The free-energy change due to the electrode oxidation reaction is, of course, electrophilic in nature and is just the reverse of that in the case of the electrode reduction process, where the use of σ^- and σ values was suitable[4,16] (the reaction is nucleophilic). Therefore, it is reasonable to say that the better description of the activated state of the oxidation reaction is made using the σ^+ values. Lastly, it is worthwhile to point out that the most important molecular orbital entering into the electrode oxidation is the HOMO, which is destabilized by introducing an electron-donating substituent such as NR_2 in the pyridine ring. This brings about the oxidation reaction more easily and makes the $|E^{oxd}_{1/2}|$ value smaller. These circumstances are just the reverse of those for the process of electrode reduction, where the $|E^{red}_{1/2}|$ value increases when the ring hydrogen atom is replaced with an electron-donating substituent.

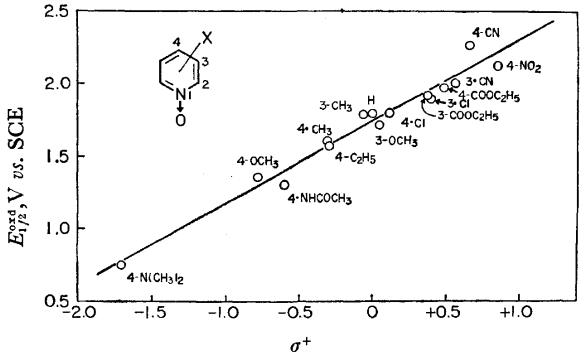

Fig. 6. Linear relation between Brown-Okamoto's σ^+ values and the half-wave oxidation potentials at the first wave of substituted pyridine *N*-oxides.

Dipole Moment and Force Constants of NSCl from Microwave Spectrum

Setsuko MIZUMOTO, Jun IZUMI, Tatsuro BEPPU,* and Eizi HIROTA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka
(Received October 4, 1971)

Dipole moment of $^{15}N^{32}S^{35}Cl$ has been determined to be $\mu_a=0.564_5\pm0.0085$, $\mu_b=1.74_7\pm0.035$, $\mu_{total}=1.83_6\pm0.036$D by analyzing the Stark effect of the $1_{1,1}\leftarrow0_{0,0}$ transition.

Twenty-eight rotational transitions of $^{14}N^{32}S^{35}Cl$ in the ground state have been analyzed to determine four centrifugal distortion constants: $\tau_{aaaa}=-6.9_9\pm0.30$, $\tau_{bbbb}=-0.011_0\pm0.0013$, $\tau_{aabb}=0.17_6\pm0.014$, and $\tau_{abab}=-0.033_4\pm0.0068$ MHz. These constants are combined with the vibrational frequencies and inertia defects to recalculate force constants: $F_{11}=10.032$ md/Å, $F_{22}=1.44_4$ md/Å, $F_{33}=0.74_9$ mdÅ, and $F_{23}=-0.08_6$ md.

The microwave spectrum of NSCl has recently been reported by Beppu *et al*,[1] who determined the molecular structure and the quadrupole coupling constant of the chlorine nucleus, and also estimated force constants using the inertia defects and vibrational frequencies. However, the dipole moment has not been evaluated because the Stark effect of the rotational spectrum of NSCl is complicated by the nuclear quadrupole coupling. In the present work the Stark effect of the $1_{1,1}\leftarrow0_{0,0}$ transition of $^{15}N^{32}S^{35}Cl$ is analyzed in detail to determine the dipole moment and its components along the a- and b-axes.

The general quadratic force field may be determined combining vibrational frequencies with other physical constants such as the inertia defects.[2] The centrifugal distortion constants have also been proved useful in force field determinations.[3-11] It may be worthwhile to improve the force field estimated in Ref. 1 using the centrifugal distortion constants and to compare derived force constants with those of related molecules such as NSF.[10,11]

Experimental

The sample of NSCl was prepared by a method described in Ref. 1. The spectrometer used was of conventional Hughes-Wilson type with a 120 kHz oscillator as a Stark modulator. The spectrum was observed at room temperature.

Dipole Moment

The Stark effect of the $1_{1,1}\leftarrow0_{0,0}$ transition of $^{15}N^{32}S^{35}Cl$ is shown in Fig. 1, where the observed frequencies of Stark components are indicated by open circles. Electric field is calibrated using the OCS molecule as a standard.[12] In the limit of the zero field the transition consists of three lines corresponding to $F=3/2\leftarrow3/2$, $5/2\leftarrow3/2$, and $1/2\leftarrow3/2$, whereas two Stark lobes, $M_I=\pm3/2$ and $\pm1/2$, are observed at strong field. In the intermediate region there are five Stark lobes, of which three are $M_F=\pm1/2$ and two $M_F=\pm3/2$. Analysis is carried out according to a procedure described previously,[13] where the rotational constants are fixed to the values reported in Ref. 1: $A=40\,355.96$, $B=4\,019.65$, and $C=3\,649.36$ MHz. A least-squares analysis gives the a and b components of dipole moment and the bb component of the quadrupole coupling constant of the chlorine nucleus as follows: $\mu_a=0.564_5\pm0.0085$D, $\mu_b=1.74_7\pm0.035$D, and $\chi_{bb}=23.8_4\pm0.50$ MHz, where errors are 2.5 times the standard deviations. The frequencies of the Stark lobes calculated using these parameters are drawn by solid lines in Fig. 1 and compared with the observed in Table 1. The χ_{bb} constant may be compared favorably with the value already reported,[1] 23.51 MHz. The total dipole moment is $\mu_{total}=1.83_6\pm0.036$D.

Centrifugal Distortion Constants and Force Constants

The line centers of all transitions assigned to the parent species, $^{14}N^{32}S^{35}Cl$, in the ground state are listed in Table 2. The hyperfine structures, where resolved, are corrected for using the quadrupole coupling constants previously reported.[1]

The first-order perturbation theory is applied to determine three rotational constants and four distortion constants. Higher-J transitions may include larger contributions of the distortion effects, but simultaneously the higher-order terms such as the P^6 terms should be taken into consideration to determine the P^4 terms precisely.[6] In the present analysis the transitions of J up to 20 are included. The values of parameters obtained by a least-squares analysis[14] are listed in Table 3, where the errors are 2.5 times the standard deviations. The line frequencies calculated using these

parameters are compared with the observed in Table 2. The average deviation is 0.18 MHz.

In Ref. 1 the four force constants, three diagonal and one off-diagonal, are determined using two vibrational frequencies, ω_1 and ω_2, and two vibrational increments of the inertia defects, Δ_2 and Δ_3. It may thus be interesting to see whether four distortion constants obtained in the present work are useful in determining two remaining force constants, F_{12} and F_{13}. This is unfortunately not the case.

A least-squares analysis is carried out using ω_1, ω_2, Δ_2, Δ_3, τ_{aaaa}, τ_{bbbb}, τ_{aabb}, and τ_{abab} as input data with the following weights: 1.0 for ω_1, 2.0 for ω_2, 1000.0 for Δ_2 and Δ_3, 0.5 for τ_{aaaa}, 130.0 for τ_{bbbb}, 10.0 for τ_{aabb}, and 25.0 for τ_{abab}. The units used here are cm^{-1} for ω, amu Å^2 for Δ, and MHz for τ. The inertia defect should be accurate to about 0.005 amu Å^2, and the weights for the distortion constants might therefore be too small. Calculation with weights of distortion constants increased by a factor of ten gives, however, force constants which agree with the former results within 2.5 times the standard deviations. When F_{12} or F_{13} or both are included as parameters, a least-squares analysis is not convergent. However, a negative F_{12} (about -0.5 md/Å) and a positive F_{13} (about 0.3 md) give much closer fitting to the observed constants, provided that the four force constants are adjusted accordingly. The result shown in Table 4 is obtained assuming both F_{12} and F_{13} equal to zero. Agreement between the observed and the calculated constants is satisfactory except for τ_{bbbb} and τ_{abab}, for which the discrepancies exceed the error limits (see Table 4). A larger discrepancy remains for ω_3, although the "observed" value is estimated, but not measured directly.[15] It is difficult to increase the calculated ω_3 to 273 cm^{-1}, because of the conditions imposed by the inertia defect.

TABLE 4. FORCE CONSTANTS OF NSCl

Force constant	Present[a]	Ref. 1
F_{11}(md/Å)	10.032 ± 0.003	10.03_1
F_{22}(md/Å)	$1.44_4\pm0.013$	1.46_5

Discussion

The total dipole moment of NSCl is $1.83_6\pm0.036$D, which is very close to that of NSF, 1.910D.[10]

After the completion of the present work Guarnieri sent us his results on dipole-moment determination.[16] He analyzed the Stark effect of three transitions, $2_{1,1}\leftarrow 2_{0,2}$ ($F=7/2\leftarrow7/2$), $3_{1,2}\leftarrow3_{0,3}$ ($F=9/2\leftarrow9/2$), and $1_{1,1}\leftarrow 0_{0,0}$, of the parent species. For the former two transitions he measures the Stark effect of the component of the largest F value (7/2 and 9/2, respectively) which is independent of the quadrupole effect, and for the last transition only the Stark effect in the strong field is used in the analysis. Dipole moment he obtains is $\mu_a=0.57\pm0.03$D, $\mu_b=1.77\pm0.02$D, and $\mu_{total}=1.87\pm0.02$D. To compare the present results with these values it is necessary to transform the principal axes of the ^{15}N species to those of the parent species, and the angle of transformation is calculated to be $31.4_4'$ using the structural parameters of Ref. 1. When μ_a and μ_b are of the same sign, the a- and b-components of the parent species are calculated to be $\mu_a=0.580_5\pm0.01$ and $\mu_b=1.74_2\pm0.04$D, whereas they are $\mu_a=0.548_5\pm0.01$ and $\mu_b=1.75_2\pm0.04$D in the case of opposite sign (see Ref. 1 for the signs of the coordinate axes). It is seen that both cases are in agreement with Guarnieri's results within experimental errors. On the other hand, the latter case ($\mu_a\mu_b<0$) is shown to be more realistic from consideration of bond moment. As shown in Table 5, the total moment of the ^{15}N species makes an angle of 57°2′ with S–Cl and 60°40′ with S–N, when μ_a and μ_b are of the same sign, whereas the two angles are 92°50′ and 24°52′ for the case of opposite sign. The total moment of 1.83_6D is then accounted for by μ(S–Cl) of 1.80_8D and μ(S–N) of 1.74_0D for the former case and μ(S–Cl) of 0.87_2D and μ(S–N) of 2.07_1D for the latter. A similar analysis is carried out for NSF, and the result is also given in Table 5. Because the

TABLE 5. BOND MOMENTS OF NSCl AND NSF

	NSCl	NSF
I. $\mu_a\mu_b>0$		
θ_1	57°2′	58°18′
θ_2	60°40′	58°37′
μ(S–X)	1.80_8D	1.82_8D
μ(S–N)	1.74_0D	1.82_2D
II. $\mu_a\mu_b<0$		
θ_1	92°50′	72°56′
θ_2	24°52′	43°59′
μ(S–X)	0.87_2D	1.48_7D
μ(S–N)	2.07_1D	2.04_7D

θ_1: angle between μ and S–X.
θ_2: angle between μ and S–X.

bond moment of S–Cl is normally of the order of 0.7D,[17] the second case is more reasonable for NSCl, although a larger moment is expected for S–Cl because of larger fraction (57%) of a resonance form N=S$^+$Cl$^-$, as discussed in Ref. 1. As for NSF, the difference between the bond moments for the two cases is smaller, because the total moment is nearly parallel to the b-axis. Yet the second case is a bit more reasonable: although the bond moment of S–F is not known, the

17) C. P. Smyth, "Dielectic Behavior and Structure," McGraw-Hill, New York, N. Y. (1955).

electronegativity difference for F and S is 1.5, whereas it is 0.5 for Cl and S. Therefore, the S–F moment of 1.48_7D of NSF in the second case seems to be more reasonable. It may be interesting to note that the value of S–N, 2.04_7D for NSF and 2.07_1D for NSCl, is very close to dipole moment of the NS radical, 1.81D.[18]

It is rather disappointing that it has not been possible to determine all three off-diagonal force constants, even if the inertia defects and centrifugal distortion constants are used in addition to vibrational frequencies. The situation is similar to the case of NSF investigated by Cook and Kirchhoff,[10] although they did not take into account the inertia defects in the excited vibrational states. The F_{11} constant of NSF (10.703 md/Å) is nearly the same as that of NSCl (10.032 md/Å), just as the bond length N–S, 1.448 Å for NSF and 1.450 Å for NSCl. The force constants associated with the halogen atom decrease their values from the case of fluoride to the chloride. It may be interesting to note that F_{23} becomes negative for the chloride. In order to improve the force constants of NSCl it is indispensable to observe the ν_3 band in the infrared spectrum.

The calculation in the present work was carried out at the Computation Center at Kyushu University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 789—793(1972)

Mordant Blue 31 as a New Fluorometric Reagent for Aluminum, Gallium, and Scandium

Keizō HIRAKI

Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka

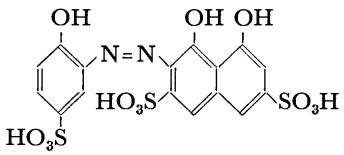
(Received June 2, 1971)

A sensitive fluorometric determination of aluminum, gallium, and scandium with Mordant Blue 31 was worked out. The reagent reacts with aluminum, gallium, scandium, yttrium, lanthanum, lutetium, indium, and magnesium in acidic or basic medium to form complexes with reddish yellow fluorescence. The complexes of aluminum (pH: 5—7), gallium (pH: 4), and scandium (pH: 6) exhibit strong fluorescence with an emission maximum at 590, 600, and 610 nm, respectively. The effects of time, pH and the concentration of the reagent were investigated. In acidic medium, aluminum, gallium, and scandium were found to form 1:1 complex with Mordant Blue 31. Under the optimum conditions, 0.1—3 μg of aluminum, 1—12 μg of gallium, and scandium in 25 m*l* sample solution could be determined. Although the fluorescence intensity of aluminum and gallium complexes was a little lower than that of the lumogallion complexes, Mordant Blue 31 was also applicable as a fluorometric reagent for aluminum and gallium. Since scandium-Mordant Blue 31 complex exhibits the strongest fluorescence of all other scandium-azo dye complexes, the reagent was used as a fluorometric reagent for scandium.

o,o'-Dihydroxyazo compounds are useful as sensitive fluorometric reagents for various metal ions.[1-6] Donald *et al.*[7] described the fluorescent properties of several metal complexes of *o,o'*-dihydroxyazo compounds. In these series chromotropic acid derivatives in particular are very sensitive and form stable fluorescent complexes with aluminum and gallium ions.

The present author describes the preparation of Mordant Blue 31 [2-(2-hydroxy-5-sulfophenylazo)-1,8-dihydroxynaphthalene-3,6-disulfonic acid], and the fluorometric determination of several metal ions.

The reagent reacts with magnesium ion to form a stable fluorescent complex in alkaline solution, determination of magnesium is described.



Mordant Blue 31

Apparatus

Spectrofluorometric measurements were carried out with a Hitachi spectrophotometer, Model FPU-2A, equipped with a Hitachi fluorometric attachment, Model G-3. A Hitachi fluorometer, Model EPL-2, was used for fluorometric measurements and a Hitachi-Horiba glass electrode pH meter Model M-5 for pH measurements.

4-sulfonic acid dissolved in 6N hydrochloric acid was diazotized with an equivalent amount of sodium nitrite under cooling with ice. Chromotropic acid dissolved in about 6N sodium hydroxide was coupled with the diazonium salt solution under cooling below 5°C. The azo compound thus obtained was repeatedly recrystallized from 6N hydrochloric acid, and dried at room temperature in a desiccator on silica gel.

Reagent. 0.1% Mordant Blue 31 solution; 0.25 g of Mordant Blue 31 was dissolved in water and diluted with water to 250 m*l*.

Standard solution of aluminum; 1.6803 g of $Al(NH_4)(SO_4)_2 \cdot 12H_2O$ was dissolved in a small amount of water and 5 m*l* of concentrated hydrochloric acid, and diluted to 100 m*l* with water (1 mg Al/m*l*). The solution was diluted with water to prepare a solution of 1.00 μg Al per m*l*.

Standard solution of gallium; 0.1344 g of Ga_2O_3 (99.99%) was dissolved in concentrated hydrochloric acid, and diluted to 100 m*l* with water (1 mg Ga/m*l*). The stock solution was diluted with 0.1N hydrochloric acid to prepare a solution of 1.00 μg Ga per m*l*.

Standard solution of scandium; 0.1534 g of Sc_2O_3 (99.9%) was dissolved in concentrated hydrochloric acid and diluted to 100 m*l* with water (1 mg Sc/m*l*). The solution was diluted with water to make a standard solution containing 1.00 μg of Sc per m*l*.

Standard Rhodamine B solution; 0.100 g of Rhodamine B was dissolved in water and diluted to 100 m*l*. The solution was diluted with water to prepare a solution of 0.168 μg per m*l*.

Experimental

Fluorescence Spectra of Metal Mordant Blue 31 Complexes. Mordant Blue 31 reacts with aluminum, gallium, scandium, yttrium, lanthanum, lutetium, indium, and magnesium in acidic or basic medium to form complexes with reddish yellow fluorescence. The excitation and emission spectra of aluminum-, gallium-, and scandium-Mordant Blue 31 complexes, which show strong fluorescence, are given in Figs. 1 and 2, respectively.

The reddish yellow fluorescent aluminum complex exhibited excitation maxima at 330 and 540 nm and fluorescence emission maximum at 590 nm. The red fluorescent gallium complex showed excitation maxima at 340 and 580 nm, and fluorescence maximum at 600 nm. The scandium complex showed excitation maxima at 340 and 535 nm, and emission maximum at 610 nm.

Fluorometric Determination of metals. *(1) Aluminum*: To about 15 m*l* of the sample solution containing 0.1—3 μg of aluminum, 0.15 m*l* of 0.1% Mordant Blue 31 solution and 2 m*l* of 20% ammonium acetate solution were added. The pH value of the solution was adjusted to 6 with dilute hydrochloric acid or ammonia water and the solution was diluted to 25 m*l* with water. After being stood for 60 min at room temperature, the fluorescence intensity of the solution was measured at 590 nm (excitation: 330 or 540 nm) against the standard Rhodamine B solution.

(2) Gallium: To the sample solution containing 1—12 μg of gallium, 0.25—0.3 m*l* of 0.1% Mordant Blue 31 solution and 2 m*l* of 20% ammonium acetate solution were added. The pH was adjusted to 4, and diluted to 25 m*l*. After being stood 15 min, the fluorescence intensity of the solution was measured at 600 nm (excitation: 340 or 580 nm) against the standard Rhodamine B solution.

(3) Scandium: Scandium was determined by the same procedure as for gallium, adjusting the pH to 6 (excitation: 340 or 535 nm, emission: 610 nm).

Results and Discussion

Effect of Time. The fluorescence of the gallium- and the scandium-complex in aqueous medium was fully developed within a few minutes after mixing the solutions, and was stable for at least 2 hr. On the other hand, the fluorescence of aluminum complex required 120 min to reach the maximum as shown in Fig. 3. The fluorescence of some metal-azo-complex

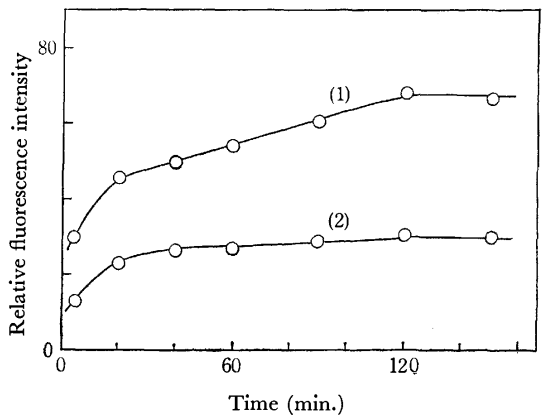

Fig. 3. Stability of fluorescence intensity of aluminum Mordant Blue 31 complex

readily reached the maximum intensity on warming at 80°C for several minutes. The aluminum complex was unstable on heating and the fluorescence intensity was measured after standing for 1 hr.

Effect of pH. The effect of pH on the fluorescence intensity of the metal-complexes is shown in Fig. 4. The pH values were adjusted with hydrochloric

acid or ammonia water, except in the case of the magnesium complex where ammonium chloride-ammonia buffer solution and sodium hydroxide solution were used for pH control.

The aluminum and scandium complexes show the maximum fluorescence intensity at pH 6. The pH-intensity curve for the aluminum complex shows maximum value at pH 5—7. The maximum fluorescence intensity of the gallium complex is obtained at pH 4, while the magnesium complex fluoresces in basic medium and gives the maximum intensity at pH 11.

Effect of Concentration of Mordant Blue 31. The effect of concentration of the reagent was examined by adding the different amounts of Mordant Blue 31 to the solution containing 3 μg of aluminum, 10 μg of gallium or 10 μg of scandium, followed by adjusting the pH to the optimum value for the metal complex.

As shown in Fig. 5, the maximum fluorescence intensity was achieved with the use of 0.15 m*l* of 0.1% Mordant Blue 31 solution for the determination of 0.1—3 μg of aluminum. For 1—12 μg of gallium, and 1—12 μg of scandium, respectively 0.25 m*l*, 0.3 m*l* of the reagent solution were required. In all cases, the fluorescence intensity decreases gradually in proportion to the amount of the reagent added. This is due to inner filter effects. Thus a definite amount of reagent was used.

Calibration Curves. Figure 6 shows the calibration curves for aluminum, gallium, and scandium obtained by the above procedures by setting up the fluorometer at 20—40 division using the standard Rhodamine B solution. A linear relationship holds between the fluorescence intensity and the metal ion concentration, showing that aluminum, gallium, and scandium could be determined in the following range: Al; 0.1—3 μg, Ga; 1—12 μg, Sc; 1—12 μg, with an average error of 3 percent.

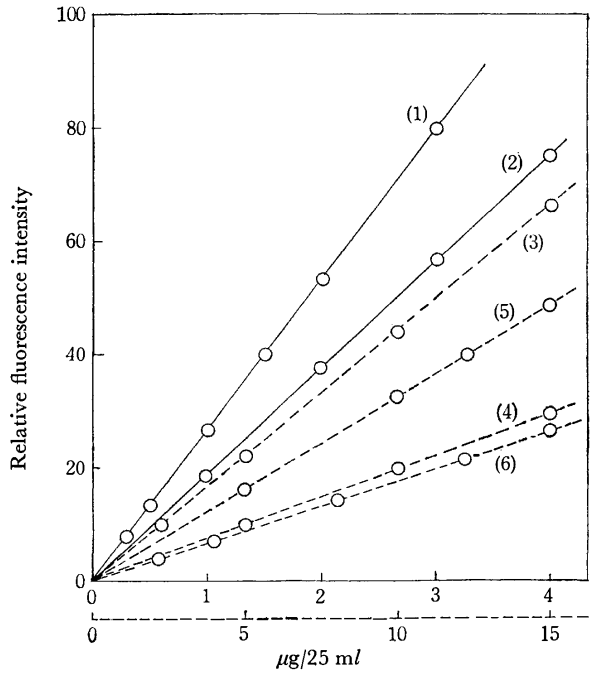

Fig. 6. Calibration curves for aluminum, gallium, and scandium
(1) Al: 20 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.15 m*l*, FPL-2 (primary filter; 365, secondary filter; 61)
(2) Al: 20 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.15 m*l*, G-3 (330 nm/590 nm)
(3) Ga: 40 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.25 m*l*, FPL-2 (primary filter; 365, secondary filter; 61)
(4) Ga: 40 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.25 m*l*, G-3 (340 nm/600 nm)
(5) Sc: 25 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.30 m*l*, FPL-2 (primary filter; 365, secondary filter; 61)
(6) Sc: 25 div. (0.168 μg Rhodamine B/m*l* standard solution), 0.1% reagent solution 0.30 m*l*, G-3 (340 nm/610 nm)

Figure 7 shows the calibration curves for some ions forming fluorescent complexes with Mordant Blue 31. The conditions for the fluorometric determinations are summarized in Table 1.

We see that magnesium, yttrium, lanthanum, lutetium, and indium can also be determined with Mordant

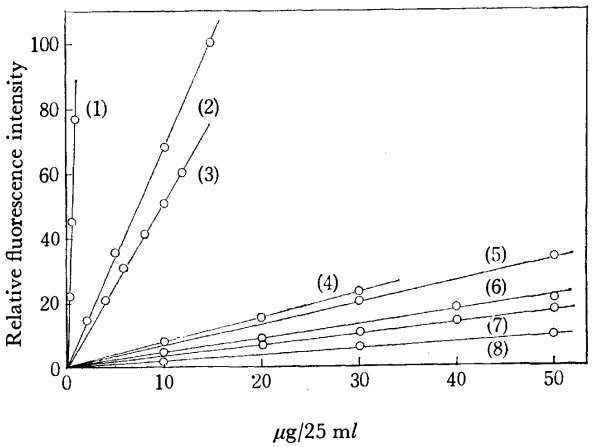

Fig. 7. Calibration curves for some fluorescent complex forming ions at 60 div. (*viz.* 0.168 Rhodamine B/m*l* standard solution, FPL-2-primary filter 365, secondary filter 61).
(1) Al, (2) Ga, (3) Sc, (4) Mg, (5) Y, (6) La, (7) Lu, (8) In

Blue 31 but with low sensitivities. Thus Mordant Blue 31 is excellent as a fluorometric reagent for aluminum, gallium, and scandium.

Effect of Diverse Ions. The effect of 26 cations on the determination of aluminum, gallium, and scandium was studied. The results are summarized in Table 2.

Determination of aluminum. Cobalt(II), iron(III), hafnium(IV), and vanadium(V) reduced the fluorescence intensity. Indium, yttrium, and scandium ions gave a positive error. The following ions did not interfere: magnesium, calcium, nickel(II), copper(II), manganese(II), zinc, cadmium, beryllium, tin(II, IV), thallium(III), arsenic(III), zirconium(IV), selenium(IV), titanium(IV), tungstate(VI), chromate(VI), and molybdate(VI) ions.

Determination of gallium. Fifty micrograms of magnesium, calcium, nickel(II), manganese(II), zinc, cadmium, cobalt(II), beryllium, indium, yttrium, thallium(III), iron(III), arsenic(III), hafnium(IV), zirconium(IV), selenium(IV), titanium(IV), and tungstate(VI) ions did not interfere. Scandium and aluminum ions gave a positive error. Copper(II), tin(II, IV), vanadate(V), chromate(VI), and molybdate(VI) ions reduced the fluorescence of gallium.

Determination of scandium. Cobalt(II), iron(III), hafnium(IV), zirconium(IV), and chromate(VI) ions

continuous variation and mole ratio methods. Figure 8 shows the results of the continuous variation method indicating the formation of a 1 : 1 complex. Mole ratio studies (Fig. 9) also gives the evidence of a 1 : 1 complex. The metal to ligand ratio can be kinetically determined when the complexes are formed with a measurable rate. Figure 10 shows the second order kinetics in the fluorescence development of aluminum-Mordant Blue 31 complex. Kinetic studies also indicate the formation of a 1 : 1 complex. The formation constants of aluminum and gallium complexes were found to be 1×10^6 at 15°C from the curves in Fig. 8.

The author wishes to express his appreciation to Prof. Tsunenobu Shigematsu, Institute for Chemical Research, Kyoto University, and Prof. Yasuharu Nishikawa, Faculty of Science and Technology, Kinki University, for their advice and suggestions.

Copper(II) Chelates of 2,4,6-Heptanetrione and Its Homologues[1]

Fumio SAGARA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received July 3, 1971)

Copper(II) chelates of heptane-2,4,6-trione as well as its methylated derivatives such as 3-methylheptane-2,-4,6-trione, 3,5-dimethylheptane-2,4,6-trione, and 2-methoxy-2-heptene-4,6-dione have been synthesized. All the ligands gave 1:2 (metal ion:ligand) chelates. The first two ligands gave in addition binuclear 2:2 chelates. The fact that a 1:2 chelate was relatively easily converted into a 2:2 chelate and the conversion occurred more easily with the chelate of the first ligand than with that of the second one was interpreted by the steric effect of the methyl group. The structures of the 1:2 and 2:2 chelates were discussed on the basis of spectroscopic and other data. Reversible addition of heterocyclic bases to the 2:2 copper chelates was observed, and the coordinating structure of pyridine adduct was found to be of a pentacoordinate square pyramid.

Heptane-2,4,6-trione (H_2daa) or diacetylacetone is a higher homologue of acetylacetone. The ligand exists as a monoanionic (Hdaa$^-$) or dianionic form (daa^{2-}), and can behave as a bidentate as well as a terdentate ligand in complex formation.

Although organic chemistry of this compound and its complexing properties have been studied to some extent,[2-8] no systematic investigation of the compound as a multidentate ligand had been reported before the publication of our communication.[9] Recently, the keto-enol tautomerism as well as the copper(II) chelates of heptane-2,4,6-trione and related triketones have been investigated by Dudley *et al.*[10,11] The characteristics of binuclear copper(II) chelates of the related β,δ-triketone ligands have also been reported by Graddon and Townsend,[12] Toy *et al.*,[13] and Murtha and Lintvedt.[14]

Three oxygen atoms in the β,δ-triketone ligands can be seen to be fixed in the same plane unable to coordinate to the same metal ion simultaneously, and it is of interest to investigate the behavior of the β,δ-triketone ligands as a multidentate ligand upon complex formation. We have investigated the fundamental properties, including keto-enol tautomerism of heptane-2,4,6-trione and its methylated derivatives,[15] the synthesis and structure of the chelates of [M(HL)$_2$] and [M$_2$L$_2$] type of divalent transition metal ions and related β,δ-triketones.[16]

In this paper we present the results of syntheses, structures, and the properties of copper(II) chelates of heptane-2,4,6-trione (H_2daa), as well as its methylated derivatives such as 3-methylheptane-2,4,6-trione (H_2-mmd), 3,5-dimethylheptane-2,4,6-trione (H_2dmd), and 2-methoxy-2-heptene-4,6-dione (Hmod).

Experimental

The Ligands. Synthesis and characterization of the ligands have been reported.[15]

Synthesis of the Chelates. 1 : 2 Chelates. Bis(heptane-2,4,6-trionato)copper(II) Dihydrate, Cu(Hdaa)$_2$·2H$_2$O. (a): A methanol solution of heptane-2,4,6-trione (1.0 g, 0.0070 mol) was added to an aqueous solution of cupric acetate monohydrate (0.70 g, 0.0035 mol, in 20 m*l* of water) under cooling in an ice-water bath. Blue precipitates were collected and dried in the air. Yield, 0.85 g (63%). Attempts to recrystallize the sample from various organic solvents were unsuccessful, because the compound was easily converted into Cu$_2$(daa)$_2$ when dissolved in the solvent even at room temperature, mp about 50°C (decompn.). However, it was converted into Cu$_2$(daa)$_2$ upon heating so easily that no reproducible melting point could be observed. Two moles of water, probably coordinated water, could not be removed even at reduced pressure and lower temperature, without causing rearrangement into Cu$_2$(daa)$_2$.

(b): Two grams (0.0049 mol) of bis(heptane-2,4,6-trionato)dicopper(II) and 10.0 g (0.070 mol) of heptane-2,4,6-trione were dissolved into 20 m*l* of pyridine containing a small amount of water at 0°C, and the solution was concentrated to about 5 m*l* by evaporating pyridine at reduced pressure at 0°C, to give blue precipitates which were collected and air-dried. Yield, 2.4 g (64%).

Bis(3-methylheptane-2,4,6-trionato)copper(II), Cu(Hmmd)$_2$. A chloroform solution (20 m*l*) of 3-methylheptane-2,4,6-trione (0.50 g, 0.0032 mol) was stirred together with an aqueous solution of cupric acetate monohydrate (0.32 g, 0.0016 mol) at room temperature. The resulting mixture was kept to stand and the chloroform layer formed was evaporated off at room temperature to give blue precipitates which were purified on a silica gel (WAKOGEL Q-23) column. Yield, 0.45 g (75%), mp about 80°C (decompn.). However, the compound converted into Cu$_2$(mmd)$_2$ by heating so easily

that no reproducible melting point could be observed.

Bis(3,5-dimethylheptane-2,4,6-trionato)copper(II), Cu(Hdmd)$_2$. A similar procedure to the above was carried out using a chloroform solution (50 m*l*) containing 3,5-dimethylheptane-2,4,6-trione (2.00 g, 0.0118 mol) and an aqueous solution (100 m*l*) of cupric acetate monohydrate (1.20 g, 0.0060 mol). The chloroform solution was evaporated to give greenish grey residue, which was purified by elution chromatography on a silica gel column. Yield, 1.42 g (60.1%), mp 162—162.5°C.

Bis(2-methoxy-2-heptene-4,6-dionato)copper(II), Cu(Hmod)$_2$. Heptane-2,4,6-trione (5.0 g, 0.035 mol) was added at 5°C into ether (30 m*l*) containing diazomethane which was prepared from nitrosomethylurea (5.0 g, 0.049 mol) and a 40% potassium hydroxide solution (9.0 m*l*). After being put to stand overnight at room temperature, the ethereal solution was evaporated to give a viscous oil which was dissolved in chloroform (100 m*l*) and treated with an aqueous cupric acetate monohydrate (15.0 g, 0.075 mol). The chloroform layer formed was evaporated to dryness, giving pale blue precipitates, which were recrystallized three times from ethanol. Yield, 2.10 g (32%), mp 160—162°C. The product was assigned to be bis(2-methoxy-2-heptene-4,6-dionato)copper(II).

A chloroform solution of the copper chelate was stirred together with 0.1N hydrochloric acid until the chloroform layer became colorless. The chloroform layer was evaporated to give an oil which was assigned to be heptane-2,4,6-trione by infrared spectral comparison and gas-liquid chromatography. The chloroform solution of the oil was again treated with aqueous cupric acetate. The resulting blue solution was evaporated to give a solid residue which was identified to be $Cu_2(daa)_2$ by infrared spectral comparison.

2:2 Chelates. Bis(heptane-2,4,6-trionato)dicopper(II), $Cu_2(daa)_2$. (a): A methanol solution of heptane-2,4,6-trione (1.0 g, 0.0070 mol) was added portionwise to an aqueous solution of cupric acetate monohydrate (1.4 g, 0.0070 mol) at 30°C with stirring. Resulting green precipitates were insoluble in most organic solvents except for strong coordinating solvents such as pyridine or dimethyl sulfoxide. The precipitates were collected, recrystallized from pyridine and dried under reduced pressure at 65°C for several hours to give green powders, decomposing at about 280°C. Yield, 1.20 g (83%).

(b): A methanol solution (10 m*l*) containing bis(heptane-2,4,6-trionato)copper(II) dihydrate, $Cu(Hdaa)_2\cdot 2H_2O$, (1.00 g, 0.00262 mol) was heated under reflux for 2 hr. The green precipitates were collected and dried under reduced pressure. The complex was identified to be the above mentioned binuclear chelate by elemental analysis and infrared spectroscopy. Yield 1.02 g (95.3%), mp 280°C (decompn.).

Bis(3-methylheptane-2,4,6-trionato)dicopper(II) $Cu_2(mmd)_2$. A similar procedure to the above (procedure (b)) was carried out using a methanol solution of bis(3-methylheptane-2,4,6-trionato)copper(II) (1.0 g, 0.0027 mol). The resulting green precipitates were recrystallized from pyridine and dried under reduced pressure at 65°C. Yield, 0.82 g (70%), mp about 280°C (decompn.).

The properties and the results of elemental analyses as well as the conditions of synthesis of the copper chelates investigated are summarized in Table 1.

Base Adducts of 2:2 Chelates. Pyridine or 4-methylpyridine adducts of $Cu_2(daa)_2$ and $Cu_2(mmd)_2$ were prepared by dissolving 1 g of the copper chelate into 50 m*l* of pyridine or 4-methylpyridine, and putting the resulting solution to stand for 1—2 days at 0—15°C. The crystalline precipitates afforded were collected by filtration and air-dried. Yield 0.3—0.6 g (29—43%). The base adducts were dark brown crystals, fairly stable in nonpolar solvents such as hexane or cyclohexane, but readily decomposed in polar solvents such as methanol or water, precipitating green 2:2 chelates.

The amount of base coordinated to the 2:2 chelates and the temperature at which the base began to dissociate were determined by thermogravimetric analysis. The results are summarized in Table 2.

When bis(heptane-2,4,6-trionato)copper(II) dihydrate ($Cu(Hdaa)_2\cdot 2H_2O$) was treated with concentrated aqueous ammonia, an ammonia adduct was obtained as brown powder. The product was not stable enough to be subjected to thermogravimetric analysis to get reliable results on the number of mole of ammonia added. However, the product was supposed to be the ammonia adduct of $Cu_2(daa)_2$, since the remaining compound after thermal decomposition was found to be $Cu_2(daa)_2$.

Attempts to prepare the solid base adducts of 2:2 chelate with other amine ligands such as ethylamine, diethylamine, triethylamine, aniline, and quinoline were unsuccessful, although adducts were formed in solution as indicated by the color change from green solid to brown solution when the solid 2:2 chelates were dissolved in these amine ligands.

Apparatus and Procedure. All melting points are uncorrected. Visible spectra were measured with a Hitachi

Results and discussion

Synthesis of Copper Chelates. Heptane-2,4,6-trione and its homologues can form two types of copper chelates; a mononuclear type, $Cu(HL)_2$, and a binuclear type, Cu_2L_2.[9] As shown in Table 1, heptane-2,4,6-trione and the 3-methyl derivative gave both types of chelates, while the 3,5-dimethyl derivative afforded only the former.

Synthetic procedures of these chelates can be classified as follows; For $Cu(HL)_2$ type chelate: Procedure 1. A cold methanol solution of a ligand was added dropwise into half a mole of aqueous cupric acetate at a lower temperature. Procedure 2. A cold chloroform solution of a ligand was stirred with half a mole of aqueous cupric acetate at a lower temperature. Procedure 3. A cold pyridine solution containing a Cu_2L_2 type complex and a large excess of the corresponding ligand was evaporated under reduced pressure at a lower temperature. For Cu_2L_2 type chelate: Procedure 4. An aqueous cupric acetate was added dropwise into a hot methanol solution of an equimolar amount of the ligand. Procedure 5. A methanol solution of $Cu(HL)_2$ type chelate was heated with or without an equimolar amount of cupric acetate as long as necessary.

Mononuclear $Cu(HL)_2$ type chelates are not so stable, and tend to convert into binuclear Cu_2L_2 chelates at higher temperatures accompanied by the liberation of free ligand (See Experimental). The maximum temperature below which $Cu(HL)_2$ type complex is stable in methanol, is 0°C for $Cu(Hdaa)_2$ and 30°C for $Cu(Hmmd)_2$. Thus, the reaction temperature in the synthetic procedure 1, 2, and 3 has to be kept below −5°C for the first, and at room temperature for the second, otherwise the mixture of $Cu(HL)_2$ and Cu_2L_2 will be obtained as the reaction product. For the third, there was no indication of conversion into binuclear complex even when heated at refluxing temperature in methanol.

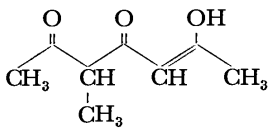
The binuclear chelates can be obtained by either procedure 4 or 5, most easily from heptane-2,4,6-trione and less easily from monomethyl derivative. Thus, $Cu_2(daa)_2$ was obtained by the reaction at room temperature, but $Cu_2(mmd)_2$ was obtained at refluxing temperature in methanol. Attempted syntheses of a binuclear chelate with the dimethyl derivative were unsuccessful under various reaction conditions including those for the above ligands. The *O*-methyl derivative gave only the mononuclear chelate as expected from its bidentate structure.

Structure of $Cu(HL)_2$ Chelates. The result of the elemental analysis on 1:2 chelate of heptane-2,4,6-trione suggests the molecular formula of $Cu(Hdaa)_2 \cdot 2H_2O$. The infrared spectra of 1:2 chelates from three

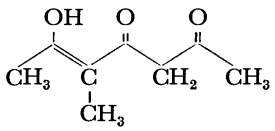
ligands, H_2daa, H_2mmd, and H_2dmd, showed a free carbonyl band at about 1720 cm^{-1} and multiplet bands in the region of 1600—1500 cm^{-1} due to a coordinated carbonyl and an olefinic group involved in the chelate ring which were not observed in the free ligand (Fig. 1). Broad bands in 1700—1600 cm^{-1} observed in the free ligands disappeared in infrared spectra of the copper chelates. The results suggest that the adjacent two of three carbonyl oxygen atoms are involved in the chelate formation with copper, leaving the side carbonyl oxygen uncoordinated.

Powder reflection spectrum of $Cu(Hdaa)_2 \cdot 2H_2O$ shows two broad bands at 16500 and 18100 cm^{-1} which are fairly close to those of bis(acetylacetonato)copper(II) in chloroform (15300, 18200 cm^{-1}). The result indicates that four carbonyl oxygen atoms around copper ion in $Cu(Hdaa)_2 \cdot 2H_2O$ are of square planar configuration as in the case of bis(acetylacetonato)copper(II), and the coordination of two moles of water to the z axis of copper ion is not strong enough to influence the electronic spectra of *d–d* transition.

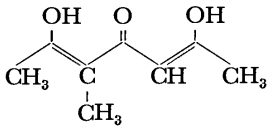
Thus, the structure of bis(heptane-2,4,6-trionato)-copper(II) dihydrate is proposed as Structure I. In the case of 3-methylheptane-2,4,6-trione, however, there remains a question as to the site of coordination of the ligand, because the ligand is no more symmetric. Although there is no definite data, NMR study on the keto-enol tautomerism of this ligand in $CDCl_3$ revealed that the fractions of monoenol (A), monoenol (B), bisenol and triketo forms were 76, 9, 12, and 3%, respectively, and these fractions did not change appreciably with temperature.[15]



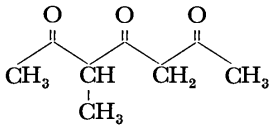
monoenol (A)



monoenol (B)



bisenol



triketo

If one recalls that 1 : 2 copper chelate of 3-methylheptane-2,4,6-trione was synthesized by contacting the chloroform solution of the ligand with an aqueous solution of cupric acetate, the possible structure of 1 : 2 copper chelate might be the one in which the methyl group is located on the middle carbon of uncoordinated side as illustrated in structure I.

		R^1	R^2
Ia)	$Cu(Hdaa)_2 \cdot 2H_2O$	H	H
Ib)	$Cu(Hmmd)_2$	CH_3	H
Ic)	$Cu(Hdmd)_2$	CH_3	CH_3

Structure I

It is of interest to note that 1 : 2 chelate of heptane-2,4,6-trione differs from those of the *C*-methylated derivatives with respect to the coordinated water. The former contained two moles of water with a multiplet band at 3530—3260 cm^{-1}, could hardly be removed. Attempted dehydration of the two moles of water under reduced pressure at room temperature resulted in conversion into an anhydrous Cu_2L_2 chelate. Thus, bis-(heptane-2,4,6-trionato)copper(II) seems to be stable only in the presence of coordinated water. On the other hand, the 1 : 2 chelates of 3-methyl- and 3,5-dimethyl derivatives can be obtained as anhydrous chelates respectively. Similarly, replacement of one or both terminal methyl groups with the phenyl group also resulted in anhydrous 1 : 2 chelates.[11]

A multiplet band at 3530—3260 cm^{-1} observed on bis(heptane-2,4,6-trionato)copper(II) dihydrate may be responsible for ν_{OH} of coordinated water as well as the enolic hydroxyl group. This suggests the partial enolization of the uncoordinated carbonyl group in the chelate. A similar situation was also observed on bis-(heptane-2,4,6-trionato)palladium(II) by NMR study.[17]

1 : 2 Copper chelates of methylated ligands $Cu(Hmmd)_2$ and $Cu(Hdmd)_2$ were obtained as anhydrous chelates. No meaningful absorption was observed in 3200—3500 cm^{-1} region. This indicates that the uncoordinated carbonyl group in the chelates of methylated ligands do not enolize appreciably. This can be explained by the steric effect of the methyl group on 3-position. In the case of keto form, the uncoordinated terminal acetyl group can rotate freely, so that there operates little steric repulsion between the methyl groups on terminal- and 3-position. On the other hand, the olefinic double bond of the enol form restricts the free rotation of the terminal group, resulting in the stable configuration. Such steric effect does not exist in bis(heptane-2,4,6-trionato)copper(II), allowing a partial enolization of the uncoordinated carbonyl group.

As to the copper chelate of 2-methoxy-2-heptene-4,6-dione, the result of elemental analysis suggests the molecular formula $Cu(Hmod)_2$. The reaction of diazomethane with heptane-2,4,6-trione gave only the *O*-methyl derivative (H_2mod) and no *C*-methyl ones (H_2mmd or H_2dmd). Methylated position of the product should be a side oxygen and not the central one, because the *O*-methyl derivative still showed the ability of chelate formation with beryllium(II) and copper (II) ions to give 1 : 2 chelate. NMR spectrum of the beryllium chelate indicated the presence of an *O*-methyl group in theligand.[17] The compound, however, could be isolated only in the form of a metal complex, and attempts to liberate the free ligand from the copper chelate were unsuccessful, and resulted in decomposition in an acid medium to give the original heptane-2,4,6-trione even at a lower temperature. This is not surprising because the enol-ether bonding usually degradates rather easily. The process of the decomposition of freed ligand could be traced by gas-liquid chromatography; a chloroform extract immediately after libera-

17) Unpublished results.

tion from the copper chelate with an acid gave a single glc peak at $R_T=1.1$ min, and after about 10 min, glc showed four broad peaks in a shorter R_T range in additon to the original peak. Forty min after the glc again showed a single peak but at $R_T=4.1$ min, which was identical with that of heptane-2,4,6-trione. Additional glc peaks which appeared on the process from the *O*-methyl derivative to heptane-2,4,6-trione were not studied in detail, though they were apparently due to tautomers of the *O*-methyl derivative.

Thus, the coordination with metal ion prevented the cleavage of the enol-ether bonding in 2-methoxy-2-heptene-4,6-dione. Since the enol-ether group does not seem to be directly involved in the coordination with metal ion, the stabilization was presumed to be due to steric hindrance in nucleophilic attack of an anion to a protonated intermediate upon the cleavage of the ether bonding.

Infrared bands in the region 1600—1500 cm^{-1} could be assigned in a similar manner to those of heptane-2,4,-6-trione and its *C*-methyl derivatives. The band at 1635 cm^{-1} was due to an olefinic group connected to oxygen. No positive evidence could be obtained to suggest a macrocyclic chelate ring. The result also indicates that diazomethane attacked a side carbonyl group in heptane-2,4,6-trione and not the central one. Volatility of the copper chelate (130°C /5 × 10^{-1} mmHg) and solubility in organic solvents such as chloroform, ethanol, and methanol suggested the 1:2 copper chelate to be of a monomeric form containing a six-membered chelate ring as shown in structure III.

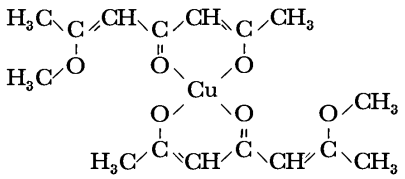
Structure II



III) $Cu(mod)_3$

Structure III

Structure of Cu_2L_2 Chelates. The results of elemental analysis of the 1:1 heptane-2,4,6-trione chelate suggests the molecular formula Cu(daa). The infrared spectra of 1:1 chelates show multiplet bands in the region 1600—1500 cm^{-1}, which could be assigned to a coordinated carbonyl and an olefinic group involved in the chelate ring as in the case of 1:2 chelates. On the other hand, no characteristic absorption band can be observed in the range 1800—1600 cm^{-1}. This suggests that all the three carbonyl oxygen atoms are involved in coordination. If we consider that the ligand is planar through its conjugated double bond system, and that three carbonyl oxygen atoms eventually can not coordinate to the same metal ion, dimeric structure II becomes the most probable. Although the polymer structure could also be assigned to the chelate, the construction of molecular model gives rise to too great strain to be acceptable. The dimeric structure was also supported by the magnetic moment study down to the liquid helium temperature as well as the ESR study. The strong antiferromagnetism of the copper(II) chelate suggests the dimeric structure. A detailed magnetic study on this system has been recently reported by Baker and others.[11]

The powder reflection spectrum of $Cu_2(daa)_2$ shows one broad band at 14700 cm^{-1}, which suggests a slight distortion from planar structure. The construction of molecular model of $Cu_2(daa)_2$ also needs the displacement of copper ion slightly above or below the plane of ligands.

Interconversion of 1:2 and 2:2 Chelates. The mononuclear and binuclear copper chelates of heptane-2,4,6-trione and its monomethyl derivative are interconvertible, as can be understood from their synthetic procedures. Mononuclear 1:2 chelate can be converted into 2:2 chelate by procedure 5, and 2:2 chelate can be converted into 1:2 chelate by procedure 3. In general, a lower temperature in the presence of excess ligand favors $Cu(HL)_2$ type chelate and a higher temperature Cu_2L_2 type chelate. As no common solvent was found for both types of chelates, equilibrium study on this system was not undertaken. $Cu(Hdaa)_2$ and $Cu(Hmmd)_2$ can be converted into $Cu_2(daa)_2$ and $Cu_2(mmd)_2$ quantitatively by heating methanol solution at 30 and 60°C, respectively.

Facility to form 2:2 chelate of heptane-2,4,6-trione as compared with 3-methyl derivative can be related to the relative enolizability of uncoordinated carbonyl group in 1:2 chelate. Partial enolization of uncoordinated carbonyl group was suggested on bis(heptane-2,4,6-trionato)copper(II), no indication of enolization being observed on bis(3-methylheptane-2,4,6-trionato)-copper(II). Thus, 2:2 chelate of heptane-2,4,6-trione can be obtained at relatively lower temperatures. However, 2:2 chelate of methylated ligand needs a higher temperature to overcome the steric repulsion of methyl groups.

In the case of 3,5-dimethylheptane-2,4,6-trione, NMR study proved that this ligand could not take the *cis*-dienol form, responsible for the 2:2 chelate, because of the steric repulsion of methyl groups.[15] Thus, attempts to synthesize 2:2 chelate of dimethyl derivative have been unsuccessful so far.

Base Adducts of 2:2 Chelates. Chelates of binuclear Cu_2L_2 type are thermally stable. They are not soluble in most organic solvents except for strong coordinating solvents such as pyridine or dimethyl sulfoxide. Green chelates turn brown when they are dissolved in pyridine, from which pyridine adducts can be obtained as brown crystalline precipitates at

higher concentration. The thermogravimetric investigation on the pyridine adducts proved that their composition is $Cu_2L_2Py_2$, in other words, each molecule of pyridine added to each copper ion, and that pyridine can be removed by heating the adduct at a relatively low temperature.

Infrared spectra and X-ray diffraction pattern of powdered sample before the addition and after the dissociation of pyridine were found to be identical. The molecular weight of 2:2 chelates in pyridine determined by a vapor pressure osmometer was found to be 412 (calcd.: 407.4) for $Cu_2(daa)_2$ and 439 (calcd.: 436) for $Cu_2(mmd)_2$.

Visible absorption spectrum of pyridine solution and powder reflection spectrum of pyridine adduct showed a maximum at the same frequency of 13520 cm^{-1}, indicating that the coordinating structure around copper ion in pyridine solution does not differ from that in solid adduct. As regard the infrared spectrum of pyridine adduct, no absorption band due to uncoordinated carbonyl group could be observed, and new bands at 410 cm^{-1} and 386 cm^{-1}, possibly due to the deformation of pyridine ring and the streching mode of N-Cu bond respectively, were observed in addition to the bands observed in the pyridine-free complex.

The results suggest that the dissolution of the 2:2 chelates in pyridine does not destroy the binuclear structure, and that the addition of pyridine is a reversible process. Thus, the structure of pyridine adduct may be of pentacoordinate square pyramid around copper(II) ion, with pyridine molecule coordinating from one side of z-axis of copper ion.

The reversible addition of heterocyclic bases to copper β-diketonates in solution has been investigated extensively.[18] If the adducts were stable, they could be isolated as definite solid adducts. In the case of bis(acetylacetonato)copper(II), mono-4-methylpyridine adduct has been obtained but not with pyridine.[19] In the cases of copper chelates of trifluoro- and hexafluoroacetylacetone, very stable mono- and bis-pyridine adducts were obtained.[20,21] The relative stability in these base adducts can be interpreted by the electron donating property of the heterocyclic nitrogen as well as the electron withdrawing property of β-diketones.

The results of thermogravimetric analysis on pyridine and 4-methylpyridine adducts of the 2:2 copper(II) chelate, as shown in Table 2, indicates a similar tendency as regards the electronic effect of the methyl group introduced on pyridine or heptane-2,4,6-trione, though the effect was not as great.

Oxovanadium(IV) Complexes of Schiff Bases Obtained from Salicylaldehyde Derivatives and Arylamines

Yoshio KUGE

Environmental Pollution Control Centre, Morimachi, Higashinari-ku, Osaka

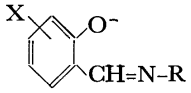
and Shoichiro YAMADA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 9, 1971)

Oxovanadium(IV) complexes of Schiff bases obtained from salicylaldehyde derivatives and arylamines (abbreviated as $VO(X\text{-}SAL.R)_2$) have been synthesized, where X=H, 5,6-benzo, 5-Cl, and 5-Br, and R=Ph, CH_3-Ph, 2,6-$(CH_3)_2$-Ph and 2,6-$(C_2H_5)_2$-Ph, Ph being phenyl nucleus. Complexes of the type $VO(5\text{-}X\text{-}SAL.Ph)_2$ in the solid state, X being Cl and Br, consist of the species having a different configuration from that of the other complexes. For the latter complexes, distortion from the square-pyramidal configuration is not apparent in the solid state or in non-donor solvents, but in pyridine they combine with one pyridine molecule to form six-coordinate vanadium(IV) complexes. Comparison shows that the tendency toward the distortion in the solid state is lower with R=aryl than with R=α-branched alkyl groups.

In a previous paper[1] we reported the synthesis of



(I)

oxovanadium(IV) complexes with *N*-alkylsalicylideneiminates (abbreviated as X-SAL.R, I). Their structure in the solid state and in solution was examined in connection with the steric effect caused by bulky α-branched alkyl groups.

As regards the corresponding complexes with *N*-

arylsalicylideneiminates, however, only a few of them have been reported,[2] and no systematic examination of the aryl complexes has ever been carried out. In the present work, oxovanadium(IV) complexes with *N*-arylsalicylideneiminates have been studied, and the results have been compared with those of the *N*-alkyl-complexes and the corresponding complexes of some other metal ions.

Experimental

Materials. Complexes of the type $VO(X\text{-}SAL.R)_2$ were synthesized by a method similar to that previously reported.[1,2] Analytical data of new complexes are shown in Tables 1 and 2. A typical method of preparation is given below.

To a solution of oxovanadium(IV) chloride (0.01 mol) in ethanol were added salicylaldehyde or its derivative (0.02 mol) and an appropriate arylamine (0.02 mol). The solution was stirred at room temperature for about 3 hr and allowed to stand overnight. The precipitate was collected by filtration and recrystallized from ethanol containing a small amount of pyridine.

μ: magnetic moment in B. M. at room temperature

All the complexes were obtained as yellow-brown or olive-green microcrystals. They are soluble in chloroform, dichloromethane and pyridine, but almost insoluble in methanol and ethanol. Some of them undergo decomposition on dissolution.

Measurements. Electronic absorption spectra of the complexes in solution and in the solid state were determined with a Shimadzu MPS-50L spectrophotometer.

Magnetic susceptibilities were determined by the Gouy method at room temperature.

Results and Discussion

It is known that the vanadium(IV) ion in most oxovanadium(IV) complexes assumes a square-pyramidal configuration.[1,2] Therefore, when R denotes such a group as phenyl and 3- or 4-substituted phenyl causing very little steric hindrance, the complexes of the type $VO(X\text{-}SAL.R)_2$ are expected to have a square-pyramidal configuration, with the two X-SAL.R groups most

br: broad, sh: shoulder

probably having a nearly planar configuration.[1,2] This is borne out by their electronic absorption spectra in non-donor solvents and in the solid state, as shown in Figs. 1 and 2, and Table 3. The spectra are similar to each other and also to those of the N-alkyl-substituted complexes.[1] The absorption maxima at about 12, 16, and 18 kK may be assigned to transitions $d(xy)\rightarrow d(xz)$ $d(yz)$, $d(xy)\rightarrow d(x^2-y^2)$ and $d(xy)\rightarrow d(z^2)$, respectively, as in the previous papers.[1,2] Comparison of their band maxima with those of the *N*-alkyl-substituted complexes[1] shows that the ligand field produced by X-SAL·aryl is slightly weaker than that by X-SAL·alkyl.

It is interesting to note that, even for R=2-CH_3-Ph, 2,6-$(CH_3)_2$-Ph and 2,6-$(C_2H_5)_2$-Ph, a significant distortion from the square-pyramidal configuration does not occur in these complexes, since their absorption maxima in the solid state and in non-donor solvents are nearly the same as those of VO(X-SAL·Ph)$_2$ as shown in Figs. 1 and 2, and Table 3. A similar result was obtained with the corresponding nickel(II) and copper(II) complexes.[3]

The electronic spectra of the complexes of the type VO(5,6-benzo-SAL.R)$_2$ in pyridine clearly differ from those of the same complexes in the solid state or in chloroform as shown in Fig. 2 and Table 3. Since their spectral change on going from the solid state to the pyridine solution is nearly the same, irrespective of whether R denotes 2,6-$(CH_3)_2$-Ph, 2,6-$(C_2H_5)_2$-Ph or Ph, and resembles that of VO(X-SAL·*n*-alkyl)$_2$,[1] their pyridine adducts are considered to have a similar configuration to that of VO(X-SAL·*n*-alkyl)$_2$.

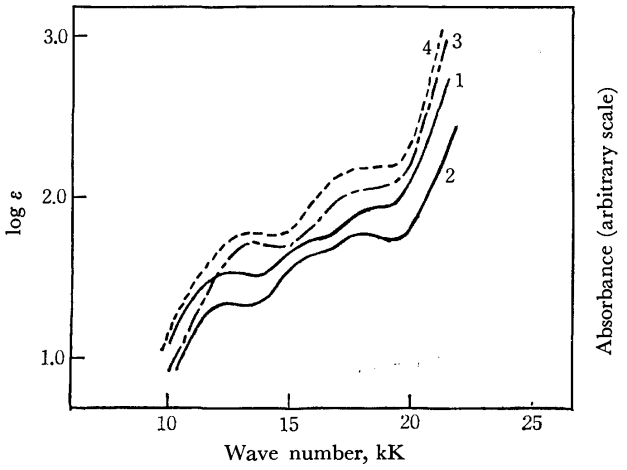

Fig. 2. Electronic absorption aspectr of VO(5,6-benzo-SAL.R)$_2$: 1, R=Ph, solid; 2, R=2,6-$(CH_3)_2$-Ph, solid; 3, R=Ph, in pyridine; 4, R=2,6-$(CH_3)_2$-Ph, in pyridine.

The complexes of the type VO(H-SAL.R)$_2$ in pyridine, R being Ph, 3-CH_3-Ph and 4-CH_3-Ph, exhibit similar spectra to those of the corresponding 5,6-benzo-complexes. On the contrary, for R=2-CH_3-Ph and 2,6-$(CH_3)_2$-Ph and X=H, the spectral change on going to the pyridine solution is different from the other complexes of the type VO(H-SAL.aryl)$_2$, as shown in Fig. 1 and Table 3, the *d-d* bands of the former in pyridine being shifted toward much lower frequencies than in the solution of the latter. This anomalous spectral change indicates that VO(H-SAL.2-CH_3-Ph)$_2$ and VO(H-SAL.2,6-$(CH_3)_2$-Ph)$_2$ in pyridine form six-coordinate pyridine adducts having a more distorted configuration than that of the corresponding adduct of VO(H-SAL.Ph)$_2$. This difference between the complexes with X=H and those with X=5,6-benzo may be ascribed to the effect of the field strength produced by the in-plane ligands. A similar difference in the stereochemistry of the complex, as a result of the introduction of a substituent in the benzene nucleus, was sometimes observed with the corresponding complexes of cobalt(II), nickel(II) and copper(II).[4]

a) Present study and ref. (1). b) Ref. (4).
c) Ref. (3). d) S. Yamada, unpublished.

Comparison of the present results with those of the previous papers[3,4] is summarized in Table 4. We see that the distortion in the solid state occurs more easily with R=α-branched alkyl groups than with R=aryl groups.

Table 4 also shows that the vanadium(IV) ion seems to take up an additional ligand such as pyridine to form a six-coordinate adduct more readily than do the cobalt(II), nickel(II), and copper(II) ions.

sh: shoulder

The spectra of VO(5-Cl-SAL.Ph)$_2$ and VO(5-Br-SAL.Ph)$_2$ in the solid state, shown in Fig. 3 and Table 5, differ remarkably from those of other complexes such as VO(H-SAL.Ph)$_2$ and VO(5,6-benzo-SAL.Ph)$_2$. Moreover, their magnetic moments (Table 2) are lower than the spin-only moment 1.73 B. M. for the d^1 system, showing that some sort of interaction may be present between vanadium(IV) ions. It is therefore likely that their configuration differs from the square pyramidal one. One of the probable configurations for these two complexes in the soid state is a binuclear one, as shown in Fig. 4. For a definite conclusion, however, an X-ray study is necessary. Examination of their infrared spectra yielded no significant conclusion. The low solubility of these compounds did not allow the determination of their molecular weights.

The 5-bromo-substituted complex is moderately soluble in non-coordinating solvents, although the 5-chloro-substituted complex is only slighlty soluble. The spectrum of VO(5-Br-SAL.Ph)$_2$ in chloroform, as shown in Fig. 3, is different from that of the same complex in the solid state but similar to the spectrum typical of the square-pyramidal oxovanadium(IV) complex of this series. It is thus found that the 5-bromo-substituted complex has a uninulcear, square-pyramidal configuration in the non-donor solvent. Inspection of the spectra also indicates that these complexes in pyridine form pyridine adducts having a similar configuration to that of VO(H-SAL.Ph)$_2$ or VO(5,6-benzo-SAL.Ph)$_2$.

Stereoselective Formation of Isomers of the *Bis*(L-aspartato)-L-(or D-)alaninatocobaltate(III) Complex[1)]

Toshitsugu MATSUDA, Tetsuro OKUMOTO, and Muraji SHIBATA
Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 22, 1971)

The reaction of racemic α-alanine, in the presence of active charcoal, on a reaction mixture of the $[Co(CO_3)_3]^{3-}$ complex with L-aspartate led to the stereoselective formation of the $[Co(L\text{-}asp)_n(ala)_{3-n}]^{n-}$ (n=0—3) complexes. By means of ion-exchange chromatography and a recrystallization procedure, three stereoisomers of the *bis*(L-aspartato)alaninato complex have been obtained; *mer*$_1$-*Λ*-$[Co(L\text{-}aspH)_2(L\text{-}ala)]\cdot H_2O$, *mer*$_2$-*Λ*-$[Co(L\text{-}aspH)_2(L\text{-}ala)]\cdot 2H_2O$, and *fac*-*Λ*-$[Co(L\text{-}aspH)_2(D\text{-}ala)]\cdot 4H_2O$ (where the *mer*$_1$ and *mer*$_2$ isomers have different geometries). These isomers have been characterized by comparing their CD and PMR spectra with those of the corresponding isomers obtained using L- or D-alanine in place of racemic alanine. The *fac*/*mer* ratio has been estimated to be *ca.* 64/36. The *Δ*/*Λ* ratio in the *fac* isomer has been estimated to be *ca.* 95/5, while the *Δ*/*Λ* ratio in both the *mer*$_1$ and *mer*$_2$ isomers has been estimated as *ca.* 25/75.

Previously, we reported that, when a large excess of racemic α-alanine was reacted with a reaction mixture of the tricarbonatocobaltate(III) complex with L-aspartate, a water-insoluble *fac-tris*(alaninato)cobalt(III) complex was precipitated, and that the precipitates consisted mainly of the *fac*-*Δ*(−)-$[Co(D\text{-}ala)_2(L\text{-}ala)]$ isomer (the (−) sign refers to the sign of the main CD peak in the first absorption band region).[2)] In those experiments, the yield of the insoluble material was usually less than 50%. This fact was an indication of the existence of water-soluble complex species in such a reaction mixture; therefore, we wanted to isolate some of those complexes.

On the other hand, we have recently reported the pra-

1) Presented at the 24th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

2) M. Shibata, H. Nishikawa, and K. Hosaka, This Bulletin, **41**, 130 (1968).

paration of a series of glycinato-L-aspartato complexes, $[Co(gly)_{3-n}(L\text{-asp})_n]^{n-}$ ($n=1,2$), and discussed the stereoselective formations of the complexes.[3] In connection with the earlier work, the present paper will report the isolation and characterization of *bis*(L-aspartato)alaninato complexes, and will discuss the stereoselectivity in the complex formations.

Experimental

Preparation. To a green solution of tricarbonatocobaltate(III) ($CoCl_2 \cdot 6H_2O$ 6.0 g scale; 0.025 mol) prepared by the usual method,[4] 6.7 g (0.050 mol) of L-aspartic acid were added; the mixture was then stirred at 60°C for 2 hr. After adding 4.5 g (0.050 mol) of racemic α-alanine and 1.0 g of active charcoal, the solution was stirred at *ca.* 50°C for 3 hr; the color of the solution then changed from violet to red-violet, and a small amount of a water-insoluble material was precipitated. After the removal of this precipitate and the active charcoal by filtration, the filtrate was adjusted to pH *ca.* 7 with 6N acetic acid. This solution was charged on an anion-exchange column containing 100—200 mesh Dowex 1×8 resin in the chloride form (diameter, 7.0 cm; resin height, 30 cm). When water was passed through the column, a non-charged *tris*(alaninato) complex was eluted out. Then a 0.03M aqueous solution of calcium chloride was poured into the column at the rate of *ca.* 0.5 ml/min. After prolonged elution, seven bands were completely separated; the first band consisted of the univalently-charged *bis*(alaninato)-L-aspartato complex including isomers of both the *mer* and *fac* forms. The second and third bands were of the bivalently-charged *bis*(L-aspartato)alaninato complex belonging to the *mer* form. The fourth and fifth bands were of the same complex belonging to the *fac* form. The last two bands were the *mer* and *fac* isomers of the *tris*(L-aspartato) complex. An attempt at crystallization was actually made for the complex species of the 2—5 bands, because the first band gave a mixture of the stereo isomers of the *bis*(alaninato)-L-aspartato complex, and because the isomers of the complex corresponding to the last two bands, the isomers of the *tris*-(L-aspartato)cobaltate(III), had already been isolated.[5]

Four bands (2—5) were collected in fractions; they were conveniently labelled mer_1, mer_2, fac_1, and fac_2 according to the elution order. Each fraction was then concentrated to a small volume under reduced pressure at temperatures below 40°C. When ethanol was added to the resulting concentrate, the desired complex was obtained as calcium salt. This was then dissolved in a minimum amount of water, and the solution was acidified with 6N hydrochloric acid to precipitate the complex as hydrogen compound. This treatment was also employed for the calcium salts precipitated from the mer_1, mer_2, and fac_1 fractions. The calcium salt precipitated from the fac_2 fraction was dissolved in a minimum amount of water, and the solution was added to a small column containing Dowex 50W×8 resin in the hydrogen form. The effluence was concentrated, and ethanol was added to the concentrate to precipitate the hydrogen compound of the complex. The recrystallization of these hydrogen compounds was performed by dissolving each of them in slightly alkaline water and by then acidifying the solution with diluted hydrochloric acid. This procedure was repeated until the main CD peak of the compound showed a constant intensity. Although the exact yields were not obtained because of the repeated crystallization, the compounds were obtained in yields of roughly 8, 50, and 50 mg for the mer_1, mer_2, and fac_2 fractions respectively. The fac_1 fraction gave a trace of the solid.

A similar experiment was carried out by using L- or D-alanine in place of racemic alanine; the amount of L-(or D-)-alanine used was 2.3 g (0.025 mol). The procedures used in the chromatographic separation and in the isolation of the isomers were those described above.

The results of the elemental analyses of the isolated compounds will be shown below.

Formation Ratios. The formation ratios were compared among the *bis*(L-aspartato)alaninato complex species and actually determined spectrophotometrically using the ε_{max} value of the first absorption band and the $\Delta\varepsilon$ value at the main CD peak in the same absorption band region. However, in the determination we assumed that the Λ and Δ isomers of a complex have the same ε_{max} and $|\Delta\varepsilon|$ values, because only the Λ or Δ isomer could be obtained as a crystal from each of the fractions.

Measurements. The electronic absorption spectra were measured with a Hitachi Perkin-Elmer Model 139 UV-VIS spectrophotometer. The circular dichroism spectra were recorded on a JASCO Model ORD/UV-5 spectropolarimeter. The proton magnetic resonance spectra were recorded on a JEOL Model C-60H spectrometer (60 MHz) at about 25°C, using deuterium oxide containing an equivalent mole of Na_2CO_3 as the solvent. The values of the chemical shifts were measured in relation to sodium 3-(trimethylsilyl)-1-propanesulfonate (Na-TPS) used as an internal reference.

Results and Discussion

Characterization of the Complexes. Since the experiments on the isolation of the isomers of the desired complex were done using racemic (DL-), L-, and D-alanine separately, the isomers obtained from these experiments may conveniently be labelled as (DL), (L), and (D); for example, a compound obtained from the mer_1 fraction in the experiment using DL-alanine will be labelled mer_1 (DL).

The results of the elemental analyses and the numerical data on the absorption and CD spectra are summarized in Table 1. There is a lack of data for the fac_1-Λ because of an extremely poor formation of the species, while the lack of data for the mer_1-Λ(D) arises from a difficulty in crystallization. The geometrical form (*mer* or *fac*) could easily be determined on the basis of the absorption spectral data.[6,7] The absolute configuration (Λ or Δ) was also assigned on the basis of the sign of the main CD peak of each isomer.[8,9] The compounds obtained from the mer_1, mer_2, and fac_1 fractions were identified as the Λ isomers, while the compound obtained from the fac_2 fraction was identified as the Δ isomer. The CD and absorption spectra for the mer_2-Λ and fac_2-Δ are shown in Figs. 1 and 2.

a) Calcd; b) 10^{13} sec^{-1}

The stereochemistry of a *tris*-type complex containing two different aminoacidato ligands provides the existence of three geometrical isomers belonging to the *mer* form and one of the *fac* form (Fig. 3), but in the present work one *fac* isomer and two *mer* isomers labelled as mer_1 and mer_2, were obtained. The PMR spectra for the fac_2-Λ(L), mer_1-Λ(L), and mer_2-Λ(L) are shown in Fig. 4. The two *mer* isomers showed different spectra in the methylene proton resonance of the chelated aspartates.

a) mixed sample of mer_2-Λ-(L) and mer_2-Λ-(D),
b) crude sample of mer_2-Λ-(DL)
c) pure sample of mer_2-Λ-(DL),
d) crude sample of fac_2-Λ-(DL)
e) pure sample of fac_2-Λ-(DL),

This fact suggests that the isomers have different geometries.

The methyl proton resonance spectra of the chelated alanine are shown in Fig. 5. The spectrum for the mer_2-Λ(L) gives a single doublet at 1.55 ppm, while the spectrum for the mer_2-Λ(D) gives a similar doublet at 1.57 ppm. When a mixed sample of the two mer_2 compounds in the same amounts was measured, the spectrum revealed two closed doublets with a slight separation of *ca.* 1.5 Hz. On the other hand, when a compound from the mer_2-Λ(DL) fraction, which had been taken in the course of the recrystallization procedure, was measured, the spectrum showed a pattern similar to that of the mixed sample. The complex on which the recrystallization procedure had been completed showed only one doublet, at 1.54 ppm. Similarly, the fac_2-Λ(L) and fac_2-Λ(D) compounds showed a single doublet due to the methyl protons at 1.43 and 1.48 ppm respectively. The fac_2-Λ(DL) compound gave a doublet at 1.48 ppm, whereas a crude material of the same compound gave two pairs of doublets with a separation of *ca.* 2.5 cps. These results indicate that the crude material of an isomer, in an experiment using racemic alanine, includes both D- and L-alanine as ligands, and that the completely recrystallized material includes either L- or D-alanine as a ligand.

In order to identify the active form (D or L) of the coordinated alanine in the completely recrystallized material obtained by the use of racemic alanine, the $\Lambda\varepsilon$ value of the isomer was compared with that of the corresponding isomer obtained by the use of L- or D-alanine. As may be seen in Table 1, the value of the mer_2-Λ(DL) is almost identical with that of the mer_2-Λ(L) and considerably different from that of the mer_2-Λ(D) isomer. When a similar comparison is made among the fac_2-isomers, a better agreement of the value of the (DL) isomer is found in that of the (D) isomer. These comparisons indicate that the mer_2-Λ(DL) isomer contains L-alanine and that the fac_2-Λ(DL) isomer contains D-alanine. Additional support is obtained from the previously-mentioned PMR data. Since the CD data for the mer_1-Λ(DL) and mer_1-Λ(L) isomers are almost identical, the former perhaps contains L-alanine.

Stereoselectivity. The percent compositions of the *mer* and *fac* isomers, and also the percent compositions of the Λ (or Δ) isomer predominantly formed for each geometrical isomer, are given in Tables 2 and 3. Simi-

Table 2. Percent compositions of the *mer* and *fac* isomers

Amino acids used	Isomers		
	mer (%)	(mer_1/mer_2)	*fac* (%)
DL-ala	36	(1/3)	64
L-ala	34	(1/3)	66
D-ala	39	(2/7)	61
gly[3]	42	—	58

Table 3. Percent compositions of Λ or Λ isomers

Amino acid used	Isomers		
	mer_1-Λ (%)	mer_2-Λ (%)	fac_2-Λ (%)
DL-ala	78	76	95
L-ala	76	78	97
D-ala	73	78	93
gly[3]	73		95

lar data for the glycinato(L-aspartato) complex[3] are also cited in the Tables for the sake of comparison. The figures themselves are not very exact because of the assumed values of ε and $\Delta\varepsilon$ for non-isolated isomers, that is, since the vicinal contribution of the optically active ligands are disregarded, but they do seem to be useful for the estimation of the stereoselectivity. The composition of the *fac*$_2$-Δ (DL, D, or L) isomers was estimated to be *ca.* 95%, and a marked stereoselectivity was found in the Δ configuration. The compositions of all the *mer*-isomers ranged from 70 to 80%, and an appreciable selectivity was found in the Λ configuration. These results are similar to those for the *bis*(L-aspartato)glycinato complex (Table 3). The compositions of the *mer* and *fac* isomers could be estimated to be around 35 and 65%, not very different from those in the corresponding glycinato complex (Table 2). From this fact, we can consider that the orientation of the methyl group of the coordinated alanine scarcely affects the stereoselectivity in the complex concerned, and that the β-carboxylate groups of the coordinated L-aspartates affect the selectivity. In a previous paper,[3] we have assumed an enhanced stability through hydrogen-bonding between the β-carboxylate group in the L-aspartato ligand and the amino group in the adjacent ligand. In the present case, this assumption also gives an explanation of the stereoselectivity.

The fact that the *mer*$_2$-Λ(DL) and *fac*$_2$-Δ(DL) contain L- and D-alanine respectively may be caused by the difference in solubility between the diastereoisomers, rather than by the preferential coordination of one of the active forms of alanine. This is confirmed by the above-mentioned PMR study.

Stereochemical Studies of Metal Chelates. VI. The Separation and Stereochemistry of Isomers of Dichloro((3*S*, 8*S*)-dimethyltriethylenetetramine)cobalt(III) Perchlorate

Masahiko SABURI and Sadao YOSHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 10, 1971)

The *cis*-α and *cis*-β isomers of dichlorocobalt(III) complexes with (3*S*, 8*S*)-dimethyltriethylenetetramine were isolated. These isomers were stereospecifically formed in the *Λ* and *Δ* absolute configurations respectively. The *cis*-β isomerh as the *Δ*-β(*RS*) geometry, in which the configurations with respect to the coordinated secondary nitrogen centersof tetramine differ from one another. The difference between the *Δ*-β(*RS*) and *Δ*-β(*RR*) (and *Λ*-β(*SS*)) forms was noticed in the circular dichroism curves in the first absorption band region.

In a study of the diacidocobalt(III) complexes of triethylenetetramine (trien),[1] Basolo first pointed out the possibility of three geometrical isomers, *i.e.*, *cis*-α, *cis*-β, and *trans* (*c.f.* Fig. 1). These were isolated and resolved into optically-active antipodes by Sargeson and Searle for the first time.[2,3] The exact geometries of trien in the α and β configurations have recently been shown by X-ray diffraction studies.[4,5] Furthermore, it was suggested that the second *cis*-β form exists as a product of the Hg^{2+}-promoted acid hydrolysis reaction of the optically-active *trans*-$[Co(trien)Cl_2]^+$ ion.[6]

The difference between the two *cis*-β geometries arises from the combination of the configuration of the coordinated secondary nitrogen centers. The asymmetric character of the coordinated secondary nitrogen atom has been well established for some cobalt(III) com-

plexes.[7-12] The structures of the two isomers of *cis-β* geometry are shown in Fig. 2. They are illustrated for the enantiomer, in which the central chelate ring takes the λ[13] conformation. The absolute configurations of the coordinated secondary nitrogen centers are the same for one isomer, designated as Λ[13]-*cis*-β(*SS*)[14] in Fig. 2 and its enantiomorph (Δ-*cis*-β(*RR*)), and different for the other, Δ-*cis*-β(*RS*)[14] in Fig. 2 and its enantiomorph (Λ-*cis*-β(*SR*)[14]). The former geometry was, in fact, observed for some *cis-β* isomers of trien complexes.[5,15-17] On the other hand, the trien cobalt(III) complex with the latter geometry has not yet been isolated except for some β_2-amino acidato complexes.[18]

A detail discussion of the chelate ring conformation of the *β*-configuration was published recently.[19] It is interesting to note that the conformations of the outer-side chelate rings are the same (δ and δ) for the Δ-*cis*-β(*RS*) geometry, while they are different (δ and λ) for the Λ-*cis*-β(*SS*) geometry, as is indicated in Fig. 2. In a recent study of the minimization of the conformational potential energy, it was suggested[20] that the most stable structures for the Δ-β_2-(*RS*) and Λ-β_2(*SR*) isomers of the $[Co(trien)(S\text{-pro})]^{2+}$ ion are those in which the side arms of trien have the same conformation.

It has been well established by X-ray diffraction[21,22] and proton magnetic resonance[23] studies that the methyl group of propylenediamine adopts preferentially the equatorial position with respect to the diamine chelate ring. (2*S*,9*S*)-Dimethyltriethylenetetramine ((2*S*,9*S*)-dimetrien) and (3*S*,8*S*)-dimethyltriethylenetetramine ((3*S*,8*S*)-dimetrien) are optically-active derivatives of trien. The abbreviations and structures of trien derivatives used in the present study are summarized in Table 1. The absolute configuration of the asymmetric carbon atoms is the same *S* configuration for these tetramines, since all the asymmetric centers are derived from the *S*-alanine used as a starting material. If the substituted methyl groups prefer the equatorial orientation, the outer-side chelate rings should have the δ conformation. Accordingly, it was supposed that the *cis-β* isomer containing (2*S*,9*S*)- and (3*S*,8*S*)-dimetrien belongs to the Δ-*cis*-β(*RS*) geometry (shown in Fig. 2), since both the outer-side chelate rings for this structure are expected to have the δ conformation, as has been mentioned previously.

Table 1. Abbreviation and structure of ligands

Abbreviation	Structure
(2*S*,9*S*)-dimetrien	
(3*S*,8*S*)-dimetrien	5(*R*)-metrien	(5*S*,6*S*)-dimetrien	(*R*)-ECE	
Asperger and Liu[24] isolated three geometrical isomers of dichlorocobalt(III) complexes coordinated with (2*S*,9*S*)-dimetrien, *i.e.*, *cis-α*, *cis-β*, and *trans*. It was noticed by these authors[24] that the *cis-α* and *cis-β* isomers have stereospecifically the Λ- and Δ-absolute configurations respectively. Although the Δ-*cis-β* isomer was isolated, the detailed structure of this complex has not yet been clarified. It was supposed that the *cis-α* and *cis-β* isomers of dichlorocobalt(III) complexes with (3*S*,8*S*)-dimetrien, if obtained, should have the Λ and Δ-configurations respectively, as well as the (2*S*,9*S*)-dimetrien complexes. This is based on the expectation that, for both ligands, the outer-side chelate rings are fixed in the δ conformation due to the substituted methyl groups, though their positions are different in the two ligands. We have succeeded in the isolation of Λ-*cis-α* and Δ-*cis*-β-$[Co((3S,8S)\text{-dimetrien})Cl_2]ClO_4$ and will report our results in the present paper.

Experimental

(2S,9S)-Dimethyltriethylenetetramine Tetrahydrochloride. This was prepared according to the method described by Asperger and Liu.[24]

(3S,8S)-Dimethyltriethylenetetramine Tetrahydrochloride. A tetraamide (11.5 g) obtained by the reaction of *S*-alanine amide with oxalyl chloride (described earlier[25]) was stirred into a suspension of lithium aluminum hydride (13.3 g) in anhydrous tetrahydrofuran (300 m*l*), after which the mixture was stirred and heated under reflux for 24 hr. After cooling to room temperature, 25 m*l* of water diluted with 50 m*l* of tetrahydrofuran was vigorously stirred, drop by drop, into the reaction mixture, after which the mixture was stirred for a further 30 min. The resultant slurry was filtered off and washed with tetrahydrofuran (100 m*l*). The residue was extracted with boiling tetrahydrofuran (200 m*l*) under reflux for 2 hr, filtered off, and washed as above. The filtrates and washing were combined, and the tetrahydrofuran was removed under reduced pressure. To the remaining liquid we added 20 m*l* of concentrated hydrochloric acid, and then ethanol was gradually added while hot until the mixture became turbid. After the solution has been cooled to room temperature overnight, the white crystals which separated were collected, washed with ethanol and ether, and dried under vacuum. Yield, 7.0 g.

Trans-*Dichloro((3S,8S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate.* The preparation of this compound was described previously.[26]

Δ-cis-*α*-*Dichloro((3S,8S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate.* The filtrate from which the *trans*-isomer has been removed as above was again cooled to 5°C, and the small amount of green crystals (*trans*-isomer) which precipitated was filtered off. To the filtrate we added 2 more m*l* of 60% perchloric acid, and the solution was stored at 5°C for 2 hr after scratching the side of the vessel with a glass rod. The violet crystals which separated was collected, washed with methanol and acetone, and air-dried. Yield, 0.1 g. *Anal.* Calcd for $[Co(C_8H_{22}N_4)Cl_2]ClO_4$: C, 23.81; H, 5.50; N, 13.88. Found: C, 23.20; H, 5.84; N, 13.51.

Δ-cis-*β*-*Dichloro((3S,8S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate.* The filtrate from the separation of the *Δ*-*cis*-*α*-isomer was left to stand at room temperature for one or two days. The reddish-purple crystals which separated were filtered off, washed with ethanol and acetone, and air-dried. Yield, 0.3 g. A second crop could be obtained by letting the filtrate stand for one or two more days. Yields, 0.2 g. *Anal.* Calcd for $[Co(C_8H_{22}N_4)Cl_2]ClO_4$: C, 23.81; H, 5.50; N, 13.88. Found: C, 23.72; H, 5.63; N, 13.84.

Δ-cis-*α*-*Dinitro((2S,9S)-dimethyltriethylenetetramine)cobalt(III) Chloride.* To a solution containing (2S,9S)-dimetrien·4HCl (3.40 g) and $LiOH \cdot H_2O$ (1.25 g) in 50 m*l* of water, we added $CoCl_2 \cdot 6H_2O$ (2.38 g) and then the solution was cooled in an ice bath. After $NaNO_2$ (1.47 g) had been added, the resultant solution was aerated with carbon dioxide-free air in an ice bath for 1 hr and then for 4 more hr at room temperature. The precipitated impurity was filtered off and washed with a small volume of water. The filtrate and washings were combined and evaporated on a steam bath to a volume of 15 m*l* and then cooled in an ice bath overnight. The yellow-brown crystals which separated were filtered off and washed with a small volume of cold water and ethanol. Yield, 1.5 g. The combined filtrate and washings were further evaporated on a steam bath to about 7 m*l* and then cooled as above. The crystals were filtered off and washed with cold water and ethanol. Yield, 1.0 g. The crude products, which were contaminated with a black impurity, were dissolved in a minimum volume of warm water, filtered, and cooled to room temperature. After the solution had stood overnight, the yellow-brown crystals were filtered off, washed with a small volume of cold water and ethanol, and air-dried. *Anal.* Calcd for $[Co(C_8H_{22}N_4)(NO_2)_2]Cl$: C, 26.64; H, 6.15; N, 23.30. Found: C, 26.52; H, 6.20; N, 23.41.

Δ-cis-α-Dichloro((2S,9S)-dimethyltriethylenetetramine)cobalt(III) Chloride Monohydrate. *Δ-cis-α*-$[Co((2S,9S)$-dimetrien$)(NO_2)_2]Cl$ (1.0 g) was dissolved in 30 m*l* of hydrochloric acid (1:1), and the resultant solution was evaporated on a steam bath almost to dryness. The residue was treated with 10 m*l* of methanol with gentle boiling, and the crystallized product was filtered off, washed with cold methanol and acetone, and air-dried. Yield, 0.7 g. *Anal.* Calcd for $[Co(C_8H_{22}N_4)Cl_2]Cl \cdot H_2O$: C, 26.88; H, 6.76; N, 15.67. Found: C, 26.60; H, 6.60; N, 15.97.

Δ-cis-β-Dichloro((2S,9S)-dimethyltriethylenetetramine)cobalt(III) Perchlorate. A mixture of *Δ-cis-α*-$[Co((2S,9S)$-dimetrien$)]Cl_2 \cdot H_2O$ (0.51 g) and Li_2CO_3 (0.15 g) in 5 m*l* of water was heated on a steam bath for 30 min, cooled to room temperature, and filtered to remove the excess Li_2CO_3. To a solution of *Δ-β*-$[Co((2S,9S)$-dimetrien$)CO_3]^+$ prepared *in situ.* as above, we added 5 N HCl (2 m*l*); the resultant solution was evaporated under a current of air on the surface at room temperarure. When the volume of solution was reduced to 2 m*l*, 60% perchloric acid (1 m*l*) was added. The green crystals of *trans*-$[Co((2S,9S)$-dimetrien$)Cl_2]ClO_4$ which separated were removed whenever necessary, and the filtrate was allowed to stand at room temperature. The reddish-purple crystals which separated were collected, washed with methanol, and air-dried.

Measurements. The visible absorption spectra were measured with a Shimadzu MPS-50L spectrophotometer. The circular dichroism spectra were measured with a JASCO J-20 automatic spectropolarimeter. The spectra of the *cis-α* isomers and of the *cis-β* isomers were measured in 5 N HCl and concentrated HCl solutions to avoid aquation of the complexes.

Results and Discussion

Yoshikawa, Sekihara, and Goto isolated a green *trans* isomer of the dichlorocobalt(III) complex with (3*S*,8*S*)-dimetrien.[25] In spite of the poor agreement between the calculated and found values, especially for

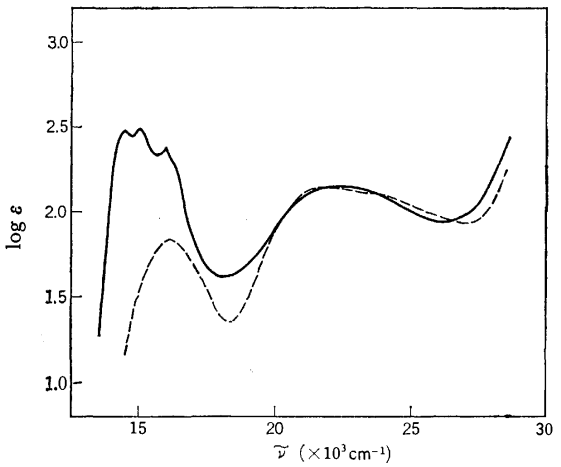

Fig. 3. Absorption Spectra of *trans*-$[Co((3S,8S)$-dimetrien$)Cl_2]_2CoCl_4$ in concentrated hydrochloric acid (———) and *trans*-$[Co((3S,8S)$-dimetrien$)Cl_2]ClO_4$ in methanol (--------).

the hydrogen proportion (Found 5.5%; Calcd 6.5%), the constitution of this compound was considered to be $[Co(C_8H_{22}N_4)Cl_2]Cl\cdot HCl\cdot 1.5\ H_2O$. However, it has now been found that the exact constitution of this complex is $[Co(C_8H_{22}N_4)Cl_2]_2(CoCl_4)$. The calculated and found values for this constitution are as follows; Calcd: C, 23.8; H, 5.5; N, 13.9; Cl, 35.1. Found: C, 24.0; H, 5.5; N, 13.9; Cl, 35.2.

The absorption spectrum of the above *trans* complex, measured in concentrated hydrochloric acid, is shown in Fig. 3, where the ε value is evaluated per mole of the Co(III) complex. The complicated strong absorption bands found in the region of 14000—17000 cm^{-1} in a concentrated HCl solution are characteristic of the tetrachlorocobaltate(II) anion.[27] The diffusion reflectance spectrum shows similar peaks in this region, indicating that the $CoCl_4^{2-}$ ion is present in the solid state as the counter ion of this dichlorocobalt(III) complex. This complex anion was also found as the counter ion of *trans*-dichlorocobalt(III) complexes containing *N*-alkyl ethylenediamines.[28] The $CoCl_4^{2-}$ ion appears to be decomposed immediately after the complex is dissolved in methanol, and so it was overlooked in the former study.[25]

We perceived some difficulties in the course of isolating the pure crystalline product of *Λ-cis*-α-[Co((2*S*, 9*S*)-dimetrien)Cl_2]Cl by the method of Asperger and Liu,[24] which can be regarded as an ordinary procedure for preparing the dichlorocobalt(III) complex. This was probably the result of the coexistence of the $CoCl_4^{2-}$ ion, which disturbs the crystallization of the desired products.

It was effective to use anions other than the chloride ion in order to isolate the pure crystalline products of the *cis*-α and *cis*-β isomers of the dichloro complex with (3*S*,8*S*)-dimetrien. We succeeded in isolating the *cis*-α and *cis*-β isomers by the use of perchlorate ion along with the *trans* isomer.

On the addition of 60% perchloric acid to a concentrated solution which seemed to contain three possible isomers of the [Co((3*S*,8*S*)-dimetrien)Cl_2]$^+$ ion, green crystals of the *trans*-[Co((3*S*,8*S*)-dimetrien)Cl_2]ClO_4 immediately crystallized out.[26] The absorption spectrum of this isomer (given in Fig. 3) resembles that of the *trans*-[Co((3*S*,8*S*)-dimetrien)Cl_2]$_2$($CoCl_4$) except for the region of the absorption due to the $CoCl_4^{2-}$ complex anion. The CD spectra of the complexes of such a type have been discussed previously.[25,29]

After the *trans* isomer has been completely removed, a small amount of blue-violet crystals was separated from the filtrate by the addition of more perchloric acid. The visible absorption and CD spectra of this complex are shown in Fig. 4. The spectral data are summarized in Table 2. The absorption spectrum shows a shoulder at a lower wave-number side of the first absorption band. The same feature in the first absorption band was also observed for the *cis*-α-[Co(trien)Cl_2]$^+$ ion, but it was not detected for the *cis*-β isomer of the trien complex. This suggests that the blue-violet isomer has the *cis*-α configuration. Further, the CD spectrum shown in Fig. 4 apparently resembles that of $(+)_D$-*cis*-α [Co(trien)Cl_2]ClO_4 shown by Sargeson and Searle,[2] which was assigned the *Λ* configuration. Therefore, it was determined that the blue-violet isomer of [Co((3*S*,8*S*)-dimetrien)Cl_2]ClO_4 takes, stereospecifically, the *Λ-cis*-α configuration.

The dichlorocobalt(III) complex of (2*S*,9*S*)-dimetrien, which has been shown to adopt preferentially the *Λ-cis*-α configuration, was also prepared. As has been mentioned previously, it was slightly difficult to

obtain the pure crystalline product of this complex by the method of Asperger and Liu.[24] Hence, we prepared it through a reaction of the corresponding dinitro complex with hydrochloric acid. The product thus obtained showed visible and CD spectra identical with those of the complex obtained by the method of Asperger and Liu,[24] shown in Fig. 4. Apparently, the first absorption band has a shoulder on the lower wave number side. This spectral feature may be regarded as a characteristics of the *cis*-α isomer of the dichlorocobalt(III) complex with tetramines. The CD curve is also similar to those of the (+)$_D$-*cis*-α-[Co(trien)Cl_2]ClO_4 and of the blue-violet isomer of the (3*S*,8*S*)-dimetrien complex.

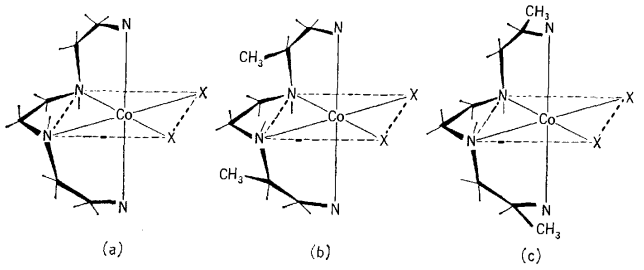

Fig. 5. Structures of *Λ*-α configurations; (a) trien, (b) (3*S*,8*S*)-dimetrien, and (c) (2*S*,9*S*)-dimetrien.

According to a recent X-ray analysis study,[4] the structure of the *Λ*-*cis*-α trien complex has been determined to be as shown in Fig. 5(a), where both the outer-side chelate rings adopt the *δ* conformation. Since the preferred conformation of the outer chelate rings of the (3*S*,8*S*)- and (2*S*,9*S*)-dimetrien is the *δ*-gauche form, as has been mentioned previously, it is reasonable that the *cis*-α isomers of these complexes give rise to the *Λ* configuration. Their probable structures are illustrated in Fig. 5, (b) and (c) respectively. For these configurations, the methyl groups are all situated in the equatorial orientations. The *Λ* isomer, in which the methyl groups should adopt the axial orientations, is energetically unstable as compared with the *Λ* isomer. This is a reason why the former isomer could not be obtained in this study.

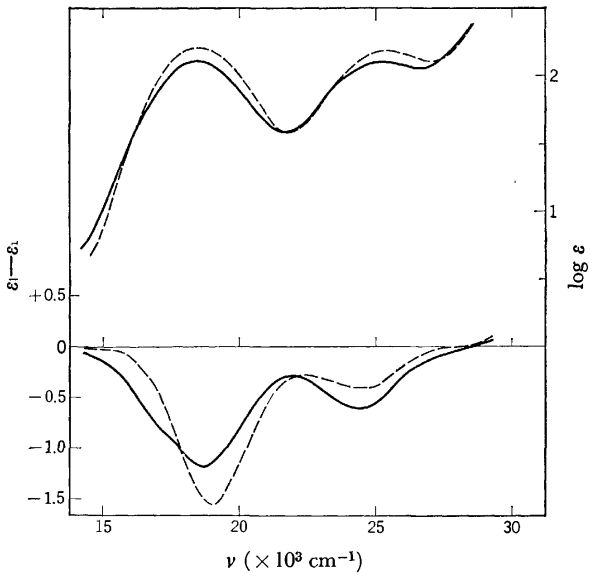

Fig. 6. Absorption and CD spectra of *Λ*-*β* (*RS*) isomers; (3*S*,8*S*)-dimetrien (——) and (2*S*,9*S*)-dimetrien (- - - -).

The third isomer of [Co((3*S*,8*S*)-dimetrien)Cl_2]ClO_4 was obtained as reddish-pink precipitates, which are separated out by letting the filtrate from which the *cis*-α isomer has been removed stand for two or three days. The visible absorption and CD spectra of this compound are shown in Fig. 6. No shoulder of the first absorption band was detected for the present complex, suggesting that it takes the *cis*-*β* configuration. The CD curve of this isomer shows only one negative peak in the first absorption band region. The *Λ*-*cis*-*β*-[Co((2*S*,9*S*)-dimetrien)Cl_2]$^+$ ion, which was first obtained by Asperger and Liu,[24] was prepared by a different method through the *Λ*-*cis*-α isomer in the present study. This complex shows the absorption and CD curves given in Fig. 6. They are apparently similar to the corresponding curves of the reddish-pink isomer of the (3*S*,8*S*)-dimetrien complex. Thus, it was determined that the reddish-pink isomer takes, stereospecifically, the same absolute configuration as the *cis*-*β* isomer of the (2*S*,9*S*)-dimetrien complex, *i.e.*, the *Λ*-*cis*-*β* configuration.

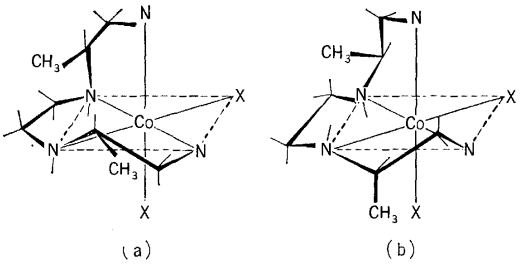

Fig. 7. Structures of *Λ*-*β* isomers of (3*S*,8*S*)-dimetrien; (a) *Λ*-*β*(*RS*) and (b) *Λ*-*β*(*RR*).

The probable structures for the *Λ*-*cis*-*β* isomer of (3*S*,8*S*)-dimetrien are illustrated in Fig. 7(a) and (b). For the *Λ*-*cis*-*β*(*RS*)[30] geometry (a), both the methyl groups are equatorially oriented, and the outer chelate rings take the *δ* conformation. On the other hand, one of the methyl groups, which is present in the "in-plane" chelate ring, having the *λ* conformation, takes the axial orientation for the *Λ*-*cis*-*β*(*RR*) geometry, though the other is in the equatorial position. Because of the difference in methyl orientation, the former geometry is more probable than the latter. The difference in axial and equatorial methyl groups was estimated to be 2.0 kcal/mole for the propylenediamine chelate ring.[31] It is reasonable to consider that the above estimation is applicable to the (2*S*,9*S*)-dimetrien complex. It was demonstrated by the X-ray diffraction method for the dinitro complex that the *Λ*-*cis*-*β*

30) The *RS* representation of the absolute configuration of the coordinated nitrogen centers is complicated in the substituted triens by the presence of methyl groups. For example, (3*S*, 8*S*)-dimetrien and trien complexes have the opposite configurations in the *Λ*-α form; (*SS*) for the former and (*RR*) for the latter. Therefore, the absolute configuration of the coordmated secondary nitrogen centers is represented by *R* and *S*, neglecting, for simplicity, the substituted methyl groups in this paper.

31) A. M. Sargeson, *Transition Metal Chem.*, **3**, 303 (1966).

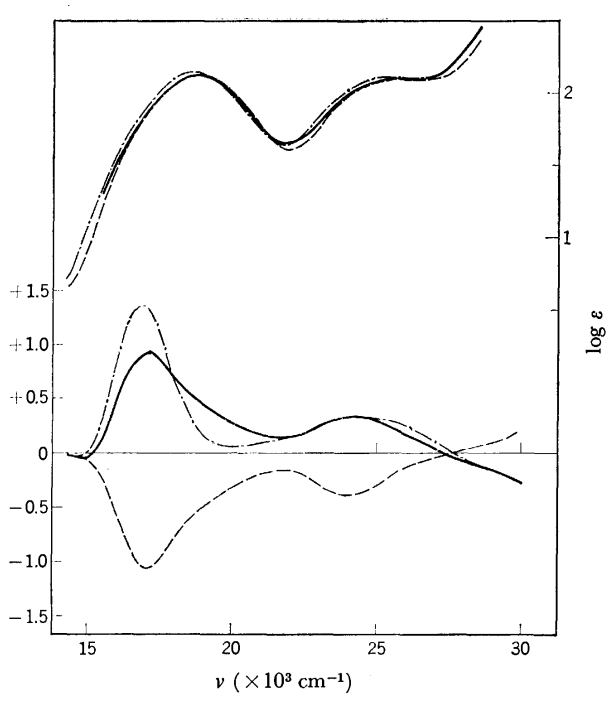

Fig. 8. Absorption and CD spectra for *Λ*-*β*(*SS*) and *Λ*-*β*(*RR*) geometries; (5*R*)-metrien (*Λ*) (——), (5*S*,6*S*)-dimetrien (*Λ*) (– – –), and (*R*)-ECE (*Λ*) (–·–·–·).

isomer of (3*S*,8*S*)-dimetrien possesses the *Λ*-*cis*-*β*(*RS*) geometry, as has been expected.[32]

It seems likely that CD curves are affected by the structural differences, *i.e.*, the absolute configuration of the coordinated secondary nitrogen center and the conformation of each chelate ring. The CD curves of the *Λ*-*cis*-*β*(*SS*) or *Δ*-*cis*-*β*(*RR*)-dichloro complexes of trien derivatives with equatorially-oriented substituents at the central diamine linkage were examined. The structures of these complexes had previously been established as indicated.[33] Their CD and absorption curves are shown in Fig. 8.

There was no definite difference in the absorption spectra of the two types of *cis*-*β* isomer. The *Δ*-*β*(*RS*) isomer exhibited its first absorption maxima at about 18500 cm^{-1}, while the *Λ*-*β*(*SS*) and *Δ*-*β*(*RR*) isomers exhibited theirs at about 18600—18800 cm^{-1}. This suggests that the difference in ligand field due to the structural changes is negligibly small for both the geometries.

On the contrary, an obvious difference in their CD curves could be noted between the *Δ*-*β*(*RS*) and *Δ*-*β*(*RR*) (or *Λ*-*β*(*SS*)) forms in the first absorption band region. The *Δ*-*β*(*RS*) isomers of (3*S*,8*S*)- and (2*S*,9*S*)-dimetrien complexes showed dominant negative CD maxima at about 19000 cm^{-1}. The *Δ*-*β*(*RR*) isomer of (5*S*,6*S*)-dimetrien showed a negative CD peak at 17000 cm^{-1}. The *Λ*-*β*(*SS*) isomers of (5*R*)-metrien and (*R*)-ECE also exhibited the corresponding positive CD peaks at about 17000 cm^{-1}. It was clearly observed that the dominant CD peak for the *Δ*-*β*(*RS*) forms is shifted by 2000 cm^{-1} to the higher wavenumber side than those for the *Δ*-*β*(*RR*) and *Λ*-*β*(*SS*) forms. The observed shift of the CD maxima in the first absorption band region may be useful for distinguishing the geometries of *cis*-*β* dichlorocobalt(III) complexes with any trien derivatives.

Chemical Studies of Minerals Containing Rarer Elements from the Far East District. LXV.[1] Pollucite from Nagatare, Fukuoka Prefecture, Japan

Kin-ichi SAKURAI, Akira KATO, Noriyuki KUWANO,* and Kozo NAGASHIMA**

Department of Geology, National Science Museum, Ueno Park, Tokyo
**Institute of Metallurgy, Faculty of Technology, Kyushu University, Fukuoka*
***Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo*

(Received September 29, 1971)

The chemical analysis of pollucite found in a granite pegmatite at Nagatare, Fukuoka Prefecture, gave SiO_2 46.03, Al_2O_3 17.76, Fe_2O_3 0.02, MnO 0.01, CaO 0.03, Li_2O 0.16, Na_2O 2.08, K_2O 1.81, Rb_2O 0.61, Cs_2O 28.88, and H_2O 2.74; total 100.13%; recalculated as $(Cs,Rb)_{0.573}(Na,K,Li,Mn,Ca)_{0.316}(Al,Fe)_{0.943}Si_{2.071}O_6 \cdot 0.411\ H_2O$ as O=6, thus satisfying the crystallochemical formula advocated by Beger. X-ray single crystal and powder studies have shown it to be cubic, the space group is Ia3d; $a_0=13.674\pm0.005$ Å. It is optically isotropic or very faintly birefringent, with $n=1.520\pm0.002$.

Granite pegmatites exposed at Nagatare, Fukuoka Prefecture, include some rare alkali-bearing minerals, such as lepidolite,[2] petalite,[3] and amblygonite-montebrasite-series minearals,[4] all except the first one being unique occurrences in Japan.

A white mass with a rugged, weathered surface collected by the third author from the dump derived from one of the pegmatites turned out to be the first pollucite in Japan, as has previously been reported.[5] The present paper will report the results of its X-ray, chemical, and optical studies.

Description of the Studied Specimen

The analyzed specimen is a part of a white mass more than 10 cm across and 500 g in weight. It is white in color and semitransluscent, with a vitreous luster. It has no cleavage, and the hardness is 5½—6 by Mohs' scale.

The associated minerals found in the mass include pale blue albite, and light and deep purple-colored lepidolites and petalite. Besides them, there are minute soft, white veinlets composed of earthy hydromica (?) with quartz. Under a microscope, pollucite is colorless and isotropic between crossed Nicols, except for a few grains which have a faint birefringence. The refractive index, as measured by the immersion method, is 1.520 ±0.002. The birefringence could not be masured by that method, but it is less than 0.002.

X-ray Studies

We used the X-ray single-crystal and powder methods to check the space group and the unit-cell constant. In its precession photographs of zero, first, and second layers, there was no diffraction spectrum violating the extinction rule of Ia3d. The X-ray powder data obtained by the diffractometer method are given in Table 1. The unit-cell constant calculated from them is 13.674± 0.005 Å, well coincident with the known value.[6]

Chemical Analysis

The chemical analysis was carried out adopting the following procedures: Cs_2O, Rb_2O, and Li_2O——atomic absorption analysis; Na_2O, K_2O——flame photometry; SiO_2, Al_2O_3, CaO, H_2O——gravimetry; Fe_2O_3, MnO——spectrophotometry. The results are shown in Table 2. The empirical formula based on O=6 is $(Cs_{0.554}Rb_{0.018})_{0.572}(Na_{0.182}K_{0.104}Li_{0.029}Mn_{0.003}Ca_{0.001})_{0.316}(Al_{0.942}Fe_{0.001})_{0.943}Si_{2.071}O_6 \cdot 0.411\ H_2O$, well satisfying the ideal formula. The adoption of the crystallochemical formula proposed by Beger,[6] $Cs_xNa_yAl_{x+y}Si_{48-x+y}O_{96} \cdot (16-x)H_2O$, where $2y \geq 16-x \geq y$, gives the following results:

empirical formula: $(Cs, Rb)_{9.150}(Na, K, Li, Mn, Ca)_{5.061}Al_{15.080}Si_{33.133}O_{96} \cdot 6.578\ H_2O$

crystallochemical formula: $(Cs, Rb)_{9.150}(Na, K, Li, Mn, Ca)_{5.061}Al_{14.211}Si_{33.789}O_{96} \cdot 6.850\ H_2O$

There is a minor excess of tetrahedrally-co-ordinated ions and a deficiency of water, both being within the limits of analytical error.

Studies on the Isomerization of 2,4-Dinitrophenylhydrazones of Some Aliphatic α-Keto Acids and the Preparation of Their Geometrical Isomers

Hirohiko KATSUKI, Chizuko TANEGASHIMA,* Masanobu TOKUSHIGE, and Shozo TANAKA**
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 22, 1971)

Cis-trans isomerization of 2,4-dinitrophenylhydrazones of some aliphatic α-keto acids takes place in water and some organic solvents by the catalysis of hydrogen ions. *Trans* isomer is more stable than *cis* isomer for lower keto acids and the reverse is the case for higher keto acids. The fraction of *cis* isomer in isomeric mixture at equilibrium in organic solvents such as ethyl acetate and ethyl ether, saturated with 6N hydrochloric acid, was larger than that in aqueous solution. The two isomers could be separated by means of the difference in their solubility characteristics in 1N sodium carbonate except for some keto acids with tertiary or quaternary β-carbon. Melting points of some pairs of the hydrazone isomers were found to be the same when measured by the usual method. This is due to the isomerization of one isomer to the other which takes place during the course of heating.

For the separation, identification and determination of carbonyl compounds, the 2,4-dinitrophenylhydrazine method is most often used in the fields of organic and biological chemistry. Studies have been carried out on physical and chemical properties of the 2,4-dinitrophenylhydrazones. However, only a limited number of studies has been reported on their geometrical isomers and isomerization.

Separation and assignment of *cis* and *trans* isomers of the hydrazones of the following α-keto acids and the related compounds were reported after the discovery of double spots on paper chromatograms of 2,4-dinitrophenylhydrazones of some α-keto acids:[1,2] pyruvic acid,[3,4] α-oxo-β,β-dimethyl-γ-butyrolactone,[5] and phenylglyoxylic acid.[6]

Although separation of the isomers has been conveniently performed by the use of paper or thin layer chromatography, preparation of a pure sample of the isomer or its identification was difficult due to the isomerization of the hydrazone during its development or elution in chromatography.[4] The first large scale separation of pure isomers has become feasible by the combination of salting-out method[3,6] with the isomerization treatment. Studies on the spectrographic properties and the isomerization with the pure hydrazone isomers thus prepared resulted in the detection[7,8] and

determination[9,10] of some aliphatic α-keto acids which are important intermediates in metabolism, irrespective of the presence of geometrical isomers in their hydrazones.

This paper deals with the isomerization of 2,4-dinitrophenylhydrazone isomers of some aliphatic α-keto acids and separation of both isomers.

Keto acids used are classified into two groups, **A**(I-VI) and **B**(VII-IX). The hydrazones of keto acids in group **A** gave *cis* and *trans* isomers. *Cis* and *trans* hydrazones are represented by notations *c* and *t*, respectively, *e.g.* I*c*, I*t*. On the other hand, the presence of the two isomers of the hydrazones in group **B** could not be demonstrated and gave two different forms by recrystallization from different solvents. The hydrazones of VII, for example, are represented by VII*x* and VII*y*, respectively.

R-CO-COOH

Group **A**

	I	II	III	IV
R:	H-,	CH_3-,	CH_3CH_2-,	$CH_3CH_2CH_2$-,

	V	VI
R:	$CH_3(CH_2)_2CH_2$-,	$(CH_3)_2CHCH_2$-

Group **B**

	VII	VIII	IX
R:	$(CH_3)_2CH$-,	$CH_3CH_2(CH_3)CH$-,	$(CH_3)_3C$-

The assignment of the geometrical isomers based on their infrared and visible spectra and other properties was described in the preceeding paper.[11]

Experimental

Preparation of Keto Acids. Most of the keto acids used were synthesized by the condensation of fatty acid esters with diethyl oxalate, followed by hydrolysis with hydrochloric acid.[12] I, II, and IX were prepared by the methods of Radin and Metzler,[13] Haward and Fraser,[14] and Glucksmann,[15] respectively.

Preparation of the Isomers and Forms of the Hydrazones. The crude hydrazone of keto acid in group **A** obtained from aqueous solution by the usual method was first mixed with sufficient 1 N sodium carbonate to dissolve the *trans* isomer. After stirring the mixture for about half an hour, the insoluble hydrazone was filtered off. The filtrate was cooled in an ice bath. Hydrochloric acid (1 N) was then added dropwise until the solution became slightly acidic. After standing it for a few minutes, the precipitate was filtered and washed several times with 0.2 N hydrochloric acid, then with cold water. When necessary, especially in the case of higher keto acid hydrazones, the separation procedure with sodium carbonate was repeated. The hydrazone thus obtained was dried in a vacuum desiccator. It was recrystallized from acetone-benzene (1:3). Paper chromatography was effectively used to confirm complete purification.

The *cis* isomer of the hydrazone of keto acid in group **A** was prepared by utilizing the isomerization treatment as follows: The crude hydrazone was dissolved in ethyl acetate saturated with 6 N hydrochloric acid. After being left to stand at 10°C for 1 hr, 1 N sodium carbonate was added and the mixture was agitated vigorously in a separatory funnel. The resulting insoluble sodium salt of the *cis* isomer was collected by filtration. The treatment of the filtrate with sodium carbonate was repeated until insoluble hydrazone no longer separated out. When necessary, the sodium salt of *cis* hydrazone was dissolved in water and the salting-out separation was repeated. The sodium salt of *cis* hydrazone was washed with 1 N sodium carbonate until the color of the filtrate became yellow and it was then suspended in a small amount of cold water. Hydrochloric acid (1 N) was added until the mixture became slightly acidic. The free *cis* hydrazone produced was immediately collected by filtration,

Table 1. Elementary analyses of the hydrazones

Hydrazones of keto acids	Formulae	C (%)		H (%)		N (%)

washed and dried as described for the *trans* isomer in order to prevent isomerization. Recrystallization was carried out in exactly the same way as described for the *trans* isomer.

In the case of the hydrazone of keto acid in group **B**, the two forms were obtained by the following method: crystals of *x* form were obtained by recrystallization of the crude hydrazone from benzene and those of *y* form from 50% aqueous ethanol.

The results of elementary analyses of the hydrazones obtained are summarized in Table 1.

Each isomer as well as each form thus obtained contained no impurities detectable by paper chromatographic analysis.[8] The *cis* isomers gave higher R_f values than the corresponding *trans* isomers in normal phase systems and *vice versa* in reversed phase systems.

Isomerization of the Hydrazones. Determination of the proportions of the two isomers of the hydrazones during their formation was carried out as follows: One m*l* of 2,4-dinitrophenylhydrazine reagent (2.5 μ mol/m*l* in 1.2 N hydrochloric acid) was added to 2 m*l* of keto acid solution containing 0.2 to 0.7 μ mole of keto acid at 30°C. At varying time intervals up to 1 hr, 7 ml of 1.6 N sodium hydroxide solution was added to an aliquot of the mixture to stop the reaction. The red color produced upon addition of alkali was measured at two different wave lengths (W_1 and W_2) after allowing the solution to stand for 10 min at room temperature. W_1 is the wavelength at which two curves representing the absorption spectra of the hydrazone isomers in alkali intersect each other. Thus both isomers show the same absorption coefficient. W_2 is the wavelength at which the difference of the two curves is the largest. If the measured absorbances at W_1 and W_2 are represented as A_1 and A_2, respectively, A_1 or A_2 is equal to the sum of the absorbance due to each isomer of hydrazones formed and the one due to the remaining hydrazine reagent. Thus the following two equations are derived:

$$A_1 = k_1(m+n) + l_1(2.5-m-n)$$

$$A_2 = k_{2c}\cdot m + k_{2t}\cdot n + l_2(2.5-m-n)$$

where m and n represent the amounts of *cis* and *trans* hydrazones (μ moles), respectively, and k_1 and l_1 represent the absorbances of 1 μ mole of *cis* and *trans* hydrazones and of the hydrazine reagent at W_1 under these conditions, respectively. Similarly, k_{2c}, k_{2t}, and l_2 represent the absorbances of 1 μ mole of the *cis* and *trans* hydrazones and of the hydrazine reagent at W_2, respectively. The wavelengths, W_1 and W_2, and the specific absorption coefficients of the hydrazones in group **A** and of the hydrazine, *viz.*, k_1, l_1, k_{2c}, k_{2t}, and l_2, are summarized in Table 2.

Experiments on the isomerization of hydrazones in organic solvent containing hydrochloric acid were carried out as follows: A definite amount of hydrazone (0.3 to 0.6 μ mole) was dissolved in 1 m*l* of organic solvent and to this solution was added 4 m*l* of the same organic solvent saturated with 6 N hydrochloric acid. The solution was kept at 30°C for various periods of time. A few drops of concd. aqueous ammonia were then added to neutralize the solution and stop the isomerization reaction. The organic solvent was evaporated *in vacuo* and the residual hydrazone was dissolved in 5 m*l* of 0.1 N sodium hydrogen carbonate. Five m*l* of 2.0 N sodium hydroxide was added and the absorbances at W_1 and W_2 were determined as described above. In this case, l_1 and l_2 in the equations were negligible because no excess reagent was present. The interference due to the decomposition products from the hydrazone was also negligible under these conditions.

Table 2. Absorption coefficient of the hydrazones and the hydrazine

Hydrazones of keto aicds	W_1	k_1	l_1	W_2	k_{2c}	k_{2t}	l_2
	mμ			mμ			
I	406	1.12	0.088	460	0.40	2.60	0.017
II	417	1.54	0.068	470	1.00	1.68	0.013
III	416	1.59	0.070	470	1.22	1.63	0.013
IV	422	1.68	0.059	470	1.26	1.63	0.013
V	420	1.65	0.060	470	1.25	1.65	0.013
VI	420	1.67	0.060	470	1.25	1.68	0.013

The method for determination of the hydrazone isomers of I and II in ethyl acetate, ethyl ether and isopropyl ether was modified in the following way: After a few drops of aqueous ammonia were added to stop the reaction, 5 m*l* of petroleum ether and 2 m*l* of 0.1 N sodium hydrogen carbonate were added. By shaking the mixture in a separatory funnel, the hydrazones were transferred completely from the upper to the lower layer, and were determined spectrophotometrically by the method described above.

Solubility in Aqueous Sodium Carbonate. An excess amount of the hydrazone was shaken thoroughly with 1 m*l* of 1 N sodium carbonate for 1 hr at 25°C or 0°C, to let the hydrazone remain undissolved in the solution. The concentration of the hydrazone in the saturated solution was determined spectrophotometrically.

Partition between ethyl acetate and 0.1 N sodium carbonate. The hydrazone was dissolved in 2 m*l* of 0.1 N sodium carbonate containing 0.01 N sodium hydrogen carbonate. The hydrazone in the solution was then extracted with 10 m*l* of ethyl acetate and the amount of residual hydrazone in the lower layer was determined spectrophotometrically.

Rusults and Discussion

Isomerization during Hydrazone Formation. The proportion of *cis* to *trans* isomer during the course of hydrazone formation in dilute hydrochloric acid upon addition of the hydrazine reagent was determined. In the case of II, completion of hydrazone formation required 5 min at 30°C. The proportion of *cis* to *trans*

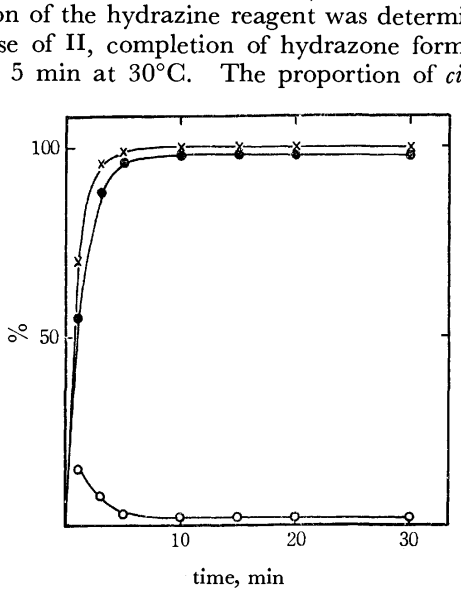

Fig. 1. Proportions of the *cis* and *trans* isomers during the formation of the hydrazone of II.
○, *cis* isomer; ●, *trans* isomer; ×, total hydrazone

isomer was found to vary depending upon experimental conditions. After the reaction for 1 min, about 23% of the hydrazone was present as the *cis* isomer. However, the *cis* isomer once produced was gradually converted into the *trans* isomer during further reaction by the action of hydrogen ions. The fraction of the *cis* isomer at equilibrium was negligible as shown in Fig. 1.

The reaction of I with hydrazine was rapid as in the case of II, but the other keto acids (III–VI) required 10—20 min for the completion of the reaction. The fraction of *cis* isomer in isomeric mixture after attainment of equilibrium in the hydrazone formation was as follows: **I**, negligibly small; III, 62%; IV, 50%; V, 81%; VI, less than 5%. Unlike the case of II, the fraction of *cis* isomer in V after 1-min reaction was 71% and increased to 81% at equilibrium state.

Although isomerization of the hydrazone in dilute hydrochloric acid in the absence of the hydrazine reagent occurred in a similar manner to that in the presence of the hydrazine reagent, hydrolysis of the hydrazone took place to a considerable extent. In the case of II, decomposition by hydrolysis after 30 min was more than 28%. The proportions of the two isomers at equilibrium were similar to those in the presence of the reagent.

The fact that one isomer is separated from the hydrazones of keto acids in group **B**, together with the above results, indicate various differences in the relative stabilities of both isomers of the hydrazones of keto acids. It might be said that, in general, the *trans* isomer is more stable than the *cis* isomer for lower keto acids, and *vice versa* for higher keto acids.

Isomerization in Organic Solvents. The hydrazones are stable in pure organic solvents unless exposed to strong light. However, in organic solvents containing hydrogen ions isomerization took place. Table 3 shows the isomerization of the hydrazones in ethyl acetate containing hydrogen ions. The fractions of *cis* isomers in an equilibrium mixture showed high values except for VI. The values in ethyl acetate were larger than the corresponding values in aqueous solution without exception.

The proportions of the two isomers at equilibrium also varied depending upon the nature of the organic solvent. The isomerization of the hydrazones of II at 10°C in several organic solvents containing hydrogen ions was investigated. The fractions of *cis* isomers in isomeric mixture at equilibrium were as follows: 14% in isopropyl ether, 23% in ethyl ether, 58% in acetone, 44% in ethanol and 56% in 50% aqueous ethanol. The decomposition of the hydrazone of II was much less (less than 7.5%) in isopropyl ether, ethyl ether and ethyl acetate than in acetone, ethanol, and aqueous ethanol. In the latter, it reached 25—55%.

Preparation of the Isomers. For the preparation of *trans* isomer, hydrazones of the keto acids in group **A** were conveniently prepared by the usual method. The hydrazine reagent dissolved in dilute hydrochloric acid was added to the aqueous solution of keto acid and the mixture was left standing for 1 hr to convert the *cis* hydrazone into the *trans* hydrazone as completely as possible. The crude hydrazones thus obtained contained more *trans* isomer than in those obtained from organic solvent as is shown in Table 3. The separation of the *trans* isomer from the *cis* isomer was carried out based on the fact that the *cis* isomer is scarcely soluble in a concentrated sodium carbonate solution.

The difference in solubilities of the two isomers in

IX	22	22

1N sodium carbonate varied considerably depending upon the kinds of keto acids as can be seen in Table 4. The difference was the largest in the case of I and gradually decreased as the number of carbon atoms of the keto acid molecule increased, though VI showed an unexpectedly large difference. Separation of the isomers from each other was thus more difficult in the case of the hydrazones of higher keto acids as compared to those of I and II. The hydrazones of keto acids in group **B** were found to be scarcely soluble in sodium carbonate solution in a similar way to the *cis* hydrazones in group **A**.

The difference in behavior of the two isomers in the salting-out is also seen in the partition of each isomer from ethyl acetate and sodium carbonate solution. Table 5 shows the amount of the hydrazone remaining in sodium carbonate solution when the hydrazone was extracted with ethyl acetate from sodium carbonate solution. Thus we see that the *cis* isomer is more easily extracted into ethyl acetate than the *trans* isomer, with the exception of VI, where the two isomers showed nearly the same value. A considerable portion of the hydrazones in group **B** showed the values of the same order of magnitude as those of *cis* isomers in group **A**. Since each hydrazone shows a characteristic value varying greatly in magnitude, measurement of the value is useful for the characterization of the hydrazone.

For the purpose of isolation of the *cis* isomer, isomerization treatment was carried out before the separation procedure by salting-out in order to increase the fraction of the *cis* isomer in the mixture. (For the details of the separation method of both isomers (group **A**), see Experimental).

Although, in general, the existence of *cis* and *trans* isomers is feasible in 2,4-dinitrophenylhydrazones of most unsymmetrical carbonyl compounds, α-keto acids can form highly stable hydrazone derivatives of *cis* form.[3,16] Curious behavior of the *cis* isomers in salting-out, solubility in sodium carbonate solution and in partition between ethyl acetate and 0.1 N sodium carbonate is due to their characteristic structures. Thus, the separation method described above is applicable only to the isomers of α-keto acid hydrazones.

Failure of isolation of the two isomers from keto acid hydrazones in group **B** indicates the instability of one isomer under the usual conditions. So far the behavior of the hydrazones seems to be concerned with keto acids with such structure as $\begin{matrix}R\\R'\end{matrix}\!>\!CHCOCOOH$ or $\begin{matrix}R\\R'\\R''\end{matrix}\!>\!CCOCOOH$.

Isomerization during Melting Point Determination. When a bath with melting point apparatus was heated gradually in the usual manner, some hydrazones did not show sharp melting points. Some pairs of the isomers showed no appreciable difference in their melting points when heated by the usual technique. However, when a capillary containing a sample was steeped into a bath preheated up to a temperature a few degrees below melting point by the usual procedure, sudden melting was often observed in one of the isomers. In such a case, the procedure was repeated in the above mentioned manner, lowering the temperature of the bath by a few degrees each time until the hydrazone did not melt any more. The melting point thus obtained was regarded as the true melting point of the hydrazone. On the other hand, no depression of the melting point was observed on the other isomer even by this method. In Table 6 shown are the melting pontis of the isomers of the hydrazones obtained by this method. The values by the conventional technique are also given when a difference was observed between the two measurements. *Trans* isomers of I and II showed higher melting points than their corresponding *cis* isomers, whereas *cis* isomers higher melting points than their corresponding *trans* isomers. Such a remarkable difference between the melting points of the isomers measured by the two methods suggests the possibility of isomerization of one isomer to the other during heating process. In fact, occurrence of isomerization could be demonstrated by subjecting the hydrazone to paper chromatography after it was kept for some time at certain temperature between the two melting points.

Table 6. Melting points of the hydrazones

Hydrazones of keto acids	Mp (Corrected) *cis* isomer	Mp (Corrected) *trans* isomer	Mp given in literature
I	182.5—183.5	205.5	203[17]
II	210—211	217—218.5	216[18]
III	202—202.5	170—171 (202—202.5)[a]	198[19]
IV	166.5—167.5	129—130 (166—168)[a]	167[19]
V	156—157	120	153[19]
VI	177—178	145.5—146.5	162[19]
	x form	*y* form	
VII	187.5—188	196—196.5	196[19]
VIII	169—170	170—171	169[20]
IX	172.5—173.5	177—178	180[15]

a) The values in parentheses show melting points measured by the usual method.

It is noticeable that the relative stabilities of both isomers, when their crystals are being heated, seem to accord with those in solution.

Although the two forms of hydrazones of keto acids in group **B** showed different melting points, they were not affected by the manner in which measurement was made. No isomerization was observed during the heating process.

The authors with to thank the late Miss Tsuya Yoshida, deceased May 4th, 1970, for her technical assistance.

The Dissociation Constants of Weak Acids in a Methanol-Water Mixture

Yasuhiko KONDO and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received April 24, 1971)

The theoretical expression of the Henry constant has been derived on the basis of the concept of an ideal associated mixture for the system in which a solute, M, exists as such clusters as $M\cdot(H_2O)_j\cdot(MeOH)_{z-j}$, which are related to each other by the equation:

$$M\cdot(H_2O)_{j-1}\cdot(MeOH)_{z-j+1} + H_2O \overset{K_j}{\rightleftarrows} M\cdot(H_2O)_j\cdot(MeOH)_{z-j} + MeOH$$

Making use of the theoretical expression, the transfer-free energies of halogen acids from water to water-methanol mixtures and the dissociation constants of weak acids in water-methanol mixtures have been analyzed and the following equilibrium constants have been obtained for a proton, assuming that a proton is in a higher free energy state in methanol than in pure water, while a counter ion is in the same free-energy state:

$$K_1 = 210, \quad K_2 \doteqdot 16, \quad K_3 \doteqdot 2, \quad K_4 \doteqdot 1$$

The maximum phenomena observed for the dissociation constants of charged acids in the same mixture could be reproduced by the combination of the above Henry constants; emphasis has been placed on the importance of the assumption of a multi-step solvation mechanism.

The solvation of electrolytes and related phenomena in mixed solvents have received very much attention and have been analyzed from various points of view. These may be classified into four categories: *i.e.*, the theoretical treatment developed by Debye[1] and refined recently by Padova,[2] the attempts taking into account the distribution of protons between water and alcohol,[3-8] Marshall's treatment of complete equilibrium constants,[9-12] and several modified forms of the Born equation.[13] A common feature of these attempts is that they all refer to some liquid state as the standard state.

In contrast to these treatments, taking an ideal gas state as the standard state, the present authors have developed a method of analyzing rate constants measured in mixed solvents from the view point of the theory of a nonelectrolyte solution.[14-16] Since the method is based on an equilibrium assumption between reactants and an activated complex, after a few modifications, it is, in principle, reasonable to apply it to the analysis of equilibrium constants measured in mixed solvents.

As will be discussed later, the behavior of dissociation constants in mixed solvents is more complex than that of rate constants. Therefore, several refinements were required for the method to be applicable to the analysis of equilibrium properties in mixed solvents. This paper is an extension of a previous series of works on the solvation of a solute in mixed solvents.[14-16]

Theoretical Expression of an Activity Coefficient in Mixed Solvents.

It is appropriate to define the following activity coefficient, β_{ij}, for the description of the partition of a component, i, between gas and solvent, j:[14]

$$\beta_{ij} = (m_{gi}/m_{li}) \tag{1}$$

where m_{gi} and m_{li} stand for the molar concentration of a component, i in the gas phase over the solution and that of the component, i, in solution.

The Henry constant of a component, i, in a solvent, j, H_{ij}, is defined by the equation:

$$H_{ij} = \lim_{x_i \to 0} (f_i/x_i)_j \tag{2}$$

where f_i and x_i stand for the fugacity and the mole fraction of a component, i, respectively.

At sufficiently low concentrations of a component, i, the following relations hold;

$$f_i = p_i \tag{3}$$

$$p_i = (n_{gi}/V) \times \boldsymbol{RT} = m_{gi} \times \boldsymbol{RT} \tag{4}$$

$$m_{li} = (n_{li}/\textstyle\sum_i n_{li} \times V_i) = x_i \times V_j^{-1} \tag{5}$$

where f_i, P_i, n_{gi}, n_{li}, V_i, x_i, and V_j stand for the fugacity, the pressure, the number of moles in a gas phase, that in a solution, the partial molar volume, and the mole fraction, each of a component, i, and the molar volume of a solvent, respectively.

At sufficiently low concentrations of a component, i, by a combination of Eqs. (1), (2), (3), (4), and (5), we obtain:

$$\beta_{ij} = (H_{ij} \times V_j/\boldsymbol{RT}) \tag{6}$$

where V_j stands for the molar volume of a solvent, j.

An electrolyte, M, can be expected to exist as such

clusters as $M\cdot(S_1)_m\cdot(S_4)_n$ in mixed solvents, where S_1 and S_4 stand for a solvent, 1 and 4; it has been suggested that the ratio of m to n changes with the composition of the solvent mixture (Refs. 25, 26, and *loc. cit*).

In order to make an explicit formula for an activity coefficient based on the above concept, let us assume the following equilibrium:

$$M + zS_4 \rightleftarrows M\cdot(S_4)_z;\ K_0$$

$$M\cdot(S_4)_{z-j+1}\cdot(S_1)_{j-1} + S_1 \rightleftarrows M\cdot(S_4)_{z-j}\cdot(S_1)_j + S_4;\ K_j$$

$$M\cdot(S_4)\cdot(S_1)_{z-1} + S_1 \rightleftarrows M\cdot(S_1)_z + S_4;\ K_z$$

where M, z, and K_j stand for an unsolvated electrolyte, the solvation number, and the equilibrium constant of a relevant step, respectively.

Hereafter, subscripts 1 and 4 will be used for a solvent, subscript 2 for a solute, and subscript jz for a cluster except for those of equilibrium constants.

One advantage of the discrete model is that it makes it possible to introduce a mathematical formalism expressing the variation in the standard-state free energy with respect to the composition changes in the solvents. Consistent results have been obtained based on the predictions of the model, as will be shown later. However, it would be safe to take the view that this does not necessarily prove the real existence of the clusters.

When the above equilibrium steps exist, for the mixture containing components 1, 2, and 4 the following material balances hold:

$$N_1 = M_1 + M_{1z} + 2\times M_{2z} + \cdots + j\times M_{jz} + \cdots + z\times M_{zz} \quad (7)$$

$$N_2 = M_2 + M_{0z} + M_{1z} + \cdots + M_{jz} + \cdots + M_{zz} \quad (8)$$

$$N_4 = M_4 + z\times M_{0z} + (z-1)\times M_{1z} + \cdots + (z-j)\times M_{jz} + \cdots + M_{z-1,z} \quad (9)$$

where N_i, M_i, and M_{jz} stand for the number of moles of a component, i, before mixing, that of a free component, i, in solutions, and that of such a cluster containing j molecules of a solvent 1, and $(z-j)$ molecules of a solvent 4, such as $M\cdot(S_4)_{z-j}\cdot(S_1)_j$.

Three kinds of mole fraction will be used in the following calculations:

$$x_i = N_i/\sum_i N_i \quad (10)$$

$$y_i = M_i/(\sum_i M_i + \sum_j M_{jz}) \quad (11)$$

$$y_{jz} = M_{jz}/(\sum_i M_i + \sum_j M_{jz}) \quad (12)$$

where x_i, y_i, and y_{jz} stand for the mole fraction defined in terms of the number of moles of a component, i, before mixing and of the number of moles of a component, i, and of a cluster, jz, in solution.

For the above equilibria, the equilibrium constant of each step is defined as follows:

$$K_0 = (y_{0z}/y_2\times y_4^z) \quad (13)$$

$$K_j = (y_{j,z}\times y_4/y_{j-1,z}\times y_1) \quad (14)$$

From Eqs. (7), (8), (9), (10), (11), and (12), we obtain:

$$x_2 = (y_2+\sum_{j=0}^{z} y_{jz})/(1+z\times\sum_{j=0}^{z} y_{jz}) \quad (15)$$

$$(y_2/x_2) = (1+z\times\sum_{j=0}^{z} y_{jz})/(1+\sum_{j=0}^{z}(y_{jz}/y_2)) \quad (16)$$

At sufficiently low concentrations of a solute 2:

$$\lim_{x_2\to 0}(y_2/x_2) = 1/(1+\sum_{j=0}^{z}(y_{jz}/y_2)) \quad (17)$$

From Eqs. (13), (14), and (17), we obtain:

$$\lim_{x_2\to 0}(y_2/x_2) = 1/(1+\sum_{i=0}^{z}(\prod_{j=0}^{i} K_j)\times x_4^{z-i}\times x_1^i) \quad (18)$$

since $x_2\to 0$, $y_1\to x_1$, and $y_4\to x_4$.

For an ideal associated mixture, a fugacity of a component, 2, f_2, is related to the fugacity of that component in the pure state, f_2^0, by the equation:

$$f_2 = f_2^0\times y_2 \quad (19)$$

$$\lim_{x_2\to 0} f_2 = H_{2,\mathrm{mix}}\times x_2 \quad (20)$$

From Eqs. (18), (19), and (20), we obtain:

$$H_{2,\mathrm{mix}} = f_2^0/(1+\sum_{i=0}^{z}(\prod_{j=0}^{i} K_j)\times x_4^{z-i}\times x_1^i) \quad (21)$$

$$H_{2,1} = \lim_{x_1\to 1} H_{2,\mathrm{mix}} = f_2^0/(1+\prod_{j=0}^{z} K_j) \quad (22)$$

$$H_{2,4} = \lim_{x_1\to 1} H_{2,\mathrm{mix}} = f_2^0/(1+K_0) \quad (23)$$

As is clear from Eqs. (13) and (23), the equilibrium constant, K_0, serves as a measure of the stability or of the solvation energy of a solute in a solvent 4.

By combining Eqs. (6) and (21), the activity coefficient of a solute in such a mixture is given by:

$$\lim_{x_2\to 0}\beta_{2,\mathrm{mix}} = \{f_2^0/(1+\sum_{i=0}^{z}(\prod_{j=0}^{i} K_j)\times x_4^{z-i}\times x_1^i)\}\times(V_{\mathrm{mix}}/\boldsymbol{R}T) \quad (24)$$

where V_{mix} means the molar volume of the mixed solvent.

Transfer-free Energy of a Solute from the Solvent 1 to a Mixed Solvent

The transfer-free energy of a solute 2 from the solvent 1 to a solvent mixture, ΔG_t°, can be defined as follows by making use of the above activity coefficient:

$$\Delta G_t^0 = \boldsymbol{R}T\ln\beta_{2,\mathrm{mix}} - \boldsymbol{R}T\ln\beta_{2,1} = \boldsymbol{R}T\{\ln(1+\prod_{j=0}^{z} K_j) - \ln(1+\sum_{i=0}^{z}(\prod_{j=0}^{i} K_j)\times x_4^{z-i}\times x_1^i)\} + \boldsymbol{R}T\ln(V_{\mathrm{mix}}/V_1) \quad (25)$$

where V_1 stands for the molar volume of a pure solvent 1.

Similarly, for the transfer of a solute from the solvent 1 to a solvent 4:

$$\Delta G_t^0 = \boldsymbol{R}T\{\ln(1+\prod_{j=0}^{z} K_j) - \ln(1+K_0)\} + \boldsymbol{R}T\ln(V_4/V_1) \quad (26)$$

For grasping the concept of the above equations, numerical calculations were performed making use of the parameters in Table 1 for the case where $V_4=V_1$, $(1+K_0\times K_1\times\cdots\cdots\times K_z)/(1+K_0)\fallingdotseq K_1\times K_2\times\cdots\cdots\times K_z$[17] $=3{,}000$; then $\Delta G_t^\circ = 2.303\ \boldsymbol{R}T\ \log(\beta_4/\beta_1) = 4.74$ (kcal mol^{-1}) at 25°C.

17) Since the solvation energy of an electrolyte is very large in usual solvents, it is reasonable to assume $K_0 \gg 1.0$. Therefore, K_0 may be dropped out of the final equation.

TABLE 1. EQUILIBRIUM CONSTANTS USED IN THE CALCULATION

Model	z	K_1	K_2	K_3	K_4	K_5	K_6	Relations between ΔG_j° and ΔG_{j-1}°
I	4	3000	1.0	1.0	1.0	—	—	$\Delta G_j^\circ=0, j\geq 2$
II	4	1000	1.88	1.37	1.165	—	—	$\Delta G_j^\circ=(1/2)\Delta G_{j-1}^\circ\ j\geq 3$
III	4	222.0	6.06	1.82	1.225	—	—	$\Delta G_j^\circ=(1/3)\Delta G_{j-1}^\circ$
IV	4	27.8	9.18	4.38	2.683	—	—	$\Delta G_j^\circ=(2/3)\Delta G_{j-1}^\circ$
V	4	7.40	7.40	7.40	7.40	—	—	$\Delta G_j^\circ=\Delta G_{j-1}^\circ$
VI	6	19.0	7.10	3.70	2.39	1.79	1.40	$\Delta G_j^\circ=(2/3)\Delta G_{j-1}^\circ$

$(\Delta G_j^\circ=-RT\ln K_j)$

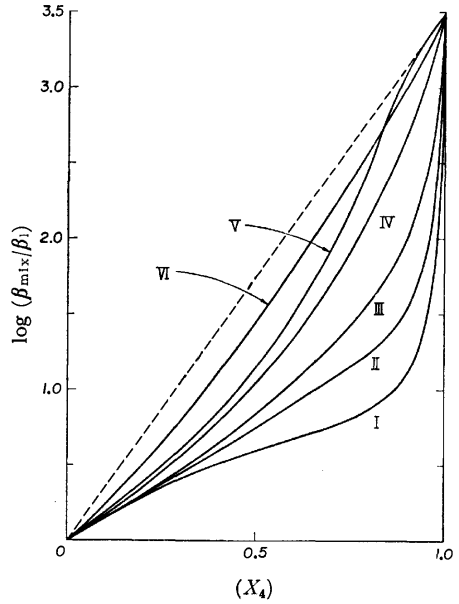

Fig. 1. Calculated values of log (β_{mix}/β_i) as a function of the solvent composition. Numbers in the figure correspond to the model number in Table 1.

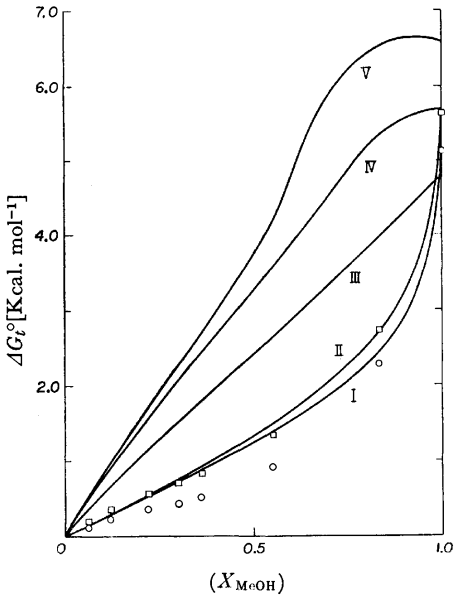

Fig. 2. Transfer-free energies of alkali metal halides and halogen acids from water to methanol-water mixtures.
Experimental results;[17] ○; HBr, □; HCl, III; LiCl, IV; NaCl, V; KCl
Theoretical values, I: HBr, II; HCl

The calculated values are shown in Fig. 1.

As is clear from Fig. 1, the negative deviation from the dotted line increases as the proportion of ΔG_1° to ΔG_t° increases. As $(\Delta G_{j-1}^\circ/\Delta G_j^\circ)\rightarrow 1.0$, and as the solvation number, z, increases, the transfer-energy curve approaches the dotted line. Thus, an important factor in controlling the shape of a transfer-energy curve may be concluded to be the ratio of ΔG_1° to ΔG_t°.

In order to compare the above idea with the experimental results, the transfer-free energies measured by Feakins *et al.*[18,19] are shown in Fig. 2. For most of the electrolytes in Fig. 2, the transfer-free energies from water to methanol are fairly close to each other. However, there is a very sharp distinction between alkali metal halides and halogen acids concerning transfer-free energy curves. The phenomena clearly demonstrate the well-known inadequacies of the Born equation.

Provided that the above model applies to the present system, the difference in transfer-free energy curves reveals that the $(\Delta G_1^\circ/\Delta G_t^\circ)$ ratio of a proton is considerably larger than that of alkali metal ions.

This idea is partly supported by the thermodynamic data for the following step-by-step addition of water to an ion, M^+, as measured by means of a mass spectrometer:

$$M^+\cdot(H_2O)_{n-1}+H_2O=M^+\cdot(H_2O)_n$$

For the reaction in the gas phase, it has been reported that the $(-\Delta H_{0,1})$ value of a proton is considerably larger than that of alkali metal ions and that, in addition, the rate of the decrease in $(-\Delta G^\circ_{n-1,n})$ with an increase in n is smaller for larger ions.[20-23]

Also, the chemical intuition of a preferential solvation of a cation by water has been experimentally proved by Mills and King for the Cr^{3+} ion;[24] it has also been suggested from mass-spectroscopic studies of the competitive solvation of a proton in a water methanol vapor mixture.[21]

Dissociation Constants of Neutral Acids and the Distribution of Clusters in Mixed Solvents

The importance of the entropy terms in determining the magnitude and the sign of the transfer-free energy of solutes from one solvent to another[27,28] has been demonstrated. However, the question of which of the constituents of the electrolyte, *i.e.*, the cation or the anion, is responsible for determining the magnitude of the transfer energy is still a matter of considerable discussion.

In the dissociation of a neutral acid, the perturbation effect brought about on a carbon skelton by the release of a proton may be expected to be small. Especially for the 2,6-dinitrophenolate anion, a negative charge is distributed over the aromatic ring and is partially prohibited from the approach of solvent molecules by two adjacent nitro groups. Also, the non-electrostatic effects by a carbon skelton may be expected to cancel each other out of the total transfer energy since the effect appears on both sides of equations. Thus, it is reasonable to assume that the dissociation constant of a neutral acid is mainly affected by the variation in the standard-state free energy of a proton accompanying the changes in the composition of the solvents.

The dissociation constant as measured in a mixed solvent, $K_{d,\mathrm{mix}}$, is given by;

$$\mathrm{HA} \rightleftarrows \mathrm{H^+} + \mathrm{A^-}$$

$$K_{d,\mathrm{mix}} = K_g(\beta_{\mathrm{HA},\mathrm{mix}}/\beta_{\mathrm{H^+},\mathrm{mix}} \times \beta_{\mathrm{A^-},\mathrm{mix}}) \qquad (27)$$

where K_g is a dissociation constant in a gas phase at an ideal state.

Based on the above assumption, and from Eqs. (21), (22), (23), and (27):

$$\begin{aligned}\ln (K_{d,\mathrm{mix}}/K_{d,4}) &= \ln \Big(1+\sum_{i=0}^{z}\Big(\prod_{j=0}^{i}K_j\Big)x_4^{z-i}x_1^{i}\Big) \\ &\quad - \ln (1+K_0) + \ln (V_4/V_{\mathrm{mix}}) \\ &\fallingdotseq \ln \Big(x_4^{z}+\sum_{i=1}^{z}\Big(\prod_{j=1}^{i}K_j\Big)x_4^{z-i}x_1^{i}\Big) \\ &\quad + \ln (V_4/V_{\mathrm{mix}}) \qquad (28)\end{aligned}$$

$$\begin{aligned}(K_{d,1}/K_{d,4}) &= \{(1+\prod_{j=0}^{z}K_j)/(1+K_0)\}(V_4/V_1) \\ &\fallingdotseq (\prod_{j=1}^{z}K_j)(V_4/V_1) \qquad (29) \\ &(\because \quad K_0 \gg 1)\end{aligned}$$

Comparisons of the calculated values with the experimental results are shown in Fig. 3, where the subscript 1 refers to water and the subscript 4, to methanol, since $(K_{d,\mathrm{water}}/K_{d,\mathrm{MeOH}})>1$. Similar calculations were performed for the transfer energies of hydrochloric acid and of hydrobromic acid on the basis of Eqs. (25) and (26) (the molar volume of the mixture was calculated from the density data of the mixture).[29]

The parameters obtained from the calculations are listed in Table 2.[30]

The most interesting feature of the table is the fact that, for all five cases, the experimental results are fairly well reproduced by similar values of K_j.

The equilibrium constants of the following reaction have been measured by several people:

$$\mathrm{MeOH_2^+} + \mathrm{H_2O} = \mathrm{H_3O^+} + \mathrm{MeOH}$$

The values are *ca.* 110—140 on the pure methanol side[3,7,34-36] and *ca.* 0.20 on the pure water side.[4-6]

At first sight, our equilibrium expression looks a little different from the above equation. However, at each step the net reaction actually taking place is the substitution of water for methanol in the cluster; as a result, the other remaining molecules in the cluster do not appear in the mass-action equation. Therefore, there is no essential difference between the two approaches.

As may partly be inferred from Fig. 3, a proton would exist as $\mathrm{H^+\cdot(MeOH)}_n$ in methanol and as $\mathrm{H^+\cdot(H_2O)}_n$ in water. Thus, our value of K_1 and K_4 should correspond to the equilibrium constant measured on the pure methanol side and on the pure water side rescpectively. They agree with each other generally, but not completely.

30) The calculations were performed as follws: the comparison of the theoretical values of Fig. 1 with the log $K_{d,\mathrm{mix}}$ *vs.* $x_{\mathrm{H_2O}}$ plot led to rough estimates of z and of the relation between equilibrium constants, *i.e.*, ΔG°_j and ΔG°_{j-1}, for the relevant system. For an assumed value of z (usually $z=3$), the value of $\prod_{j=1}^{z}(K_j)$ has been obtained on the basis of the boundary condition, *i.e.*, Eq. (29). After that, the values of $\log(K_{d,\mathrm{mix}}/K_{d,4})$ have been calculated on the basis of Eq. (28) for various sets of equilibrium constants. Similar calculations were repeated for several values of z until satisfactory agreements with the experimental results were attained. Similar procedures were adopted for the other systems.

Theoretical values; ——

The results in the table are also of interest in showing the fall in equilibrium constants as the number of water molecules in a cluster increases.

A trend of the equilibrium constants similar to that obtained above, *i.e.*, $K_1 > K_2 > K_3 > K_4$, has been observed for the proton hydration equilibria in acetonitrile.[37-39]

Thus it may be seen that completely different procedures can lead to similar conclusion about the proton hydration equilibria in mixed solvents.

By making use of the equilibrium constants in Table 2, it is possible to calculate the distribution of each cluster, F_{iz}, over the full composition ranges of the solvent by means of Eq. (30):

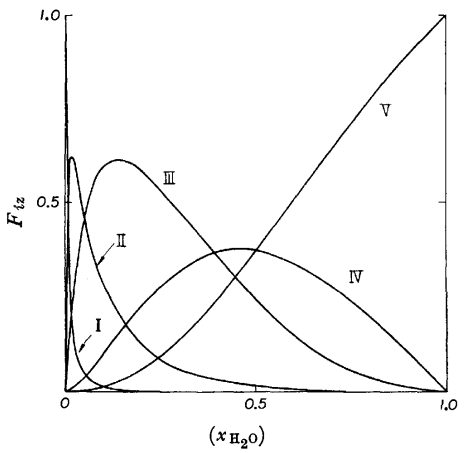

Fig. 4. Distributions of the clusters as a function of the solvent composition.
I: $H^+ \cdot (MeOH)_4$, II: $H^+ \cdot (MeOH)_3 \cdot (H_2O)$, III: $H^+ \cdot (MeOH)_2 \cdot (H_2O)_2$, IV: $H^+ \cdot (MeOH) \cdot (H_2O)_3$, V: $H^+ \cdot (H_2O)_4$.

37) I. M. Kolthoff and M. K. Chantooni, Jr., *Anal. Chem.*, **39**, 1080 (1967).
38) I. M. Kolthoff and M. K. Chantooni, Jr., *J. Amer. Chem. Soc.*, **90**, 3320 (1968).
39) M. K. Chantooni, Jr., and I. M. Kolthoff, *ibid.*, **92**, 2236 (1970).

$$\lim_{x_2 \to 0} F_{iz} = \lim_{x_2 \to 0} M_{iz} / \sum_{j=0}^{z} M_{jz}$$
$$= (\prod_{j=0}^{i} K_j) x_4^{z-i} x_1^{i} / \sum_{i=0}^{z} (\prod_{j=0}^{i} K_j) x_4^{z-i} x_1^{i} \quad (30)$$

The calculated values of F_{iz} for the set of equilibrium constants of hydrochloric acid are plotted against the mole fraction of water in Fig. 4.

As may be inferred from the figure, such clusters as $H^+ \cdot (MeOH)_4$ and $H^+ \cdot (MeOH)_3(H_2O)$ exist only over quite narrow ranges of solvent compositions. In contrast, on the water side, the fraction of the $H^+ \cdot (H_2O)_4$ cluster decreases nearly linearly with the composition of the solvent and the following relation holds over a fairly wide range.

$$F_{44} + F_{34} \doteqdot 1 \quad (31)$$

These factors should be taken into account when attempts are made to correlate the solvation-related properties with the macroscopic properties of the mixed solvents.

Similar distribution curves of a hydrated proton were estimated by Chantooni and Kolthoff in acetonitrile-water mixtures.[39]

Dissociation Constants of Charged Acids in Mixed Solvents

There is a marked difference in the dissociation behavior of charged acids and uncharged acids as measured in mixed solvents. One of the main reasons for such a difference is the charge type of the acids. Since, for the charged acids, electrostatic charging effects appear on both sides of the equilibrium expression, most parts of the effects compensate one another. Thus, the result of such a compensation is a maximum in the plot of log K_d *vs.* the composition of the solvents.

As has been mentioned above, in contrast to the case of hydrogen halogenide acids, the transfer-free energy of alkali metal halides varies monotonously with the change in the composition of the solvents. Also, the

behavior of the transfer energy of tris(hydroxymethylamine) hydrochloride, *i.e.*, a charged acid, has been reported to resemble that of LiCl.[13]

Thus, the following calculations have been performed from the point of view that the variation in the dissociation constants of charged acids in mixed solvents are mainly controlled by the dissimilarities of the transfer-energy behaviours between charged acid and a proton.

By a procedure similar to that used for uncharged acid, for the equilibria:

$$BH^+ \rightleftarrows B + H^+$$

$$\ln(K_{d,\mathrm{mix}}/K_{d,4}) = [\ln\{1+\sum_{i=0}^{z}(\prod_{j=0}^{i}K_j)x_4^{z-i}x_1^{i}\}-\ln(1+K_0)]_{H^+} - [\ln\{1+\sum_{i=0}^{z}(\prod_{j=0}^{i}K_j)x_4^{z-i}x_1^{i}\}-\ln(1+K_0)]_{EH^+} + \ln(V_4/V_{\mathrm{mix}}) \quad (32)$$

$$(K_{d,1}/K_{d,4}) = [\{(1+\prod_{j=0}^{z}K_j)/(1+K_0)\}_{H^+}/ \{(1+\prod_{j=0}^{z}K_j)/(1+K_0)\}_{BH^+}]\times(V_4/V_1) \quad (33)$$

As is clear from Eqs. (32) and (33), it is necessary to determine two sets of equilibrium constants, *i.e.*, for a proton and for a charged acid. The set of equilibrium constants obtained from the transfer energy of hydrochloric acid has been substituted into Eqs. (32) and (33) for those of a proton; the other parameters used in the calculations are listed in Table 3. A comparison of the experimental results with the calculated values is shown in Fig. 5.

It may be seen from Fig. 5 that the general tendency of the dissociation behaviors of charged acids can be reproduced in mixed solvents by the procedure described above.

In several aqueous-organic mixtures, the acidity function, $-H_0$, goes through a minimum with changing water concentration at fixed concentration of the acid (which corresponds to the maximum in the log K_{BH^+} of the indicator used for the measurements); several attempts have been made to interpret this phenomenon.[40]

A similar maximum phenomenon has been observed for the rate of Wolff-Kishner reaction in mixed solvents.[41]

In previous works, the present authors developed theoretical methods for analyzing the rate constants in solvent mixtures and performed theoretical calculation for the rate constants based on several solvation patterns.[14-16] However, in none of these calculations could a maximum or a minimum phenomenon be simulated. Thus, it is inevitable to assume a multi-step solvation mechanism for reproducing a maximum or a minimum phenomenon in solvent mixtures, although the necessary procedure is much more complicated.

A Consideration of Orbital Interaction in Nitrogen Extrusions of Cyclic Azo Compounds

Satoshi INAGAKI and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received June 9, 1971)

The stereochemical paths of nitrogen extrusions from cyclic azo compounds have been examined from the point of view of particular orbital interaction. The stereoselectivity of the recyclization of 1-pyrazoline derivatives and the homologues on the extrusion can be understood in terms of interaction between the frontier orbitals of the C–N–N–C σ-bond system and of N–N π-bond. Other cyclic azo compounds are found also to behave consistently with the direction of the particular orbital interaction between the relevant parts *e.g.*, strained σ-bonds, π-bonds and lone pairs, and two weakened C–N bonds, and of the interaction between approximate *p* orbitals at the α carbons with respect to the nitrogen and unstrained σ-bond to be cleaved.

Both pyrolytic and photolytic reactions of cyclic azo compounds have been reported in many papers. However, no comprehensive, detailed mechanism and steric course have yet been discussed. Here, we intend to interpret the experimental results from the point of view of orbital interaction. The use of a particular orbital interaction scheme is recommended for the purpose of recognizing steric paths in chemical reactions in general.[1] The fundamental proposition lies in the following statement; "A majority of chemical reactions should take place at the position, and in the direction, of maximum overlapping of the highest occupied (HO) molecular orbital (MO) and the lowest unoccupied (LU) MO of the reacting species; in the reacting species with a singly-occupied (SO) MO, this plays the part of the HOMO or the LUMO, or of both." The consideration of the interaction of these particular MO's is convenient in describing the nature of chemical reactions.[2,3] The procedure for discussing the direction and the position of chemical reactions has been established on the basis of the proposition given in a preceding article.[1] In short, reacting species involved in intramolecular reactions are divided into two parts so that new bonds may form across the surface which borders the parts. The sign relation of the orbital lobes in these parts plays an important role in the reaction. The resultant sketch of the reacting molecules shows the path which they should trace; the reaction should proceed so that the signs are congruent on the atoms where the bonds are newly formed. This formularized procedure will here be applied to the nitrogen extrusion of cyclic azo compounds, of which the stereospecificity has so far been suspended without any comprehensive understanding. The following speculation may assist in understanding the extrusion reactions.

First of all, the decompositions of cyclic azo compounds are classified, in terms of their intrinsic difference as chemical species, into three groups; (1) the nitrogen extrusions of the derivatives of 1-pyrazolines and the homologues, (2) those of the compounds with a conjugative part interacting with weakening C–N bonds, and (3) those of the compounds undergoing a cleavage of the unstrained σ-bond bridging the β and β′ carbons. Now our discussion is compelled to enter upon a treatment of each class, since the way of dividing the reactants and the assignment of the frontier orbitals depend on the nature of the reactants as well as on the reaction environments.

The Derivatives of 1-Pyrazolines and the Homologues

In the case of the pyrolysis, the respective interactions between the HOMO and the LUMO of the N–N π-bond system and the LUMO and the HOMO of the C–N–N–C σ-bond system presumably initiate the extrusion reaction, whereas in the photo-induced reactions the energy incorporated through $n\rightarrow\pi^*$ or $\pi\rightarrow\pi^*$ excitation at the nitrogens is transferred to the σ-bond system by way of the orbital interaction between the LUMO of the σ-bond system and the SOMO at the N=N moiety to weaken the C–N bonds and promote the extrusion. The results of the sensitized photolysis of azo compounds tempt us to expect that cyclic azo compounds decompose through both excited singlet and triplet states, while acyclic azo compounds dissociate and undergo *cis-trans* isomerization by way of singlet and triplet states respectively.[4]

Now it is necessary to know the nodal properties of each bond system in order to further our thinking. In the ground state, two electrons, localized at the N–N π-orbital, occupy the MO which is symmetrical (S) with respect to the mirror plane passing through the middle of the N–N bond. The LUMO or the SOMO has an anti-symmetrical (A) character with respect to the plane. In contrast with π-orbital systems, the symmetry of the σ-bond system has not been established completely. The knowledge obtained from the hybrid-based MO calculations[5] is helpful on the present occa-

sion. Among the three MO's essentially occupied by the six bonding electrons in the C–N–N–C system, the lowest has no node; the three bonds being bonding therefore symmetrical (S) with respect to the mirror plane (Fig. 1A). The next has one node between the nitrogens (A), while the last one, which is also the HOMO of this system, has two (S) (Fig. 1B and 1C respectively). Moreover, the LUMO has three nodes, alternating the signs along the bond chain (A) (Fig. 1D).

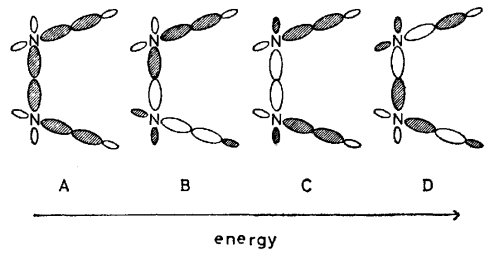

Fig. 1. Relation between orbital symmetry and energy level of three σ-bonds chain.

Assuming that the orbital interaction between the C–N–N–C bond system and the N=N π-bond responsible for the weakening of the C–N bonds governs the stereochemical path both in the pyrolysis and in the photolysis, it is unquestionably necessary to divide 1-pyrazoline and to assign an orbital symmetry for the pyrolysis (A) and the photolysis (B), as is shown in Fig. 2.

In the thermolysis, the particularly important orbital interactions are that between the HOMO of the N–N π-bond system and the LUMO of σ-bond system and that between the LUMO of the former and the HOMO of the latter. One of the interactions, that between π-HOMO and σ-LUMO, is illustrated in Fig. 2A. Fig. 2B represents the mode of the interaction between the LUMO of the σ-bond system and the lowest-excited N–N π-bond, which is caused by an excitation transfer from the neighboring excited N=N π-bond. As a result, 1-pyrazoline decomposes into cyclopropane and nitrogen under both thermal and light-irradiated conditions, with single inversion and with retention at C_α or/and $C_{\alpha'}$ during the recyclization respectively. At first sight, the orbital interaction consideration seems unable to cover all the experimental results listed in Tables 1 and 2. However, it still proves effective in explaining the steric course with the help of the stereochemistry of the reactants. In the pyrolysis, by taking account of the reluctance to rotation of the bulky group at C_α and $C_{\alpha'}$ inward to the breaking five-membered ring, and in the photolysis, by taking account of the multiplicity of the excited state, the particular orbital

interaction turns out to work clearly in directing the path of these reactions as follows.

The Pyrolysis. The thermolytic reactions of α,α′-disubstituted cyclic azo compounds will be discussed first. They obey the directions of orbital interaction to invert singly at either α or α′ carbons, when the repulsive force is not considerably outstanding between the approaching groups with the progress of the reaction (*cis*- and *trans*-Ia, *cis*-Ib, *cis*-IIa, and *cis*-IIb). *Trans*-species which have bulky groups at both α and α′ carbons suffer such a repellent action during the single inversion that they neglect the orbital interaction, giving the corresponding compounds with a retention of the original configurations (*trans*-Ib and *trans*-IIa and b). In these cases, thermodynamics overcome the orbital interaction.

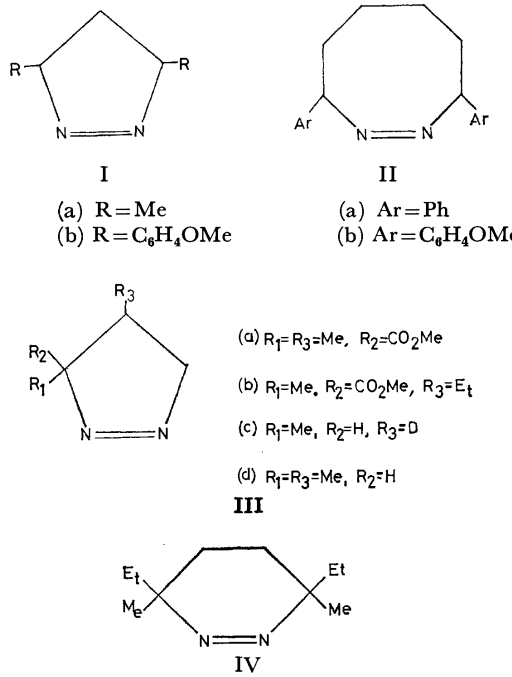
The second object of our discussion is the group of α, α-disubstituted cyclic azo compounds. When α carbon is occupied by two substituents (except for very small groups, for instance, hydrogen and deuterium), the single inversion undoubtedly occurs more probably at the unsubstituted α′ carbon to produce apparent retention products (IIIa and b).

Thirdly, α,β-disubstituted-1-pyrazolines will be treated. If these compounds dispose the substituent at the β carbon with respect to leaving nitrogens in the *anti*-position in the transition state of the thermolysis, as has been proposed by Crawford and Mishra,[13] *cis*- and *trans*-α, β-disubstituted-1-pyrazolines will have methyl groups at the α carbon at the axial and the equatorial positions respectively. Since the axial group is compelled to rotate inwardly, the *cis*-reactant must rotate a methyl group but *trans*-species rotate hydrogen. From these requirements, it is evident that *trans*-pyrazolines yield more an apparent inversion product than *cis*-pyrazoline. The experiments on *cis*- and *trans*-IIId exhibit this tendency, but it cannot be explained by these discussions why *trans*-IIId apparently gives more of the single inversion product than the retention product. However, in the case of a small substituent at the β carbon (IIIc), the reactants, whether in the *cis*- or *trans*-form, yield *cis*- and *trans*-products in equal amounts, since the small substituent has no influence on the inward rotation at the α carbon.

The Photolysis. Subsequently, let us proceed to a detailed discussion of the photolysis on the assumption that orbital interaction favors the configurational retention path. If these compounds undergo dissociation through the excited singlets, the stereochemical course will be consistent with our predictions based on Fig. 2B. There can, however, exist some factors independent of the orbital interaction. For example, the interventions of triplets would add to a thermodynamically stable product or *trans*-compound, and the deactivation of an excited singlet to the vibrationally-exicted ground state would compete with the path through excited singlets, in some case giving the inversion product. That is why the stereochemical path in thermolysis is complicated.

All the compounds listed in Table 2 except for *cis*-Ia in 95% ethanol and *trans*-Ia in the gas phase more or less exhibit a tendency toward obedience to orbital interaction control. Here, we may find the causes of the two exceptions and some poorly stereoselective reactions mainly in the intervention of triplets, but it is premature to arrive at conclusive interpretations because of the insufficiency of physical information about 1-pyrazolines, the quantum yield of intersystem crossing, the structural geometry of triplets, *etc.* However, it seems that it will be meaningful to make a tentative proposal.

Some experimental results suggest that cyclic azo compounds extrude nitrogen molecules *via* triplets as well as singlets, but that acyclic azo compounds undergo *cis-trans* isomerization *via* triplets, while they dissociate only through singlets.[4] From this generalization, it can be expected that the dissociation through the triplets depends upon the geometrical structure of the reacting molecules. The geometry in the triplet is considered to suffer some twist, which is probably caused by electronic repulsion between two electrons with parallel spins. Assuming that relief from the twisted strain drives the extrusion, the more the triplet species is



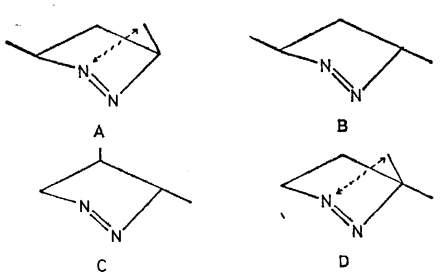


Fig. 3. The repulsion of twisted 1-pyrazoline derivatives in the triplets; (A) *trans*-α,α-dimethyl-1-pyrazoline, (B) *cis*-α,α-dimethyl-1-pyrazoline, (C) α,β-dimethyl-1-pyrazoline, and (D) α,α-substituted 1-pyrazoline.

12) P. D. Bartlett and N. A. Porter, *J. Amer. Chem. Soc.*, **90**, 5317 (1968).
13) R. J. Crawford and A. Mishra, *ibid.*, **88**, 3963 (1966).

strained, the more facile a decomposition it is submitted to.

Now let us proceed to a detailed discussion of this assumption. The distortion of α,α'-disubstituted 1-pyrazolines (I) brings about strains of different extents between *cis*- and *trans*-isomers. With respect to *cis*-I, a suitable repulsion arises from the unavoidable approach of the substituent and the originally remoter nitrogen (Fig. 3A), thus accelerating the extrusion through the triplets so remarkably as to compete with the singlet path. The participation of triplets contributes to the formation of thermodynamically stable products or *trans*-isomers. That probably results in the low stereospecificity of *cis*-I (*cis*-Ia in the gas phase and *cis*-Ib in tetrahydrofuran). Further, in the liquid phase, as the deactivation of an excited singlet to the vibrationally-excited ground state by collision with the surrounding molecules adds to inversion products by way of the ground state, the mode of stereospecificity may be reversed in *cis*-reactants (*cis*-Ia in ethanol). In contrast, *trans*-I can be twisted without bringing the substituents close to the nitrogens (Fig. 3B); therefore, the triplet species might decompose too slowly, as compared with the excited singlets, to exert any remarkable influence on the distribution of products. That implies the predominant control of orbital interaction in determining the stereochemical path in the gas phase (this conclusion contradicts the experimental finding with regard to *trans*-Ia in the gas phase).[14] Since there is little intervention of triplets, the stereospecificity of *trans*-I in the solution is lower by an extent corresponding to the deactivation of the excited singlets to the ground state by solvents (*trans*-Ia in ethanol). However, large substituents at both α and α' carbons keep themselves from approaching at the cost of thermodynamical stability. That is why *trans*-Ib is converted with a high stereospecificity of configurational retention.

Some 1-pyrazolines, α,β-disubstituted compounds (IIId), can avoid the strain, as is illustrated in Fig. 3C. Accordingly, these species obey the direction of orbital interaction in the excited singlets without any disturbance.

The α,α-disubstituted compounds, IIIa and IV, also suffer an appropriate strain (Fig. 3D) enough to take the triplet path of competing explicitly with the singlet path. However, the triplet reactions of these compounds do not affect the product ratios, since the resulting biradical intermediates have nearly equal thermodynamical stabilities whether they assume the *cis*-form or *trans*-form. In fact, the experiments seem to show that IIIa and IV behave as if the triplets were not concerned in distributing the product in spite of the suitable strains. This interpretation is supported by the fact that, while the photo-induced transformation of *meso*- and *d,l*-IV yield the respective products, thus maintaining the configuration, both *cis*- and *trans*-reactants in general give the same product as the major component in the triplet-sensitized reactions under thermodynamical control.

The Compounds with a Conjugative Part Interacting with Weakening C-N Bonds

Before discussing other cyclic azo compounds, we must consider how they diverge from 1-pyrazolines and their homologues. The cyclic azo compounds treated in this section have a "conjugative" part interacting with incipient orbitals appearing at the carbons as the C–N bonds are weakened. This orbital interaction, rather than that which is responsible for the weakening of the C–N bonds, presumably governs the stereochemical path. This assumption is founded on the fact that two C–N bonds can be approximately separated from the N–N σ-bond since weakening σ-bonds tend to have a π character to some extent. In consequence, the whole of the reactant may be divided into the part and two C–N bonds. The respective MO's of the C–N bond system are assigned in Fig. 4.

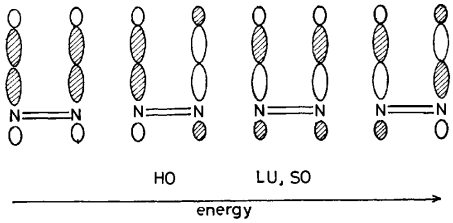

Fig. 4. Relation between orbital symmetry and energy level of two σ-bonds system.

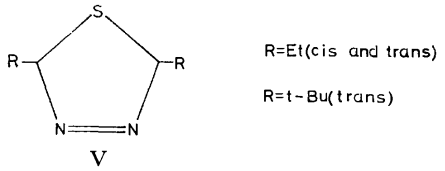
Our discussions will begin with the reaction of 1-pyrazoline and the analogue bearing a conjugative part at the β carbon. When the conjugative part consists of *exo* π-orbitals, *e.g.*, 4-alkylidene-1-pyrazolines, the particularly important orbital interactions are probably that between the HOMO (S) of the π-orbitals and the LUMO (S) of the C–N bonds and that between the LUMO (S) of the former and the HOMO (A) of the latter.[15] Accordingly, the stereospecificity of the compounds depends upon the balance between these two competitive modes of orbital interactions. That is, the configuration may be retained during the reaction when the interaction between symmetrical and symmetrical MO's prevails over the other and may be singly inverted when symmetrical and anti-symmetrical interaction dominates. No information has been obtained so far which shows which mode is predominant. However, when the conjugative part is a lone pair (V), there is no appropriate LUMO localized on this part. This implies the exclusive operation of the orbital interaction between the lone pair as the HOMO (S) and the LUMO (S) the C–N-bond system (Fig. 5). It follows that V goes through thiocarbonyl ylide as an intermediate to produce an adduct with a certain dipolarophile by way of a 4+2 π thermally-allowed-cycloaddition process, with the configuration retained throughout the re-

14) This exceptional distribution of products which slips out of our consistent interpretation does not argue radically against the effectiveness of orbital interaction scheme. The internal conversion of electronic excited state to vibrationally excited state in photolysis take place considerably even in the gas phase. (See Ref. 4a and the references therein.)

15) However there is a communication that the thermolysis of VII yields as a major the recyclization product due to C_α–$C_{\alpha'}$ bond formation against the distribution in the equilibrium. This observation suggests that 4-alkylidene-1-pyrazoline could partially neglect the alkylidene part to behave as 1-pyrazoline. (See Ref. 18c.)



V

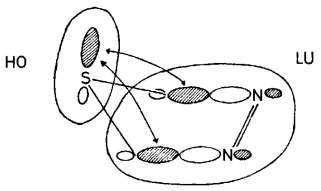


Fig. 5. The mode of orbital interaction in the pyrolysis of thiadiazoline.

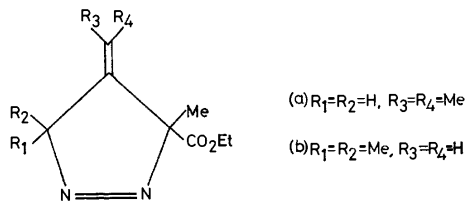
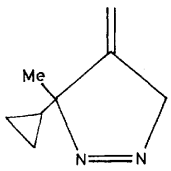
action.[16]

The orbital symmetry assigned to 1-pyrazoline under irradiation is still quite important in any discussion of the photochemical transformation of 4-alkylidene-1-pyrazoline on the grounds that an orbital interaction responsible for weakening C–N bonds is desirable for the incipient orbitals at the carbons to move in the same direction.[17] As a result, the extrusion reaction provides, as a major product, the product arising from the direct bond formation by overlapping between the orbitals which result as the C–N bonds weaken. A few related experiments are known.[18]

In the sensitized reaction, the resultant unpaired electrons with parallel spins have an opportunity to redistribute themselves, which would allow the trimethylenemethane intermediate to reach a stable state. That these reactions occur under the thermodynamical control is supported by the experiment which has demonstrated that the distributions of two possible alkylidenecyclopropanes due to recyclization, originating from VIa and from VIb, are nearly identical.[18] The further the two unpaired electrons with parallel spins are separated from each other, and the greater the extent to which these electrons can be delocalized, the more stable the electronic state becomes. According to this principle, all sorts of unsaturated groups or those substituents with lone-pair electrons, attached to the carbon atom at which an unpaired electron appears, will facilitate



VI



VII

the cyclization. A few experiments are compatible with the results of this discussion, showing that lone pairs at chlorine and at oxygen of the ester group help unpaired electrons to delocalize.[18] With respect to VII, the π character of the cyclopropane ring acts a part corresponding to that of the pure π orbitals.[18c]

The stereochemical behavior of the compounds with one conjugative or strained bond between β and β' carbons will now be discussed. The particularly important orbital interactions in the thermolysis include that between the HOMO (S) of the C_β–$C_{\beta'}$ bond and the LUMO (S) of the C–N bonds and that between the LUMO (A) of the former and the HOMO (A) of the

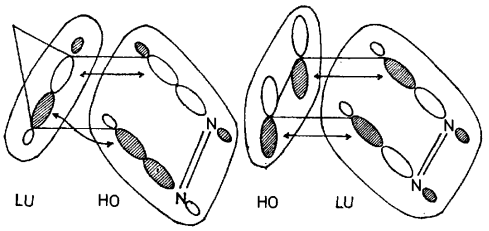

Fig. 6. The mode of orbital interaction in the pyrolysis of bicyclic azo compounds with strained β,β' σ-bond.

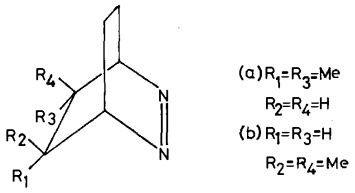
Fig. 7. The mode of orbital interaction in the pyrolysis of cyclic azo compounds with a π-bond.

latter. These modes of orbital interaction favor the disrotatory opening of a fused small ring (Fig. 6) or the formation of two π-bonds adjacent to the original π-bond (Fig. 7). These processes accompanying the extrusion are thermally possible (Experiments 1, 2, and 3). The steric paths of the photochemical reactions are complicated by the variable extent to which the photochemically generated SOMO participates directly in the orbital interaction determining the stereochemical course. The initial orbital interaction between the LUMO of the C–N–N–C-bond system and the SOMO of the N–N π-bond may only weaken the C–N bonds, without having any other effects. The HOMO, the level of which must be considerably elevated by this bond weakening, will participate in the interaction with the LUMO of the C_β–$C_{\beta'}$ bond. This orbital interaction is identical with that which operates in the pyrolytic extrusion, leading to the corresponding compounds as well as to thermolysis (Ex. 1 and 2a). The bond formation between the carbons next to the nitrogen (Ex. 1 and 3) may be ascribed to the favorable movement of the atomic orbital lobes in the same direction as was illustrated in connection with the photolysis of 1-pyrazoline (Fig. 2B).

The Compounds Undergoing Cleavage of the Unstrained σ-Bond Bridging between β and β' Carbons

Fig. 8 shows a presumptive energy level relationship between the HOMO and the LUMO of strained and unstrained C_β–$C_{\beta'}$, bonds as well as the C–N-bond system. The reactants with a strained C_β–$C_{\beta'}$ bond could initiate the orbital interaction between the strained bond and the C–N bonds on the weakening of the C–N bonds, for the energy gaps between the frontier orbitals



(a) $R_1=R_3=Me$, $R_2=R_4=H$
(b) $R_1=R_3=H$, $R_2=R_4=Me$

VIII

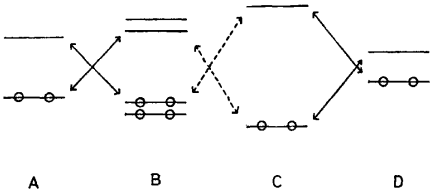


Fig. 8. Estimated energy levels of frontier orbitals of a strained σ-bond (A), two C–N bonds system. (B), an unstrained σ-bond (C) and a quasi-σ-bond (D).

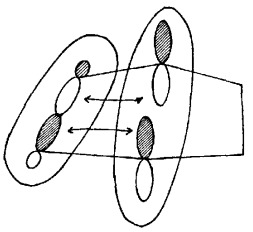

Fig. 9. The mode of orbital interaction in the pyrolysis of cyclic azo compounds with unstrained β,β' σ-bond.

are narrow. In contrast with the strained bond, the level separation between the frontier orbitals of the unstrained bond are so large that the orbital interaction will not be sufficient to break the C_β–$C_{\beta'}$ bond until the C–N bonds become seriously weakened. According to the weakening of the C–N bonds, the appearing orbitals on α carbons come to have an approximate π character. "quasi-π" orbitals can interact with the unstrained C_β–$C_{\beta'}$ bond to cause the fission. The assignment of the orbital lobes and the mode of division of the reactant are analogous to the ring opening of cyclobutene, as is depicted in Fig. 9. This illustration explains the conrotatory bond scission of the unstrained bond in the pyrolysis.[22]

Remarks

The stereospecificity of the extrusion reactions of cyclic azo compounds, which seems to be chaotic, is found to be put into order comprehensively under the government of orbital interaction between the relevant parts in the molecule. During a consideration on the basis of orbital interaction we have found that the parts between which the orbital interaction should be considered to determined the stereochemical course are variable, even in the reaction of similar compounds, and that thermal and photochemical reactions are not always counterparts of each other in the sense of stereospecificity.

The mechanism is proposed by the reporters that the compound undergoes conrotatory ring opening after the bridge bond cleaves to produce cyclopentane-1,3-diyl biradical; J. A. Berson, W. Bauer, and M. M. Campbell, *J. Amer. Chem. Soc.*, **92**, 7515 (1970).

Synthetic Reactions by Complex Catalysts. XXV.[1] The Copper-catalyzed Reaction of Allyl Isocyanide with Carbonyl Compounds and Olefins. Syntheses of 4-Vinyl-2-oxazoline and 5-Vinyl-1-pyrroline Derivatives

Takeo SAEGUSA, Ichiki MURASE, and Yoshihiko ITO
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
(Received June 11, 1971)

This paper describes two reactions of allyl isocyanide (AIC) by means of the Cu_2O catalyst; these reactions produce heterocyclic compounds with vinyl substituents. First, the reactions of AIC with such carbonyl compounds as ketones and aldehydes produce 4-vinyl-2-oxazoline derivatives (**1**) in good yields. Second, AIC also reacts with the C=C double bond of α,β-unsaturated nitriles and esters to produce 5-vinyl-1-pyrroline derivatives (**4**, **5**, and **6**). A mechanistic scheme involving an isocyanoallylcopper complex (**11**) has been assumed.

This paper will describe the Cu_2O-catalyzed reactions of allyl isocyanide (AIC) with carbonyl compounds (Eq. (1)) and with olefins (Eq. (2)). The products are 4-vinyl-2-oxazoline and 5-vinyl-1-pyrroline derivatives respectively. These synthetic reactions have been found

in a series of exploration studies of the catalytic behavior of the copper-isonitrile complexes.[2-4] Especially, they are closely related to our recent finding of oxazoline and pyrroline syntheses[4] in which benzyl isocyanide (**3a**) and carbethoxymethyl isocyanide (**3b**) are reacted with carbonyl compounds and with olefins respectively in the presence of Cu_2O as the catalyst (Eqs. (3) and (4)).

Results and Discussion

Reaction of AIC with Carbonyl Compounds. Synthesis of 4-vinyl-2-oxazoline Derivatives. The results of the reaction of AIC with carbonyl compounds by means of the Cu_2O catalyst are shown in Table 1. 4-Vinyl-2-oxazoline derivatives (**1**) were obtained in high yields with high selectivities. Here, the oxazolines, **1b**, **1e**, and **1f**, are mixtures of the two diastereomers due to the 4-C and 5-C configurations. The ratios are given in Table 1.

In this reaction, the isomerization of AIC to propenyl isocyanide (PPIC) takes place concurrently. After the reaction, the unreacted AIC was found to isomerize to PPIC. The IR spectrum of the lower-boiling fraction (at 5 mmHg, room temperature) from the reaction mixture showed an absorption at 2120 cm^{-1} of $\nu_{N\equiv C}$ of PPIC,[5] which differed from that of AIC ($\nu_{N\equiv C}$ at 2150 cm^{-1}). The isomerization from AIC to PPIC is, however, reversible. With the Cu_2O catalyst, PPIC was reacted with benzaldehyde to produce **1e** in an almost quantitative yield (Table 1). As will be mentioned later, the reversible isomerization of AIC⇄PPIC probably proceeds through the α-isocyano-organocopper complex (**11**), which is also the key intermediate in the reaction of AIC with carbonyl compounds to produce oxazoline derivatives.

Reaction of AIC with Olefins. Synthesis of 5-Vinyl-1-pyrroline Derivatives. The results of the Cu_2O-catalyzed reaction of AIC with α,β-unsaturated esters and nitriles are shown in Table 2. The derivatives of 1-

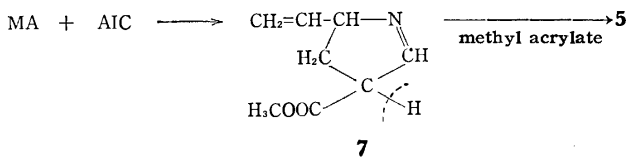
pyrroline, **4**, **5**, and **6**, were produced. In this reaction, **4a**, **4b**, and **5** were obtained as mixtures of the two isomers due to the 3-C and 5-C configurations (The ratios are given in Table 2).

As is shown in Table 2, the selectivity of the pyrroline synthesis by the AIC-olefin reaction is generally lower than that of the oxazoline synthesis shown in Table 1. The dimerization and polymerization of olefin by the Cu_2O-isonitrile system occur simultaneously, and together they decrease the pyrroline yield.

Similarly to the case of the reaction with carbonyl compounds, the isomerization of AIC to PPIC occurred concurrently. Sometimes PPIC was isolated from the reaction mixture of AIC by vacuum distillation (5 mmHg) at room temperature. Furthermore, the reversibility of AIC⇄PPIC isomerization was also demonstrated in this reaction; *i.e.*, **4a** was produced in the reaction of PPIC with methyl methacrylate. The conversion of PPIC to a dark tarry material disturbed the pyrroline formation. In the PPIC-olefin reaction, only a trace of unreacted PPIC remained, and the PPIC was converted mostly to a dark-brown tar. The strong tendency of PPIC to polymerize to a dark tar was observed also in an experiment isomerizing AIC to PPIC.[5]

As has been mentioned previously, the AIC-olefin reaction is not always clean. In the reaction of AIC with methyl acrylate, **5** was isolated as the main product; it was thought of as being formed by the Michael addition[3,4] of the first pyrroline product, **7**, to another molecule of olefin. Here, the first pyrroline product was not isolated. Probably the rate of the formation of **7** is slower than that of the Michael reaction of **7** with methyl acrylate.

In the case of crotononitrile, the main reaction was its dimerization. The dimerization of crotononitrile by the Cu_2O-isonitrile system has already been found by us.[2] In the AIC-crotononitrile·Cu_2O mixture, the crotononitrile dimerization suppressed the pyrroline formation (Table 2). In addition, the pyrroline product of



7

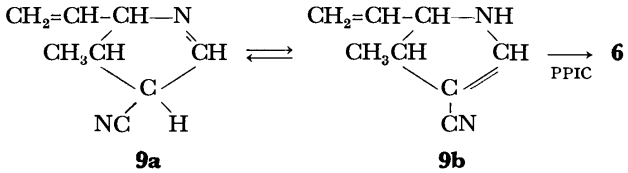
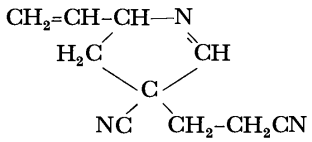
8

this reaction was **6**, which was explained as being derived from the primary product (**9a**) by the copper-catalyzed formimidation[6] of this tautomer (**9b**) with PPIC. The tautomerization of **9a**⇄**9b** has been found in our previous study of the pyrroline synthesis;[4] the copper-catalyzed formimidation of the >NH bond has also been reported.[6]



9a **9b**

In the reaction of AIC with acrylonitrile in benzene and DMF, only a trace of the pyrroline product, **10**, was detected by glpc (silicones; column temperature, 200°C). This was due to the polymerization of acrylonitrile by Cu_2O-isonitrile.[7] The polymerization of acrylonitrile by the Cu_2O-isonitrile system as well as the Cu_2O-isonitrile-active hydrogen compound system has been reported by us.[7]



10

Reaction Scheme

On the basis of the scheme for the reactions of benzyl and carbethoxymethyl isocyanide with carbonyl and olefinic compounds, the following scheme may be presented for the reactions of AIC in the present study. First, the isocyanoallylcopper-isonitrile complex (**11**) is formed by the abstraction of α-hydrogen from AIC by Cu_2O. Probably, the coordination of the isocyano group of AIC to another copper complex facilitates the hydrogen abstraction by decreasing the electron density of the α-carbon atom. The α-isocyanoallylcopper complex (**11**) adds to the >C=O or >C=C< group to produce a new-formed copper species (Step 2), and the intramolecular reaction between the copper species and the isocyano group in **12** gives rise to the ring closure, thus producing **13** (Step 3). The abstraction of the α-hydrogen of another AIC molecule by **13** produces **11** and the final product, **14** (Step 4). Thus, the organocopper species is regenerated and the reactions proceed catalytically.

The α-isocyanoallylcopper complex acts as the key intermediate in the AIC⇄PPIC isomerization[5] also as is indicated in the scheme. The formation of **11** is supported by the fact that when the AIC-Cu_2O mixture was treated with allyl bromide, 3-isocyano-1,5-hexadiene (**15**) was isolated.[5]

$$\mathbf{11} + CH_2CH\text{-}CH_2Br \longrightarrow CH_2{=}CHCH(CH_2CH{=}CH_2)\text{-}NC$$

15

Experimental

Reagents. AIC was prepared according to Ugi's procedure,[8] while PPIC was prepared by the isomerization of AIC by the Cu_2O catalyst.[5] The carbonyl compounds were all commercial reagents and were purified by distillation under nitrogen. The α,β-unsaturated esters and nitriles were all commercial reagents which has been purified by distillation under nitrogen. The cuprous oxide was a commercial reagent of an analytical reagent grade and was dried under a nitrogen atmosphere prior to use.

Reactions with Carbonyl Compounds. An equimolecular mixture of isonitrile and carbonyl compounds and catalytic amounts of Cu_2O in benzene was reacted in a sealed test tube under nitrogen under the conditions shown in Table 1. The products were then isolated by vacuum distillation and purified by preparative glpc. The product structures were determined by IR, NMR, and elementary analysis. The identification data of the products are summarized in Table 3.

Reactions with Olefins. The reactions were carried out by a procedure similar to those used with carbonyl com-

The identification of **8** was made by a comparison of its IR and NMR with those of an authentic sample.[2] The identification of **6** was made by means of its IR and NMR, while the structure of **10** was assumed on the basis of its IR spectra. The identification data of the AIC-olefin reaction products are summarized in Table 4.

Studies of Thioiminocarbonates. II. The Cyanide Ion-catalyzed Addition of Alcohols to Thiocyanates

Kazuhiko TANAKA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received June 17, 1971)

It was found that thiocyanates reacted with methanol in the presence of a catalytic amount of cyanide ion to give thioiminocarbonates. The effects of other catalysts upon the addition of methanol to thiocyanates were examined: the azide ion and the methoxide ion were effective, while triethylamine, sodium thiocyanate, potassium iodide, triphenylphosphine, sodium acetate, and mercuric cyanide were ineffective. A plausible reaction mechanism involving the addition of the cyanide ion to thiocyanates was proposed.

Although the scission of unsymmetrical diaryl disulfides by various S-nucleophiles has been discussed by Parker and Kharasch,[1] the cleavage products have not been isolated and characterized. Hiskey and Carroll investigated the cyanide-ion cleavage of unsymmetrical disulfides in detail.[2]

They reported that, when methyl phenyldithioacetate was treated with the cyanide ion, 12.5% yields of phenyl thiocyanate were obtained. However, no report has appeared concerning the scission of symmetrical diaryl disulfides by the cyanide ion. In a previous paper, we reported that symmetrical diaryl disulfides were readily cleaved by the cyanide ion in alcohol to afford aryl mercaptides and aryl thiocyanates, which then reacted with the alcohol used as the solvent to afford alkyl aryl sulfides:[3]

$$ArS\text{-}SAr + CN^- \rightleftharpoons ArS^- + ArSCN \quad (1)$$

$$ArSCN + ROH \longrightarrow ArS\text{-}\underset{\displaystyle OR}{\underset{|}{C}}{=}NH \quad (2)$$

$$ArS\text{-}\underset{\displaystyle OR}{\underset{|}{C}}{=}NH + CN^- \longrightarrow ArSR + OCN^- + HCN \quad (3)$$

When *p*-tolyl thiocyanate was treated with an equimolecular amount of the cyanide ion in methanol at a low temperature, a mixture of methyl *p*-tolyl sulfide and *O*-methyl *S*-*p*-tolyl thioiminocarbonate was obtained.[4] In continuing these investigations, we have found that the treatment of thiocyanates with methanol in the presence of a catalytic amount of the cyanide ion gave thioiminocarbonates in good yields.

Results and Discussion

When phenyl thiocyanate (0.1 mol) was treated with methanol in the presence of a catalytic amount of sodium cyanide (0.014 mol) at 0°C for 6 hr, *O*-methyl *S*-phenyl thioiminocarbonate was obtained in a 72% yield. The product showed NMR peaks at τ 5.94 (OCH_3), 2.86 (NH), and 2.27 (C_6H_5), with relative intensities of 3: 1: 5. Its infrared spectrum contained a strong band at 1628 cm^{-1} (C=N) and a weak band at 3300 cm^{-1} (NH). In a similar way, various thioiminocarbonates were prepared from thiocyanates and methanol by using the cyanide ion as the catalyst. The results are summarized in Table 1. Of the various catalysts examined, it was found that sodium azide and sodium methoxide were effective, while triethylamine, sodium thiocyanate, potassium iodide, triphenylphos-

phine, sodium acetate, and mercuric cyanide were ineffective, in the formation of thioiminocarbonates.

Information about the mechanism of the base catalysis can be obtained by measuring the pseudo-first-order rates at varying cyanide-ion concentrations. The plot of [NaCN] against 10^2k gives a straight line, showing that the catalytic effect is directly proportional to the concentration of the cyanide ion. The calculated values of 10^2k in Table 2 are derived from the expression: $k=3.70\times10^{-3}+1.90\times10^{-1}$[NaCN], where the 3.70×10^{-3} value is that for the slow uncatalyzed reaction and 1.90×10^{-1}, that for the catalytic coefficient (k_c) of the cyanide ion.[5]

The pseudo-first-order rates of the reaction of substituted aryl thiocyanates are listed in Table 3. The rates are slightly accelerated when the substituent is electron-withdrawing. On the basis of the observations presented earlier, the reaction scheme of the addition of methanol to thiocyanates in the presence of a cyanide-ion catalyst may be postulated to be as follows:

Table 2. Rates of cyanide ion-catalyzed addition of *p*-tolyl thiocyanate with methanol at 0°C

thiocyanate,[9] and ethyl thiocyanate[10] were prepared as has been described in the literature. *p*-Tolyl thiocyanate and *m*-tolyl thiocyanate were prepared by the same method from the corresponding toluidines. *p*-Tolyl thiocynate, bp 127—129°C/19 mmHg; *m*-tolyl thiocyanate, bp 111—115°C/11 mmHg.

Preparation of Thioiminocarbonates. After a mixture of phenyl thiocyanate (0.1 mol, 13.5 g) and powdered sodium cyanide (0.0143 mol, 0.7 g) in absolute methanol (200 m*l*) has been stirred at 0°C for 6 hr, the methanol was evaporated *in vacuo*. Petroleum ether (200 m*l*) was added, and the mixture was washed with water two times. An organic layer was separated and dried with anhydrous sodium sulfate. The filtrate was evaporated, and the residual oil was distilled *in vacuo*; bp 82—89°C/3 mmHg. The recrystallization of the distillate, which solidified at room temperature, from petroleum ether gave 12 g (72%) of *O*-methyl *S*-phenyl thioiminocarbonate as a transparent rhombic crystal; mp 35—36°C. IR: 3300 (NH), 1628 cm^{-1} (C=N). NMR (in CCl_4) τ 5.94 (3H, s, OCH_3), 2.86 (1H, s, NH), 2.27 (5H, s, C_6H_5). In a similar way, other thioiminocarbonates were prepared. Their physical properties and elemental analyses are listed in Table 4.

Effects of Catalysts. To a solution of *p*-tolyl thiocyanate (0.05 mol) in absolute methanol (50 ml), we added 0.01 mol of a catalyst, after which the mixture was stirred at 0°C for 1 hr. Then the methanol was evaporated under reduced pressure, and ether was added to the residue. A usual work-up and distillation gave a colorless oil. Sodium cyanide, sodium azide, and sodium methoxide were effective, and *O*-methyl *S*-*p*-tolyl thioiminocarbonate was obtained, as is shown in Table 1. Triethylamine, sodium thiocyanate, potassium iodide, triphenylphosphine, sodium acetate, and mercuric cyanide were ineffective, and the *p*-tolyl thiocyanate was recovered unchanged (77—99%).

Determination of the Reaction Rates. Sodium cyanide ($1.17—10.5\times10^{-3}$ mol) was dissolved in a solution of 2.94×10^{-2} mol of aryl thiocyanates in 200 m*l* of absolute methanol placed in a constant-temperature bath at 0 ± 0.05°C. At various intervals, 15-m*l* aliquots were removed and poured into a mixture of *n*-hexane (10 m*l*) and saturated aqueous sodium chloride (50 m*l*). The sample was extracted and again with 10 m*l* of *n*-hexane. From each run thus obtained, the amount of thiocyanate were measured by glc.

The author wishes to thank Professor A. Kaji and Dr. J. Hayami for their discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 836—840(1972)

Isolation of the Intermediate in the Tricyanovinylation of Indole and *N*-Methylindole

Yasuhiko SHIROTA, Sadayuki EZAKI,* Shigekazu KUSABAYASHI,** and Hiroshi MIKAWA
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka
(Received June 28, 1971)

The intermediate has been isolated in the tricyanovinylation of indole and *N*-methylindole. The neutral adduct structure at the 3-position is assigned on the basis of spectroscopic as well as chemical evidence. The mechanism for tricyanovinylation is discussed.

The tricyanovinylation of aromatic amines at either N-position or *para*-position by the reaction with tetracyanoethylene is well known.[1] Indole and its derivatives are also known to undergo tricyanovinylation at the 3-position.[2,3] In these tricyanovinylation reactions tetrahydrofuran, dimethylformamide or pyridine has usually been used as the solvent. Kinetic studies in chloroform or in dichloromethane have shown that the reaction involves three steps:[4,5] (a) rapid formation of a 1: 1 charge-transfer complex (π-complex), (b) formation of a zwitterionic σ-complex, (c) elimination of hydrogen cyanide from the σ-complex to form the final product. In the process of hydrogen cyanide elimination which is the rate-determining step, the

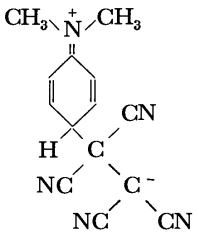
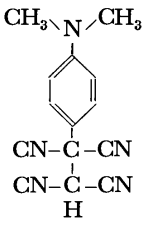
amine or indole is suggested to act as a proton-abstractor. The proposed mechanism with indole is shown as an example in Scheme 1.

Concerning the above mechanism it should be mentioned that while the formation of the charge-transfer complex is visually observable, the intermediacy of the σ-complex was inferred by indirect evidence.[6] Recently Farrell *et al.* have succeeded in isolating an intermediate from the tetracyanoethylene-*N,N*-dimethylaniline reaction by changing the solvent. The structure of the isolated intermediate had first been assigned to the zwitterionic σ-complex (I),[7] but later the neutral adduct structure (II) was shown to be the correct one.[8] Rappoport and



(I)



(II)

Shohamy have also achieved the isolation of intermediates in the tricyanovinylation of several primary aromatic amines by introducing the *ortho*-substituents to the amino group.[9] In this case tricyanovinylation occurs at the *para*-position instead of the N-position owing to steric crowding. It has been claimed that the *ortho*-substituted amine is too bulky to be very effective as a proton-abstractor from the intermediate, thus increasing its lifetime and enabling its isolation. Neutral adduct structure like II is assigned from the spectroscopic evidence.

Indole and its derivatives are less basic than aromatic amines, and thus less effective as a proton-abstractor since the unpaired electrons on nitrogen atom participate in the aromatization. It was therefore expected that under favorable conditions isolation of the intermediate would be possible.[10] In the present study we have isolated the intermediate in the tricyanovinylation of indole and *N*-methylindole. Spectroscopic evidences are presented to indicate the neutral adduct structure (III), and the mechanism for tricyanovinylation is discussed.

Results and Discussion

When a half equimolar amount of tetracyanoethylene was mixed with *N*-methylindole in benzene at room temperature, a blackish purple color characteristic of the charge-transfer complex developed immediately. The solution was left at room temperature for 24 hr, during which time the initial blackish purple color slowly faded away to become slighlty reddish yellow. White crystalline solids were precipitated from the solution, collected by filtration and recrystallized from benzene to give white needles. Removal of the solvent *in vacuo* gave additional white solids together with recovered *N*-methylindole. When equimolar amounts of tetracyanoethylene and *N*-methylindole were refluxed in benzene for 7 hr, white needles and the final tricyanovinylated compound, *N*-methyl-3-tricyanovinylindole (VIIa), were obtained simultaneously. The isolated white needles were almost quantitatively converted into VIIa with a loss of hydrogen cyanide when heated in methanol for a few hours. The molecular ion peak of the isolated white needle is observed at *m/e* 259 in the mass spectrum. From these results and from other spectral evidences described below together with the elemental analysis, the isolated white needle was concluded to be the intermediate adduct between *N*-methylindole and tetracyanoethylene, which led to the final substitution product VIIa. The yields of the isolated intermediate were 97% in the reaction at room temperature and 65% in the reaction under reflux. Simultaneous formation of VIIa under reflux appears to result from a thermal decomposition of the isolable intermediate.

The intermediate in the tricyanovinylation of indole was similarly isolated. A benzene solution of indole was added to a solution of a half equimolar amount of tetracyanoethylene in benzene. The initial blackish purple color faded slowly and after 24 hr the solution turned reddish orange. From this solution the intermediate adduct and the final tricyanovinylated compound, 3-tricyanovinylindole (VIIb), were obtained in 83% and 16% yields, respectively. When the reaction solution was refluxed for 7 hr, the main product isolated was VIIb (54%), the intermediate adduct being obtained only in a 14% yield. The isolated intermediate from the reaction of indole was likewise con-

8) P. G. Farrell and R. K. Wojtowski, *ibid., B*, **1970**, 1390.

9) Z. Rappoport and E. Shohamy, *ibid., B*, **1969**, 77.

10) Before kinetic studies of the tricyanovinylation reaction were made by Rappoport,[4] and Foster and Hanson,[5] Noland *et al.*[3] had reported in their synthetic studies of tricyanovinylated compounds from indole and its derivatives that in one case, with 2-methylindole, the intermediate was isolated and found to be the adduct tetracyanoethane based on a brief characterization.

verted almost quantitatively into VIIb when heated in methanol. The elementary analysis of the intermediate was in good agreement with the adduct structure between indole and tetracyanoethylene.

Both of the isolated intermediates are relatively stable and can be stored for several days when kept dry below room temperature. The intermediate derived from indole is less stable than that derived from *N*-methylindole, which is also reflected in the results of their preparative reactions described above. They are almost insoluble in carbon tetrachloride but soluble in acetone or tetrahydrofuran. On contact with moisture or basic solvent they slowly turn through pink to red to form the final tricyanovinylated compounds.

The follwing possible structures from IIIa and IIIb to VIa and VIb are conceivable for the isolated intermediates which lead to the final substitution products VIIa and VIIb. Of these structures IIIa and IIIb were assigned from the sepctral evidences.

Infrared Spectra. The infrared spectrum of the isolated intermediate from *N*-methylindole in KBr disk shows a sharp strong absorption at 2900 cm^{-1} which is characteristic of the intermediate and assignable to the aliphatic tertiary C–H stretching vibration. The absorption at 2900 cm^{-1} in the intermediate corresponds to that observed at 2900 cm^{-1} in tetracyanoethane and in *N,N*-dimethyl-4-(1,1,2,2,-tetracyanoethyl)aniline (II).[9] While a sharp absorption characteristic of the conjugated C≡N group appears at 2200 cm^{-1} in VIIa, only a very weak absorption of the unconjugated C≡N group appears at 2260 cm^{-1} in the isolated intermediate. Similarly the spectrum of the intermediate derived from indole in KBr disk shows the characteristic absorption at 2900 cm^{-1}. In this case a very weak absorption at 2260 cm^{-1} and a sharp absorption at 2200 cm^{-1} are observed in the cyano-band region. It is suspected that the intermediate decomposed partly to VIIb during the preparation of the disk as suggested from its reddish orange color. When the spectrum is taken in Nujol mull with a freshly prepared sample, no absorption appears at 2200 cm^{-1}, although in VIIb a sharp strong band appears at 2200 cm^{-1} due to the conjugated C≡N group. The absorption of the unconjugated C≡N group of the intermediate at 2260 cm^{-1} is so weak as to be hardly detectable in Nujol mull. It is generally accepted that cyano-compounds with electron-withdrawing substituents at the α-position frequently show only weak absorption or sometimes no absorption of the C≡N group.[11] It should also be noted that many compounds containing $-C(CN)_2$ moiety are reported to show two medium bands at the unsaturated cyano-band region.[12] In the spectrum of the intermediate derived from indole a single, rather strong band of the secondary N–H stretching vibration appears at 3300 cm^{-1} as observed in indole and in VIIb at 3380 and 3200 cm^{-1}, respectively. No absorption ascribable to the $-\overset{+}{N}H_2$ or $C=\overset{+}{N}H$ group is observed in the regions, 2780—2500 cm^{-1} or 2500—2325 cm^{-1}, respectively[13,14] in both intermediates. The infrared spectra eliminate the σ-complex structures such as IV or V for the isolated intermediates, thus favoring structure III.

NMR Spectra. The NMR spectra of the isolated intermediate were measured in hexadeuterioacetone as soon as possible after the solutions were prepared. The intermediate derived from *N*-methylindole shows a singlet at τ 6.0 due to *N*-methyl protons, a singlet at τ 3.75 and multiplets at τ 1.9—2.8 due to aromatic protons including the proton at the 2-position in the indole ring, the relative ratios being 3 : 1 : 5. The singlet peak at τ 3.75 is reasonably attributed to the methine proton of the dicyanomethyl moiety in structure IIIa from consideration of the chemical shift value of τ 4.19 for tetracyanoethane.[9] The peak due to the *N*-methyl protons appears as a singlet at τ 6.63 (in $CDCl_3$) in *N*-methylindole[15] and at τ 5.84 in VIIa. Similarly the spectrum of the intermediate derived from indole exhibits a singlet at τ 3.74 and multiplets at τ 1.9—2.8 in the relative ratios of 1 : 6. In the latter the indole ring protons and the N-H proton are included. The NMR spectra exclude the cyclo-adduct structure VI with two methine protons which should couple with each other. Structures IV and V are also unlikely from the position and the relative intensity of the signals. In these structures the methine proton at the 3-position should be coupled with the neighboring carbon-bound hydrogen at the 2-position.[14] Thus the isolated intermediates leading to the tricyanovinylated compounds VIIa and VIIb are assigned to structures IIIa and IIIb, respectively, from both the infrared and NMR spectra.

Electronic and Mass Spectra. The electronic spectra of the intermediates IIIa and IIIb in benzene show maxima at 282 nm (log ε 3.62) and 279 nm (log ε 3.76), respectively.

Although the mass spectrum is of no particular use for distinguishing between the adduct structures, it is briefly described. Both intermediates IIIa and IIIb show very low molecular ion peaks at *m/e* 259 and *m/e* 245, respectively. The base peak appears at *m/e* 232 in IIIa and at *m/e* 218 in IIIb, which corresponds to the loss of hydrogen cyanide from the molecular ion. The position and relative intensity of the peaks below *m/e* 232 in IIIa and *m/e* 218 in IIIb are almost the same as those of the tricyanovinylated compounds VIIa and VIIb, respectively, except for the peaks at *m/e* 195 (very low intensity) and *m/e* 194 in IIIa and *m/e* 181 (very low intensity) and *m/e* 180 in IIIb. The characteristic peaks at *m/e* 195 and *m/e* 194 in IIIa and at *m/e* 181 and at *m/e* 180 in IIIb which are absent in the spectra of VIIa and VIIb correspond to the direct loss of $:C(CN)_2$ and $\cdot CH(CN)_2$ from the molecular ion, respectively. Other fragments below *m/e* 232 in IIIa and *m/e* 218 in IIIb are suggested to be formed by the fragmentation of VIIa and VIIb. The main peaks over *m/e* 180 observed in IIIa and IIIb are listed in the Table and the fragmentation course from the molecular ion to the ion of

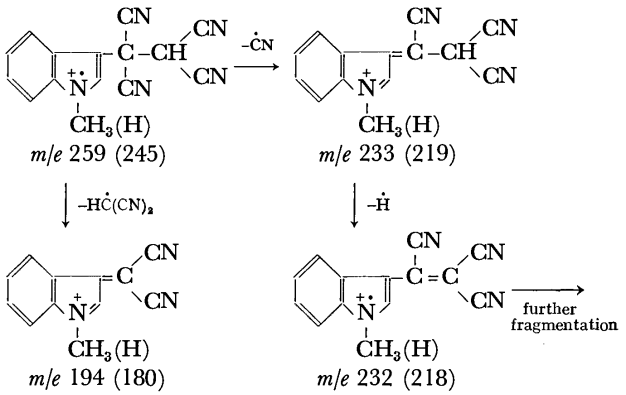

Scheme 2

the tricyanovinylated compound is depicted in Scheme 2.

Mechanism for Tricyanovinylation. It was shown from kinetic studies that the tricyanovinylation of aromatic amines or indole by tetracyanoethylene proceed in three steps as shown with indole in Scheme 1. However, a neutral adduct tetracyanoethane has recently been isolated as an intermediate in the tricyanovinylation of aromatic amines, and a general mechanism as shown in Scheme 3 has been proposed by Rappoport and Shohamy[9] for the tricyanovinylation of aromatic amines. In the present study a similar adduct tetracyanoethane has been isolated as an intermediate in the tricyanovinylation of indole and *N*-methylindole. Consequently, the same general mechanism as has been proposed for the tricyanovinylation of aromatic amines may be written also for the tricyanovinylation of indole and its derivatives.

$\longrightarrow$ Zwitterionic σ-Complex $\rightleftarrows$ Neutral Adduct
Final Substitution Product

Scheme 3

Although the neutral adduct intermediate was isolated under the present reaction conditions, it should be noted that there might be a possibility that the reaction proceeds as described in Scheme 1 under different reaction conditions. Especially, in strongly basic solvents such as pyridine or dimethylformamide it is likely that the tricyanovinylated compound is formed directly from the σ-complex, the basic solvent abstracting a proton from the 3-position in the σ-complex. Whether the final tricyanovinylated compound is formed *via* the neutral adduct intermediate or directly from the σ-complex under the given reaction conditions, where the intermediate can not be isolated, can be seen by examining the hydrogen isotope effect, the presence of which is expected in the elimination of hydrogen cyanide from the σ-complex (IV) owing to the relatively low acidity of the hydrogen at the 3-position.[16]

Experimental

Materials. Indole was obtained commercially and purified by recrystallization from *n*-hexane three times, mp 52°C. *N*-methylindole was prepared from indole as described by Potts and Saxton.[19] Crude distilled product was contaminated with unreacted indole as revealed by the N–H absorption in the infrared spectrum. Chromatograph over alumina and subsequent two distillations *in vacuo* yielded pure *N*-methylindole, bp 128—129°C/25 mmHg (lit.[19] bp. 133°C/26 mmHg). Tetracyanoethylene was obtained commercially, recrystallized from chlorobenzene and sublimed twice *in vacuo*, mp 201°C. Benzene was purified and dried in the usual way, and distilled from sodium wire immediately before use.

Spectra. Infrared spectra were taken with Hitachi EPI-G2 and Jasco IR-G infrared spectrophotometers. Electronic spectra were taken with a Hitachi 124 spectrophotometer. NMR spectra were obtained with a Japan Electron Optics Laboratory JNM 3H-60 spectrometer. Mass spectra were recorded with a Hitachi RMU-6E mass spectrometer by means of a direct inlet with an ionization energy of 70 eV.

Isolation of N-methyl-3-(1,1,2,2-tetracyanoethyl)indole (IIIa). Reaction 1. To a solution of tetracyanoethylene (0.64 g, 0.005 mol) in 40 m*l* benzene was added *N*-methylindole (1.31 g, 0.01 mol) dissolved in 5 m*l* benzene. A blackish purple color appeared immediately and the solution was left at 20°C for 24 hr. During that time the initial characteristic color of the charge-transfer complex slowly faded to a slightly reddish yellow. From the solution were precipitated white crystalline solids (IIIa), which were collected by filtration. Evaporation of the solvent *in vacuo* gave additional IIIa together with recovered *N*-methylindole (0.34 g). The total yield of IIIa was 1.26 g (97%). It was recrystallized from dry benzene to give a white needle. Prolonged heating or repeated recrystallization caused its partial decomposition to *N*-methyl-3-tricyanovinylindole (VIIa). On heating it gradually turned through pink to red above 100°C accompanied by its decomposition to VIIa, and melted at *ca.* 210°C.

Found: C, 70.07; H, 3.48; N, 26.22%. Calcd for $C_{15}H_9N_5$: C, 69.49; H, 3.50; N, 27.02%.

16) A kinetic hydrogen isotope effect was observed with a k_H/k_D value of 3.6 in the tricyanovinylation of *N,N*-dimethylaniline in chloroform owing to the relatively low acidity of *para*-hydrogen in I, while no isotope effect was found in the amine-catalyzed elimination of hydrogen cyanide from II due to the more acidic hydrogen in II[17,18]

19) K. T. Potts and J. E. Saxton, "Organic Synthesis," Vol. 40, (1960), p. 68.

Reaction 2. Solutions of tetracyanoethylene (1.28 g, 0.01 mol) and *N*-methylindole (1.31 g, 0.01 mol) were mixed and refluxed in 45 m*l* benzene for 7 hr. In this case the color of the solution remained black at the end of the reaction. Purple solids were obtained on cooling of the reaction solution. Evaporation of the solvent from the mother liquor also gave additional solids. They were collected and 50 m*l* of benzene was again added and reheated. The hot benzene solution was filtered to separate the insoluble red solids (VIIb, 0.23 g, 10%), which were recrystallized from methanol to give red fine needles. Cooling of the filtrate gave slightly pinkish white needles (IIIb, 1.69 g, 65%).

Isolation of 3-(1,1,2,2-tetracyanoethyl) indole (IIIb). Reaction 1. To a solution of tetracyanoethylene (0.77 g, 0.006 mol) in 40 m*l* benzene was added indole (1.41 g, 0.012 mole) in 5 m*l* benzene and left at 20°C for 24 hr. The initial blackish purple color faded slowly to a deep bluish purple and then to yellow and after 24 hr the solution turned reddish orange. The precipitated reddish pink solids were collected and dissolved rapidly in warm benzene. Insoluble red solids (VIIb) were separated (0.2 g, 16%) and from the filtrate was obtained IIIb as slightly pinkish white needles on cooling. The yield of IIIb was 1.23 g (83%). When heated to determine the mp, it gradually turned pink above 50°C and bove 100°C it turned reddish brown, decomposing to VIIb, mp *ca* 273—278°C. IIIb is less stable than IIId and prolonged heating or repeated recrystallizations from benzene caused considerable decomposition to VIIb.

Found: C, 68.29; H, 2.74; N, 28.50%. Calcd for $C_{14}H_7N_5$: C, 68.56; H, 2.88; N, 28.56%.

Reaction 2. Indole (1.17 g, 0.01 mol) dissolved in 5 m*l* benzene was added to a benzene solution (40 m*l*) of tetracyanoethylene (1.28 g, 0.01 mol) and refluxed for 7 hr. The solution was then cooled to 20°C and the precipitated blackish purple-colored solids were filtered off. Benzene (50m*l*) was again added, reheated to boiling for several minutes and filtered to separate the insoluble red solids (VIIb, 1.18 g, 54%). When the filtrate was cooled, slightly pinkish white needles (IIIb, 0.34 g, 14%) precipitated. In addition, small amounts of brown-colored solids were obtained from the initial mother liquor, which appeared to be *N*-tricyanovinylindole, since N–H absorption disappeared and strong conjuagted C≡N absorption was observed at 2200 cm^{-1} in the infrared spectrum.

Decomposition of IIIa and IIIb to VIIa and VIIb. IIIa or IIIb was heated in methanol for a few hours. The solution gradually turned red, and on cooling red fine needles VIIa or VIIb precipitated. The decomposition of the neutral adduct tetracyanoethane to the final substitution product was almost quantitative in each case.

Identification of VIIa and VIIb. VIIa: mp 226—226.5°C (recryst. from MeOH), (lit.[3] mp 218—219°C). IR: $\nu_{C\equiv N}$ 2200 cm^{-1}. Mass: M^+ *m/e* 232 (calcd 232). NMR: (in acetone) τ 5.84 (3H, singlet, N–CH_3), τ 1.9—2.8 (5H, multiplet, aromatic protons). UV and V: λ_{max} (in MeOH), 252 (log ε 3.91), 286 (log ε 3.99), and 460 nm (log ε 4.39). [lit.[3] in 95% EtOH. 262 (log ε 4.11), 280 (log ε 3.97), and 465 nm (log ε 3.91).]

Found: C, 71.89; H, 3.29: N, 24.06%. Calcd for $C_{14}H_8N_4$: C, 72.40; H, 3.47; N, 24.13%.

VIIb: mp 273—275°C (recryst. from MeOH), (lit.[3] mp 268—270°C). IR: $\nu_{C\equiv N}$ 2200 cm^{-1}, ν_{N-H} 3200 cm^{-1}. Mass: M^+ *m/e* 218 (calcd 218). NMR: (in acetone), τ 1.9—2.8 (multiplets, N–H proton and aromatic protons), UV and V: λ_{max} (in MeOH), 249 (log ε 3.95), 284 (log ε 4.00), and 454 nm (log ε 4.34). [lit.[3] in 95% EtOH, 251 (log ε 3.86), 285 (log ε 3.90), 357 (log ε 4.08), and 464 nm (log ε 4.33).]

Found: C, 71.84; H, 2.36; N, 25.11%. Calcd for $C_{13}H_6N_4$: C, 71.56; H, 2.57; N, 25.69%.

The Cope Rearrangement of Bridged Homotropilidenes Studied by MINDO Methods[1)]

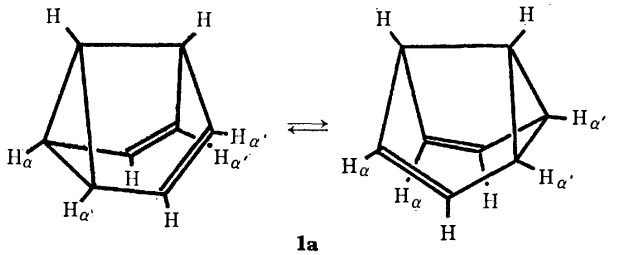
(Received July 2, 1971)

The theoretical structures and heats of formation of semibullvalene (**1a**), barbaralane (**1b**), and bullvalene (**1c**) have been investigated by the MINDO methods. The strain energies are estimated to be 19.7, 8.8, and 0.5 kcal/mol, respectively. The activation energies for the Cope rearrangement of these bridged homotropilidenes were obtained by a comparison of the results of a similar study on the biallylic transition states for the rearrangement. They are in good agreement with the experimental values. Extremely facile rearrangement in **1a** is attributed to the partial release of strain energy through the formation of the transition state, and to the proximity (2.16 Å) of the non-bonded termini of the divinylcyclopropane unit in the ground state.

Semibullvalene (**1a**) is unique for its extremely facile Cope rearrangement. The activation energies for the Cope rearrangement of homotropilidenes generally fall into the range 12 ± 1 kcal/mol when they are bridged by a chain of two carbon units as in bullvalene (**1c**) and dihydrobullvalene. One carbon bridged homotropilidenes undergo rearrangement more easily; barbaralane (**1b**) and barbaralone have an activation energy of *ca.* 8 kcal/mol.[2)] The NMR spectrum of **1a** consists of only three multiplets at δ 2.97, 5.08, and 4.17 ppm in the intensity ratio of 2:2:4, indicating that the chemical shift between the protons α and α' is averaged out in the time scale of NMR spectroscopy. The spectral pattern remains unchanged even at $-100°$ at 100 MHz.[3)] The activation energy of the degenerate Cope rearrangement represented by the following equation is thus expected not to exceed 5 kcal/mol.

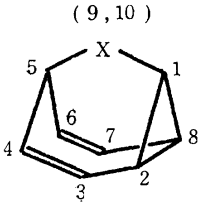


1a

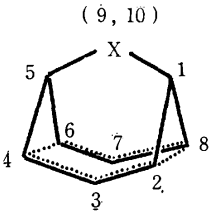
With no experimental technique available for obtaining further kinetic information on **1a**, and in view of recent success in the quantitative evaluation of the heat of formation by the all valence electron SCF MO theory at various levels of sophistication,[4)] we adopted this theoretical tool to clarify the structural uniqueness of semibullvalene which causes the lower barrier to the Cope rearrangement.

Method of Theoretical Calculation

In order to evaluate the activation energy for the Cope rearrangement theoretically, it is necessary to calculate and compare the total energy or heat of formation of the ground state and the corresponding transition state of the bridged homotropilidenes. Since the rearrangement is degenerate, the transition state geometry should be



1a, X = zero carbon bridge
1b, X = CH_2
1c, X = CH=CH



2a, X = zero carbon bridge
2b, X = CH_2
2c, X = CH=CH

symmetric with respect to the plane passing through the center of X and the carbon atoms numbered 3 and 7 as represented by **2a**—**c**, of which there is no *a priori* information as regards the precise geometry. Even the ground state conformation of the bridged homotropilidenes **1a**—**c** has not been reported except for bullvalene.[5)] The equilibrium geometry should be determined by minimizing the molecular energy with respect to all the bond lengths and angles for the ground state as well as the biallylic transition state.

In principle, optimization of geometry has to be made with respect to $3N-6$ internal coordinates. Although the number of the unknown is cut down considerably by the symmetry of the molecule, the computation time required would still be too long. As an example, reasonable assumption of C_s symmetry of **1a** still leaves the number of degree of freedom as 23. Fortunately we are allowed to take many of the bond lengths to be fixed to the standard values. In an extreme case, we may start with the standard bond lengths to effect faster

approach to the final geometry. This is necessary, when the MINDO/1 approximation is to be used, becuase the method is parametrized to give the observed heat of formation accurately only with the use of fixed standard bond lengths of Baird and Dewar.[6]

The methods employed here for calculating the geometry of **1** and **2** are based on the MINDO/2 approximation to the full SCF equations of Roothaan. A complete specification of this method together with a discussion of the approximations have been given.[7] The calculations were performed on a HITAC 5020E computer with the use of a modified MINDO program originally written by Baird and distributed by the QCPE organization.[8] The Jacobi method for diagonalization of the F matrices is replaced by the Householder method. The calculations were carried out to a level of self consistency where the change in energies and the maximum change in the bond order matrix were less than 0.0001 eV and 0.0004, respectively.

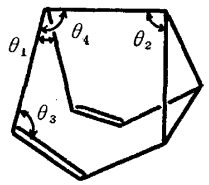

Fig. 1. Definition of angles changed as variables.

The procedure for calculating the geometry is exemplified by **1a**. Essentially the heat of formation was calculated for a systematically chosen set of bond angles shown in Fig. 1, and then minimized graphically. A set of numerical values were assigned to θ_1 to θ_4 and the coordinates of atoms were calculated using the standard bond lengths. The initial set of the angles was measured on molecular framework models of Prentice Hall, Inc.[9] Angle θ_1 was first adjusted by minimizing the molecular energy. Angles θ_2, θ_3, and then θ_4 were similarly calculated with the computed value for θ_1. θ_1 was recalculated with the new values for θ_2 through θ_4. The process was repeated until an absolute minimum in energy was obtained within 1° with respect to all bond angles. The coordinates for H_1 and H_5, the protons attached to C_1 and C_5, respectively, were similarly adjusted on the mirror plane of the molecule. The coordinates for H_3 and H_4 were calculated by assuming that they lie in the $C_2C_3C_4$ and $C_3C_4C_5$ planes, and the C_3–H_3 and C_4–H_4 bonds bisect the $C_2C_3C_4$ and $C_3C_4C_5$ angles, respectively. Finally optimization with respect to the carbon to carbon bond lengths was carried out. Since the optimized bond lengths always differ from the standard values by less than 1%, the change in the bond lengths is considered not to affect the optimized bond angles materially. In the MINDO/1 approximation, a value of 1.09 Å was assumed for all C–H bonds except 1.08 Å for the vinylic C–H bonds. All the C–H bond legths were uniformly shifted by +0.1 Å in the MINDO/2 calculations as suggested by Baird *et al.*[6,7]

As to the conformation of the transition state **2a**—**2c**, the bond lengths of C_1–C_2 and C_2–C_3, the interatomic distance C_1C_5, θ_1, θ_2, and θ_3 were taken as variables. θ_1 is defined as the angle between the planes $C_1C_2C_4C_5$ and $C_5C_6C_8C_1$. Displacement of C_3 and C_7 out of these planes, respectively, is expressed in terms of θ_2.

Results for Ground State Geometry

The theoretical structures for **1a**—**1c** are summarized in Table 1 together with the bond indices of Wiberg.[10] As the method is intended for calculation of the ground state geometry for which no experimental information is so far available, or of the transition state geometry which is not amenable to experimental investigation, it is desir-

able to test the computational method with molecules of known geometry. The calculated bond lengths in the cyclopropane rings of **1a—c** are uniformly 1.510 Å and are considerably shorter than 1.544 Å experimentally obtained for bullvalene.[5] They are, however, in good agreement with those usually observed in the cyclopropane derivatives.[11] The adjacent C_2C_3 distance of **1c** is optimized at 1.483 Å; the experimental value is smaller by 0.017 Å. The reason for the discrepancy is as yet not clear. Only for the consistency of comparison, the optimized geometry is adopted in the following discussion.
