(S) (+)-(N-α-Pipecolylmethyl)ferrocene (I). The optical resolution of α-pipecoline was performed by fractional recrystallizations of its hydrogen tartrate from water.[9] A mixture of (*S*) (+)-α-pipecoline ($[\alpha]_D$ +32.0° (neat) (*i.e.*, 89% optical purity based on the reported value 36.0°), 96.9 g, 980 mmol) and (dimethylaminomethyl)ferrocene methiodide (74.8 g, 200 mmol) in water (70 m*l*) was stirred under refluxing (120°C) for 65 hr. Work-up, followed by distillation, gave (*S*) (+)-I as a dark red oil (61.3 g, 96%); bp 147—150°C/0.3 mmHg; $[\alpha]_D$ +69.1° (*c* 2.1, EtOH). The IR and NMR spectra were superimposable on those of an authentic sample.[1]

Methyl (1S) (−)-2-Hydroxymethylferrocenecarboxylate (III). The lithiation of the amine (+)-I ($[\alpha]_D$ +69.1° (EtOH), 36.3 g, 130 mmol) with *n*-BuLi, followed by carbonation, gave a lithium salt of the amino acid.[1] The treatment of the lithium salt with an excess of methyl iodide in methanol gave a crude methiodide (124 g), which was subsequently heated under reflux for 25 hr with aqueous KOH (10%, 600 m*l*). The resulting product was esterified with diazomethane to afford (*1S*) (−)-III ($[\alpha]_D$ −22.5° (*c* 5.5, $CHCl_3$), 8.0 g, 23%). This alcohol was identified by comparison with an authentic sample (IR, NMR).[1]

Preparation of Methyl (1S) (−)-2-(β-Methoxycarbonylvinyl)-ferrocenecarboxylate (VI). A mixture of the alcohol (1*S*) (−)-III ($[\alpha]_D$ −22.5°, 8.0 g, 29 mmol) and dry, active MnO_2 (35 g, 400 mmol) in chloroform was stirred under reflux in a nitrogen atmosphere for 2 hr. The subsequent filtration from an inorganic solid and the evaporation of the filtrate gave the aldehyde (*1S*) (−)-IV ($[\alpha]_D$ −384° (*c* 0.60, EtOH), 7.9 g 99%). IR (neat): 1710, 1670, 1290, 1275, 1220, 1190, 1160, 1150, 1080, 1035, 1005, 825, 805, and 750 cm^{-1}. NMR ($CDCl_3$, 10%); δ 10.68 (s, 1H, -CHO), 5.15 (m, 2H), 4.78 (m, 1H), 4.33 (s, 5H, cyclopentadienyl ring protons), and 3.88 (s, 3H, $-CO_2Me$). The semicarbazone was prepared as usual and was recrystallized from chloroform; mp 210°C (decomp.).

Found: C, 50.6; H, 4.6; N, 12.5%. Calcd for $C_{14}H_{15}FeO_3N_3$: C, 51.1; H, 4.6; N, 12.8%.

A mixture of the aldehyde ($[\alpha]_D$ −384°, 7.9 g, 29 mmol), malonic acid (5.4 g, 52 mmol), and piperidine (20 drops) dissolved in pyridine (130 m*l*) was heated under reflux (90—100°C) in a nitrogen atmosphere for 1.5 hr. The reaction mixture was evaporated *in vacuo*, and the residue was dissolved in chloroform. After the solution had been washed with aqueous phosphoric acid, the acidic product was extracted with excess aqueous NaOH. The aqueous layer was acidified with aqueous phosphoric acid and extracted with ether–chloroform to give the (1*S*) (−)-acid, V ($[\alpha]_D$ −520° (*c* 0.10, acetone), 2.0 g, 22% based on the starting amount of III), which was sufficiently pure for a further reaction. The esterifcation of V with diazomethane, followed by column chromatography (benzene elution), gave VI as dark red needles; ($[\alpha]_D$ −324° (*c* 0.56, EtOH), mp 92.5—94°C (from EtOH). IR (KBr): 1710, 1695, 1627, 1273, 1250, 1220, 1190, 1155, 1083, 1030, 1015, 992, 940, 850, and 812 cm^{-1}. NMR ($CDCl_3$, 5%): δ 8.37 (*d*, 1H, -CH=), 6.15 (*d*, 1H, -CH=), 5.00, 4.80, 4.60 (m, 3H) and 4.20 (s, 5H, cyclopentadienyl ring protons), and 3.80, 3.85 (s, 6H, $-CO_2Me$). ORD (*c* 0.7): $[M]_{520}$ −2280°, $[M]_{490}$ 0°, $[M]_{446}$ +4560°, $[M]_{384}$ 0°, $[M]_{368}$ −1930°, $[M]_{324}$ 0°, $[M]_{300}$ −300°.

Found: C, 58.9; H, 5.1%. Calcd for $C_{16}H_{16}FeO_4$: C, 58.6; H, 4.9%.

Preparation of Methyl (1S) (−)-2-(β-Methoxycarbonylethyl)-ferrocenecarboxylate (VIII). A mixture of the acid V ($[\alpha]_D$ −520°, 0.30 g, 1.0 mmol), PtO_2 (0.03 g), and ethanol was stirred under a hydrogen atmosphere at room temperature for 12 hr. A usual work-up, followed by column chromatography (ethanol elution), gave VII as fine, yellow-orange crystals; ($[\alpha]_D$ 0°, $[\alpha]_{545}$ −25.0° (*c* 4.5, EtOH), 0.27 g, 90%). The saturated acid, VII, was esterified with diazomethane in water–benzene–ether (1 : 1 : 1 ratio). Column chromatography (benzene elution) gave fine, yellow-orange crystals; diester VIII ($[\alpha]_D$ −10° (*c* 0.56, EtOH), 0.25 g, 90%), mp 66.5—68°C (from EtOH). IR (Nujol): 1730, 1715, 1305, 1290, 1257, 1215, 1193, 1175, 1138, 1105, 1030, 818, and 780 cm^{-1}. NMR ($CDCl_3$, 10%): δ 4.73 (m, 1H), 4.28 (m, 2H), 4.13 (s, 5H, cyclopentadienyl ring protons), 3.79, 3.15 (s, 6H, $-CO_2Me$), and 3.30—2.85, 2.65—2.35 (m, 4H, methylenes). ORD (*c* 0.3): $[M]_{524}$ −270°, $[M]_{494}$ 0°, $[M]_{454}$ +540°, $[M]_{418}$ 0°, $[M]_{400}$ −216°, $[M]_{384}$ 0°, $[M]_{364}$ +270°, $[M]_{350}$ 0°, $[M]_{296}$ −620° and $[M]_{260}$ 0°.

Found: C, 58.4; H, 5.6%. Calcd for $C_{16}H_{18}FeO_4$: C, 58.2; H, 5.5%.

Cyclization of VIII to (1S) (−)-2,3-ferrocenocyclopentenone (X). A mixture of VIII ($[\alpha]_D$ −10°, 0.33 g, 1.0 mmol) and NaH (50%) (0.20 g, 4.0 mmol) in dry tetrahydrofuran (25 m*l*) was stirred under reflux in a nitrogen atmosphere for 7 hr.[5] After cooling, methanol (10 m*l*) was added to the reaction mixture. Acidification with aqueous hydrochloric acid, followed by ether extraction, gave the crude β-ketoester, IX (0.20 g, 70%).

The product, IX (0.20 g, 0.7 mmol), dissolved in tetra-

hydrofuran-benzene (1:2) (15 m*l*), was heated with aqueous NaOH (4%, 5 m*l*) for 5 hr under reflux in a nitrogen atmosphere. After cooling, the dark red benzene layer was separated from the aqueous tetrahydrofuran layer, and then benzene (10 m*l*) was added to the aqueous tetrahydrofuran layer in the reaction vessel. The mixture was again refluxed. This operation was repeated until no dark red color appeared in the new benzene layer. The combined benzene layers were then washed with water, and dried (Na_2SO_4). Column chromatography (benzene elution) gave X as dark red crystals; ($[\alpha]_D$ −49° (*c* 0.32, EtOH), 0.10 g, 60%), mp 82—83°C (from MeOH). IR (KBr): 1685, 1300, 1255, 1230, 1194, 1100, 1082, 1039, 999, 838, 827, and 815 cm^{-1}. NMR ($CDCl_3$, 7%): δ 4.57 (m, 3H), 4.12 (s, 5H, cyclopentadienyl ring protons), and 2.83 (*m*, 4H, methylenes). MS (relative abundance): *m/e* 240 (100), 212 (80), 186 (9), 184 (9), 146 (14), 121 (41), and 56 (60). ORD (*c* 1.7): $[M]_{580}$ −16°, $[M]_{564}$ −83°, $[M]_{550}$ 0°, $[M]_{494}$ +1849°, $[M]_{448}$ 0°, $[M]_{428}$ −414°, $[M]_{398}$ 0°, $[M]_{362}$ +1242°, $[M]_{341}$ +662°, $[M]_{305}$ +2070°, $[M]_{284}$ +1242°, $[M]_{230}$ +2484°. λ_{max} (EtOH): 465 nm (log, ε 2.39), 328 nm (log ε 2.84).

Found: C, 65.1; H, 5.1%. Calcd for $C_{13}H_{12}FeO$: C, 65.0; H, 5.0%.

The authors are indebted to the staffs of the Sankyo Co. for the measurement of the high-resolution mass spectra. This work was initiated by the valuable suggestions of Dr. Tadatosi Aratani. Financial support from the Ministry of Education, the Japanese Government, and from the Toray Science Foundation is acknowledged with pleasure.

The Constituents of Hops (*Humulus lupulus* L.). VII.[1] The Rapid Analysis of Volatile Components

Yoko NAYA and Munio KOTAKE
The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received February 5, 1972)

The volatile constituents from several varieties of Hops have been investigated by the direct loading of fresh plant tissue through GC-MS. The Saaz variety was distinguished among the examined varieties by its high content of β-farnesene. Hallertau was characterized by a low content of myrcene and a high content of humulenes. Shinshu-wase differed in its high content of myrcene and its low content of humulenes. Northern Brewer was rather close to Hallertau, whereas Yakima appeared to be closely related to Shinshu-wase. The myrcene content of hop oil was observed to correlate competitively with the total amount of humulenes, caryophyllene, and farnesene. 2-Methylbutyl isobutyrate accumulates in company with myrcene. The biosynthetic implication of these relationships have been briefly discussed.

Hop oil is conventionally obtained by the steam distillation of hops involving solvent extraction. The analytical results of the volatiles have, therefore, usually been affected by various treatments after the picking of the cones. Recently, Hautke *et al.*[2] reported a headspace analysis useful for the discrimination of hop varieties, but the identification of the volatile compounds has generally been limited to the major constituents. The technique[3] to release the volatile constituents from fresh plant tissue seemed to demand a simple and rapid analysis of the hop aroma by combined gas chromatography-mass spectrometry (GC-MS), as has been previously described.[1] The present work will report the analytical results by GC-MS from several varieties of hops, using a solid-sampler for direct volatilization from fresh plant tissue "lupulin". The correlation between the characteristic volatile constituents and the varieties of hops has also been attempted in order to connect this experiment with phylogeny.

Experimental

Commercial hop samples harvested in 1971 were used for the experiment (Table 1). Lupulin, glands of hop oil, were sifted from hop cones after manual grinding under freezing with liquid nitrogen or dry ice. For the quantitative glc analysis, a Hitachi Model K-53 apparatus equipped with an inlet-arrangement "solid-sampler" (an optional part of the JEOL SS-801) and a flame ionization detector was used in connection with a digital integrator (Takedariken TR-2213). The capillary column used for the analysis was 45 m × 0.25 mm; it was made of stainless steel and was coated with HB 2000. A precolumn trap system was provided for the condensation of the volatiles. The trapped volatiles were then evaporated at once; the temperature was programmed so

a) Tentatively identified.

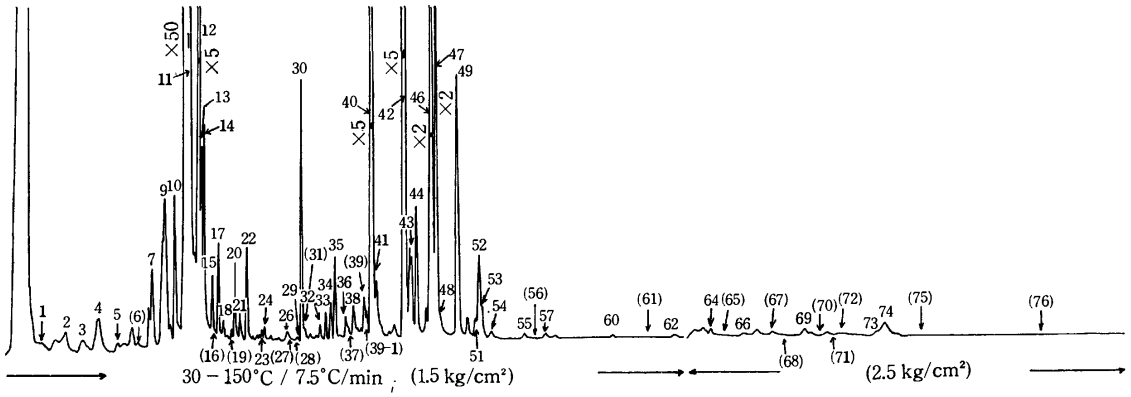

Fig. 1. Gas chromatographic record obtained from 5 mg of lupulin from Shinshu-wase, through capillary column (HB 2000, 45 m × 0.25 mm) with the vapor splitting assembly (1:70). The peak numbers correspond to those of Table 2. Those in parentheses were found in the different varieties.

that the volatiles could be detected as very sharp bands. 5 mg of lupulin was placed in the solid-sampler, and then the solid-sampler placed inside the injection block heated at 180°C for 1.5 min under a nitrogen-carrier gas-inlet pressure of 1.5 kg/cm², which swept the volatilized constituents onto the trapping column cooled by dry ice–isopropanol. After the cooling jacket had been taken off, the whole column system was heated by temperature programming from 30° to 150°C at the rate of 7.5°C/min. It was necessary to heat the injection block at around 180°C and to withdraw the plunger within 2 min in order to obtain a sufficient volatility of the volatiles without any thermal decomposition.

For the GC-MS analysis, a capillary column (45 m × 0.5 mm) coated with HB 2000 was used. The sample amount was about 10 mg for each analysis, which was done by the technique described above (hellium-carrier gas-inlet pressure, 0.7 kg/cm²; temperature programming, 30—150°C at 5°C/min. The mass spectrometer was a Hitachi Model RMU-6 apparatus, and the operating conditions were as follows: ionization energy, 80 eV; acceleration voltage, 2000 V. The compounds were identified by the agreement of the mass spectra, as well as by that of the retention time on glc, with those of authentic samples or of published standard references.

Results and Discussion

In our study, 10 mg of lupulin were sufficient for the identification of about fifty constituents, amounting to more than 97% of the total oil (Table 2). 5 mg of

lupulin were required for a satisfactory gas chromatogram, obtained through a capillary column equipped with a vapor-splitting assembly (1: 70). The gas chromatogram (Fig. 1) obtained for 5 mg of lupulin from Shinshu-wase is shown as an example. The chromatogram obtained using 1 mg of the sample without the splitting assembly was still sufficient for the purpose of comparison. A chromatogram using an essential oil from the same variety, obtained by the conventional method, was compared with the above chromatogram; it was found that low-boiling constituents were inevitably lost to a certain extent in the course of steam distillation and solvent extraction.

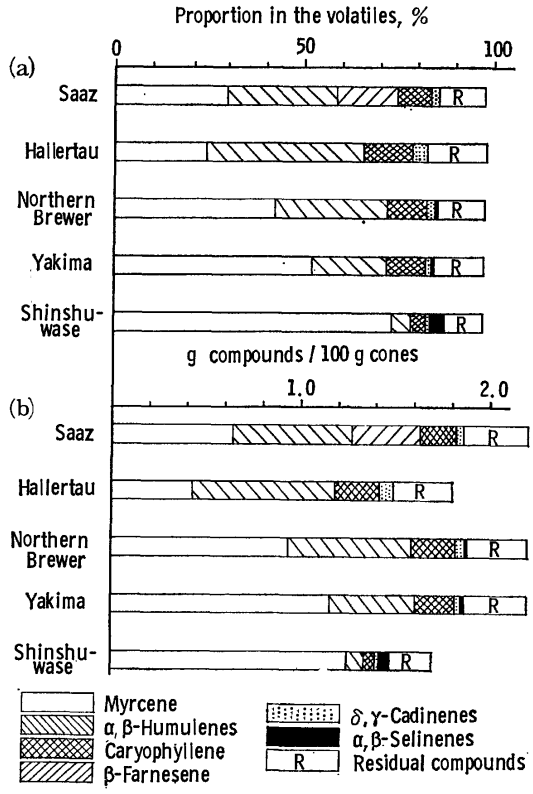

Fig. 2. Variation in the varieties and correlation among the contents of some hydrocarbons: (a) Proportion in the volatiles. (b) amounts calculated for the yield of essential oil.

The results (Fig. 2) indicate the differences among the varieties. A substantial amount of β-farnesene is contained only in the lupulin from Saaz. This fact is in agreement with the report of Šorm *et al.*[4] though not with that of Haward *et al.*[5] In this point, Saaz can be clearly distinguished from Hallertau, Northern Brewer, Yakima, and Shinshu-wase. The major hydrocarbons of Shinshu-wase, caryophyllene, and a mixture of α- and β-humulenes have been shown[1] to be characteristic constituents throughout the whole plant and to be no concern in ripening, while the amount of myrcene increases greatly in the course of ripening. Thus, Shinshu-wase is characterized by a high content of myrcene and a low content of humulenes. On the contrary, Hallertau is characterized by a low content of myrcene and a high content of humulenes. Furthermore, the composition of the hydrocarbons from Northern Brewer was similar to that of Hallertau, whereas Yakima appeared to be closely related to Shinshu-wase. The myrcene content of hop oil is observed to correlate competitively with the total amount of humulenes, caryophyllene, and farnesene. The biosyntheses of myrcene, humulenes, caryophyllene, and farnesene possibly proceed through enzymic transformations in the limited supply of the common intermediate. Accordingly, an increase in the amount of the one must cause a corresponding decrease in the amount of the rest. It is also observed that the selinene group competes with cadinenes from the common intermediate, the germacrenium ion.[6] The myrcene-rich varieties show a high content of selinenes, whereas the humulene-rich varieties are characterized by a high content of cadinenes. We can not explain readily the correlation in the contents between myrcene and selinenes as well as between humulene and cadinenes.

The oxygenated compounds can be divided into the two groups based on the difference in development. The one formed by the deterioration of the hop consists of oxidized volatiles (caryophyllene-oxide, humulene-epoxide-I and -II, humulenol-II, *etc.*) and the decomposed bitter principles[7] (dimethylvinylcarbinol, dimethylcrotonolactone *etc.*) (Fig. 3). The other group, in the course of the maturing of the cones, probably contains some monoterpenic alcohols, methyl ketones, and methyl esters and higher esters of various fatty acids. 2-Methylbutyl isobutyrate, which was the most rich component among the esters, can be correlated with myrcene. The myrcene-rich varieties show high contents of this esters (Fig. 4). Therefore, 2-methylbutyl isobutyrate must correspond to the Peak II-substance,[5] which accumulates in company with myrcene according to Haward *et al.* In fact, the amount of

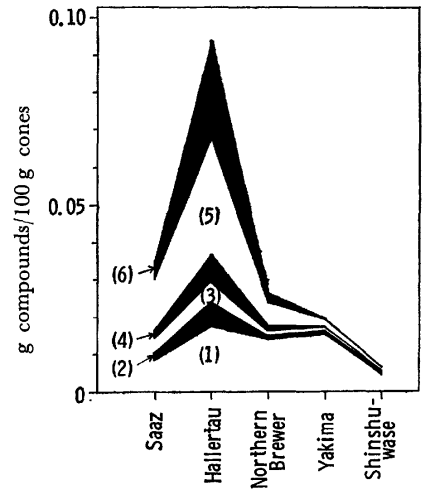

Fig. 3. Proportion of some oxygenated compounds caused from deterioration of hop. (1): dimethylvinylcarbinol, (2): 4,4-dimethylcrotonolactone, (3): caryophyllene-oxide, (4): humulene-epoxide-I, (5): humulene-epoxide-II, (6): humulenol-II.

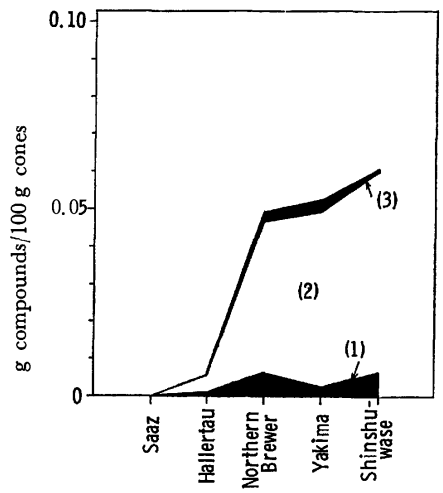

Fig. 4. Proprotion of some higher esters in the volatiles. (1): isobutyl isobutyrate, (2): 2-methylbutyl isobutyrate, (3): 2-methylbutyl isovalerate.

2-methylbutyl isobutyrate increases in the course of ripening in proportion to the formation of myrcene.[1] It has been shown that[8] a representative group of bitter principles, alpha-acid (I), and essential oil do not all reach a maximum at the same time. That is, the volatiles are accumulated later than alpha-acid. The various pieces of evidence above suggest that the formation of 2-methylbutyl isobutyrate is possibly connected with the biosynthesis of the acyl side-chains[9] of bitter principles, while myrcene is connected with isoprenyl units of them. Further study is now under way.

In spite of the short history of hop cultivation in Japan (since 1915),[10] the phylogeny of Japanese hops is uncertain. In order to elucidate the phylogeny of these hops, investigation[11] has been done on the basis of cytology. It is said that the sex chromosome types of wild and garden male hops are the same and are characteristic of their geographical groups namely, those of European origin are of the XY^w type, those of American origin are of the XY^h and XY^{nw} types, and those of Japanese origin are of the XA^vAY^a type. Only a few simple XY^h and XY^{nw} types were found in Japanese garden hops. This shows that intercrossings between the cultivated and wild hops have actually occurred. Thus, when the hops were introduced to a new region, acclimated new varieties have grown in the new habitat. From the viewpoint of phylogeny, our study lends support to the assumption that the local varieties in Europe named Saaz and Hallertau went over to America and then came to Japan, where they developed into a new local variety.

Syntheses and Reactions of Ferrocene-Containing Polymers. VI. Polarography and Electron Transfer Equilibria of Some Ferrocene-Containing Polymers[1]

Toshihide NAKASHIMA and Toyoki KUNITAKE*

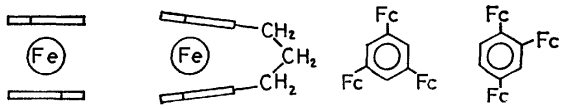
Department of Organic Synthesis, Faculty of Engineering, Kyushu Universtiy, Fukuoka

(Received February 17, 1972)

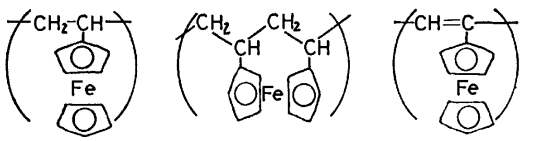
Polarography and electron transfer equilibria of some ferrocene-containing polymers were studied in comparison with small-molecule analogs. The oxidation half-wave potentials of polyvinylferrocene and polydivinylferrocene (almost completely cyclized) in CH_2Cl_2 were close to those of ferrocene and [3]ferrocenophane, respectively. This is in line with structural similarity. Only one oxidation step was observed in the polarogram of triferrocenylbenzene and polyethynylferrocene, suggesting that the electronic interactions between ferrocene units are small in these compounds. Electron transfer equilibrium was observed between ferrocene units in polymer and iodine. Equilibrium constants of the [3]ferrocenophane unit were greater than those of the unbridged ferrocene unit. The ferrocene unit in polymer showed greater equilibrium constants than those of their small-molecule analogs.

Ferrocene-containing polymers are expected to show interesting physical properties,[2] and the electrical property of the polymers prepared by polycondensation and polyrecombination has been studied.[3] However, detailed structural studies were often difficult, since many of these polymers were infusible and insoluble, and it was not possible to clarify the correlation between structure and property.

We have synthesized some ferrocene-containing polymers through addition polymerization of vinylferrocene, 1,1'-divinylferrocene and ethynylferrocene, and determined their structures by spectroscopic and other means.[4-7] Since the structures are rather simple, it was thought that the structure-property relationship would be comparatively straightforward. In this paper we describe the results of polarographic study and electron-transfer equilibria of these polymers in solutions.



Ferrocene [3] Ferrocenophane 1,3,5- and 1,2,4-Triferrocenylbenzene



Poly(vinylferrocene) Cyclized poly(divinylferrocene) Poly(ethynylferrocene)

Fc: Ferrocenyl group

Experimental

Materials. Polymerizations of vinylferrocene, 1,1'-divinylferrocene and ethynylferrocene have been described.[4-7] The polymerization conditions are given in each case. Triferrocenylbenzene (mixture of 1,3,5- and 1,2,4-isomers) was prepared by the trimerization of ethynylferrocene.[7] [3]-Ferrocenophane(1,1'-trimethyleneferrocene) was prepared from formylferrocene according to the method of Rinehart *et al.*,[8] mp 97.3—99.0°C (lit, mp 107.5—108°C). The NMR spectrum showed sharp singlets in line with that in literature. Minor impurity (<4%) peaks observed might be ascribed to *n*-propylferrocene and/or to 1,2-trimethyleneferrocene. Found: C, 69.05; H, 6.08%. Calcd for $C_{13}H_{14}Fe$: C, 69.05; H, 6.25%.

Methyltriethylammonium triiodide was prepared from triethylamine, methyl iodide, and iodine, according to the method of Buckles *et al.*,[9] mp 65.0—65.6°C; λ_{max} ($CHCl_3$) 365 nm ($\varepsilon=2.4\times10^4$) (lit,[9] $(CH_3)_4NI_3$ λ_{max} ($ClCH_2CH_2Cl$) 365 nm ($\varepsilon=2.53\times10^4$)).

Instruments. Polarographic study was carried out with a Yanagimoto Polarograph PA 102 using rotating platinum electrode as a cathode and mercury pool as an anode. Electronic spectra were obtained with a Shimadzu UV 200 spectrophotometer.

Results and Discussion

Polarography. It is well-known that ferrocene compounds undergo one-electron oxidation to ferricenium ions electrolytically, photolytically, and by organic and inorganic oxidants. Thus polarographic studies have been made for many ferrocene derivatives

(small molecules).[10-13] On the other hand, ferrocene-containing polymers have seldom been investigated polarographically, because of the limited solubility in solvents used for the polarographic study.[14,15]

Polarographic measurements were made in CH_2Cl_2 solution with tetra-n-butylammonium fluoroborate (n-Bu_4NBF_4) as supporting electrolyte. The system was selected beacuse of better solubility and conductivity than the following combinations: $LiClO_4$/tetrahydrofuran, $LiClO_4$/benzene-dioxane, and n-Bu_4NBF_4/benzene-dioxane. The oxidation half-wave potentials ($E_{1/2}$) of the ferrocene-containing polymers and their low-molecular-weight analogs are given in Table 1. The potentials are given relative to that of the mercury pool. Sample concentrations were 0.1 and 1 mM. Reproducibility of $E_{1/2}$ was good, being almost independent of concentration. However, lower concentrations seem to be favorable for removing the maxima on the polarogram which seem to be due to the adsorption of the product on the electrode. The $E_{1/2}$ values of polyvinylferrocene and cyclized polydivinylferrocene were close to those of ferrocene and [3]ferrocenophane, respectively. This supports the fact that the repeat unit of cyclized polydivinylferrocene is a [3]ferrocenophane derivative.[5] The polymer main chain does not seem to exert a great influence upon the oxidation potential of the pendent ferrocene ring.

It is established that two cyclopentadienyl rings of ferrocene are parallel with each other with 3.3 Å separation.[16] However, the two rings cannot be parallel in some heteroannularly-bridged ferrocenes such as [m]ferrocenophane with $m \leq 3$, owing to geometrical limitation.[17,18] Ferrocene derivatives of this type (hot-dog structure) are known to possess unique electronic properties.[19-21]

A polarographic study of bridged ferrocenes has been reported by Gorton *et al.*[13] They found that the half-wave potential of [2]ferrocenophane was appreciably lower than that of its unbridged counterpart, but the half-wave potential of [3]ferrocenophane was close to that of 1,1′-diethylferrocene. The difference in $E_{1/2}$ we observed between ferrocene and [3]ferrocenophane ($\Delta E_{1/2} = -0.07$ V) coincides with their data. Thus, the influence of bridging on the electronic property does not seem to be great in [3]ferrocenophane compared with that in [2]ferrocenophane. On the other hand, the difference in $E_{1/2}$ between polyvinylferrocene and cyclized polydivinylferrocene ($\Delta E_{1/2} = -0.11$ V) is greater than that found between 1-alkyl and 1,1′-dialkylferrocenes (small molecule).[11] Thus bridging seems to lower the oxidation potential.

Only one-step oxidation was observed in the polarogram of triferrocenylbenzene. It is known that two-step oxidation is involved with some binuclear ferrocene derivatives such as [1.1]ferrocenophane[13] and biferrocenyl.[22] This is interpreted as follows. A ferricenium group formed in the initial oxidation enhances the oxidation potential of the second ferrocene nucleus by interactions operating through the carbon skeleton of the ligands or directly between the iron atoms. The one-step oxidation polarogram indicates that there is no appreciable interaction among ferrocene nuclei in triferrocenylbenzene.

The electronic spectral data similarly indicate that there is no strong interaction between the ferrocene nuclei. The absorption coefficient of triferrocenylbenzene at 450 nm region (d-d^* transition of ferrocene nucleus) was approximately three times as large as that of phenylferrocene.[23]

The $E_{1/2}$ value of polyethynylferrocene agreed with that of triferrocenylbenzene within experimental error (0.59 and 0.58 V, respectively), which also shows that there is not much interaction between ferrocene nuclei directly or through the polyene chain.

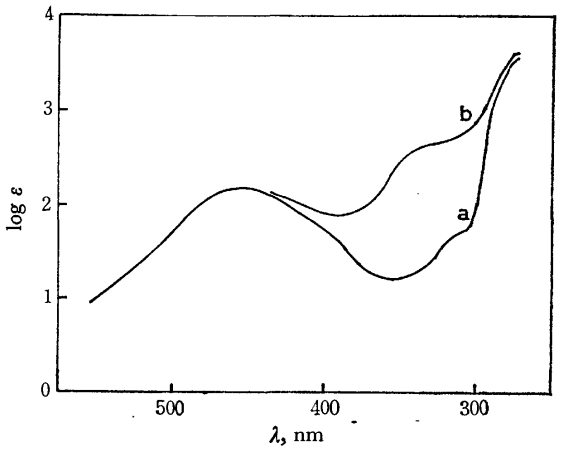

Fig. 1. Electronic spectra of poly(vinylferrocene). Solvent a: cyclohexane, b: CCl_4.

Electron Transfer Equilibria. Although ferrocene-containing polymers have been shown to react with appropriate acceptors to give corresponding ferricenium ions,[24] no quantitative studies have been made on electron transfer.

The electronic spectrum of ferrocene shows a peculiar solvent effect at around 300 nm in some halogenated hydrocarbon solvents. This was attributed to the dissociative charge transfer between ferrocene and a solvent molecule.[25] A similar solvent effect was observed in polyvinylferrocene as shown in Fig. 1. The extinction coefficient in the 300—400 nm region is greater in CCl_4 than in cyclohexane.

It has been reported that electron transfer equilibria hold between ferrocene and iodine in appropriate solvents.[25,26]

$$\text{Fe} + \frac{3}{2}I_2 \underset{}{\overset{K}{\rightleftharpoons}} \text{Fe}^+I_3^- \qquad (1)$$

The equilibrium was studied in chloroform with ferrocene-containing polymers. The equilibrium constant K was determined from the absorption of the triiodide anion at 365 nm.

$$K = \frac{[Fc^+I_3^-]}{[Fc][I_2]^{3/2}} = \frac{[Fc^+I_3^-]}{([Fc]_0-[Fc^+I_3^-])([I_2]_0-3/2[Fc^+I_3^-])^{3/2}} \qquad (2)$$

Fc: ferrocene unit

It was confirmed by using $CH_3(C_2H_5)_3N^+I_3^-$ that Beer's law holds. Formation of the triiodide anion by dissociation of iodine was negligible under the experimental conditions. The absorption at 365 nm was measured by the continuous variation method. The variation of absorption intensity with composition is given in Fig. 2.

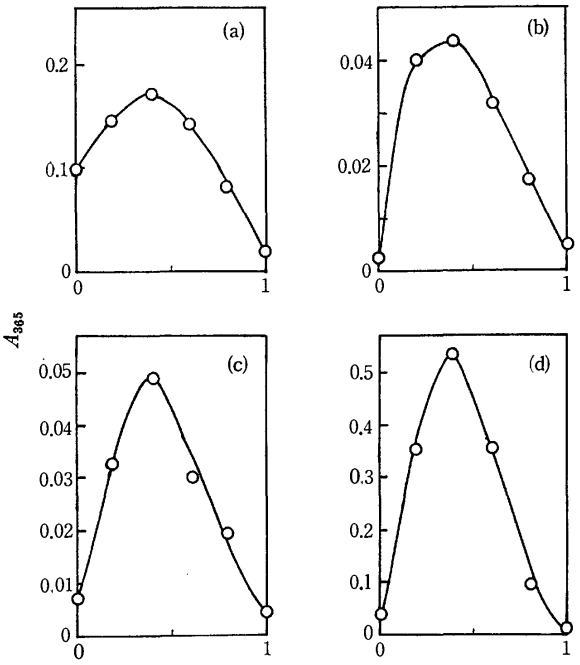

Fig. 2. Determination of the equilbrium constant of electron transfer by the continuous variation method. Solvent: chloroform. 1 cm silica cell. A_{365}: absorption intensity of I_3^- at 365 nm.
a: Ferrocene/I_2 (total concentration, 10^{-3} M), b: [3]Ferrocenophane/I_2 (total concentration, 10^{-4} M), c: Poly(vinylferrocene)/I_2 (total concentration, 10^{-4} M), d: Poly(divinylferrocene)/I_2, (total concentration, 10^{-4} M)

The maximum of A_{365} (absorption intensity at 365 nm) observed for ferrocene–iodine, mole fraction of ferrocene *ca.* 0.4, was in line with the stoichiometry of Eq. (1). Similar results were obtained for [3]ferrocenophane and ferrocene-containing polymers. The total concentration was set at 10^{-4}M in the case of ferrocene-containing polymers in order to avoid precipitation of oxidized polymers. Since polyethynylferrocene possesses a broad absorption in this region, determination of the equilibrium constant was impossible.

TABLE 2. EQUILIBRIUM CONSTANT OF THE ELECTRON TRANSFER REACTION FROM POLYMERS AND RELATED COMPOUNDS TO IODINE
28±2°C, Total concentration 10^{-4}M.

Poly(vinylferrocene)	5.4	5.3	5.3	5.5	5.4
Cyclized poly(divinylferrocene)	7.2	7.1	7.0		7.1
Cyclized poly(divinylferrocene)	6.5	6.5	6.2	7.2	6.6

a) Total concentration 10^{-3}M.

24) C. U. Pittman, Jr., J. C. Lai, D. P. Vanderpool, M. Good, and R. Prado, *Macromolecules*, **3**, 746 (1970).
25) J. C. D. Brand and W. Snedden, *Trans. Faraday Soc.*, **53**, 894 (1957).
26) A. V. Savitskii and Ya. M. Syrkin, *Dokl. Akad. Nauk SSSR*, **120**, 119 (1958).

The equilibrium constants were calculated for each run (Table 2). It is of interest that the bridged ferrocene units show greater K values than the unbridged units ([3]ferrocenophane *vs.* ferrocene, and cyclized polydivinylferrocene *vs.* polyvinylferrocene). Thus, electron transfer occurs more readily with the ferrocenophane structure, in line with the polarographic data. On the other hand, the polymers possess greater equilibrium constants than the low-molecular-weight analogs, in contrast with the polarographic results. Accumulation of the ferrocene unit along the polymer chain may make electron transfer favorable, probably through interactions of neighboring cyclopentadienyl rings with iodine molecule and/or through the change of polymer conformation associated with the reaction with iodine.

The authors are grateful to Professor W. Sakai for use of the polarographic apparatus. They also appreciate the helpful advice and encouragement of Dr. C. Aso during the course of investigation.

Studies on Tritylated Sucrose. II. Di-*O*-Tritylsucroses

Toshiki OTAKE

Nippon Electric Varian, Ltd., Azabu, Iigura-machi, Minato-ku, Tokyo

(Received January 31, 1972)

Three isomeric di-*O*-tritylsucrose were isolated from a mixture of tritylated sucrose by the reaction of sucrose and trityl chloride in mole ratio 1: 2. Structures of isomeric diethers were established by application of NMR to the hexa acetyl derivatives. They are recognized as 6,6′-, 1′,6-, and 1′,6′-di-*O*-tritylsucrose. The former two substances were crystallized as colorless prisms.

In the preceding paper,[1] the isolation and structure of mono-*O*-tritylsucroses through the reaction of sucrose with trityl chloride in mole ratio 1: 1.2 were described. The content of monoether in the reaction product was 53% for total tritylated sucrose. The trityl groups on monoethers obtained were at 6- and 6′-position of sucrose. No other positional isomer such as 1′-mono-*O*-tritylether was detected. However, by thin-layer chromatography, at least three kinds of di-*O*-tritylsucroses and one triether were recognized in the reaction mixture. Formation of the three diethers suggests that at least one reactive hydroxyl group against trityl chloride should be present on sucrose in addition to the hydroxyl groups of 6- and 6′-position. The structures of diethers were established by NMR spectra. The structure of the triether was confirmed by McKeown *et al.*[2] McKeown and Hayward[3] and Bredereck *et al.*[4] to be 1′,6′,6-tri-*O*-trityl sucrose from the analysis according to the complex chemical procedures. In both works, one mole of sucrose was tritylated with 3 mol of trityl chloride, followed by acetylation in the same vessel, no description being given on mono- and di-*O*-tritylethers.

Results and Discussions

After removal of mono-*O*-tritylsucrose from the product obtained by the reaction of sucrose and trityl chloride in 1: 2 mole ratio, the residue was chromatographed on silica gel to divide it into fractions of di-*O*-tritylsucroses, tri-*O*-tritylsucroses, and non-sugar trityl compounds. On the total solid recovered by chromatography, the yields of mono-*O*-tritylsucroses, di-*O*-tritylsucroses, tri-*O*-tritylsucrose, and non-sugar trityl-compounds were accounted for in 27, 37, 17, and 19% weight, respectively. The thin-layer chromatogram of diethers showed that the diethers fraction consisted of at least three isomers and the order of amount of each isomer was IIa (R_f value 0.62)>IIb (R_f value 0.67)>IIc (R_f value 0.72).

Diethers IIa and IIc were crystallized, and melted at 124.5—126.5 and 133°C (corr), respectively, while IIb was obtained as colorless amorphous powder, softening at 129°C. The yield for crystalline IIa was 74%, as compared with 14% for IIb and 12% for IIc, on the total weight of the di-*O*-tritylsucroses. The IR spectra of all the diethers exhibited the O–H stretching absorption near 3500 cm^{-1} and the characteristic phenyl absorption at 1600, 1495, and 1450 cm^{-1}. On the UV spectra, the diethers and trityl chloride showed almost the same absorption pattern (λ_{max} = 260 mμ) and the molar extinction coefficient of the diethers (ε_{max}: IIa 1440, IIb 1415, and IIc 1460) gave twice the value of trityl chloride (ε_{max} 720). Thus, it is confirmed that IIa, IIb, and IIc are all di-*O*-tritylsucroses. The peracetyl derivative of III was crystallized in 70% yield against the total acetyl product of III-fraction. Its melting point (mp 234.4°C corr) was equal to that of 1′,6′,6-tri-*O*-trityl penta-*O*-acetylsucrose which had been reported by McKeown and Bredereck.

Diethers IIa, IIb, and IIc were acetylated with

1) T. Otake, This Bulletin, **43**, 3199 (1970).
2) G. G. McKeown, R. S. E. Serenius, and L. D. Hayward, *Can. J. Chem.*, **35**, 28 (1957).
3) G. G. McKeown, and L. D. Hayward, *ibid.*, **35**, 992 (1957).
4) H. Bredereck, H. Zinner, A. Wagner, G. Faber, W. Greiner, and W. Huber, *Chem. Ber.*, **91**, 2824 (1958).

acetic anhydride in a pyridine solution. The residues on evaporation were chromatographed on silica gel to obtain di-*O*-trityl-hexa-*O*-acetylsucroses (IVa, IVb, and IVc) in good yield. The product IVa was crystallized as colorless prisms (mp 102°C), while the others remained as amorphous solid by the same treatment. IR data of each product showed no absorption corresponding to the O–H stretching vibration, and the thin-layer chromatogram showed the products to be homogeneous. It was thus revealed that acetylation of the diether was completed.

In the NMR spectra of the acetyl derivatives, the integrated intensities of acetyl, trityl, and other protons agreed with the theoretical values calculated as di-*O*-trityl-hexa-*O*-acetylsucrose. The chemical shifts of the acetyl-group protons were in the δ value 1.5—2.0, showing certain differences between them: IVa; δ 1.57 (3H), 1 88 (3H), 1.92 (3H), 1.98 (3H), 2.00 (6H), IVb; δ 1.78 (3H), 1.91 (3H), 1.95 (3H), 1.96 (3H), 1.98 (3H), 2.03 (3H), IVc; δ 1.66 (3H), 1.88 (3H), 1.97 (3H), 2.00 (9H).

In each case, signals arising from the methine and the methylene protons fell into the region between δ 2.5 and δ 5.9, which could be subdivided into the three non-overlapping regions; A (δ 2.5—3.5 (4H)), B (δ 3.6—4.5 (4H)), and C (δ 4.5—5.9 (6H)).

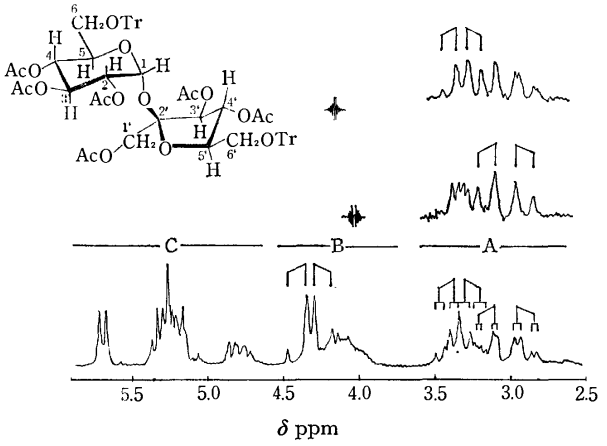

Fig. 1. Partial NMR spectrum of 100 MHz of IVa in $CDCl_3$.

The signals in region A may be assigned to the protons of the methylene groups to which *O*-trityl group is directly attached.[1] For IVa, the signals in A are considered to consist of the two independent AB parts in each ABX system (Fig. 1). This was confirmed for IVa by carrying out irradiation near δ 4.0 and observing the perturbation of the signals, as it gives the two groups of signals with each four transitions. The following simulation spectrum was obtained by a computer, confirming the proposed ABX system defined by δ (1) 2.91, δ (2) 3.15, and δ (3) 4.15, with J (1, 2) −10.8, J (1, 3) 4.0, and J (2, 3) 2.0 Hz, δ (1′) 3.28, δ (2′) 3.41, and δ (3′) 4.15 with J (1′, 2′) −10.0, J (1′, 3′) 6.8, J (2′, 3′) 6.3 Hz,

	1	2	3	4	5	6	7	8
Observed (δ)	2.83	2.88	2.94	2.98	3.10	3.12	3.21	3.23
Generated (δ)	2.83	2.86	2.93	2.97	3.10	3.12	3.21	3.23

	1′	2′	3′	4′	5′	6′	7′	8′
Observed (δ)	3.17	3.24	3.27	2.34×2		3.40	3.44	3.50
Generated (δ)	3.17	3.24	3.27	3.34×2		3.41	3.44	3.51

On the basis of these observations, the signals in region A can be assigned to the methylene protons of H-6 and H-6′, and the original diether IIa should be 6,6′-di-*O*-tritylsucrose. By comparison with the chemical shifts of H-6 or H-6′ on mono-*O*-trityl-sucrose,[1] it is concluded that the signals of lower field in region A is ascribed to H-6′, and those of high field to H-6. The AB quartet observed in the lower field of region B is assigned to protons of C-1′methylene-group to which an *O*-acetyl group is directly attached, giving further confirmation of the structure.

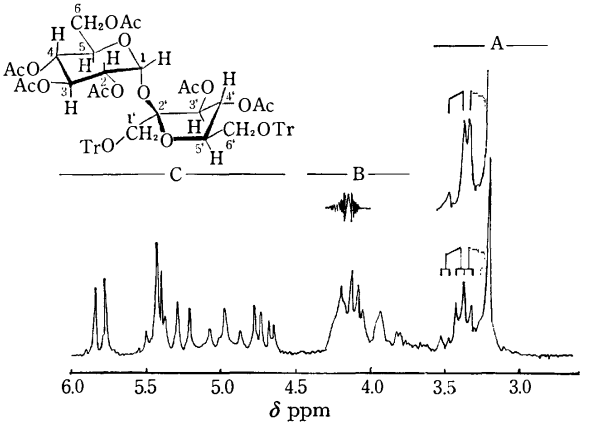

Fig. 2. Partial NMR spectrum at 100 NHz of IVb in $CDCl_3$.

In the spectrum of IVb (Fig. 2) a broad singlet at δ 3.30 is considered to be due to protons of C-1′ methylene. The other signals in region A (δ 3.3—3.6) are assumed to be AB part of an ABX system which is turned to four-transition signals by irradiation near 4 ppm. The generated spectra in NMR spin simulation defined by δ (1) 3.31, δ (2) 3.43, and δ (3) 4.10, with J (1, 2) −10.5, J (1, 3) 4.5, and J (2, 3) 5.0 Hz, agreed with the observed spectrum of region A:

	1	2	3	4	5	6	7	8
Observed (δ)	—*	3.29	3.32	3.37×2		3.42	3.46	3.52
Generated (δ)	3.21	3.26	3.32	3.36	3.37	3.42	3.48	3.53

* overlapped with the protons of H-1′.

This system is almost consistent with that formed with the protons of C-6′methylene and H-5′ on 6′-mono-*O*-trityl-hepta-*O*-acetylsucrose. Thus the original diether IIb is perceived to be 1′,6′-di-*O*-tritylsucrose.

Signals in region A of IVc (Fig. 3) are considered to be overlapping signals of part AB in system ABX and system AB. The latter is assigned to the protons of C-1′methylene to which a trityl group is directly attached. Irradiation near 4 ppm gave rise to the collapse of signals other than those of C-1′methylene in region A and the appearance of four-transition signals. Comparison of the observed and the generated spectra in region A which is defined by δ (1) 2.85, δ (2) 3.3, and δ (3) 4.15 with J (1, 2) −10.7, J (1, 3)

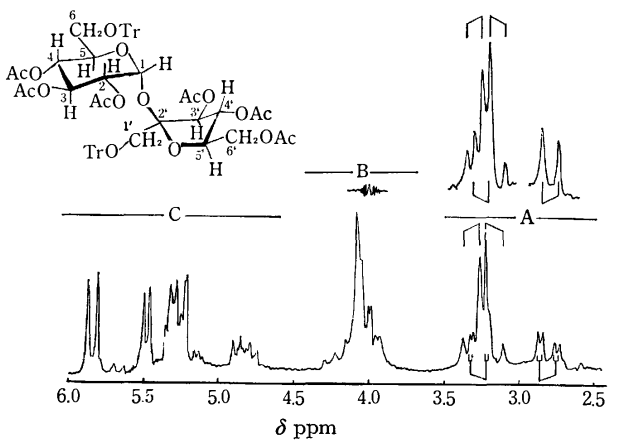

Fig. 3. Partial NMR spectrum at 100 NHz of IVc in $CDCl_3$.

3.2, and J (2, 3) 2 Hz, and δ (1') 3.22, δ (2') 3.33 with J (1', 2') −10.2 Hz, is as follows.

	1	2	3	4	5	6	7	8
Observed (δ)	2.78	2.81	2.88	2.91	3.23	3.25	3.34	3.36
Generated (δ)	2.77	2.81	2.88	2.91	3.24	3.26	3.34	3.37

	1'	2'	3'	4'
Observed (δ)	3.16	3.26	3.30	3.40
Generated (δ)	3.15	3.25	3.30	3.40

The above approximate three-spin system agreed well with that consisting of the proton of C-6 methylene and H-5 on 6-mono-trityl-hepta-*O*-acetylsucrose. Thus, the original diether should be 1,6-di-*O*-trityl-hepta-*O*-acetylsucrose.

The three possible isomeric diethers through the tritylation at two of the three primary alcohol (1'-, 6'-, and 6-position) are all recognized in the reaction mixture. The trityl group at the 1'-position was not observed in mono-*O*-tritylsucroses.[1] It should be noted that the tritylation at 1'-position is only observed in the ethers of higher trityl content.

Inactivity of 1'-hydroxyl group has also been observed in the *trans*-esterification of sucrose.[5] Formation of 1',6-, and 1',6'-di-*O*-tritylsucrose may take place through 6-, or 6'-mono-*O*-tritylsucrose gradually.

Experimental

General Methods. Thin-layer chromatography was carried out using Merck silica gel G as an adsorbent in a thickness of 0.25 mm and with the solvent systems: (A) methanol–water–acetone–chloroform (20: 4: 2: 56) for tritylated sucrose, (B) methyl ethyl ketone (MEK)–toluene for the *O*-acetyl derivatives of sucrose. The developed plates were sprayed with 50% sulfuric acid and heated at 120°C. Column chromatography was carried out using silica gel, 60—80 mesh (Kanto Chemical Co.). IR and UV spectra were measured with a Hitachi EPI-II RI spectrometer and a Cary Model 14R recording spectrophotometer, respectively. The NMR spectra were recorded with a Varian HA-100D (100 MHz) spectrometer using chloroform-*d* with tetramethylsilane as an internal lock, the signal positions being expressed in δ values. The NMR simulations were accomplished by a Varian Spectro. System SS-100 equipped with a Varian 620/i computer.

Tritylation of Sucrose. Commercial granulated sucrose (6.84 g) was reacted with recrystallized trityl chloride (11.4 g) in dry pyridine (100 m*l*) at room temperature. The reaction was accelerated by agitation of the reaction solution for 96 hr. At the end of the reaction period, the solution was dried *in vacuo* on a rotary evaporator. The residue was dissolved in 1-butanol (200 m*l*) and then washed with a Mckirrvin buffer (pH 7.0) and water in order to remove the free sucrose. Evaporation of the butanol solution under reduced pressure left 15.25 g of tritylated sucrose as colorless glass.

Separation of di-O-tritylsucroses. The mixture of tritylated sucrose was then subjected to counter currentgraphy for separation into mono-*O*-tritylsucroses and a mixture of ethers of higher trityl content. Evaporation of non-polar layer yielded the mixture (11.25 g) as colorless glass, which was subsequently chromatographed on 50 g of silica gel. After washing the column with chloroform (1 *l*) and with 2% methanol/chloroform (1 *l*), the diethers were eluted with 6% methanol/chloroform (1 *l*). Evaporation of the last solution left 5.319 g of a mixture of diethers.

6,6'-di-O-tritylsucrose (IIa). The mixture of diethers was resolved in an admixture of *n*-hexane and trichloroethylene (1: 1 vol/vol) (50 m*l*) at 55°C. The solution was then left at room temperature to precipitate an admixture of IIa and IIb. The residue of the filtration was dissolved in 80% methanol (30 m*l*) to crystallize IIa. By crystallization twice, 1.893 g of IIa was obtained as colorless prisms, melting at 125—126°C. Further 0.941 g of crystalline IIa was obtained from the mother liquid of recrystallization by recycling column chromatography.

Found: C, 70.78; H, 6.39%. Calcd for $C_{50}H_{58}O_{11}\cdot H_2O$: C, 71.09; H, 6.16%.

1',6'-di-O-tritylsucrose (IIb). Evaporation residue (0.9 g) from the mother liquid of the recrystallization of IIa from 80% methanol was added to silica gel (10 g) column as a chloroform solution; the column was then gradually washed with 4, 5, 6, and 7% methanol/chloroform (200 m*l* each). The eluent was divided into sixteen 50 m*l*-fractions after all the solvent passed through the column, each fraction was returned gradually to the column. After repeating the recycling procedure, each fraction was examined by thin-layer chromatography to find out the fractions consisting of IIb. Evaporation of the fractions yielded 0.602 g of IIb as amorphous colorless powder melting at 129°C.

Found: C, 72.72; H, 6.37%. Calcd for $C_{50}H_{58}O_{11}$: C, 72.63; H, 6.09%.

1',6-di-O-tritylsucrose (IIc). The evaporation residue of the mother liquid of the crystallization of IIa with an admixture of *n*-hexane and trichloroethylene was chromatographed in the same manner as in the separation of IIb. The residue of IIc fraction (0.536 g) was crystallized twice from 5 m*l* of 80% methanol solution to yeild about 0.4 g of crystalline IIc melting at 133°C.

Found: C, 71.37; H, 6.22%. Calcd for $C_{50}H_{58}O_{11}\cdot H_2O$: C, 71.09; H, 6.16%.

Di-O-trityl-hexa-O-acetylsucroses (IVa, IVb, and IVc). Acetylation of di-*O*-tritylsucroses was caried out as reported.[1] Each residue of reaction solution was chromatographed on a silica gel (10 g) column. After washing the column with 200 m*l* of toluene, each hexa-*O*-acetyl derivative (IVa, IVb, and IVc) was eluted with 7% methyl ethyl ketone (MEK)/toluene (200 m*l*) in an almost theoretical yield. IVa was

5) T. Otake, *Nippon Kagaku Zasshi*, **90**, 393 (1969).

obtained in a crystalline form, melting at 102°C, by recrystallization with 10 m*l* of 80% methanol, in about 85% yield against the evaporation residue; attempts to crystallize the other hexa-*O*-acetyl derivatives were unsuccessful. Each acetyl derivative was found to be homogeneous on the thin-layer chromatogram developed with MEK-toluene (1; 1 vol/vol); every compound had the same R_f value of 0.89.

Found, IVa: C, 69.28; H, 5.72%. Calcd for $C_{62}H_{62}O_{17}$: C, 69.01; H, 5.79%.

The author wishes to thank Professor Tetsuo Suami, Keio University, for his helpful advice and Mr. Iwao Miura for determination of NMR spectra.

Electrocatalytic Chemistry of the Transition Metal Complexes. II. Dehydrogenation of Cyclohexene Catalyzed by the Electroreduced Cobalt Complex of α,β,γ,δ-Tetraphenylporphine

Hironori KAGEYAMA, Masanobu HIDAI, and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 17, 1971)

The metal complexes of α,β,γ,δ-tetraphenylporphine (M(TPP), M=Co(II), Ni(II), FeCl(III), Pd(II), Pt(II), Cu(II), MnCl(III), and V(IV)O) were electrolyzed at −2.0 V *vs.* Ag wire in the presence of cyclohexene under nitrogen atmosphere. The cobalt complex only had the catalytic activity of dehydrogenating cyclohexene to 1,3- and 1,4-cyclohexadiene and benzene. With the use of dimethylformamide, dioxane, and hexamethylphosphoric triamide as solvent, cyclohexadienes were produced, and with that of benzonitrile, and dimethyl sulfoxide, benzene was produced and cyclohexadienes were scarcely produced at all. In all cases, the current efficiency of the products was much higher than 100%, indicating that the dehydrogenation reaction is catalytic. The composition of the products also varied with the reaction temperature. When ethanol was added to the reaction solution, the amount of cyclohexadienes increased with benzonitrile used as solvent. The ESR spectrum observed at $g=2.003$ under electrolysis at the second wave potential is due to the anion radical of cobalt(I) tetraphenylporphine. From polarographic data and other experiments, the species is considered to be an intermediate for dehydrogenation of cyclohexene. The active sites for dehydrogenation are considered to be both the central metal atom and the conjugated ring.

The chemistry of metal complexes of α,β,γ,δ-tetraphenylporphine has currently received much interest with respect to their catalysis. Some works have been carried out in which these complexes were used as catalysts such as synthesis of ammonia from hydrogen and nitrogen,[1] isomerization from quadricyclene to norbornadiene,[2] oxidation of olefins,[3] syntheses of aniline and benzene from 1,4-cyclohexadiene and nitrobenzene.[4]

While there are many reports on the electrochemical studies of the transition metal complexes, only a few have appeared in which electroreduced metal complexes were used as catalysts such as oligomerization of butadiene and polymerization of acrylonitrile catalyzed by the electroreduced tetrakis(pyridine)dichloronickel(II),[5] oligomerization of butadiene catalyzed by the electroreduced nickel acetylacetonate.[6]

The electroreduced species in the above two cases were very stable after the current was cut off. It is well-known that an analogous species is produced by the reduction of nickel acetylacetonate with chemical reagents such as $AlEt_3$, $LiAlH_4$.[7]

In a previous paper,[8] the authors briefly reported that the electroreduced cobalt complex of α,β,γ,δ-tetraphenylporphine had the catalytic activity of dehydrogenating cyclohexene to cyclohexadienes and benzene, and the electroreduced species was unstable. In this paper a detailed study of the catalytic reaction is given.

Experimental

Materials. All solvents were purified by refluxing over dehydrating agents and distilled several times. Cyclohexene was purified by refluxing over $CaSO_4$ and fractionally distilled twice. Tetra-*n*-butylammonium perchlorate (TBAP) used as a supporting electrolyte was obtained by adding hydroperchloric acid to aqueous tetra-*n*-butylammonium bromide and was recrystallized from ethanol three times after washing with water.

α,β,γ,δ-Tetraphenylporphine free base (H_2(TPP)) was prepared from benzaldehyde and pyrrole according to the method of Ball *et al.*[9]

The cobalt complex of TPP (Co(TPP)) was prepared from cobalt acetate and H_2(TPP).[10] Ni(TPP), Cu(TPP), and MnCl(TPP) were obtained by a similar method.[10] Pd(TPP), Pt(TPP), and VO(TPP) were prepared by using $PdCl_2$, K_2PtCl_4, and vanadyl acetylacetonate, respectively.[11,12]

Reaction Apparatus. The reaction apparatus is an H type cell with an arm to enable the insertion of the reference electrode. The platinum coil, platinum plate (electrode area, 2.7 cm^2), and silver coil were used as cathode, anode, and reference electrode, respectively.

Procedure. M(TPP), 1.0×10^{-4} mol and TBAP, 2.0×10^{-3} mol were dissolved in 10.0 m*l* of the solvent under nitrogen atmosphere, and 2.0 m*l* (*ca* 2×10^{-2} mol) of cyclohexene was added to the solution. After stirring for 30 min at room temperature, the solution was introduced into the electrolytic cell. The cathode potential was set up and controlled *vs.* silver wire using a Yanagimoto Controlled Potential Electrolyzer Model VE-3.

Electrolysis was carried out for 6—24 hr at room temperature. After the reaction the solution was analyzed by gas chromatography. The current was measured by a copper coulometer.

Analysis. The polarograph used was a Yanagimoto Model PB-105. Polarography was carried out by using an H type cell. The cathode and anode were a dropping mercury electrode and a mercury pool, respectively. The concentration of the metal complexes and TBAP were 5.0×10^{-3} mol/*l* and 2.0×10^{-1} mol/*l*, respectively.

Quantitative analysis of the dehydrogented products was carried out by gas chromatography. Column, Carbowax 1500 (10%) on Diasolid M (60—80 mesh) 2 m; Column temperature, 40°C; Carrier gas, H_2 30 cc/min; Detector, Thermal conductivity cell.

Detection of hydrogen evolved was carried out by gas chromatography. Column, Molecular sieve 5A 2 m; Column temperature, 20 °C; Carrier gas. N_2 5 cc/min.

ESR Measurement. The ESR spectra were recorded using a JEOL JS-3BS-X Spectrometer. The cathode, anode and reference electrode were a mercury pool, platinum wire and silver wire, respectively. The ESR spectra were measured under controlled potential electrolysis under nitrogen atomosphere.

Visible Spectra. The visible spectra of the complexes were measured using a Shimadzu MPS-50L Spectrophotometer. All operations were carried out under nitrogen atmosphere.

Results and Discussion

Electrolysis of the Metal Complexes in the Presence of Cyclohexene. The half wave potentials of Co(TPP), Ni(TPP), Pd(TPP), Pt(TPP), Cu(TPP), FeCl(TPP), and MnCl(TPP) used as the metal complexes are shown in Table 1. The electrolysis of the above-mentioned complexes and VO(TPP) were carried out at −2.0 V *vs.* Ag wire which was more negative than the second wave potential of all complexes, in a dimethylformamide(DMF) solution of cyclohexene for 6 hr at room temperature.

Table 1. The half wave potentials of the metal complexes

Complex	Prewave	$E_{1/2}$ (1)	$E_{1/2}$ (2)	Δ[b]
H_2 (TPP)[a]	−0.70	−1.05	−1.47	0.42
Co (TPP)[a]	—	−0.82	−1.87	1.05
Ni (TPP)[a]	—	−1.18	−1.75	0.57
Pd (TPP)	—	−1.00	−1.53	0.53
Pt (TPP)	—	−1.18	−1.71	0.53

Only when the cobalt complex was electrolyzed in the presence of cyclohexene, cyclohexene was dehydrogenated to 1,3- and 1,4-cyclohexadiene with evolution of hydrogen, no cyclohexane being observed in the reaction mixture. The subsequent experiments were carried out by using the cobalt complex as the metal complex.

Dehydrogenation of Cyclohexene Catalyzed by the Electroreduced Co(TPP) in a Variety of Solvents. The current efficiency for the formation of 1,3-cyclohexadiene(1,3-CHD) and 1,4-cyclohexadiene(1,4-CHD), benzene(Bz) was defined as follows:

$$\eta_{CHD} = (\text{Amount of CHD(mol)} \times 2/\text{Current passage(Faraday)}) \times 100$$

Table 2. Dehydrogenation of cyclohexene catalyzed by the electroreduced Co(TPP) in various solvents

Solvent	cC_6'/Co mole ratio	Yield (%) CHD[a]	Yield (%) Bz[b]	CHD/Co mole ratio	Bz/Co mole ratio	η_{CHD}[c] (%)	η_{Bz}[d] (%)	Dielectric constant

$$\eta_{Bz} = (\text{Amount of Bz(mol)} \times 4/\text{Current passage(Faraday)}) \times 100$$

We see from Table 2 that 1,3-CHD and 1,4-CHD were formed when DMF, dioxane, and hexamethylphosphoric triamide(HMPT) were used as solvent. When dimethyl sulfoxide(DMSO) and benzonitrile (PhCN) were used as solvent, benzene and only a little cyclohexadienes were obtained. When pyridine was used as solvent, only a little of the dehydrogenated products were obtained. This may be ascribed to the strong coordination of pyridine to cobalt atom thus preventing the coordination of cyclohexene.

When DMF, dioxane, DMSO, HMPT, and PhCN were used as solvent, the current efficiency of the dehydrogenated products was much higher than 100%, indicating that the dehydrogenation reaction is catalytic.

No direct relation was found between the dielectric constants of the solvents and the current efficiency of the products.

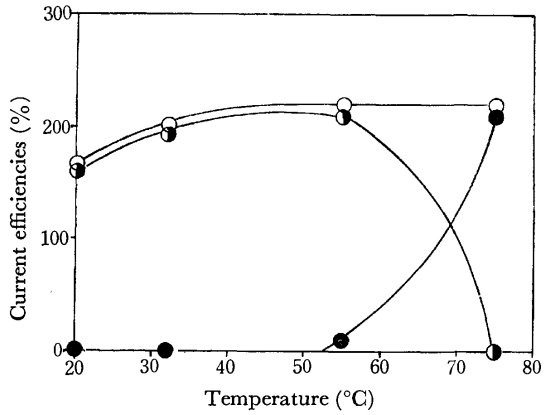

Fig. 1. Effects of the reaction temperature in DMF.
-○- $\eta_{Bz}+\eta_{CHD}$ -●- η_{Bz} -◑- η_{CHD}
η_{Bz}: current efficiency for the formation of benzene
η_{CHD}: current efficiency for the formation of cyclohexadienes

Effects of the Reaction Temperature. The current efficiency of CHD and Bz varied with the reaction temperature when DMF was used as solvent. The results are shown in Fig. 1. Only cyclohexadienes were obtained at 20 and 32°C, cyclohexadienes and benzene at 55°C and only benzene at 75°C. The maximum value of η_{CHD} was 220% at 50°C.

TABLE 3. EFFECTS OF ADDITION OF ETHANOL

Solvent	cC_6'/Co mole ratio	Yield (%) CHD[a]	Yield (%) Bz	η_{CHD}[b] (%)	η_{Bz}[c] (%)	η[d] (%)
PhCN	226	2.2	24.0	8.6	188	197
HMPT	199	trace	trace	~0	~0	~0

Conditions: concentration of Co (TPP), 1.0×10^{-2} mol/*l*; TBAP, 2.0×10^{-1} mol/*l*; EtOH, 1.0 m*l*; potential, −2.0 V *vs.* Ag wire; time, 24 hr; temp., room temp.; solvent, 10.0 m*l*.
a) total amount of 1,3- and 1,4-cyclohexadiene
b) current efficiency for formation of cyclohexadienes
c) current efficiency for formation of benzene
d) $\eta=\eta_{CHD}+\eta_{Bz}$

Effects of the Addition of Ethanol to the Reaction Solution. η_{CHD} and η_{Bz} varied with the addition of 1.0 m*l* of dry ethanol to the reaction solution of HMPT and PhCN. The results are given in Table 3.

When ethanol was added to the HMPT solution, η_{CHD} was about 0%, and by adding ethanol to the PhCN solution, η_{Bz} was much lower than that when ethanol was not added. Addition of ethanol thus prevented the formation of CHD in the case of HMPT solution, and that of benzene in the case of PhCN solution.

The ESR Spectra of the Reaction Solution. When the ESR spectra of the DMF solution of Co(TPP) were measured during electrolysis at the first wave potential, no signal was observed in any of the cases. However, at the second wave potential a signal (g= 2.003, peak-to-peak width 5.7 gauss, total width 12 gauss) was observed.

In general, the reduction steps of the metalloporphyrins(MP) are described as follows:

$$MP \xrightarrow{e^-} MP^- \xrightarrow{e^-} MP^{2-} \xrightarrow{e^-} MP^{3-} \xrightarrow{e^-} MP^{4-}$$

The paramagnetic species are the metalloporphyrin monoanion(MP^-) and trinegative ion(MP^{3-}).

Felton and Linschitz reported[13] that in the case of Co(TPP), one electron was transferred into the central metal atom to geve $[Co^I(TPP)]^-$ under electrolysis at the first wave potential, while in other metal complexes of TPP, the electron was transferred into the conjugated ring of TPP at the first wave potential, because there is a big difference between the first wave potential ($E_{1/2}$ (1)) and the second ($E_{1/2}$ (2)), *viz.*, Δ was 1.05 V as shown in Table 1, and the visible spectra of the Co(TPP) electroreduced at the first wave potential differed a great deal from the typical spectra of the monoanion of M(TPP), *viz.*, $M(TPP)^-$ (M=Zn, Cd, Mg, and H_2)[13] whose electrons were delocalized on the conjugated ring of TPP.

The signal observed when the Co(TPP) was electrolyzed at the second wave potential was similar to that of $M(TPP)^-$ as shown in Table 4. On the trinegative ion, Hush and Rowland reported[14] that the ESR spectra of the metal porphyrins such as zinc tetrabenzporphine, zinc etioporphyrin I reduced with sodium in tetrahydrofuran showed hyper fine structure,

TABLE 4. ESR SPECTRAL CHARACTERISTICS OF $M(TPP)^-$

Compound	g value	Peak-to-peak width(gauss)	Total width (gauss)
$Zn(TPP)^{-}$[a]	2.0000	20	100
$Cd(TPP)^{-}$[a]	2.0025	7	22
$Mg(TPP)^{-}$[a]	2.0024	4.7	15
$H_2(TPP)^{-}$[a]	2.0027	3.8	15
$[Co(TPP)^{2-}]^-$	2.003	5.7	12

Conditions: concentration of Co (TPP), 5.0×10^{-3} mol/*l*; supporting electrolyte, TBAP, 2.0×10^{-1} mol/*l*; solvent, DMF; cathode, Hg pool; anode, Pt wire; reference electrode, Ag wire; potential −2.0 V *vs.* Ag wire.
a) Ref. 9

13) R. H. Felton and H. Linschitz, *J. Amer. Chem. Soc.*, **88**, 1113 (1966).
14) N. S. Hush and J. R. Rowlands, *ibid.*, **89**, 2976 (1967).

and the paramagnetic species was considered to be either a trinegative ion of the porphyrin or a phlorin dianion in which hydrogen atom was attached to a methine carbon atom of the porphyrin skelton. (*cf.* Fig. 2)

The signal observed at the second wave potential was singlet and no hyper fine structure was observed. The ESR characteristics of the signal observed at the second wave potential indicates that electron is delocalized on the conjugated ring of porphyrin. Thus it is reasonable to conclude that the signal observed at the second wave potential is due to the anion radical of Co(I), *viz.*, $[Co^{I}(TPP)^{\cdot-}]^{-}$.

It is assumed that the reaction steps in the electroreduction of Co(TPP) dissolved in DMF are described as follows:

$$\text{1st step}\quad Co^{II}(TPP) \xrightarrow{e^-} [Co^{I}(TPP)]^{-} \quad E_{1/2} = -0.82\ \text{V}$$

$$\text{2nd step}\quad [Co^{I}(TPP)]^{-} \xrightarrow{e^-} [Co^{I}(TPP)^{\cdot-}]^{-} \quad E_{1/2} = -1.87\ \text{V}$$

The color of $[Co^{I}(TPP)]^{-}$ dissolved in tetrahydrofuran[15] and also that of $[Co^{I}(TPP)^{\cdot-}]^{-}$ is green.

The Intermediate for Dehydrogenation of Cyclohexene. The dehydrogenated products were not considered to be derived from the decomposition of the metal complex, since the molar ratio of the products to the metal complex was over 4. The products were obtained only when the reaction solution was electrolyzed at −2.0 V *vs.* Ag wire. No products were formed when the reaction solution was not electrolyzed and kept at room temperature under nitrogen or oxygen, or when the electrolysis was performed at −1.5 V *vs.* Ag wire (the first wave potetential) under nitrogen atmosphere. The results indicate that the dehydrogenation reaction was not catalyzed by $Co^{II}(TPP)$ or $[Co^{I}(TPP)]^{-}$.

When a cell with diaphragm (glass filter) was used and the electrolysis was carried out in DMF at −2.0 V *vs.* Ag wire, the dehydrogenated products were detected only in catholyte, and none in anolyte. On the other hand, when the electrolysis was carried out at −2.0 V *vs.* Ag wire under oxygen atmosphere, no products were obtained.

Thus the products were not formed by the electrooxidation of cyclohexene. It is reasonable to conclude that the species electroreduced at the second wave potential had catalytic activity for dehydrogenating cyclohexene to cyclohexadienes and benzene, $[Co^{I}(TPP)^{\cdot-}]^{-}$ being reaction intermediate.

Felton *et al.* reported that in the cases of metal complexes (M=Ni, Cu, Pb, Mg *etc.*) except for the cobalt complex, the difference between the first wave potential and the second, Δ was constant 0.44±0.04 V. Thus one electron was transferred to the ring of porphyrin rather than the central metal atom to give the monoanion of M(TPP) at the first wave potential and the dianion of M(TPP) at the second wave potential.

In the cases of Pd(TPP), Pt(TPP), FeCl(TPP), and MnCl(TPP), Δ was much lower than Δ in the case of Co(TPP) (1.05 V) as shown in Table 1. Thus it is considered that the dianion of these complexes was produced under electrolysis at the second wave potential.

It should be noted that the metal complexes except for the cobalt complex in which electrons were transferred to the conjugated ring of TPP under electrolysis had no activity for the dehydrogenation of cyclohexene.

The Active Sites of the Reaction Intermediate for the Dehydrogenation of Cyclohexene. No products were detected when the electrolysis was carried out in pyridine solution. This might be ascribed to the strong coordination of pyridine to the cobalt atom preventing the coordination of cyclohexene. One of the active sites is therefore considered to be the central metal atom.

No products were detected when the electrolysis of H_2TPP in HMPT solution was carried out at the first wave potential (−1.2 V *vs.* Ag wire). Thus the dehydrogenation reaction of cyclohexene was not catalyzed by H_2TPP^{-} which had only the conjugated ring of TPP.

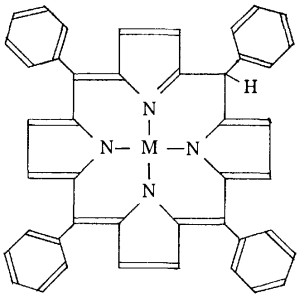

Fig. 2. The structure of tetraphenylphlorin.

Closs and Closs reported[16] that $[Zn(TPP)]^{2-}$ obtained by the reduction of Zn(TPP) with anthracene negative ion was reacted with equimolecular methanol to give the monoanion of zinc tetraphenylphlorin as shown in Fig. 2. When $[Zn(TPP)]^{2-}$ is reacted with excess methanol, the monoanion of zinc tetraphenylchlorin in which two hydrogen atoms are attached to a pyrrole fragment of porphyrin skeleton is produced.[16] Thus it may be reasonable to assume that added alcohol

reacts with the conjugated ring of the porphyrin skeleton to cleave or weaken the conjugated ring, and the composition of the dehydrogenated products changes with the addition of ethanol.

On the other hand, Ichikawa *et al.* reported[17] that the active site for the exchanging reaction of H_2 and D_2 catalyzed by the Na-phthalocyanine electron donor-acceptor complexes may be the conjugated ring of the phthalocyanines[17]. Thus the active sites for the dehydrogenation of cyclohexene are considered to be both the central metal atom and the conjugated ring of $[Co^{I}(TPP)^{\cdot-}]^{-}$.

The visible spectrum of the reaction solution after electrolysis is shown in Fig. 3. The band at 620 nm assigned to that of the cobalt complex of tetraphenylchlorin,[18,19] and free hydrogen molecule was detected by gas chromatography. It might be considered that the hydrogen molecule extracted from cyclohexene hydrogenated the conjugated ring of porphyrin giving rise to the evolution of hydrogen molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2902—2906 (1972)

Aroyl Arenesulfonyl Peroxides. VI. Benzoyloxylation and *p*-Toluenesulfonyloxylation of Aromatic Compounds with Benzoyl *p*-Toluenesulfonyl Peroxide[1]

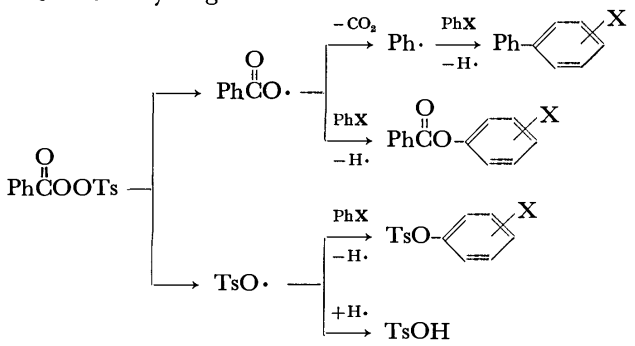
Ryuki HISADA, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

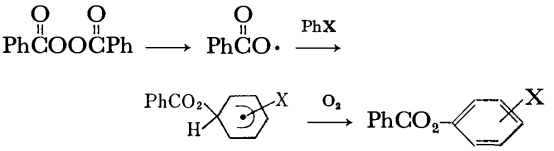
(Received March 18, 1972)

Benzoyl *p*-toluenesulfonyl peroxide (BTP) was decomposed in benzene, toluene, chlorobenzene, nitrobenzene, or anisole in a nitrogen or oxygen atmosphere. Yields of aryl benzoates and *p*-toluenesulfonates were always greater in an oxygen atmosphere than those in a nitrogen atmosphere, except those with nitrobenzene. The isomer distributions of these aryl benzoates and *p*-toluenesulfonates were determined. The rate of decomposition in anisole was considerably greater than those in other arenes. When BTP[carbonyl-^{18}O] was decomposed in anisole, the *o*- or *p*-anisyl benzoate formed was found to contain about equal amounts of oxygen-18 at both the carbonyl and phenoxy oxygens. On the basis of these findings the mechanisms of benzoyloxylation and *p*-toluenesulfonyloxylation were discussed.

A previous paper from our laboratories described that decomposition of benzoyl *p*-toluenesulfonyl peroxide (BTP) in benzene with suspended magnesium oxide under nitrogen yielded 44% diphenyl, 8% phenyl benzoate, and 1% phenyl *p*-toluenesulfonate.[2] It was proposed that under these conditions BTP decomposes homolytically, yielding phenyl radical and benzoyloxy radical, and *p*-toluenesulfonyloxy radical functions as an efficient hydrogen-abstractor.[3]



Benzoyloxylation of arenes with benzoyl peroxide (BPO) was studied by various groups.[4-7] Nakata, Tokumaru, and Simamura investigated the thermolysis and photolysis of BPO in arenes, and reported that the yields of aryl benzoates under oxygen are considerably greater than those under nitrogen.[4]



An investigation on the photolysis by use of BPO-[carbonyl-^{18}O] ascertained that this benzoyloxylation involves benzoyloxy free radical.[8]

BTP is a new reagent for benzoyloxylation, and a detailed investigation seems desirable. The decom-

position of BTP and BTP[carbonyl-^{18}O] in arenes with suspended magnesium oxide in oxygen atmosphere has been investigated under various conditions, and the results will be described in this paper.

Results and Discussion

In an oxygen atmosphere, BTP was decomposed in benzene, toluene, chlorobenzene, or nitrobenzene with suspended magnesium oxide for 15 hr at 45°C. Since BTP decomposes very rapidly in anisole, a dichloromethane solution of BTP was stirred into anisole containing suspended magnesium oxide under oxygen. Yields and isomer distributions of the products are shown in Table 1.

The yields of the products are much affected by the kinds of the atmosphere with the exceptions of the decompositions in nitrobenzene and anisole. Under nitrogen, the yields of phenylated products are greater than those of benzoyloxylated products, whereas under oxygen the yields of benzoyloxylated products are greater than those of phenylated products. Since the isomer distributions of aryl benzoates are similar in both atmospheres, the mechanism must be the same. The yields of aryl benzoates decrease in the order of anisole, toluene, benzene, chlorobenzene, and nitrobenzene, and the yield in nitrobenzene is zero. These results are in agreement with those of Nakata *et al.*[4)] The increases in the yields of the esters are more extensive in toluene, benzene, and chlorobenzene than those in anisole.

In nitrobenzene, BTP gave no nitrophenyl benzoate, and phenyl *p*-toluenesulfonyl carbonate was formed in 52—60% yield. This suggests that the main reaction in nitrobenzene is the carboxy-inversion even though magnesium oxide was suspended in the medium. A previous paper described that, when magnesium oxide was absent, the main reaction of BTP in benzene was the carboxy inversion.[2)] It is reasonable that the ionic carboxy inversion process takes place more easily in polar solvents such as nitrobenzene. Even when BTP undergoes homolysis to some extent, both radicals produced ($PhCO_2\cdot$ and $TsO\cdot$) are strongly electrophilic and not likely to attack the electron-deficient nitrobenzene.

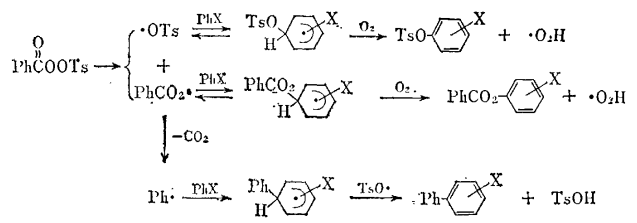
It is possible that aryl benzoates are produced by the attack of benzoyloxy cation. However, this possibility is rejected by the findings that 1) much substituted diphenyls are produced, 2) in nitrobenzene the main products are *ortho* and *para* nitrodiphenyls which must be formed by the attack of phenyl free radical, not by phenyl cation, and 3) the yields of aryl benzoates are much greater under oxygen because of abstraction of hydrogen from the substituted cyclohexadienyl radicals by oxygen.

Except nitrobenzene, all the arenes are *p*-toluenesulfonyloxylated although the yields are not so great. The yields under oxygen are greater than those under nitrogen (1.5—2.7 times), but the mechanism must be similar since the isomer distributions do not differ.

Dannley and his co-workers reported that the reactions between *m*-nitrobenzenesulfonyl peroxide and arenes are ionic, and electrophilic attack of the peroxidic oxygen on arenes results in the formation of aryl *m*-nitrobenzenesulfonates.[9,10)] In the reactions of BTP with toluene and chlorobenzene, considerable amounts of *meta* substituted products were found. It is concluded that these aryl *p*-toluenesulfonates arise, not from electrophilic attack of the *p*-toluenesulfonyloxy oxygen, but from attack of *p*-toluenesulfonyloxy radical, on the basis of the findings that 1) free radical phenylation and benzoyloxylation take place simultaneously, 2) yields of aryl benzoates and *p*-toluenesulfonates are greater under oxygen, and 3) considerable *meta*-substitution takes place with toluene and chlorobenzene. The decomposition of BTP in arenes is the first example which clearly indicates the attack of a sulfonyloxy radical on an aromatic ring.

The mechanism of the substitutions of an arene is expressed as follows.

9) R. L. Dannley and G. E. Corbett, *J. Org. Chem.*, **31**, 153 (1966).
10) R. L. Dannley, J. E. Gagen, and O. J. Stewart, *ibid.*, **35**, 3076 (1970).



Additions of *p*-toluenesulfonyloxy and benzoyloxy radicals on an arene are reversible. When abstraction of a hydrogen atom from the cyclohexadienyl radicals is slow (under nitrogen), *p*-toluenesulfonyloxy and benzoyloxy radicals are reformed; the latter further decomposes to carbon dioxide and phenyl radical.

The decomposition of BTP in anisole is quite different from the decompositions in other solvents; 1) the rate of decomposition was much faster, 2) even under nitrogen the yields of benzoates were very large (that is, very little decarboxylation of benzoyloxy radical occurs) and the yields under oxygen are only slightly greater, and 3) no carboxy inversion product (phenyl *p*-toluenesulfonyl carbonate, PTC) was found. Therefore, attack of free benzoyloxy radical on anisole does not appear to be the reaction which is taking place in an anisole solution of BTP.

It is conceivable that the electron-rich anisole nucleus attacks the electron-deficient O–O bond of BTP, and thus the rate is faster and the yields of benzoates are greater. In order to check this possibility, BTP-[carbonyl-^{18}O] was synthesized and decomposed in anisole in the presence and absence of suspended magnesium oxide. Even in the absence of magnesium oxide, anisyl benzoates were formed in 40 mol% yield ($o:m:p$ =41:<1: 59%) and PTC was formed only in 10 mol% yield. The compounds I—VII shown in the following scheme were converted to carbon dioxide,[11] which was then analyzed by use of a mass spectrometer. The results are shown in Table 2.

It is clear that within experimental error the carbonyl

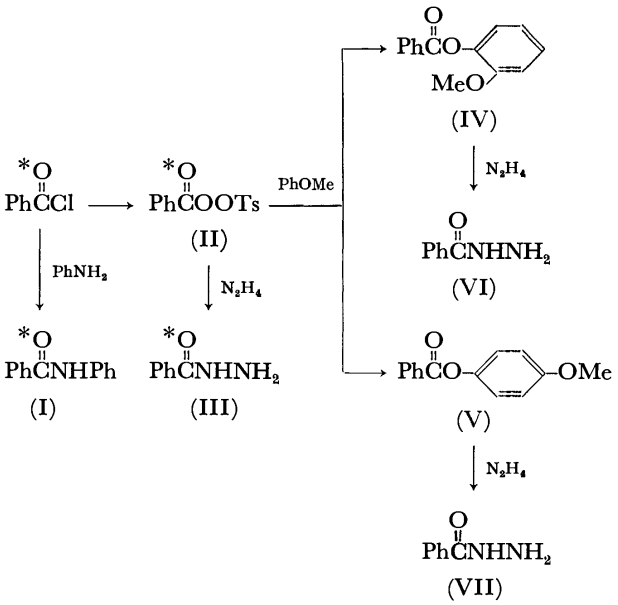
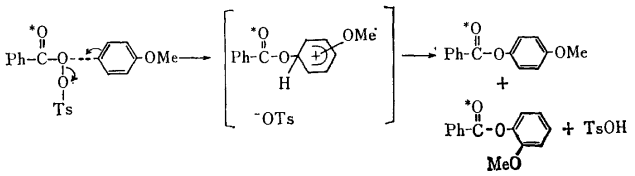
a) Experimental error in two measurements with the same sample was ±0.02 excess atom %.
b) Calculated on the assumption that the carbonyl oxygen is completely equilibrated with the ester oxygen.

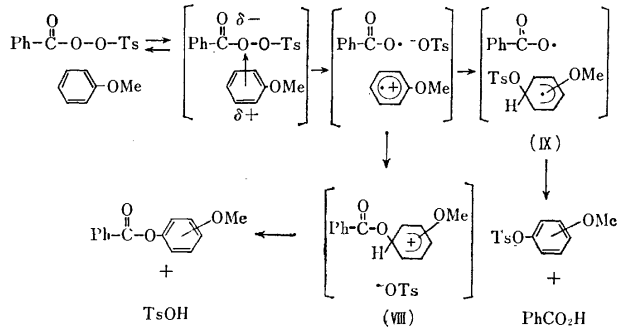
11) D. Rittenberg and L. Ponticorvo, *Int. J. Appl. Radiat. Isotopes*, **1**, 208 (1956).



oxygen of BTP is completely equilibrated between the carbonyl and phenoxy oxygens in anisyl benzoates (IV) and (V). These results are similar to those of the photochemical benzoyloxylation of benzene with BPO[8] and $CuCl_2$-catalyzed benzoyloxylation of *p*-xylene with BPO.[12] The results of the ^{18}O study reject the possibility of the electrophilic (S_N2 type) attack of the benzoyloxy oxygen on anisole.



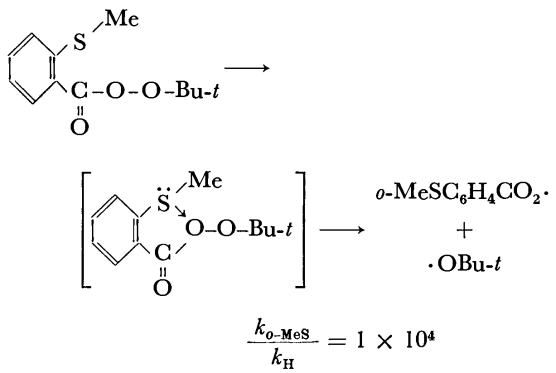
Since the rate of decomposition of BTP in anisole is much greater than those in other solvents, some sort of interaction between BTP and anisole must exist. On the basis of all the results obtained so far, the following scheme seems to represent what is taking place in an anisole solution of BTP.



A charge-transfer complex is formed by donation of π-electrons of anisole to the antibonding orbital of the O–O bond of BTP, and the O–O bond scission is much accelerated by this electron donation. A related example is the enhancement of the homolysis rates of

12) C. G. Reid and P. Kovacic, *J. Org. Chem.*, **34**, 3308 (1969).

ortho substituted perbenzoates.[13]



$$\frac{k_{o\text{-MeS}}}{k_H} = 1 \times 10^4$$

The C. T. complex formed from BTP and anisole dissociates to give a trio of benzoyloxy radical, *p*-toluenesulfonate anion and anisole radical cation in cage. A one-electron transfer reaction of this kind is observed in the reaction of BPO with dimethylaniline.[14] Two processes are possible from the trio of benzoyloxy radical, *p*-toluenesulfonate anion and anisole radical cation; benzoyloxy radical and anisole radical cation may combine to form a benzenium ion (VIII), or *p*-toluenesulfonate anion and anisole radical cation may combine to form a cyclohexadienyl radical (IX).

When BTP was photolyzed in benzene under oxygen or nitrogen with a high pressure mercury lamp at 9°C for 5 hr, the results were similar to those shown in Table 1; under oxygen the yield of diphenyl is lower and the yields of phenyl benzoate and *p*-toluenesulfonate are greater. The results of the photolyses also support the hypothesis that benzoyloxylation and *p*-toluenesulfonyloxylation of arenes proceed by the free radical mechanism.

Experimental

Materials. Benzene and substituted benzenes were purified by the procedures described previously.[15] BTP and BTP[carbonyl-^{18}O] were prepared by the method described in the previous papers.[2,16]

Decomposition of BTP in Benzene, Toluene, Chlorobenzene, or Nitrobenzene with Suspended Magnesium Oxide under Nitrogen or Oxygen. A solution of BTP (4 mmol) in benzene, toluene, chlorobenzene, or nitrobenzene (50 m*l*) with suspended magnesium oxide (40 mmol) was stirred with a mechanical stirrer for 15 hr at 45°C. Throughout the reaction nitrogen or oxygen was bubbled in the reaction mixture. After the completion of the decomposition the internal standard samples for gas chromatographic analyses of the products were added to the mixture. After the magnesium oxide was filtered off, the filtrate was washed successively with a sodium hydrogen carbonate solution and water, and dried over anhydrous magnesium sulfate. It was concentrated under reduced pressure, and subjected to gas chromatographic analyses.

Decomposition of BTP in Anisole with Suspended Magnesium Oxide under Nitrogen or Oxygen. Nitrogen (or oxygen) was bubbled through a solution of BTP (4 mmol) in dichloromethane (10 m*l*) for 15 min. Nitrogen (or oxygen) was also bubbled through anisole (50 m*l*) with suspended magnesium oxide (40 mmol). Then, the BTP solution was added drop by drop with stirring into the anisole, and the mixture was stirred for 10 hr at 25°C with bubbling of nitrogen (or oxygen). The work-up procedure was the same as described above.

Gas Chromatography. The amounts of substituted diphenyls, aryl benzoates, and aryl *p*-toluenesulfonates produced were determined by a Hitachi Gas Chromatograph K-53, on the basis of the comparison with authentic samples. The columns and the internal standard samples used are described in Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2906—2909 (1972)

Photolyses of Diaryl α-Disulfones[1)]

Michio KOBAYASHI, Koji TANAKA, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received April 15, 1972)

Di-*p*-tolyl disulfone and diphenyl disulfone were decomposed in various arenes by irradiation of UV light. The products found were arenesulfonic acids, arenesulfonic anhydrides, thiolsulfonates, diaryl sulfones, biaryls, and sulfur dioxide. All the findings indicate that photolyses of α-disulfones yield a pair of arenesulfonyl radicals.

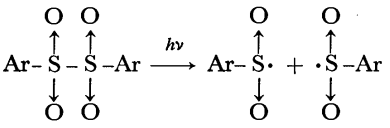
In comparison with the thiyl radicals, the sulfonyl radicals have been investigated to a much lesser extent. Some of the methods described in the literature for generation of sulfonyl radicals are thermolyses[2)] and photolyses[3)] of azosulfones, oxidation of sulfinic acids in water,[4)] and thermolyses and photolyses of arenesulfonyl iodides.[5)] It was reported that no substitution occurs from the reaction of arenes with the sulfonyl radicals formed by addition of phenyl radical to sulfur dioxide,[6)] photolyses of diaryl sulfones,[7)] or oxidation of *N,N'*-diarenesulfonylhydrazines.[8)] Kice and Favstritsky studied the thermolysis of di-*p*-tolyl disulfone in bromobenzene, and the formation of phenyl *p*-tolyl sulfone was ascribed to the attack of *p*-toluenesulfonyl radical to bromobenzene.[9)]

In an attempt to understand the chemistry of arenesulfonyl radicals, di-*p*-tolyl disulfone (I) and diphenyl disulfone (II) have been photolyzed in various arenes, and the products formed have been investigated. The results will be described in this paper.

Results and Discussion

Diaryl α-disulfones are very stable at room temperature, but were found to decompose fairly rapidly upon irradiation of UV light. After 30 min of irradiation, a thin layer chromatographic analysis showed the presence of diaryls, and more than 50% of disulfones were found to decompose in 2—3 hr.

Diaryl α-disulfones have an absorption maximum near 250 nm, which matches with the wavelength of the light at 253.7 nm from a mercury lamp. The recently reported value[10)] for S-S bond length (2.193 Å) in diphenyl disulfone is 0.16 Å longer than the average bond length of the ordinary disulfides. The elongation of the bond length means the weakning of the S-S bond in α-disulfones, which may explain the easy splitting of these compounds by photolyses.



The results of the photolyses of di-*p*-tolyl disulfone (I) and diphenyl disulfone (II) in aromatic solvents are shown in Table 1 and 2. It should be noted that

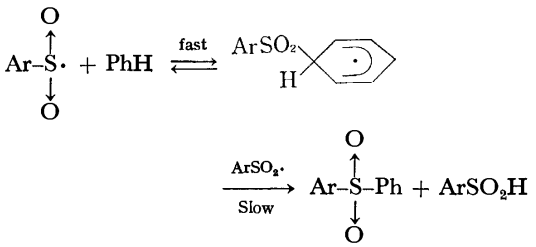
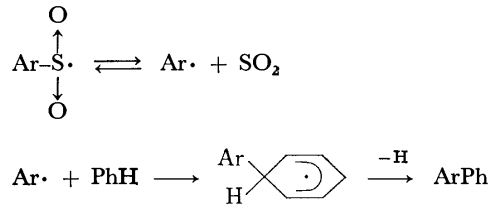
4.05	300	7	94.9	b)	12.4	1.2	4.4	1.2	b)	3.0

a) Extent of photolysis was estimated to be 70—80%, but exact determination was not possible. Yields are based on the amount of disulfone initially added.
b) Not determined.

the yields of sulfones are very small. Addition of arenesulfonyl radicals to benzene is considered as a reversible step and hydrogen abstraction from an arenesulfonylcyclohexadienyl radical must be a very slow step in comparison with the dissociation of the cyclohexadienyl radicals.

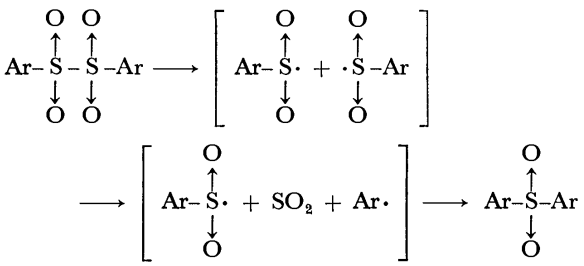


Formation of methylbiphenyls shows that the following desulfonylation takes place to some extent. This reaction is known to be a reversible process.[11]

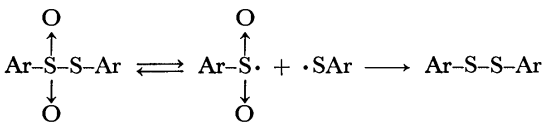


Bond dissociation energy $D(C\text{–}SO_2\cdot)$ of the related methanesulfonyl radical is estimated to be 23 kcal/mol.[12] This rather high value suggests that the cleavage of sulfur dioxide from the sulfonyl radical must be much slower than that of carbon dioxide from the corresponding aroyl radicals. In order to ascertain that arenesulfonyl radicals lose sulfur dioxide under these conditions, a benzene solution of (I) was degassed and irradiated in a quartz tube. Sulfur dioxide was found as a product; yield, 0.26 mol per mol of (I). Other products found were *p*-toluenesulfonic acid (86 mol%), *p*-tolyl *p'*-toluenethiolsulfonate (50 mol%), and *p*-methylbiphenyl (10 mol%).

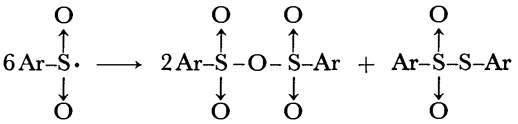
Di-*p*-tolyl sulfone among the decomposition products of (I) in benzene is probably the product of combination of radicals in cage.



Di-*p*-tolyl disulfide is the product of dimerization of ArS· radical, which is probably formed by photolysis of thiolsulfonates.



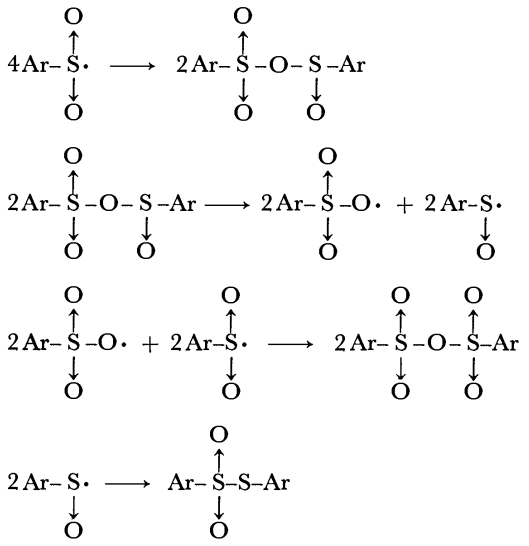
Formation of *p*-toluenesulfonic anhydride and *p*-tolyl *p*-toluenethiolsulfonate can be explained as the result of disproportionation of sulfonyl radicals as suggested by da Silva Correa and Waters.[5]



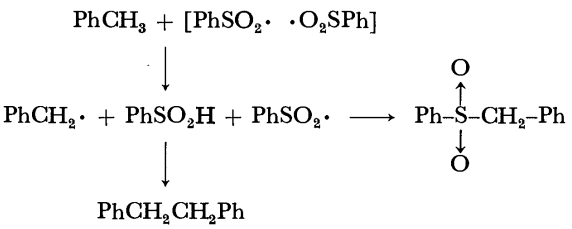
The above equation is the summary of the following

11) H. Goldwhite, M. S. Gibson, and C. Harris, *Tetrahedron*, **20**, 1613 (1964).
12) W. K. Busfield, K. J. Ivin, H. Mackle, and P. A. G. O'Hare, *Trans. Faraday Soc.*, **57**, 1064 (1961); A. Good and J. C. J. Thynne, *ibid.*, **63**, 2708 (1967).

multi-step reactions.



The results shown in Table 2 are generally in agreement with those in Table 1 except the formation of benzyl phenyl sulfone and bibenzyl, which can be explained as the products of combination of two radicals.



The higher yields of these products than those of phenyl *p*-tolyl sulfones suggest that abstraction of a benzyl hydrogen from toluene is faster than substitution on the aromatic ring.

Although it has been reported that substitution of arenes with arenesulfonyl radicals does not occur,[6,7] formation of phenyl *p*-tolyl sulfone in this investigation clearly shows that an arenesulfonyl radical reacts with an arene ring to some extent. In order to study the aromatic substitution with benzenesulfonyl radical in detail, the isomer distribution of aryl phenyl sulfones were determined in toluene, anisole, and chlorobenzene. The results of benzenesulfonylation and phenylation are summarized in Table 3.

Table 3. Isomer distribution of substituted biphenyls and phenyl aryl sulfones produced from photolysis of diphenyl disulfone (II) in arenes

Arene	Isomer distributions %					
	PhC_6H_4X			$PhSO_2C_6H_4X$		
	o-	*m*-	*p*-	*o*-	*m*-	*p*-
PhMe	32.7	40.0	27.3	31.6	35.8	32.6
PhOMe	46.6	19.9	33.5			
PhCl	33.4	35.1	31.5			

The isomer distributions of substituted biphenyls in Table 3 are different from what is expected for phenylation with phenyl cation,[13,14] and are similar to those observed for phenylation with phenyl radical produced from thermolyses of benzoyl peroxide or *N*-nitrosoacetanilide. However, the amounts of *ortho*-substituted products are much less than those usually observed for phenylation with the phenyl radical produced by thermolyses. It is possible that the behavior of thermally produced phenyl radicals and that of photolytically produced phenyl radicals are somewhat different due to the difference of the extent of the solvation. The isomer distributions of substituted biphenyls in Table 3 are in agreement with those reported for phenylation with the phenyl radical produced from the photolysis of diphenyl sulfone (Me; *o*-, 30.4, *m*-, 43.5, *p*-, 26.1; MeO; *o*-, 32.3, *m*-, 13.5, *p*-, 55.2; Cl; *o*-, 41.8, *m*-, 28.6, *p*-, 29.6),[15] and those with the phenyl radical produced from the photolysis of phenylazo *p*-tolyl sulfone.[3]

In the photolysis of diphenyl disulfone in chlorobenzene, 176 mol chlorobiphenyls and 15.2 mol biphenyl were formed from 100 mol disulfone. These results show that chlorobenzene itself was photolyzed under these conditions.

When diphenyl disulfone was irradiated in nitrobenzene with a low pressure mercury lamp for 22 hr, almost no reaction took place. It appears that nitrobenzene absorbs light but does not transfer the energy to the disulfone.

In order to estimate the electrophilicity of sulfonyl radicals, di-*p*-tolyl disulfone was photolyzed in anisole, and the amounts of isomeric anisyl phenyl sulfones were determined. From 6.5 mmol of the disulfone, 0.031 mmol of the *p*-anisyl sulfone and 0.180 mmol of the *o*- and *m*-anisyl sulfones were formed (separation of the *o*- and *m*-isomers was not possible). Therefore, the isomer distribution is *o*+*m*, 85.3% and *p*-, 14.7%.

The isomer distribution of substituted diphenyl sulfones shown in Table 3 indicate that this benzenesulfonylation involves not benzenesulfonyl cation, but benzenesulfonyl radical. Electrophilic arenesulfonylation of arenes is known as a highly selective reaction. Cationic *p*-toluenesulfonylation of toluene gave the *o*- and *p*-(main product) sulfones exclusively, and no *m*-substituted product was found.[16]

The result of the present investigation clearly shows the occurrence of free radical arenesulfonylation of aromatic rings, whereas it was stated in the literature[6,7] that the sulfonyl radical generated in an aromatic solvent is not reactive enough to give a sulfone. This contradiction can be ascribed to the difference of the hydrogen abstracting agent from the sulfonylcyclohexadienyl radical. In the photolyses of the sulfonyl iodide, the hydrogen must be abstracted by iodine

16) M. Kobayashi, H. Minato, and Y. Kohara, This Bulletin, **43**, 234 (1970); Y. Kohara, M. Kobayashi, and H. Minato, *ibid.*, **43**, 520 (1970).

atoms which have very low reactivity for this role. In the thermolyses or photolyses of azosulfones, the sulfonyl radicals mainly act as the hydrogen abstractor from the arylcyclohexadienyls formed by the attack of aryl radicals on arene. In the photolyses of diaryl disulfones, sulfonyl radicals abstract hydrogen atom from the sulfonylcyclohexadienyl radicals produced by the attack of sulfonyl radicals on arene, and therefore, considerable amounts of diaryl sulfones are isolated.

Experimental

Materials. Benzene, toluene, anisole, and chlorobenzene were purified according to the methods described in the literature.[17] Di-*p*-tolyl disulfone was prepared by $KMnO_4$-oxidation of *p*-toluenesulfinic acid in acetic acid;[18] yield, 28%; recrystallized from acetone, and then three times from benzene; mp (decomp.) 217—219°C (lit, 211°C,[18] 218—220°C,[19] 220°C[20]). Diphenyl disulfone (II) was synthesized by $KMnO_4$-oxidation of benzenesulfinic acid in acetic acid; yield, 22%; recrystallized from acetone and then twice from benzene; mp 190—192°C (lit, 193—194°C,[18] 193°C[20]).

Photolysis of I in Benzene under Nitrogen. A benzene solution (500 m*l*) of (I) (3—5 mmol) was stirred and irradiated with a 100 W high pressure mercury lamp at 16—22°C under nitrogen. Then the reaction mixture was washed with water, and the amount of *p*-toluenesulfonic acid in the aqueous layer was determined by converting it into *S*-benzylisothiuronium *p*-toluenesulfonate. The organic layer was dried over anhydrous magnesium sulfate, concentrated under reduced pressure, and the residue was separated to its components by column chromatography (Florisil, 100—200 mesh). *p*-Methylbiphenyl (eluted with hexane), di-*p*-tolyl disulfide (hexane–benzene) and *p*-tolyl *p'*-toluenethiolsulfonate (benzene) were identified by comparison with authentic samples. Compounds containing a sulfone group (eluted with diethyl ether) were identified by use of an Ohkura Gas Chromatograph 1100 on an SE-30 column. The amount of *p*-toluenesulfonic anhydride was determined by converting it to *N*-phenyl-*p*-toluenesulfonamide and anilinium *p*-toluenesulfonate by the reaction with aniline.

Photolysis of I in Degassed Benzene. A benzene solution (60 m*l*) of (I) (0.32 mmol) in a quartz vessel was degassed by the freeze-thaw technique, and then irradiated with a 1 kW high pressure mercury lamp for 2 hr at 16—17°C. Then, the mixture was distilled at room temperature in high vacuum. Sulfur dioxide contained in the distillate was extracted with a 5% sodium hydroxide solution, and its amount was determined by iodometry. From the higher boiling fraction the unchanged (I) was filtered off, and then the rest was separated by column chromatography.

Photolysis of II in Toluene under Nitrogen. The photolysis was carried out according to the procedure described for (I). Diphenyl disulfide (eluted with hexane–benzene), phenyl benzenethiolsulfonate (benzene), diphenyl sulfone (benzene), and benzyl phenyl sulfone (benzene) were identified by comparison with authentic samples. A mixture of phenyl *o*-, *m*-, *p*-tolyl sulfones and a mixture of *o*-, *m*-, *p*-methylbiphenyls and bibenzyl (eluted with hexane) were analyzed by use of a Hitachi Gas Chromatograph K53.

Photolysis of II in Anisole under Nitrogen. An anisole solution of (II) (4.05 mmol) was stirred and irradiated with a 6 W low pressure mercury lamp under nitrogen at 16—19°C for 21.5 hr. The reaction mixture was analyzed in a manner similar to that described above.

Diazotization of Tetrafluoroanthranilic Acid and Several Reactions of Related Compounds

Sei-ichi HAYASHI and Nobuo ISHIKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 8, 1972)

Diazotization of tetrafluoroanthranilic acid with nitrosylsulfuric acid in acetic acid gave a ring-hydroxylated, stable diazonium salt **4**, which was isolated in high yield. Several reactions on this diazo compound were carried out. Replacement of the diazonium group with hydrogen, chlorine, or bromine was accomplished with the usual reagents. The reaction of diazo compound with diazomethane afforded a benzoxadiazine compound **13**. Other related polyfluoroaromatic compounds were prepared.

Tetrafluoroanthranilic acid (**1**) is a valuable precursor of tetrafluorobenzyne through the diazotized intermediate, tetrafluorobenzenediazonium-2-carboxylate (**2**).[1] Since an unsubstituted benzenediazonium-2-carboxylate is known as a stable, isolable compound,[2] we intended to isolate the analogous stable diazonium compound from **1**. When **1** was diazotized with sodium nitrite in dilute hydrochloric acid in the usual

Chart A

manner, only a clear diazo solution was obtained, from which any attempted isolation of the diazonium compound was unsuccessful.

When the reaction was carried out with nitrosylsulfuric acid in acetic acid, however, a very stable diazonium compound of mp 187°C (decomp.) was obtained in good yield, and the structure of this compound was proved to be 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate (**4**) by ^{1}H and ^{19}F NMR and mass spectra. In this case, it was evident that the fluorine atom *ortho* to diazo group had been nucleophilically replaced with hydroxyl group during the course of the diazotization. This is not peculiar since a halogen substituent in *para* or *ortho*, especially the latter, to diazonium group is known readily replaceable by nucleophile.[3,4] As for polyfluoroaromatic compounds, it was reported that pentafluoroaniline gave *p*-hydroxytetrafluorobenzenediazonium salt exclusively when it was diazotized with sodium nitrite in hydrochloric acid or in 70% sulfuric acid.[5]

For the purpose of clarifying the structure and reactivity of a exceptionally stable diazonium compound **4**, we examined several reactions on this material. On heating with aqueous hypophosphorous acid it was reduced into 2,3,4-trifluoro-5-hydroxybenzoic acid (**5**) with evolution of nitrogen gas. The same reaction occurred when the diazonium compound was warmed with copper powder in either water, or ethanol, or dimethylformamide.

The diazonium group was also readily replaced with halogens affording 2,3,4-trifluoro-6-halogeno-5-hydroxybenzoic acid, **6** and **7**, in good yields when **4** was treated with the corresponding cuprous halides in aqueous hydrogen halides. However, the replacement of the diazonium group with iodine was unsuccessful. With aqueous potassium iodide alone there was no reaction, whereas in the presence of copper powder diazonium group was split off to give 2,3,4-trifluoro-5-hydroxybenzoic acid (**5**). This might be attributed to the steric effect on the attack of the bulky iodide ion. The NMR spectra of the compound **5**—**10** served for the determination for the positions of substituents (*loc. cit.*).

When diazomethane was allowed to react with 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate, an interesting heterocyclic compound, 6,7,8-trifluoro-5-methoxycarbonyl-4H-1,3,4-benzoxadiazine (**13**), was obtained. The yield was rather good (83%), and the structure was derived from its mass, NMR, and IR spectra. In the course of this reaction diazomethane should have attacked 3,4,5-trifluoro-2-methoxycarbonylbenzenediazonium-6-oxide (**12**), and this was confirmed preparatively.

Thus, the diazo oxide **12**, obtained from tetrafluoroanthranilic acid by methylation with methanol-sulfuric acid and subsequent diazotization of the resulting ester **11** with nitrosylsulfuric acid, was similarly converted to the oxadiazine **13** on treating with diazomethane. An analogous reaction between a diazo oxide and a substituted diazomethane was reported by R. Huisgen *et al.*[6] who observed the formation of 5,6,7,8-tetrachloro-2-phenyl-4*H*-1,3,4-benzoxadiazine from 3,4,5,6-tetrachlorobenzenediazonium-2-oxide and phenyldiazomethane.

The structure of the trifluoromethoxycarbonylben-

b) J^m_{HF} 6.5, 9.0, J^p_{HF} 2.8 Hz.
c) J^m_{HF} 7.5, 7.8, J^p_{HF} 2.5 Hz.
d) J^m_{HF} 7.2, 8.1, J^p_{HF} 2.6 Hz.

zenediazonium oxide (**12**) was easily deduced by converting it to methyl 2,3,4-trifluoro-5-methoxybenzoate (**8**). Thus, treatment of **12** with 50% hypophosphorous acid afforded the phenol **14**, which gave **8** with diazomethane, indicating the validity of the assignment of structure **12** to the diazo oxide.

Benzoxadiazine **13** reacted with acetic anhydride to give 2-acetoxy-3,4-diacetyl-6,7,8-trifluoro-5-methoxycarbonyl-2*H*-3,4-dihydro-1,3,4-benzoxadiazine (**15**). The structure was confirmed by ^{1}H NMR spectrum.

For the generation of tetrafluorobenzyne, tetrafluoroanthranilic acid was diazotized with *n*-butyl nitrite in organic solvent.[1] No hydroxylation or other nucleophilic reaction seemed to occur in this case. To confirm this we carried out the above diazotization in the presence of copper powder. As a result 2,3,4,5-tetrafluorobenzoic acid (**3**) was obtained in 62% and no other product was detected. Formation of **3** could be rationalized by the reductive decomposition of tetrafluorobenzenediazonium-2-carboxylate, which had not been hydroxylated in the absence of water.

NMR Spectra. In NMR spectra of polyfluoroaromatic compounds, it is generally known that the hydrogen nucleus in XCH_3 (X=O, N, S *etc.*) couple with both fluorine nuclei in *ortho* positions,[7] but if one *ortho* position is unsubstituted such a coupling is not observed.[8] This rule played an important role in the determination of positions of substituents in our compounds. Thus, in trifluoromethoxybenzoic acid **9** which was derived from **4**, *via* **5** and **8**, the signal of OCH_3 appeared as a sharp singlet. This means that the methoxyl group has one *ortho* fluorine atom and the other *ortho* position is unsubstituted. Among four trifluoromethoxybenzoic acids which can be considered in this case, only 2,3,4-trifluoro-5-methoxybenzoic acid is suited for this limitation (Table 1).

As for chlorotrifluoromethoxybenzoic acid (**10**), the NMR signal of OCH_3 protons appeared as a doublet (J=1.5 Hz). This also supports the assignment of structure of **10** as 6-chloro-2,3,4-trifluoro-5-methoxybenzoic acid, because it means one *ortho* position to methoxyl group is occupied with fluorine and the other with chlorine.

The structure of the methyl trifluoromethoxybenzoate (**8**) was deduced from the ^{19}F NMR spectrum. Utilizing Bruce's substituent shielding parameter,[9] the chemical shifts of the various fluorine atoms for two possible structures, methyl 2,3,4-trifluoro-5-methoxybenzoate (**8**) and methyl 2,4,5-trifluoro-3-methoxybenzoate (**8a**) were calculated. The observed fluorine chemical shifts are in agreement with those expected for the former (**8**) (Fig. 1).

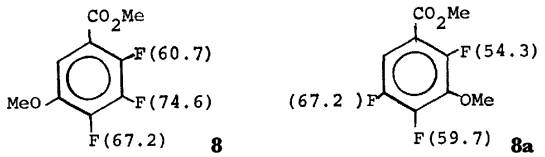

Fig. 1. Calculated ^{19}F NMR chemical shift for **8** and **8a**.

Regarding ^{19}F NMR spectra of polyfluoroaromatic compounds it is also known that the signal of fluorine atom lying between two *ortho* fluorine atoms shift considerably to the upper field.[10] In the spectra of the polyfluorodiazo compounds **4** and **12**, however, a shift to lower field of the 4-F signal was observed. This was probably caused by the strong electron-withdrawing effect of diazo group. A similar observation in the case of 3,4,5,6-tetrafluorobenzenediazonium-2-oxide was reported recently.[11]

The structure for the acetoxy compound **15** was

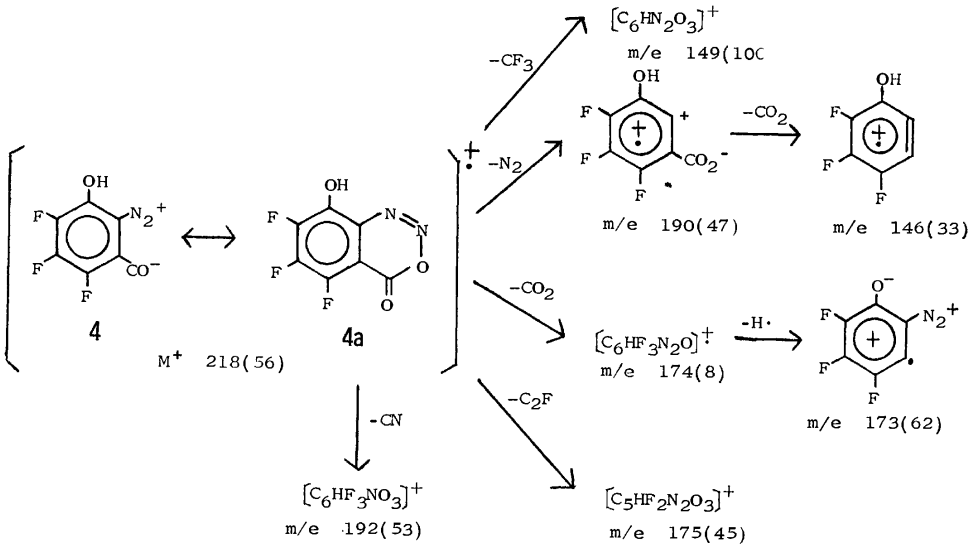

Fig. 2. MS fragmentation of **4**.

deduced from a consideration of the ^1H NMR spectrum. It showed five singlet signals, namely 7.88, 7.74, 7.65, 6.07, and 1.77 at τ-value. Signals, each integrating for three protons, at 7.88 and 7.74 were assigned to $=N-COCH_3$, while those at 7.65 and 6.07 were attributed to $COCH_3$ and CO_2Me respectively. Since it is well-known that methyl shift of acetamide is 7.85—8.25, usual acetic compounds 7.65—8.05 and methyl ester 5.8—6.6,[12] a signal at 1.77 was assigned to a methine proton.

Mass Spectra. The spectrum of 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate (**4**) was explained by the various fragments shown in Fig. 2. The intensity of the molecular ion (*m/e* 218) was unexpectedly strong. As anticipated, loss of N_2 (*m/e* 190) and then of CO_2 gave the ion of mass number 146, which was ascribed to ionized trifluorohydroxybenzyne. The ions of *m/e* 149 (base peak) and 175 could be rationalized by elimination of CF_3 and C_2F respectively, since such fragmentations are characteristic of polyfluorinated aromatic compounds.[13] Aside from the expected fragmentations, loss of CN (*m/e* 192) is interesting, as this ion could be considered to have been derived only from the structure (**4a**).

In the spectrum of 2,3,4-trifluoro-5-hydroxybenzoic acid (**5**), a strong molecular ion, also the base peak, was observed at *m/e* 192. Besides the expected decompositions, namely loss of OH, CO_2H, and (CO_2H+CO), peaks corresponding to *m/e* 149 and 69 were also observed. These could similarly be rationalized, as in the case of **4**, by eliminations of C_2F or CF_3 ion itself.

For 6,7,8-trifluoro-5-methoxycarbonyl-4*H*-1,3,4-benzoxadiazine (**13**), the spectrum showed a peak *m/e* 214 which corresponded to an ion formed by elimination of CH_3OH from the molecular ion (*m/e* 246), thus suggesting the presence of a H-containing group located on an *ortho* position to the methoxycarbonyl group[14] (Fig. 3). Other significant decompositions observed were loss of OMe (*m/e* 215), followed by eliminations of CO and HCN to give ions of *m/e* 187 and 160 respectively, the last process being charac-

teristic of nitrogen heterocycles.[15]

Experimental

3,4,5-Trifluoro-6-hydroxybenzenediazonium-2-carboxylate (4). Nitrosylsulfuric acid, prepared from sodium nitrite (7.6 g; 110 mmol) and concentrated sulfuric acid (60 ml), was added to a vigorously stirred solution of tetrafluoroanthranilic acid (20.9 g; 100 mmol) in glacial acetic acid (100 ml) during 15 min, the temperature of the reaction mixture being maintained below 40°C. The mixture was further stirred for 2 hr at room temperature and then poured onto crushed ice. After stirring for a further 1 hr, the mixture was left overnight in a refrigerator. The orange precipitate (15.4 g) was filtered, washed successively with cold water, cold ethanol-ether (1: 1 v/v) and dried. The filtrate was saturated with sodium chloride and extracted with ethyl ether. The ether extract was washed with saturated aqueous sodium chloride, dried and the solvent was removed under reduced pressure. After rinsing with a small amount of ether, the residue (2.4 g) was combined with the initial crop to give 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate (17.8 g, 81.5%), which crystallized from dioxane as orange crystals, mp 187°C (decomp.).

Found: C, 38.5; H, 0.40; F, 26.2; N, 13.2%. Calcd for $C_7HF_3N_2O_3$: C, 38.6; H, 0.46; F, 26.1; N, 12.8%. IR (KBr): 2800 (OH), 2180 ($-N_2^+$), 1710 (CO), 1630, 1474 (Ar). 1550, 1415 (CO_2^-) cm^{-1}. ^{19}F NMR: (δ ppm from ext. CF_3CO_2H in DMF) +61.8 (5-F, dd, J_{54} 21.3, J_{53} 4.2 Hz), +68.2 (4-F, dd, J_{43} 15.4 Hz), +71.0 (3-F, dd).

2,3,4-Trifluoro-5-hydroxybenzoic Acid (5). *a) With Hypophosphorous Acid*: A mixture of 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate (5.0 g; 22.9 mmol) and 50% hypophosphorous acidd (50 ml) was refluxed for 1 hr. After cooling to room temperature, the reaction mixture was extracted with ethyl ether. The ether extract was washed with water, dried and evaporated to give 2,3,4-trifluoro-5-hydroxybenzoic acid (3.0 g, 68%), which crystal lized from chlorobenzene, mp 163—165°C.

Found: F, 30.2%. Calcd for $C_7H_3F_3O_3$: F, 29.7%. IR (KBr): 3208 (OH), 1681 (CO), 1618, 1489 (Ar) cm^{-1}.

b) With Copper in Ethanol: A mixture of copper powder (0.5 g) and diazoniumcarboxylate **4** (0.5 g; 2.29 mmol) in ethanol (5 ml) was heated on a steam-bath for 1 hr. After cooling to room temperature, the copper was filtered and the filtrate was evaporated to dryness. The solid was treated with 2% aqueous sodium hydroxide and insoluble matter was removed by filtration. The filtrate was acidified and then extracted with ethyl ether. Evaporation of the dried ether extract afforded a residue (0.18 g, 41%) which was recrystallized from toluene to give **5**, mp 163—165°C, undepressed on admixture with a sample from *a*).

c) With Copper in Water: Diazoniumcarboxylate **4** (1.0 g; 4.58 mmol) was added in small portions to a mixture of copper powder (1.0 g) and water (10 ml) at 60°C. After the evolution of gas had subsided the mixture was refluxed for 10 min. The reaction mixture was treated as described in *b*) to give **5** (0.73 g, 83%), mp 163—165°C.

d) With Copper in Dimethylformamide: A solution of diazoniumcarboxylate **4** (1.0 g; 4.58 mmol) in dimethylformamide (5 ml) was added dropwise to a mixture of copper powder (1.0 g) and dimethylformamide (5 ml) at room temperature during 20 min. The reaction mixture was stirred for 40 min, then heated on the steam-bath for 30 min, and similarly treated as in *b*) to give **5** (0.31 g; 35%), mp 163—165°C.

5-Acetoxy-2,3,4-trifluorobenzoic acid. 2,3,4-Trifluoro-5-hydroxybenzoic acid (**5**) (1.0 g; 5.21 mmol) was heated with acetic anhydride (92 ml) and a trace of concentrated sulfuric acid at 60—65°C for 10 min. The mixture was poured onto ice and stirred. The acetoxyl compound was collected (0.98 g; 80%) and recrystallized from cyclohexane. mp 154°C.

Found: F, 24.2%. Calcd for $C_9H_5F_3O_4$: F, 24.3%. IR: 3080 (Ar-H), 2840 (OH), 1782, 1682 (CO), 1616, 1476 (Ar) 1190, 1110 (C-F) cm^{-1}.

Methyl 2,3,4-Trifluoro-5-methoxybenzoate (8). An ethereal solution of diazomethane was added dropwise to hydroxybenzoic acid **5** (1.0 g; 5.21 mmol) in ether (10 ml) and then stirred for 2—3 hr at room temperature. Evaporation of the ether, followed by recrystallization from *n*-hexane gave **8** (1.06 g, 92%), mp 60—62°C.

Found: F, 25.5%. Calcd for $C_9H_7F_3O_3$: F, 25.9%.

2,3,4-Trifluoro-5-methoxybenzoic Acid (9). Methyl ester **8** was refluxed with 5% sodium hydroxide solution for 0.5 hr to give **9** (86%), mp 161—162°C (from benzene).

Found: F, 27.6%. Calcd for $C_8H_5F_3O_3$: F, 27.7%.

6-Chloro-2,3,4-trifluoro-5-hydroxybenzoic Acid (6). 3,4,5-Trifluoro-6-hydroxybenzenediazonium-2-carboxylate (**4**) (2.0 g; 9.16 mmol) was added in small portions to a stirred solution of cuprous chloride (5.0 g) in concentrated hydrochloric acid (20 ml) at 60—70°C during 10 min. The mixture was refluxed for 0.5 hr and worked up as described for the compound **5** (Method *b*) to give chlorotrifluorohydroxybenzoic acid **6** (2.09 g; quantitatively). The acid has mp 131—132°C after sublimation followed by recrystallization from dichloroethane.

Found: Cl, 15.6; F, 25.5%. Calcd for $C_7H_2ClF_3O_3$: Cl, 15.6; F, 25.2%. IR: 3227 (OH), 1720 (CO), 1611, 1485 (Ar), 1119, 1049 (C-F), 858 (C-Cl) cm^{-1}.

6-Chloro-2,3,4-trifluoro-5-methoxybenzoic Acid (10). Excess ethereal diazomethane was added dropwise to a stirred solution of the acid **6** (0.77 g; 3.40 mmol) in ether and the reaction mixture was stirred for 2 hr at room temperature. After the solvent was evaporated the residual solid was refluxed with 5% aqueous sodium hydroxide (20 ml) for 40 min, then acidified with hydrochloric acid. The precipitate (0.53 g; 65%) was recrystallized from cyclohexane, and after sublimation the pure product showed mp 99—100°C.

Found: F, 23.2%. Calcd for $C_8H_4ClF_3O_3$: F, 23.7%.

6-Bromo-2,3,4-trifluoro-5-hydroxybenzoic Acid (7). Diazoniumcarboxylate (**4**) (2.0 g; 9.16 mmol) was treated similarly with cuprous bromide (5.0 g) in 47% hydrobromic acid (20 ml) as described for **6** gave bromotrifluorohydroxybenzoic acid **7** (1.18 g; 73%) which was purified by crystallization from cyclohexane-benzene followed by sublimation, mp 146—147°C.

Found: Br, 29.8; F, 20.7%. Calcd for $C_7H_2BrF_3O_3$: Br, 29.5; F, 21.0%. IR: 3240 (OH), 1718 (CO), 1620, 1475 (Ar), 1194, 1038 (C-F) cm^{-1}.

5-Acetoxy-6-bromo-2,3,4-trifluorobenzoic Acid. The acid **7** (0.50 g; 1.84 mmol) heated with acetic anhydride (1 ml) and concentrated sulfuric acid (2 drops) at 60—80°C for 10 min gave the acetate (0.50 g, 87%), mp 192—194°C (from 1,2-dichloroethane).

Found: F, 18.8%. Calcd for $C_9H_4BrF_3O_4$: F, 18.2%.

2,3,4,5-Tetrafluorobenzoic Acid (3). A solution of tetrafluoroanthranilic acid (4.2 g; 20 mmol) in dioxane (15 ml) was added dropwise to a mixture of *n*-butyl nitrite (2.6 g; 25 mmol), copper powder (6.8 g) and dioxane (20 ml) during 1 hr at 50°C. Stirring was continued for a further 5 hr at 90—93°C, the mixture was then cooled, filtered and the

15) Q. N. Porter and J. Baldas, "Mass Spectrometry of Heterocyclic Compounds", Wiley-Interscience, (1971), Chap. 11—14.

filtrate was made alkaline by adding 2% aqueous sodium hydroxide solution. The aqueous layer was then acidified with hydrochloric acid, and the separated matter extracted with ether. The ether extract was washed with water, dried and then evaporated to give 2,3,4,5-tetrafluorobenzoic acid (**3**) (2.4 g; 62%), which was purified by sublimation followed by recrystallization from *n*-hexane, mp 90—92°C (lit,[16] mp 92—92.5°C).

Found: F, 39.2%. Calcd for $C_7H_2F_4O_2$: F, 39.2%. NMR (CCl_4): ^1H: τ −0.43 (s, CO_2H), 2.15—2.65 (m, Ar–H), ^{19}F (δ ppm from ext. CF_3CO_2H) +59.2 (2-F), +59.6 (5-F), +72.8 (4-F), +74.9 (3-F).

*6,7,8-Trifluoro-5-methoxycarbonyl-4H-1,3-benzoxazine (**13**).* *a) From 3,4,5-trifluoro-6-hydroxybenzenediazonium-2-carboxylate (**4**)*: An excess of ethereal diazomethane was added dropwise to the diazoniumcarboxylate **4** (1.00 g; 4.58 mmol) in ether (20 m*l*) with stirring. Evolution of gas was observed immediately and the reaction mixture changed to a reddish solution. After further stirring for 2 hr at room temperature the solvent was evaporated, 2% aqueous solution of sodium hydroxide was added and the mixture kept overnight in a refrigerator. The yellowish green solid (0.94 g, 83%) was filtered, washed successively with dilute hydrochloric acid and water then recrystallized from cyclohexane to give the benzoxadiazine **13**, mp 153—154°C.

Found: C, 44.3; H, 1.99; F, 22.8; N, 11.0%. Calcd for $C_9H_5F_3N_2O_3$: C, 43.9; H, 2.05; F, 23.2; N, 11.4%. IR: 3289 (NH), 1695 (CO), 1650 (C=N), 1603, 1470 (Ar), 1218 (–O–), 1110, 1073 (C–F) cm^{-1}. NMR (in acetone at 50—60°C): ^1H, τ 1.63 (br, =NH), 3.55 (s, CH), 6.10 (s, CO_2Me). ^{19}F (δ from ext. CF_3CO_2H), +60.6 (6-F), +71.4 (8-F), +89.9 (7-F).

*b) From 3,4,5-trifluoro-2-methoxycarbonylbenzenediazonium-6-oxide (**12**)*: Instead of the diazoniumcarboxylate **4** in the above reaction, diazo oxide **12** (1.00 g) in acetone (10 m*l*) was used. The reaction was run similarly and the solid (0.91 g, 86%) obtained was recrystallized to give **13**, mp 151—152°C, which was identified with that prepared in *a*) by IR and mixed mp.

*2-Acetoxy-3,4-diacetyl-6,7,8-trifluoro-5-methoxycarbonyl-2H-3,4-dihydro-1,3,4-benzoxadiazine (**15**).* A mixture of the benzoxadiazine **14** (0.50 g; 2.03 mmol), acetic anhydride (5 m*l*) and concentrated sulfuric acid (3 drops) was refluxed for 5 min, then cooled and poured onto ice-water. The precipitate (0.60 g, 76%) was recrystallized from ethanol to give the triacetate **15**, mp 152—153.5°C.

Found: C, 46.2; H, 3.29; N, 6.88%. Calcd for $C_{15}H_{13}F_3N_2O_7$: C, 46.2; H, 3.36; N, 7.18%. NMR ($CDCl_3$): ^1H τ 7.88 (s), 7.74 (s), 7.65 (s), 6.07 (s), 1.77 (s), relative intensity, 3:3:3:3:1.

*Methyl Tetrafluoroanthranilate (**11**).* A mixture of tetrafluoroanthranilic acid (20.9 g; 100 mmol), methanol (200 m*l*) and concentrated sulfuric acid (50 m*l*) was refluxed for 5 hr. The excess methanol was evaporated under reduced pressure, and the mixture poured onto ice-water. The precipitate (17.4 g, 73%) was filtered, washed with water, dried, and recrystallized from methanol to give the methyl ester **11**, mp 104—105°C.

Found: F, 33.9; N, 6.28%. Calcd for $C_8H_5F_4NO_2$: F, 34.1; N, 6.28%.

*3,4,5-Trifluoro-2-methoxycarbonylbenzenediazonium-6-oxide (**12**).* Methyl tetrafluoroanthranilate (**11**) (16.25 g; 73 mmol in glacial acetic acid (70 m*l*) was treated similarly with nitrosylsulfuric acid [prepared from sodium nitrite (5.54 g; 80 mmol) and concentrated sulfuric acid (50 m*l*)] as described for the compound **4** to give the diazonium oxide **12** (11.85 g, 70%), mp 117—117.5°C.

Found: C, 41.3; H, 1.22; N, 12.4%. Calcd for $C_8H_3F_3N_2O_3$: C, 41.4; H, 1.30; N, 12.1%. IR: 2144 ($-N_2^+$), 1720 (CO), 1656, 1477 (Ar), 1141, 1078 (C–F) cm^{-1}. NMR ($CDCl_3$): ^1H; τ 6.00 (s, CO_2Me). ^{19}F; δ +58.6 (4-F), +67.9 (5-F), +68.3 (3-F).

*Methyl 2,3,4-Trifluoro-5-hydroxybenzoate (**14**).* A mixture of the diazo oxide **12** (2.0 g; 8.62 mmol) and 50% hypophosphorous acid (20 m*l*) was refluxed for 2 hr, then cooled to room temperature, and the precipitate (0.90 g) was filtered. The filtrate was extracted with ether which was then evaporated, and the solid residue (0.57 g) was crystallized from chlorobenzene. The purified product (0.43 g) was combined with the precipitate obtained earlier to give the hydroxybenzoate **14** (1.33 g, 77%), mp 154—156°C after recrystallization from chlorobenzene.

Found: F, 27.3%. Calcd for $C_8H_5F_3O_3$: F, 27.6%.

The hydroxy benzoate **14** (0.88 g; 4.27 mmol) was methylated with ethereal diazomethane to give methyl 2,3,4-trifluoro-5-methoxy benzoate, **8** (0.91 g, 97%), mp 61—62°C.

Constituents and Properties of Ammoniated Slurry From Wet-process Phosphoric Acid

Takashi AKIYAMA and Jumpei ANDO

Faculty of Science and Engineering, Chuo University, Kasuga Bunkyo-ku, Tokyo

(Received October 20, 1971)

A large amount of gel-like substance is formed during the ammoniation of wet-process phosphoric acid and affects the production of phosphate fertilizers. The authors have found that the main constituent of the gel-like substance is a compound "S" whose composition has been determined to be $(Al,Fe)NH_4HF_2PO_4$. Several other compounds, $Fe_3NH_4H_8(PO_4)_6\cdot 6H_2O$, $(Fe,Al)NH_4H_2(PO_4)_2\cdot 1/2H_2O$, $Fe(NH_4)_2H_2F(PO_4)_2\cdot xH_2O$, $(NH_4)_3AlF_6$, gelatinous silica, *etc.*, are also formed during the ammoniation and curing of the ammoniated slurry, depending upon pH, atomic ratio of F/(Al+Fe) and temperature. Tests also were made on the properties of the ammoniated slurry; solubility, viscosity, filterability, and the rate of sedimentation. It has been found that the properties vary with the formation of the above compounds. A high-temperature modification of $(NH_4)_2HPO_4$ which is stable above 155°C has been newly found during the tests.

Wet-process phosphoric acid has been produced in large amounts in many countries. Most of the acid is ammoniated to pH 4—8 to give a slurry which is used for the production of granular, slurry, and liquid fertilizers.

Gel-like substance is formed in a large amount during the ammoniation and affects the properties of the slurry and consequently the production of the fertilizers. The constitution of the gel-like substance, however, was not clear. It sometimes happens in commercial scale plants that the properties of the slurry change seriously for some unknown reason causing much trouble in the operation of the plants. In the present study, tests were made on the constitution and the properties of the ammoniated slurry.

Acids Used for the Tests. The chemical compositions of the acids used for the tests are shown in Table 1.

The acids W-1 and W-2 were produced from Florida phosphate ore by the hemihydrate-dihydrate process with the addition of silica to promote the hydration of hemihydrate. Their atomic ratios F/Si are close to 6 illustrating that most of the fluorine is present in the form of SiF_6^{2-}. The acid W-3 was produced from Florida ore by the dihydrate process. The ratio of the acid is larger than 6 indicating that a considerable portion of the fluorine is not combined to silica. Other acids are composite acids prepared with chemical reagents.

Ammoniation and Measurement of pH. For most tests, 100 m*l* each of the acids was put in a polyethylene bottle and ammoniated with gaseous ammonia at a rate of about 2 g NH_3 per minute at about 100°C.

The pH of the ammoniated slurry was tested with a glass electrode pH meter after being diluted with 100 times as much water. The composition of the liquid phase corresponds to $NH_4H_2PO_4$ with $(NH_4)_2SO_4$ at pH 4.5 and $(NH_4)_2HPO_4$ with $(NH_4)_2SO_4$ at pH about 8.

Major Water-insoluble Compounds Formed During the Ammoniation. After the ammoniation to various

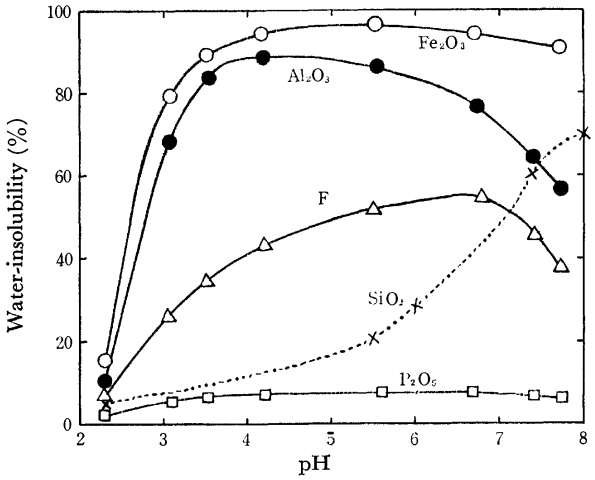

Fig. 1. Change of water-insolubility of each component of W-1 during the ammoniation at 100°C.

TABLE 1. ACIDS TESTED

Marks	Composition (%)						Atomic ratio	
	P_2O_5	SO_3	Fe_2O_3	Al_2O_3	SiO_2	F	F/(Al+Fe)	F/Si
W-1	26.2	4.5	0.7	1.0	1.1	2.4	4.5	6.9
W-2	25.1	5.1	1.0	1.3	1.1	2.1	2.9	6.0
W-3	30.0	2.4	0.7	0.8	1.0	2.5	5.5	7.9
R-1	25.0	4.1	0.7	1.0	0	0	0	—
RF-1	25.0	4.1	0.7	1.0	0	2.5	4.6	—

R-2	26.0	5.1	1.3	1.0	0	0	0	—
RF-3	25.0	4.1	2.3	0	0	2.5	4.5	—
R-4	25.0	4.1	0	1.5	0	0	0	—
RF-4	25.0	4.1	0	1.5	0	2.5	4.6	—

pH, the slurries were kept at 95°C for 30 min, filtered, washed with water and acetone, dried at 50°C and tested by chemical and X-ray analyses. Some of the samples were tested by electron microscope.

The change of water-insolubility of each component of W-1 during the ammoniation at about 100°C is shown in Fig. 1. Insoluble compounds started to form around pH 2.3. The amount of insoluble Fe_2O_3 and F reached maximum at pH about 6, and that of insoluble Al_2O_3 at pH 4.5. The amount of insoluble silica increased markedly above pH 6 indicating the decomposition of SiF_6^{2-} ions. Tests with W-2 and W-3 gave similar results.

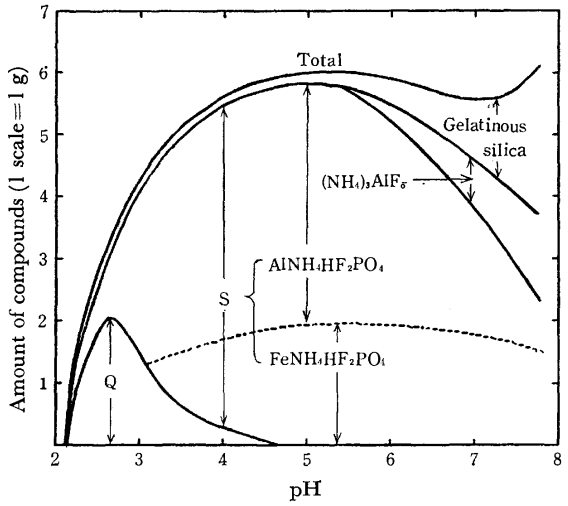

Fig. 2. Water-insoluble compounds formed from 100 g of W-1 during the ammoniation at 100°C.
(Amount of each compound is shown by the scale between 2 curves)
S: (Al, Fe)$NH_4HF_2PO_4$
Q: (Fe, Al)$NH_4H_2(PO_4)_2 \cdot 1/2\ H_2O$

The relation between pH and the amount of water-insoluble compounds formed during the ammoniation of W-1 at 100°C is shown in Fig. 2. The amounts are approximate values estimated by X-ray and chemical analyses. The water-insoluble phosphate first formed at pH 2.3 was gelatinous immediately after the ammoniation and crystallized gradually to form a compound (Fe,Al)$NH_4H_2(PO_4)_2 \cdot 1/2H_2O$[2] which will be referred to as "Q".

On further ammoniation "Q" decreased and a large amount of other gel-like phosphate formed. Tests with X-ray diffraction, electron microscope, and chemical analysis have shown that the main constituent of this gel-like substance is not (Fe,Al)$PO_4 \cdot nH_2O$ as was generally assumed but a compound "S" which has been determined as (Al,Fe)$NH_4HF_2PO_4$.[1] "S" is a solid solution of $AlNH_4HF_2PO_4$ and $FeNH_4HF_2PO_4$. "S" consists of very small round shaped particles about 20 millimicrons in diameter as shown in Fig. 3.

Above pH 5, $AlNH_4HF_2PO_4$ decreased with the formation of $(NH_4)_3AlF_6$; "S" became richer in $FeNH_4HF_2PO_4$. Gelatinous silica increased substantially above pH 6. When a small amount of Na^+ ion was added to W-1 and ammoniated, $(NH_4)_2NaAlF_6$ formed above pH 5.

Tests were made to study the effect of fluorine on the

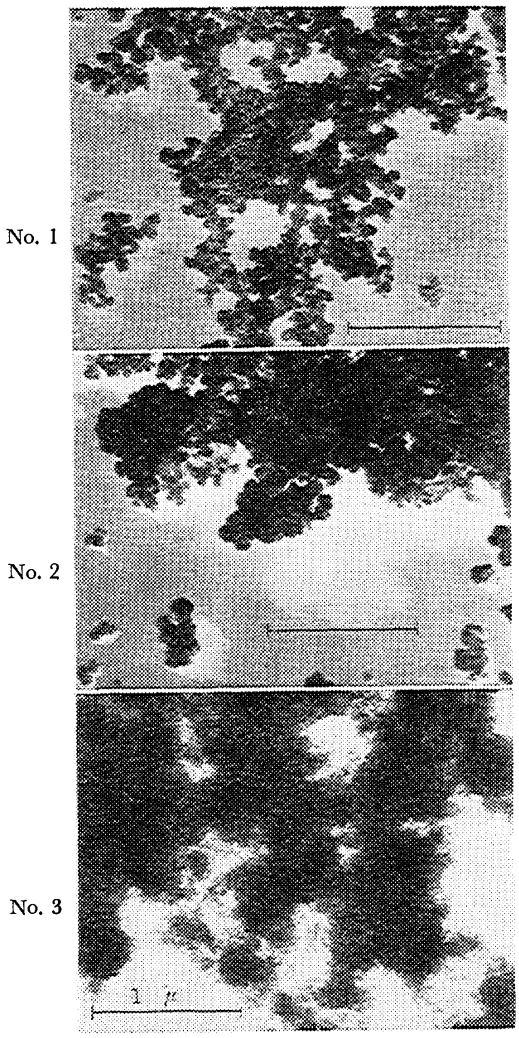

Fig. 3. Electron microscopic photographs of water-insoluble gel-like compounds formed during ammoniation at 100°C.
No. 1: RF-1 at pH 3.5, (Al, Fe)$NH_4HF_2PO_4$
No. 2: W-1 at pH 3.5, mainly (Al, Fe)$NH_4HF_2PO_4$
No. 2: R-1 at pH 6.5, gelatinous ferric aluminium phosphate

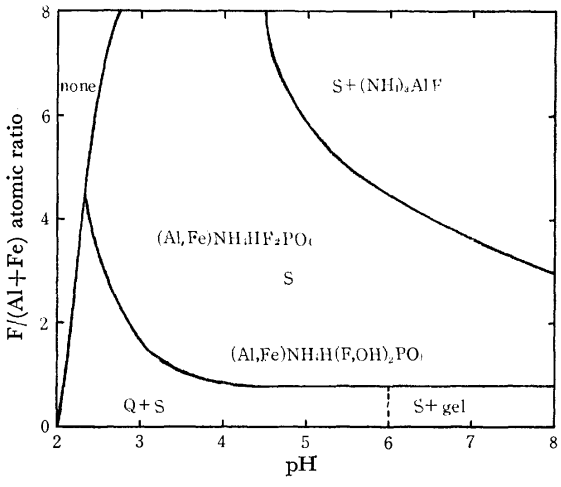

Fig. 4. Water-insoluble ferric and aluminium compounds formed at various F/(Al+Fe) ratio and pH (from W-1).

1) T. Akiyama, M. Hashimoto, H. Muraoka, and J. Ando, *Kogyo Kagaku Zasshi*, **74**, 1774 (1971).

formation of these compounds. Acids with large F/(Al+Fe) ratios were prepared by adding H_2SiF_6 to W-1. Those with small ratios were prepared by adding small amount of K_2CO_3 to W-1 to precipitate and separate K_2SiF_6. The relation between the ratio of the acid and the compounds formed at various pH is shown in Fig. 4.

Only "S" was detected in a wide range above pH3 with the acids whose ratios were larger than 1. The stoichiometric F/(Al+Fe) ratio of "S" is 2. When the ratio of the acid was smaller than 1, "Q" and "S" were present between pH 2 and 6 while gelatinous ferric aluminium phosphate hydrate and "S" were present above pH 6. $(NH_4)_3AlF_6$ formed at pH 4.5 when the ratio was 8 and at higher pH as the ratio decreased.

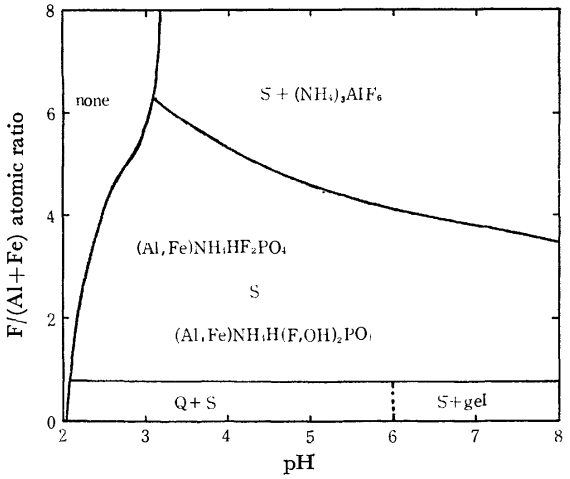

Fig. 5. Water-insoluble ferric and aluminium compounds formed at various F/(Al+Fe) ratio and pH (R-1 and HF, without silica).

The results of similar tests with the acid R-1 to which various amounts of HF were added are shown in Fig. 5. Silica was absent in the system. In this case, "Q" did not form when the ratio was larger than 1 even at pH 2.3. $(NH_4)_3AlF_6$ formed at pH 3.5 when the ratio was larger than 6.

These results illustrate that F^- ions favor the formation of "S" to depress the formation of "Q" and that silica combines with fluorine at lower pH to favor the formation of "Q" depressing the formation of $(NH_4)_3AlF_6$.

X-Ray Diffraction Patterns and Data. X-Ray powder diffraction patterns of the water-insoluble residues of the six samples of the ammoniated slurries are shown in Fig. 6. Each acid was ammoniated to pH 3.5 or 6.5 at 100°C, filtered, washed with water, dried and tested by means of X-ray diffraction. Nos. 1 and 3 of Fig. 6 show the diffraction patterns of "S". Nos. 2 and 4 show those of $AlNH_4HF_2PO_4$ and $FeNH_4HF_2PO_4$, respectively. The diffraction peaks are very broad illustrating the low crystallinity of the compounds. X-ray tests on crystal size have indicated that the single crystals are much smaller than 20 mμ.

No. 5 indicates the pattern of $(Fe,Al)NH_4H_2(PO_4)_2 \cdot 1/2H_2O$ ("Q") formed on ammoniating the acid R-1 to pH 3.5 and No. 6 gelatinous ferric aluminium phsophate hydrate formed on ammoniating the acid to pH 6.5.

The crystallinity of "S" was found to vary widely with the conditions of the formation, particularly with the temperature. The diffraction patterns of $AlNH_4$-

4	1.270	1.269	2 1 3			

Other Minor Water-insoluble Compounds. A very small amount of compound "R", $Fe_3NH_4H_8(PO_4)_6 \cdot 6H_2O$[2] was found to form when the ammoniated slurry of W-1 at pH 2 was kept at 100°C for 2 hr. Another compound "T"[3] formed in a small amount when the slurry of W-1 at pH 6 was kept at 100°C for several hours. Similar results were obtained with a composite acid RSF-1. The composition of "T" has been determined to be nearly $Fe(NH_4)_2H_2F(PO_4)_2$; "T" might contain some water of crystallization.

A very small amount of "R" formed when the acid R-1 was ammoniated at pH 2, but disappeared above pH 2 to form "Q". On further ammoniation of R-1, "Q" disappeared above pH 6 to form gelatinous ferric aluminium phosphate hydrate whose electron microscopic photograph is shown in Fig. 3.

During the concentration of the slurry at pH 7 containing the gelatinous phosphate by evaporation at 110°C, another compound "U" formed in a small amount. The X-ray diffraction pattern of "U" resembles that of $KFe_2(PO_4)_2(OH) \cdot 2H_2O$.[4] When ammonium fluoride was added at 100°C to the ammoniated slurry of R-4 at pH 6 to give the F/Al ratio of 1, another compound formed in a very small amount. The X-ray pattern of this compound is similar to that of $K_2O \cdot 2Al_2O_3 \cdot 2P_2O_5 \cdot 1.6HF \cdot 6.2H_2O$.[2]

Change of Solubility. The change of citric solubility of P_2O_5 during the ammoniation of three acids is shown in Fig. 9. With R-2 which does not contain fluorine only "Q" formed in a large amount above pH 2 and the citric solubility decreased. "Q" is soluble in alkaline citrate but less soluble in citric acid, while "S" is soluble in both citrate and citric acid. "Q" also formed with W-2, but the amount was much less than with R-2. Only a small amount of "Q" formed with W-3 containing fluorine which was not combined with silica.

Tests also were made on the solubility of other phosphates. Like "Q", "R" is soluble in alkaline citrate but less soluble in citric acid. "T" is less soluble in alkaline citrate but soluble in citric acid, contrary to "Q" and "R". "U" is less soluble in both citrate and citric acid.

The change of water-solubility of P_2O_5 during the ammoniation is shown in Fig. 10. The solubility was much lower with R-2 than with W-2 and W-3 although all these acids contain nearly equal amounts of Fe_2O_3+Al_2O_3. The difference in solubility is caused by the difference of compounds formed. "Q" containing 2 mol P_2O_5 per 1 mol Fe_2O_3 or Al_2O_3 formed in a large amount with R-2, while "S" containing 1 mol P_2O_5 per 1 mol Fe_2O_3 or Al_2O_3 formed in similar amount with W-2 and W-3.

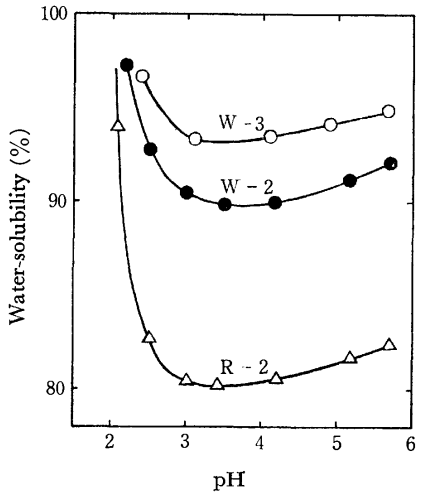

Fig. 10. Change of water-solubility of P_2O_5 during ammoniation at 100°C.

Viscosity of the Ammoniated Slurry. The viscosity of the ammoniated slurry of W-1 is shown in Fig. 11. For the tests about 500 m*l* of W-1 was first ammoniated to pH 8. The ammoniated slurry was then acidified to pH 2.5 by adding the acid W-1. The viscosity was tested after the slurry was kept for about 5 min at various pH during the ammoniation and acidification. The temperature of the slurries was 90—100°C.

Relatively high viscosity was obtained around pH 2.7. Immediately after ammoniation to this pH the water-insoluble substance formed was gelatinous and the viscosity was as high as 100 cp. The viscosity decreased to about 20 cp by curing for 5 min as "Q" crystallized with the decrease of the gel. On further ammoniation "S" formed and the viscosity decreased to 10 cp. The viscosity increased above pH 6, presumably because of the increase of gelatinous silica. The viscosity during the acidification was higher than that during the ammoniation when the pH was above 5 and lower below pH 5.

The change of viscosity on the ammoniation of W-1

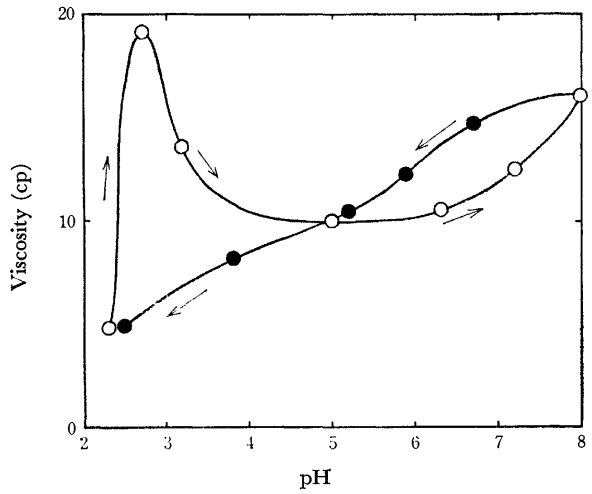

Fig. 11. Change of viscosity of ammoniated slurry of W-1 during ammoniation and acidification at 100°C.
○: in case of increasing pH on ammoniation
●: in case of decreasing pH on acidification

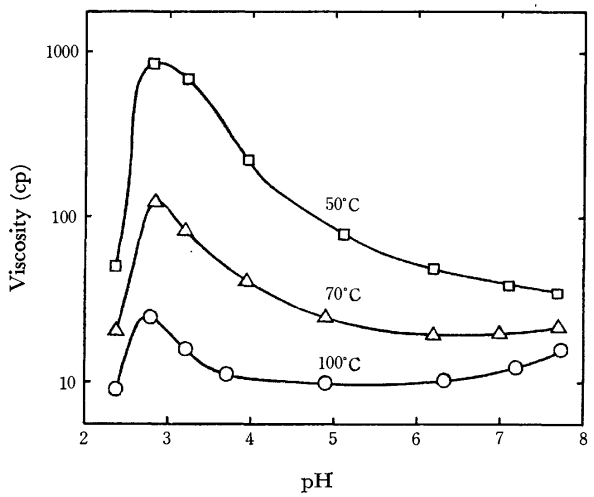

Fig. 12. Change of viscosity of ammoniated slurry during ammoniation at different temperatures.

at different temperatures is shown in Fig. 12. The viscosity was much higher when ammoniated at lower temperature due to the poor crystallinity of the insoluble substance and was as high as 800 cp when ammoniated to pH 2.7 at 50°C. Such low-temperature ammoniation occurs in commercial scale plants where dilute ammonia gas such as coke-oven gas is used.

Rate of Sedimentation. W-1 was ammoniated to various pH at 100°C and diluted with an equal amount of water to prevent the crystallization of ammonium phosphate on cooling. About 50 m*l* of the diluted slurry was put in a glass cylinder to a depth of 140 mm and kept at room temperature. The depth of the clear solution layer which formed on the surface of the slurry due to the sedimentation of the insoluble substance was measured several times in 150 hr. The results are shown in Fig. 13.

The rate of sedimentation was larger for the slurries at pH 4.0 and 5.9 which had lower viscosity than for the slurries at pH 2.8 and 7.2. The slurry ammoniated to pH 8 and then acidified to pH 5.4 showed the smallest rate.

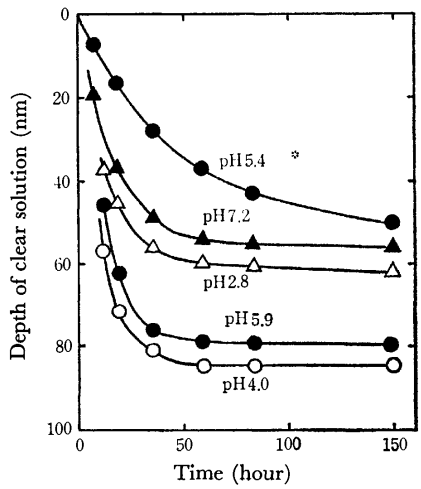

Fig. 13. Rate of Sedimentation of gel-like substance in ammoniated slurry of W-1 (Ammoniated and then diluted. *The sample ammoniated and then acidulated to pH 5.4).

In other series of tests, W-1 was first diluted with an equal amount of water and then ammoniated to various pH for measurement of the rate of sedimentation. The results are shown in Fig. 14. The rate was considerably smaller than that shown in Fig. 13, possibly because of the lower crystallinity of "S" formed at lower temperature.

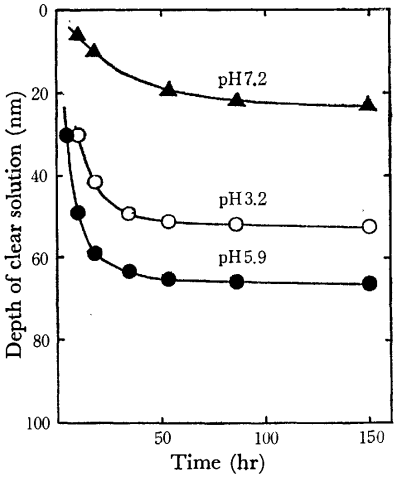

Fig. 14. Rate of sedimentation of gel-like substance in ammoniated slurry of W-1 (Diluted and then ammoniated).

Filterability. For the tests of filterability, 100 m*l* each of the acids was ammoniated to various pH at 100°C in most tests and at 50°C in some tests. The slurry was filtered with a filter paper (diameter 11 cm) in a Buechner funnel (diameter 12 cm) applying a vacuum of 100 mmHg below atmospheric pressure. The amount of the filtrate was recorded every 30 sec.

The best filterability obtained with the slurry at pH about 4 is shown in Fig. 15. The poor filterability with slurry ammoniated at lower temperature is in good agreement with the results shown in Figs. 12 and 13.

High Temperature Modification of $(NH_4)_2HPO_4$. X-Ray tests of a commercial product of diammonium phosphate manufactured by ammoniation of wet-process phosphoric acid in a spray tower showed that the major phase of the product was a previously unknown compound while the product contained small amounts of ammonium sulfate and the compound "S". The

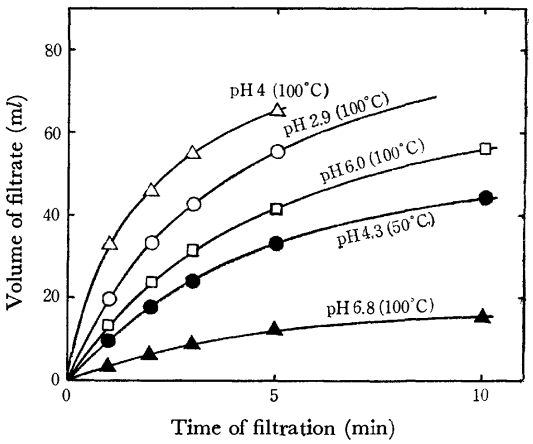

Fig. 15. Effect of pH and temperature on the filterability of ammoniated slurry of W-1.

unknown compound has been identified as a high temperature modification of $(NH_4)_2HPO_4$. This modification can be prepared in a laboratory by heating the usual form of $(NH_4)_2HPO_4$ at 160°C in a sealed tube to prevent the loss of ammonia during the heating. The inversion occurred above 155°C indicating that the ammoniation reaction in the spray tower occurred above this temperature. The presence of ammonium sulfate and "S" did not appreciably affect the inversion temperature. X-Ray diffraction data of the modification are shown in Table 3. This modification can stay at room temperature as long as it is dry. Addition of moisture at room temperature resulted in an instantaneous conversion into the usual form of $(NH_4)_2HPO_4$.

Spectrophotofluorometric Determination of Terbium with α,α'-Ethylenediiminodi(o-hydroxyphenylacetic acid)

Tomitsugu TAKETATSU and Setsuko YOSHIDA
College of General Education, Kyushu University, Fukuoka

(Received December 11, 1971)

Spectrophotofluorometric methods for the determination of terbium have been described using 1,10-phenanthroline-salicylic acid,[1] potassium carbonate,[2] ethylenediaminetetraacetic acid-sulfosalicylic acid,[3] 2-thenoyltrifluoroacetone,[4] and hexafluoroacetylacetone–trioctylphosphine oxide.[5] These methods are based on the measurement of luminescence, which is characteristic of the metal ion and shows the line-like spectrum, enhanced by the formation of the metal complexes. Recently we have found that the intensity of the fluorescence spectrum of terbium was remarkably enhanced by the formation of α,α'-ethylenediiminodi-(*o*-hydroxyphenylacetic acid), (EDDHA), chelate. In the present paper, the fundamental conditions for the spectrophotofluorometric determination of terbium with EDDHA will be described.

Experimental

Reagents. Standard solutions of metal ions were prepared by dissolving the 99.9% pure oxides (scandium, yttrium, and the rare earths except for cerium), chlorides (cerium-[III] and thorium), and nitrate (uranyl) in dilute hydrochloric acid. The concentration of scandium, yttrium, rare earth, and thorium ions were determined titrimetrically with EDTA using Xylenol Orange as an indicator. The titration of uranyl ion with EDTA was made using PAN as an indicator.

Standard solution of EDDHA was prepared by dissolving the known amount of the reagent obtained from the Dojindo Co., Ltd. Research laboratories in dilute sodium hydroxide solution.

All other chemicals used were analytical reagent grade.

Apparatus. Fluorometric measurement was carried out using a Hitachi fluorescence spectrophotometer Model 203 with a medium pressure mercury lamp. 1 cm × 1 cm quartz cell was used.

Procedure. A dilute hydrochloric acid solution containing less than about 50 μg was transferred into a beaker. Then, 5 *ml* of 2.5×10^{-3} M EDDHA solution and 2 *ml* of 5% triethanolamine solution were added to the solution. After the pH of the solution was adjusted to 7.6—7.8 with dilute hydrochloric acid and sodium hydroxide solutions, the solution was transferred into a 25 *ml* volumetric flask and made up to volume with water. The intensity of the fluorescence of the solution was measured on the spectrophotofluorometer. The apparent excitation and fluorescence wavelengths used were 295 and 545 nm, respectively. The content of terbium was calculated by using the calibration curve obtained from the standard. A solution of quinine sulfate was used to a constant reading for measurement made at 545 nm.

Results and Discussion

Fluorescence Spectrum. The apparent fluorescence spectrum of the solution (pH 7.7), containing the terbium-EDDHA chelate, excited with radiation at a wavelength of 295 nm is shown in Fig. 1. The apparent wavelengths of the prominent maxima of the fluorescence spectrum are 487, 545, and 585 nm and the most intense wavelength is 545 nm.

Effect of pH. Figure 2 shows the variation of the fluorescence at 545 nm as a function of pH. The apparent fluorescence gives almost constant over pH range 7.5—7.8. In this case, triethanolamine was used as the buffer reagent because it gave an effective buffer action in the pH region from 6.5 to 8 and the intensity of fluorescence was not influenced by an addition of excessive amounts of the reagent.

Effect of EDDHA Concentration. The variation of intensity of the fluorescence was investigated as a function of mole ratio (EDDHA/Tb^{3+}) plots. The intensity of the fluorescence gives almost constant over

the mole ratio range 20—100 as shown in Fig. 3.

Stability of Fluorescence with Time. The intensity of the fluorescence remained sensibly constant for 7 hr after a few minutes.

Calibration Experiments. It is found that the fluorescence is a linear function of the concentration in the range from 0.03 to 1.5 μg/ml of terbium as shown in Fig. 4. Also, by amplifying the sensitivity of the instrument, the linear relationship is obtained for solutions containing from 0.0015 to 0.015 μg/ml.

Effect of Other Substances. The effect of other rare earth, scandium, yttrium, thorium, and uranyl ions was studied under the optimum conditions. The results are shown in Table 1. Lanthanum, gadolinium, dysprosium, holmium, erbium, thulium, ytterbium, lutetium, scandium, yttrium, and uranyl ions do not interfere. Cerium, praseodymium, neodymium, samarium, and europium give a slight interference. Thorium gives a serious interference.

EDDHA	0.03—1.5 g/ml and 0.0015—0.015 μg/ml	in weak alkaline solution at pH 7.5—7.8	This paper

[EDDHA]/([EDDHA]+[Tb^{3+}]) of 0.5 indicates combining ratio of one EDDHA molecule per one terbium ion.

Comparison with Other Methods. Table 2 shows a comparison amoung the data reported by several investigators. The EDDHA method can be carried out more easily and rapidly in comparison with the methods[1,5] which are in need of solvent extraction procedure. Also it is known that the present method is almost similar to or superior to the other methods concerning the range of linearity and the degree of limit of detection though the comparison is not always appropriate because the data depend upon the performance of instruments used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2923—2924 (1972)

Mono- and Bi-photonic Ionization of Aromatic Molecules in Liquid Solutions by the 347 nm Light Pulse

Yoshio TANIGUCHI, Yasuzo NISHINA, and Noboru MATAGA*

Department of Chemistry, Faculty of Engineering Science, Osaka Universtiy, Toyonaka, Osaka

(Received February 21, 1972)

The photoionization of aromatic molecules constitutes a primary step of growing importance in photochemical processes. Richards *et al.* observed the absorption spectra of the pyrene cation radical which was produced by the biphotonic absorption of the 347 nm light pulse.[1] The ionization of perylene was found to occur by a biphotonic process.[2] Recently, a monophotonic ionization of perylene has been suggested when the excitation is below 230 nm.[3] However, the monophotonic ionization of aromatic molecules in liquid solutions by the excitation with the 347 nm light pulse has not been reported.

We have confirmed by means of the laser photolysis and transient photoconductivity measurements that the ionization of *N,N*-diphenyl-*p*-phenylenediamine (DPPD) and phenothiazine in an acetonitrile solution occurs by monophotonic excitation at 347 nm.

The second harmonics of a Q-switched ruby laser (Japan Electron Optics, JLR-02A) was used as an exciting light pulse. The produced ion radicals were observed by measuring the photocurrent induced by laser excitation. Details of the measurement are given elsewhere.[4] For examining the effect of the excitation light intensity on the photocurrent, the intensity of the laser pulse was reduced by using neutral filters composed of wire gauzes. Relative values of the exciting intensity were monitored by measuring the intensity of light partially reflected by means of a beam splitter with a photomultiplier. The absolute value was determined by a ballistic thermopile TRG model 100 (Hadron).

The samples were purified in the usual way. All the solutions for the measurment were deaerated completely by repeated freeze-pump-thaw cycles.

The effects of the exciting light intensity on the peak photocurrent of the acetonitrile as well as the tetrahydrofuran (THF) solutions of the aromatic molecules at room temperature are shown in Figs. 1 and 2, respectively.

One can see from Fig. 1 that the ionization process of phenothiazine as well as that of DPPD in acetonitrile are monophotonic. Since the curves of the photocurrent consist of the exponential rise curve and the hyperbolic decay curve which varies with the initial

concentration of ions, *i.e.*, the decay is more remarkable at higher exciting light intensity, the observed value of the peak photocurrent appears to be somewhat smaller than the true value at high light intensity. Therefore, the slopes of the straight lines in Figs. 1 and 2 seem to give slightly smaller values than the real ones. Contrary to this, both ionization processes of the phenothiazine–THF and the DPPD–THF systems are not monophotonic but biphotonic as indicated in Fig. 2. We have confirmed also that the photoionization process of DPPD by the 347 nm pulse is biphotonic in nonpolar solvents.

It has been suggested from a detailed kinetic study that the photo-oxidation of DPPD originates from the upper excited singlet state.[5] Then, the photoionization of DPPD may occur from the upper excited singlet state, since it seems to be certain that the intermediate of the photo-oxidation is a DPPD cation radical.[5] In relation to the above statement, we have observed the laser-induced photocurrent with the rise and decay curves quite similar to the laser pulse in the case of the DPPD-nonpolar as well as moderately polar solvent systems.[6] Although the details of the result will be given elsewhere, the laser-induced photocurrent with very short lifetime might be ascribed to the electrons with a quite large mobility produced by the ionization from the excited Franck-Condon state.

Now, the photoionization process in a considerably polar solvent such as acetonitrile is monophotonic as described above, although the ionization potential of DPPD in the gas phase may be much larger than the energy of 347 nm excitation. However, the energy required for the separation of cation and electron may be compensated by the solvation energies for them. The circumstance in the case of the monophotonic ionization of phenothiazine may be quite similar to that of DPPD. One might suppose that acetonitrile forms a molecular complex with the solute in the ground state and the complex ionizes in the excited state. We have, however, confirmed that there is no indication of such a complex formation in the absorption spectra of these molecules in acetonitrile. Since the solvation energy of THF for the cation and an electron may be much smaller than that of acetonitrile, the monophotonic ionization cannot take place in a THF solution.

We have confirmed that both of the photoionization processes of pyrene and perylene in acetonitrile by the 347 nm pulse are biphotonic as shown in Fig. 1. Of course, the photoionization processes of these molecules in a THF solution are biphotonic. However, it seems to be rather difficult at the present stage of investigation to determine whether the biphotonic ionization process involves excited singlet or triplet state as photoactive intermediate. It might be possible also that both of excited singlet and triplet states are involved in the process as the intermediates.

Mechanism of Chromic Acid Oxidation of Aldehydes

C. GOSWAMI and Kalyan K. BANERJI*
Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received August 23, 1971)

In a previous communication[1] we showed that the oxidation of acetaldehyde by Cr(VI) involves an attack on the keto-form of the aldehyde and suggested that the reaction proceeds through the transfer of a hydride ion. The present study of the oxidation of chloroacetaldehydes and formaldehyde by chromic acid was undertaken to substantiate the mechanism proposed earlier.

Results

Product Analysis. Oxidation of monochloro-, dichloro-, trichloro-acetaldehydes and formaldehyde by aqueous chromic acid yielded the corresponding carboxylic acid as characterized by the spot tests.[2]

It was observed that for every mole of Cr(VI) consumed, nearly 1.5 mol of the carboxylic acid was formed. The overall reaction may be written as follows.

$$3RCHO + 2CrO_4^{2-} + 10H^+ \longrightarrow 3RCOOH + 5H_2O + 2Cr^{3+} \quad (1)$$

Rate Laws. When the concentrations of the aldehyde and hydrogen ion are in excess, the rate of disappearance of Cr(VI) follows first order rate laws, but the values of rate constants decrease with increase in the concentration of Cr(VI). The results show that the reaction is strictly of first order with respect to acid chromate ion $HCrO_4^-$. Since the results in all aldehydes are similar, only results of reaction with monochloroacetaldehyde (MCA) are reproduced (Table 1).

Table 1. Dependence of reaction rate on the concentration of chromic acid
[MCA] 5.0×10^{-2}M, [H$^+$] 1.0M, temp. 30°C

10^3[Cr(VI)] mol·l^{-1}	10^4[$HCrO_4^-$] mol·l^{-1}	10^5k_1 sec^{-1}	$\frac{10^5k_1[Cr(VI)]}{[HCrO_4^-]}$
1.0	9.24	6.5	7.0
2.5	21.2	5.9	7.0
4.0	31.7	5.6	7.1
5.0	38.0	5.3	7.0
10.0	64.9	4.5	6.9

The concentrations of $HCrO_4^-$ were calculated assuming a value of 2.3×10^{-2} for association constant for dichromate formation ($K=[HCrO_4^-]^2/[Cr_2O_7^{2-}]$) at 30°C.[3]

Table 2. Dependence of the reaction rate on the concentration of aldehyde
[Cr(VI)] 1×10^{-3}M, [H$^+$] 1.0M, temp. 30°C

10^2[MCA]mol·l^{-1}	1.0	2.0	3.0	4.0	5.0
10^4k_1(sec^{-1})	1.3	2.6	4.0	5.4	6.5
10^2k_1/[MCA]	1.30	1.30	1.33	1.35	1.30

The reactions are also of first order with respect to aldehyde (Table 2).

Under the conditions of constant ionic strength the rate is proportional to the square of hydrogen ion concentration (Table 3). There is also a marked positive ionic salt effect.

Table 3. Acidity dependence of the reaction rate
[MCA] 2×10^{-2}M, [Cr(VI)] 1×10^{-3}M, temp. 30°C
Ionic strength (μ)=2.0M

[H$^+$] mol·l^{-1}	0.50	0.75	1.00	1.25	1.50	2.0
10^4k_1 (sec^{-1})	1.2	2.8	5.0	8.1	11.5	20.0
10^4k_1/[H$^+$]^2	6.0	5.0	5.0	5.2	5.1	5.0

Effect of Solvent Composition. Increase in the proportion of acetic acid in the solvent mixture increases the rate of oxidation (Table 4), probably because of the lowering of dielectric constant of the medium,[4] which favours reactions involving protonation. Moreover, in acetic acid, chromic acid exists as acetochromic acid which is assumed to be a stronger acid and a much more powerful oxidizing agent.[5] This also contributes to the increase in the reaction rate.

Effect of Temperature. Data on the effect of temperature on the oxidation rate are summerized in Table 5. A plot of log k against the inverse of temperature gives a straight line. The Arrhenius equation is, therefore, valid for these reactions. The specific rate constant k is obtained from the relation $k=k_1/[\text{Aldehyde}]\,[H^+]^2$.

The activation parameters were also evaluated (Table 6).

Discussion

It has been proposed that aliphatic aldehydes are oxidized *via* their hydrates.[6,7] The aldehydes we studied exist mostly as hydrates in solution, and hence either the aldehyde hydrate or its simple derivative is the most likely intermediate. Since the aldehyde hydrates so closely resemble the alcohols in structure

as well as in practically all aspects of oxidation, it is reasonable to expect a similarity in the mode of their oxidation as well.

Recently, Wiberg and Schafer[8)] established that oxidation of alcohols by chromic acid proceeds *via* the chromate esters. We have shown[1)] that oxidation of aldehydes is also best represented by assuming the formation of a similar intermediate which then decomposes in the rate-determining step.

The activation parameters suggest that C–H bond is ruptured in the rate-determining step.[9,10)] This was confirmed by the fact that formaldehyde shows a primary isotope effect.[6)] It is, however, far less clear whether hydrogen leaves as a proton, an atom or an anion. Wiberg and Mill,[11)] and Graham and Westheimer[12)] preferred the abstraction of proton whereas Rocek[7)] favoured the transfer of hydride ion from the substrate to the oxidant. When the rate constants of the aldehydes studied here are plotted against Taft's σ* values,[13)] a straight line is obtained with a value of ρ* approximately −1.1 (Fig. 1).

This result indicates that oxidation is facilitated by

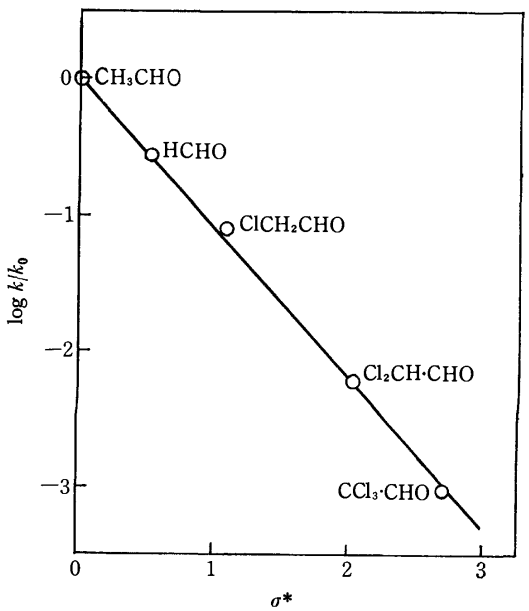

Fig. 1. Dependence of rate constants on Taft's σ* values (Rate data of MeCHO are taken from Ref. 1).

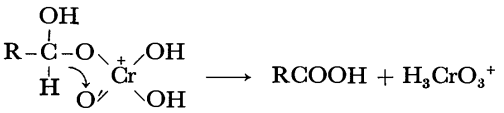
a high electron density at the C–H bond and strongly suggests that the oxidation of aldehydes by chromic acid involves a hydride transfer as follows:



Experimental

Materials. Aldehydes were purified by the usual methods. Perchloric acid (60%, E. Merck) was used as a source of hydrogen ions. Acetic acid (B. D. H., AnalR) was distilled over chromic acid before use. All other chemicals used were chemically pure.

Product Analysis. For a quantitative estimation of carboxylic acid, the completely reduced reaction mixture was shaken with ether, and the amount of the acid present in the ether solution was determined colorimetrically by ferric hydroximate method.[14)]

Kinetic Measurements. The reactions were carried out at constant temperature (±0.05°C). Unless otherwise stated the solvent was 20% acetic acid (v/v). The aldehydes were always kept in excess. Reactions were followed iodometrically.

The Influence of Off-axial Ligands on the Crystal-field Energies of the Copper(II) Ion

R. J. FEREDAY
University Malaya, Kuala Lumpur, Malaysia

(Received August 30, 1971)

The assignment of the electronic spectra of various complexes of the copper(II) ion has been put on a sounder basis recently by the polarised single-crystal measurements of several workers.[1-10] This has resulted in the reassessment[11-13] of the various theoretical methods used to calculate the *d*-electron energy levels in the copper(II) ion. Both crystal-field[12,13] and orbital overlap[11] methods have been used and found to be in general agreement.[14] The crystal-field approach being the simpler approach, while perhaps not giving as good a physical picture as the orbital overlap method, has been adopted here, as virtually similar results are obtained by both procedures.

One of the problems highlighted by this reinvestigation was the role played by the off-axial ligands in determining the energy of the one-electron *d*-orbitals, especially in the case of the complex $CaCu(CH_3CO_2)_4 \cdot 6H_2O$, which has D_{2d} symmetry, where several reports have been published.[15,16] Off-axial coordination is also found in basically axial copper(II) systems, *e.g.* $Cu(NH_3)_2(CH_3CO_2)_2$ (Ref. 17). This note reports the effect on the *d*-electron orbitals of the inclusion of off-axial coordination and discusses the importance of their contribution in determining the energy-level sequences.

Crystal-field Calculations. These calculations were based on a point charge model described by Krishnamurthy and Schaap[18] and Garner and Mabbs.[13] The same approximations as in Refs. 12 and 13 are made, that is, Dq and Cp of the long bonded ligand have been taken to be:

$$(Dq)' = Dq \times a^5$$

$$\text{and } (Cp)' = Cp \times a^3$$

where $a = R_E/R_A$ (where R_E and R_A are the lengths of the equatorially and axially bonded ligands respectively) and θ is the angle between the axial ligand and the z-axis. The eigenvalues and eigenfunctions resulting from the perturbation by the crystal fields have been evaluated for various values of a and θ.

Results and Discussion

The values chosen for the parameters Dq, Cp, θ, and a were in line with those of other workers,[13,20] and correspond to known physical situations in order that the sensitivity of the energy-levels to the variation of the parameters may be meaningful. The results are presented graphically and are conveniently split into two types, the first representing the variation of the energies of the *d*-orbitals with a (at several values of θ) and the second the variation with θ (at different values of a).

(a) The Effect of Varying a. The effect of the variation of a on the *d*-orbital energy-levels, while maintaining a fixed value of Dq ($=1000\ cm^{-1}$) and Cp ($=4000\ cm^{-1}$) is shown in Fig. 1 which represents several values of θ.

Figure 1 represents the changes in energy of the one electron orbitals, when a is varied, and the angle between the z-axis and the long bonded ligands is 5, 15, and 25° respectively. From these figures it can be

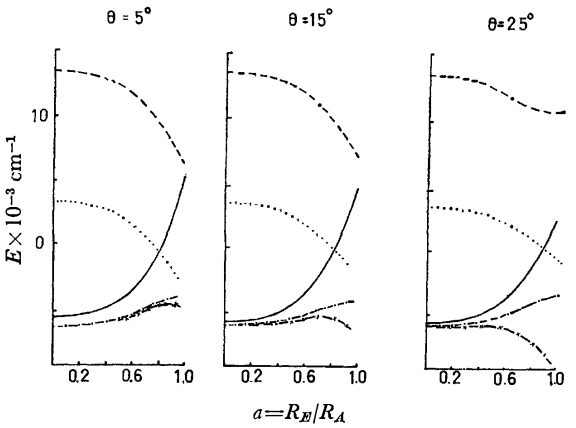

Fig. 1. The variation of the *d* orbital energies with a, when θ=5, 15, and 25°.

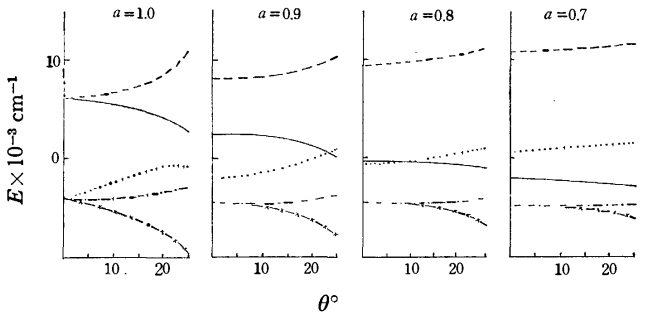

Fig. 2. The variation of the d orbital energies with $\theta°$, when a=1.0, 0.9, 0.8, and 0.7.
——: d_{z^2}, – – –: $d_{x^2-y^2}$, ·····: d_{xy}, –·–·: d_{xz}, ×–×–: d_{yz}

seen that, although the ligands are not directed along the z-axis, they still have a profound effect upon the d-orbital energies. The first obvious difference in these diagrams is the easily intuitively predictable stabilization of the d_{z^2} orbital as θ increases, at least at larger values of a. This effect is still small at θ=5°, but when θ=15 and 25° the d_{z^2} orbital is stabilized by approximately 1500 and 2000 cm^{-1} respectively at $a\approx1.0$. Similarly the $d_{x^2-y^2}$ and d_{xy} orbitals are increased in energy by a corresponding amount. The other obvious feature is the lifting of the degeneracy of the d_{xz} and d_{yz} orbitals, the d_{xz} orbital being destabilized due to the larger potential of the off-axial ligands as they become closer, while the d_{yz} orbital is lowered in energy. The energy-level sequences show little variation with change in the angle θ and are essentially similar to the tetragonal-octahedral case; we might therefore expect similar experimental data. The experimental data available for the complex Cu(ethoxyacetate)$_2\cdot2H_2O$ (Ref. 21) (a=0.84; θ=15°) gives the energy level sequence of the one-electron orbitals as $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{yz} > d_{xz}$, with the d_{xy} orbital lying close to the d_{z^2} orbital. This is in reasonable agreement with Fig. 1 (θ=15°) with, in fact, the d_{xy} orbital as suggested in Ref. 21, lying very close in energy to the d_{z^2} orbital. However, the relative ordering of the d_{xz} and d_{yz} orbitals are reversed. This may be a result of π-bonding or any covalency effects which are totally ignored in the crystal-field approach.

(b) Variation with θ. A significant feature of all these diagrams is that at values of $a\approx0.7$, the energy-levels obtained for the one-electron orbitals vary very little with the angle θ. This suggests that, although the off-axial ligands have a significant effect on the crystal-field potential as the metal-ligand distance alters (just as in the tetragonal-octahedral case), the variation of θ has little significance and, therefore, the actual position of the ligands (be it axial or off-axial) is of little importance compared with the metal-ligand distance. Thus only when $a\approx1.0$ do the d-orbital energy-levels vary significantly with the angle θ and this is shown most clearly in Fig. 2 which plots the energy of the d-orbitals as θ varies (for several values of a). When $a\approx0.8$, a variation of θ produces little change in the one-electron energy-levels, but at a=1.0, the d-orbital energies have been altered by approximately $\pm$4000 cm^{-1}, a not insignificant change.

In short then, when attempting the assignment of the electronic spectra of copper(II) complexes, which contain off-axial ligands, we may in essence treat the problem as being that of assigning a tetragonal-octahedral complex, as the most important contribution in determining the energy of the one-electron d-orbitals is the metal-ligand distances and the actual value of θ is, at best, only a secondary consideration. Notwithstanding this, when $a\approx1.0$, then the value of θ does become significant and may cause a change in transition energy by as much as 4000 cm^{-1}.

Nevertheless, it must be noted that the crystal-field approach will tend to overestimate the contribution due to the long-bonded ligands,[14] much smaller effects being predicted when using the orbital overlap procedure and a certain amount of care must be employed in the assignment of these spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2929—2930 (1972)

ESR Study of V_2O_5, MoO_3, and V_2O_5–MoO_3 Catalysts

R. S. MANN and K. C. KHULBE
Faculty of Science and Engineering, University of Ottawa, Ottawa, Canada

(Received October 8, 1971)

Tarama and co-workers[1] and other investigators[2,3] have demonstrated the usefulness of electron spin resonance (ESR) in obtaining information about the local structure surrounding V^{4+} ion in V_2O_5 catalyst. Petcherskaya *et al.*[4] and Kazanskii and co-workers[5] could not observe any ESR signal in pure vanadium pentoxide, while Tarama *et al.*[1,5] reported a single broad ESR signal. This contrast may be due to the different methods employed for the preparation of the catalysts. In this note the results of ESR studies of the catalysts V_2O_5, MoO_3, and V_2O_5–MoO_3 system, have been compared with the results of the other investigators.

The mixed oxide catalyst was prepared by weighing ammonium molybdate (B. D. H., A. R. Grade) and ammonium metavanadate (Fisher) according to a desired ratio of the MoO_3 and V_2O_5. Ammonium molybdate dissolved in distilled water was mixed with ammonium metavanadate to make a paste. The paste was dried for 12 hr at 40°C and for 6 hr at 150°C. The temperature was increased stepwise and maintained successively for 2 hr at 200, 300, and 400°C. The catalyst was calcined at 500°C for 6 hr and activated at 600°C for 2 hr. Pure MoO_3 and V_2O_5 were obtained by thermal decomposition of ammonium molybdate and purified ammonium metavanadate. The catalysts were calcined at same temperature similar to their mixtures.

Recently Dosi[6] studied the oxidation of methanol over these catalysts and observed that 20: 80 vanadium pentoxide and molybdenum trioxide catalyst proved to be highly active and selective for the formaldehyde formation and gave nearly 99% conversion of methanol to formaldehyde for a feed ratio, (W/F), of 31.7 gm·hr/mol and 8 mol percent methanol in air.

The ESR measurements were carried out by a Varian E9, ESR spectrometer, in which the microwave frequency was in the X band and a 2G modulation was adopted. All measurements were made at room temperature unless otherwise noted.

Pure V_2O_5 showed an asymmetric broad ESR signal (Fig. 1) for which g value was 1.972. Pure MoO_3 gave no ESR signal. On addition of 10% V_2O_5 to MoO_3, strong signals were obtained (Fig. 2). Similar

6) M. K. Dosi, M. A. Sc. Thesis, University of Ottawa, Ottawa, 1971.

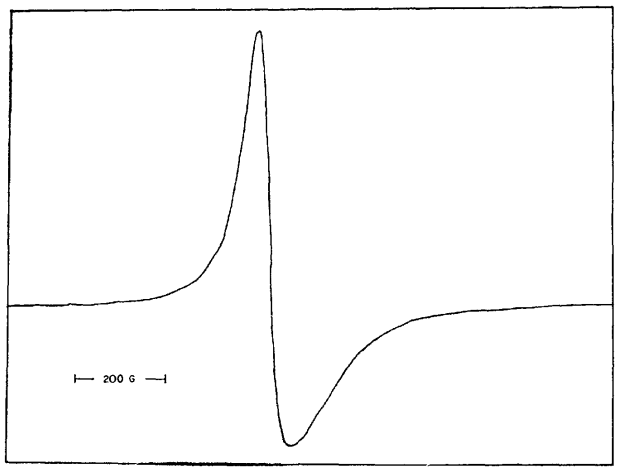

Fig. 4. 75% V_2O_5–25% MoO_3.

results were obtained by Tarama *et al.*[5] for the sample containing 15 mol% V_2O_5 and 8.5 mol% $K_2S_2O_7$. Tarama *et al.*[1] observed that every sample of the V_2O_5–MoO_3 system (5, 25, 50, 75, 95, and 100% V_2O_5) gave a single broad ESR spectrum and their shapes were similar to the pattern of the pure V_2O_5 sample. In the present study 10% V_2O_5–90% MoO_3 showed more than eleven components (Fig. 2). However, these components disappeared on further addition of V_2O_5 to MoO_3 (Figs. 3 and 4). Catalyst containing 75% V_2O_5 and pure V_2O_5 gave one broad signal. The intensity of ESR signal was highest for 10% V_2O_5–75% MoO_3 catalyst and decreased with increasing concentration of V_2O_5 in the system. The disparity between the shape of spectra observed by Tarama *et al.*[1] and in the present study in MoO_3–V_2O_5 system are atrributed to the dissimilarity in the methods of preparation of the two catalysts. The present work supports the views of Tarama *et al.*,[1] who suggested that the ESR spectrum of the system is not due to Mo^{5+} as proposed by Petcherskaya *et al.*,[4] but due to V^{4+}.

Kazanskii *et al.*,[2] found that pure MoO_3 and V_2O_5 do not give any ESR signals (at room temperature and at −196°C), but in freshly prepared mixed catalysts which have not been used in a reaction an ESR signal was observed whose width and intensity depended on the molybdenum content. With a molybdenum content less than 5% the signal has hyperfine structure (HFS) consisting of two groups of lines with a split between the 50 and 140G components in each group. But in the present study no such spectra were observed. It seems that the method for the preparation of the catalyst plays an important role to give ESR spectra.

For the purpose of comparison, the ESR spectrum of Analar Grade V_2O_5 (Fisher certified) was taken. The signal intensity observed with the sample (Fisher) was approximately 6 times less than the intensity of V_2O_5 catalyst prepared in our laboratory, confirming the dependence of the ESR spectrum on the method of the preparation and activation of the catalyst.

On raising the temperature of the catalyst, (upto 400°C) the intensity of ESR signals of V_2O_5 and V_2O_5–MoO_3 decreased.

The authors wish to thank Dr. I. C. P. Smith, National Research Council, Canada for allowing us the use of the ESR apparatus and NRC, Canada for grant.

The Preparation of Acyl Alkoxycarbonyl Sulfides and the Related Compounds

Shinichi MOTOKI and Hikaru SATSUMABAYASHI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 19, 1971)

A number of mixed carboxylic carbonic anhydrides (**1**) were prepared by the reaction of carboxylic acid and chloroformate in a series of studies by Tarbell.[1] *p*-Nitrobenzoic thiolcarbonic anhydrides (**3**), the sulfur analogue of the mixed anhydride, were prepared from *p*-nitrobenzoic acid and thiolchloroformate more recently.[2] In the present paper, the preparation of another types of sulfur analogues of the mixed anhydride such as acyl alkoxycarbonyl sulfides (**2**) and acyl alkylthiocarbonyl sulfides (**4**) is described.[3]

$$RCOXH + ClCOYR' \longrightarrow R\text{-}\overset{\overset{O}{\|}}{C}\text{-}X\text{-}\overset{\overset{O}{\|}}{C}\text{-}Y\text{-}R'$$

a) Calculated based on the assumption that these compounds were formed by the decomposition of **2** according to the following reaction; 2 RCOSCOOR′ ⟶ $(RCO)_2S+(R'OCO)_2S$, [*Ann.*,**730**, 121 (1969)].

pared from thiocarboxylic acid and alkyl chloroformate in THF at −50°C in the presence of triethylenediamine (Table 1). In the preparation, diacyl sulfides (**5a**—**f**) and bis(alkoxycarbonyl)sulfides (**6a**—**f**) were isolated as by-products (Table 2). The NMR spectra and the analytical values were in accord with the expected structure for **2a**—**f** and **6a**—**f** (Tables 1 and 2) and the IR spectra of **2a**—**f** showed the double peaks (about 1780 and 1720 cm^{-1}) in the carbonyl region which resemble closely the typical anhydride absorption. Butyryl methoxycarbonyl sulfide (**2g**) and butyryl ethoxycarbonyl sulfide (**2h**) were not isolated because the boiling point was very close to those of the by-products. When triethylamine was used in the reaction instead of triethylenediamine, **2** was not obtained but **5** and **6** were formed. *p*-Nitrobenzoyl benzyloxycarbonyl sulfide (**2i**) was obtained as pale yellow crystals by a similar procedure, accompanied by no bis(*p*-nitrobenzoyl)sulfide (**5i**) or bis(benzyloxycarbonyl)sulfide (**6i**) as by-products.

Although *p*-nitrobenzoic thiolcarbonic anhydrides (**3**) were already prepared by Tarbell,[2] preparation of acetic ethylthiolcarbonic anhydride (**3a**) was unsuccessful in the present study, and the reaction in the presence of triethylamine afforded acetic anhydride (**7a**) and diethyl dithiolcarbonate (**8a**).

Similarly, *p*-nitrobenzoyl benzylthiocarbonyl sulfide (**4b**) was obtained from *p*-nitrothiobenzoic acid and benzyl thiolchloroformate but acetyl ethylthiocarbonyl

sulfide (**4a**) was not obtained from thioacetic acid and ethyl thiolchloroformate. Diacetyl sulfide (**9a**) and bis(ethylthiocarbonyl)sulfide (**10a**)[4] were formed as by-products.

Experimental

Materials. Thioacetic acid was obtained commercially. Thiopropionic acid was prepared by the method of Kitamura.[5] *p*-Nitrothiobenzoic acid prepared by the method of Khaletskii and Yanovitskaya[6] was recrystallized from *n*-hexane, mp 94—95°C (lit,[7] mp 94°C).

Methyl, ethyl, isobutyl, and benzyl chloroformates obtained commercially were purified by distillation. *n*-Propyl chloroformate and benzyl thiolchloroformate were prepared by the method of Tarbell and Longosz.[8]

Commercially available triethylenediamine was used after sublimation.

Acyl Alkoxycarbonyl Sulfides (2a—f). To a cooled solution of 0.1 mol of triethylenediamine in 500 m*l* of anhydrous THF, 0.2 mol of thiocarboxylic acid was added slowly. After cooling the mixture to −50°C, 0.2 mol of alkyl chloroformate was added dropwise over a period of 1 hr with vigorous stirring. The stirring was continued for additional 2 hr and then the temperature of the mixture was allowed to rise to −10°C. The amine hydrochloride was removed by filtration, and the THF was evaporated under reduced pressure. Fractional distillation of the residue gave acyl alkoxycarbonyl sulfide (**2a—f**), diacyl sulfide (**5a—f**) and bis(alkoxycarbonyl)sulfide (**6a—f**). The results are shown in Tables 1 and 2.

p-*Nitrobenzoyl Benzyloxycarbonyl Sulfide (2i).* To a solution of 3.66 g (0.02 mol) of *p*-nitrothiobenzoic acid and 3.41 g (0.02 mol) of benzyl chloroformate in 200 m*l* of anhydrous ether, 1.12 g (0.01 mol) of triethylenediamine in a mixture of 20 m*l* of ether and 10 m*l* of THF was added dropwise over a period of 1 hr with vigorous stirring at −60°C. The stirring was continued for additional 3 hr and then the temperature of the mixture was allowed to rise to 10°C. The amine hydrochloride was filtered, and the solvent was evaporated at room temperature. Recrystallization of the solid residue from chloroform-petroleum ether yielded 2.83 g (45%) of **2i** as pale yellow needles, mp 92—94°C.

Found: C, 56.92; H, 3.57; N, 4.50; S, 10.11%. Calcd for $C_{15}H_{11}O_5NS$: C, 56.78; H, 3.49; N, 4.41; S, 10.10%. IR ($CHCl_3$) cm^{-1}: 1766, 1694 (>C=O).

p-*Nitrobenzoyl Benzylthiocarbonyl Sulfide (4b).* This sulfide was prepared from 3.66 g (0.02 mol) of *p*-nitrothiobenzoic acid, 3.73 g (0.02 mol) of benzyl thiolchloroformate and 1.12 g (0.01 mol) of triethylenediamine in 200 m*l* of THF in a similar way to the preparation of **2i**. After removing the THF, the residue was filtered to yield 2.83 g of solid material which melted at 60—130°C. Petroleum ether (500 m*l*) was added to the solid. The mixture was refluxed for short time, and filtered to remove insoluble material. Cooling the filtrate gave 0.65 g (10%) of **4b** as pale yellow needles, mp 72—73°C with decomposition.

Found: C, 54.04; H, 3.32; N, 4.19; S, 19.27%. Calcd for $C_{15}H_{11}O_4NS_2$: C, 54.04; H, 3.33; N, 4.20; S, 19.24%. IR ($CHCl_3$) cm^{-1}: 1731, 1690, 1646 (>C=O).

Recrystallization of the insoluble material from toluene gave 0.70 g (21%) of bis(*p*-nitrobenzoyl)sulfide (**9b**) as yellow needles, mp 135.5—137°C.

Found: C, 50.63; H, 2.42; N, 8.36; S, 9.52%. Calcd for $C_{14}H_8O_6N_2S$: C, 50.60; H, 2.43; N, 8.43; S, 9.65%.

4) Bp 108—109°C/1 mmHg, Found: C, 34.62; H, 4.85; S, 45.30%. Calcd for $C_6H_{10}O_2S_3$: C, 34.25; H, 4.79; S, 45.75%.

Reactions between Acyl Halides and Silver Hyponitrite

Masatsugu SEKIGUCHI, Michio KOBAYASHI, and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received March 31, 1972)

Organic esters of hyponitrous acid (HON=NOH) have not been studied extensively, the only examples reported being ethyl,[1] benzyl,[2] and *t*-butyl[3] esters. In connection with the generation of sulfonyloxy radicals, disulfonyl hyponitrites appear to be of interest as a possible source of sulfonyloxy radicals. The reaction between silver hyponitrite and *p*-toluenesulfonyl bromide and that between silver hyponitrite and benzoyl chloride have been investigated, and the results are given in this paper.

Results and Discussion

Since silver hyponitrite decomposes slowly upon irradiation of light, the reactions were carried out in its absence. Silver hyponitrite is hardly soluble in any organic solvent (including DMF, HMPA, and DMSO), and the reactions were carried out in heterogeneous media in the presence of excess hyponitrite.

When *p*-toluenesulfonyl bromide was let to react with silver hyponitrite in various solvents at room temperature or lower temperatures (0 to −30°C), di-*p*-toluenesulfonyl hyponitrite was not formed and nitrous oxide and nitrogen evolved. The results of the products analyses are given in Table 1.

a) Products were analyzed after the time shown, except for gaseous products which were analyzed when the reaction appeared essentially complete; the time which elapsed before the analyses of gas is shown in parentheses.
b) The amount of total gas was determined with a gas buret.

No *p*-toluenesulfonic anhydride was found in acetonitrile. Silver *p*-toluenesulfonate is soluble in acetonitrile, but not in other solvents in which it covers the surface of silver hyponitrite hindering the reaction between silver hyponitrite and *p*-toluenesulfonic anhydride in solution. Silver *p*-toluenesulfonate does not behave thus in acetonitrile, and *p*-toluenesulfonic anhydride is smoothly converted into silver *p*-toluenesulfonate by the reaction with silver hyponitrite. By a separate experiment, it was confirmed that *p*-toluenesulfonic anhydride reacts with silver hyponitrite, forming silver *p*-toluenesulfonate.

Since the reaction took place between the solid salt and *p*-tosyl bromide in solution and the solubility of the salt differed with the solvent, the results of the reaction varied with solvent. In 1,2-dichloroethane, considerable amounts of nitrogen were evolved. This indicates that the following homolysis takes place to some extent in 1,2-dichloroethane.

$$\mathrm{AgON{=}NOAg + 2TsBr \xrightarrow{-2AgBr}}$$
$$\mathrm{TsON{=}NOTs \longrightarrow 2TsO\cdot + N_2} \quad (1)$$

In order to obtain further evidence for the formation of *p*-tosyloxy radicals, the reaction was carried out in benzene, which is expected to be substituted by *p*-tosyloxy radical. However, it was found that in benzene almost all the gas evolved was not nitrogen but nitrous oxide, and thus the homolysis shown above must be a very minor reaction in benzene.

As for the reaction responsible for evolution of nitrous oxide, the following two processes are possible.

$$\mathrm{AgON{=}NOAg + 2TsBr \xrightarrow{-2AgBr}}$$
$$\mathrm{TsON{=}NOTs \longrightarrow TsOTs + N_2O} \quad (2)$$
$$\mathrm{AgON{=}ONAg + TsBr \xrightarrow{-AgBr}}$$
$$\mathrm{TsON{=}NOAg \longrightarrow TsOAg + N_2O} \quad (3)$$

Silver *p*-tosylate can be converted into *p*-toluenesulfonic anhydride, and *vice versa*, depending upon the reaction conditions; the reaction between silver *p*-tosylate and *p*-tosyl bromide yields *p*-toluenesulfonic anhydride, and that between *p*-toluenesulfonic anhydride and silver hyponitrite yields silver *p*-tosylate.

$$\mathrm{TsOAg + TsBr \xrightarrow{-AgBr} TsOTs}$$
$$\mathrm{\uparrow \xleftarrow[-N_2O]{+AgON{=}NOAg} \downarrow}$$

It was reported that a mixture of benzoyl halides and silver hyponitrite initiates polymerization of ethylene.[4] However, products and the mechanism of the reaction were not described. In order to ascertain whether or not free radicals are produced from these reactants, the reaction was studied in some detail. The results are given in Table 2.

The major component of the gas evolved was nitrous oxide. Thus homolysis (4) should be a minor reaction, Nitrous oxide was evolved either by reaction (5) or (6).

$$\mathrm{AgON{=}NOAg + 2BzCl \xrightarrow{-2AgCl}}$$
$$\mathrm{BzON{=}NOBz \longrightarrow 2BzO\cdot + N_2} \quad (4)$$
$$\mathrm{AgON{=}NOAg + 2BzCl \xrightarrow{-2AgCl}}$$
$$\mathrm{BzON{=}NOBz \longrightarrow BzOBz + N_2O} \quad (5)$$
$$\mathrm{AgON{=}NOAg + BzCl \xrightarrow{-AgCl}}$$
$$\mathrm{BzON{=}NOAg \longrightarrow BzOAg + N_2O} \quad (6)$$

Chlorodiphenyls and nitrodiphenyls were formed in small yields from the reactions in chlorobenzene and nitrobenzene, respectively. In order to clarify the nature of this phenylation, the isomer distributions of the substituted diphenyls were studied by gas chromatography. The isomer distribution of chlorodiphenyls is *o*- 59.8, *m*- 23.3, and *p*- 16.9%; that of nitrodiphenyls is *o*- 53.5, *m*- 12.5, and *p*- 33.9%. They are similar to the isomer distributions found in free radical phenylation with benzoyl peroxide or *N*-nitrosoacetanilide. This also supports the idea that homolysis (4) takes place to a small extent.

In summary, the reactions between *p*-tosyl bromide and silver hyponitrite yield both nitrogen and nitrous oxide, the former probably being a product of the homolysis of di-*p*-tosyl hyponitrite formed as an intermediate, and the latter a product of ionic reactions.

a) not determined.

The reactions between benzoyl chloride and silver hyponitrite were essentially similar.

Experimental

Materials. Silver hyponitrite was prepared by the reduction of silver nitrate with sodium amalgam.[5] *p*-Toluenesulfonyl bromide was synthesized by the reaction of sodium *p*-toluenesulfinate and bromine.[6] Solvents were purified by conventional procedures.[7]

Reactions between Silver Hyponitrite and p-*Toluenesulfonyl Bromide.* In a helium atmosphere, well-dried powder of silver hyponitrite (1.380 g, 5 mmol) was slowly added for about 1 hr to a stirred solution of *p*-toluenesulfonyl bromide (0.470 g, 2 mmol) in 1,2-dichloroethane (6 m*l*) at room temperature. After stirring was continued for 3 hr, the gas evolved was collected in a sampling tube and subjected to gas-chromatographic analysis (a Shimadzu Gas Chromatograph GC3AH, helium 60 m*l*/min, 35°C, a 1 m silica gel column; retention time, O_2 and N_2, 0.30 min, N_2O, 4.2 min). The possibility of contamination of nitrogen from air was checked by observing the amount of oxygen in the gas (a 1 m molecular sieve 5A column, helium 120 m*l*/min, 35°C; retention time, O_2, 0.45 min, N_2, 0.55 min). The identity of nitrous oxide and nitrogen was further confirmed by use of a mass spectrometer. The mass spectrum of the gas evolved showed peaks at 44 (N_2O), 30 (NO), and 28 (N_2). By comparison with the mass spectra of pure N_2O (at 70 eV, N_2O 100, NO 25.6, N_2 11.0) and pure N_2, the presence and the amounts of N_2O and N_2 in the gas evolved were determined.

The reaction mixture was filtered, and the residue was washed with 1,2-dichloroethane. When the filtrate and washings were combined and evaporated under reduced pressure, white solids of *p*-toluenesulfonic anhydride (0.309 g) were obtained (IR, 1400, 1200, and 1180 cm^{-1}). The identity of *p*-toluenesulfonic anhydride was further checked by the reaction with aniline; from 100 mg of the anhydride, 67 mg of $PhNH_3^+OTs^-$ and 88 mg of PhNHTs were obtained. When a similar reaction mixture was allowed to stand overnight at room temperature, the amount of the anhydride decreased (0.281 g, 0.862 mmol) and a considerable amount of silver *p*-tosylate was found (0.085 g, 0.305 mmol). The amount of silver *p*-tosylate was determined by converting it into *S*-benzylisothiuronium *p*-tosylate by the reaction with *S*-benzylisothiourea hydrochloride.

Reactions in dichloromethane, benzene, and acetonitrile were carried out in a similar manner.

Reactions between Silver Hyponitrite and Benzoyl Chloride. In a helium atmosphere, well-dried powder of silver hyponitrite (1.104 g, 4.0 mmol) was slowly added for about 1 hr to a stirred solution of benzoyl chloride (0.560 g, 4.0 mmol) in chlorobenzene (11.26 g). After 3.5 hr, the gas collected was analyzed as described above.

The reaction mixture was filtered, the filtrate and washings were combined and extracted with a saturated $NaHCO_3$ solution. From the alkaline extracts, 35 mg (0.287 mmol) of benzoic acid was obtained. Benzoic anhydride contained in the organic layer was converted into PhCONHPh by the reaction with aniline; 0.337 g (1.71 mmol).

For determination of the amounts of chlorodiphenyls, a similar reaction mixture was prepared by a separate experiment, and concentrated. Benzoic anhydride was decomposed by refluxing with a 10% NaOH solution (10 m*l*) and ethanol (10 m*l*). The mixture was extracted with ether, the ethereal extracts were dried over anhydrous magnesium sulfate, and then concentrated. The amounts of *o*-, *m*-, and *p*-chlorodiphenyl in the residue were determined by gas chromatography (a Hitachi K-53 Gas Chromatograph, a 5 m Apiezon grease L column, 190°C; internal standard, dibenzyl).

Grateful acknowledgment is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

Preparation of Rhodium Acrolein Complexes

Masanobu HIDAI, Kazuo ISHIMI, Masa-aki IWASE, and Yasuzo UCHIDA
Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo

(Received May 18, 1972)

Several acrolein complexes of nickel,[1] iron,[2] molybdenum,[3] and copper[4] have been known. We have now prepared rhodium acrolein complexes from acrolein and the rhodium(I) cyclooctene complex $[RhCl(C_8H_{14})_2]_2$.

Acrolein reacts smoothly with $[RhCl(C_8H_{14})_2]_2$ in toluene at $-10°C$ under nitrogen and a brown complex formulated as $RhCl(CH_2{=}CHCHO)_2$ (I) was obtained in a high yield. Infrared spectroscopic evidence indicates the manner of attachment of acrolein to the metal atom. The C=C stretching frequency of acrolein is shifted about 13 cm^{-1} to the lower frequency side by the ligation. Two strong C=O stretching bands are observed at 1670 and 1545 cm^{-1}. The former band is very close to the aldehydic carbonyl absorption for the free ligand in the liquid state (1675 cm^{-1}). The latter band is 130 cm^{-1} lower than that of free acrolein. These indicate the presence of two types of coordinated acrolein ligands: One coordinates to the rhodium metal with both C=O and C=C groups, while the other coordinates with only the C=C bond.

The reaction of acrolein with $[RhCl(C_8H_{14})_2]_2$ at 30°C also yields a brown complex with the same empirical formula as the above complex in a high yield. However, the IR spectrum of the complex exhibites a sharp band at 2000 cm^{-1} and a weak band at 1740 cm^{-1} in addition to two bands at 1670 and 1545 cm^{-1} described above. The reaction of this complex with excess of triphenylphosphine yields a mixture of $RhCl(CO)(PPh_3)_2$ and $RhCl(PPh_3)_3$ in a ratio of about 4:1 with evolution of ethylene. The band at 2000 cm^{-1} is, therefore, assigned to C≡O stretching vibration. Furthermore, the intensity of the band at 1670 cm^{-1} is weak compared with that of the complex obtained at $-10°C$, indicating that some of acrolein ligands coordinating to the metal *via* the C=C bond are converted into ethylene and carbon monoxide ligands and $RhCl(CO)(CH_2{=}CH_2)(CH_2{=}CHCHO)$ (II) is formed. On the other hand, the weak band at 1740 cm^{-1} in the keto-region may indicate the presence of a small amount of an acyl complex. From these results, it may be reasonable to conclude that the acrolein complex obtained at 30°C is a mixture of I, II, and an acyl complex.

$$[RhCl(C_8H_{14})_2]_2 + CH_2{=}CHCHO \longrightarrow \underset{(I)}{RhCl(CH_2{=}CHCHO)_2} + \underset{(II)}{RhCl(CO)(CH_2{=}CH_2)(CH_2{=}CHCHO)} + \text{Acyl complex}$$

These rhodium acrolein complexes are fairly air-stable. They are slightly soluble in tetrahydrofuran and scarcely soluble in benzene and ether. The thermal decomposition of the complexes occurs *in vacuo* above about 145° with evolution of ethylene and carbon monoxide, yielding $[RhCl(CO)_2]_2$. Numerous fruitless attempts were made to isolate the complex II and the acyl complex in a pure state.

Experimental

All reactions were carried out under a nitrogen atmosphere. The rhodium(I) cyclooctene complex $[RhCl(C_8H_{14})_2]_2$ was prepared by the published procedure.[5]

Reaction of Acrolein with $[RhCl(C_8H_{14})_2]_2$ at $-10°C$. To a stirred solution of $[RhCl(C_8H_{14})_2]_2$ (1.0 g) and toluene (80 m*l*) was added 2 m*l* of acrolein at 0°C. After stirring for 3 hr, a brown complex precipitated was washed with toluene and petroleum ether several times (0.38 g, 54% yield).

Found: C, 28.55; H, 3.40; O, 12.86; Cl, 14.46%. Calcd for $C_6H_8O_2ClRh$: C, 28.77; H, 3.22; O, 12.78; Cl, 14.15%.

Reaction of Acrolein with $[RhCl(C_8H_{14})_2]_2$ at 30°C. The procedure was the same as above, except that the reaction temperature was 30°C and the reaction time was 0.5 hr (0.40 g, 57% yield).

Found: C, 28.97; H, 3.38; O, 11.52; Cl, 14.60%. Calcd for $C_6H_8O_2ClRh$: C, 28.77; H, 3.22; O, 12.78; Cl, 14.15%.

Ultraviolet Luminescence of Ternary Compounds (La, Al, Ce)F_3[1)]

Kazuo NARITA and Akira TAYA

Toshiba Research and Development Center, Tokyo Shibaura Electric Co., Ltd. Komukai Toshiba-cho, Kawasaki

(Received May 11, 1972)

Luminescence of trivalent metal fluorides activated by Ce^{3+} ion has been reported by several authors.[2-4)] Emission due to the Ce^{3+} center was found in the ultraviolet and/or the blue region. In these papers, however, descriptions were made only on pure CeF_3 and on binary fluorides containing CeF_3. Relations between the preparing conditions of the phosphors and their luminescence efficiency were not mentioned.

We prepared ternary (La, Al, Ce)F_3 phosphors by solid state reaction at high temperatures and found the best composition and firing conditions for these phosphors. Reflection, excitation and emission spectra were also measured.

Experimental

LaF_3 (99.999%), CeF_3 (99.99%) and other rare earth fluorides were obtained from Shin-etsu Chemical Company. AlF_3 was a C.P. reagent of Amend Drug and Chemical Co. The weighed materials were dry-mixed, placed in ceramic crucibles and fired in air for 30 min at 800°C. Firing above or below 800°C resulted in much poorer efficiency. The chemical composition of the finished phosphors was approximately the same as that before firing. X-ray diffraction data showed that the phosphors consist of two tysonite phases, one having a lattice constant slightly smaller than LaF_3, the other having a lattice constant slightly larger than CeF_3. AlF_3 diffraction lines were very weak. Thus, under the preparing conditions mentioned above, LaF_3 and CeF_3 seem to react poorly, whereas AlF_3 appears to be dissolved almost completely into two tysonite phases.

Spectroscopic measurements were made with a Perkin-Elmer Model E-1 spectrometer. A deuterium discharge lamp was used as a light source for reflection and excitation measurements. Photoluminescence was excited by 2537 Å Hg line from a low pressure mercury lamp.

Results and Discussion

Figure 1 shows the emission spectra of $(La_{0.5}Al_{0.3}Ce_{0.2})F_3$ at 300 and 77°K. In the former, the peak is located at 2860 Å. In the latter, two well-separated peaks are observed with an energy separation of about 2000 cm^{-1}, which is close to the splitting of the ground state in a Ce^{3+} free ion, 2253 cm^{-1}. In the (La, Al, Ce)F_3 system, the feature of the emission spectrum does not depend on the chemical composition, but it shifts to the longer wavelength region when La is replaced by Y. For example, $(Y_{0.5}Al_{0.2}Ce_{0.3})F_3$ has its emission peak at 2933 Å at 300°K.

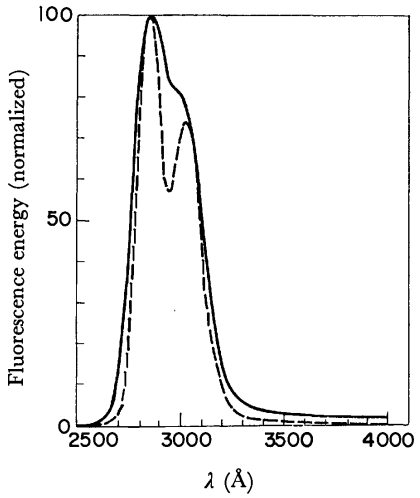

Fig. 1. Emission spectra of $(La_{0.5}Al_{0.3}Ce_{0.2})F_3$ phosphor under 2537 Å excitation.
———: 300°K, - - - - - -: 77°K

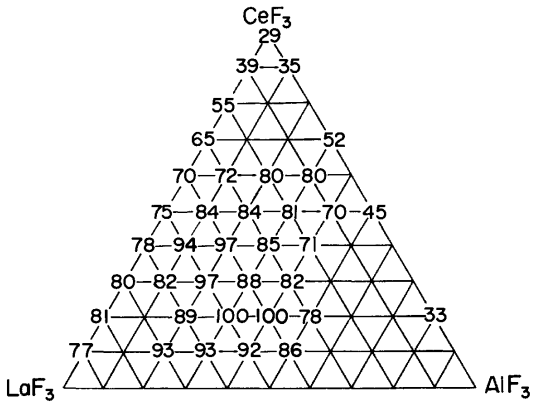

Fig. 2. Relative fluorescence efficiency of (La, Al, Ce)F_3 system.

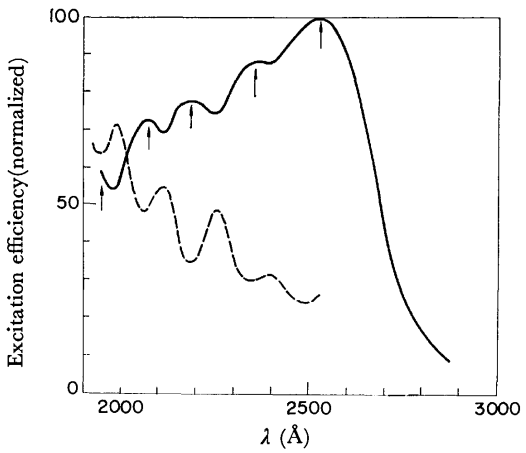

Fig. 3. Excitation and reflection spectra of $(La_{0.5}Al_{0.3}Ce_{0.2})F_3$.

4) G. Blasse and A. Bril, *J. Chem. Phys.*, **51**, 3252 (1969).

Figure 2 shows the fluorescence efficiency of (La, Al, Ce)F_3 as related to phosphor compositions. The maximum efficiency is obtained for $(La_{0.5}Al_{0.3}Ce_{0.2})F_3$ and $(La_{0.4}Al_{0.4}Ce_{0.2})F_3$, which have 20% more output than the best binary solid solution $(La_{0.8}Ce_{0.2})F_3$.

Figure 3 shows the excitation as well as the diffuse reflection spectrum at 300°K. The excitation spectrum is similar to that reported by Blasse and Bril.[4] In the present spectrum, however, five bands are identified with the peaks at 1950 (51280 cm^{-1}), 2070 (48300 cm^{-1}), 2190 (45660 cm^{-1}), 2350 (42540 cm^{-1}), and 2535 (39520 cm^{-1})Å, the energy splittings between the sequent peaks being 2980, 2640, 3120, and 3020 cm^{-1}, respectively.

In the treatment of the $5d$ excited state of Ce^{3+}, the spin-orbit interaction is usually neglected and only the crystal field splitting is considered.[5,6] This approximation seems to be justified also in the case of (La, Al, Ce)F_3, since the spin-orbit coupling energy, which is 2489 cm^{-1} with the coupling constant $\zeta_{5d}=995.6$ cm^{-1} [7] in a free Ce^{3+} ion and is expected to become smaller by several tens of per cent in the crystal,[8] is too small to account for the splitting observed in the excitation and reflection spectra. The space group of tysonite structure is D_{3d}, in which the cation occupies the site with C_2 symmetry.[9] Hence, the $5d(^2D)$ state splits into five Kramer's doublets. This is in agreement with the observation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2937—2938 (1972)

Synthesis of Aliphatic Isoselenocyanates by the Reaction of Aliphatic Isocyanides with Selenium in the Presence of Triethylamine

Noboru SONODA, Goro YAMAMOTO, and Shigeru TSUTSUMI

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received November 19, 1971)

Bulka and co-workers[1] have reported that the reaction of selenium with aryl isocyanide produces aryl-isoselenocyanate. However, the reaction of selenium with aliphatic isocyanide has not been reported yet. We tried the reaction of aliphatic isocyanide under the same conditions to those employed in the reaction of aryl isocyanide.[1] However, the corresponding isoselenocyanate was not obtained. Recently we confirmed that amine catalyzed the reaction between carbon monoxide and selenium to give carbonyl selenide[2] and this fact prompted us to try to use of strongly basic tertiary amine as catalyst in the present reaction, because of similarity of electronical structure between isocyanide and carbon monoxide. Now, we found that the addition of triethylamine promoted the reaction effectively, and aliphatic isoselenocyanate was obtained in a high yield. The results obtained from representative isocyanides were shown in Table 1. The aliphatic isoselenocyanates isolated were identified by IR, NMR, mass spectroscopy, and elemental analyses. These isoselenocyanates were somewhat unstable and gradually decomposed at room temperature.

$$\text{R-NC} + \text{Se} \xrightarrow{\text{Et}_3\text{N}} \text{R-N=C=Se}$$

R: -, *n*-C_4H_9-, *tert*-C_4H_9-

Some characteristic reactions of the isoselenocyanates were carried out. The reaction of aliphatic isoselenocyanates with *n*-butylamine produced corresponding selenoureas in excellent yields, which were fairly stable

Cyclohexyl	22	—	740	24	78	*N*-Cyclohexylselenocarbamate	49

a) Based on selenium used.

at room temperature. Selenocarbamate was easily obtained by the reaction of isoselenocyanate with ethanol. These results were summarized in Table 2.

$$R\text{-}N{=}C{=}Se + R'\text{-}NH_2 \longrightarrow R\text{-}NH\text{-}\underset{\underset{Se}{\|}}{C}\text{-}NH\text{-}R'$$

$$R\text{-}N{=}C{=}Se + R'\text{-}OH \longrightarrow R\text{-}NH\text{-}\underset{\underset{Se}{\|}}{C}\text{-}OR'$$

Furthermore, it was confirmed that the reaction of isocyanide with selenium and *n*-butylamine yielded the corresponding selenourea directly. In this case *n*-butylamine might catalyze the reaction of isocyanide with selenium to give isoselenocyanate as an intermediate.

Experimental

Cyclohexyl Isoselenocyanate. To a solution of 5.79 g (53 mmol) of cyclohexyl isocyanide in 45 m*l* of THF were added 3.00 g (38 mg atom) of selenium and 3.85 g (38 mmol) of triethylamine. The mixture was stirred under reflux for 4 hr, and at this stage selenium was completely dissolved. The mixture was concentrated, and distillation of the residual liquid gave 6.90 g (96%) of colorless product: bp 90—92°C (3.0 mm); IR 2130 cm^{-1} (N=C=Se); NMR (CCl_4) τ 7.7—8.9 (10H), 6.2 (1H); Mass *m/e* 189 (parent ion containing ^{80}Se), 83 ($C_6H_{11}^+$).

Found: N, 7.32%. Calcd for $C_7H_{11}NSe$: N, 7.45%.

n-*Butyl Isoselenocyanate.* To a solution of 1.74 g (21 mmol) of *n*-butyl isocyanide were added 1.18 g (15 mg atom) of selenium and 1.52 g (15 mmol) of triethylamine. The mixture was stirred under reflux for 1.5 hr. Selenium was dissolved completely and the solution became dark brown. The mixture was concentrated and distillation of the residue gave 2.02 g (83%) of colorless liquid: bp 56—58°C (3 mm); IR 2160 (N=C=Se); NMR (CCl_4) τ 8.8—9.2 (3H), 7.9—8.8 (4H), 6.2—6.4 (2H); Mass *m/e* 163 (parent ion containing ^{80}Se), 57 ($C_4H_9^+$).

Found: N, 8.52%. Calcd for C_5H_9NSe: N, 8.60%.

tert-*Butyl Isoselenocyanate.* To a solution of 1.74 g (21 mmol) of *tert*-butyl isocyanide were added 1.18 g (15 mg atom) of selenium and 1.52 g (15 mmol) of triethylamine. The mixture was concentrated *in vacuo* to give 2.37 g (97%) of colorless solid. This solid was fairly unstable and decomposed on recrystallization or on standing overnight: mp 51—52°C; IR 2050 cm^{-1} (N=C=Se); NMR (CCl_4) τ 8.5 (s); Mass *m/e* 163 (parent ion containing ^{80}Se), 57 ($C_4H_9^+$).

Found: N, 8.43%. Calcd for C_5H_9NSe: N, 8.60%.

N-n-*Butyl*-N'-*cyclohexylselenourea.* *A*: To a solution of 0.55 g (3 mmol) of cyclohexyl isoselenocyanate in 5 m*l* of THF was added 0.24 g (3 mmol) of *n*-butylamine. The solution was allowed to stand for 48 hr at room temperature, then was concentrated *in vacuo* to dryness, and the yellow solid deposited was filtered and recrystallized from ethanol to yield 0.67 g (90%) of colorless crystal: mp 107.5—108.5°C; IR 3210 cm^{-1} (NH); NMR (CCl_4) τ 7.8—9.1 (17H), 6.6 (2H), 5.9 (1H), 3.0 (2H); Mass *m/e* 262 (parent ion containing ^{80}Se), 83 ($C_6H_{11}^+$), 99 ($C_6H_{11}NH_2^+$), 57 ($C_4H_9^+$).

Found: N, 10.68%. Calcd for $C_{11}H_{22}N_2Se$: N, 10.72%.

B: To a solution of 3.85 g (35 mmol) of cyclohexyl isocyanide in 20 m*l* of THF were added 2.37 g (30 mmol) of selenium and 2.20 g (30 mmol) of *n*-butylamine. The mixture was stirred under reflux for 4 hr, and at this stage selenium was dissolved. The mixture was concentrated and the yellow solid deposited was filtered and recrystallized from ethanol to yield 7.60 g (97%) of colorless crystal which was identical with *N*-*n*-butyl-*N'*-cyclohexylselenourea obtained by the procedure *A*.

N,N'-*Di*-n-*butylselenourea.* To a solution of 0.73 g (5 mmol) of *n*-butyl isoselenocyanate in 9 m*l* of THF was added dropwise 0.37 g (5 mmol) of *n*-butylamine. After complete addition of *n*-butylamine, the reaction mixture was stirred under reflux for 0.5 hr to complete the reaction. The solution was concentrated *in vacuo* and the residual solid was recrystallized from benzene–petroleum ether mixture to give 1.05 g (98%) of colorless plates: mp 72—73°C; IR 3220 cm^{-1} (NH); NMR τ 8.8—9.2 (6H), 8.0—8.8 (8H), 6.2—6.8 (4H), 2.5—3.0 (2H); Mass *m/e* 236 (parent ion containing ^{80}Se), 57 ($C_4H_9^+$).

Found: N, 12.13%. Calcd for $C_9H_{10}N_2Se$: N, 11.91%.

N-n-*Butyl*-N'-tert-*butylselenourea.* To a solution of 0.89 g (5.5 mmol) of *tert*-butyl isoselenocyanate in 15 m*l* of THF was added dropwise 0.46 g (5.5 mmol) of *n*-butylamine. After addition of *n*-butylamine, the reaction mixture was stirred under reflux for 0.5 hr to complete the reaction. The reaction mixture was concentrated and the yellow solid deposited was recrystallized from benzene to yield 1.15 g (89%) of colorless plates: mp 76—77°C; IR 3220 cm^{-1} (NH); NMR τ 8.2—9.2 (16H), 6.2—6.7 (2H), 3.1—3.4 (2H); Mass *m/e* 236 (parent ion containing ^{80}Se), 57 ($C_4H_9^+$).

Found: N, 11.68%. Calcd for $C_9H_{10}N_2Se$: N, 11.91%.

N-*Cyclohexylselenocarbamate.* Cyclohexyl isoselenocyanate, 4.19 g (22.3 mmol), was added to 43 m*l* of ethanol. The mixture was refluxed for 24 hr. The resulting solution was concentrated to give yellow solid, which was recrystallized from ethanol to yield 2.57 g (49%) of colorless plates: mp 77—78°C; IR 3210 cm^{-1} (NH); NMR τ 7.7—9.1 (13H), 6.3 (1H), 5.4 (2H), 1.8 (1H); Mass *m/e* 235 (parent ion containing ^{80}Se), 83 ($C_6H_{11}^+$).

Found: N, 5.82%. Calcd for $C_9H_{17}NOSe$: N, 5.98%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2939—2940 (1972)

Heat Capacity Changes of Some Sodium Alkylsulfates in Aqueous Solutions

Kunio TAMAKI, Yoshio ISOMURA, and Yōko ŌHARA

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received January 31, 1972)

Recently, the physical properties of aqueous electrolyte solutions have mainly been discussed in terms of the resultant change in the water structure upon the introduction of ions into water.[1] Small ions, such as lithium, sodium, and fluoride ions, have a net structure-making effect on the water structure, while large ions, such as potassium, chloride, and bromide ions, have a net structure-breaking effect.[1] On the other hand, nonpolar solutes such as hydrocarbons and amphiphilic compounds, such as alkyl alcohols or fatty acids, act as water-structure-making solutes in water; that is, the water molecules form an "iceberg" around nonpolar groups of the molecules.[2] This type of hydration is called "hydrophobic hydration" or "hydration of the second kind."[1]

It seems that it would be interesting to study the strength of hydrophobic hydration for amphiphilic electrolytes, that is, the molecules with both nonpolar and ionized groups. The solute-solvent interaction of this kind of compound is determined from the balance of the two different modes of hydration (ionic hydration and hydrophobic hydration). The object of this paper is to consider the role of alkyl groups in the change in the water structure, in the case of a series of sodium alkylsulfates; this work is based on the experimentally-determined values of the change in the partial molal heat capacity. The method has been applied to tetraalkylammonium salts,[3] sodium tetraphenylboron,[4] aliphatic alcohol,[5] and poly(ethylene glycol) and related compounds.[6]

At a constant pressure, the following relation is derived between the heat of solution at an infinite dilution, ΔH_s^0, and the temperature, T:[7]

$$d\Delta H_s^0/dT = \Delta C_p^0 = \bar{C}_p^0 - C_p^s$$

where ΔC_p^0 is the change in the heat capacity for dissolution, $\bar{C}_p^0$ is the partial molal heat capacity of the solute at an infinite dilution, and C_p^s is the heat capacity of the pure solute. As the C_p^s values of the sulfates are unavailable at present, discussion will be limited to the ΔC_p^0 values in this paper.

Experimental

Materials. The sodium methylsulfate used in this work was prepared from the precipitation by the addition of petroleum benzine to an ethanol solution of commercial sodium methylsulfate monohydrate. Analysis showed the obtained sample was anhydrous. The other sodium alkylsulfates were synthesized by the esterification of the corresponding alcohols by concentrated sulfuric acid, and were neutralized with a concentrated solution of sodium hydroxide. The reaction mixtures were dried in air and extracted with ethanol, and then the products were recrystallized twice from ethanol and dried in a vacuum desiccator. The water was obtained by redistillation from an alkaline permanganate solution.

Apparatus. Heat-of-solution measurements at 10, 25, and 45°C were made with an Ōyodenki Kenkyujo (Tokyo) Model CM-204D1 twin conduction calorimeter. An ampoule containing an apropriate amount of a sample was mechanically broken into 50 cc of water at a constant temperature. Because of the hygroscopic property of the sodium alkylsulfates used, the samples introduced into ampoules were dried in a vacuum before final weighing. The calorimeter was checked by measuring the heats of solution of potassium chloride. The values thus obtained were within 2% of those reported in the literature.[8]

Results and Discussion

The heat of solution at an infinite dilution is generally obtained by extrapolating the plot of the heat of solution as a function of the concentration (or the square root of the concentration in the case of electrolytes). However, it was found that the results obtained at concentrations below 0.01 M showed some scattered values. Thus, the heats of solution at 0.01 M, ΔH_s, are presented in Table 1. A correction for the heats of dilution must be made to obtain ΔH_s^0. With sodium chloride, a typical uni-univalent electrolyte, the heat of dilution from a solution at 0.01 M to one at an

infinite dilution is −0.039 kcal/mol;[9] this value is sometimes comparable with the range of error of this work. The average values of ΔC_p^0 between 10 and 45°C are calculated by assuming that the change in the partial molal heat capacity at 0.01 M is equal to that at an infinite dilution. The ΔC_p^0 values obtained on the basis of this assumption are also listed in Table 1. A procedure similar to this was employed by Greyson and Snell.[10]

As will be seen in Table 1, sodium methylsulfate shows only negative ΔC_p^0 values in the homologous series. Though the ΔC_p^0 or $\bar{C}_p^0$ value of an electrolyte naturally consists of the sum of the contributions of both cation and anion, so far no reliable procedure for assigning a value to the individual ions has been established. The $\bar{C}_p^0$ values, and thus the ΔC_p^0 values, of most simple electrolytes are negative;[11] *e.g.*, the $\bar{C}_p^0$ value of sodium chloride is −22.1 cal/deg·mol at 25°C.[11] As the ΔC_p^0 value of methyl alcohol is 23.1 cal/deg·mol,[5] the methyl group must cause a positive change in the ΔC_p^0 value. The overall change in the partial molal heat capacity of sodium methylsulfate is as low as −17 cal/deg·mol as is shown in Table 1; this means that the methyl salt displays behavior rather similar to that of simple salt in the water phase. In this sense, sodium methylsulfate may be considered to behave as a net structure-breaking salt.

The ΔH_s values of sodium ethylsulfate are virtually independent of the temperature. With this salt, the contributions of the two types of hydration (ionic and hydrophobic) seem to cancel each other out.

The ΔC_p^0 values of sodium propylsulfate and higher homologues are positive; these salts exhibit an excellent water-structure-making effect. The positive ΔC_p^0 values in Table 1 indicate that the promotion of the water structure ("iceberg" formation[2]) around the nonpolar groups of these salts increases with the number of carbon atoms of alkyl chain.

Nuclear Quadrupole Resonance of the 1:1 Molecular Complex between Antimony Trichloride and Ethylbenzene

Tsutomu OKUDA, Yoshihiro FURUKAWA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received February 7, 1972)

We have already reported on the antimony-halogen bond character and the molecular shape of antimony trihalide in its 2:1 molecular complex with an aromatic compound, as determined by means of the nuclear quadrupole resonance (NQR).[1-3] As for the 1:1 molecular complex, NQR studies have been performed by several authors.[4] All of them, however, used polycrystalline samples, and their crystal structures are still unknown except for $SbCl_3 \cdot C_6H_5NH_2$,[5] in which the NQR has not yet been observed.

In the present experiment, we observed the Zeeman effect of NQR in $SbCl_3 \cdot C_6H_5C_2H_5$ in order to obtain information on the Sb-Cl bond character and the molecular structure of antimony trichloride in its molecular complex.

The molecular complex was prepared by the method of Shinomiya and Asahina,[6] and the single crystal was obtained by the Bridgman-Stockbarger method. A Weber-Todd type[7] super-regenerative oscillator was used for the detection of the resonance line. The magnetic field used for the Zeeman study was provided by a Helmholtz coil[8] with a field strength of about 200 gauss.

TABLE 1. NUCLEAR QUADRUPOLE RESONANCE FREQUENCIES, ν, ASYMMETRY PARAMETERS, η, AND QUADRUPOLE COUPLING CONSTANTS, eQq_{zz}, IN ANTIMONY TRICHLORIDE AND ITS COMPLEX WITH ETHYLBENZENE AT ROOM TEMPERATURE (20°C)

Compound	Resonance line	ν, MHz	η, %	eQq_{zz}, MHz
$SbCl_3 \cdot C_6H_5C_2H_5$	^{35}Cl ν_1	19.010	5.5±1.4	38.001
	^{35}Cl ν_2	19.388	13.5±1.7	38.426
	^{35}Cl ν_3	19.641	9.0±1.5	39.126
	^{123}Sb ν (1/2—3/2)	35.478	13.3±0.3	467.698
$SbCl_3$	^{35}Cl ν'_1	19.180	15.3	38.211
	^{35}Cl ν'_2	20.422	5.7	40.822
	^{123}Sb ν' (1/2—3/2)	37.431	15.9	481.560

The NQR frequencies of ^{35}Cl and ^{123}Sb were observed between the temperature of liquid nitrogen and room temperature, as is shown in Fig. 1. The present molecular complex gave three ^{35}Cl resonance lines (designated as ν_1, ν_2, and ν_3) and one ^{123}Sb ($1/2 \leftrightarrow 3/2$) resonance line (designated as $\nu(1/2—3/2)$), as Table 1 shows.

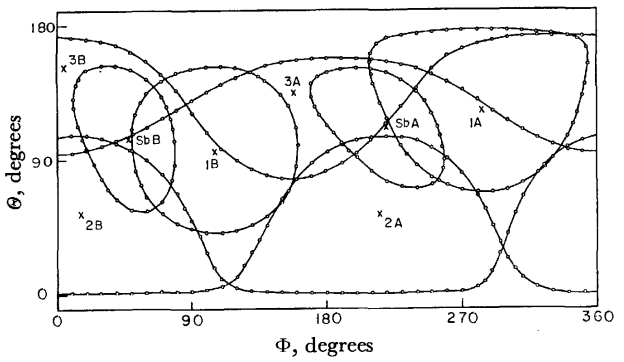

Fig. 2. Zero-splitting patterns of ^{35}Cl and ^{123}Sb Zeeman lines in $SbCl_3 \cdot C_6H_5C_2H_5$. Θ and Φ are polar and azimuthal angles, respectively, in the coordinate fixed to the sample.

The patterns of the zero-splitting were obtained by measuring the Zeeman effect on the resonance line as is shown in Fig. 2. Two patterns were obtained for each resonance line, indicating that the molecular complex is monoclinic. The angles between any two Sb–Cl bonds can be calculated by assuming that the z axis of the field gradient of chlorine is parallel to the Sb–Cl bond. The bond angles, ∠Cl–Sb–Cl, thus obtained are 90°26′, 93°8′, and 96°1′. These angles are almost the same as those of pure antimony trichloride[9] and $2SbCl_3 \cdot C_{10}H_8$,[10] indicating that the molecular shape of antimony trichloride hardly changes upon complex-formation with ethylbenzene. On the other hand, it is considerably different from that of $SbCl_3 \cdot C_6H_5NH_2$, though both crystals are 1:1 molecular complexes. This discrepancy may be attributed to the difference in the strength of the intermolecular bond, which may deform the molecular shape to various degrees.

The values of the asymmetry parameter were determined from the distortion of the zero-splitting loci. Once the asymmetry parameter was obtained, the quadrupole coupling constant could be calculated from the observed resonance frequency. The results are listed in Table 1, along with those for pure antimony trichloride. In pure antimony trichloride, the quadrupole coupling constant and the temperature gradient of the lower ^{35}Cl resonance line (ν'_1) is considerably smaller than those of the higher (ν'_2), so the former is assigned to the chlorine atom, which forms the stronger Sb···Cl intermolecular bond.[9,11] In the present complex, since the quadrupole coupling constants and the temperature gradients of ν_1 and ν_2 are smaller than those of ν_3 and all comparable to those of ν'_1 in pure antimony trichloride, ν_1 and ν_2 may be assigned to the chlorine atoms (Cl_1 and Cl_2) in the stronger Sb···Cl intermolecular bonds, and ν_3, to that (Cl_3) in the weaker bonds. However, the asymmetry parameter of ν_1 is too small to be attributed to that in the stronger Sb···Cl intermolecular bond. This suggests the presence of another effect such as the *trans* effect, which is considered to exist in $2SbCl_3 \cdot C_{10}H_8$.[10] That is, if the configuration of the antimony atom in the present complex is a distorted sp^3d or sp^3d^2 environment and if the Cl_1 atom occupies the position opposite to the intermolecular bond between ethylbenzene and antimony trichloride, a part of the charge from ethylbenzene may transfer to the Cl_1 atom through the antimony atom. Such an effect will cause the quadrupole coupling constant to decrease without any increase in the asymmetry parameter because the electron populations of the p_z orbital increase. As the temperature increases, the degree of the charge transfer to the Cl_1 atom decreases since the intermolecular bond becomes weaker, resulting in the smaller change of ν_1 in comparison with that of ν_3.

The Syntheses and Properties of Some 2-Methyl-4-phenyl-1,5-benzodiazepinium Chlorometalates

Akiko FURUHASHI, Sumio KOMATSU, and Akira OUCHI*

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo

**Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo*

(Received March 22, 1972)

In a previous paper,[1] the present authors reported on the syntheses of 2,4-dimethyl-1,5-benzodiazepinium halogenometalates. However, similar compounds with different substituent on the 2 and/or the 4 position of the 1,5-benzodiazepinium ring have not yet been studied. It seemed that it would be of interst to study the influence of the substituents on the stability of the complex. In this way, some new compounds, 2-methyl-4-phenyl-1,5-benzodiazepinium chlorometalates, were obtained by the same synthetic technique as was used for the 2,4-dimethyl derivatives.

Experimental

The Syntheses of the 2-Methyl-4-phenyl-1,5-benzodiazepinium Chlorometalates. The chloride was synthesized from *o*-phenylenediamine and benzoylacetone by Thiele's method.[2] The chloride and the anhydrous metal chloride were separately dissolved in ethyl alcohol and then mixed. The mixture was kept in a refrigerator overnight, thus yielding crystalline products.

Instruments. The IR spectra were obtained by means of a JASCO model IR-G IR as well as model 403G spectrophotometer. The electronic spectra were obtained with a Hitachi EPS-3T-type automatic recording spectrophotometer.

Results and Discussion

The analytical results of the 2-methyl-4-phenyl-1,5-benzodiazepinium salts are shown in Table 1.

The magnetic moment of the tetrachlorocobaltate(II), as measured by a Gouy balance at room temperature, was 4.44 B.M (per mole of cobalt(II)); this fact shows the cobalt(II) ion is coordinated and is in the tetrahedral configuration.[3]

In the far IR region, the spectra of all of these chlorometalates have the characteristic bands, as is shown in Table 2; these bands are not observed in the spectrum of the simple chloride. They were identified as ν(M-Cl) bands by reference to Nakamoto's[4] and Ferraro's[5] data. This proves the existence of the tetrahedral chlorometalate ion in these compounds. As the wave numbers of the bands of 2-methyl-4-phenyl derivatives are lower than those of the corresponding 2,4-dimethyl-1,5-benzodiazepinium salts, the chlorometalate ions of the former compounds can be said to be less stable.

The IR spectra in the 400—4000 cm^{-1} region of these chlorometalates and of the simple chloride with the same 1,5-benzodiazepinium ion were almost identical. Consequently, in these compounds the 2,4-disubstituted 1,5-benzodiazepinium ion does not seem to coordinate to the metal ion, but seems to work as a counter cation, although some kind of interaction between the cation and the anion may exist as in the case of dithiolium halogenometalates.[6,7]

Table 1. Elemental analyses (%)

ν(N–H)	3275(m) 3200(m)	3275(m) 3200(m)	3250(m) 3175(m)	3270(m) 3200(m)
ν(C=C), ν(C=N) or the mixture of them	1639(s) 1595(s)	1625(m) 1598(s)	1610(s) 1590(s)	1615(s) 1590(s)
δ(C–H) of benzene ring	760(s)	760(s)	760(s)	760(s)

It is of interest to compare some wave numbers of the infrared absorption bands of the 2-methyl-4-phenyl-1,5-benzodiazepinium salts with those of 2,4-dimethyl derivatives. The results are shown in Table 3. The assignments of the band were obtained by reference to those of 2,4-dimethyl derivatives presented in the previous paper[1] as well as in Bellamy's books.[8,9]

The bands caused by the benzene ring of the cation are almost identical in the two types of salts, as in the case of the δ(C–H) (760 cm^{-1}) of the benzene ring shown in the table.

The ν(C=C), ν(C=N), or mixed bands appear in the 1400—1600 cm^{-1} region of both derivatives are not very different from each other. In the spectra of both derivatives, two ν(N–H) bands at about 3200—3270 cm^{-1} were observed, on the other hand, no characteristic bands appeared in the 2550—2800 cm^{-1} region (ν(N–H) of $-NH_3^+$).

From these results, the seven-membered rings of both ions seem to have pseudo aromaticity and to be stabilized. The ring of the 2-methyl-4-phenyl derivative is, however, likely to be less stable; consequently, the cation cannot stabilize the tetrabromometalate anion and solid tetrabromometalates were not obtained, although those of the 1,4-dimethyl derivatives had already been synthesized.[1]

Table 4. Electronic spectra of the 1,5-benzodiazepinium salts in ethyl alcohol solution

Figures are given in kK and logε (calculated about the cation) in parentheses

$[C_{11}H_{13}N_2]_2[CoCl_4]\cdot H_2O$	$[C_{16}H_{15}N_2]_2[CoCl_4]\cdot H_2O$
44.5 (4.09)	44.1 (4.10)
38.2 (4.35)	37.6 (3.80)
37.2 (3.32)	36.6 (4.40)
30.1 (2.90)	29.7 (3.20)
28.4 (3.00)	
19.6 (2.90)	19.4 (3.01)

These 2-methyl-4-phenyl-1,5-benzodiazepinium chlorometalates as well as the chloride are all deep violet in color, and the electronic absorption spectra of their ethyl alcohol solutions are almost identical. The data of the main peaks of the chlorometalates, together with those of the 2,4-dimethyl derivative, are shown in Table 4. The *d-d* band was covered by stronger bands and was not identified. The patterns of the spectra of the salts containing the same cation are almost the same; moreover, the spectra of the 2,4-dimethyl and 2-methyl-4-phenyl derivatives resemble each other. These spectral patterns and their intensities seem to be characteristic of the 1,5-benzodiazepinium seven-membered ring of the cation; therefore, both the rings seem to have a considerable pseudo-aromatic character.

The chlorides of the 2,4-dimethyl-, 2-methyl-4-trifluoromethyl-, and 2,4-bis(trifluoromethyl)-1,5-benzodiazepinium were synthesized by almost the same method, but they were much less stable than those of the 2,4-dimethyl or the 2-methyl-4-phenyl derivatives. The solid chlorides obtained were pale in color and were crystallized out only from concentrated hydrochloric acid media. They were easily decomposed even by a dilute acid solution or when kept in the open air for several days. Their solid halogenometalates were not separated when the metal chloride was added to a concentrated hydrochloric acid solution of the chloride.

A ν(N–H) band of these chlorides appeared at 2550 cm^{-1}, as in usual amine hydrochlorides. Consequently, it may be concluded that the seven-membered ring cation with delocalized π-electrons is stabilized by the electron-donating property of the methyl groups on the 2 and/or 4 position of the ring; on the other hand, if such an electron-withdrawing group as a phenyl or trifluoromethyl group is bonded to the position, the ring is destabilized. The halogenometalate anion seems to be stabilized by such a stable, large-size cation. Therefore, if the cation is not stable, the halogenometalate anion is not stabilized and the salts are not obtained in the solid state.

Acylation of Sydnones

Hsien-Ju TIEN and Masaki OHTA

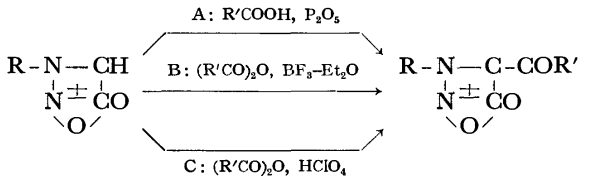
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 31, 1972)

4-Acetyl-3-phenylsydnone was prepared by the reaction of the Grignard reagent obtained from 4-bromo-3-phenylsydnone, with acetic anhydride.[1] Acylation of sydnone is an electrophilic reaction which shows the aromaticity of sydnone ring. Successful results were obtained by using aliphatic carboxylic acid in the presence of phosphorus pentoxide[2] (method A) and acetic anhydride in the presence of boron trifluoride etherate[3] (method B). Formylation of sydnone by the Vilsmeier reaction was also reported.[4] However, only a few 4-acylsydnones were obtained by these methods.

In this note we report on some attempts at acylation by methods A and B, and present a new mode of acylation of sydnones with acid anhydride and perchloric acid (method C).

Acylation of 3-phenylsydnone with phenylacetic acid, cyclohexanecarboxylic acid, or *trans*-cinnamic acid in the presence of phosphorus pentoxide afforded the corresponding 4-acyl derivatives. However, acylation with chloroacetic acid, α-bromopropionic acid or crotonic acid was unsuccessful, resulting in the recovery of 3-phenylsydnone or the formation of benzene-insoluble tarry product. 3-Phenylsydnone also was not acylated by either the action of carboxylic acid in the presence of dicyclohexylcarbodiimide in benzene solution or that of acid anhydride in the presence of sulfuric acid. Benzoylation of 3-phenylsydnone by benzoyl perchlorate in benzene was also unsuccessful. Acylation of 3-benzylsydnone by method A or B afforded 4-acetyl-3-benzylsydnone.



We found that acylation of sydnones with acid anhydrides in the presence of perchloric acid took place easily at room temperature with good yields. However, there is a limit in the effectiveness of acid anhydride, and acylation with acid anhydrides having electron-withdrawing groups such as monochloroacetic anhydride, trichloroacetic anhydride, trifluoroacetic anhydride, or benzoic anhydride was unsuccessful.

The 4-acyl derivatives obtained are given in the following Table.

Experimental

4-Acetyl-3-phenylsydnone (1). A typical procedure for the preparation of 4-acyl-3-substituted sydnones is as follows. To a suspension of 3-phenylsydnone (3.2 g) in 15 m*l* of acetic anhydride, 1 m*l* of perchloric acid (60%) was added drop by drop with stirring in an ice-salt bath. After stirring and cooling for 0.5 hr, the cooling bath was removed and stirring was continued for 12 hr at room temperature. The reaction mixture was poured into cold water, stirred to decompose the excess acetic anhydride and neutralized with sodium carbonate. The product, a viscous oil at first, solidified gradually on standing overnight. Recrystallization from ethanol gave 2.5 g (61%) of **1**, colorless plates, mp 143°C. IR: 1795, 1778, 1667 cm^{-1}.

3-Phenyl-4-propionylsydnone (2). The reaction of 3-phenylsydnone (1.6 g) with propionic anhydride (15 g) in the presence of perchloric acid (0.5 m*l*) afforded 1.5 g of crude product (mp 87—88°C), which was recrystallized from ethanol to give 1.1 g (50%) of **2**, colorless thin needles, mp 90—91°C. IR: 1798, 1666 cm^{-1}.

4-Acetyl-3-cyclohexylsydnone (3). The reaction of 3-cyclohexylsydnone (0.42 g) with acetic anhydride (5 m*l*) in the

presence of perchloric acid (3 drops) afforded 0.49 g of crude product (mp 38°C), which was recrystallized from ethanol to give 0.39 g (74%) of **3**, colorless plates, mp 42—43°C. IR: 1771, 1658 cm^{-1}.

4-Acetyl-3-benzylsydnone (4). Method A. 4.4 g of 3-benzylsydnone, 2 m*l* of glacial acetic acid and 12 g of phosphorus pentoxide afforded 1.6 g (29%) of **4**, colorless needles, mp 61—62°C.

Method B. 0.88 g of 3-benzylsydnone, 2.0 g of acetic anhydride and three drops of boron trifluoride-etherate afforded 0.49 g (45%) of **4**, mp 62—63°C (from ether–petroleum ether).

Method C. 3.52 g of 3-benzylsydnone, 15 m*l* of acetic anhydride and 1 m*l* of perchloric acid afforded 4 g of the crude product (mp 56—59°C) which was recrystallized from ether–petroleum ether to give 3.2 g (73%) of **4**, colorless needles, mp 60—62°C. IR: 1780, 1662 cm^{-1}. The IR spectra of the three product obtained above are superimposable.

4-Cychohexylcarbonyl-3-phenylsydnone (5). Method A. 4 g of 3-phenylsydnone, 3.5 g of cyclohexanecarboxylic acid and 12 g of phosphorus pentoxide afforded 4 g (59%) of **5**, mp 101—102°C (from ethanol). IR: 1785, 1665 cm^{-1}.

3-Phenyl-4-phenylacetylsydnone (6). Method A. 4 g of 3-phenylsydnone, 4.3 g of phenylacetic acid and 12 g of phosphorus pentoxide afforded 1.34 g (19%) of **6**, colorless needles, mp 96—97°C. IR: 1790, 1655 cm^{-1}.

4-Cinnamoyl-3-phenylsydnone (7). Method A. 4 g of 3-phenylsydnone, 4.5 g of cinnamic acid (*trans*) and 12 g of phosphorus pentoxide afforded the crude product containing cinnamic acid anhydride and was recrystallized from methanol to give 2.5 g (34%) of **7**, colorless needles, mp 142°C. IR: 1786, 1650 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2945—2947 (1972)

Linear Relationships between CN Stretching Frequencies and Polar Substituent Constants of L in $Co(CN)_5L^{3-}$ Complexes

Takuzo FUNABIKI and Kimio TARAMA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 26, 1971)

In the chemistry of pentacyanocobaltate(II), ultraviolet and visible spectroscopies have usually been used to establish the structures of the complexes and to clarify the reaction mechanisms kinetically, but they have scarcely been used to distinguish the organocobalt complexes. In the study to elucidate the reaction mechanism and the novel solvent effect on the selectivity in the hydrogenation of butadiene by pentacyanocobaltate(II),[1] infrared spectroscopy was expected to be useful to observe directly the variation of the intermediates under the reaction condition. In this paper, CN stretching frequencies of various substituted pentacyanocobaltates and some tetracyanocobaltates measured in the aqueous reaction solutions are reported. Also presented here linear relationships between the CN stretching frequencies and polar substituent constants.

Results and Discussion

CN stretching frequencies of substituted pentacyanocobaltate are given in the Table 1 together with other published data. The complexes in aqueous solutions exhibit single bands in the CN stretching region probably on account of the broadening effect. As shown in Fig. 1, a linear relationship is found between $\Delta\nu_{CN}$ and Taft's σ_I function of substituent L. With regard to the organic and hydridic substituents, a much better linear relationship is found with Taft's σ^* function as shown in Fig. 2. Similar correlations have been found in substituted metal carbonyls between ν_{CO} and substituent constants,[2] but the linear relationships reported here are the first for the metal cyano complexes and are noteworthy because L is bound directly to the cobalt atom and the linearity holds in the wide range of L.

In metal cyano complexes, the variation of the CN stretching frequency has been interpreted in terms of the following resonance structures; *i.e.* the larger the contribution of II, the lower the CN stretching frequency.[3,4]

$$\underset{\text{I}}{M-C\equiv N:} \longleftrightarrow \underset{\text{II}}{\overset{+}{M}=C=\overset{-}{\underset{\cdot\cdot}{N}}:} \qquad (1)$$

According to El-Sayed and Sheline,[3] the CN stretching frequencies of cyano complexes depend on: (i) the electronegativity, (ii) the oxidation state, and (iii) the coordination number of the metal. The variation of the CN stretching frequency in the substituted pentacyanocobaltates is related to (ii), but the concept of the oxidation state of the metal atom does not seem to be enough to explain the linear variation of the CN stretching frequency with polar substituent constants. The results are explained as follows. From the correlation of σ_I or σ^* value with the inductive electron-withdrawing power of the substituent L, it is reasonable to suppose that the net charge density on the substituent L increases with the increasing σ_I or σ^* value, which, consequently, decreases the contribution of structure II in Eq. (1). Thus, in the case of the complexes such as $Co(CN)_6^{3-}$ and $Co(CN)_5X^{3-}$ (X=halogen), the net charge density on the substituents must be large, and the contribution of the structure II must be small. This is supported by the fact that the linearity holds for $Co(CN)_6^{3-}$, because the linear relationship in Fig. 1 holds when there is little back donating of electron from the cobalt atom to the substituent L. In these complexes the oxidation state of Co(III) seems appropriate as proposed. On the other hand, in the case of alkyl complexes, the net charge density on the alkyl groups must be small or nil. The small $\Delta\nu_{CN}$ values suggest that Co(II) may be preferable to Co(III) although Co(III) has been proposed for these complexes. This difference in the net charge density on the substituent may be connected with the difference in the type of fission of the Co–L bond. In the former complexes, the Co–L bond is split heterolytically[5] and in the latter homolytically. From this point of view, it would be interesting to study the type of fission of the Co–SR bond in $Co(CN)_5SR^{3-}$, because it is assumed from the CN stretching frequency in Table 1 that the net charge density on SR and the contribution of structure II in Eq. (1) are intermediate between the above two groups of complexes.

With regard to $Co(CN)_5H^{3-}$, which is the active complex in the hydrogenation reactions, the oxidation state of Co(I),[6] Co(II),[7] and Co(III)[8] have been proposed. Figure 1 indicates that the net charge density on the hydrogen atom may be only slightly larger than that on the alkyl substituents. This is consistent with the low basicity of the complex[9] and the homolytic fission of the Co–H bond in the catalytic hydrogenation. Thus, Co(II) seems most preferable for this complex. The linear relationships in Figs. 1 and 2 may be used to estimate the approximate sub-

stituent constant: $\sigma^*(-CH_2CH=CH_2)=0.26$, $\sigma^*(-CH_2-CHC=(CH_3)_2)=0.0$.

The CN stretching frequencies of π-allyl- and *syn*-π-(1-methylallyl)-tetracyanocobaltates were observed at 2102 and 2098 cm^{-1}, respectively.[10] They are higher than those of σ-allyl- and σ-but-2-enyl-pentacyanocobaltates, which is consistent with the postulate that an increase in the coordination number results in the decrease in the CN stretching frequency.[11]

Experimental

Aqueous solutions of the complexes with a cobalt concentration of 0.2M were prepared at 0°C. In all experiments, the $CoCl_2$ solution was added to the KCN solution, and organic substances were added to the KCN solution before the addition of the $CoCl_2$ solution. The complexes were prepared either by the reaction of $Co(CN)_5^{3-}$ with alkyl halides and mercaptans, or by the reaction of $Co(CN)_5H^{3-}$ with conjugated dienes. In the reaction with alkyl halide, rapid transformation of $Co(CN)_5X^{3-}$ to $Co(CN)_5OH_2^{2-}$ was observed.[5] In the reaction with mercaptans, two distinct bands corresponding to $Co(CN)_5SR^{3-}$ and $Co(CN)_5H^{3-}$ were observed, demonstrating the proposed mechanism for this reaction,[12] and that was confirmed by the observation of the single band of $Co(CN)_5SR^{3-}$ in the reaction with dialkyldisulfides. $Co(CN)_6^{3-}$ was prepared by the method described by Benedetti-Pichler.[13]

Formations and structures of the organocobalt complexes were confirmed by the NMR spectra of the reaction solution as reported earlier in the case of σ-but-2-enyl and *syn*-π-(1-methylallyl) complexes.[10]

Samples in small polyethylene envelopes were placed between two plates of rock salt, and the infrared spectra were recorded on a JASCO DS-403G spectrophotometer in the 2000—2200 cm^{-1} region. Frequencies were accurate to within ± 1 cm^{-1}.

Effect of Transition Metal Chlorides in the Coupling of Allyl Chloride and *n*-Butylmagnesium Bromide[1]

Yoshihiro OHBE and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812

(Received June 5, 1972)

Coupling reaction of allylic halides with Grignard and other organometallic reagents has been a subject of investigations[2] and used as synthetic procedure. Contrary to the Kharasch reaction which involves the coupling of alkyl halides in a Grignard reagent solution in the presence of transition metal salts, the allylic coupling does not usually require any added catalysts. Probably because of this reason which certainly is attributable to the enhanced reactivity of the halides, there are few works which threw attention into a catalytic effect of added metal salts in the latter reaction.

In the previous paper[3] we showed a considerable difference in their catalytic features among various metallic chlorides in the Kharasch coupling. This paper concerns with another example of a pronounced difference in activity among iron(III), copper(II), cobalt(II), and nickel(II) chlorides in the coupling reaction of allyl chloride with *n*-butylmagnesium bromide. To a solution of anhydrous metallic chloride suspended in anhydrous ether, a filtered ethereal *n*-butylmagnesium bromide (0.2 mol) was added and stirred under reflux until the evolution of gas ceased (reaction A) for 0.5 to 1 hr. To the resultant dark solution, an equivalent amount of allyl chloride in ether was added in a period of 10 min and again stirred under reflux for 3 to 5 hr (reaction B) until concurrent evolution of larger amount of gas stopped. After the reaction mixture was hydrolyzed and treated in a usual manner, distillation of the ethereal solution gave a mixture of liquid products. The compositions of gaseous products in reaction A and B, and the liquid products were analyzed by gas chromatography.

The effects of four metal salts in varying concentrations on the amounts of gas in reaction A and B, and the yields of the liquid products were illustrated in Figs. 1 to 4. The quantities of gas evolved in reaction A, indicative of the amount of the Grignard reagent utilized in the reduction of the metallic salts to lower valence states, were rather small and nearly independent on the kind of the metal salts when the relative concentration of the salts to the Grignard reagent are less than 10^{-2}. A pronounced difference, however, was observed in reaction B. When cobalt(II) and nickel(II) salts were used, a large amount of gas which were

	1-Butene	3510	3907	3180	3653	546	3420	765	2970
	Propylene	3740	3387	3130	3120	165	155	510	1080

a) 1 ML at 25 °C under atmospheric pressure.

consisted mainly of 1-butene and propylene resulted, but the yields of liquid products stayed at a low level throughout the catalyst concentrations adopted in this study. On the other hand, iron(III) and copper(II) salts showed an enhanced promoting effect in the coupling between allyl chloride and *n*-butylmagnesium bromide to afford 1-heptene as a major product with optimal concentrations of 5×10^{-3} equivalent for iron(III) and 1×10^{-3} for copper(II) salts. However, the reaction of allyl chloride with itself to give 1,5-hexadiene was little affected by the presence of any metal salt, and the yields remained at a low level irrespective of the nature of the added catalysts. Another information of interest was obtained by inspection of the compositions of gas in reaction B illustrated in Table 1 for the representative concentrations of each salts.

The major role of Grignard reagent in alkyl halide coupling under similar condition has been inferred[3)] to be regeneration of active catalytic species by reduction of the transition metal salts oxidized in the course of the coupling reaction, on the basis that the composition of the gas in reaction B was closely analogous to that of reaction A, which was consisted of alkane and alkene derived from the alkyl group of the Grignard reagent utilized. The striking contrast between the previous observation and the results in Table 1 could be rationalized as follows: (1) all four metallic chlorides are taking part in the reaction between allyl chloride and the Grignard reagent in their reduced forms, (2) cobalt(II) and nickel(II) chlorides promote exclusively the transfer of hydrogen from the alkyl group of the Grignard reagent to allyl chloride, thus, giving a nearly equal amount of propylene and 1-butene, and (3) substitution of the alkyl group is more favored in the presence of iron(III) and copper(II) chlorides (1a and 1b).

$$CH_2{=}CH{-}CH_2{-}Cl + CH_3(CH_2)_2CH_2MgBr$$

$$\text{1a: } \overset{Co(II)}{Ni(II)} \swarrow \qquad \searrow \text{1b: } \overset{Fe(III)}{Cu(II)}$$

$$CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}C_2H_5 + MgBrCl \qquad CH_2{=}CH{-}(CH_2)_4{-}CH_3 + MgBrCl$$

Although the amount of gas in reaction B markedly increased with iron(III) and copper(II) salts in the concentrations around 10^{-2}—10^{-1} equivalent, the results in Table 1 seems to suggest that the difference among two pairs of the salts is retained, especially in the case of copper(II) salt even in this concentration range. Alkyl metals have been recently proposed to be the active species in Kharasch coupling[4a)] and related reaction[4b)]. The present results could be accounted by assuming that these unstable species react with allyl chloride to form either ion-pair[2a)] or radical-pair[2c)] intermediate and the nature of carbon-metal bond of the alkyl metals determines which route favors 1a or 1b. However, a possibility of the intermediate

formation of π-allylmetal species could not be entirely excluded in view of our preliminary observation that the reaction of crotyl halides with ethylmagnesium bromide afforded a mixture of three kinds of dienes which produced by coupling of the halide itself as principal product but little of hexenes, irrespective of the metallic chlorides utilized, and the chemical behavior[5] of π-allylnickel complexes which react rapidly with allylic halides and tosylates to give nonspecific cross coupling products.

Further studies are in progress to disclose the reason of the marked difference between allyl and crotyl halides and also a plausible structure of active intermediate.

Sensitized Delayed Fluorescence in Frozen Aqueous Solutions of Dinucleotide- and Polyadenylic Acid-Proflavine Systems

Yukio KUBOTA

Department of Chemistry, Yamaguchi University, Yamaguchi

(Received December 24, 1971)

We have previously shown that the sensitized delayed fluorescence (SDF) in frozen aqueous solutions of DNA- and mononucleotide-acridine dye systems arises from the triplet-singlet energy transfer, in which excitation energy is transferred from the triplet state of the DNA base to the singlet state of the dye.[1] This phenomenon has also been observed in frozen aqueous solutions of dinucleotide- and polynucleotide-acridine systems. This paper will present the results on adenosine dinucleotide- and polyadenylic acid-proflavine systems.

Experimental

Adenosine monophosphate (AMP) and cytidine monophosphate (CMP) were purchased from the Sigma Chemical Co. Thymidine monophosphate (TMP), adenyl-3′: 5′-adenosine (ApA), adenyl-3′: 5′-cytidine (ApC), and polyadenylic acid (poly A) were purchased from Miles Laboratories, Inc. Proflavine (PF) was the same sample as has been described previously.[2]

The emission spectra were measured at 77°K in the same way as has been described previously.[2] The solvents used were a 0.01M phosphate buffer (pH 7.0) and an ethylene glycol-buffer mixture.[3] The concentration of nucleotide was 5×10^{-3}M (in base units); it was spectrophotometrically determined.[4,5] The concentration of PF was changed from 5×10^{-6} to 2×10^{-4}M. Unless otherwise stated, all the luminescence data presented in this paper were obtained by an excitation at 280 nm.

Results and Discussion

ApA- and Poly A-PF Systems. Figures 1 and 2 show the total and delayed emission spectra of the ApA- and poly A-PF systems respectively. In the

absence of PF, the band centered at 340 nm is ascribed to the adenine fluorescence, and the emission at 390—500 nm, to the adenine phosphorescence.[6] In the presence of PF, the delayed emissions are composed of adenine phosphorescence, SDF (490 nm), and the phosphorescence (570 nm) of PF. It may be seen from Fig. 1 that the adenine phosphorescence is selectively quenched in the presence of PF. Further, the excitation spectrum of SDF is the same as that of the adenine phosphorescence. As has been interpreted previously in connection with mononucleotide-PF systems,[1] it may be concluded that this SDF is caused by the energy transfer from the triplet state of the adenine residue to the singlet state of PF.

Next, the phosphorescence efficiency of the adenine residue, ϕ_P^D, can be estimated from the energy-transfer data. ϕ_P^D is given by the following equation:[7,8]

$$\phi_P^D = \frac{\Phi_P}{\Phi_{SDF}} \cdot \frac{\phi_{TR}}{1-\phi_{TR}} \Phi_F^A$$

where Φ_P is the quantum yield of the adenine phosphorescence in the presence of PF; Φ_{SDF}, the quantum yield of SDF; ϕ_{TR}, the efficiency of energy transfer,[9] and Φ_F^A, the quantum yield of the PF fluorescence.[10] From our data, the ϕ_P^D values of AMP, ApA, and poly A were estimated to be 0.28, 0.22, and 0.16 respectively. These values are not extremely accurate because of some sources of error;[7] however, the value of AMP can be compared with the value of 0.3 calculated from the data of Guéron *et al.*[12] It may be considered, therefore, that the values presented here are reasonable and that the ϕ_P^D value of poly A is somewhat smaller than that of AMP.

ApC-PF Systems. Recently, triplet-triplet energy transfer between nucleotide molecules has been found to occur in dinucleotides or in mixtures of nucleotide molecules.[13–15] In order to obtain some information on the relation between this energy transfer and SDF, we also examined the ApC-PF, (AMP+CMP)-PF, and (AMP+TMP)-PF systems. In the case of ApC or mixtures of mononucleotides, the phosphorescence intensity of adenine lowers remarkably compared with that of AMP alone, while the phosphorescence intensity of cytosine or thymine increases; this phenomenon may be ascribed to the occurrence of the triplet-triplet energy transfer. In parallel with this phenomenon, the decay of SDF in the case of ApC or mixtures becomes faster than that in the case of AMP alone (Fig. 3). As may be seen from Fig. 3, all the decays of SDF deviate from single exponentials. It is, therefore, impossible to determine meaningful rate constants as reciprocals of the decay times of SDF. For convenience,

8) W. C. Galley and L. Stryer, *Biochemistry*, **8**, 1831 (1969).

9) ϕ_{TR} can be estimated from the measurements of the ratio of the phosphorescence to the fluorescence of adenine in the presence of PF, (I_P/I_F), and in the absence of PF, $(I_P/I_F)_0$:

$$\phi_{TR} = 1 - \frac{(I_P/I_F)}{(I_P/I_F)_0}$$

10) Φ_F^A in nucleotide solutions was determined to be 0.37 by using 9-aminoacridine as the standard of the quantum yield.[11]

we adopt the half-life, $\tau_{1/2}$, as a qualitative measure of rate constants. As may be noticed from Table 1, the $\tau_{1/2}$ values in the cases of the mononucleotide-PF systems depend on the phosphorescence lifetimes of nucleotides, τ_P, and are about one tenth of τ_P. Consequently, the $\tau_{1/2}$ values will tell us which nucleotide is important as the energy donor in the case of ApC or mixtures. The $\tau_{1/2}$ value in the case of ApC or mixtures is comparable to that in the case of CMP or TMP (Table 1). This indicates that the triplet state of CMP or TMP plays an important role; that is, first, a base-to-base energy transfer produces the triplet state of CMP or TMP, and next, the triplet energy is transferred to the singlet state of PF. This

a) Ref. 1.

conclusion confirms our previous interpretation of SDF in DNA-acridine complexes.[1] On the other hand, the $\tau_{1/2}$ values in the cases of ApA and poly A are much smaller than that in the case of AMP; this phenomenon probably results from the difference in conformation between the monomer and the polymers of adenylic acid.[4,5]

The Photosensitized Reduction of 4-Nitropyridine *N*-Oxides

Isao ONO and Norisuke HATA

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University
Chitosedai, Setagaya-ku, Tokyo

(Received March 2, 1972)

4-Nitropyridine *N*-oxides are photochemically reduced to afford 4-hydroxylaminopyridine *N*-oxides in ethanol under nitrogen atmosphere.[1] From the measurements of the quantum yields and the flash-spectrophotometric experiments, such a photochemical reduction has been considered to proceed through an intermediate species originating from the excited singlet state of 4-nitropyridine *N*-oxide.[2,3] However, the photochemical reduction of aromatic nitro compounds are generally thought to proceed through the lowest n,π^* triplet state;[4] detailed investigations have been performed on the nitrobenzene,[5] 1-nitronaphthalene,[6] and 4-nitropyridine.[7] Therefore, it seems to be of importance, in elucidating the reaction mechanism, to clarify whether or not the reduction of 4-nitropyridine *N*-oxide can occur from the lowest triplet state. In the present investigation, the biacetyl-sensitized reac-

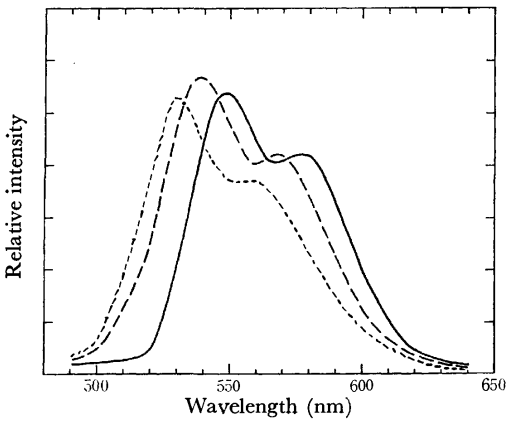

Fig. 1. The phosphorescence spectra of 4-nitropyridine *N*-oxide (——), 3-methyl-4-nitropyridine *N*-oxide (----) and 3,5-dimethyl-4-nitropyridine *N*-oxide (-·-·-) in 2-propanol at 77°K.

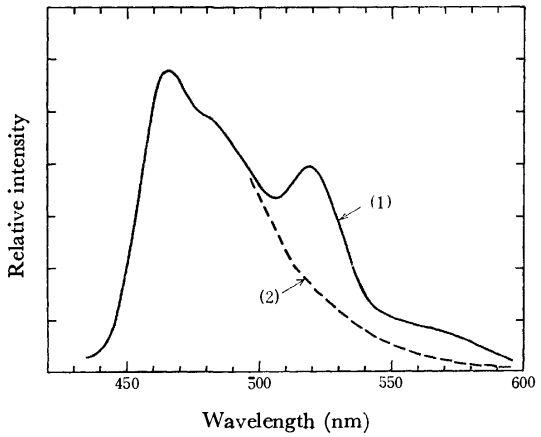

Fig. 2. Quenching of the biacetyl phosphorescence by an addition of 4-nitropyridine *N*-oxide in deaerated 2-propanol at room temperature.
(1) biacetyl alone (5×10^{-2}M)
(2) biacetyl (5×10^{-2}M) and 4-nitropyridine *N*-oxide (1×10^{-3}M)

tions of 4-nitropyridine *N*-oxide (I), 3-methyl-4-nitropyridine *N*-oxide (II), and 3,5-dimethyl-4-nitropyridine *N*-oxide (III) were carried out in deaerated 2-propanol or ethanol.

The lowest triplet state of 4-nitropyridine *N*-oxide has been studied by Kubota *et al.*[8] by means of both its phosphorescence and S-T absorption spectroscopy. As a result, the lowest triplet state of 4-nitropyridine *N*-oxide has been concluded to be a π,π^* state with an excitation energy of about 52 kcal·mol^{-1}. Figure 1 shows the phosphorescence spectra of (I), (II), and (III) in 2-propanol glass at 77°K. Consequently, the biacetyl (E_T=56.3 kcal·mol^{-1}) is expected to be usable as a triplet sensitizer for these *N*-oxides, (I), (II), and (III). As is shown in Fig. 2, the biacetyl phosphorescence in deaerated 2-propanol (5×10^{-2}M) at room temperature was observed to be completely quenched by the addition of the 4-nitropyridine *N*-oxide (1×10^{-3}M). Similar results were also obtained when (II) or (III) was used as a triplet quencher instead of (I). In addition, Fig. 3 shows the progressive spectral change in 4-nitropyridine *N*-oxide in deaerated 2-propanol containing biacetyl when the solution was irradiated with the visible light longer than 400 nm which is absorbed by biacetyl alone; there, it was observed that the absorption spectrum of 4-nitropyridine *N*-oxide decreased progressively in intensity and a new absorption band with its maximum at about 290 nm appeared.

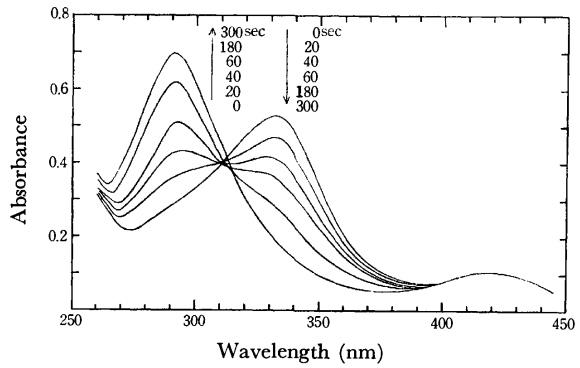

Fig. 3. The progressive spectral change of 4-nitropyridine *N*-oxide (5×10^{-5}M) in deaerated 2-propanol containing 5×10^{-3}M biacetyl on visible light irradiation (>400 nm). Numbers refer to the irradiation time.

Next, the separation and identification of the photoproducts formed in the photosensitized reactions of (I), (II), and (III) were carried out; the procedures will be described below.

An 2-propanol or ethanol solution containing 100 mg of (I) and 200 mg of biacetyl in a quartz cylindrical reaction vessel (5.0 cm in length and 4.5 cm in diameter) was irradiated with a high-pressure mercury lamp (Toshiba H-400 P) equipped with a Hoya L-42 filter for 14 hr while nitrogen was bubbled in. After the removal of the solvent under reduced pressure in an atmosphere of nitrogen, benzene was added to the residue. Then, the undissolved product was collected and washed with a mixture of ethanol and diethyl ether (1 : 1). The mp of the photoproduct (Ia) thus obtained was 213—215°C (decomp.), and that of its hydrochlorate, 157—159°C (decomp.). In the same way, the photoproduct (IIa) was also isolated from the irradiated solution of (II): mp 210—213°C (decomp.), and its hydrochlorate, 175—176°C (decomp.). The UV and IR spectra of the two photoproducts, (Ia) and (IIa), were superimposable upon those of 4-hydroxylaminopyridine *N*-oxide or 3-methyl-4-hydroxylaminopyridine *N*-oxide.[9]

In the case of 3,5-dimethyl 4-nitropyridine *N*-oxide (III), white crystals (IIIa) were isolated by the same procedures as those used for (I) and (II): recrystallized from ethanol in a nitrogen atmosphere, mp 151°C (decomp.), yield 35%, UV λ_{max}^{EtOH} 296 nm (log ε 4.24), NMR (CF_3COOH, TMS) δ 2.45 ppm (s, 6H, $(CH_3)_2$), 7.94 ppm (s, 2H, aromatic), molecular weight (meas-

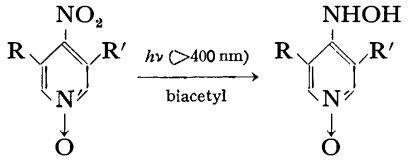
ured by freezing-point depression of benzoic acid) 160, Found: C, 54.00; H, 6.48; N, 18.08%. Calcd for $C_7H_{10}N_2O_2$: C, 54.56; H, 6.49; N, 18.18%. On the basis of these analytical data, the photoproduct (IIIa) was assumed to be a 3,5-dimethyl-4-hydroxylaminopyridine *N*-oxide. Further confirmation of the structure (IIIa) was provided by its conversion into 4,4'-azoxy or 4-nitroso derivative in the following way. The treatment of 100 mg of (IIIa) with 5m*l* of 10% aqueous ammonia resulted in a red coloration, which then gradually faded to yellow. After the solution has been allowed to stand for 20 min, extraction with chloroform gave *ca.* 40 mg of yellow crystals (IIIb). The (IIIb) thus obtained was purified by recrystallization from ethanol: mp 265°C (decomp.), UV λ_{max}^{EtOH} 275 nm (log ε 4.21), NMR ($CDCl_3$, TMS) δ 2.22 ppm (s, 6H, $(CH_3)_2$), 2.40 ppm (s, 6H, $(CH_3)_2$), 8.08 ppm (s, 4H, aromatic), Mass (M^+)=288, Found: C, 58.20; H, 5.66; N, 19.25%. Calcd for $C_{14}H_{16}N_4O_3$: C, 58.33; H, 5.56; N, 19.44%. Thus, the product (IIIb) was identified as 4,4'-azoxy-3 5-lutidine 1,1'-dioxide. Similarly, a 100-mg portion of (IIIa) was treated with 5 m*l* of a 10% $FeCl_3$ solution, then, extraction with chloroform gave 70 mg of greenish-yellow crystals (IIIc): mp 203—205°C (decomp.), UV λ_{max}^{EtOH} 253 nm (log ε 3.80), 363 nm (log ε 4.10), NMR ($CDCl_3$, TMS) δ 2.63 ppm (s, 6H, $(CH_3)_2$), 8.05 ppm (s, 2H, aromatic), Mass (M^+)=152, Found: C, 54.54; H, 5.21; N, 17.78%. Calcd for $C_7H_8N_2O_2$: C, 55.26; H, 5.26; N, 18.42%. These analytical data indicate that the product (IIIc) is 3,5-dimethyl-4-nitrosopyridine *N*-oxide



R and R'=H or CH_3

It was revealed by the present experiments that the 4-nitropyridine *N*-oxide and its methyl-substituted derivatives were reduced by a biacetyl sensitization to the corresponding 4-hydroxylamino derivatives; this suggests that the hydrogen abstraction from a solvent molecule can occur from the lowest π,π^* triplet state of 4-nitropyridine *N*-oxide. This is of particular interest because Rosenberg and Servé's mechanism of the hydrogen abstraction by a π,π^* triplet molecule[10] appears to be operative in the photosensitized reduction of 4-nitropyridine *N*-oxide. For this reason, further studies are necessary in order to elucidate the nature of the lowest lying triplet state of 4-nitropyridine *N*-oxide.

The Second CMC of the Aqueous Solution of Sodium Dodecyl Sulfate. III. Light-scattering

Michiko KODAMA, Yukio KUBOTA,* and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 24, 1972)

In our previous papers, the micelle structure of the aqueous solution of sodium dodecyl sulfate (SDS) has been investigated, mainly in the concentration region above the 1st critical micelle concentration (CMC), through the measurements of the conductivity,[1] the viscosity, and the density.[2] In the present study, the light-scattering measurements were carried out in order to obtain further information about the micelle structure of the aqueous solution of SDS.

Experimental

Dust-free water was obtained by the distillation method.[3] The SDS solutions were prepared in the same way as has previously been described[1] and then repeatedly filtered through a Graba-type filtering apparatus (membrane ultrafilter, No. 8) under a pressure of 5—10 cmHg until the solutions became completely clear. The light scattering was measured with a Brice-type light-scattering photometer (Shimadzu Seisakusho) using a semioctagonal cell. The reduced scattering intensities (R_θ) at $\theta=45$, 90, and 135° were calculated by the following equation:

$$R_\theta = \phi_\theta \cdot G_\theta / G_0 \qquad (1)$$

where G_θ and G_0 are the intensities of the scattered light at $\theta°$ and 0° respectively, and where ϕ_θ is the apparatus constant, which was determined by using the Rayleigh ratio (R_{90}) of benzene.[4] The refractive index increments (dn/dC) were measured with a Debye-type differential refractometer (Shimadzu Seisakusho). All the measurements were made at 25°C and at the wavelengths of 436 and 546 mμ.

Results and Discussion

Figure 1 shows a plot of R_{90} against the concentration of SDS in the neighborhood of the 1st CMC. R_{90}

remains small until the 1st CMC is reached, and then it increases with the concentration of the SDS solution. As is well-known, the Debye Eq. (2) is used to calculate the micellar molecular weight; the reciprocal of the micellar molecular weight is obtained by plotting $K(C-C_0)/(R_{90}-R_{90,0})$ against $(C-C_0)$:

$$K(C-C_0)/(R_{90}-R_{90,0}) = 1/M + 2B(C-C_0), \qquad (2)$$

where $R_{90,0}$ is the Rayleigh ratio at the 1st CMC, M is the micellar molecular weight, B is a constant, C is the concentration of the solution (g/ml), C_0 is the 1st CMC, $K=2\pi^2 n_0^2(\partial n/\partial C)^2/N_A\lambda^4$, n and n_0 are the refractive indices of solution and solvent respectively, N_A is the Avogadro number, and λ is the wavelength of the light.

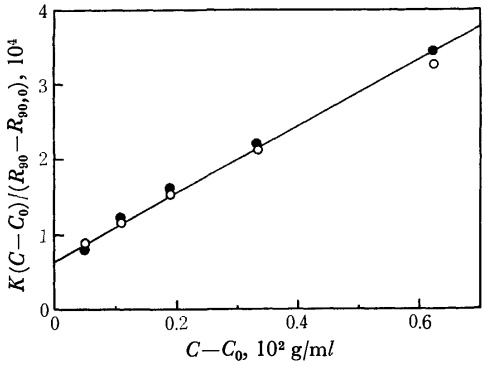

Fig. 2. Debye plot of SDS solution.
—○—: 436 mμ, —●—: 546 mμ.

As can be seen in Fig. 2, the Debye plot for the SDS solutions shows a linear nature at low micellar concentrations. Since the Debye equation is strictly valid only for the uncharged colloidal particles, it is necessary to take into account the effect of the charge of the micelles on the light-scattering properties. Therefore, the aggregation number and also the micellar molecular weight were calculated by using the equation[5] corrected for the effect of the charge of the micelles. The values thus obtained were 60 and 17200

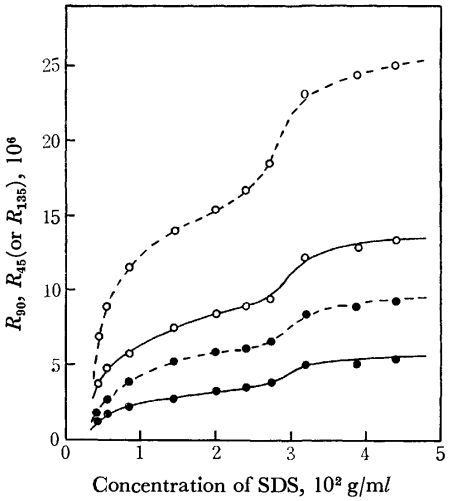

Fig. 3. Light-scattering of SDS solution in the neighborhood of the 2nd CMC.
—○—: R_{90} at 436 mμ, —●—: R_{90} at 546 mμ, --○--: R_{45}(or R_{135}) at 436 mμ, —●--: R_{45} (or R_{135}) at 546 mμ.

Table 1. The 1st and 2nd CMC's of SDS solution

1st CMC (mmol/l)	2nd CMC (mmol/l)	Method
8.3	70	Light-scattering
8.3	65	Conductivity[1]
8.0—8.5	65—70	Viscosity[2]
8.5	65	Density[2]

respectively, in fairly good agreement with those obtained by Mysels and Princen.[5]

The values of R_{90} and R_{45} (or R_{135}) in the high-concentration region of the SDS solution are plotted against the concentration in Fig. 3. It may be noted from this figure that R_{90} shows a marked rise at the concentration corresponding to the 2nd CMC,[1,2] as it does at the 1st CMC in Fig. 1, and that the behavior of R_{45} (or R_{135}) is quite similar to that of R_{90}. The 1st and 2nd CMC's obtained in the present study are listed in Table 1 along with those reported in previous works.[1,2] Ekwall and his co-workers[6] measured the light-scattering of the aqueous solution of cetyl trimethylammonium bromide and found that there is an extremely marked rise in the intensity of the scattered light in the high-concentration region above the 1st CMC. Robins and Thomas[7] also observed similar light-scattering behavior in aqueous solutions of 2-dodecylaminoethanol salts. In our previous paper, the viscosity and density studies of the aqueous solution of SDS revealed that, below the 2nd CMC, only one type of micelle, with an almost constant size and shape, spherical or nearly so, may exist but that at the 2nd CMC there occurs a change in the micelle structure caused by a variation in the type of aggregation of SDS molecules and by a decrease in the counter-ion

binding by the micelle. Very recently, we found, from our measurements of the fluorescence depolarization of acridine dye solubilized in the SDS micelle, that the micellar volume at the 2nd CMC increases by *ca.* 30% more than that below the 2nd CMC.[8]

It can be concluded, therefore, that the marked rise of R_{45}, R_{90}, and R_{135} at about the 2nd CMC is to be attributed to a certain change in the micelle structure, probably an increase in the size of the micelle. On the other hand, the dissymmetry (Z_{45}), expressed as the ratio of R_{45} to R_{135}, will provide available information regarding the shape of micelle. The values of Z_{45}, however, were in the region of 1.00—1.02 over the whole range of SDS concentrations investigated. Therefore, even in the high-concentration region, the size of the SDS micelle may be too small to cause any appreciable dissymmetry in the scattered light.[9]

Aromatic Nitration. III.[1] Competitive Nitration of Toluene and Benzene in Carbon Tetrachloride

Akiko HIROSE, Kohji MATSUI, and Shizen SEKIGUCHI*

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma

(Received February 22, 1972)

In the previous paper[2] we reported competitive nitration of toluene and benzene with nitric acid in several organic solvents, such as carbon tetrachloride, *n*-hexane, cyclohexane, methylene dichloride, and nitromethane. The rate ratios (k_T/k_B) were in the range of 2.0 to 3.2 in the first three solvents and in the range of 15.8 to 19.7 in the latter solvents. The reaction showed the high positional selectivities in all above solvents. In nitromethane at 30°C the ratio and the selectivity factor were 19.7 and 1.219, respectively. The results were similar to those obtained by Ingold *et al.*[3]

The results in the non-polar solvents (carbon tetrachloride, *n*-hexane, and cyclohexane) are contrary to the expectation that nitric acid in non-polar solvents is a weak electrophile. Therefore, in the present paper we have investigated the effects of concentrations of nitric acid, the polarity of mediums on the substrate (k_T/k_B) and positional selectivities (o/p) in the competitive nitration of toluene and benzene in carbon tetrachloride.

The results are shown in Table 1. With increasing amount of nitric acid, the positional selectivities (o/p) increased. The selectivity factors were comparatively low in comparing with those (about 1.2 to 1.3) obtained in the previous works.[4] The result, obtained when 0.12 mol of 75% nitric acid was used, is much similar to that of Olah *et al.*[3] This suggests that the system of nitric acid–carbon tetrachloride may become a strong electrophile.

Next, the results of the competitive nitration in a mixed solvent of carbon tetrachloride and nitromethane (1 : 1 by volume) are shown in Table 2. These results are comparatively similar to that of Ingold *et al.*,[3]

indicating that the polarity of mediums has a large effect on the substrate selectivities.

Further, the results of the competitive nitration in carbon tetrachloride with one volume percentage of other solvent are shown in Table 3. The rate ratios are intermediate between those in Table 1 and 2, indicating that even the addition of a small amount of a polar solvent has a large effect on the rate ratios.

Experimental

Materials. Benzene, toluene, nitrobenzene, and *o*-, *m*-, and *p*-nitrotoluene were commercial materials of the highest available purity. Their purities were examined by vapor phase chromatography on a column containing 10% polypropylene glycol in Diasolid M at 170°C.

Competitive Nitration. The competitive nitration and product analysis were carried out by the method described in the previous paper.[1)]

^{119}Sn Mössbauer Quadrupole Splittings in Compounds with Sn-Mn Bonds

B. V. LIENGME, J. R. SAMS*†, and J. C. SCOTT*

Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada

**Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada*

(Received October 12, 1971)

Onaka, Sasaki, and Sano[1] have recently reported ^{119}Sn Mössbauer data for the four series of compounds $(CO)_5MnSnR_{3-n}X_n$, where R=Me, Ph, and X=Cl, Br. The quadrupole splitting values (Δ) for n=1, 2 are always higher than those for n=0, 3, rather than showing a monotonic change as n increases, but no explanation was offered for this unexpected order. We have recently suggested[2] that a similar trend in Δ for the compounds $(\pi\text{-}C_5H_5)Fe(CO)_2SnPh_{3-n}Cl_n$ is due to a change in sign of the quadrupole coupling constant, which can be explained on the basis of point-charge calculation. We wish to show that the results of Onaka, *et al.*[1] are susceptible to a like explanation.

The point-charge model assumes that the electric field gradient (EFG) is an additive quantity,[3] so that the quadrupole splitting can be evaluated from partial quadrupole splitting (PQS) values, [L], for the various ligands. Since the EFG at tin is largely due to an imbalance in the polarity of the tin-ligand σ-bonds, [L] values are related to this polarity and can be correlated with the Taft inductive constants for the ligands.[4] The model has been discussed in detail by Parish and Platt,[4] who also derived a number of PQS values from data for pentacoordinate tin compounds. It has been suggested that these PQS values should not be applied to compounds in which the tin atom has a different coordination number.[5] For the

present tetracoordinate derivatives we have therefore derived a self-consistent set of PQS values. If we assume an arbitrary value for [Cl], then point-charge expressions for molecules of the types $SnAB_3$ and SnA_2B_2[4] with experimental Δ values[2] for $(CO)_5Mn$-$SnCl_3$, $(CO)_5MnSnMe_3$, and $[(CO)_5Mn]_2SnPh_2$ yields PQS values for $(CO)_5Mn$, Me, and Ph, respectively.[2] A value for [Br] is obtained from the measured[1] splitting in $(CO)_5MnSnBr_3$. These [L] values are given in footnote (a) to Table 1. It should be noted that our results are independent of the value chosen for [Cl].[2] These PQS values are used to compute the EFG tensor elements, assuming tetrahedral bond angles.[6] After diagonalising the tensor, the nonvanishing elements are ordered such that $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$, then the asymmetry parameter $\eta = (V_{yy} - V_{xx})/V_{zz}$ and

$$\Delta = \frac{1}{2} eQV_{zz}\left(1 + \frac{\eta^2}{3}\right)^{1/2}$$

are calculated. The results for a number of compounds with Sn–Mn bonds are presented in Table 1, along with experimental Δ values.

Table 1. Measured and predicted quadrupole splittings for some compounds with Sn–Mn bonds[a]

Compound	Δ_{obs}[b] (mm sec^{-1})	Δ_{pred} (mm sec^{-1})	η_{pred}
$(CO)_5MnSnCl_3$	1.57	+	0
$(CO)_5MnSnMeCl_2$	2.62	+2.37	0.85

$(CO)_5MnSn(Cl)[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$	2.02[e]	−1.73	0.18

a) PQS values used in the calculations are (in mm sec^{-1}): [Cl] = +0.63, [Br] = +0.56, [Me] = −0.56, [Ph] = −0.40, $[(CO)_5Mn]$ = −0.15.
b) Experimental values from Ref. 1) except as noted.
c) Splitting not resolved.
d) Reference 15.
e) Reference 16.

The calculated Δ values are in only moderately good numerical agreement with the measured[1] ones. The lack of better agreement between Δ_{pred} and Δ_{obs} may be due largely to distortions from tetrahedral symmetry. Although insufficient structural data are available to allow a quantitative estimate of such effects, X-ray data for related compounds[7-11] suggest that the distortions are likely to be such as to increase the calculated $|V_{zz}|$ values.[6,12] Another possible source of discrepancy is a variation in the σ-character of the tin-halogen bonds as the number of halogens bonded to tin changes. Such an effect has been suggested[13] for the compounds $RSnCl_3$ and R_2SnCl_2 (R = *n*-Bu, Ph) on the basis of ^{35}Cl NQR data.

More important than the actual numerical agreement is the fact that in all four series $(CO)_5MnSnR_{3-n}X_n$ the magnitude of Δ is predicted to be greater for $n=1$ and 2 than for $n=0$ and 3, as observed experimentally. The sign of Δ_{pred} is the sign of the quadrupole coupling constant, eQV_{zz}. This sign has recently been shown to be positive for both $(CO)_5MnSnCl_3$ and $(CO)_5Mn$-$SnCl_2Me$,[14] but the signs of eQV_{zz} for the remaining derivatives in Table 1 have not yet been reported. The positive eQV_{zz} for $(CO)_5MnSnCl_3$ shows that the charge distribution about tin is prolate, *i.e.*, there is greater electron density near the tin atom along the *z*-(Sn–Mn bond) direction than in the *xy*-plane, as expected from the greater electronegativity of Cl. The increase in Δ upon replacing one halogen by an organic group is due in part to the non-zero η, but the largest contribution comes from a reorientation of the *z*-axis of the EFG and a concomitant increase in $|V_{zz}|$. When there are two or three organic groups attached to tin, our calculations predict a negative eQV_{zz} (oblate charge distribution). We hope to verify these predictions in the near future. It is relevant to note that eQV_{zz} for tin is positive in $YSnCl_3$ and negative in $YSnBu_3$ ($Y = (\pi\text{-}C_5H_5)Fe(CO)_2$[14] as predicted by the point-charge model.[2]

The small (or zero) observed splittings for $(CO)_5Mn$-SnR_3[1] and $[(CO)_5Mn]_2SnPh_2$[2] suggest that the σ-bonding characteistics of the $(CO)_5Mn$ group and Me or Ph are quite similar. This presumably accounts for the fact that the predicted value of η is less than ~0.5 for the cases $(CO)_5MnSnR_2X$, and greater than ~0.8 for $(CO)_5MnSnRX_2$. The former molecules approximate to the stoichiometry SnA_3B (for which $\eta=0$), whilst the latter approximate to SnA_2B_2 (for which $\eta=1$ if tetrahedral bond angles are assumed).

Finally, it should be noted that our calculations give an adequate estimate of $|\Delta|$ for $(CO)_5MnSn(Cl)$-$[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$, in which the tin atom is bonded to two different transition metals.

We wish to thank the National Research Council of Canada for financial support, and Dr. G. M. Bancroft for a preprint of his paper.

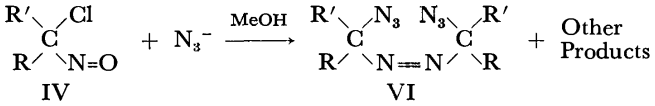
SHORT COMMUNICATION

Synthesis and Thermal Decomposition of 2,2′-Diazido-2,2′-azoadamantane

Masuo FUNABASHI,[1] Akira TANAKA,[2] and J. Pierre ANSELME*

Department of Chemistry, University of Massachusetts at Boston, Boston, Massachusetts, 02116 USA

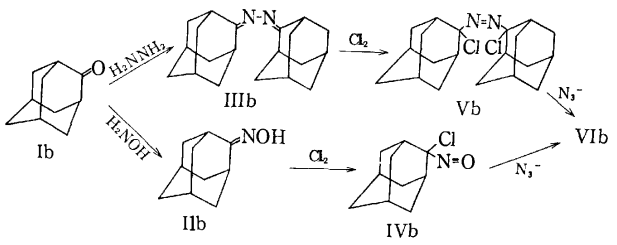
During the couse of our investigation of the reaction of 1,1-chloronitrosocyclohexane (IVa) with azide ion,[3] we have identified 1,1′-diazido-1,1′-azocyclohexane (VIa) as one product of a very complex reaction mixture. The reported explosive nature of the corresponding isopropyl analogue (VIc)[4] and our hope to reduce the number of products formed led us to utilize 2-chloro-2-nitrosoadamantane (IVb)[5] as a substrate with azide



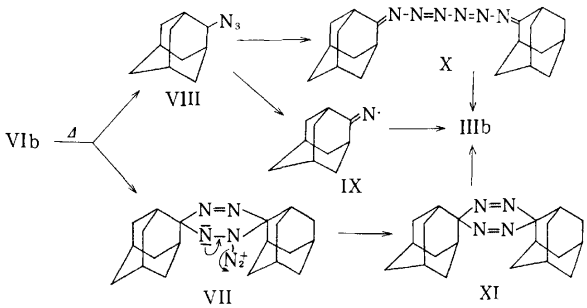
IV VI

a) R, R′ = $-(CH_2)_5-$
b) R, R′ = 2-adamantyl
c) R, R′ = CH_3

ion. As expected, the number of products decreased drastically[6] and 2,2′-diazido-2,2′-azoadamantane (VIb), mp 164°C (decomp.), was isolated as yellow crystals. It exhibited a strong azide absorption at 2080 cm^{-1} and was conclusively identified by its elemental analysis and by comparison with an authentic sample prepared from 2,2′-dichloro-2,2′-azoadamantane (Vb).[7]



The presence of two functional groups capable of eliminating nitrogen prompted us to investigate the behavior of VIb on pyrolysis.[4] A solution of VIb in 1,2-dichlorobenzene at reflux smoothly evolved nitrogen as it gradually changed from yellow to colorless. Evaporation of the solution gave an 88% yield of a colorless solid, mp >300°C, which was identified as adamantanone azine (IIIb). Since α,α′-diazidoazoalkanes (VI) can be regarded as "formal" dimerization products of α-azidonitrenes, it is interesting to contrast our results with the fact that in all the decompositions of *gem*-diazides studied so far,[8] only in one case was azine reported as a minor product; an α,α′-diazidoazoalkane (VI) was suggested as a possible precursor to the azine.[9] Although mechanistic studies have yet to be carried out, one may speculate that rupture of the azo linkage would yield radical VIII which can eliminate to the ketimino radical (IX) or couple to give the hexazatetraene (X), both of which could lead to the azine by coupling or further loss of nitrogen respectively. Alternatively, internal "displacement" a nitrene intermediate (VII) on the neighbouring azide could lead to the cyclic bis azo compound XI, thence to IIIb.



We are presently investigating the scope and the mechanism of the decomposition of α,α′-diazidoazoalkanes.

Support for this work was provided by the Alfred P. Sloan Foundation to whom the senior author is deeply grateful for the award of a Fellowship.

* Fellow of the Alfred P. Sloan Foundation; Visiting Professor, Research Institute of Industrial Science, Kyushu University; Fellow of the Japan Society for the Promotion of Science; to whom inquiries should be addressed.

1) Present address: Tokyo Institute of Technology, Tokyo, Japan.

2) Present address: Meijo University, Nagoya, Japan.

3) The origin of the α,α′-diazidoazoalkanes is still not completely clear. One possible reaction path might involve the *dimeric* nitroso compounds; this will be discussed as part of the report of our investigation of *gem*-chloronitroso compounds with azide ion.

4) Authentic VIa was prepared by the reaction of azobis(1-chlorocyclohexane) with azido ion; E. Benzing, *Ann.*, **631**, 1 (1960).

5) Mp 161—163°, prepared in 95% yield as shown in the equation. Since the completion of this work, the preparation and photolysis of IVb has been reported by A. H. M. Kayen, L. R. Subramanian and Th, J. DeBoer, *Rec. Trav. Chim. Pays-Bas*, **90**, 866 (1971). We wish to thank Prof. DeBoer and Dr. Kayen for informative correspondence.

6) Glc examination of the product mixture of the reaction of *gem*-chloronitrosocyclohexane with azide ion revealed the presence of at least thirteen components. The presumption was that the presence of α-hydrogens was in large part responsible for the complexity of the reaction. This presumption was confirmed by the fact that in addition to nitrous oxide (formed as a major product), only five solid products were formed. They were identified as 2,2′-diazidoadamantane, 2,2′-dichloroadamantane, 2-chloro-2-nitroadamantane, adamantanone and VIb.

7) 2,2′-Diazido-2,2′-azoadamantane (VIb) was obtained in 70% yield (from ethanol). So far as we have been able to determine, it dose not display the explosive properties reported for VIc; a correct elemental analysis was obtained routinely. However, we *urge all due caution* because no detailed study of its properties has been performed.

The Crystal Structure of Cupric Complex with Succinimide I. Cesium Tetrakis(succinimidato)copper(II) Dihydrate

Tomitake TSUKIHARA, Yukiteru KATSUBE, Kumiko FUJIMORI, and Toshiaki ITO

Faculty of Engineering, Tottori University, Koyama-cho, Tottori

(Received February 23, 1972)

The crystal structure of cesium tetrakis(succinimidato) copper(II) dihydrate, $Cs_2(Cu(sucim)_4).2H_2O$, has been determined by means of X-ray analysis. The crystals are violet rhombic plates. Dimensions of the triclinic unit cell are $a=9.19$, $b=15.32$, $c=8.39$ Å, $\alpha=88.7°$, $\beta=92.0°$, $\gamma=93.8°$, and $z=2$. The space group is $C\bar{1}$. The structure has been determined by the Patterson synthesis, a series of Fourier syntheses and the least-squares method. The coordination around the copper atom is a square planar. Two independent cesium ions have a quite different environment. Complex anions, $(Cu(sucim)_4)^{2-}$, are linked with each other through the hydrogen bonds between water and carboxyl oxygen atoms.

Succinimide forms complexes with various metallic ions. A number of cupric compounds with succinimide having the general formula $M_2^+[Cu(sucim)_4]^{2-}\cdot nH_2O$ and a red or violet color in solid state have been reported.

A structural investigation of compounds of this type is thought to be of interest from the viewpoint of the coordination chemistry of cupric complexes. Some of these complexes have been studied spectroscopically.[1]

As a part of studies of the crystal structure of such complexes, a detailed description of the crystal structure of cesium tetrakis(succinimidato)copper(II) dihydrate is given in this paper.

Experimental

The crystals are violet rhombic plates. Preliminary Weissenberg and oscillation photographs established that the crystal was triclinic with axis *a* along an edge of the plate and axes *b* and *c* along the diagonals of the rhombic plane (Fig. 1). By the systematic extinction of *hkl* for odd $h+k$ the space group was restricted to $C1$ or $C\bar{1}$. The cell dimensions were obtained by means of the least-squares method. The crystal data were collected on a Rigaku Denki Computer-controlled four-circle diffractometer, using Ni-filtered Cu$K\alpha$ radiation. All the intensities were obtained from a crystal with dimensions $0.25\times0.25\times0.08$ mm³. Reflections with 2θ values up to 120° in octants of *(hkl)*, *($\bar{h}$kl)*, *(h$\bar{k}$l)*, and *($\bar{h}\bar{k}$l)* were measured by ω-2θ scanning technique at a scan rate of 2° per minute. The scan range of ω for each reflection was calculated by the formula $\omega=0.90°+0.15°\tan\theta$, and the backgrounds were measured at both ends of the scan range for 10.0 seconds. Attenuators were inserted automatically when the maximum counting rate exceeded 8000 cps. Reflections whose counts at mid point of the scan range were less than 10 cps were not measured. The intensities of two reference reflections $I(006)$ and $I(008)$ were measured after every fifty reflections. Owing to sublimation of the crystal, the intensities of these two reflections decreased gradually during the course of measurement. Correction was made for a decay of the crystal by multiplying each reflection by a factor found from the normalized plot of the intensities of the reference reflections. Application of Lotrentz-polarization factors was made but no correction for absorption.

Structure Determination and Refinement

A sharpened three-dimensional Patterson function showed that a copper atom and two cesium ions should be located on the special positions (0,0,0), (1/4,1/4,0) and (1/4,1/4,1/2), respectively. The space group was restricted to $C\bar{1}$ by an interpretation of the Patterson function.

The remaining light atoms were located by successive cycles of structure factor calculations and difference Fourier synthesis. The trial structure was refined by a diagonal least-squares procedure with the positional and isotropic thermal parameters. The isotropic refinement converged the reliability index ($R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 0.19. Further refinement was carried out by the least-squares of block-diagonal matrix approximation with the positional parameters for all the non-hydrogen atoms, the anisotropic thermal parameters for three metal atoms and the isotropic thermal parameters for the other atoms. The final value of R was 0.11. The atomic scattering factors were taken from the literature.[2] Those of copper and cesium atoms were corrected for real and

imaginary parts of anomalous dispersion: $\Delta f_{Cu}'=-2.1$, $\Delta f_{Cu}''=0.7$, $\Delta f_{Cs}'=-1.8$, and $\Delta f_{Cs}''=8.0$. The composite electron density map is given in Fig. 2, and the final atomic parameters in Table 2. The standard deviations of the positional parameters are 0.02 Å for oxygen, nitrogen, and carbon atoms. Table 3 containing the observed and calculated structure factors is kept as Document No. 7208 at the Chemical Society of Japan.

Description and Discussion of the Structure

The bond distances and angles are given in Table 4. The structure of the complex anion $(Cu(sucim)_4)^{2-}$ is centrosymmetric about the copper atom. Four nitrogen atoms of four succinimides take a square planar arrangement around the copper atom with a mean Cu–N distance of 2.00 Å. The distance is in good agreement with that generally found in the planar part of other Cu(II)-complexes: 1.963 Å in ethyl-

* Atom not included in the least-squares calculations.

enebidiguanide copper(II) chloride monohydrate,[3] 2.01 Å in Bis(pyridine-2-acetamide)copper(II) perchlorate[4] and 2.003 Å in copper(II) complex with *o*-hydroxyacetophenone isobutylimine.[5] Since the copper atom is located at the center of symmetry, it is exactly on a coordination-plane defined by the four nitrogen atoms. An orientation of the coordination-plane is given in Fig. 3.

The dimensions of the succinimides in the complex anion are consistent with those of the free molecule.[6] Each succinimide ring is planar within a limit of error. The best planes determined by the least-squares calculation are given in Table 5. The dihedral angle between the coordination-plane and the A-ring of succinimide is 90.6° and that for the B-ring 90.4°. Four succinimide rings are therefore almost perpendicular to the coordination-plane. Thus, the complex anion has approximate symmetry of D_{4h}. This configuration agrees with that proposed spectroscopically for $K_2(Cu(II)(sucim)_4)\cdot 6H_2O$ by Yamada and Miki.[1] The structure of the complex anion is given in Fig. 4.

Two independent cesium ions exist in the structure. That at (1/4,1/4,0), Cs1, has eight oxygen atoms situated at the corners of an almost perfect tetragonal prism with dimensions $3.32\times3.34\times4.09$ Å^3. These atoms belong to the carbonyl groups. This arrangement may be compared to the CsCl-type structure of eight-coordination. The cesium ion at (1/4,1/4,1/2), Cs2, fits into a cavity in the crystal, and is surrounded by six oxygen atoms which form a somewhat distorted octahedron. Two of these belong to water molecules and the other four are carbonyl oxygen atoms. The Cs2 ion is also at the center of symmetry with respect to the six oxygen atoms. The mean value 3.04 Å

Key for molecular position

a: $(0.5+x, 0.5+y, z)$ b: $(x, y, 1.0+z)$ c: $(0.5+x, 0.5+y, 1.0+z)$, d: $(-x, -y, 1.0-z)$

of the Cs2-O(carbonyl) is slightly less than 3.12 Å of Cs1-O(carbonyl). The arrangement around the Cs2 ion may be compared to the six-coordination NaCl-type structure. The Cs-O distances are in fairly good agreement with the sum of ionic radii, 3.09 Å. Thus all the oxygen atoms gather around the cesium ions whose positive charges are probably neutralized by negative charges of the oxygen atoms. The environment is illustrated in Fig. 5 and Table 6.

The complex anions are linked to the neighbouring anions in the [110] direction through the hydrogen bonds between the water molecules and carbonyl oxygen atoms and through the ionic contacts between the cation of Cs1 and carbonyl oxygen atoms. The complex anions are also linked together by Cs2-O(carbonyl) contacts in the direction of axis *c*.

The crystal structure is shown in Fig. 6.

The authors express their thanks to Dr. S. Komorita for valuable discussions and the kind supply of crystals, and to Dr. T. Ashida for permission to use his program.

Study on Reverse Osmosis. The Permeation Behavior of Amino Acid Solutions through Cellulose Acetate Membranes

Chiyoshi KAMIZAWA, Hitoshi MASUDA, and Seiichi ISHIZAKA
National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo

(Received November 2, 1971)

Transport phenomena of some aliphatic amino acids and aminobenzoic acids were investigated with Loeb type membranes annealed at 60—80°C.

The quantitative relation between permeability through the membrane and dissociation of amino acid was examined. The charged species are rich in the solutions of amino acids such as L-leucine, L-alanine, and L-glutamic acid, regardless of the pH of solution, thus making the rejection by membranes large; the rejection of L-leucine which had a rejection of 35% for NaCl, was 63.2% even for the membrane cured at 60°C. On the other hand, for aminobenzoic acids, the number of uncharged species in solution varied with the change in pH, and the rejection varied with pH. The fluxes of aminobenzoic acids were in linear relation to the calculated amount of uncharged species. The results of adsorption experiments indicate that the amounts of adsorbed aminobenzoic acid to cellulose acetate were in logarithmic relation to calculated amounts of undissociated species. The results support the view that dissociated species are more difficult to be distributed in membrane than undissociated ones.

It is known that electrolytes such as NaCl, $MgSO_4$, and CH_3COONa[1] can hardly pass through the Loeb type skinned membranes annealed at or above 80°C, but non-electrolytes such as phenol,[2] acetic acid[3] can do so easily. However, the relation between the ionic dissociation of the molecules in solution and the amount of transport in reverse osmosis processes has not been sufficiently discussed. Aliphatic amino acids and aminobenzoic acids were chosen to clarify the relation, since they are amphoteric and the charged state of molecules can easily be controlled by changing the pH of the solution.[4]

Experimental

The modified cellulose acetate (E-398-3) membranes were prepared by the method reported by Loeb and Manjikian.[5] DDS-880 membranes (Loeb type, De Danske Sukkerfabrikker, Denmark) were also used. Annealing temperatures of the Loeb type membranes were 60, 70, 75, and 80°C. Evaporation temperature was 18±1°C and evaporation time was 1 minute for all Loeb type membranes. The effective membrane area in the desalination cell[3] was 12.6 cm^2. The pressurized (40 atm) solution was circulated along the surface of the membrane at 250 ml/min to reduce concentration polarization. For aminobenzoic acids, a batched type apparatus[6] with 28.3 cm^2 effective membrane area was used in order to obtain more precise values. The impeller was rotated over the membrane at 300 r.p.m. by magnetic induced force. Solutions of 0.1 N NaCl, 0.01 N L-leucine, L-alanine, L-glutamic acid, 0.001 N *p*-aminobenzoic acid, and *m*-aminobenzoic acid were tested. Their pH was controlled by adding 0.1 N HCl to the solution. In all the experiments the permeated water was collected one hour after the beginning of the operation. Analysis of the components was performed by the method of Yemm and Cocking[7] for amino acids and by photo-absorption at 254 mμ and 214 mμ for *p*- and *m*-aminobenzoic acid, respectively, with a spectrophotometer (Simazu MPS 50L). The properties of the membrane were shown by water flux (g/cm^2·sec), salt flux (mol/cm^2.sec) and salt rejection. Salt rejection is given by

$$Re = (1 - C_p/C_f) \times 100 \quad (1)$$

where C_p and C_f are solute concentration of product and feed solutions, respectively. The membrane is known to be degradated by hydrolysis[8] in strong alkaline solutions. Thus no base was added to the feed solution, although it was desirable to test the pH effect on transport phenomena.

To avoid marked pH change, experiments were carried out as rapidly as possible.

Results

Rejection of Amino Acids. The rejection of amino acids was larger than that of NaCl as shown in Fig. 1. For instance, the rejection of L-leucine was 63.2% and 99.6% for the membrane annealed at 60°C and 80°C, respectively. There was a difference in the rejection of amino acids, the rejection of L-glutamic acid being somewhat larger than that of L-leucine, especially of the membrane annealed at low temperature (Fig. 1).

Effect of pH on the Transport of Amino Acids. To find the relation between the dissociation of the acids and their transport behavior, the permeation of *p*- and *m*-aminobenzoic acids was examined. Since it was required to analyze data more precisely, a DDS-880 membrane reheated at as high a temperature as 85°C was used in order to reduce membrane defects through which the feed solution would permeate at its concentration.

The rejection of NaCl by this membrane was 98.4% at 40 atm. As shown in Fig. 3, the rejection of *p*- and *m*-aminobenzoic acid changed with the pH of feed solution, the rejection of *m*-aminobenzoic acid being 57.0% and 95.7% at pH 3.88 and 1.77, respectively.

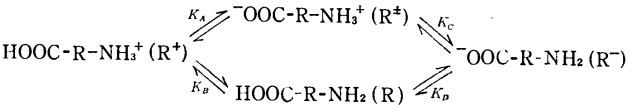
Discussion

Rejection of Amino Acids. An evidence for the zwitter-ion structure of amino acids has been presented.[4] Amino acids dissociate as follows.



The equilibrium can be represented by the equations

$$K_1 = \frac{(H^+)[(R\pm)+(R)]}{(R^+)} = K_A + K_B \qquad (2)$$

$$K_2 = \frac{(H^+)(R^-)}{(R\pm)+(R)} \quad ; \quad \frac{1}{K_2} = \frac{1}{K_C} + \frac{1}{K_D} \qquad (3)$$

where K_A, K_B, K_C, and K_D are equilibrium constants for R^+ and $R^\pm$, R^+ and R, $R^\pm$ and R^-, and R and R^-, respectively. We obtain the relation

$$K_Z = \frac{(R\pm)}{(R)} = \frac{K_A}{K_B} = \frac{K_D}{K_C} = \frac{K_1}{K_E} - 1 \qquad (4)$$

where K_E, the dissociation constant of the amino acid ester, was assumed to be almost equal to K_B and is used in place of K_B. As K_1 is much larger than K_E, for aliphatic amino acids[9] Eq. (4) is reduced to

$$K_Z = \frac{K_1}{K_E} \quad ; \quad -\log K_Z = pK_Z \qquad (5)$$

K_Z is of the order of 10^5 for most amino acids, and the quantity of uncharged species normally present in their solutions is insignificant. If the pH of the solution is changed, the composed ratio of R^+, $R^\pm$, R, and R^- changes, but the quantity of uncharged species remains insignificant. This seems to be the cause of the large rejection of amino acids regardless of the change of pH in the solution. The $R^\pm$; NH_3^+-R-COO^- species of the amino acid are of a dissociated form, but the apparent effective charge is zero. Thus in electrophoresis, ions do not move as if they had no charge but seem to act as charged species in reverse osmosis experiments.

Rejections of Aminobenzoic Acids. Only in the case of aminobenzoic acids, where -pK_Z are −0.70, +0.36, and −0.87, for *o*-, *m*-, and *p*-compounds, respectively, the uncharged species assumes comparable concentration (Fig. 4). The behaviors of *m*- and *p*-compounds whose values of $R^\pm$/R are 2.29 and 0.135, respecitively, were examined with values of K_A, K_B, K_C, K_D, K_1, and K_2 taken from a table.[10] The quantities of $R^\pm$, R^+, R, and R^-, were calculated from Eqs. (2), (3), (4), and (5). The calculated values of R in the *m*- and *p*-aminobenzoic solutions at various pHs are shown in Fig. 4. The relation between the concentration of R, uncharged species in equilibrium at pH of the feed and the permeated fluxes of *m*-aminobenzoic acid is shown in Fig. 5. The solute fluxes of *m*-aminobenzoic acid are proportional to the amounts of the uncharged species in the feed solutions. In the same manner, the relation holds for *p*-aminobenzoic acid. It can thus be said that the dissociation of the molecule plays an important role in the transport phenomena through the Loeb type membrane. Some differences were seen between the pH of feed and permeated solu-

tions, as 3.86 and 4.19, respectively, in the case of *m*-aminobenzoic acid. Thus a gradient of pH exists in the membrane.

However, in spite of the pH gradient, the interface between the membrane and the feed solution seems to be more effective for the transport of the solute than the charged molecules in the membrane, as is indicated by the result shown in Fig. 5.

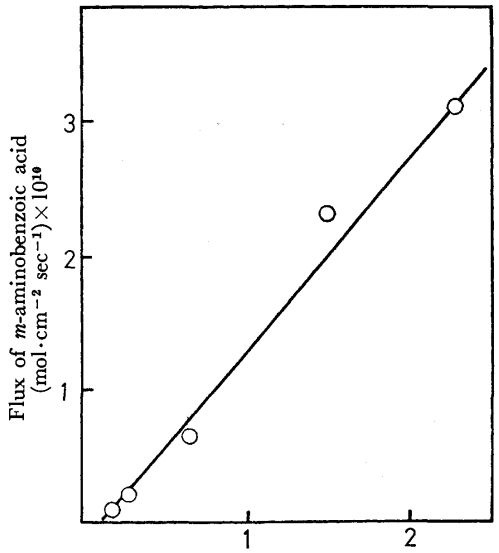

Fig. 5. The relation between the quantity of uncharged molecules and the flux.

Adsorption of m-*Aminobenzoic Acid to Cellulose Acetate Powder.* To understand the relation between the permeation and the dissociation of the solute more precisely, the adsorption of *m*-aminobenzoic acid to cellulose acetate powder was measured.

A definite amount of each of the *m*-aminobenzoic solutions (0.001 N) containing various amounts of HCl, was mixed with 3 g of dry cellulose acetate powder in a 200 m*l* conical flask. It was left at ambient temperature and shaken vigorously from time to time, The apparent adsorbed amount was determined from the difference between the solute concentrations before and after the adsorption. Adsorption of water to cellulose acetate was not taken into consideration.

The adsorbed amounts of *m*-aminobenzoic acid were proportional to the logarithm of calculated amounts of uncharged species (R) in the form of Freundlich type adsorption isotherm (Fig. 6).

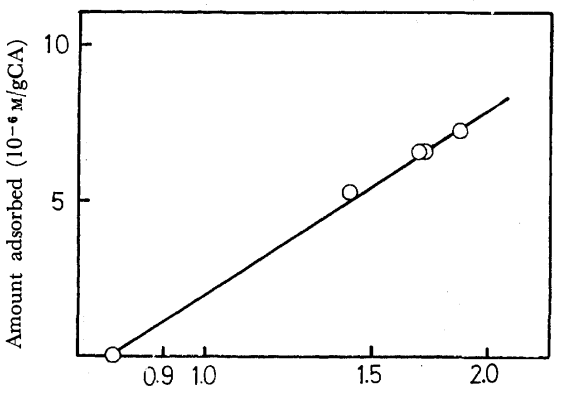

Fig. 6. Amounts adsorbed of *m*-aminobenzoic acid to cellulose acetate powder.

This seems to indicate that undissociated species have greater affinity to cellulose acetate. If affinity of solute to cellulose acetate is considered to be an important factor for determining the distribution coefficient, our result would support the fact that the dissociated species are more difficult to be distributed in the membrane than the undissociated ones. On the rejection of electrolytes, Glueckauf described[11] the potential wall by dielectric constant of cellulose acetate, but this is not satisfactory for explaining the behavior of most electrolytes.[12]

The authors wish to thank Mr. Ryozo Hiraoka for his help in the experiment.

Study on Reverse Osmosis. The Permeation Behavior of Surfactant Solutions through Cellulose Acetate Membranes

Chiyoshi KAMIZAWA and Seiichi ISHIZAKA

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo

(Received November 2, 1971)

Transport phenomena of some surfactants were investigated with Loeb-type skinned membranes annealed at 60, 70, 75, and 80°C, with the following results. (1) The rejection of cationic and anionic surfactants is larger than that of nonionic surfactants, especially at concentrations below CMC. (2) In the case of nonionic surfactants, their fluxes decrease with the increase of molecular weight. (3) The effect of CMC on the transport of surfactants is great, particulary in the case of nonionic surfactants. (4) Concentration polarization on the surface of the membrane can be predicted by taking into account the difference between surfactant fluxes below and above CMC.

Waste water contains various solutes of which surfactant is one of the most troublesome because of its harmfulness to human bodies. In this work, the behavior of anionic, cationic and nonionic surfactants was examined with Loeb-type skinned membranes. We intended to clarify the transport phenomena of various solutes with the membranes. However, in order to make the problem simpler a solution containing only one solute was examined in each case.

Expermental

Modified cellulose acetate (E-398-3) membranes were prepared by the method reported by Loeb and Manjikian[1] at annealing temperatures 60, 70, 75, and 80°C. The evaporation temperature was 18°±1°C, and evaporation time one minute. The membranes were placed in a stainless desalination cell described previously.[2] The pressurized (40 atm) solution was circulated along the surface of the membrane at 250 ml/min to reduce concentration polarization.

Solutions of sodium dodecylbenzenesulfonate (ABS) as anionics, tetradecylbenzylammonium chloride (TDBNC) as cationics and polyoxyethylene nonylphenyl ether (NP) as nonionics were tested at their various concentrations, since the surfactants have their critical micelle concentration (CMC). In the case of NP, NP-10 (C_9H_{19}-  -O-(CH_2-CH_2O)$_n$ H; $n=10$), NP-16 (where : $n=16$) and NP-27 (where : $n=27$) were used to test the effects of the molecular weight on the permeation of surfactants. Analysis of surfactants was performed by photo-absorbance at 224 mμ for ABS, at 214 mμ for TDBNC and NP. The critical micelle concentrations were estimated from the plots of surface tension *vs.* surfactant concentration and from those of photo-absorption *vs.* surfactant concentration. Surface tensions were measured by the ring method.[3] Properties of the membrane were shown by water flux, salt flux, and salt rejection.[2,4]

Results

Rejection of Surfactants. The rejection of ABS was larger than that of the other two surfactants. The rejection of ABS was 88.9% even for the membrane annealed at 60°C and 99.8% for that annealed at 80°C (Table 1-1). The rejection was so large that no significant difference was observed between the solute fluxes below and above CMC. TDBNC also has a large rejection, *e.g.*, 86.5% and 93.4% for the membranes annealed at 60°C and 75°C, respectively. The rejection of NP-27 was the smallest, *e.g.*, 26% for the membrane annealed at 60°C (Fig. 1) and 86% for the membrane annealed at 80°C. The rejection of NP was almost the same as that of NaCl. The results obtained below CMC are given in Fig. 1.

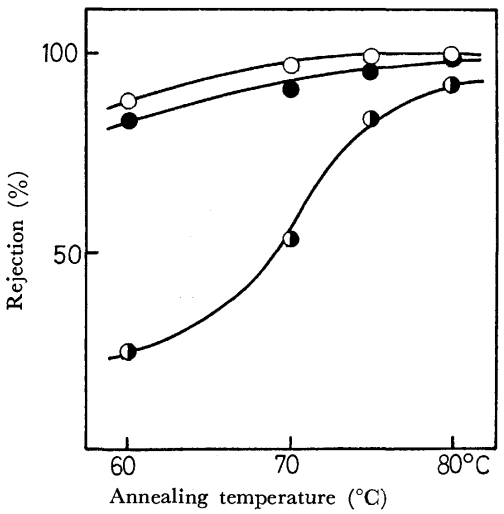

Fig. 1. Rejections of surfactants.
○: ABS 6.00×10^{-4} M
●: TDBNC 2.67×10^{-4} M
◑: NP-27 5.08×10^{-5} M

Effect of CMC. The effect of CMC on permeability through the membrane was measured. No detectable difference was found in the cases of ABS and TDBNC. The influence was remarkable in the case of NP, since its rejection was small below CMC, *e.g.*, the rejection of NP-10 was 42.1% below, and 83.9% above CMC for the membrane cured at 75°C (Table 1-2).

Effect of Molecular Weight. The influence of molecular weight on permeability through the membrane was examined for NP by changing the mole number of oxyetheylene unit. The flux of NP decreases with the increase of molecular weight of NP and

Discussion

Rejections of Surfactants. The rejection of ABS and TDBNC is approximately the same and greater than that of NP-27 (Fig. 1). It was observed that the dissociated species can hardly pass through the membrane.[4] The present results seem to support this. The size of the molecule should be closely related to its permeability, but to explain molecular permeability through the membrane by ascribing it mainly to the molecule is not satisfactory since the molecular weights of ABS, TDBNC, and NP-27 are 348, 327, and 1408, respectively.

Effect of Molecular Weight. The permeation of NP changes with its molecular weight, but it cannot be said whether this is due to the molecular size or to hydrophilic property by increasing ethylene oxide units. No difference was found between the decreasing tendencies of NP flux with increasing molecular weight below and above CMC. Most of the permeated NP is supposed to be a monomer in equilibrium with micelle. According to Kesting *et al.*,[5] water flux increases with the increase of hydrophilic property of the surfactant, but in the present work, the change of water flux with chemical property of surfactant was within experimental error.

Effect of CMC. It is generally recognized that in the case of inorganic salts, their fluxes are in linear proportion to the concentrations of the feed solution.[6,7] In the case of NP the rejection of the solute below CMC differs remarkably from that above CMC for each membrane (Table 1-2). In other words the solute fluxes are not in proportion to the feed concentration for a determined membrane. To make this effect clearer, the relation between concentration of the feed and the solute flux was investigated in detail with NP-27. The fluxes of NP-27 were in linear proportion to the concentration of the feed before it reached a certain concentration, at which an abrupt decrease occurred (Fig. 3). It might be considered that the concentration of NP-27 at the surface of the membrane reached CMC. The concentration polarization can be given by[8]

$$\frac{C_2-C_3}{C_1-C_3}=e^{J_v/K}$$

where C_1, C_2, and C_3 are the bulk concentration of the feed, the concentration at the membrane surface and the concentration of the product, respectively. J_v is water flux (cm/sec), and K is mass-transfer coefficient (cm/sec). If we know the critical feed concentration which would cause the concentration at the membrane surface to amount to CMC, the ratio of the concentration at bulk solution to that at boundary layer ($=C_2/C_1$) could be estimated.

Under the assumption that the value of K remains constant below and above CMC, the value of K was calculated by the above equation with the values of C_2 ($=1.45\times10^{-4}$ mol/l=CMC), C_3 ($=0.30\times10^{-4}$ mol/l), and J_v ($=1.62\times10^{-3}$ cm/sec), the data for the membrane annealed at 70°C. The value of C_1 was assumed to be the average 0.89×10^{-4} mol/l of the concentrations which lie on both sides of inflection (see Fig. 3). The critical values ($=C_1$) for the other membranes were then calculated with $K(=2.40\times10^{-3}$ cm/sec) estimated above. The concentrations shown by dotted lines indicate calculated values (Fig. 3). A micelle is supposed to be composed of 20—30 monomers, making it large enough to be rejected by the membrane.

From the results (Fig. 3) the ratio of the concentration at bulk solution to that at boundary layer ($=C_2/C_1$) is found to be between 1.32—1.61 depending on the membrane under conditions described in the experimental section.

The authors wish to thank Dr. Hiroshi Suzuki for his kind advice and the supply of materials, and Mr. Masato Moroishi for his help in the experiments.

Shapes of Fundamental Bands of Liquid Carbon Disulfide. Vibrational and Reorientational Relaxations

Masao KAKIMOTO and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 27, 1972)

The shapes and intensities of the fundamental bands, ν_2 (the CSC bending) and ν_3 (the C–S antisymmetric stretching), were measured for liquid carbon disulfide and its chloroform solutions. The intensity data were corrected for the effect of the dielectric field at each frequency. The analyses of the ν_2 and ν_3 bands indicate that the band-widths of liquid carbon disulfide can not be explained only in terms of reorientational relaxation. It is also shown that the vibrational relaxation of the resonance type can well explain the concentration dependence of the observed band-widths. The magnitudes of the vibrational and reorientational relaxations obtained from the band-shape analyses are given. It is emphasized that the measurement of the absolute intensity is indispensable for the analyses of the infrared-band shapes of condensed phases.

In recent years it has been realized that the band shapes of infrared absorption spectra of liquid should yield much information about molecular motion. The descriptions of Shimizu[1] and Gordon[2] have encouraged infrared spectroscopists interested in the rotational motions of molecules in the liquid phase. However, progress has been rather disappointing because of many problems, both experimental[3–5] and theoretical. A question has arisen about the analyses of band shapes by the use of reorientational-relaxation theories, that is, it has been questioned whether or not the half band-widths of the infrared absorption spectra of liquids can be completely explained in terms of the reorientational relaxations. One of the criteria is whether or not the half-widths associated with the same symmetry species of a molecule have the same value. In fact, the fundamental bands of methyl cyanide or carbon disulfide have been found to be too strange to be explained only in terms of the reorientational relaxations.[6,7]

The present report will be concerned with observations of the band shapes for liquid carbon disulfide and with the introduction of vibrational relaxation to explanations of the band-widths. The theoretical and experimental evaluation of vibrational relaxation in liquids is under active discussion.[8–13] We will tentatively follow the idea of Valiev[13] in the present work.

Theoretical

The intensity distribution of an infrared absorption band, $I(\omega)$, has been shown to be a Fourier transform of a dipole correlation function, $\Phi(t)$:[1,2]

$$I(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi(t)e^{-i\omega t}\mathrm{d}t \tag{1}$$

and:

$$\Phi(t) = \int_{-\infty}^{\infty} I(\omega)e^{i\omega t}\mathrm{d}\omega = <\boldsymbol{M}(0)\boldsymbol{M}(t)>_{av} \tag{2}$$

where ω is the angular frequency displacement from a band origin, $\boldsymbol{M}(t)$ is the Heisenberg operator of the transition dipole moment of the vibration concerned, and $\langle\ \rangle_{av}$ means an ensemble average over the equilibrium distribution. If we assume that the mechanisms of the vibrational and reorientational relaxation processes are not correlated, then the ensemble average can be taken separately with respect to the two processes:[14]

$$\Phi(t) = \Phi_v(t)\Phi_r(t) \tag{3}$$

where $\Phi_v(t)$ and $\Phi_r(t)$ refer to the vibrational and reorientational correlation functions respectively.

If both $\Phi_v(t)$ and $\Phi_r(t)$ are assumed to be exponential functions, $\Phi(t)$ is expressed as:

$$\Phi(t) = e^{-|t|/\tau} \tag{4}$$

Therefore:

$$(1/\tau) = (1/\tau_v) + (1/\tau_r) \tag{5}$$

where τ_v and τ_r are the vibrational and reorientational relaxation times respectively. The intensity distribution function, $I(\omega)$, is calculated from Eqs. (1) and (4):

$$I(\omega) = \frac{1}{\pi}\frac{(1/\tau)}{(1/\tau)^2+\omega^2} \tag{6}$$

Thus, the half band-width of the absorption band, $\Delta\nu_{1/2}$, is given by:

$$\frac{1}{2}\Delta\nu_{1/2} = (1/\tau_v) + (1/\tau_r) \tag{7}$$

Equation (7) means that a total half-width of an absorption band is a sum of the vibrational and reorientational widths. In some cases the assumption of an exponential function for $\Phi_v(t)$ or $\Phi_r(t)$ may not be appropriate. This can be checked by seeing whether

or not the observed band shapes are of the Lorentzian type of Eq. (6).

If we assume that the contribution of the vibrational relaxation to a band shape is much smaller than that of the reorientational relaxation, $\Phi(t)$ may be set equal to a reorientational relaxation function, $\Phi_r(t)$. Then the observed half-width, $\Delta\nu_{1/2}$, of the band can be simply related to τ_r by:

$$\frac{1}{2}\Delta\nu_{1/2} = 1/\tau_r \tag{8}$$

If we designate the molecular fixed axes by i (where $i=x$, y, and z), the physical meaning of $(1/\tau_r)^i$ is the rate of reorientation of a molecule around the i-th axis. For example, consider the parallel and perpendicular bands of a linear or symmetric-top molecule. For a parallel band,

$$\frac{1}{2}\Delta\nu_{1/2}^{(p)} = 2(1/\tau_r)^x \tag{9a}$$

and for a perpendicular band,

$$\frac{1}{2}\Delta\nu_{1/2}^{(s)} = (1/\tau_r)^x + (1/\tau_r)^z \tag{9b}$$

If absorption-band shapes of both parallel and perpendicular types are observed, we can determine τ_r^x and τ_r^z from Eq. (9) provided that the contributions of the vibrational relaxation are negligibly small.

On the other hand, when the contribution of the vibrational relaxation is predominant, an observed half-width, $\Delta\nu_{1/2}$, is directly related to the vibrational relaxation time, τ_v. At first, let us confine ourselves to one type of vibrational relaxation—the transfer of vibrational energy from a vibrationally-excited molecule to its surroundings by resonance between oscillators of the same type. For this particular case, Valiev[13] evaluated the probability per unit time that an excited molecule undergoes a transition $n\rightarrow n-1$. Some further modification of Eq. (24) of the reference leads to, for a fundamental band:

$$W_{1-0} = \frac{c}{2\pi}\sqrt{\rho\frac{c_m}{3W_m}}S\cdot\Gamma \tag{10}$$

where c is the velocity of light (cm/sec); ρ, the density of a solute itself (g/cm^3); W_m, the molar weight of a solute (g/mol); c_m, the molar concentration of a solution (mol/cm^3), and Γ, the absolute intensity of a vibration band (cm^2/mol). It is found that n_i' of Eq. (24) of the reference should be replaced by a factor, S, defined by:

$$S = \frac{1}{2}\left(1 + \frac{1}{\tanh(\hbar\omega_i/2kT)}\right) \tag{11}$$

This arises from the fact that, in the derivation of Eq. (24) of the reference,[13] only one transition, $n'-1\rightarrow n'$, is taken into account for the surrounding molecules. Actually, all the transitions, $0\rightarrow1$, $1\rightarrow2$, $2\rightarrow3$, $\cdots$ *etc.*, should be considered. Moreover, Valiev multiplies Eq. (10) by the probability of a molecule being in a n-th vibrational state, or by the Boltzmann factor. However, as the quantity we need is not a joint probability but a condition probability that the vibrational energy of a molecule relaxes if it is in a state n at time zero, multiplication by the Boltzmann factor is not necessary. A little observation of Eq. (10) leads to the conclusion that the vibrational width depends on both the vibrational intensity and the molar concentration of a solute. In the case of liquid carbon disulfide, where $W_m=76.14$, $\rho=1.2634$, and $c_m=\rho/W_m$, an absolute intensity of 4×10^3 cm^2/mol corresponds to 1 cm^{-1} of the W_{1-0} of Eq. (10) if S is put equal to 1.

In case where the contributions of vibrational and reorientational relaxations to the band shapes are comparable, the explanation of a half-width is not straightforward. However, it is very probable that the rate of reorientation depends little upon the molar concentration. If so, observations of half-widths for various concentrations can be useful in identifying vibrational and reorientational widths, because a vibrational width is concentration-dependent.

Experimental

The carbon disulfide and chloroform used in the present work were commercial products. Prior to each observation, samples were purified following the procedures described in a reference.[15]

The infrared spectra were recorded by the use of a Perkin-Elmer 112G single-beam infrared spectrometer and a Perkin-Elmer 12C single-beam infrared spectrometer mounted with a CsBr prism. These spectrometers had been carefully modified to eliminate the effect of stray light or thermal emission originating from the spectrometers themselves. The spectrometers were operated with a resolution of about 2 cm^{-1} and at room temperature (23°C). The thicknesses of the sample cell were determined by means of the interference fringes. The observed spectra of ν_2 (the CSC bending vibration) of liquid carbon disulfide are shown in Fig. 1. The spectra were corrected for the dielectric field using the method described in the Appendix. Measurements were also made for ν_2 of carbon disulfide in chloroform solutions (80, 60, 40, 20, and 0.6 mol%).

The spectra for the ν_3 (the C–S antisymmetric stretching) of carbon disulfide were recorded only for dilute solutions because of its very strong intensity. For higher concentrations, the ATR data observed by William Krueger of the University of Minnesota were used.[16] In Fig. 2, the observed

16) W. C. Krueger, Thesis submitted to the University of Minnesota (1966).

spectra for dilute solutions are illustrated. In this case, the dielectric-field correction was rather straightforward, because the refractive indices are also available from the ATR data. The effect of the slit function on the observed band shapes was ascertained to be small for both ν_2 and ν_3.

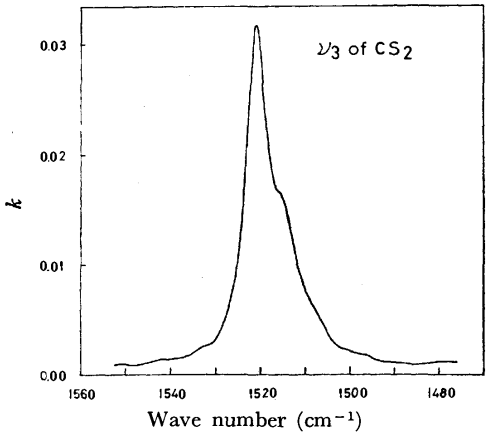

Fig. 2. Absorption index for ν_3 band of carbon disulfide in chloroform solution (0.6 mol%).

Discussion

Band Shape and Evaluation of Half-band-width. As both ν_2 and ν_3 suffer considerably from the effect of overlapping with other bands, especially in chloroform solutions, too detailed discussions of the band shapes might be misleading, especially for the wing parts of the bands. It may be concluded, however, that the band shape of the ν_2 of liquid carbon disulfide follows a good Lorentzian-type function. Figure 3 shows the logarithmic time-correlation function calculated from the observed $I(\omega)$ through Eq. (2). It may be seen that the logarithmic plot of the time-correlation function of ν_2 falls beautifully on a straight line. This justifies the assumption used in the derivation of Eq. (4) and, at the same time, indicates that free rotational reorientation does not play an important role in the relaxation process of liquid carbon disulfide.

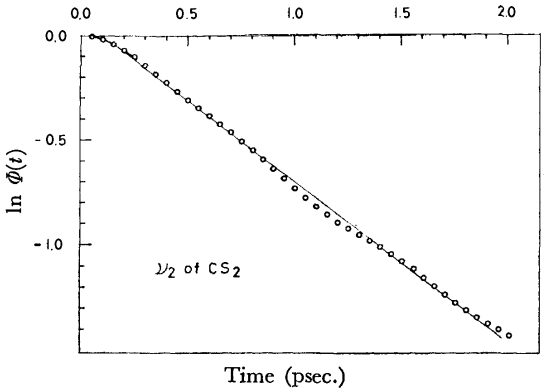

Fig. 3. Logarithmic time-correlation function for ν_2 band of liquid carbon disulfide.

It is known that the ν_3 band of carbon disulfide is overlapped with the hot band, $\nu_2+\nu_3-\nu_2$.[17] It may be seen from Fig. 2 that the separation of these two bands is not large enough for us to evaluate the half-band-width directly from the observed spectra. The situation is even more serious for higher concentrations. Therefore, we resolved the bands into two Lorentzian-type bands by means of numerical calculations. It seems reasonable to assume that the shapes of these bands are of a Lorentzian type because of the conclusion obtained from the ν_2 band.

The evaluated half-band-widths for ν_2 and ν_3 are listed in Table 1, together with the observed absolute intensity values.

Analysis of Half-band-width. It may be seen from Table 1 that the half-width of the ν_3 band changes its magnitude approximately from 5 to 20 cm^{-1} as the concentration of the chloroform solution increases, while that of ν_2 takes a constant value of about 7 cm^{-1}.

If the band-widths are treated as being completely determined by the reorientational motions of the solute, then the reorientational relaxation times around the principal axes can be evaluated from Eqs. (8) and (9):

17) D. F. Smith, Jr. and J. Overend, *Spectrochim. Acta*, **26A**, 2269 (1970).

$$(1/\tau_r)^x = \frac{1}{4}\Delta\nu_{1/2}^{(\nu_3)}$$

and:

$$(1/\tau_r)^z = \frac{1}{4}\left(2\Delta\nu_{1/2}^{(\nu_2)} - \Delta\nu_{1/2}^{(\nu_3)}\right) \quad (12)$$

where $\Delta\nu_{1/2}^{(\nu_2)}$ and $\Delta\nu_{1/2}^{(\nu_3)}$ are the half-widths of ν_2 and ν_3 respectively. The reciprocal relaxation times thus obtained are shown in Fig. 4 (designated as "apparent $(1/\tau_r)$").

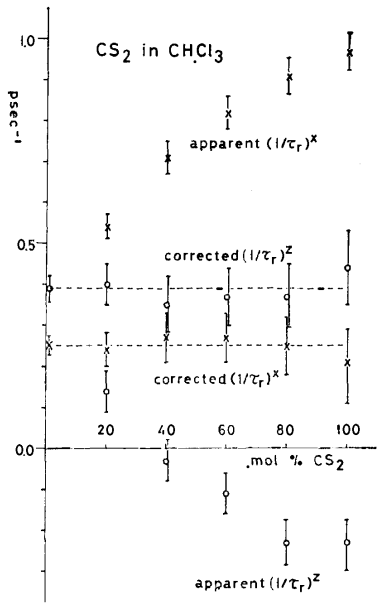

Fig. 4. Reciprocal reorientational relaxation times for carbon disulfide in chloroform solutions. Vertical lines indicate limit of experimental errors.

The results are peculiar in showing that:

(1) The $(1/\tau_r)^x$'s are larger than the $(1/\tau_r)^z$'s for all the concentrations, which means that carbon disulfide rotates around the molecular axis much slower than it does around the axis perpendicular to the molecular axis, and

(2) $(1/\tau_r)^z$ becomes negative for the higher concentrations. Thus, it may be concluded that the band-widths are not determined only by the reorientational relaxation.

Let us consider next the effect of the vibrational relaxation of the resonance type. The vibrational relaxation width, W_v, is calculated from Eq. (10) and the relation:

$$W_v = (1/\tau_v) = W_{1-0} \quad (13)$$

The results thus calculated are summarized in Table 1. It may be seen from the table that the calculated W_v's are smaller than the observed half-widths. If we assume that the contributions of vibrational and reorientational relaxations to the band-widths are comparable and that the difference between the observed band-width and the calculated W_v value originates from the reorientational relaxation, then the reciprocal reorientational relaxation time can be calculated from Eq. (12). The results are visualized in Fig. 4 (designated as "corrected $(1/\tau_r)$").

Now we can see from Fig. 4 that the corrected $(1/\tau_r)$ does not vary over the entire concentration range, $(1/\tau_r)^z$ being always greater than $(1/\tau_r)^x$. The results seem reasonable in the sense that the molecule rotates around the molecular axis more rapidly than it does around the axis perpendicular to the molecular axis. We are not going to assert too strongly that the difference between the observed band-width and W_v is due to the reorientational relaxation only. However, the constancy of the reciprocal relaxation times for all the concentrations seems to support this idea, for the reorientational relaxation time is expected to be rather independent of the concentration.

Table 2. Concentration dependence of reciprocal reorientational relaxation times.
(Numbers in parentheses indicate standard errors.)

mol%	$(1/\tau_r)^x$ psec^{-1}	$(1/\tau_r)^z$ psec^{-1}
100	0.21 (0.08)	0.44 (0.09)
80	0.25 (0.07)	0.37 (0.08)
60	0.27 (0·06)	0.37 (0.07)
40	0.27 (0.06)	0.35 (0.07)
20	0.24 (0.04)	0.40 (0.05)
0.6	0.25 (0.01)	0.39.0.03)

Conclusion

The mechanism of reorientation is mainly governed by the diffusional reorientation, rather than by the free rotation of the carbon disulfide molecule. This can be concluded from the band shape of ν_2.

It is evident from the analyses of the ν_2 and ν_3 bands that the band-widths of liquid carbon disulfide can not be explained only in terms of the reorientational relaxation. It can also be concluded that the vibrational relaxation of the resonance type can well explain the concentration dependence of the band-widths. The differences between the observed band-widths and W_v's may be ascribed to the reorientational relaxation.

The reciprocal reorientational relaxation times are calculated to be:

$$(1/\tau_r)^x \simeq 0.25 \text{ (psec}^{-1}\text{)}$$

and: $$(1/\tau_r)^z \simeq 0.39 \text{ (psec}^{-1}\text{)}$$

This means that carbon disulfide rotates by these rates around the molecular axis (z-axis) and the perpendicular axis (x,y-axes) respectively.

Appendix Dielectric-field Correction for Transmittance Data

It has previously been pointed out that dielectric-field correction is indispensable for band-shape analyses of condensed phases.[4,18,19] For this correction, a formula has been presented expressing the corrected absorption index, k_c, in terms of the observed absorption index, k, and the refractive index, n, assuming the Lorentz field for the internal field.[18] When k and n are measured simultaneously (*e. g.*, by the ATR method), k can be corrected at

18) A. A. Clifford and B. L. Crawford, *J. Phys. Chem.*, **70**, 1536 (1965).

19) T. Fujiyama and B. L. Crawford, Jr., *ibid.*, **72**, 2174 (1968).

each frequency. On the other hand, when the measurement of an absorption band is carried out by the use of the transmittance method, the correction can not be made straightforwardly. In this case, however, the following method may be conveniently used.

As is well known, n and k are related by the Kramers-Kronig dispersion formula:

$$n(\nu) = n_0 + \frac{2}{\pi}\int_0^\infty \frac{k(\nu')\nu'}{\nu'^2-\nu^2}d\nu'$$

Therefore, when reliable data of $k(\nu)$ are available, $n(\nu)$ can be calculated by this formula, and then $k(\nu)$ can be corrected at each frequency. In doing so, the most difficult problem is to determine the constant n_0. Generally, n_0 is not equal to the refractive index in the visible region or to the square root of the static dielectric constant. Furthermore, n_0 may take different values for different absorption bands. There is, in fact, no general way to estimate n_0. The only way to override this difficulty is to observe $n(\nu)$ experimentally for at least one point near the absorption band. Once n_0 is determined for an absorption band, the n_0 corresponding to the next lower-frequency band can be estimated as follows: Let ν of Kramers-Kronig's formula go to infinity; then

$$n(\nu) \to n_0 \quad (\nu\to\infty)$$

and if ν goes zero,

$$n(\nu) \to n_0 + \frac{2}{\pi}\int_0^\infty \frac{k(\nu')}{\nu'}d\nu' \quad (\nu\to 0)$$
$$\simeq n_0 + (c_m\Gamma/2\pi^2\nu_0)$$

where ν_0 is the resonance frequency in cm^{-1}, and Γ, the absolute intensity in cm^2/mol. Thus, the increment in n_0 by this absorption band, Δn, is $c_m\Gamma/2\pi^2\nu_0$. $n_0+\Delta n$ may be considered to be the n_0 for the next-lower-frequency band. In Fig. 1, the $n(\nu)$ curve is calculated using $n_0=1.6000\pm 0.0046$, which is estimated in this way from the $n(\nu)$ and $k(\nu)$ curves of ν_3 as observed by the ATR method.

The authors are indebted to all the members of Shimanouchi Laboratory for their helpful correspondence about this work. They are particularly grateful to Professor Takehiko Shimanouchi of the University of Tokyo for giving them the opportunity of publishing this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2974—2976 (1972)

Vibronic Bands of Phosphorescence Spectra of Quinoxaline in Host Crystals

Kasumi IKEGAMI and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received January 11, 1972)

The polarized phosphorescence spectra of quinoxaline in durene and *p*-dimethoxybenzene host crystals were observed at 4.2°K, and the vibronic bands of the phosphorescence spectrum were assigned. It was found that the intensity of vibronic bands polarized along long molecular axis arises from the vibronic spin-orbit coupling routes

$$^1A_2(\pi, \pi^*) \begin{cases} \xrightarrow{b_1} {}^1B_1 \\ \xrightarrow{R_z} {}^3A_2 \end{cases} \begin{cases} \xrightarrow{R_z} \\ \xrightarrow{b_1} \end{cases} {}^3B_2(\pi, \pi^*)$$

and the intensity of vibronic bands polarized along short molecular axis from the routes

$$^1B_2(\pi, \pi^*) \begin{cases} \xrightarrow{R_z} {}^3B_1 \\ \xrightarrow{a_2} {}^1B_1 \end{cases} \begin{cases} \xrightarrow{a_2} \\ \xrightarrow{R_z} \end{cases} {}^3B_2(\pi, \pi^*)$$

It was concluded that all the vibronic phosphorescence bands of quinoxaline originate from the Tz zero-field sublevel. This is in line with the results of El-Sayed and Brewer deduced from the magnetic field effect on the phosphorescence spectrum.

Effects of vibronic coupling or vibronic spin-orbit coupling on the phosphorescence spectrum of quinoxaline have been studied by several investigators using the method of photoselection[1,2] or with mixed crystal.[3,4] However, discussion is limited because of the ambiguity in the assignment of the fundamental vibrational frequencies. In this work the ploarized phosphorescence spectra of quinoxaline in several host crystals have been observed at liquid helium temperature, the orgin in vibronic bands being discussed.

Experimental

The polarized phosphorescence spectra were measured photographically with a Shimadzu GE-100 grating spectrograph (of reciprocal linear dispersion of 8.4 A/mm in the first order) equipped with a Wollaston prism behind entrance slit. A 500 W Hg lamp was used as an exciting source. A quarter-wave plate was placed behind the slit of the spectrograph for correction of the polarization characteristic of the spectrograph. Photoelectric recording of the spectra was also carried out with a Narumi 750Z—1200 grating double monochromator having a reciprocal linear dispersion of 11 A/mm in the first order.

Quinoxaline (Tokyo Kasei Co.) was purified by repeated recrystallization and distillation under several times reduced pressure. Durene and *p*-dimethoxybenzene used as host

crystals were purified by recrystallization and zone refining.

The single crystals were obtained by cutting large crystals grown by the Bridgeman method. The crystallographic axes were determined by observation of isogyric pattern under a polarizing microscope and by X-ray diffraction. The crystal was fixed on the copper plate of a helium cryostat and immersed directly into liquid helium.

Results and Discussion

The *p*-dimethoxybenzene crystal belong to a space group $V_h^{15}(P_{bca})$ with four molecules in a unit cell.[5] Projection of the molecule on plane *ab* of the crystal is shown in Fig. 1. The durene crystal belongs to a space group $C_{2h}^5(P_{2_1/a})$ with two molecules in a unit cell.[6,7] Rrojection of the molecules on plane *bc** of the crystal is shown in Fig. 2. In the mixed crystals of quinoxaline, we assumed that quinoxaline molecule occupies substitutional positions in the host crystals with the molecular orientation in which the *L,M,N* axes of quinoxaline molecule coincide with the *L,M,N* axes of the host molecules, respectively.

We see from Fig. 1 that when the polarized spectra of the guest molecule are observed on plane *ab* of *p*-dimethoxybenzene crystal, it is possible to distinguish the in-plane and out-of-plane polarized transitions of the guest molecule. The polarized phosphorescence spectra of quinoxaline on plane *ab* of *p*-dimethoxybenzene crystal at 4.2°K is shown in Fig. 3. It is clear that the bands 0-0, 0-527, and 0-603 cm^{-1} are out-of-plane polarized ones and the 0-466, 0-490, 0-635, and 0-872 cm^{-1} in-plane polarized ones. The vibrational frequency 527 cm^{-1} forms a long progression starting from band 0-0 and corresponds to the strong Raman line of 535 cm^{-1}.[8] Band 0-603 cm^{-1} is also the origin of a short progression of 527 cm^{-1}. Since bands 0-527 and 0-603 cm^{-1} behave in a similar way to band 0-0, the frequencies of 527 and 603 cm^{-1} are assigned to vibrational mode a_1.

On the other hand, when the polarized spectra are measured on plane *bc** of durene crystal, the short axis polarized transition can be distinguished from the long axis and out-of-plane plarized transitions (Fig. 2). The polarized phosphorescence spectra on plane *bc** of durene crystal is shown in Fig. 4. We see that bands

TABLE 1. THE MAIN VIBRONIC BANDS OF QUINOXALINE PHOSPHORESCENCE IN *p*-DIMETHOXYBENZENE HOST CRYSTAL AT 4.2°K AND THEIR POLARIZATIONS

Vibronic bands of quinoxaline in *p*-dimethoxybenzene host crystal (cm^{-1})	Polarization direction of the vibronic band	Assignment of fundamental vibration involved
0-466	*Y*	a_2
0-490	*Z*	b_1
0-527	*X*	a_1
0-603	*X*	a_1
0-635	*Y*	a_2
0-872	*Z*	b_1
0-1204	*X*	a_1

0-466 and 0-635 cm^{-1} are the short polarized along axis. The remaining bands of 0-490 and 0-872 cm^{-1} are necessarily assigned to be polarized along the long axis. The polarization direction of the individual vibronic bands are given in Table 1.

Let us consider the symmetry species of the vibrations involved in the vibronic bands. In their study of the vapor absorption spectrum of quinoxaline, Glass *et al.* reported a hot band involving the vibration of 454 cm^{-1} which assigned to mode a_2 from the rotational contour of the band.[9] On the other hand, the 0-635 cm^{-1} band behaves in a similar way to the 0-466 cm^{-1} bands in the various polarization spectra, and thus the frequencies of 466 and 635 cm^{-1} are assigned to mode a_2. The vibrational frequencies of 490 and 872 cm^{-1} are assigned to mode b_1 based on the assignment by Mitchel *et al.*[8] The assignments are given in Table 1. It was found that the vibronic bands involving fundamental vibrations a_1, a_2, and b_1 are out-of-plane (*X*), short-axis (*Y*) and long-axis (*Z*) polarized, respectively.

The low-lying electronic states of quinoxaline are shown schematically in Fig. 5. The lowest singlet excited state of quinoxaline molecule is $^1B_1(n,\pi^*)$. The two higher states are $^1A_1(\pi,\pi^*)$ and $^1B_2(\pi,\pi^*)$ which correspond to $^1B_{1u}$ and $^1B_{2u}$ of naphthalene, respectively. For the triplet states, the lowest is established to be $^3B_2(\pi,\pi^*)$. $^3B_1(n,\pi^*)$ seems to lie at a slightly higher energy than $^3B_2(\pi,\pi^*)$ although its existence is not yet confirmed experimentally. Since the spin-orbit coupling between n,π^* and π,π^* is generally much greater than that between $\pi,\pi^*,^1B_1(n,\pi^*)$ is expected to be the intensity source of band 0-0 and the vibronic bands involving fundamental vibration a_1.

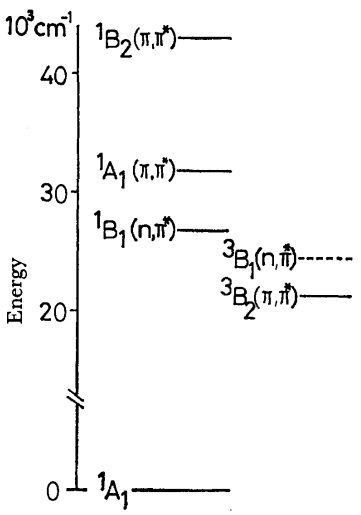

Fig. 5. The low-lying electronic states of quinoxaline.

The expectation is confirmed by our observation that they are out-of-plane polarized bands. Thus for band 0-0 and the vibronic bands involving fundamental vibration a_1, the route $^1B_1(n,\pi^*) \overset{R_z}{\text{----}} {}^3B_2(\pi,\pi^*)$ is given,[10] where R_z is rotation operator of the spin-orbit coupling. For occurrence of the vibronic bands involving nontotally symmetric vibrations, we must consider the spin-orbit interaction as well as the vibronic interaction. For the long-axis polarized vibronic bands involving vibration b_1(0-490, 0-872) the following vibronic spin-orbit coupling routes are most probable.

$$^1A_1(\pi,\pi^*) \begin{cases} \xrightarrow{b_1} {}^1B_1(n,\pi^*) \xrightarrow{R_z} \\ \xrightarrow{R_z} {}^3A_2(n,\pi^*) \xrightarrow{b_1} \end{cases} {}^3B_2(\pi,\pi^*)$$

For the short-axis polarized bands involving vibtation a_2(0-466, 0-635), the following routes are given.

$$^1B_2(\pi,\pi^*) \begin{cases} \xrightarrow{R_z} {}^3B_1(n,\pi^*) \xrightarrow{a_2} \\ \xrightarrow{a_2} {}^1B_1(n,\pi^*) \xrightarrow{R_z} \end{cases} {}^3B_2(\pi,\pi^*)$$

It is seen that all the routes commonly involve the spin-orbit coupling through R_z. This means that the phosphorescence of all the vibronic bands originates from Tz sublevel of state $^3B_2$. This supports the results given by Zigler and El-Sayed that band 0-0 and all the vibronic bands occur from Tz sublevel in study of the magnetic field effect.[11]

The authors wish to thank Dr. N. Mikami for helpful discussions and advice.

Rate-controlling Processes in the Phosphidation of Copper by Phosphorus Vapor

Yoshinori SASAKI and Shiro UEDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received October 12, 1971)

The phosphidation kinetics of a copper exposed to a phosphorus atmosphere from 1 to 10 Torr absolute pressure in the temperature range of 150—250°C have been determined with a closed system. The reaction rate in the earlier periods of time was linear and, subsequently, parabolic; therefore, it can be considered that the rate-determining process changes from adsorption to diffusion. The linear rate constants were expressed as a function of the phosphorus pressure on the basis of the Langmuir adsorption isotherm. The P_4 molecule is chemically adsorbed as two $-P=P-$, whereas at higher temperatures and pressures the solubility process appears to be predominant. From the phosphorus distribution in cross sections of scaling films, it has been revealed that, in the adsorptoin-controlled regions, the phosphorus content is maintained at a constant concentration, corresponding to Cu_3P, and that, in the diffusion-controlled regions, solid solutions more rich in phosphorus than Cu_3P are formed at the outer layers. The faceted crystals of Cu_3P have sometimes developed with an orientation of the (300) plane, depending on the reaction conditions.

In the nineteenth century, the existence of copper phosphides with various compositions, namely, Cu_3P, Cu_5P_2, Cu_2P, Cu_3P_2, CuP, and CuP_2, was reported. In 1907, Heyn and Bauer[1] determined the equilibrium diagram of copper-phosphorus systems up to 15 wt% phosphorus. The rate of the combination of copper and phosphorus was first investigated by Edwards and Murphy.[2] Haraldsen[3] pointed out, on the basis of the thermal analysis and the X-ray diffraction, that the CuP_3 and Cu_2P_5 compounds are solid solutions, in which a phosphorus dissolves in any CuP_2-matrix, and concluded that no compounds other than Cu_3P and CuP_2 exist as copper phosphides. The crystal structures of Cu_3P[3] and CuP_2[4], the magnetic[3] and electrical[5] properties of these two phosphides, and the heats of formation[6] of the two have been investigated.

The present authors reported previously[7] the rate of the reaction of copper with gaseous phosphorus, as determined by gravimetric means, using a spring-helix method, in a flow system in the temperature range of 400—650°C and under the partial pressures of 0.8 to 110 Torr. According to those results, the copper was linearly phosphidized in the early stages of reaction, and when the phosphide layers reached a certain thickness, a transition from linear to parabolic behavior took place.

The present paper will deal with the behavior of copper at comparatively lower temperatures (150—250°C) in a gaseous phosphorus at pressures of 1 to 10 Torr, as determined by means of a sealed-tube method.[8]

Experimental Details

Materials. A copper sheet 0.5 mm thick was cut in the form of rectangles of approximately 7 by 25 mm. The purity was about 99.95 wt%; this sheet contains as much as 0.05 wt% phosphorus as an impurity. The copper coupons were abraded lightly with emery paper, defatted with trichloroethylene, and polished chemically for 120 sec at 70°C in a solution consisting of 200 parts (by volume) of 85% H_3PO_4, 100 parts of 60% HNO_3 and 120 parts of glacial acetic acid. The coupon specimens thus cleaned were then weighed, and their apparent geometric surface areas were determined.

Red phosphorus was treated with a boiling 10% aqueous solution of sodium hydroxide for about 5 hr, and then with dilute hydrochloric acid. After being washed with distilled water, the refined red phosphorus was stored in a desiccator with phosphorus pentoxide.

Methods. A closed reaction system was used for the phosphidation. Figure 1 represents schematically the apparatus employed; it consists of a tube placed over two temperature zones and controlled within variations of less than 3°C, the first zone being used to heat the sample copper sheet in the sealed tube, and the second zone, to control the vapor pressure of phosphorus. The vapor pressure of phosphorus is governed by the minimum temperature in the closed system.

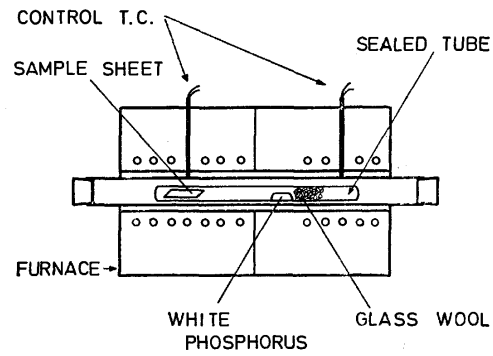

Fig. 1. Schematic drawing of the phosphidation apparatus.

The vapor pressure, P_{Torr}, of white phosphorus is given as a function of the absolute temperature, T, as follows:[9]

$$\log P_{Torr} = 7.808 - 2.729 \times 10^3/T,$$

$$349.6° \text{ (1 Torr)} \leq T \leq 553°K \text{ (760 Torr)}$$

This equation was used to obtain the desired pressure.

The gaseous phosphorus molecule in the form of symmetrical P_4 tetrahedra dissociates into P_2 molecules according to the following equation[10]:

$$\log K_{atm} = \log (P_d^2/P_t) = 7.5787 - 11489/T°K$$

where P_d and P_t denote the pressures, in atmospheres, of the diatomic and tetratomic molecules respectively. Therefore, for the temperature region of 150—250°C employed in this study, the phosphorus vapor can be regarded as being made up of P_4 molecules.

The sealed tube containing the copper specimen and white phosphorus was prepared as follows. A moderate amount of the refined red phosphorus was introduced into a one-side-closed Pyrex tube (inside diameter: 7 mm). Some clean glass wool was packed in, and then the copper specimen was put in this tube. This tube was evacuated to 10^{-2} Torr, then filled to 1 atm with argon gas purified by having been passed through phosphorus pentoxide and heated active copper, and finally reevacuated. The evacuating and the filling were repeated five times at 200°C in order to remove any moisture, oxygen, and other gaseous impurities adsorbed on the red phosphorus, the glass wool, and the inner wall of the tube. In this case, only the copper specimen placed near the entrance end of the tube was not heated. After these operations, this tube was sealed under a vacuum.

Although red phosphorus is generally amorphous, it can also have various crystal structures; hence, a conversion from red to white phosphorus is necessary to secure stable pressures of phosphorus vapor. In this study, the phosphorus vapor which evolved when the red phosphorus was heated in the sealed tube was condensed into white phosphorus by water cooling in the neighborhood of the packed glass wool.

After selected periods of time of the phosphidation, the tube was taken out of the furnace; the end of the tube opposite the specimen was immediately quenched in order to avoid the condensation of the phosphorus vapor on the phosphidized specimen. Then, this was removed from the sealed tube and weighed. No appreciable attack on the Pyrex tube was detected.

The constituents of the corrosion products were identified by X-ray analyses. Information about the diffusion profiles of the phosphorus across the scale was obtained by means of a scanning electron microscope (JSM-U3, Japan Electron Optics Laboratory Co., Ltd.).

Experimental Results

Kinetics. The results are based on the experimental observations of copper coupons from 150° to 250°C at absolute phosphorus pressures of 1 to 10 Torr. These are plotted in Figs. 2 and 3 as the log of the weight gain per unit area *vs.* the log of the reaction time. The points represented are scattered. It should be noted that each point was obtained by phosphidizing an individual specimen.

The rate of phosphidation obviously increases with an increase in the temperature and with an increase in the phosphorus pressure. Generally, at the temperatures and pressures investigated, copper was found to phosphidize according to the linear mechanism during the first periods of time, showing a phase-boundary-control mechanism. However, when the thickness of the phosphide layers reached a certain

Using a nickel-filtered copper radiation. The employed range of diffraction angle: $15° \leq \theta \leq 30°$.

value, the kinetics undergo a gradual transition from the linear to the parabolic law; the rate-controlling process changes from adsorption to diffusion. This fact is constituent with the previous conclusion reached under the experimental conditions of a 400—650°C temperature range and a pressure range of 0.8—110 Torr in a flow system.[7]

The values of the linear rate constant, K_l, and the parabolic one, K_p, are listed in Table 1.

Phase Identification and Scale Morphology. The phosphidation commenced with the growth of many phosphide crystallites. The coupon specimens have been phosphidized more rapidly at the edges and corners than at the centers of the flat faces. The scaling layers formed on the unchanged copper beneath were examined on a X-ray spectrometer, using nickel-filtered copper radiation. The d values, the interplanar spacings, of the phosphides obtained under various reaction conditions are summarized in Table 2. A division was made between the results obtained for pulverized phosphides and those obtained for the phosphide films. The diffraction pattern of the powder reflects the bulk of the scaling layers.

The known d values of Cu_3P[3] and CuP_2[4] are given in the same table. The d values obtained from the powder patterns revealed that all the scaling films are essentially Cu_3P. No special dependence of the X-ray patterns on the phosphorus pressure was observed.

According to Haraldsen,[3] the Cu_3P compound is silver grey, while CuP_2 is black. In the linear-rate portions, regardless of the reaction conditions, the phosphide surfaces are mostly silver; black products are rare. The silver surfaces are very flat, and the black, apparently porous. The silver products were almost completely Cu_3P. The black products were composed of the Cu_3P phase containing slight amounts of CuP_2 (Table 2-J). Otherwise, in the parabolic-rate portions, the surface products were almost all dark silver grey and were chiefly composed of Cu_3P, X-ray-spectrographically speaking.

The reverse sides of the phosphide films were obviously composed of Cu_3P; it is noteworthy that, at the phosphide/copper interface, the formation of Cu_3P takes place.

As examples, electron micrographs of the silver surfaces of the specimen phosphidized at 150°C for 2 hr in 7 Torr phosphorus are given in Fig. 4. The crystal features are clear; the upper micrograph shows many small pillars; the second, faceted grains which are the largest in faceted crystals grown under the reaction conditions employed and which have the orientation of the (300) plane; and the lower, a chain of mountains composed of numerous crystallites.

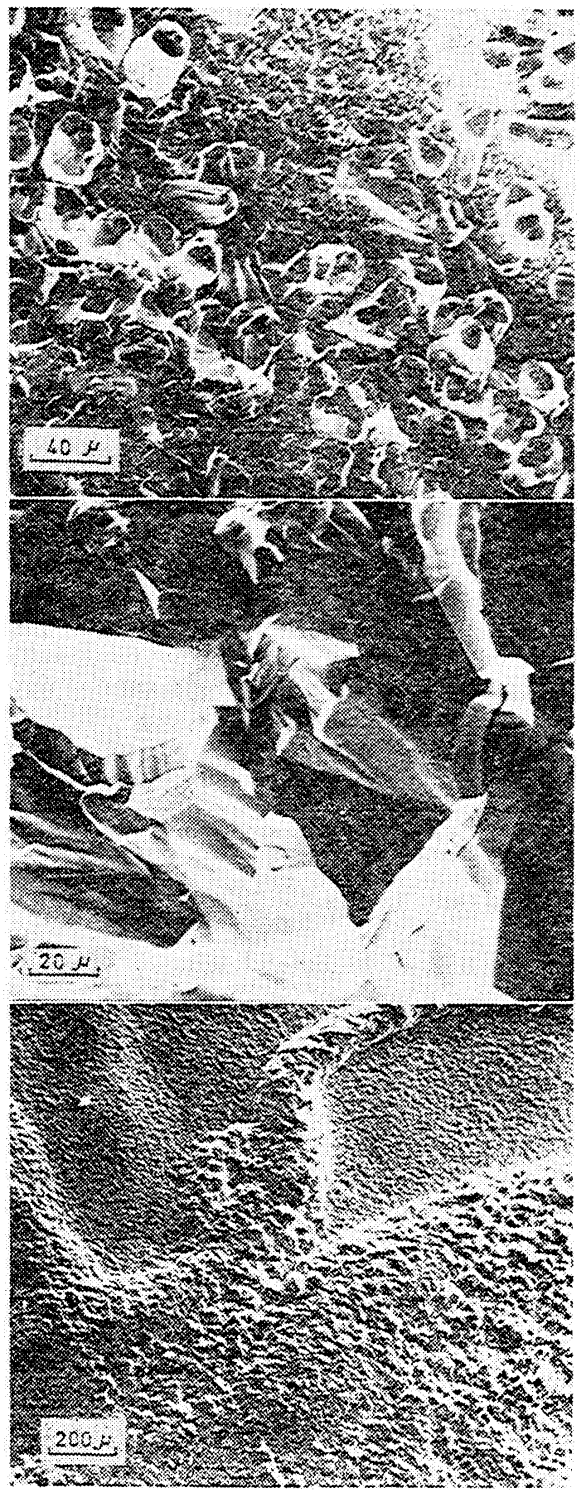

Fig. 4. Electron micrographs of the silver surface of the specimen phosphidized at 150°C for 2 hr in 7 Torr. Upper micrograph, showing many pillars; the second, the faceted crystals; and the lower, a chain of mountains.

These three micrographs were obtained from the different positions of the same phosphidized specimen. As has been indicated just above, all these products are made up of Cu_3P. Localized phosphidation leads to the growth of the porous black products containing CuP_2 as a higher phosphide, such as is exemplified in Fig. 5, in polarized light, showing tablet-like crystals.

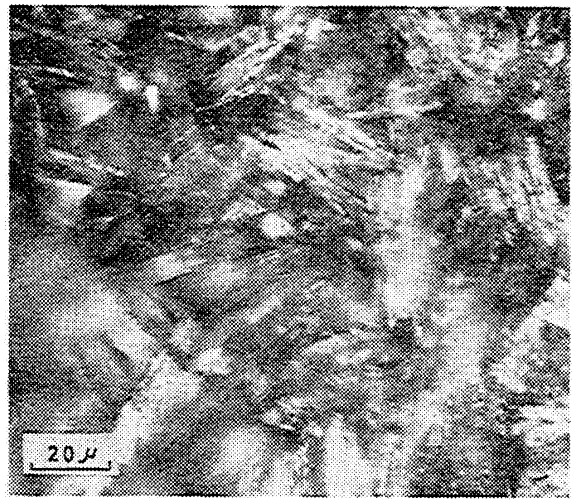

Fig. 5. Optical micrograph showing tablet-like crystals formed for 1.5 hr at 200°C in phosphorus vapor at 1 Torr, in polarized light.

Figure 6 represents a typical cross section of the scale, showing approximatly the formation of two scaling layers. Almost all the scaling films formed in the present study were similar to that shown in Fig. 6. In general, the scales are laminar; the generation of fissures was also faintly observed. This is apparently due to the tensile stresses produced in the outer layers of the scale by the outward pressure of the newly-forming phosphide.

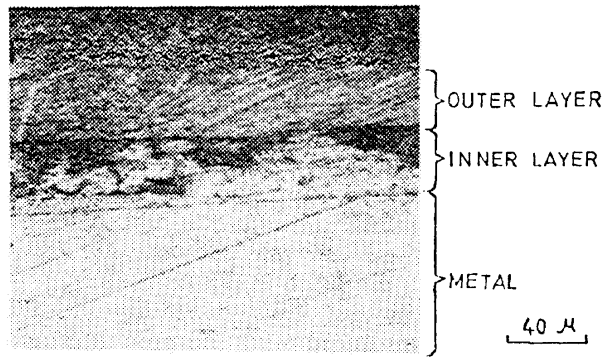

Fig. 6. The cross section of the specimen phosphidized at 150°C for 2.5 hr in 7 Torr, showing the scale to consist of two phosphide layers.

The distributions of phosphorus in phosphide films, obtained with the electron microprobe, suggest that, in the linear-rate portion (Fig. 7A), the phosphorus concentration is held constant, corresponding to Cu_3P, while in the parabolic-rate portion (Fig. 7C) the solid solutions that phosphorus dissolves in the Cu_3P-matrix are formed; the outer layers of the scale are more phos-

phorus-rich than the inner. It is reasonable that some phosphorus-activity gradient exists across the adherent layer, thus providing the driving force for the phosphorus flux required by the reactions at the inner interface. However, at the linear rate, since an adsorption process is slower than a diffusion process, it can be concluded that the content of phosphorus was maintained at the constant concentration. The reaction conditions of Fig. 7B exactly correspond to that of the neighborhood of a transition point from a linear to a parabolic rate (Fig. 2); this pattern may be due to the rate-determining diffusion.

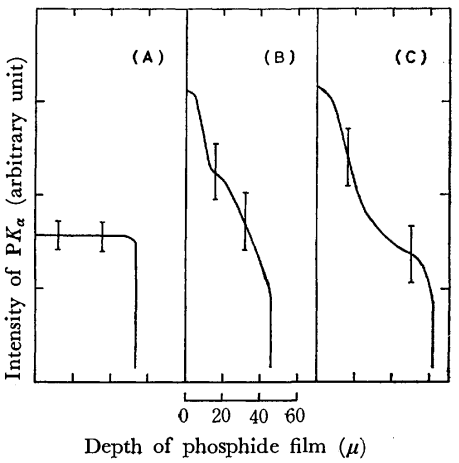

Fig. 7. The profiles of distribution of phosphorus in the phosphide films, obtained with electron microprobe facilities: (A) 250°C, 4 Torr, 1 hr; (B): 150°C, 7 Torr, 2.5 hr; (C): 150°C, 4 Torr, 5 hr.

Discussion

During the earlier stages of the reaction, the observed rates of phosphidation are linear; hence, the rate-determining step is presumably a surface reaction, that is, a phase-boundary reaction or an adsorption process. The generalized mechanism for such a heterogeneous surface reaction involves the following consecutive steps: (a) the diffusion of gas molecules to the surface, (b) the adsorption of gas on the surface, (c) a reaction on the surface, (d) the desorption of the products, and (e) the diffusion of the products away from the reacting surface.

The general form of the linear equation in terms of the weight gained, $w=K_l t$, is not suitable to account for the effect of the pressure at a constant temperature. It is possible to explain the pressure dependence of the reaction by assuming that (I) the phosphorus concentration at some interface is determined by an equilibrium adsorption process, and (II) the rate of the rate-determining process is a function of the phosphorus concentration at this interface. On this model, the interface concentration is given by a Langmuir isotherm. If an adsorbed molecule dissociates into n phosphorus atoms, the fractional coverage of the adsorption interface, θ, is given by:

$$\theta = \alpha P^{1/n}/(1+\alpha P^{1/n}) \qquad (1)$$

where P is the pressure of the vapor composed of P_4 molecules and where α is the chemisorption equilibrium constant, and where an interaction between the adsorbed matters is neglected completely. At low pressures, $\alpha P^{1/n} \ll 1$ and $\theta = \alpha P^{1/n}$.

Assuming that the chemical adsorption of the phosphidation obeys a Langmuir isotherm and that the rate of nucleation and the growth of phosphide nuclei are proportional to the number of chemisorbed phosphorus atoms, the linear rate may be rewritten as:

$$rate = dw/dt = k'\theta = k'\alpha P^{1/n}/(1+\alpha P^{1/n}) \qquad (2)$$

where k' is a specific rate constant.

As Fig. 8 demonstrates, plots of K_l against the pressure on a log-log scale give about 0.5 as a slope, namely, $n=2$ under the experimental conditions of "150°C, 1—10 Torr," "200°C, 1—4 Torr," and "250°C, 1—4 Torr." It should be emphasized that the adsorption takes place with the dissociation of the P_4 molecule into two –P=P– or P≡P. This can be explained in terms of the facility of the dissociation of P_4 into two P_2 molecules at high temperatures in the gas phase. For the pressure range of 1—2 Torr at 150°C, however, the slope appears to become somewhat smaller (the broken line in Fig. 8), showing $n=ca.$ 4; this suggests that the P_4 molecule probably adsorbs as four phosphorus atoms.

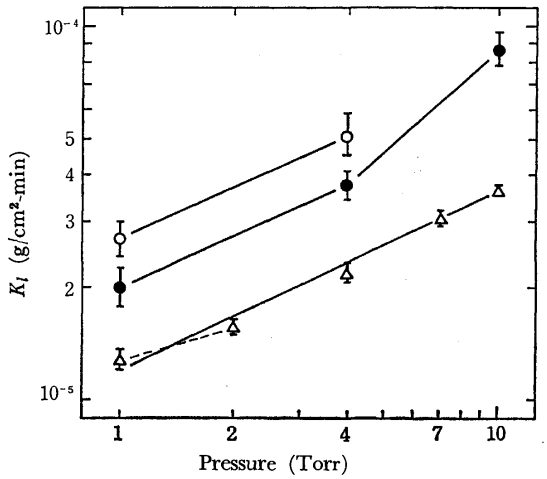

Fig. 8. Influence of the phosphorus pressure on the rate of phosphide formation on copper: ○ 250°; ● 200°; △ 150°C.

On the other hand, for 4—10 Torr at 200°C, the solubility process seems to govern the reaction, because n is approximately equal to unity. This process appears to be predominant at higher temperatures and pressures.

From the above, the processes of the phosphidation can be described as:

$$1/2\ P_4(g) + 2\ \text{Site(Cu or Phosphide)} \rightleftarrows \underset{\underset{\text{P-Site}}{\|}}{\text{P-Site}}\ (\text{Chemisorbed})$$

or; $1/4\ P_4(g) + \text{Site} \rightleftarrows \text{P-Site}$

$$\text{Site-P=P-Site or P-Site} + \text{Cu} \underset{\text{dissolution}}{\overset{\text{diffusion}}{\longrightarrow}} \text{Cu-P solid solution} \underset{\text{growth}}{\overset{\text{nucleation}}{\longrightarrow}} \text{Cu}_3\text{P and CuP}_2$$

In Table 3, the values of n, k', and α in Eq. (2), calculated from the observed values of K_l, are summarized.

The empirical equations obtained from Table 3 are based on a reaction mechanism in which the rate-controlling process is linearly dependent on the concentration of the phosphorus adsorbed as P_2 or P_4. Figure 9 indicates the curves of these equations. Since the original kinetic data are scattered, these calculated curves are of a low precision. The fractional coverages were found to be, for instance, 0.18 at 150°C–10 Torr, 0.12 at 200°C–10 Torr, and 0.05 at 250°C–1 Torr, on calculation.

Table 3. Values of n, k', and α

Temp (°C)	Pressure range (Torr)	n	$k' \times 10^4$ (g/cm²-min)	α
150	1—10	2	1.9	0.068
200	1—4	2	2.9	0.075
250	1—4	2	5.2	0.055
200	4—10	1	7.7	0.013

$K_l = k'\alpha P^{1/n}/(1+\alpha P^{1/n})$

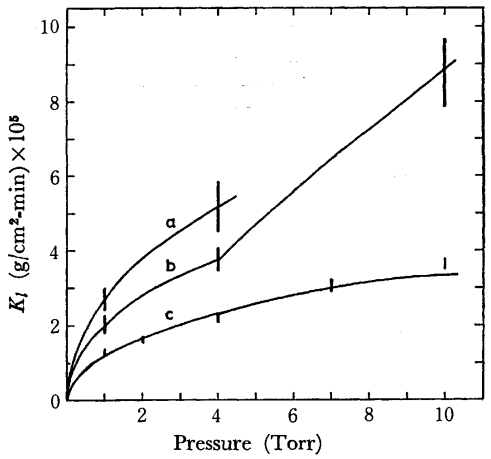

Fig. 9. The relations between K_l and the pressure of phosphorus vapor composed of P_4 molecule: a, 250°; b, 200°; c, 150°C. Curve: calculated, Rod: observed.

From Eq. (2) and the Clausius-Clapeyron equation, $q = RT^2(\mathrm{d}\ln P/\mathrm{d}T)$, the following relation can be derived;

$$q = -RT^2 n(\partial \ln \alpha/\partial T)_\theta \qquad (3)$$

Accordingly, $\alpha = \alpha_0 \exp(q/RTn)$, where α_0 is a constant and where q is the heat of adsorption. From the $\log \alpha$ —$1/T$ plots at $n=2$, it has become apparent that q falls into the category of approximately 2—6 kcal/mol.

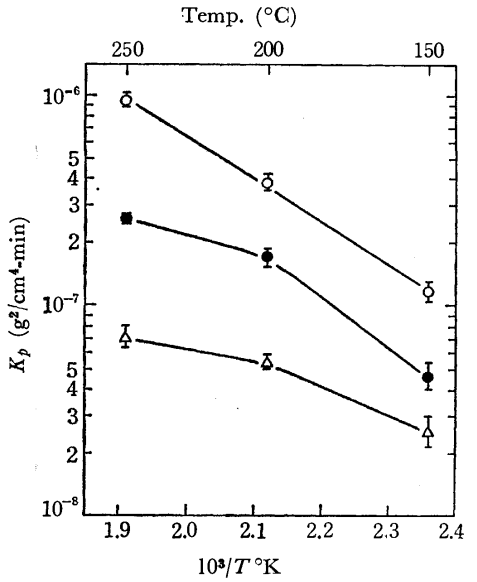

Fig. 11. Temperature dependence of the parabolic rate of phosphidation of copper: The same symbols as in Fig. 10.

The temperature dependence of K_l and K_p is plotted in Figs. 10 and 11. The apparent activation energies, E, evaluated from them are represented in Table 4.

The Eyring absolute-rate theory[11] was used here for a further discussion of the linear behavior. From the θ and the specific rate constant expressed as $\kappa(kT/h)\exp(-\Delta G^{\ddagger}/RT)$, the linear rate constant may be written as follows:

$$K_l = k_0\theta\kappa(kT/h)\exp(-\Delta G^{\ddagger}/RT)$$
$$= k_0\{\alpha P^{1/n}/(1+\alpha P^{1/n})\}\kappa(kT/h)\exp(\Delta S^{\ddagger}/R - \Delta H^{\ddagger}/RT) \qquad (4)$$

where k_0 is a proportionality constant; κ, the transmission coefficient; k, Boltzmann's constant; h, Planck's constant, and T and R, the usual significance.

11) S. Glasstone, K. J. Laidler, and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., New York, N. Y. (1941).

In the case of the present phosphidation, the enthalpy of activation is expressed as $\Delta H^{0\neq}=E-RT$. Therefore,

$$K_l = k_0\theta\kappa e(kT/h)\exp(\Delta S^{0\neq}/R)exp(-E/RT) \quad (5)$$

In Eq. (5), the usual assumption is made that the κ is unity. By the division of the experimental values of K_l on the Arrhenius plot in Fig. 10 by θ, the relation can be obtained as independent of the change in the surface concentration of phosphorus. Figure 12 shows the $\log(K_l h/\theta kT)-1/T$ relationship, which gives about 3.6 kcal/mol as the free energy of activation, $\Delta G^{0\neq}$, for the 150—250°C range. Hence, since E_l is, for example, at 4 Torr and 200°C, 3.9 kcal/mol, the value of $\Delta H^{0\neq}$ is approximately 3 kcal/mol, and the entropy of activation, $\Delta S^{0\neq}$, is about —1.3 e. u. The negative value in $\Delta S^{0\neq}$ is thus reasonable.

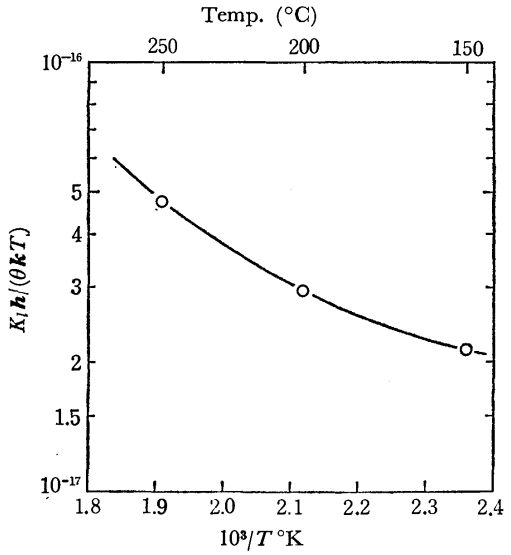

Fig. 12. Absolute rate of reaction of copper in phosphorus vapor *vs.* reciprocal temperature.

The decomposition of CuP_2 has been found to be as follows[3,10]:

$$12/5\ CuP_2(s) \rightleftarrows 4/5\ Cu_3P(s) + P_4(g)$$

$$\log P_{atm} = -11370/T°K + 10.946$$

where P_{atm} stands for the pressure of the P_4 vapor. In Fig. 13, the chemical potential diagram of the copper-phosphorus system reveals that the phase structure becames (P_4 vapor)/CuP_2/Cu_3P/Cu under the present experimental conditions, because the CuP_2 and Cu_3P compounds alone exist in the phosphorus-copper system. The formation of CuP_2 mentioned before can be explained on these thermodynamic grounds.

The pressure dependence of K_p is shown in Fig. 14, which yields following relations: $K_p \propto P^{0.6}$ at 150°, $K_p \propto P^{0.9}$ at 200°, and $K_p \propto P^{1.1}$ at 250°C. The Cu_3P compound was formed at the scale/metal interface. Even if the mass action law is applied as a *p*-type scale to the lattice-defect equation:

$$1/4\ P_4(g) \rightleftarrows Cu_3P + 3\ Cu\square' + 3\oplus,$$

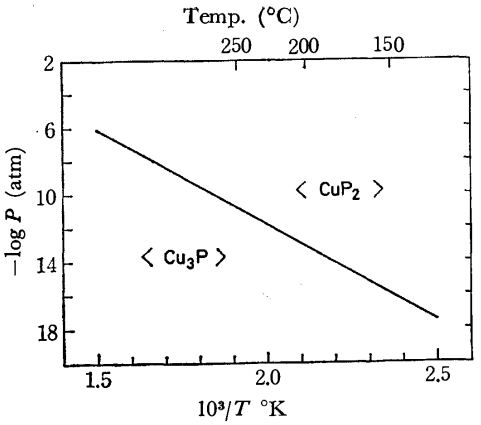

Fig. 13. Chemical potential diagram of the copper-phosphorus system.

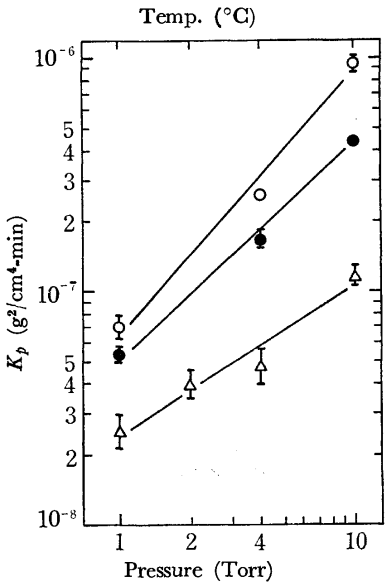

Fig. 14. Phosphorus-pressure dependence for the parabolic rate of phosphidation of copper: The same symbols as in Fig. 8.

the pressure dependence of the parabolic rate is only 1/24 power of the pressure. According to the phase diagram,[1,10] the solubility of phosphorus in metallic copper is about 0.5 wt% *viz.* 1 at% around 200°C. The higher pressure-dependence of K_p, shown above, can probably be attributed to the phosphorus-solubility process. The temperature dependence of K_p at 1 and 4 Torr (Fig. 11) gives two apparent activation energies; this fact may result from differences in the nucleation and growth of copper phosphides and in the solubility of phosphorus in metallic copper.

Although several explanations have been proposed, the fundamental mechanism underlying the phosphidation phenomena has hardly been clarified yet.

This study was supported in part by a Grant from the Ministry of Education.

Ternary Diffusion in the ^{20}Ne–^{22}Ne–CO_2 System

Yasumichi OISHI, Masayasu SUGISAKI, Yoshinobu KAMEI, and Yasuyuki SHONO

Department of Nuclear Engineering, Faculty of Engineering, Kyushu University, Fukuoka

(Received January 13, 1972)

Self-diffusion coefficients of CO_2 of the binary system of Ne and CO_2 were measured for the whole composition range at 25°C under 760 mmHg. The system was also analysed as a ternary system of ^{20}Ne, ^{22}Ne, and CO_2. The isotope separation of ^{20}Ne and ^{22}Ne during the course of diffusion was measured and analyzed by means of the ternary diffusion equations obtained by an extension of Darken's binary diffusion equation. The experimentally observed $^{22}Ne/^{20}Ne$ ratios agreed well with the values calculated by the equations. The results show that the concept of the intrinsic diffusion flux density, introduced by Darken for binary diffusion, is valid and applicable to ternary diffusion in the gaseous system.

Darken derived the following equation for the binary diffusion in a thermodynamically ideal system[1] in order to explain the Kirkendall effect which takes place in interdiffusion of a binary metallic alloy:

$$J_i = -D_i\frac{\partial C_i}{\partial x} + C_i v \tag{1}$$

where J is the diffusion flux density, D the intrinsic diffusion coefficient, C molar concentration, v the velocity of mass flow, and subscript i refers to component i. Eq. (1) is defined with respect to the volume center reference frame. It also holds with respect to the cell-fixed reference frame in the case where partial molar volumes of the respective components remain constant, *viz.*,

$$\sum C_i = C_0 = \text{constant} \tag{2}$$

The first term in Eq. (1) is the diffusion flux density relative to the mass flow velocity and is called intrinsic diffusion flux density. The magnitude of v is equal to the sum of intrinsic diffusion flux densities of both components, *i. e.* the difference of their absolute values, and can be represented by

$$v = \frac{1}{C_0}\left(D_1\frac{\partial C_1}{\partial x} + D_2\frac{\partial C_2}{\partial x}\right) \tag{3}$$

Substituting Eq. (3) in Eq. (1), Darken obtained

$$J_i = -(N_2D_1 + N_1D_2)\frac{\partial C_i}{\partial x} \tag{4}$$

where N_i is the mole fraction of the ith component. He also derived the following binary diffusion equation for a nonideal system:

$$J_i = -(N_2D_1 + N_1D_2)\frac{\partial C_i}{\partial x}\left(1+\frac{\mathrm{d}\ln\gamma_i}{\mathrm{d}\ln N_i}\right) \tag{5}$$

where γ_i is the activity coefficient of the ith component on the mole fraction basis.

Darken's binary diffusion equations have been tested with many metallic alloy systems, but the lack of thermodynamical information on metallic alloys has made quantitative validity of the equations ambiguous. Some binary organic liquid systems showed the validity of Darken's equation quantitatively[2] but not others.[3]

If Darken's analysis is sound for binary diffusion, it could be extended to ternary diffusion and also to general multicomponent diffusion. The purpose of present work is to confirm experimentally the validity of ternary diffusion equation obtained by extending Darken's binary diffusion equation.

In order to avoid a complex effect of thermodynamical nonideality, gaseous systems are utilized. The Kirkendall effect also was experimentally demonstrated for binary diffusion of gaseous system.[4]

We have employed the ^{20}Ne–^{22}Ne–CO_2 system. Validity of the derived ternary diffusion equations was confirmed by comparing the experimental gaseous compositions with the calculated ones for interdiffusion between CO_2 and mixture of ^{20}Ne and ^{22}Ne by a diaphragm-cell method.

Theoretical

A. Ternary Diffusion Equations in Terms of Intrinsic Diffusion Coefficients. If the system is thermodynamically ideal, Eq. (1) can also be applied to ternary diffusion. In this case, Eq. (3) should be replaced by the following equation.

$$v = \frac{1}{C_0}\left(D_1\frac{\partial C_1}{\partial x} + D_2\frac{\partial C_2}{\partial x} + D_3\frac{\partial C_3}{\partial x}\right) \tag{6}$$

If Eq. (2) also holds in a ternary system, we obtain

$$\sum\frac{\partial C_i}{\partial x} = 0 \tag{7}$$

Substitution of Eq. (6) in Eq. (1) with the use of Eq. (7) leads to

$$\left.\begin{aligned} J_1 &= -D_1\frac{\partial C_1}{\partial x} - N_1\left[(D_1-D_2)\frac{\partial C_2}{\partial x} + (D_1-D_3)\frac{\partial C_3}{\partial x}\right] \\ J_2 &= -D_2\frac{\partial C_2}{\partial x} - N_2\left[(D_2-D_3)\frac{\partial C_3}{\partial x} + (D_2-D_1)\frac{\partial C_1}{\partial x}\right] \\ J_3 &= -D_3\frac{\partial C_3}{\partial x} - N_3\left[(D_3-D_1)\frac{\partial C_1}{\partial x} + (D_3-D_2)\frac{\partial C_2}{\partial x}\right] \end{aligned}\right\} \tag{8}$$

A similar derivation is also applicable to the general multicomponent diffusion, giving

$$J_i = -D_i\frac{\partial C_i}{\partial x} - N_i\sum_{j}^{i\neq j}(D_i-D_j)\frac{\partial C_j}{\partial x} \tag{9}$$

Ternary diffusion described by Eqs. (8) is characterized by the curved diffusion path on the ternary composition diagram. In special cases the diffusion path becomes linear on the ternary diagram, the following equations being satisfied.

$$J_1 : J_2 : J_3 = \frac{\partial C_1}{\partial x} : \frac{\partial C_2}{\partial x} : \frac{\partial C_3}{\partial x} \tag{10}$$

The conditions which lead Eqs. (8) to Eq. (10) are as follows:

(i) $D_1=D_2=D_3$.
(ii) $D_1=D_2$ for the diffusion with no concentration gradient for component 3.
(iii) $D_1=D_2$ for the diffusion between two compositions with an equal ratio of concentrations 1 and 2.

If D_1 is greater than D_2 in the diffusion between two compositions with an equal ratio of two concentrations, the diffusion path is curved in an S shape on the ternary diagram as shown schematically in Fig. 1. If D_1 is smaller than D_2, the diffusion path should be in a reversed S shape.

The greater the difference between the two diffusion coefficients or the smaller the value of D_3 than of the other two, the more curved the diffusion path on the diagram. Detailed characteristics of ternary diffusion have been discussed elsewhere.[5]

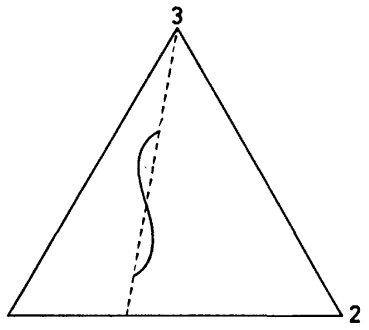

Fig. 1. Schematic diagram of diffusion path for ternary diffusion.

In a ternary diffusion given by Eqs. (8), a linear combination of two of the three concentrations given by Eq. (11) obeys Fick's law as is given by Eq. (12), in which the diffusion coefficient is $1/\mu^2$.

$$C = rC_2 + sC_1 \tag{11}$$

$$\frac{\partial C}{\partial t} = \frac{1}{\mu^2}\frac{\partial^2 C}{\partial x^2} \tag{12}$$

The μ and the ratio of r and s are defined as follows:

$$\mu_1 = \left\{\frac{D_1+D_2+N_1\,{}_3D_1+N_2\,{}_3D_2+[{}_2D_1{}^2+2{}_2D_1(N_2\,{}_3D_2-N_1\,{}_3D_1)+(N_1\,{}_3D_1+N_2\,{}_3D_2)^2]^{1/2}}{2(D_1D_2+N_1D_2\,{}_3D_1+N_2D_1\,{}_3D_2)}\right\}^{1/2},$$
$$\mu_2 = \left\{\frac{D_1+D_2+N_1\,{}_3D_1+N_2\,{}_3D_2-[{}_2D_1{}^2+2{}_2D_1(N_2\,{}_3D_2-N_1\,{}_3D_1)+(N_1\,{}_3D_1+N_2\,{}_3D_2)^2]^{1/2}}{2(D_1D_2+N_1D_2\,{}_3D_1+N_2D_1\,{}_3D_2)}\right\}^{1/2}, \tag{13}$$

$$R_1 = 1/S_1 = (r/s)_1 = \frac{{}_2D_1-N_1\,{}_3D_1+N_2\,{}_3D_2-[{}_2D_1{}^2+2{}_2D_1(N_2\,{}_3D_2-N_1\,{}_3D_1)+(N_1\,{}_3D_1+N_2\,{}_3D_2)^2]^{1/2}}{2N_2\,{}_3D_1},$$
$$R_2 = 1/S_2 = (r/s)_2 = \frac{{}_2D_1-N_1\,{}_3D_1+N_2\,{}_3D_2+[{}_2D_1{}^2+2{}_2D_1(N_2\,{}_3D_2-N_1\,{}_3D_1)+(N_1\,{}_3D_1+N_2\,{}_3D_2)^2]^{1/2}}{2N_2\,{}_3D_1}, \tag{14}$$

where ${}_iD_j=D_i-D_j$,
D is the intrinsic diffusion coefficient regarded as equal to the self-diffusion coefficient, N is the mole fraction, and subscript numbers refer to components.

B. Diaphragm-Cell Diffusion of Ternary System. When diffusion takes place through a diaphragm between two well-stirred cells, the concentration difference between the two cells varying with time is given by

$$\Delta c' = \Delta c \exp(-DKt) \tag{15}$$

where Δc is the concentration difference between two cells at time zero, $\Delta c'$ that at time t, D the diffusion coefficient, and K the cell constant.[6]

Similarly for a diaphragm-cell diffusion in a ternary system, the difference of linear combinations of the two concentrations between two cells is given by

$$\Delta C' = \Delta C \exp\left(-\frac{Kt}{\mu^2}\right) \tag{16}$$

where ΔC is the difference of linear combinations of two concentrations between two cells at time zero and $\Delta C'$ is that at time t, which are given by the following equations derived respectively from Eq. (11).

$$\Delta C = r\Delta C_2 + s\Delta C_1, \tag{17}$$

$$\Delta C' = r\Delta C_2' + s\Delta C_1', \tag{18}$$

where ΔC_i and $\Delta C_i'$ are the concentration differences of component i between two cells at times zero and t, respectively. It should be noted that Eq. (16) is quadratic, since μ and r/s are given in two pairs as in Eqs. (13) and Eqs. (14). Substituting Eqs. (17) and (18) in Eq. (16) we obtain

$$\left(\frac{r}{s}\right)_1\Delta C_2' + \Delta C_1' = \left[\left(\frac{r}{s}\right)_1\Delta C_2+\Delta C_1\right]\exp\left(-\frac{Kt}{\mu_1{}^2}\right) \tag{19a}$$

$$\left(\frac{r}{s}\right)_2\Delta C_2' + \Delta C_1' = \left[\left(\frac{r}{s}\right)_2\Delta C_2+\Delta C_1\right]\exp\left(-\frac{Kt}{\mu_2{}^2}\right) \tag{19b}$$

By solving the simultaneous equations for $\Delta C_1'$ and $\Delta C_2'$, we obtain the following equations.

$$\Delta C_1' = \frac{(\Delta C_2+S_1\Delta C_1)\exp\left(-\frac{Kt}{\mu_1{}^2}\right)-(\Delta C_2+S_2\Delta C_1)\exp\left(-\frac{Kt}{\mu_2{}^2}\right)}{S_1-S_2} \tag{20a}$$

5) Y. Oishi, *J. Chem. Phys.*, **43**, 1611 (1965).
6) J. H. Northrop and M. L. Anson, *J. Gen. Physiol.*, **12**, 543 (1929).

$$\Delta C_2' = \frac{(R_1\Delta C_2+\Delta C_1)\exp\left(-\frac{Kt}{\mu_1^2}\right)-(R_2\Delta C_2+\Delta C_1)\exp\left(-\frac{Kt}{\mu_2^2}\right)}{R_1-R_2} \tag{20b}$$

where

$$R_1=\frac{1}{S_1}=\left(\frac{r}{s}\right)_1, \qquad R_2=\frac{1}{S_2}=\left(\frac{r}{s}\right)_2.$$

Eqs. (20a) and (20b) give the differential concentrations between two cells for two of three components varying with time for the diaphragm-cell diffusion of a ternary system. The concentrations of the three components in the two cells are given by combining Eqs. (20a) and (20b) with the conditions of mass conservation for the respective components as follows.

$$C'_{1a}=\frac{\alpha C_{1a}+C_{1b}+\Delta C_1'}{1+\alpha} \tag{21a}$$

$$C'_{2a}=\frac{\alpha C_{2a}+C_{2b}+\Delta C_2'}{1+\alpha} \tag{21b}$$

$$C'_{3a}=(C_{1a}+C_{2a}+C_{3a})-(C'_{1a}+C'_{2a}) \tag{21c}$$

$$C'_{1b}=\frac{\alpha C_{1a}+C_{1b}-\alpha\Delta C_1'}{1+\alpha} \tag{22a}$$

$$C'_{2b}=\frac{\alpha C_{2a}+C_{2b}-\alpha\Delta C_2'}{1+\alpha} \tag{22b}$$

$$C'_{3b}=(C_{1b}+C_{2b}+C_{3b})-(C'_{1b}+C'_{2b}) \tag{22c}$$

where C_{ia} and C_{ib} are the initial concentrations of component i in cell a and cell b, respectively, C_{ia}' and C_{ib}' the concentrations of component i at time t in cell a and cell b, respectively, and α the ratio of the volumes of cell a and cell b. The concentrations of the three components in the two cells can be calculated for an arbitrary time by using Eqs. (21a), (21b), (21c), (22a), (22b), and (22c).

Experimental

Apparatus. Experiments were carried out by means of the diaphragm-cell technique of Ney-Armistead type[7] (Fig. 2). Cell 1 is movable along the ground glass plate relative to cell 2. Balance of pressures of cells 1 and 2 was ascertained by using an oil-manometer. Pressure was measured with a mercury manometer. The cell constant of the apparatus, K, was determined by using the self-diffusion coefficient of carbon dioxide by Winn[8] as a standard.

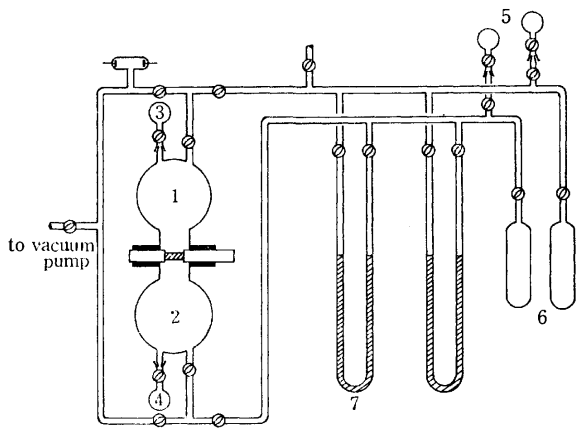

Fig. 2. Diffusion Apparatus:
1: upper cell, 2: lower cell, 3: upper sample holder, 4: lower sample holder, 5: sample holder, 6: gas holder, and 7: manometer.

Samples. Commercial neon gas of 99.99% purity (Mathison Co., U.S.A.) and commercial carbon dioxide gas of 99.95% purity (Nihon Tansan, Japan) were used without further purification. The isotope ratios of these gases are of natural abundance ratios. CO_2 gas was ^{18}O-enriched with the use of exchange reaction between $C^{16}O^{16}O$ and ^{18}O-enriched oxygen of 5% enrichment on the surface of a red-heated iron wire. The ^{18}O-enriched oxygen gas was obtained from commercial ^{18}O-enriched water by electrolysis.

Procedures. For measurement of the cell constant, the ^{18}O-enriched CO_2 gas was placed in cell 2 and natural CO_2 gas in cell 1 with the diffusion path between the two cells shut off by a glass plate. After the pressure of cell 1 was balanced to that of cell 2, cell 1 was shifted relative to cell 2 to open the diffusion path through the glass filter. A similar procedure was taken for the measurements of self-diffusion coefficients of CO_2 in a binary mixture of Ne and CO_2. All the experiments were carried out at 25°C under 760 mmHg. The diffusion apparatus was set in a vinyl sheet case installed in a temperature controlled room within 25±0.5°C. The diffusion time was about 100 minutes so that the ratio of M_t/M_∞ came up to one third. M_t and M_∞ stand for the amounts of diffusion at time t and infinity, respectively.

The composition of binary mixture of Ne–CO_2 system and the isotope ratio of ^{20}Ne and ^{22}Ne were determined by a mass spectrometer (Hitachi RM-60R). Accurate measurement of the isotope ratio of ^{20}Ne and ^{22}Ne in the mixture of Ne and CO_2 gases is disturbed by the coexisting CO_2, since the mass spectrometer does not distinguish $^{22}Ne^+$ ion from $^{44}CO_2^{2+}$ ion. To get rid of the disturbance it was necessary to remove CO_2 from the gas mixture with a cold trap of liquid nitrogen.

Results

The self-diffusion coefficients[9] of CO_2 for the binary system of Ne and CO_2 were measured for various compositions. The results are summarized in Table 1. The reciprocals of the self-diffusion coefficients of CO_2 are plotted in Fig. 3 as a function of the mole fraction of CO_2.

The variation of the isotope ratio of $^{22}Ne/^{20}Ne$ during interdiffusion of Ne and CO_2 was examined by considering the system as a ternary system of ^{22}Ne, ^{20}Ne, and $^{44}CO_2$. The results are given in Table 2 and plotted in Fig. 4, where M_t and M_∞ stand for the amounts of Ne diffusing into the CO_2 cell after time t, and infinite time, respectively, and R_i and R_t are the $^{22}Ne/^{20}Ne$ ratios at times zero and t, respectively. In Fig. 4 the circles show experimental results and the

9) "Self-diffusion coefficient" referred to in this paper is defined as the diffusion coefficient for diffusion in a homogeneous system where no chemical concentration gradient exists. The term is used for the diffusion coefficient not only in a pure system of a single component but also in a homogeneous multicomponent system. Thus, the intradiffusion coefficient defined by Albright and Mills (*J. Phys. Chem.*, **69**, 3120 (1965)) and McCarty and Mason (*Phys. Fluids*, **3**, 908 (1960)) is included in the definition of self-diffusion coefficient given above.

soild lines represent the theoretical values calculated by Eqs. (20a) and (20b) with the values of the self-diffusion coefficients of ^{20}Ne,^{22}Ne, and $^{44}CO_2$.

For calculation of the theoretical values, the self-diffusion coefficients of the respective components for the composition of 0.5 mole fraction of CO_2 were taken as average values. The self-diffusion coefficients of ^{20}Ne for the composition of 0.5 mole fraction of CO_2 was estimated by making use of Darken's relation

$$D = N_2D_1^* + N_1D_2^*$$

where D denotes the binary diffusion coefficient of

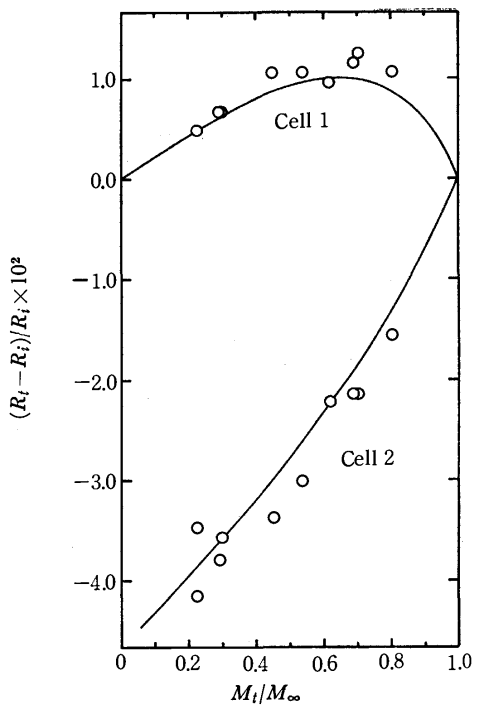

Fig. 4. Variation of isotope ratio $^{22}Ne/^{20}Ne$ during diffusion of a ternary system ^{20}Ne-^{22}Ne-CO_2 at 25°C and 760 mmHg.

the system of Ne and CO_2, D_1^* and D_2^* repersent the self-diffusion coefficients of Ne and CO_2, and N_1 and N_2 mole fractions of the components, respectively. Thus the self-diffusion coefficient of ^{20}Ne can be calculated since we have measured the self-diffusion coefficient of CO_2 and the interdiffusion coefficient of the binary system are known.[10] Estimation of the self-diffusion coefficient of ^{22}Ne was made by means of the mass correction

$$D(^{22}Ne) = \left(\frac{M_2+M_1}{M_2+M_3}\times\frac{M_3}{M_1}\right)^{1/2} D(^{20}Ne) \qquad (23)$$

where $D(^{22}Ne)$ denotes the self-diffusion coefficient of ^{22}Ne in the binary system of ^{22}Ne and $^{44}CO_2$, $D(^{20}Ne)$ the self-diffusion coefficient of ^{20}Ne in the binary system of ^{20}Ne and $^{44}CO_2$, and M_1,M_2, and M_3, the masses of ^{22}Ne, $^{44}CO_2$, and ^{20}Ne, respectively.

Discussion

A. Self-diffusion Coefficients. A kinetic theory gives the following relations between three kinds of diffusion coefficients:

$$\frac{1}{D_1^*} = \frac{N_1}{D_{11}} + \frac{N_2}{D_{12}}$$
$$\frac{1}{D_2^*} = \frac{N_2}{D_{22}} + \frac{N_1}{D_{12}} \qquad (24)$$

where D_1^* and D_2^* denote self-diffusion coefficients of species 1 and 2 for a binary mixture, D_{11} and D_{22} self-diffusion coefficients for the respective pure system, D_{12} an interdiffusion coefficient for the binary system,

10) B. K. Annis, A. E. Humphreys, and E. A. Mason, *Phys. Fluids*, **12**, 78 (1969).

and N_1 and N_2 mole fractions of the respective components. The equations show that the reciprocal of the self-diffusion coefficient of one component in a binary system are dependent linearly upon its mole fraction if the interdiffusion coefficient is independent of composition. The experimental results for CO_2 support the relation (Fig. 3). The data for the smaller mole fractions of CO_2 deviate from the straight line. This is probably due to the experimental error tending to be larger than that for the larger mole fraction of CO_2 because of the fact that the CO_2 content in the binary system is insufficient for accurate measurement of isotope ratios of $C^{16}O^{18}O/C^{16}O^{16}O$.

B. Isotope Separation in Ternary Diffusion. The agreement of the theoretically calculated variation of the isotope ratio $(R_t-R_i)/R_i$ with the experimental results indicates the validity of Eqs. (8).

Consequence of Eqs. (8), (20a), and (20b) with respect to the present isotope separation of neon shows that the greater the difference of self-diffusion coefficients of ^{22}Ne and ^{20}Ne, the higher the degree of isotope separation of neon, and that the smaller the self-diffusion coefficient of CO_2 that those of ^{22}Ne and ^{20}Ne, the greater the mass flow toward the neon side and the higher the degree of isotope separation of neon.

Kinetic theory predicts the mass dependency of the ratio of the self-diffusion coefficients:

$$\frac{D_1^*}{D_2^*} \propto \frac{(1/M_1+1/M_3)^{1/2}}{(1/M_2+1/M_3)^{1/2}} = \left(\frac{M_2}{M_1} \times \frac{1+M_1/M_3}{1+M_2/M_3}\right)^{1/2} \quad (25)$$

where M_i is the mass of i species.

Therefore, when M_3 is much larger than M_1 and M_2, the D_1^*/D_2^* ratio tends to approach the maximum value $(M_2/M_1)^{1/2}$, if M_2 is greater than M_1. Moreover, the large mass of the third component relative to ^{20}Ne and ^{22}Ne gives rise to its small self-diffusion coefficient and subsequently to the large mass flow, which is more effective for the purpose of the isotope separation of ^{20}Ne from ^{22}Ne. Consequently the larger separation factor can be obtained when the mass of the third component is larger than that of CO_2.

Photochemistry of Acridines. XVIII. Photoreduction by Nonpolar H-donors and the Disproportionation of C-Radicals

Mikio HOSHINO, Shigeya NIIZUMA, and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received February 18, 1972)

It was found that the photoreduction of acridine in cyclohexane and toluene occurs *via* molecular and radical mechanisms. The T-energy transfer experiments using biacetyl as an energy acceptor have revealed that the molecular mechanism occurs in the $T(n-\pi^*)$ state, and the radical in the singlet excited state. The effect of the addition of piperylene on the quantum yield of photoreduction was investigated in cyclohexane, methanol, ethanol and isopropanol. The results have been interpreted on the following assumptions. 1) Complete T-energy transfer from acridine to piperylene. 2) No quenching action of piperylene on the singlet excited acridine. 3) Complete transformation of C-radicals of acridine to stable products by piperylene. The results have led to the conclusion that the C-radical undergoes disproportionation in cyclohexane, methanol and ethanol, while it is completely transformed to an acridan-type compound in isopropanol.

Studies on the photoreduction of acridines have been made extensively,[1,4] but most of them dealt with photoreduction in various alcohols. We have investigated the kinetics of photoreduction in nonpolar H-donors such as cyclohexane and toluene. It has been established that both radical and molecular mechanisms occur in these solvents just as in alcoholic solvents.[4l] However, energy transfer experiments with the use of biacetyl have revealed that the radical mechanism occurs mainly in the singlet state while molecular mechanism, in the $T(n-\pi^*)$ state, in contrast to the case with alcoholic solvents.

We have tried using piperylene as a T-energy ac-

ceptor to confirm the above result. We found that the compound acts as a radical scavenger as well as T-energy acceptor which indicates that the C-radical in cyclohexane, ethanol and mehtanol undergoes disproportionation. The results with the latter two solvents are in complete agreement with our previous conclusion.[4m] In the case of isopropanol it was found that semiquinone is most likely reduced further to acridan by isopropanol or by the isopropyl radical.

In view of the present results and another unpublished one concerning φ_{ST}, the values of Φ_M^S, Φ_R^S, Φ_M^T, and Φ_R^T previtusly published[4i] have been criticized and corrected to some extent.

Experimental

Acridine was recrystallized twice from aqueous ethanol. Biacetyl was purified by distillation immediately before use. Piperylene used was a mixture of *cis*- and *trans*-forms, and was subjected only to distillation. Ethanol, cyclohexane, and isopropanol were purified by the usual method. Methanol, G. R. grade of Wako Junyaku was used without further purification. The apparatus and procedures were described previously.[4d,m]

Results and Discussion

Photoreduction of Acridine in Cyclohexane and Toluene.

Photoreduction of acridine in cyclohexane which occurs upon irradiation at 365 nm is distinct. In the couse of the reduction, gradual decrease of acridine peak at 356 nm and a well-defined isosbestic point at 320 nm were observed. The feature of the reaction is similar to that in alcohols, occurring both in the deaerated and aerated solutions. The product has an absorption peak at 278—279 nm which differs slightly from that of acridan dissolved in cyclohexane (a peak at 282~283 nm). It is likely that the product is a mixture of acridan and an acridan-type compound.

The kinetic runs, *i. e.*, the plots $\ln(10^D-1)$ *vs.* t always give good straight lines. From the slopes the quantum yields in the deaerated and aerated solutions were obtained as $\Phi_{dea}=0.14_4$—0.14_9 and $\Phi_{aer}=0.05_1$, respectively. These values are a little larger than those in methanol and ethanol. The contributions of the molecular and radical mechanisms are 35 and 65%, respectively, of the entire reaction.

To determine the contribution of singlet excited state and triplet n-π^* state to the molecular and radical mechanisms, the effect of the addition of biacetyl as a T-energy acceptor was examined. Experiments were carried out in the same way as in alcohols[4i] for both the aerated and deaerated solutions. They are given in Fig. 1. It is seen that the quantum yeild in the aerated solution Φ_M decreases remarkably with the increase in biacetyl concentration. Judging from the concentration of biacetyl, this quenching is mostly related to T(n-π^*). This is in sharp contrast to alcohol systems in which the molecular mechanism scarcely occurs or not at all in T(n-π^*).

It has been found that the radical mechanism is scarcely affected by the adition of biacetyl in this concentration region. As shown in Fig. 1, the calculated values for $(\Phi/\Phi_0)_{dea}$ fit fairly well the experimental ones on the assumption that only Φ_M is decreased by the above amount. It is thus concluded that the radical mechanism occurs mainly in the singlet excited state. This is also remarkable in view of our previous results where T(n-π^*) contributes to radical mechanism to some extent in the case of methanol and ethanol.[4i]

The photoreduction of acridine in cyclohexane occurs mainly according to the following scheme,

$$A \xrightarrow{h\nu} A^*(S) \xrightarrow{RH_2} AH\cdot + RH\cdot \rightsquigarrow \text{acridan or acridan-like compound}$$
$$A^*(S) \rightarrow A(T n\text{-}\pi^*) \xrightarrow{HR_2} \text{acridan-like compound}$$

The reason for such a difference between alcohols and cyclohexane is unknown at the present stage but it might possibly be related to the presence or absence of the OH group which interacts specifically with N of acridine. We thus carried out similar experiments to those above, replacing cyclohexane with toluene. The relative quantum yields for the aerated and deaerated solutions obtained as a function

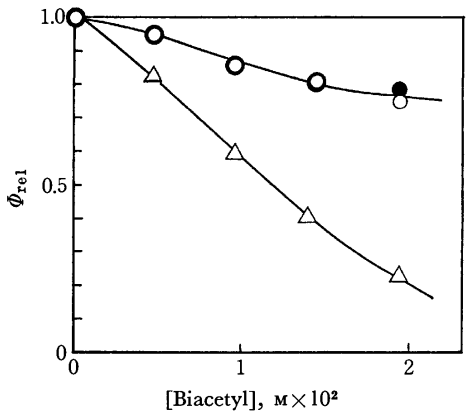

Fig. 1. Dependence of Φ_{rel} on biacetyl concentration for the aerated (Φ_M) and the deaerated ($\Phi_M+\Phi_R$) cyclohexane solutions.
△: Φ_M, ○: $\Phi_M+\Phi_R$, ●: ($\Phi_M+\Phi_R$)-values calculated on the assumption that Φ_R is not affected by biacetyl.

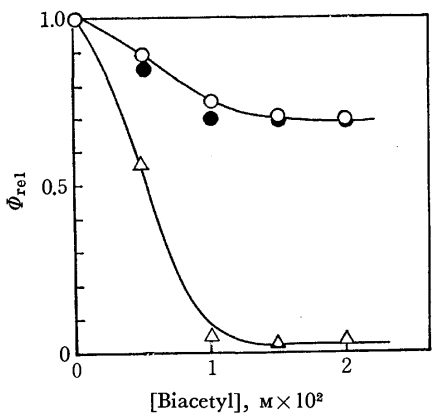

Fig. 2. Dependence of Φ_{rel} on biacetyl concentration for the aerated (Φ_M) and the deaerated ($\Phi_M+\Phi_R$) toluene solutions.
△: Φ_M, ○: $\Phi_M+\Phi_R$, ●: ($\Phi_M+\Phi_R$)-values calculated on the assumption that Φ_R is not affected by biacetyl.

of biacetyl concentration are given in Fig. 2. It is seen that biacetyl acts as a more effective quencher in aerated toluene than in aerated cyclohexane. This might be due to the difference in viscosity. All other results were much the same as those with cyclohexane. Thus we might say that in nonpolar solvents having no such group as OH, molecular mechanism does not occur in the singlet state but occurs in the T(n-π^*) state and that radical mechanism occurs mainly in the singlet state.

Reevaluation of the Values of Φ_M^S, Φ_R^S, Φ_M^T *and* Φ_R^T. Since these values were reported,[41] the values of $\Phi_R=\Phi_R^S+\Phi_R^T$ for ethanol and methanol were found to agree respectively with the quantum yeilds of oxygen consumption during the photoreduction of acridine in the aerated ethanol and methanol solutions,a reasonable interpretation being given. This confirmed the reliability of our values for $\Phi_R^S+\Phi_R^T$,[4m] but not of our individual values of Φ_R^S and Φ_R^T.

From recent measurements of the values of intersystem crossing probabilities of acridine in methanol, ethanol and isopropanol, our Φ_R^S and Φ_R^T values for ethanol appeared to be somewhat unreliable[5] and we reinvestigated our previous method. Taking ethanol as an example, the values of Φ_R^T,Φ_R^S and Φ_M^S (Φ_M^T is zero for ethanol) were determined in the following way from the plots given in Fig. 3. Φ_M^S was determined from the quantum yield of photoreduction in the areated solution. The value of $\Phi_M^S+\Phi_R^S$ was evaluated from the intercept of part b of the plot for the dearated solution. However, the slopes of part b of the Φ_0/Φ *vs.* [Biacetyl] plots (k_q) for the deaerated solutions in methanol, ethanol and isopropanol were always larger than the corresponding slopes of the aerated solutions. The latter agreed very well with the quenching constants of acridine fluorescence by biacetyl. We mentioned that somewhat larger values for the deaerated solutions might be due to participation of the T(n-π^*) state. From this viewpoint it would be more reliable to use the slopes of the aerated solutions and to calculate the $\Phi_M^S+\Phi_R^S$ value from the intercept of the dotted line shown in Fig. 3.[6] The recalculated values of Φ_M^S, Φ_R^S, Φ_M^T and Φ_R^T (italicized) are listed in Table 1 along with the old values.

The new values of Φ_M^S,Φ_R^S, and Φ_R^T for n-propanol and ethanol are about the same percentage of the Φ_{total}-value. Although the difference between the new and old values is not so great, except in the case of ethanol, and could be considered within experimental accuracy, most of the results, particularly for ethanol, might be well comprehended on the basis of the new data.

Effect of the Addition of Piperylene on the Photoreduction Quantum Yield in Cyclohexane. It is well-known that piperylene ($CH_3-CH=CH-CH=CH_2$) acts as a good T-energy acceptor.[7] Therefore in order to reconfirm the results obtained

	0.03 (35%)	0.058 (65%)	0	0	

5) It has been found that the apparent inconsistence is also due to another quite different fact.

6) From the Φ *vs.* [Biacetyl] plot, it seems appropriate to draw the dotted line from a point located in a p~q region. If it is drawn from the neighborhood of q, the Φ_R^T and Φ_R^S-values become about 10% smaller and greater, respectively.

7) G. H. Hammond, J. Salticel, A. A. Lamola, N. J. Turro, I. S. Bradshaw, D. O. Cowan, R. C. Counsell, V. Vogt and C. Datton, *J. Amer. Chem. Soc.*, **86**, 3197 (1964).

from the effect of the addition of biacetyl, we have made similar experiments using piperylene. It was confirmed that the spectral change and the $\ln(10^D-1)$ *vs.* t plots run just as in the absence of piperylene.

The effect, however, was found to be contrary to expectation. Thus the quantum yield does not decrease but increases with addition of piperylene both in the aerated and deaerated solutions (Fig. 4). The increase is especially remarkable for the deaerated solution, the Φ-value reaching 10^{-1} M piperylene about one and a half times the value in the absence of piperylene. The increase for the aerated solution is about 10%. Thus

Φ_{dea}(in the presence of piperylene)$=0.22$
Φ_{aer}(in the presence of piperylene)$=0.05_6$

as compared with

Φ_{dea}(in the absence of piperylene)$=0.146$
Φ_{aer}(in the absence of piperylene)$=0.051$

from which $\Phi_R=0.095$, $\Phi_M=0.051$

The above result for the deaerated solution may be interpreted in the following way. The concentration of piperylene is so high that the T-energy transfer from acridine to piperylene is considered to be practically complete. However, piperylene acts as a radical scavenger and the intermediate produced is stabilized most likely as follows,

$$AH\cdot + P \rightarrow AH-P\cdot \quad (1)$$

$$2AH-P\cdot \rightarrow (AH-P)_2$$

$$\text{or } AH-P\cdot + AH\cdot \rightarrow AH-P-AH \quad (2)$$

The essential point is that all the intermediates are stabilized without reconverting to acridine. If we assume that acridine semiquinone undergoes the following disproportionation as in the case of ethanol and methanol,[4m]

$$2AH \rightarrow A + AH_2\ , \quad (3)$$

then the addition of piperylene is expected to double the value of Φ_R^S. Hence the expected value of

Φ_{dea}(in the presence of piperylene)$=0.19$.

Taking the experimental error into account, the agreement is fairly satisfactory.

It is to be noted that two assumptions have been made:

1) the complete quenching of $T(n\text{-}\pi^*)$
2) no quenching action of piperylene on the singlet excited acridine.

The result for the aerated solution is difficult to explain, because the features of reaction seem to be very complicated. Firstly, much higher concentrations of piperylene than that of oxygen make the deactivation of $T(n\text{-}\pi^*)$ by piperylene predominant. Whether oxygen or piperylene acts as a deactivator does not matter as long as both act as simple deactivators. The complication may be caused by various types of reaction involving semiquinone. It is expected that competition occurs between reaction (1) and the following reaction

$$AH\cdot + O_2 \rightarrow A + HO_2\cdot \quad (4)$$

High concentrations of piperylene make reaction (1) more favorable. The intermediate produced by this reaction may also be attacked in part by oxygen;

$$AH-P\cdot + O_2 \rightarrow AH-P-O_2\cdot \quad (5)$$

and the product is expected to act as an oxidizing agent toward acridine semiquinone. Moreover radicals produced from cyclohexane will be oxidized to peroxy-radical which again acts as an oxidizing agent. Thus the eventual reactions consist of the recovery of acridine and the formation of an acridan-like compound. Quantitative treatment is far outside our scope. What we can say is only that the result is reasonable at least qualitatively on the basis of the above reasoning.

The value of $\Phi_{aer}=0.056$ is only about 30% of $\Phi_R\times 2=0.19$ which is expected if all the intermediates produced by reaction (1) undergo reaction (2).

Effect of the Addition of Piperylene on the Quantum Yield of the Photoreduction of Acridine in Methanol. In order to make clearer the reactions in the presence of piperylene and to confirm the assumptions made above, photoreduction in methanol has been investigated. The experiments and the analysis of the reuslts were made in the same way as in the case of cyclohexane.

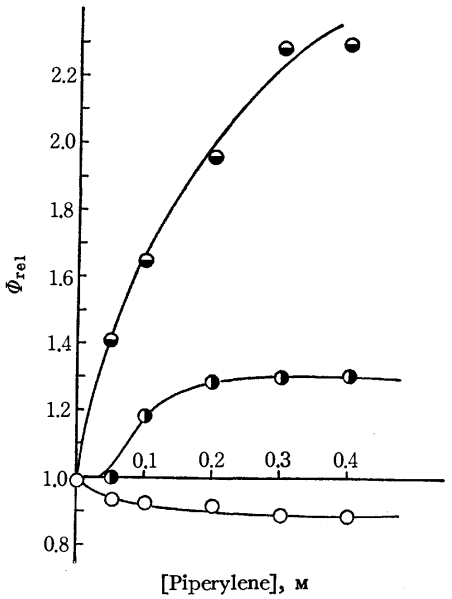

Fig. 5. Plot of Φ_{rel} *vs.* piperylene concentration in the aerated and deaerated solution of acridine in methanol.
◒: for the first stage, ◑: for the later stage } aerated.
○: deaerated.

For the aerated solutions, the plots $\ln(10^{+D}-1)$ *vs.* t consist of two steps, the slopes in the later stage being about 1/2 of those in the early one. This suggests the complicated nature of the entire reaction. It is more suitable to adopt the slopes in the early stage (up to about 15% decrease of acridine) because of the anticipated participation of the reaction products in the later stage. The results are shown in Fig. 5. It is seen that in contradistinction to the result for cyclohexane, a remarkable increase of Φ_{aer} occurs, *i. e.*, the Φ_{aer} value reaches 2.3 times that in the absence of piperylene. The value of Φ_{dea} decreases by about

10%. Thus

Φ_{dea}(in the presence of piperylene)$=0.115$
Φ_{aer}(in the presence of piperylene)$=0.07_6$

The value of Φ_{dea} is discussed as follows. According to our previous result,[4m] acridine semiquinone undergoes mainly disproportionation in methanol. It is likely as in cyclohexane that in the presence of piperylene, all the acridine semiquinone is stabilized to an acridan-like compound. If we further assume, as before, the complete quenching of $T(n\text{-}\pi^*)$ and no quenching action of piperylene on the singlet excited state of acridine, the values calculated using the data in Table 1 are

$\Phi_{dea}=0.32\times2+0.027=0.091$...with the new data
$\Phi_{dea}=0.039\times2+0.027=0.105$...with the old data

Both values agree with the experimental one within about twenty percent.

On the other hand, Φ_{aer}(in the presence of piperylene is 75—80% of the value expected on the assumption that reaction (2) overwhelms reaction (4) or other types of reaction recovering acridine.

Effect of the Addition of Piperylene on the Photoreduction of Acridine in Ethanol and Isopropanol. The results for ethanol are shown in Fig. 6. Thus

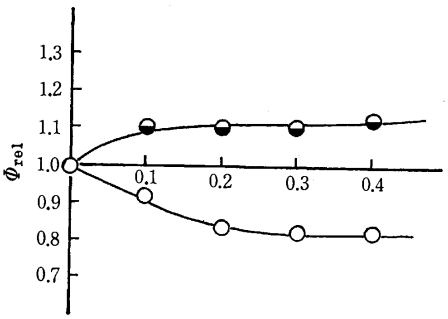

Fig. 6. Plot of Φ_{rel} *vs.* piperylene concentration in the aerated and deaerated solution of acridine in ethanol.
◒: aerated, ○: deaerated.

Φ_{dea}(in the presence of piperylene)$=0.10_7$
Φ_{aer}(in the presence of piperylene)$=0.04_7$

If we make the same assumptions as in the case of cyclohexane and methanol. Φ_{dea} is expected to be 0.129 with the new data but 0.177 with the old one. Thus the experimental value is about 20% less for the former.

The value of Φ_{aer} is about 30% of the value expected if reaction (2) overwhelms reaction (4) or similar oxidizing reactions.

The results for isopropanol are given in Figure 7. This system is considered to be simple in one sense because only singlet excited state participates in the reaction. From the plots given in Fig. 6.

Φ_{dea}(in the presence of piperylene)$=0.08_0$

But a reliable value of Φ_{aer} can not be obtained from the plot. In our previous paper,[4m] we could not make any conclusion about the behavior of acridine semiquinone in isopropanol. Hence it is quite unknown

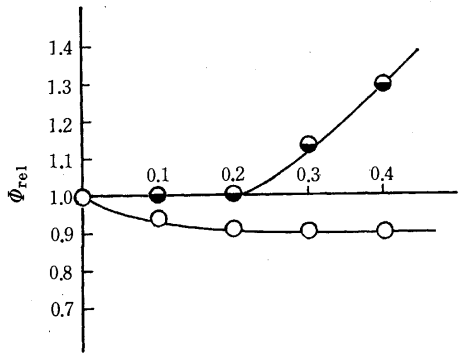

Fig. 7. Plot of Φ_{rel} *vs.* piperylene concentration in the aerated and deaerated solution of acridine in *iso*-propanol.
◒: aerated, ○: deaerated.

whether $2AH\rightarrow A+AH_2$ or $AH+RH\rightarrow AH_2+R$ or $AH+RH_2\rightarrow AH_2+RH$ occurs predominantly. If we assume that disproportionation is predominant, Φ_{dea} should reach $0.058\times2+0.03=0.15$ which exceedes very much the experimental value of Φ_{dea}. If one considers that for other alcohols and for cyclohexane the calculated values of Φ_{dea} (on the assumption of disproportionation of semiquinone) agree with the experimental Φ_{dea}-value within *ca.* 20%, the disagreement in the present case is too large to attribute it to the experimental error. It seems therefore more likely to consider that the reaction

$$AH + \text{isopropanol} \rightarrow AH_2 + (CH_3)_2C - OH$$
$$\text{or } AH + RH \rightarrow AH_2 + R \qquad (6)$$

mainly occurs in isopropanol. This is not unreasonable in view of the high reactivity of isopropanol. If we assume reaction (6), the experimental value of Φ_{dea} is about 10% less than the calculated one, $0.058+0.03=0.088$. This may be within experimental error, but one can safely say that even if piperylene deactivates singlet excited state the amount does not exceed 10% or so of Φ^S in isopropanol. The results for other solvents are consistent with this conclusion. Thus the second assumption made at the start has been substantiated to some extent.

In conclusion, we can say firstly that in nonpolar solvents with a hydrogen atom easily detachable, radical mechanism mainly occurs in the singlet excited state and molecular mechanism in $T(n\text{-}\pi^*)$. This may be due to the non-existence of a specific interaction between acridine and H-donor. Under such conditions, a two site reaction like molecular mechnaism may not be able to occur during the lifetime of singlet excited state. A little longer lifetime of $T(n\text{-}\pi^*)$ may be favorable for the occurrence of this mechanism in $T(n\text{-}\pi^*)$.

Secondly, the results obtained from the experiments concerning piperylene effects have led to the conclusion that in the case of methanol, ethanol and cyclohexane, the half-reduced radical of acridine mainly undergoes disproportionation while in the case of isopropanol it is highly probable that semiquinone is further reduced by isopropanol or by isopropyl radical.

Statistical Thermodynamics and Adsorption

Ralph J. TYKODI

Department of Chemistry, Southeastern Massachusetts University, North Dartmouth, Massachusetts 02747, U.S.A.

(Received November 12, 1971)

The proper correlation of thermodynamic quantities derived from experimental gas-solid adsorption systems with those derived from statistical mechanical models is discussed; the usual method of making the correlation is found to be unsatisfactory, and a new method is proposed.

The considerations of this paper apply to systems involving the physical adsorption of gases on solids.

In some treatments of the thermodynamics of gas-solid adsorption[1,2] the change of pertinent bulk (not merely surface) properties of the solid component with amount adsorbed is an important feature of the development. It is not customary, however, in the usual statistical mechanical treatments of gas-solid adsorption explicitly to allow for changes in the bulk properties of the solid component.[3] Given that the macrothermodynamic considerations of references 1 and 2 are correct, should not the usual statistical mechanical procedure be mended so as to allow for, at least implicitly, changes in the bulk properties of the solid component?

A Special Case

In order to show clearly the issues involved, let us first examine the special case of an ideal localized monolayer.[4] Consider an enclosure containing a solid component and a gas component, with N_A of the gas molecules adsorbed on the surface of the solid. For purposes of discussion attribute to the solid surface a site structure and consider the ideal localized monolayer adsorption of the N_A molecules on N_S sites.

Represent the (Helmholtz) free energy of the solid component *in vacuo* as

$$F^{\circ}_{sol(id)} = F^{\circ}_{b(ulk)} + F^{\circ}_{sur(face)}, \tag{1}$$

and with N_A molecules adsorbed on its surface as

$$F_{sol} = F_b + F_{sur}. \tag{2}$$

We can then write for the total free energy of the enclosure

$$F_{tot(al)} = F_b + F_{gas} + F_{mix}, \tag{3}$$

where F_{gas} is the free energy contribution of the unadsorbed gas molecules and F_{mix} is the contribution of the "mixture" of N_A adsorbed molecules and N_S sites. We can now define an excess free energy F_f by

$$F_f \equiv F_{tot} - F_{gas} - F^{\circ}_{sol} = F_{mix} - F^{\circ}_{sur} + F_b - F^{\circ}_b. \tag{4}$$

We find[2,3] that F_f is expressible as

$$F_f = \mu N_A - \phi A, \tag{5}$$

where $\mu \equiv (\partial F_f/\partial N_A)_{T,A}$ is the chemical potential of an adsorbed molecule, A is the surface area of the solid, and $\phi \equiv -(\partial F_f/\partial A)_{T,N_A}$ is commonly called the spreading pressure.

Now the statistical mechanical free energy F of the assembly of N_A molecules adsorbed on N_S sites in just[3]

$$F = -kT \ln Q_{ads}, \tag{6}$$

$$Q_{ads} = \frac{N_S!}{(N_S - N_A)!\,N_A!} e^{N_A\chi/kT} j^S(T)^{N_{Ac}}, \tag{7}$$

where Q_{ads} is the partition function for the adsorbed monolayer, $j^S(T)$ is the partition function for the internal degrees of freedom of an adsorbed molecule (including vibrations relative to its mean position on a site), and $(\pm)N_A\chi$ may be viewed either $(+)$ as a minimum energy required to desorb the N_A molecules and carry them to the gas state at infinite separation or $(-)$ as the potential energy of the N_A asdorbed molecules relative to the gas state at infinite separation.[3,5]

The very crux of the matter is that investigators dealing with the statistical mechanics of gas-solid adsorption customarily assert that

$$F^{(1)} \equiv F_{mix} - F^{\circ}_{sur} = F_f, \tag{8}$$

$$F_b - F^{\circ}_b = 0, \tag{9}$$

$$\phi A \equiv F^{\circ}_{sol} - F_{sol} = F^{\circ}_{sur} - F_{sur}; \tag{10}$$

and consequently also that

$$(\partial F^{(1)}/\partial N_A)_{T,A} = \mu, \tag{11}$$

$$-(\partial F^{(1)}/\partial A)_{T,N_A} = \phi. \tag{12}$$

(The index on F merely shows that this is the first of several assertions about the relationship of F to F_f.)

At this point a brief digression concerning the structure of Eq. (5) will prove instructive. Although Eq. (5) is a thermodynamic identity, it is nevertheless possible to produce equations of the same general form, also identities, but subject to different interpretation. For any equation of the form

$$F_*{}^{(k)} \equiv F_f + Af_*{}^{(k)}(T, N_A/A), \tag{13}$$

where $f_*{}^{(k)}(T, N_A/A)$ is an arbitrary function of the indicated arguments, it follows that

$$F_*{}^{(k)} = N_A(\partial F_*{}^{(k)}/\partial N_A)_{T,A} + A(\partial F_*{}^{(k)}/\partial A)_{T,N_A} \tag{14}$$

holds identically. Since Eq. (14) has the same general form as Eq. (5), we may, if we wish, write it as

$$F_*{}^{(k)} = \mu^{(k)} N_A - \phi^{(k)} A, \tag{15}$$

with $\mu^{(k)} \equiv (\partial F_*{}^{(k)}/\partial N_A)_{T,A}$ and $\phi^{(k)} \equiv -(\partial F_*{}^{(k)}/\partial A)_{T,N_A}$. Equations (13)—(15) point up a possible pitfall in the sort of work that we are discussing: we might find ourselves in possession of a free energy such as $F_*{}^{(k)}$

1) T. L. Hill, *J. Chem. Phys.*, **18**, 246 (1950).
2) R. J. Tykodi, *ibid.*, **22**, 1647 (1954).

4) *ibid.*, pp. 426 and 427.
5) T. L. Hill, *J. Chem. Phys.*, **17**, 762 (1949).

and, having determined that the functional relationship (14) holds, we might be tempted to conclude that we are dealing with Eq. (5)—clearly such need not be the case, and in general $\mu^{(k)} \neq \mu$ and $\phi^{(k)} \neq \phi$.

Returning now to the case of the ideal localized monolayer, note that the assertions (8)—(10) are not simple deductions from Eqs. (4), (6), and (7). In order to investigate the matter more closely, let us express F as $F=E-TS$ and $F^{(i)}$ as $F^{(i)}=E^{(i)}-TS^{(i)}$; then it follows from Eq. (6) that

$$F = -N_A\chi + E_{int} - TS_{config} - TS_{int}, \tag{16}$$

where S_{config} is the configurational entropy deducible from the factorial part of Q_{ads} and E_{int} and S_{int} are, respectively, those parts of E and S deducible from the $j^s(T)^{N_A}$ portion of Q_{ads}.

Suppose first that $-N_A\chi$ represents a change in energy for the process

N_A gas molecules at infinite separation + bare solid component → N_A molecules adsorbed on the solid component;

i.e., suppose that

$$-N_A\chi = E_{mix} + E_b - E^0_{sol} - E^0_{gas}, \tag{17}$$

where E^0_{gas} is the energy (potential energy plus that due to internal degrees of freedom) of N_A gas molecules at infinite separation. In addition let the zero of (potential) energy be chosen in such a way that the potential energy of N_A gas molecules at infinite separation is zero. Under the assumptions operative in the case of ideal localized monolayer adsorption[3,5] it then follows that $E^0_{gas}=E_{int}$.

From Eqs. (16) and (17) we see that

$$F^{(2)} = E_{mix} + E_b - E^0_{sol} - TS_{config} - TS_{int}. \tag{18}$$

Since $S_{mix} \equiv S_{config}+S_{int}+S_{sur}$, we may express Eq. (18) as

$$F^{(2)} = F_{mix} + TS_{sur} - E^0_{sol} + E_b; \tag{19}$$

and, with some further manipulation, we may reduce it to the form

$$F^{(2)} = F_{mix} - F^0_{sur} + F_b - F^0_b + T(S_{sol}-S^0_{sol}). \tag{20}$$

Referring back to Eq. (4) we see that under the present assumptions

$$F^{(2)} = F_f + T(S_{sol}-S^0_{sol}); \tag{21}$$

i.e., the statistical mechanical free energy $F^{(2)}$ fails to take into account possible changes in the entropy content of the solid component with varying amounts adsorbed.

Suppose next, in Eq. (16), that a different interpretation is given to the term $-N_A\chi$. Let $-N_A\chi$ now be considered as representing a form of (potential) energy associated (merely by convention) with the adsorbed molecules alone; *i.e.* suppose that

$$-N_A\chi = E_{mix} - E_{int} - E_{sur}. \tag{22}$$

Substituting from Eq. (22) into Eq. (16), we obtain

$$\begin{aligned} F^{(3)} &= E_{mix} - E_{sur} - TS_{config} - TS_{int} \\ &= F_{mix} - F_{sur}. \end{aligned} \tag{23}$$

Referring back to Eq. (4), we note that Eq. (23) can be written as

$$F^{(3)} = F_f - (F_{sol}-F^0_{sol}) = F_f + \phi A. \tag{24}$$

Thus the statistical mechanical free energy $F^{(3)}$ fails to take into account possible changes in the free energy content of the solid component with varying amounts adsorbed.

(The preceding material relating to $F^{(2)}$ and $F^{(3)}$, shows that *contrary to expectation* $F^{(i)} \neq F_f$ $(i=2,3)$ and that the reason for $F^{(i)} \neq F_f$ is the indicated one in each case.)

Since we usually assume the $\phi=\phi(T,N_A/A)$, we see that Eq. (24) is of the general form of Eq. (13); consequently the relation

$$\begin{aligned} F^{(3)} &= N_A(\partial F^{(3)}/\partial N_A)_{T,A} + A(\partial F^{(3)}/\partial A)_{T,N_A} \\ &= \mu^{(3)}N_A - \phi^{(3)}A, \end{aligned} \tag{25}$$

where $\mu^{(3)} \equiv (\partial F^{(3)}/\partial N_A)_{T,A}$ and $\phi^{(3)} \equiv -(\partial F^{(3)}/\partial A)_{T,N_A}$, holds identically.

A relation similar to (25) would hold in the case of $F^{(2)}$ also, provided we could show that $T(S_{sol}-S^0_{sol}) = Af_*^{(2)}(T,N_A/A)$.

General Considerations

The foregoing considerations pose a serious problem for the comparison of statistical mechanical models with experimental adsorption systems. In the experimental case we deal with quantities such as μ, ϕ, F_f, S_f, *etc.* and with relations between such quantities —hereafter called *proper quantities* and *proper relations*—; whereas in the statistical mechanical case we produce quantities such as $\mu^{(i)}$, $\phi^{(i)}$, $F^{(i)}$, $S^{(i)}$, *etc.* and relations between such quantities—hereafter called *eikonic quantities* and *eikonic relations*. There would be no problem if we found that the assertions of Eqs. (8)—(12) hold true; however, in view of the considerations advanced in references 1 and 2 and in view of experimental results such as those of Yates[6,7] (*e.g.*), the assertions of Eqs. (8)—(12) appear to be untenable.

It appears then that the usual statistical mechanical treatment of the physical adsorption of gases on solids (whether couched in terms of ordinary or grand partition functions) always produces eikonic quantities and relations rather than proper ones, the exact nature of the eikonic quantities depending upon how the various parts of $E^{(i)}$ are interpreted. The notation $F^{(i)}$ in this section is used to denote the free energy derived from *any statistical mechanical model whatsoever* in which —speaking somewhat loosely— the "energy of the adsorbed molecules" is interpreted in the same manner as the term $-N_A\chi$ was interpreted in the discussion of the ideal localized monolayer. The conventional statistical mechanical treatments of gas-solid adsorption, therefore, fail to consider either (a) changes in the entropy content or (b) changes in the free energy content of the solid component with varying amounts adsorbed; and so, unwittingly, in the past, we have been led to compare theoretical eikonic quantities with experimental proper ones —the correct procedure is to make a comparison either on an eikonic-eikonic or on a proper-proper basis *via* suitable equations of transformation.

6) D. J. C. Yates, *Proc. Roy. Soc., Ser. A*, **224**, 526 (1954).
7) D. J. C. Yates, *J. Phys. Chem.*, **60**, 543 (1956).

It appears that the statistical mechanical work to date has produced statistical free energies $F^{(3)}$ and associated eikonic quantities and variables, in that most treatments of gas-solid adsorption take the quantity analogous to $-N_A\chi$ as being the potential energy of interaction of the adsorbed molecules with the solid component, this potential energy of interaction being conventionally treated as a property of the assembly of adsorbed molecules. As we saw previously, such a treatment leads to free energies of the type $F^{(3)}$.

In the remainder of this paper we will therefore limit our attention to $F^{(3)}$ and related eikonic quantities, with no further mention of $F^{(2)}$.

The comparison of statistical mechanical models with experimental gas-solid adsorption systems may proceed along either of two different lines: (a) we may transform the proper quantities and relations derived from the experimental data to appropriate eikonic quantities and relations by means of suitable equations of transformation and so compare them to the eikonic quantities and relations generated from $F^{(3)}$ by standard methods; or (b) we may attempt to win from the statistical mechanical model proper quantities and relations and compare these directly with the proper quantities and relations derived from experiment. Procedure (a) is a relatively easy and mechanical procedure; whereas procedure (b) can be exceedingly difficult to put into practice.

At this point let us drop the uncomfortable formalism (bulk properties, surface properties, *etc.*) thus far developed, and carry on the remainder of the discussion in terms of the molar macroscopic thermodynamic formalism established in reference 2.

For purposes of orientation note that the Gibbs adsorption is written as

$$\mu_f = -\boldsymbol{R}T\int_0^P X d\ln P, \tag{26}$$

where μ_f is the change in the chemical potential of the solid component due to the adsorption process and $X \equiv \Gamma/n_s$ is the adsorption excess (in terms of moles of gas component) per mole of solid. Integral molar excess properties are indicated by a superior bar and differential molar excess properties by a superscript partial differential operator; thus

$$Z_f^{\partial} \equiv (\partial Z_f/\partial\Gamma)_{T,n_s} = \bar{Z}_f + X(\partial\bar{Z}_f/\partial X)_T. \tag{27}$$

The change in a molar property for an adsorption process

$$i(\text{gas}) \rightarrow i(\text{adsorbed})$$

is written as $\Delta\bar{Z} \equiv \bar{Z}_f - \bar{Z}_g$; thus, the integral molar heat of adsorption $Q \equiv \bar{H}_f - \bar{H}_g$, according to this convention, is normally a *negative* quantity. For convenience functions appropriate to processes at constant μ_f —*isomunal* processes— are defined; in reference 2, script capital letters were used to designate these special functions; in this paper they are designated by means of square brackets, which thus correspond to the script capital symbols in reference 2. As an example, note that the ordinary integral molar heat of adsorption is related to the isomunal integral molar heat of adsorption by the equation

$$\Delta[H] \equiv \Delta\bar{H} - (\mu_f/X). \tag{28}$$

Eikonic Relations

In terms of the present notation[8] we would write relation (13) as

$$F_*^{(k)} \equiv F_f + n_s f_*^{(k)}(T, X); \tag{29}$$

correspondingly, the identity (14) would appear as

$$F_*^{(k)} \equiv \Gamma(\partial F_*^{(k)}/\partial\Gamma)_{T,n_s} + n_s(\partial F_*^{(k)}/\partial n_s)_{T,\Gamma} \tag{30}$$

and the form (15) as

$$F_*^{(k)} = \Gamma\mu_g^{(k)} + n_s\mu_f^{(k)}, \tag{31}$$

with $\mu_g^{(k)} \equiv (\partial F_*^{(k)}/\partial\Gamma)_{T,n_s}$ and $\mu_f^{(k)} \equiv (\partial F_*^{(k)}/\partial n_s)_{T,\Gamma}$.

For convenience let us write $\mu_g^{(k)}$ as

$$\mu_g^{(k)} = \mu^{\dagger}(T) + \boldsymbol{R}T\ln P^{(k)} \tag{32}$$

and refer to $P^{(k)}$ as the eikonic pressure; we may call a relation such as $P^{(k)} = P^{(k)}(T,X)$ an eikonic isotherm relation. Of course eikonic quantities and variables are merely mathematical constructs and are related to the proper experimental quantities and variables by suitable equations of transformation.

The proper equilibrium condition for gas-solid adsorption systems is[2]

$$\mu_g = G_f^{\partial} \equiv [G_f]. \tag{33}$$

The corresponding eikonic relations are

$$F^{(3)} = G_f - n_s\mu_f, \tag{34}$$

$$\mu_g^{(3)} = (G_f - n_s\mu_f)^{\partial}. \tag{35}$$

The following transformation relations hold between proper variables and the corresponding eikonic variables:

$$X^{(3)} = X, \tag{36}$$

$$T^{(3)} = T, \tag{37}$$

$$\mu_g^{(3)} = \mu_g - (\partial\mu_f/\partial X)_T, \tag{38}$$

$$\mu_f^{(3)} = X(\partial\mu_f/\partial X)_T. \tag{39}$$

Equations (26), (32), (38), and the perfect gas assumption lead to the relations

$$\ln(P^{(3)}/P) = (\partial\ln P/\partial\ln X)_T, \tag{40}$$

$$q_{st}^{(3)} = q_{st} - (\partial\mu_f/\partial X)_T + T(\partial^2\mu_f/\partial T\partial X), \tag{41}$$

$$Q^{(3)} = Q - (\mu_f/X) + TX^{-1}(\partial\mu_f/\partial T)_X = q_{st}, \tag{42}$$

where q_{st} is the proper isosteric heat of adsorption, Q is the proper integral molar heat of adsorption, and

$$q_{st}^{(3)} = -\boldsymbol{R}T^2(\partial\ln P^{(3)}/\partial T)_X,$$

$$Q^{(3)} = X^{-1}\int_0^X q_{st}^{(3)} dX(\text{constant } T).$$

Let us here introduce molar eikonic integral and differential quantities which are related to the proper quantities of the adsorption system in the following way:

$$\bar{G}_f^{(3)} = [G_f], \tag{43}$$

$$\bar{H}_f^{(3)} = [H_f] + TX^{-1}(\partial\mu_f/\partial T)_X, \tag{44}$$

$$\bar{S}_f^{(3)} = \bar{S}_f + X^{-1}(\partial\mu_f/\partial T)_X, \tag{45}$$

and

$$\{Z_f^{(3)}\}^{\partial} \equiv (\partial Z_f^{(3)}/\partial\Gamma)_{T,n_s} = \bar{Z}_f^{(3)} + X(\partial\bar{Z}_f^{(3)}/\partial X)_T \tag{46}$$

for any extensive property Z. The additional relations

8) In passing, note that $E_f \equiv H_f$ and $F_f \equiv G_f$ because of the way in which the adsorption excesses are defined (see Ref. 2).

$$\bar{H}_g^{(3)} = \bar{H}_g, \tag{47}$$

$$\bar{S}_g^{(3)} = \bar{S}_g + T^{-1}(\partial\mu_f/\partial X)_T, \tag{48}$$

follow from Eq. (38) and the perfect gas assumption. Now a little calculation will show that

$$q_{st}^{(3)} = \{H_f^{(3)}\}^\partial - \bar{H}_g^{(3)}, \tag{49}$$

$$q_{st}^{(3)}/T = \{S_f^{(3)}\}^\partial - \bar{S}_g^{(3)}, \tag{50}$$

$$Q^{(3)} = \bar{H}_f^{(3)} - \bar{H}_g^{(3)}, \tag{51}$$

$$Q^{(3)}/T = \bar{S}_f^{(3)} - \bar{S}_g^{(3)} + (\mu_f^{(3)}/TX). \tag{52}$$

A consequence of Eqs. (36)—(39), (43)—(48), and the definitions

$$[H_f^{(3)}] \equiv \bar{H}_f^{(3)} - (\mu_f^{(3)}/X), \tag{53}$$

$$[G_f^{(3)}] \equiv [H_f^{(3)}] - T\bar{S}_f^{(3)}, \tag{54}$$

is that *all the thermodynamic identities of reference 2 remain valid when the proper quantities and variables in each equation are replaced by the corresponding eikonic quantities and variables.*

Isotherm Relations

Let us investigate some of the simpler relations between proper and eikonic isotherm equations, basing our considerations chiefly on Eq. (40). Consider the twin problems (a) Given the form of the proper isotherm deduce from it the eikonic isotherm and (b) Given the form of the eikonic isotherm deduce from it the proper isotherm.

From the proper isotherm relations

$$P = kX^\nu \text{ (Freundlich)}, \tag{55}$$

$$bP = X/(X_m - X) = \theta/(1-\theta) \quad \text{(Langmuir)}, \tag{56}$$

with $\theta \equiv X/X_m$, we obtain by means of Eq. (40) the relations

$$P^{(3)} = Pe^\nu = k^{(3)}X^\nu, \tag{57}$$

$$bP^{(3)} = bP\exp\{1/(1-\theta)\} = \{\theta/(1-\theta)\}\exp\{1/(1-\theta)\}. \tag{58}$$

Thus Freundlich-type isotherms (of which Henry's law isotherms are a special case) remain formally invariant under the transformation; whereas Langmuir isotherms become changed somewhat in form.

The inverse case for the Langmuir isotherm is a good deal more peculiar. From the relation

$$bP^{(3)} = \theta/1-\theta \tag{59}$$

and Eq. (40) it follows that

$$bP = \{\theta/(1-\theta)\}(1-\theta)^{1/\theta}\exp(-K/\theta), \tag{60}$$

where K is an arbitrary constant. The rather bizarre relation (60), which implies a finite pressure for $\theta=1$, is simply a consequence of the fact that $F^{(3)} \neq F_f$.

First Order Phase Changes

Statistical mechanical considerations[3] indicate that first order phase changes should be possible in theoretical gas-solid adsorption systems. In some previous work[2,9] it was argued that first order phase changes in experimental gas-solid adsorption systems are thermodynamically unlikely. We can reconcile the apparent discrepancy between the preceding two conclusions if we consider that the statistical mechanical deductions pertain to *eikonic* relations rather than to *proper* relations.

In experimental adsorption systems we assume that a first order phase change occurs when $(\partial X/\partial P)_T=\infty$ or, equivalently, when $(\partial P/\partial X)_T=0$ or $(\partial \ln P/\partial X)_T=0$. Now these statistical mechanical considerations[3] merely imply that $(\partial \ln P^{(3)}/\partial X)_T=0$ and not that $(\partial \ln P/\partial X)_T=0$ (eikonic interpretation of statistical mechanical procedures).

We see from Eq. (40) that

$$\left(\frac{\partial \ln P^{(3)}}{\partial X}\right)_T = \frac{1}{X}\frac{\partial}{\partial X}\{X^2(\partial \ln P/\partial X)_T\}. \tag{61}$$

The condition $(\partial \ln P^{(3)}/\partial X)_T=0$ then leads to the relation

$$\ln P = -L_m(T)X^{-1} + M_m(T), \tag{62}$$

where L_m and M_m are constants of integration and the subscript m allows for the possibility that the condition $(\partial \ln P^{(3)}/\partial X)_T=0$ may be satisfied at several different points on the adsorption isotherm.

In the case of the eikonic interpretation of $F^{(3)}$ the condensation type phenomena predicted by theory will probably produce smooth, rolling bumps in the *proper* adsorption isotherm;[10,11] in the regions where the theoretically predicted "phase changes" take place the proper isotherm relation will satisfy Eq. (62).

In statistical mechanical discussions of first order phase changes in gas-solid adsorption systems we may retain all those thermodynamic relations developed for such changes[2] provided we understand that they deal in the statistical mechanical case with *eikonic* quantities and variables; *e.g.* during the "phase change" $\delta\mu_f^{(3)}=0$ (and not $\delta\mu_f=0$).

Eikonic Programming

The foregoing considerations indicate that in the construction of partition functions for various statistical mechanical models of gas-solid adsorption systems we must have clearly in mind the type of statistical free energy —Eq. (8), (21), or (24)— that we expect to generate. Whereas in the past free energies $F^{(3)}$ were produced by ignoring possible variations in the properties of the solid component with changing amounts adsorbed, we can make such a procedure a well-defined technical operation, an operation to which the name *eikonic programming* will be attached. Under the eikonic programming procedure we would concern ourselves only with the energetic behavior of the gas component, treating the solid component as merely the source of the requisite potential field, and we would *deliberately* ignore the changes in the properties of the solid concomitant with the adsorption process. We would then derive eikonic quantities and variables from the eikonic programming free energy $F^{(3)}$ by the usual methods, and we would either (a) convert such eikonic quantities and variables into proper ones by means of Eqs. (34), (36)—(39), (43)—(48), (53), and (54) (also see below) in order to compare them to the proper quantities and variables of experimental adsorption systems or (b)

9) R. J. Tykodi, *J. Phys. Chem.*, **59**, 383 (1955).

10) R. A. Beebe and D. M. Young, *ibid.*, **58**, 93 (1954).

11) J. H. Singleton and G. D. Halsey, Jr., *ibid.*, **58**, 1011 (1954).

convert the proper quantities and variables of experimental adsorption systems into eikonic ones by means of the appropriate equations of transformation and compare the experimental eikonic quantities to those derived from the statistical mechanical model.

Under an eikonic programming procedure the comparison of theory with experiment is relatively easy. From Eq. (34) and section 2 of reference 2 it follows that

$$F^{(3)} = \Gamma\mu_g; \tag{63}$$

so in order to establish the *proper* isotherm appropriate to the theoretical model we need merely set $F^{(3)}/\Gamma$ equal to the chemical potential in the gas phase. Of course if we wish, we may derive the *eikonic* isotherm from the relation $(\partial F^{(3)}/\partial\Gamma)_{T,n_s} = \mu_g^{(3)}$. *Another attractive feature of the eikonic programming procedure is that eikonic integral molar quantities are identical with proper differential molar quantities,*[12] *i.e.* $\bar{Z}_f^{(3)} \equiv Z_f^{\ominus}$. *Thus in discussing the entropy or the heat capacity of the adsorbed molecules we should compare the appropriate integral molar (eikonic) properties of the theoretical model with the differential molar (proper) properties of experimental adsorption systems.*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 2997—3002 (1972)

The Catalytic Exchange of Hydrogen-Deuterium on Copper-Nickel Alloy Plates after Various Surface Treatments

Yoshio TAKASU and Toshiro YAMASHINA

Department of Nuclear Engineering, Hokkaido University, Sapporo

(Received October 13, 1971)

The catalytic activities of nine copper-nickel alloys (5 cm^2 in area) in hydrogen-deuterium exchange were examined at 1.5 Torr partial pressures of hydrogen and deuterium, using an ultra-high vacuum apparatus incorporated with an omegatron mass spectrometer for continuous gas analysis. Without any surface treatment, the activity was greatest on pure nickel, decreased gradually as the content of copper in the alloys increased and virturally vanished in the alloys containing copper more than 70%. The activity of each alloy sample was observed to be extremely enhanced by a slight surface treatment of oxidation-reduction (P_{O_2}=2.3 Torr at 500°C for 1 min, P_{H_2}=16 Torr at 300°C for 2 hr). The activity of the 85% copper alloy after the oxidation-reduction treatment was greatest, one hundred times that of pure nickel. Annealing for a short time in an ultra-high vacuum subsequent to the oxidation-reduction treatment caused the catalytic activity to decrease abruptly at a critical temperature (425°C). On the bases of the electron microscopic observations and the measurement of the surface roughness changed by the pre-treatments, the nature of active sites on copper-nickel alloys was discussed.

A number of investigations have been undertaken in order to confirm the influence of the electronic structure of alloys, particularly the copper-nickel system, on catalytic activity since the proposal of the *d*-band theory by Dowden and Reynolds.[1,2] In recent investigations of this subject, vacuum evaporated alloy films have frequently been used because they are capable of producing clean surfaces by adaptation to ultra-high vacuum conditions. However, there have been pronounced discrepancies of the catalytic activity patterns in the experimental results reported for copper-nickel alloy catalysts.

A series of papers by Sachtler and his co-workers[3-5] have reported that the activity pattern for benzene hydrogenation showed a constant activity in overall compostion; this is in agreement with the expectation from the work function measurement and also from the thermodynamical fact that the surface compositions of the copper-nickel system should be the same in most of the overall alloy composition region due to the miscibility gap of the system at 200°C. In contrast to these results, many investigators, including Russell,[6] Emmett,[7] and Takeuchi[8] have reported, in similar studies of copper-nickel film catalysts, that the maximum of catalytic activity for the hydrogenation reaction is found in the alloy region, and that it is approximately ten times as active as pure nickel. Particularly, Campbell and Emmett,[7] in their X-ray measurement of film structure, found only one alloy phase containing 60% copper in any case after heating to 500°C in hydrogen; nevertheless they also observed the maximum activity in the alloy region.

These facts suggest that the catalytic activity does not always correspond to the composition of the alloy film. Several possible reasons for the discrepancies in the experimental results for alloy-film catalysts can be considered, as has, for example, been pointed out by Plank and Sachtler.[5]

Many findings have shown that the catalytic activity of film, foil, or metal plate and alloy plate can be greatly influenced by the treatment of their surfaces.

In the study of catalysis by metals and alloys, increased in activity due to deformation with cold-rolling and ion-bombardment have been found. Results have been obtained for nickel[9-12] and silver[13] by plastic deformation, and for nickel,[14,15] platinum,[14] silver,[16] palladium[17] and copper-nickel alloys,[15,18] by ion-bombardment. In these studies, most of the authors have considered that increases in activity may be attributed to the introduction of lattice imperfections by the treatments. In the cases of the catalytic behaviour of alloy films, as reviewed above, lattice imperfections as active sites should be taken into consideration, since it is well known that various imperfections can be produced in films during evaporation.

We have previously studied[18] the catalysis for the clean surfaces of copper-nickel alloy plates after argon-ion bombardment in the reaction of ethylene hydrogenation, and found that the maximum activity of the 60% copper alloy was the greatest, fifteen times greater than that of pure nickel; we explained the activity increases in association with the formation of the lattice defects due to the removal of copper atoms, which are nearest neighbors of the nickel atoms.

The purpose of the present study was to obtain more detailed information on the nature of active sites of the copper-nickel alloy surface by means of various experimental techniques, and to compare these information with the results described above.

By using an ultra-high vacuum apparatus, the surfaces of copper-nickel alloy plates have been treated by oxidation-reduction, hydrogen reduction, annealing and so on, and the catalytic activity for hydrogen-deuterium exchange at low pressures has been measured as a function of the copper-nickel alloy composition.

Experimental

Materials. High-purity nickel (>99.9%) and copper (>99.99%), and nine copper-nickel alloys with compositions of 95,90, 85, 80, 60, 40, 30, 20, and 10 weight per cent copper have been investigated. Each sample was about 0.6 mm in thick and 4.8 cm^2 in total surface area. These samples were polished with metallographic emery paper, an aqueous suspension of alumina, and then with fine cloth in streaming water, and rinsed in distilled water and acetone. Gaseous reactant hydrogen and deuterium of a high purity in a glass cylinder from the Takachiho Chemical CO. were used without further purification. The oxygen and argon gases were prepared by bulb-to-bulb distillation from commerical cylinders at the temperature of liquid nitrogen.

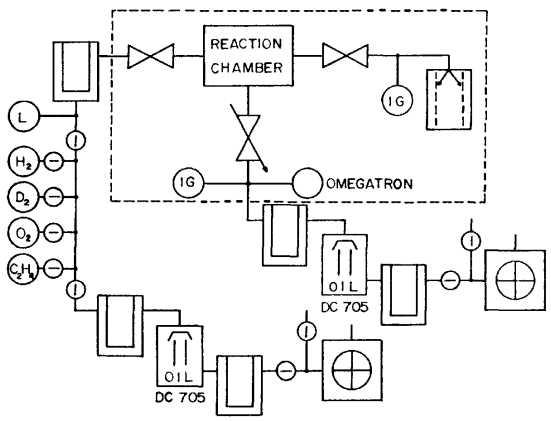

Fig. 1. Ultra-high vacuum apparatus for catalytic measurement (The inside part of dotted line is bakable).

Catalytic Activity. The main features of the vacuum apparatus for catalytic activity measurements are shown schematically in Fig. 1, which has a configuration similar to that used by Farnsworth *et al.*[14,15] The vacuum apparatus consisted of three separate systems—a reaction-chamber, a mass spectrometer, and a gas handling system. These systems could be connected with each other through metal stop cocks and valves. The reaction chamber was a vessel approximately 300 cc in volume, capable of being evacuated to 1×10^{-8} Torr or less by means of a sputter ion pump (8 *l*/sec). The progress of the reaction at low pressures was observed with an omegatron rf. mass spectrometer, which could be evacuated and baked to obtain a residual pressure of 5×10^{-8} Torr or less. The sensitivity and resolution of the omegatron were very satisfactory for tracing the course of the reaction. All the reactant gases were admitted to the reaction chamber through cold traps at the temperature of liquid nitrogen. These gases were mixed at a pressure of 1.5 Torr before they were admitted into the reaction chamber. The pressure in the mass spectrometer was kept at precisely 2×10^{-7} Torr by adjusting the variable leak valve. The reaction rate was determined by using the following equation;[19]

$$k_m = n\cdot\frac{1}{t}\ln\frac{x_e-x_o}{x_e-x_t}\left(\frac{1}{60\cdot A}\right)\ \text{molecules/cm}^2\cdot\text{sec.}$$

where n is the number of molecules in the reaction space and where x_o, x_t, and x_e are the fractions of hydrogen deuteride present at time zero, t, and at equilibrium. A is the geometrical surface area of the samples. The k_m rate is termed the catalytic activity in the present paper.

Surface Area. Changes in the surface area (roughness factor of sample plates with various treatments could be detected precisely by the rapid measurement method for a small surface area.[20]

Results

Catalytic Activity of Copper-Nickel Alloys after Oxidation-reduction Treatments. Figures 2 and 3 show the catalytic activity curves after various surface treatments for the hydrogen-deuterium exchange reaction as a function of the alloy composition. In all the cases shown in the figures, the reaction temperature was 100°C and the initial pressures of both hydrogen and

Number of each activity point of 80% copper alloy signifies different oxidation condition as follows;

Number	O-R treatment	
	Oxidation (1 min)	Reduction (2 hr)
1	P_{O_2}=2.3 Torr	P_{H_2}=16 Torr
2	0.175	16
3	0.135	16
4	0.068	16
5	0.024	16
6	0.017 (2 min)	16

deuterium were 1.5 Torr. The number of each curve on the figures indicates the order of surface treatment procedure as follows:

(1) Non-treatment: Mechanically-polished with metallographic emery paper and alumina powder, and then with fine cloth in a stream of water.

(2) Hydrogen-treatment: Heated in hydrogen (16 Torr) at 300°C for 1 hr subsequent to the (1) treatment.

(3) Oxidation-reduction Treatment: Deoxidized by hydrogen (16 Torr) at 300°C for 2 hr after oxidation with oxygen (2.3 Torr) at 500°C for 1 min subsequent to the (1) and (2) treatments (in that order) (hereinafter referred to as the O-R treatment).

(4) Annealing-treatment: Vacuum-annealed under below 5×10^{-8} Torr at 500°C for 0.5 hr subsequent to the (1), (2), and (3) treatments (in that order).

In the case of the (1) treatment, the activity was observed to be greatest on pure nickel, to decrease gradually as the content of copper in the alloys increases, and virtually to vanish in the alloys containing more than 70% copper. After the (2) treatment, however, the activity of pure nickel decreased while catalytic activity appeared in the range of copper-rich compositions.[21] Besides, after the O-R treatment, the activity curve appeared to be quite different from the others, as may be seen in Fig. 3, in which the catalytic activity of copper-nickel alloys may be seen to be much greater than that of pure nickel; in particular, the activity of the 85% copper alloy was found to be greater than that of pure nickel, after the same treatment, by a factor of one hundred. Of particular interest in Fig. 3 is the very narrow range of composition around the 85% copper alloy. Such a high activity was found to remain unchanged even after several days and several reaction runs. When the catalysts activated by the O-R treatment were annealed, the catalytic activity was decreased drastically, as is shown in Fig. 3(4); the activity values were nearly the same regardless of the alloy composition.

Effect of Vacuum Annealing. In order to examine the nature of the active sites produced by the O-R treatment, the deactivation process of the catalytic activity due to thermal annealing *in vacuo* was examined.

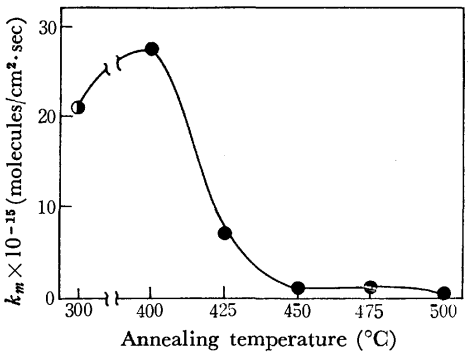

Fig. 4. Effect of annealing on catalytic activity of 80% copper alloy for hydrogen-deuterium exchange reaction at 100°C (Annealing time, 10 min).

21) It should be noted that the fluctuation in the activity data was found to be quite large after the (2) treatment.

Figure 4 shows the effect of the annealing temperature on the catalytic activity of the 80% copper alloy after the O-R treatment, where each sample was annealed under below 5×10^{-8} Torr for 10 min at various temperatures. The reaction temperature for the hydrogen-deuterium exchange was 100°C.

The catalytic activity is found not to be changed after annealing at 300°C and to increase slightly after annealing at 400°C, while it decreases abruptly at temperatures above 425°C. Figure 5 shows the effect of the annealing time on the catalytic activity. It is seen that, at 300°C, the activity remained nearly the same even after 8 hrs' annealing, and that at 400°C, the maximum activity was found to be twice that before annealing, but at 500°C a rapid decrease of activity for the initial few minutes was observed. It should be noted that there was a critical temperature at which the activity decreased drastically.

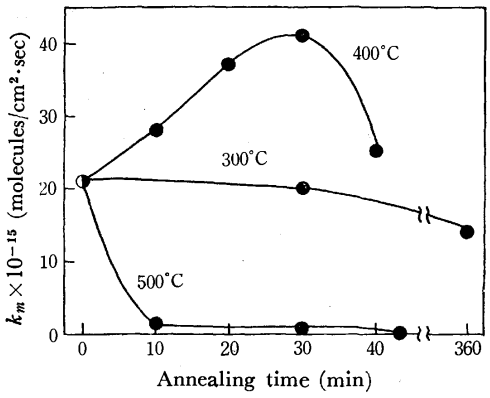

Fig. 5. Effect of annealing time on catalytic activity of 80% copper alloy for hydrogen-deuterium exchange reaction at 100°C.

Observation of the Surface State. Figure 6 represents the results of the electron-microscopic observation of the surface of the 80% copper alloy after each treatment, (1) to (4), as is shown above. As may be seen in the figure, the surface became smooth after the hydrogen treatment (2), many pits on the surface appeared after the O-R treatment (3), and the surface was invisibly changed by the annealing treatment (4). The values of the roughness factor (the ratio of the true surface area to the geometric surface area), as estimated by means of the above method,[20] are also shown in Fig. 6. The roughness factor of the surface was increased about twice by the O-R treatment, but no change was found in the values between those after the O-R treatment and the subsequent annealing treatment. It should also be emphasized that changes in the roughness factor with the surface treatment were not related to changes in the catalytic activity shown in Fig. 3.

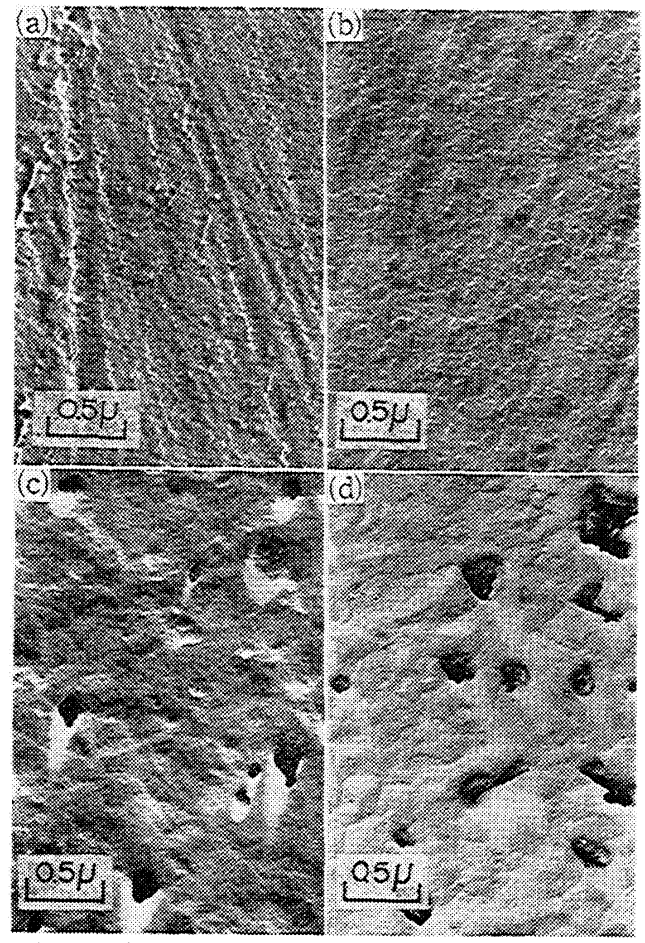

Fig. 6. Electron micrographs and roughness factor of 80% copper alloy surface after various treatments.
(a): Non-treatment (1), Roughness factor 3.1
(b): Hydrogen-treatment (2), Roughness factor 3.1
(c): Oxidation-reduction treatment (3), Roughness factor 5.7
(d): Annealing-treatment (4), Roughness factor 5.6

Discussion

As has descrived above, the catalytic activities of copper-nickel alloy plates were extremely enhanced by the O-R treatment; the activity was greatest after the O-R treatment in the very narrow range of alloy composition lying around 85% copper. On the contrary, pure metals, copper, and nickel were not activated by the treatment.

The thickness of the surface layer which was oxidized and deoxidized by the O-R treatment was estimated by means of a tortional microbalance with high sensibility. The results from this experiment, after treatment under different oxidation conditions, are shown in Table 1. In each case, the oxide layer was observed to be completely deoxidized by the reduction treatment. From these results, it should be pointed out that the very thin layer (a few monolayers) on the alloy surface is possibly closely related to the catalytic phenomena.

Two possible reasons for the enhancement in catalytic activity after the treatment may be considered to be : (a) an increase in the surface area (the roughness factor) of the catalyst, and (b) a production of new active sites after the O-R treatment. Measurement of the changes in the surface area indicated that the roughness factor was increased only about twice after the O-R treatment; it did not correspond to the catalytic activity. Consequently, it is possible to conclude that the origin of the remarkable enhancement of activity is the production of new active sites by the

TABLE 1. RESULTS OF GRAVIMETRIC MEASUREMENT WITH SURFACE TREATMENT

Treatment		Mass Gain after Oxidation	Thickness of oxide layer	Roughness factor after reduction	Catalytic activity ($H_2+D_2=2HD$)
Oxidation	Reduction

treatment.

In our previous study[18] of the effect of ion bombardment on the catalytic activity of copper-nickel alloys, a result similar to that of the present work was obtained; we found the composition of the copper-nickel alloy which gives the maximum activity, fifteen times that of pure nickel. Measurement of the annealing effect of alloy catalysts after ion bombardment also showed that, for the copper-nickel alloys, the critical temperatures at which the activity began suddenly to decrease were observed to be between 300 and 500°C. When we compare the activity pattern and deactivation process after the ion bombardment with those after the O-R treatment, many similar general tendencies can be found.

To account for the enhancement of activity after the treatments, it is assumed that lattice defects resulting from the O-R treatment or the ion bombardment contribute to the greatly-enhanced catalytic activity. According to the study of the effect of ion bombardment on the surface of silver by Sosnovsky,[16] the catalytic activity of silver is increased in the order of several tens of times by the treatment; it was concluded on the basis of the evidence by Ogilvie[22] that ion bombardment produces disoriented regions bounded by stable arrays of dislocations, that the reaction occurs at sites where dislocation lines intersect the surface. Takeuchi *et al.*[8] also concluded that the activity of copper-nickel alloy films can be explained by taking the unstable lattice imperfactions into considerations. Similarly, large numbers of structural defects of various kinds were found in thin oxide films on copper, nickel, and alloys.[23] It seems likely that same structural defects in oxide films, especially dislocation, remain even after the hydrogen reduction of the oxide in the temperature range below 300°C. Uhara and his co-workers[11] pointed out that the catalytic activity of cold-worked metals was decreased in two temperature ranges during annealing; those ranges correspond to the disappearance of vacancies (>200°C) and dislocations (>400°C).

Considering these results, it can be concluded that the active sites produced by the O-R treatment may be related to surface dislocations of a particular type on copper-nickel alloys. Otherwise after the O-R treatment the active sites seem to be associated with a heterogeneous surface in alloy composition. Kubaschewsky and his co-workers[24] have shown that the miscibility gap forms a phase separation in copper-nickel alloys at temperatures lower than 322°C. On the other hand, Hall and Emmett[25] in their study of powder catalysts of copper-nickel alloys, found activity pattern in the effect of hydrogen pre-adsorption quite similar to that of the O-R treatment (Fig. 3) in the present study. The effect of pre-adsorbed hydrogen by alloy surfaces is probably important in accounting for the remarkable enhancement of the catalytic activity.

As has been described in the Introduction, a number of papers on the catalysis of copper-nickel alloy films have been published. Sachtler *et al.*[3-5] have shown that particular copper-nickel alloys in copper-rich appear to be formed preferentially after heating at 200°C; they also revealed, by calculations, that the free energy of the formation of an alloy containing 80% copper at 200°C appears to be favored as a result of a wide miscibility gap of the alloy system, and suggested on the basis of experiments on the CO adsorption, that the 80% copper alloy must exist in the surface layer. In similar experiments, Campbell and Emmett[7] found that when alloy films were homogenized by heating to 500°C in hydrogen from an alloy containing about 60% copper (bulk composition), the excess of

nickel or copper present gives the X-ray diffraction pattern of the pure metals. The activity patterns obtained by Sachtler *et al.*[3-5] showed a constant value over these films with an equal surface composition, while that obtained by Campbell and Emmett[7] showed a promoting effect, increasing to a value of from five to fifteen times as great as for pure nickel in spite of the wide miscibility gap. The structure and surface phenomena of alloy films might be very complicated in comparison with the plates of the alloys used in the present work.

Finally, plots of the logarithm of the pre-exponential B_m factor against the energy of activation are shown in Fig. 7. It appears that the tendency for increased energies of activation to be compensated for by an increase in the pre-exponential factor was found to be separable in pure nickel and in the copper-nickel alloy.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3002—3005 (1972)

ESR Studies of the Conformation and Restricted Rotation of 4-Phenyl-1,3-dioxane Anion

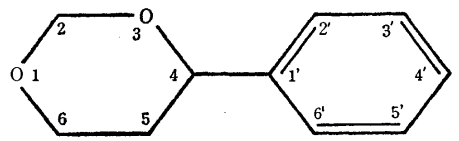
Masamoto IWAIZUMI, Takashi MATSUZAKI, and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai

(Received January 5, 1972)

The ESR of the 4-phenyl-1,3-dioxane anion shows a line-width alternation effect which can be attributed to the restricted rotation between the 1,3-dioxane and benzene rings. From the temperature dependence of the line-width alternation effect, the activation energy was determined to be 180 ± 110 cal·mol^{-1}. The preferential conformation between the two rings was estimated from the hyperfine splitting constant of the proton at the 4 position in the 1,3-dioxane ring, to be that where the two rings have some angle close to 90° rather than the structure where they are parallel. It was also found that an odd electron, which mainly occupies a vacant π orbital in the benzene ring, delocalizes appreciably into a part of the 1,3-dioxane ring.

Studies of hindered intramolecular motion have attracted much interest. In some cases, ESR has been a very effective technique for this kind of study. In this paper we wish to report an investigation of the restricted rotation and the preferential conformation between the benzene and 1,3-dioxane rings in the anion of 4-phenyl-1,3-dioxane (I) by means of ESR.



[I]

The ESR of this anion shows a line-width alternation effect, which can be connected to the restricted rotation between the benzene and 1,3-dioxane rings. Since β-proton hyperfine splitting constants are sensitive functions of molecular geometry,[1] the hyperfine splitting constants of the proton at the 4 position of the 1,3-dioxane ring are also an effective source of information about the conformation and restricted rotation between the two rings. Although the conformational analysis of saturated heterocyclic rings is one of the most interesting problems in organic stereochemistry, no information about the structure of the 1,3-dioxane ring of this anion can be obtained by ESR. It can be seen, however, from a NMR study of the neutral molecule of 4-phenyl-1,3-dioxane that the phenyl group is in an equatorial position of the 1,3-dioxane ring. The details of the NMR study of this material, however, will not be discussed here.

Experimental

The anion of 4-phenyl-1,3-dioxane was prepared by the reduction of 4-phenyl-1,3-dioxane with sodium-potassium alloy using a mixed solvent of tetrahydrofuran (THF) and 1,2-dimethoxyethane (DME) in a 1 : 1 volume ratio. The 4-pheyl-1,3-dioxane used was obtained commercially (Tokyo Kasei's product) and was purified by distillation. The distilled 4-phenyl-1,3-dioxane was stored over a potassium metal in a bottle connected to a vacuum line. For the preparation of the anion, the compound was taken by distillation from the bottle through the vacuum line into a reaction vessel. The reduction reaction did not proceed in THF or when sodium or potassium was used separately.

The ESR spectra were obtained on a Hitachi Model 771 X-band ESR spectrometer. Variable temperature experiments were performed using a Hitachi gas-flow-temperature control unit. The calculation for the simulation of the spectra was carried out using the NEAC 700 computer at the Tohoku University Computer Center.

Results and Discussion

Reaction of 4-phenyl-1,3-dioxane with Sodium-potassium Alloy. A colorless solution of 4-phenyl-1,3-dioxane turns orange upon contact with sodium-potassium alloy and then changes to green in a few hours. This reaction rate is prompted by an increase

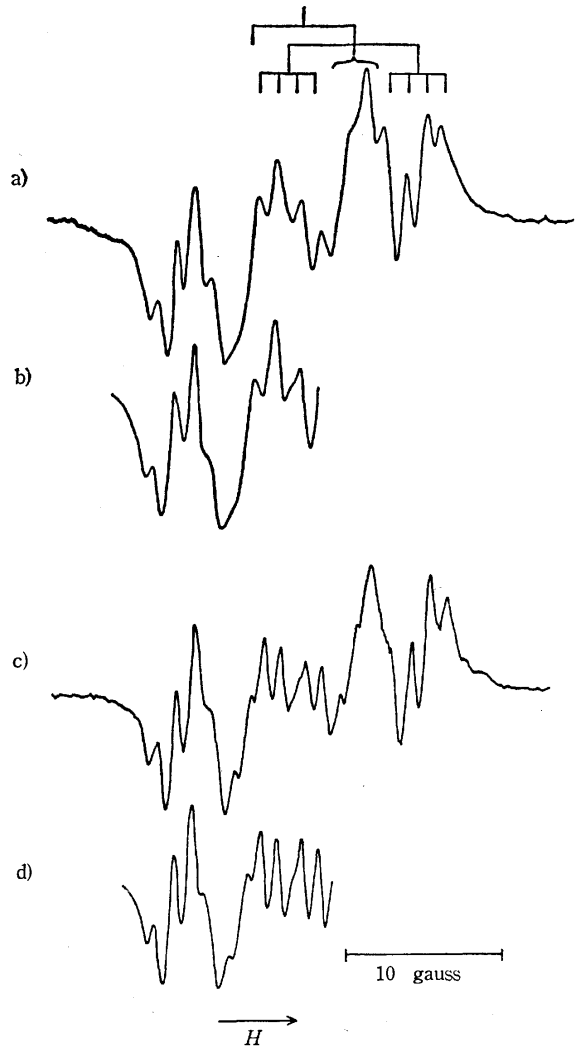

Fig. 1. ESR spectra of the 4-phenyl-1,3-dioxane anion.
a) Spectrum at −8°C. b) Computer-simulated spectrum for (a) using the hyperfine splitting constants listed in Table 1 and the parameters, $\Delta a=1.30$ gauss, $\tau=1.6\times10^{-7}$ sec, and $T_2^{-1}=2.43$ MHz. c) Spectrum at −100°C. d) Computer-simulated spectrum for (c) using the hyperfine splitting constants listed in Table 1 and the parameters, $\Delta a=1.30$ gauss, $\tau=2.0\times10^{-7}$ sec, and $T_2^{-1}=1.80$ MHz.

in the quantity of DME in the mixed solvent. Both the orange and green solutions show ESR spectra. Figure 1 shows the spectra which were taken from the orange solution. This spectra can be attributed to the 4-phenyl-1,3-dioxane anion, while the spectrum taken from the green solution consists of $25(=5\times5)$ hyperfine lines and fits perfectly with the hyperfine pattern of the naphthalene anion.[2] The change in color from orange to green, therefore, may be attributed to the formation of the naphthalene anion from the 4-phenyl-1,3-dioxane anion. The reaction mechanism will be discussed elsewhere.

The Line-width Alternation Effect in ESR and the Restricted Rotation between the Benzene and 1,3-dioxane Rings. Figure 1 shows that the spectra of the 4-phenyl-1,3-dioxane anion are temperature-dependent, although the change with the temperature is not very drastic. The spectra at room temperature can be analyzed in terms of two sets of doublet splittings due to hyperfine interaction with single protons, a triplet splitting which is due to two protons and which shows a line-width alternation effect, and a quartet splitting due to the interaction with three protons. It is seen, through the computer simulation of the spectra, that the quartet splitting splits to a doublet and a triplet splitting at lower temperatures. The hyperfine splitting constants, as determined by the computer simulation of the spectra, are listed in Table 1. The assignment of the hyperfine splitting constants to the proton positions was reasonably made by comparison with the hyperfine splitting constants for the acetophenone or benzaldehyde anion previously reported by Steinberger and Fraenkel.[3] The hyperfine splitting constants for the 4-phenyl-1,3-dioxane and benzaldehyde anions are compared in Table 1. Apparently the protons which show the line-width alternation effect can be assigned to the protons at the 2′ and 6′ positions of the benzene ring. In the cases of the acetophenone and benzaldehyde anions, the carbonyl groups are locked into the plane of the aromatic ring, and the two ortho protons as well as the two meta protons show different hyperfine splitting constants. It seems likely that, as in the case of the acetophenone or benzaldehyde anion, the hyperfine splitting constants of two protons at the 2′ and 6′ positions of the 4-phenyl-1,3-dioxane anion have different splitting constants because of the presence of the oxygen atom at the 3 position in the

1,3-dioxane ring. The line-width alternation effect, therefore, can be attributed to the modulation effect of the 2′ and 6′ proton hyperfine splittings caused by the restricted rotation between the benzene and 1,3-dioxane rings, the modulation of the hyperfine splittings having an out-of-phase correlation for the two protons.

By using Bloch's two-jump model,[4] the spectra at various temperatures were analyzed in order to estimate the activation energy for the rotation. According to the theory of the line-width alternation effect,[4d,5] the line-width broadening is proportional to the square of the magnitude of fluctuation in the hyperfine splitting, Δa, and to the correlation time for the fluctuation, τ, *i. e.*, proportional to $\Delta a^2 \cdot \tau$. Since the hyperfine splitting constants for the static conformation of the molecule were not available, we assumed the magnitude of the fluctuation for the 2′ and 6′ proton hyperfine splittings to be 1.30 gauss by reference to the case for the hyperfine splitting constants of the benzaldehyde anion. By neglecting the temperature dependence of the value for Δa, the τ values were evaluated for the spectra at various temperatures by computer simulation of the spectra. Of course, the absolute magnitude for the τ thus obtained contains some error, because of the use of an assumed value for Δa. However, the error in the τ will not lead to a large error in the calculation of the activaiton energy for the rotation, since a large part of the error in τ can be compensated for the procedure for obatining the activation energy by the Arrhenius relation. In Fig. 2, the plot of $\log_{10}(1/\tau)$ *vs.* $1/T$ is shown. The activation energy is obtained as 180 ± 110 cal·mol^{-1} from the slope by the Arrhenius relation. Here the $1/\tau = k$ relation was assumed, where k is a rate constant for rotation.

In the cases of the acetophenone and benzaldehyde anions, the meta protons also have different hyperfine splitting constants, just as they have different ortho

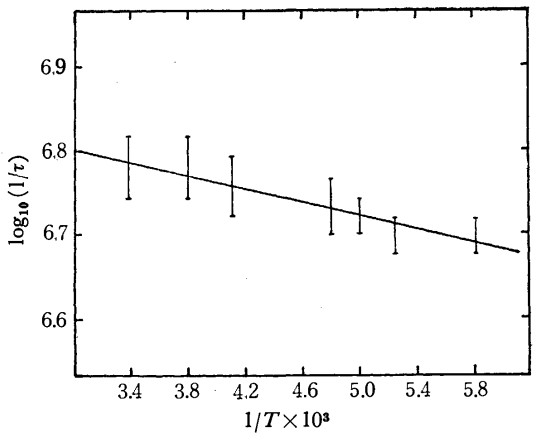

Fig. 2. Plot of $\log_{10}(1/\tau)$ against $1/T \times 10^3$.

proton hyperfine splittings. In the present case, however, it was not obvious from the computer simulation of the spectra whether or not the hyperfine splitting of the 3′ and 5′ protons also shows a line-width alternation effect.

It should be noticed here that the evaluated activation energy is small compared to kT. In such a situation, the two-jump model, which assumes a "jump" between the two conformations, may not be strictly correct for treating the system. However, it may not be unreasonable to consider that the activation energy thus estimated still has meaning as an approximate value.

Electron-spin Delocalization in the Molecule. It is well known that the hyperfine splitting constant of the aromatic ring proton, a_i^H, can be related to the spin density, ρ_i^H, on the carbon atom to which the proton is attached by McConnell's relation, $a_i^H = Q^H \rho_i^H$, or a modification of it.[6] Here, Q is an empirical constant and has a value of $-22.5 \sim -30$ gauss. In Table 2 the spin densities evaluated by McConnell's relation using $Q = -22.5$ guass are listed. From a comparison with the calculated spin densities for the acetophenone or benzaldehyed anion,[3] a negative sign

Table 2. Spin densities for the 4-phenyl-1,3-dioxane and benzaldehyde anions

4-Phenyl-1,3-dioxane anion		Benzaldehyde anion	
Positions	Spin densities[a]	Positions	Spin densities[b]

c) See text.

was assigned to that for the 3′ and 5′ positions. As Table 1 shows, the hyperfine splitting constant for the protons at the 3′ and 5′ positions has a positive temperature coefficient, showing a contrast to the other ring-proton hyperfine splittings. On a basis of a consideration of the vibrational effects on the proton hyperfine splitting constants,[7] the assignment of the negative sign to the spin density at the 3′ and 5′ positions may also be justified by this positive temperature coefficient of the hyperfine splitting constant.

Interstingly, it is shown that the spin density on the benzene ring is far less from unity. That is, the algebraic sum of the spin densities for the carbon positions from 2′ to 6′ is only 0.6; in order for the sum of the spin densities on the benzene ring to be unity, one must consider the spin density of the 1′ position

to be 0.4. One can see from the comparison with the spin densities for the acetophenone or benzaldehyde anion that this estimated spin density for the 1 position is unreasonably large; about 0.1 seems to be suitable for this position. The spin density on the benzene ring is, therefore, apparently far from a full unit. This decrease in the spin densities on the benzene ring from unity indicates that the electron spin delocalizes into a part of the 1,3-dioxane ring.

In studies of the conformation of organic π radicals with a cyclopropyl substituent, it has been shown that the cyclopropyl ring preferentially adopts a bisected conformation to the aromatic ring except in sterically-crowded environments, and that the electron-donative hyperconjugation effect of the cyclopropyl ring has an important role in the adoption of the conformation.[8] This hyperconjugation effect of the cyclopropyl ring has been explained by Walsh's model,[9] which considerd the sp^2 hybridization for the carbon valency to hydrogen and the $2p$ atomic orbital for carbon valencies to carbon. Walsh points out, in his theoretical study of cyclopropane and related compounds, that even cyclohexane appears to have a greater tendency towards a $2p$ character in the carbon valencies to carbon. In view of the fact that the 1,3-dioxane ring prefers a conformation at right angles to rather than planar with the benzene ring, as will be discussed later, the electron-spin delocalization may take place by means of the hyperconjugation effect of the 1,3-dioxane ring. On the other hand, the charge-transfer effect of a lone-pair electron on the oxygen atom at the 3 position may be considered as another possible mechanism for the electron-spin delocalization into the 1,3-dioxane part. In both cases, an electron with a β spin will transfer from the 1,3-dioxane ring or the lone-pair electron of the oxygen into the vacant π orbital of the benzene ring, leaving a α spin on the 1,3-dioxane part. However, there is not definite experimental proof on which mechanism is dominant.

Conformation Preference of the 1,3-*dioxane Ring in Relation to the Benzene Ring.* The β proton hyperfine splitting constants are sensitive to the conformation of the C-H$_\beta$ bond. When the alkyl group is undergoing torsional oscillation about a particular equilibrium conformation of a restricted rotation, the β proton hyperfine splitting constants are temperature-dependent and are generally expressed by the equation;[1a]

$$a_\beta^{\mathrm{H}} = B\langle\cos^2\theta\rangle_{\mathrm{av}}\rho_i \qquad (1)$$

Here, B is an empirical constant and in the range of of 45 ± 6 gauss, ρ_i, is the spin density at the trigonal carbon (i) of the attachment, and θ is the dihedral angle between the C-H$_\beta$ bond and the $2p$ orbital on the i-th carbon. The average $\langle\mathrm{con}^2\theta\rangle$ depends upon the nature of the rotation and is expressed by the following equation:

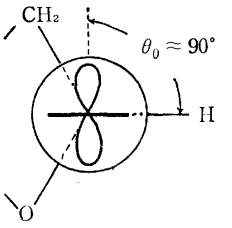
$$\langle\cos^2\theta\rangle_{\mathrm{av}} = \frac{\sum_{j=0}^{\infty} g_j\langle\cos^2\theta\rangle_j \exp(-E_j/kT)}{\sum_{j=0}^{\infty} g_j \exp(-E_j/kT)} \qquad (2)$$

with:

$$\langle\cos^2\theta\rangle_j = \langle\phi_j(\alpha)\,|\cos^2(\alpha+\theta_0)|\,\phi_j(\alpha)\rangle \qquad (3)$$

in which ϕ_j and E_j designate the wave function and the energy eigenvalue respectively for the torsional quantum state or rotational state j, in which g shows the degeneracies of the state, and in which θ_0 is the equilibrium angle of the θ. The ϕ_j and E_j values used for these equations are obtained by solving the Schrödinger equation for the torsional oscillation or restricted rotation of the system. In the present case, as Table 1 shows, the proton at the 4 position shows a temperature-dependent hyperfine splitting with a positive temperature coefficient. However, it is not quantitatively treated here, and only the equilibrium conformation of the 1,3-dioxane ring against the benzene ring is qualitativaly considered.

Stone and Maki[1] calculated the values of $\langle\cos^2\theta\rangle$ for some typical cases as a function of the activation energy for four possible values of θ_0 and $T=298$°K. We refer to his calculation for estimating θ_0 for the case of the 4-phenyl-1,3-dioxane anion. In the present case, if it is assumed that the spin density at the 1′ position is 0.1, and if we use $B=45$ guass, $\langle\cos^2\theta\rangle$ is obtained as 0.25, corresponding to $\langle\theta\rangle=60°$. The value of $\langle\theta\rangle$ for the free rotation is 45°, and as the potential barrier for rotation increases, the value of $\langle\theta\rangle$ approaches the value for the equilibrium conformation. Taking into consideration the fact that



[II]

the activation energy for the rotation of the 4-phenyl-1,3-dioxane anion is 180 cal·mol^{-1}, the equilibrium angle of the C-H bond must be larger than 60°, and rather close to 90° (II). The positive temperature coefficient of the hyperfine splitting constant for this proton will support such a bisected conformation of the 1,3-dioxane ring against the benzene, ring. Such a conformation seems plausible from the point of view of the steric effect between the two rings, and also in view of the conjugative electronic interaction discussed above, although the contribution of both interactions are small, as is shown by the small activation energy obtained.

Computer Simulations of the ESR Spectra of the Triplet Dimers of Bis-(*N*-Salicylidenemethylaminato)copper(II) in Toluene

Makoto CHIKIRA and Taro ISOBE

Chemical Reserach Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai

(Received January 31, 1972)

It has been concluded, from computer simulations of the observed ESR line shapes, that the dimeric structure of bis-(*N*-salicylidenemethylaminato)copper(II) in a frozen toluene solution is similar to that in its γ-form crystals. Furthermore, the difference between the hyperfine splittings observed at both edges of the triplet spectra for $\Delta M=1$, the large frequency dependence of the fine-structure splitting, and the additional hyperfine structures observed in the field range between the so-called low-field parallel and perpendicular lines have been found to be due to the noncoincidence of the principal axes of the g tensor with those of the fine-structure tensor.

The ESR spectra of the triplet dimers of copper complexes in frozen solutions have been studied by many authors.[1-7] Although there are a variety of dimeric structures, it has always been assumed that the spin Hamiltonian applied to the dimers is axially symmetric and that the principal axes of the g tensor are coincident with those of the fine-structure tensor, $\boldsymbol{D}$. Recently, Yokoi and Isobe[7] found that triplet dimers are formed at considerably high concentrations in the toluene solutions of some 1 : 2 β-diketone chelate complexes of copper(II) and that the dimers are in equilibrium with the monomers. We established that such a equilibrium exists in the toluene solution of bis-(*N*-salicylidenemethylaminato)copper(II) (abbreviated as Cu(Mesal)$_2$). Furthermore, its ESR line shapes at 77°K could not be explained in terms of the spin Hamiltonian usually applied.

The dimeric structure shown in Fig. 1 is found in the γ-form crystals of Cu(Mesal)$_2$.[8] It can naturally be supposed that the complex in toluene has the same dimeric structure as in the γ-form crystals. The axes of the fine-structure tensor due to magnetic dipole interactions in such a dimer do not coincide with those of the g tensor. The purpose of this paper, therefore, is to estimate the dimeric structure of the complex in toluene on the basis of computer simulations of the ESR line shapes of randomly-oriented triplet dimers, using a more general spin Hamiltonian.

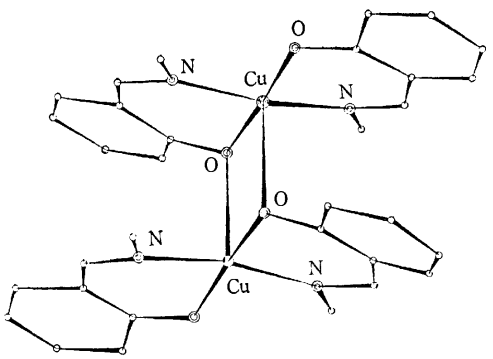

Fig. 1. Structure of the dimer in the γ-form crystals of Cu(Mesal)$_2$.[8]

Experimental

The ESR spectra of Cu(Mesal)$_2$ in toluene were recorded at 77°K with two HITACHI ESR spectrometers, Model 771 (*X*-band) and Model MES 4001 (*K*-band). The field was calibrated with an NMR probe and then with a benzen solution of vanadyl acetylacetonate. Cu(Mesal)$_2$ was prepared according to the method in the literature[9] and was recrystallized from methanol several times.

Results and Discussion

ESR Spectra of the Triplet Dimers. The *X*-band and *K*-band ESR spectra of Cu(Mesal)$_2$ in toluene measured at 77°K are shown in Figs. 2, 3, and 4. The spectra in Figs. 2 and 4 consist of two kinds of spectra; one is due to monomer species ($S=1/2$), and the other, to triplet dimer species ($S=1$). Various magnetic parameters are defined in these figures; A_3 is the hyperfine splitting constant of the so-called[4] minimum-field lines of $\Delta M=2$ transitions, A_L and A_H are those of the low-field and high-field parallel lines of $\Delta M=1$

transitions, respectively. D_2 is one half of the splitting between the full-field parallel lines, and D_1 is a splitting between the full-field perpendicular lines. The values of g_1 and g_2 were determined from the centers of the full-field perpendicular and parallel lines respectively. These results are listed in Table 1.

The ESR spectra of the triplet dimers of copper complexes show seven-line hyperfine patterns upon the coupled nuclear spin ($I=3$) of two copper ions ($I=3/2$), and the separations of the hyperfine components can be expected to be about one half of those observed for the monomer.[10] It should be noted that the A_3, A_L, and A_H at the X-band spectra are all different, and that they decrease in this order. In the K-band spectrum, A_L becomes a little larger, but the A_H is considerably smaller than that in the X-band spectrum. It is also evident that the D_2 in the X-band differs both from the D_1 in the same band and from the D_2 in the K-band. In addition, the g_2 is considerably smaller than the g_z of the monomers. If the dimers were axially symmetric and if the axes of the g, D, and hyperfine tensors were all coincident with each other, A_L and D_2 would have to be almost equal to A_H and D_1 respectively.[3,4] In this case, therefore, the small difference between A_L and A_H must be attributed to the second-order effect of hyperfine interactions. However, this difference cannot be explained only by this effect, because the second-order effect weakens as the resonance frequency increases. This fact contradicts the experimental result that the difference between A_L and A_H in the K-band becomes quite a bit larger than that in the X-band. Moreover, we must point out that additional hyperfine structures, which are indicated by arrows in Figs. 2 and 4, were found in the field range between the so-called low-field parallel and perpendicular lines; it is clear that the hyperfine structures are due not to the monomers, but to the dimers. Similar hyperfine structures had been found more clearly in the spectra of the aqueous solutions of copper tartrates at 77°K.[4] However, these structures have not yet been explained theoretically.

Table 1. Magnetic parameters

	Observed values		Case A		Case B	
	X-band	K-band	X-band	K-band	X-band	K-band
A_3	87 G					
A_L	79	82 G	75 G	81 G	80 G	85 G
A_H	65	46	60	51	64	52
g_1	2.069				2.116	2.094
g_2	2.170	2.169	2.126	2.127	2.164	2.186
D_1	394 G				475 G	430 G
D_2	563	657 G	753 G	830 G	560	679

Magnetic parameters of the monomer; $g_z=2.220$, $A_z=0.0192\,cm^{-1}$, $g_0=2.112$, $A_0=0.0079\,cm^{-1}$, where g_0 and A_0 were determined from the X-band spectra at room temperature. (X-band: 9.2202 GHz, K-band: 23.816 GHz).

The resonance conditions of triplet dimers for the $\Delta M=1$ transitions can be expressed by this first-order approximation:[11]

$$\hbar\omega = g(z,\varphi)\beta H \pm D(z,\varphi) + A(z,\varphi)M_I;\ z=\cos\theta \quad (1)$$

where θ and φ are the polar co-ordinates of the direction of the static magnetic field, where M_I is the quantum number of the hyperfine component of the coupled nuclear spin, and where ω is the angular frequency of the oscillating magnetic field. Then, the resonance magnetic field can be calculated from Eq. (1) as:

$$H(z,\varphi) = \frac{\hbar\omega \mp D(z,\varphi) - A(z,\varphi)M_I}{g(z,\varphi)\beta} \quad (2)$$

It was indicated by Kottis and Lefebvre[12] that the ESR spectrum of a paramagnetic powder or a glassy solution show characteristic peaks in the fields where the stationary conditions (3) are satisfied:

$$dH = \frac{\partial H}{\partial z}dz + \frac{\partial H}{\partial \varphi}d\varphi = 0 \quad (3)$$

From Eqs. (2) and (3), two stationary conditions for the $\Delta M=1$ transitions can be obtained according to the plus and minus signs in Eq. (2). If the principal axes of the g, D and A tensors are coincident with each other, the two conditions will be simultaneously satisfied in the directions of the tensor axes, because both $\partial H/\partial z$ and $\partial H/\partial\varphi$ always vanish in those directions. If these axes do not coincide with each other, the ori-

entations which satisfy Eq. (3) will differ according to the plus or minus sign in Eq. (2), and they will not generally agree with the orientation of the principal axes. In that case, the observed parameters are not the principal values of these tensors. These facts suggest that the unusual behavior of the observed hyperfine and fine-structure splittings is due to the noncoincidence of the principal axes of the g tensor with those of the D tensor. In order to confirm this speculation more quantitatively, computer simulations of the ESR line shapes of the randomly-oriented triplet dimers were performed in this investigation. All the calculations were carried out at the Computer Center of Tohoku University.

Simulations of the ESR Line Shapes. The appropriate spin Hamiltonian for the triplet dimers can be expressed as:

$$\mathscr{H} = \boldsymbol{H}\cdot\boldsymbol{g}\cdot\boldsymbol{S} + \boldsymbol{H}_d + \boldsymbol{S}\cdot\boldsymbol{A}\cdot\boldsymbol{I} + J\boldsymbol{S}_1\cdot\boldsymbol{S}_2 \qquad (4)$$

where $\boldsymbol{S} = \boldsymbol{S}_1 + \boldsymbol{S}_2$, $\boldsymbol{I} = \boldsymbol{I}_1 + \boldsymbol{I}_2$

and:

$$\boldsymbol{H}_d = \left(\frac{\beta^2}{r^3}\right)\left\{(\boldsymbol{g}\boldsymbol{S}_1\cdot\boldsymbol{g}\boldsymbol{S}_2) - \frac{3}{r^2}(\boldsymbol{g}\boldsymbol{S}_1\cdot\boldsymbol{r})(\boldsymbol{g}\boldsymbol{S}_2\cdot\boldsymbol{r})\right\} \qquad (4a)$$

where $\boldsymbol{S}_1$, $\boldsymbol{S}_2$, $\boldsymbol{I}_1$, and $\boldsymbol{I}_2$ are the electron and nuclear spin operators of the copper ions, $\boldsymbol{H}_d$ is the operator of the spin dipole interaction, $\boldsymbol{r}$ is the distance between the two ions, and the other symbols have their usual meanings. We assumed here that (a) the g tensors of the two molecules are identical, (b) the spin-exchange interaction parameter, J, is large enough for the coupled electronic and nuclear spin quantum numbers ($S=1$, $I=3$) to be good ones, although the contribution of J to the fine-structure splitting is negligibly small as compared with that of $\boldsymbol{H}_d$, (c) the principal axes of the g and the A tensors are coincident with each other, and (d) $\boldsymbol{H}_d$ can be estimated from a point-dipole approximation.

Our method of calculating the line shapes is essentially the same as that used by many other authors.[12-16] We first calculated the resonance magnetic fields as a function of the orientation with respect to the static magnetic field, integrated it into the powder pattern, and convoluted it with the derivatives of Gaussian or Lorenzian line shapes. We chose the spin eigenfunctions of the Zeeman and exchange interaction terms for a basis set, and regarded $\boldsymbol{H}_d$ and $\boldsymbol{SAI}$ as small perturbations. The line shapes of the $\Delta M=2$ transitions in the X-band will not be discussed here. In the case of the $\Delta M=2$ transitions, the amount of Zeeman splitting is not large enough, as compared with the fine-structure or hyperfine splittings, for the perturbation calculations to give proper energy levels. Since the angular dependence of the transition probability cannot be neglected, it is necessary to solve the higher-order secular equations in order to obtain the exact energy levels and matrix elements of the transition moments. The perturbation calculations were made to the seconds order for $\boldsymbol{H}_d$ and to the first order for $\boldsymbol{SAI}$. As Fig. 5 shows, the x, y, and z axes of the Cartesian co-ordinates were chosen as the principal axes of the g and A tensors. The directions of the static magnetic field and of the copper-copper axes are expressed by the polar co-ordinates, (θ, φ) and (ξ, η) respectively.

Figure 6 shows the angular dependence of the resonance magnetic field for the $\Delta M=1$ transitions for the $M_I=0$ hyperfine component. The parameters used in these calculations were estimated from the parameters of the monomer species and from the structure of the γ-form crystals. These adopted parameters

may not be accurate. It is considered, however, that they do not differ from the exact ones greatly enough for the essential features of the line shapes to disappear, because the electronic states of this complex are not changed very much by the weak dimerization force. As is clearly shown in these figures, the dimers which are resonating at both edges of the $\Delta M=1$ spectra are differently oriented; their θ values are different. The approximate values of A_L, A_H, D_2, and g_2, which are defined in Figs. 2 and 4, can be estimated from these figures. If we put $A_{//}=0.0095$ cm^{-1} and $A_{\perp}=0.0010$ cm^{-1}, values which are about one half of those observed for the monomers, A_L and A_H can be calculated from Eq. (5),[11] as is shown in Case A of Table 1:

$$gA=\sqrt{A_{//}^2g_{//}^2\cos^2\theta+A_{\perp}^2g_{\perp}^2\sin^2\theta} \tag{5}$$

These values agree satisfactorily with the observed values. D_2 and g_2 values similarly obtained from the figures are also tabulated there. These values do not agree with the experimentally-obtained values quantitatively, as the A values do, but they do agree qualitatively. For instance, in both the calculations and the experiment, the D_2 in the X-band is smaller than that in the K-band, and the g_2 is significantly smaller than the g_z usually observed for various five-co-ordinated copper complexes. These facts suggest that the structures of the dimers in toluene are very similar to those in the γ-form crystals. In order to determine the parameters more precisely, A_L, A_H, g_2, and D_2 were estimated graphically at different values of r and ξ. First of all, we will discuss the behaviors of g_2 and D_2. From Eq. (1), g_2 and D_2 can be expressed to the first-order approximation:

$$g_2=\frac{2g_Lg_H}{g_L+g_H} \tag{6}$$

and:

$$2D_2=\frac{\hbar\omega}{\beta}\left(\frac{1}{g_H}-\frac{1}{g_L}\right)+\frac{1}{\beta}\left(\frac{D_H}{g_H}-\frac{D_L}{g_L}\right) \tag{7}$$

where g_L, g_H, D_L, and D_H are the g factors and the fine-structure splittings of the dimers, whose orientations can be determined graphically from the minimum and maximum resonance fields of the $\Delta M=1$ transitions. Practically, g_2 is almost equal to $g(\xi, \eta)$. The difference between g_L and g_H becomes larger as the anisotropy of the g tensor, the frequency of the oscillating magnetic field, and the gaps between the copper-copper axis and g tensor axes increase. Accordingly, the first term of Eq. (7) varies greatly with the microwave frequency. On the other hand, the values of the second term changes only a little with the frequency. If the fine-splittings are due only to the magnetic dipole interactions, the value of the second term will be approximately determined by the distance between the two cupric ions and, therefore, somewhat affected by a change in the ξ value. In the X-band spectra, the first term of Eq. (7) is negligibly small as compared with the second one. In this case, the D_2 in the X-band almost agrees with one of the principal values of the zero-field splitting tensor, which is usually represented as Eq. (8) for a point-dipole interaction:

$$D_{d-d}=\frac{3}{4}g^2\beta^2\left\{\frac{1-3\cos^2\theta}{r^3}\right\}_{\max} \tag{8}$$

Accordingly, the distance between the two cupric ions in the dimers can be calculated from Eq. (8) to be 3.39 Å, using the value of g_2 and D_2 obtained from Fig. 6. It is almost the same as the value of r (3.4 Å) used for the calculations in Fig. 6. The ξ and r dependence of D_2 is shown in Fig. 7. As is evident from Fig. 7, the ξ dependence of D_2 in the K-band is larger than that in the X-band. When ξ is closer to 0° or 90°, the difference between the D_2 values in the X-band and the K-band becomes very small. In other words, if the difference is large and the second-order effect of the fine-structure tensor is negligible, there will be a large gap between the copper-copper and g tensor axes.

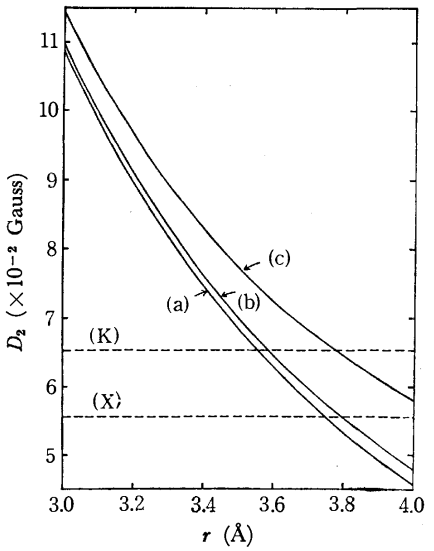

Fig. 7. The relation between D_2 and r. $g_{//}=2.22$, $g_{\perp}=2.04$; As ξ changes $0°\rightarrow 90°$, D_2 changes (a)→(b)→(a) at X-band, and (a)→(c)→(a) at K-band. The broken lines, (K) and (X), indicate the observed values of D_2 at K-band and X-band, respectively.

Next, we will discuss the hyperfine structures of the so-called full-field parallel lines. The dependence of A_L and A_H on r for different values of ξ in the X-band is shown in Fig. 8. This figure indicates that the calculated values of A_L and A_H depend sharply on ξ, but that they do not change greatly with r at any of the ξ values. In these figures, the observed values of A_L and A_H are also indicated. The approximate values of ξ could be estimated from these figures to be between 30° and 40°. The difference between A_L and A_H increases with the increase in the anisotropy of the g tensor. The relations between ΔA and Δg can be understood well from Fig. 9, where $\Delta A=A_L-A_H$ is plotted against ξ for different values of $\Delta g=g_L-g_H$. As is evident from these figures, the change in ΔA with Δg depends on the ξ angle and on the frequency of the oscillating magnetic field. It also depends naturally on the anisotropy of the A tensor. When the shift of the spectral lines due to the anisotropy of the g tensor is smaller than that due to the fine-structure tensor, ΔA becomes zero at $\xi=0°$ and 90°. This condition is not satisfied in the case of (5) in the K-band in Fig. (9). In this case, the $(-1\rightarrow 0)$ transition at the minimum resonance field or the $(0\rightarrow 1)$ transition at the maximum does not occur in the directions of these principal axes. The angular

dependence of the resonance magnetic field, however, becomes so small that the lines of the various hyperfine splitting constants overlap with each other in the corresponding narrow range of the magnetic field. Consequently, the hyperfine splittings are completely smoothed out and the calculated A values are of no practical use.

Finally, we calculated the total line shapes according to the method by Taylor and Bray.[16] For the sake of simplicity we neglected the angular dependence of the transition probabilities. The patterns which were made up by neglecting the linewidths of all the transitions were convoluted with the Gaussian line shapes, and then numerically differentiated. As the absorption lines of the monomers overlap greatly with those of the dimers, it is impossible to fit the total line shapes of the calculated spectra to those of the observed ones. Therefore, we adjusted the magnetic parameters so that the parameters defined in Figs. 2 and 4 became consistent with those experimentally determined. Figures 7—11 suggest the ranges of the more exact parameters of the triplet dimers. Since the behavior of the hyperfine structures can be adequately explained by the parameters used for the calculations in Fig. 6, the true values will not deviate too much from them. We made them change gradually by the trial-and-error method, and finally obtained the spectra

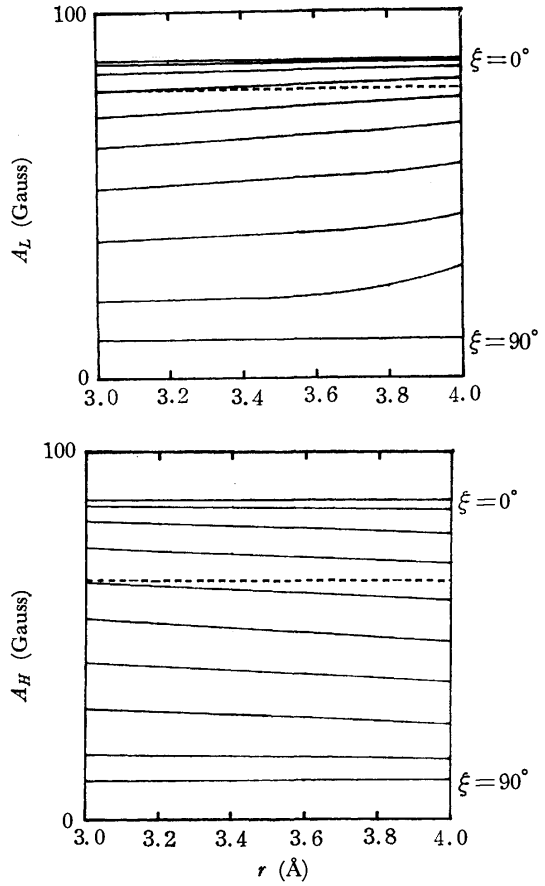

Fig. 8. The r and ξ dependence of A_L and A_H at X-band. $A_{//}=0.0090\,cm^{-1}$, $A_\perp=0.0010\,cm^{-1}$, $g_{//}=3.22$, $g_\perp=2.04$; Broken lines in the figure indicate the observed values of A_L and A_H; A_L and A_H were calculated changing ξ at intervals of 10°.

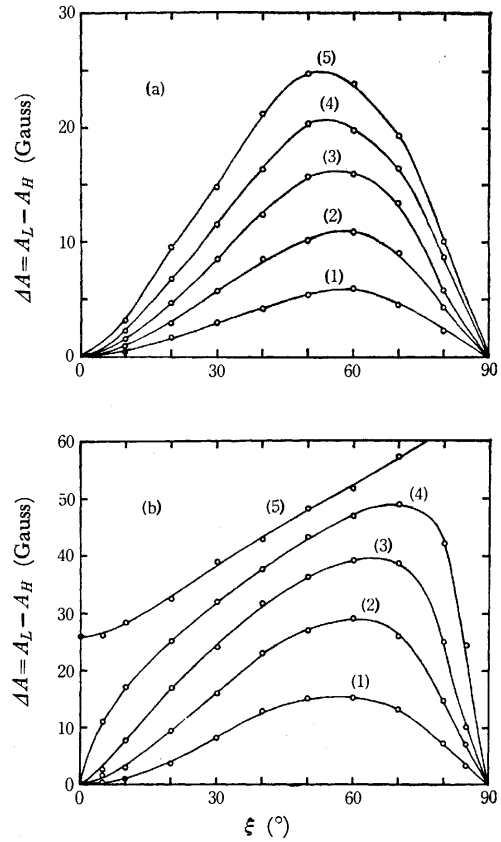

Fig. 9. The relation between $\Delta A=A_L-A_H$ and $\Delta g=g_L-g_H$ at different values of ξ. (a) X-band, (b) K-band; $A_{//}=0.0090\,cm^{-1}$, $A_\perp=0.0010\,cm^{-1}$, $g_\perp=2.05$, $g_{//}=$, (1), 2.10, (2), 2.15, (3), 2.20, (4), 2.25, (5), 2.30.

shown in Fig. 10. The parameters determined from Fig. 10 are tabulated in Case B of Table 1; the magnetic parameters for the triplet dimer are shown below, with a rough estimation of the maximum errors:

$$g_{//}=2.23\begin{cases}+0.08\\-0.03\end{cases} \qquad g_\perp=2.05\pm0.02$$

$$A_{//}=90\pm5 \qquad A_\perp=10\pm5 \quad (\times10^{-4}\,cm^{-1})$$

$$r=3.75\begin{cases}+0.05\\-0.35\end{cases}\ (Å) \qquad \xi=35°\pm5° \qquad \eta=0°$$

The agreement of the calculated spectra with the observed spectra is good in the low-field range. In the high-field range, however, the calculated intensity of the perpendicular component becomes larger and the calculated linewidth becomes smaller than those of the observed spectra. As a result, it seems that the hyperfine structures in this region appear only indistinctly.

The calculated spectra clearly show unusual hyperfine structures in the field range between the low-field parallel and perpendicular lines. The structures became more distinct in the K-band spectra. The perpendicular transitions occur when the static magnetic field is oriented along the direction perpendicular to the copper-copper axis. If the symmetrical axes of the g and D tensors are not coincident with each other, the perpendicular transition will split as a result of the anisotropy of the g tensor. Hence, the $\Delta M=1$ transitions do not show the typical pattern due to the axially symmetric tensors, and the stationary resonant field conditions for the low-field perpendicular transitions

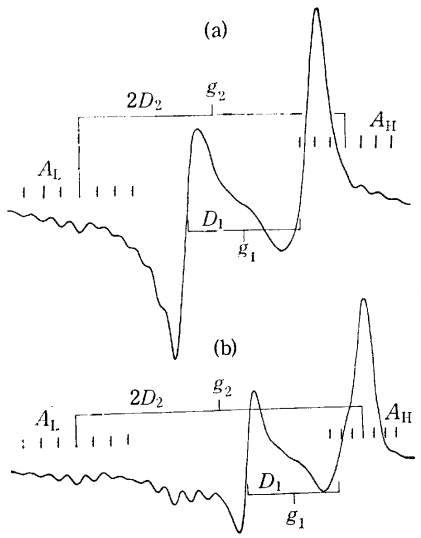

Fig. 10. The calculated ESR spectra of the triplet dimers of $Cu(Mesal)_2$. (a) *X*-band, (b) *K*-band; $g_{//}=2.23$, $g_{\perp}=2.05$, $A_{//}=0.0090\,cm^{-1}$, $A_{\perp}=0.0010\,cm^{-1}$, $r=3.75$ Å, $\xi=35°$; These spectra were convoluted by Gaussian line shapes, ($\Delta H=25$ Gauss).

are satisfied at the angle of a considerably large hyperfine coupling constant.

Estimation of the Copper-Copper Distance. In the above calculations, we neglected the effect due to the distributions of electron spins in their orbitals and the effect of pseudo-dipolar interaction. Taking this distribution effect into account will bring about a decrease in the estimated value of r, as was indicated by Chasteen and Belford.[4] Moreover, if a super-exchange interaction through the oxygen atoms operates anti-ferromagnetically, the sign of the pseudo-dipolar interaction will become positive[17] and opposit to that of the real spin dipolar interaction. This effect may reduce the estimated value of r. However, the principal axes of the pseudo-dipolar interaction are directed along the direction parallel or perpendicular to the two co-ordination planes, rather than to the copper-copper axis.[17] If the total fine-structure tensor, $\boldsymbol{D}$, results mainly from the psudo-dipolar interaction, the principal axes of the $\boldsymbol{D}$ will be close to those of the g tensor. The calculated value of $\xi=35°\pm5°$ suggests that the D value originates mostly from the real dipolar interactions. At any rate, the estimated value of r (3.75 Å) will be the upper limit of the distance and the real value may possibly be smaller than this estimated value.

The authors would like to express their grateful acknowledgement to Dr. H. Yokoi for many helpful discussions and suggestions throughout this work.

Infrared Absorption Intensities of Out-of-plane CH Bending Vibrations of Substituted Benzenes. IV. Solvent Effect on the Intensities of the Bands of Aniline

Seiichiro HIGUCHI, Eisaku KUNO, Shigeyuki TANAKA, and Hitoshi KAMADA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo; Bunkyo-ku, Tokyo

(Received February 3, 1972)

The infrared absorption intensities of out-of-plane CH bending and ring out-of-plane deformation vibrations of aniline have been measured in an acetone solvent mixed with various quantities of acetic acid. When such solvents are used, new peaks attributable to aniline interacting with the acid appear as shoulders of each of the original bands. A marked decrease in the sums of the intensities of the above two modes (A_0) has been observed for the bands of aniline interacting with the acid. It is demonstrated that the degree of such a decrease in intensity depends on the molar ratios of aniline and the acid. When there exists enough the acid in comparison with aniline, the values of A_0 become minimum. On the other hand, when the numbers of the exsiting acetic acid molecules are much smaller than those of aniline, the values of A_0 are considerably greater than those in the former case. In this case, a farily long time is needed until the interaction reaches an equilibrium state. Finally, when a very large amount of the acid is added, the bands attributable to aniline interacting with the acid are no longer observed. An attempt has been made to interpret these phenomena in terms of the state of the aggregation of aniline, acid and acetone molecules in the solutions.

In our previous studies, we examined the infrared absorption intensities of the out-of-plane CH bending and ring out-of-plane deformation vibration bands of various monosubstituted (PhX-, Ph_2X-, and Ph_3X-type molecules) and meta disubstituted benzenes and discussed the intensities of those bands in terms of several basic factors, *i. e.*, the forms of group vibrations, the C–H bond dipole moment, and the structural factors, including the angles of rotation of benzene rings (in case of Ph_n X-type molecules) and the conformational isomerism.[1-3] Several conclusions have been drawn from these studies. Those of them essential to the

2. Y. Gōda, S. Higuchi, S. Tanaka, and H. Kamada, *ibid.*, **92**, 21 (1971).
3. S. Higuchi, Y. Gōda, S. Tanaka, and H. Kamada, *ibid.*, **92**, 670 (1971).

present problem are enumerated below.

1) The forms of group vibrations corresponding to the two strong bands in the 800—670 cm^{-1} region are determined by strong coupling of the two vibrational modes, *i.e.*, out-of-plane CH bending and ring out-of-plane deformation vibrations. As a result of this, there occurs an intensity borrowing between these two vibrational modes.

2) The degree of coupling of the above two modes is sensitive to slight changes in the structure of substituents attached to the benzene ring. Thus, the forms of the group vibrations corresponding to each of the bands are not characteristic of the series of related compounds.

3) Considering that the moment induced by the ring out-of-plane deformation mode is much smaller than that by the out-of-plane CH bending mode (in the case of monosubstituted benzenes, we can estimate the former to be about one-fifth of the latter, thus, in intensity, it is about 4 percent of the latter.), the sums of the intensities of the two bands in question can be regarded as approximately corresponding to an out-of-plane CH bending vibrational mode similar to that of benzene, which is the in-phase vibration of all the hydrogen atoms attached to the benzene ring.

4) The vibrational coordinates corresponding to these sums of intensities can be considered characteristic of the series of the related compounds.[1] Consequently, the differences in the intensity sums among the compounds can be discussed in terms of the alterations in the C–H bond moment, the electric factor of the intensities of the vibrations in question. From the correlations between the intensity sums and the wavelength of the benzenoid bands in the UV spectra, it was pointed out that, when there is n-π conjugation between substituents and the benzene ring, the intensity sums (hence, the C–H bond moment) increase considerably with the effect, while, otherwise, they stay approximately constant.

On the basis of these results, we have examined this time the effect of solvents on the intensity sums, which we will hereafter call the group characteristic intensities, A_0. As the solute molecule, we have selected aniline. In this molecule, the effect of n-π conjugation, which has been found to be the major factor in determining the magnitude of the C–H bond moment, is considerably pronounced; it is interesting to examine the solvent dependences of A_0 in relation to the effect of solvents on the n-π conjugation between the substituent and the benzene ring. Thus, in this study, we have tried to consider from this viewpoint the factors attributable to the media and responsible for the changes in A_0.

Experimental

A Japan Spectroscopic Company Model DS-403G Infrared Spectrophotometer was used for the measurement of the intensities. The spectra were recorded in absorbance with a frequency scale in cm^{-1}, and the integrated areas were obtained directly from the instrumental charts. The concentration range was about 0.3—1.0 mol/l, and the cell thickness, 33 and 38 μm. The solvents used were cyclohexane, dioxane, carbon disulfide, acetone, nitromethane, acetonitrile, and mixed solvents of acetone and various carboxylic acids (acetic acid, n-propionic acid, n-butyric acid, and p-hydroxybenzoic acid). The slit width, $S/\Delta\nu_{1/2}$, was kept between 0.2 and 0.1. The scanning speed was about 10 cm^{-1}/min.

As will be shown later, two bands overlap for each of out-of-plane CH bending and ring out-of-plane deformation vibration modes, and it becomes necessary to divide these overlapping bands into components. In this study, such curve resolution was made by the use of a Du Pont 310 Curve Resolver, assuming the Lorentzian band contour for each component. The bands of aniline in the acetone solvent have shapes relatively close to those of Lorentzian curves. However, it should be noted that, strictly speaking, the asymmetric character of the band shapes is slightly more pronounced in the case of the acetone solvent than in the case of nonpolar solvents; moreover, the wings of the bands do not fit so well with the Lorentzian contours. Taking these facts into consideration, it may be necessary to make allowance for errors of 10—15 percent in the measured areas through the use of this procedure of curve resolution.

The root-mean-square difference between the individual intensity values and their mean was found to be less than 10 percent.

Results and Discussion

1. *The Behaviour of A_0 of Aniline in Usual Polar and Nonpolar Solvents.* Table 1 lists the observed intensities of the out-of-plane CH bending (A_1) and ring out-of-plane deformation vibration bands (A_2), and their sums (A_0) of aniline in six different solvents. These values of A_0 are plotted in Fig. 1 against the corresponding "reaction-field constant" $(\varepsilon-1)/(2\varepsilon+1)$, which is used here as a quantitative measure of the polarity of the solvents. These plots show distinctly that A_0 is little influenced by the polarity of solvents in the usual sense of the word. Such a situation has also been observed in the cases of other monosubstituted benzenes. Figure 1 shows the plots for toluene for the sake of comparison. Although the absolute magnitudes of A_0 are different between aniline and toluene, a difference which is attributable to the difference in the substituent effect between NH_2 and CH_3 groups, the behaviour of the A_0 according to the polarity of the solvents is always similar. This may be due to the facts that the major factor in determining the values of A_0 is the conjugation effect between the substituent and the benzene ring and that the solvents used here can not be expected to affect this very much.

Table 1. The observed intensities A_1, A_2 and their sum A_0 of aniline in various solvents

Solvent	A_1	A_2	A_0
Cyclohexane	4270	1790	6060
Dioxane	4350	1950	6300
Carbon disulfide	4190	1860	6060
Acetone	4070	1950	6020
Nitromethane	4330	1800	6130
Acetonitrile	4320	1890	6210

Unit of intensities: [$cm^{-2}\cdot l\cdot mol^{-1}$]

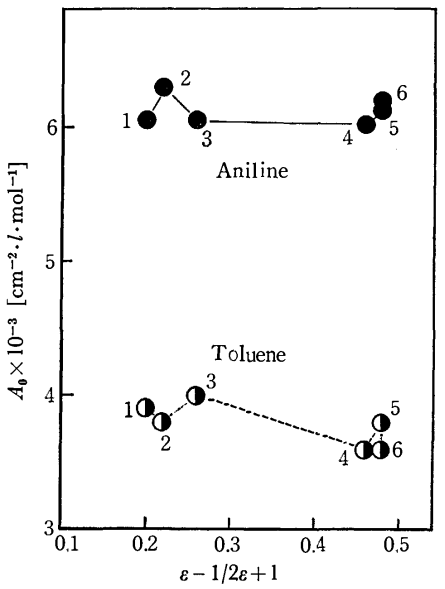

Fig. 1. The behaviors of A_0 of samples in polar and nonpolar solvents, 1: cyclohexane, 2: dioxane, 3: carbon disulfide, 4: acetone, 5: nitromethane, 6: acetonitrile.

2. *The Behavior of A_0 of Aniline in Acetone Mixed with Various Quantities of Acetic Acid.* From above experimental results, the marked changes in A_0, if any, may be expected when the solvent contains some chemical species which have a strong interaction with the *n*-electrons on the NH_2 group. Thus, we next examined the behaviour of A_0 of aniline in a mixed solvent consisting of acetone and organic acids.

Figures 2 and 3 show the spectra of aniline in acetone and in an acetone-acetic acid mixed solvent. As is shown in Fig. 3, two new bands, 1′ and 2′, appear as shoulders of the original peaks, 1 and 2, when the mixed solvent is used. These four bands can be interpreted as follows. The 1 and 2 bands are assigned, respectively, to out-of-plane CH bending and ring out-of-plane deformation vibrations of aniline not interacting with the acid, and the 1′ and 2′ bands, to the corresponding vibrations of aniline interacting with the acid. As has already been mentioned, these overlapping bands have been divided into components with a Lorentzian band contour, using a Du Pont 310 Curve Resolver. An example of such curve resolving is shown in Fig. 3.

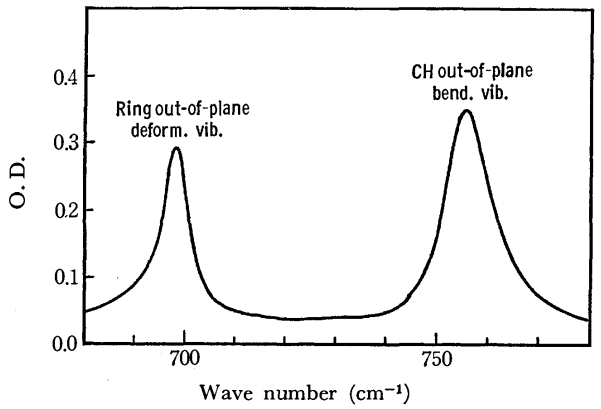

Fig. 2. The spectrum of aniline in acetone solvent.

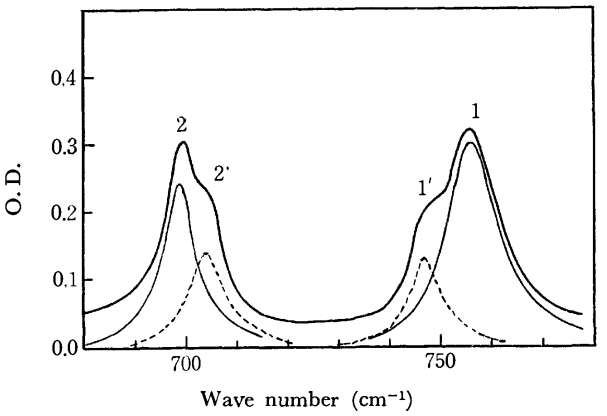

Fig. 3. The spectrum of aniline in the mixed solvent.

Table 2. The kinds of added acids and A_0 of aniline interacting with the acid

Acid	pK_a	A_0
Acetic acid	4.76	3500
n-Propionic acid	4.85	2900
n-Butyrlic acid	4.82	3400
p-Hydroxybenzoic acid	4.54	3300

Unit of intensities [cm^{-2}·l·mol^{-1}]

In order to calculate the intensities of each of the four bands, it is necessary to estimate the concentrations of aniline interacting and not interacting with the acid. For this purpose, the concentrations of aniline not interacting with the acid have been obtained from the areas of each of the two bands attributed to this kind of chemical species. In doing this, it was assumed that the concentration of not-interacting aniline corresponding to a certain area of a band is equal to that corresponding to the same area of the band of aniline in an acetone solvent. From the results of this procedure, the concentration of aniline interacting with the acid has been determined. It may be worth mentioning that the concentrations determined from the two different bands agree with each other within the limits of experimental error.

Figure 4 shows the plots of the intensity sums, A_0, of aniline interacting with the acid against the cor-

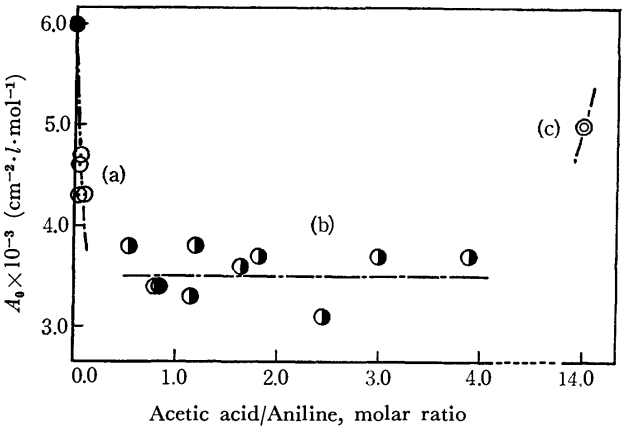

Fig. 4. The dependence of A_0 on the concentrations of the acid.

responding molar ratios of aniline and acetic acid. It can be seen from this figure that the intensity behavior can be classified into at least three categories, (a), (b) and (c). We will now consider these types of intensity behavior individually.

First, we will discuss the molar ratio range, (b), where the magnitude of A_0 becomes lower than in the case of the acetone solvent. In this case, the intensity value, 3500 ± 200 cm$^{-2}\cdot l\cdot$mol^{-1}, has been obtained as the A_0 value of aniline interacting with the acid; this value is remarkably lower than that of 6000 ± 100cm$^{-2}\cdot l\cdot$mol^{-1} when no acetic acid is added. This lowering of the intensity is considered to be due to a decrease in the interaction of n-electrons on the NH_2 group with π-electrons of the benzene ring as a result of a strong interaction of the acid with n-electrons of the substituent.

The validity of the above discussion of the physicochemical mechanism of the decrease in intensity can be inferred from the correlations of A_0 with the wavelengths of the benzenoid bands in the UV spectra. Fig. 5 shows the correlations for several monosubstituted benzenes. It is known that the maximum absorption of aniline occurs at 288 nm in the case of a neutral solution, while, in the case of an acidic solution, it appears at 254 nm.[4] It can be seen that the values of A_0 for aniline in acetone-acetic acid mixed solvents are well on the correlation curve in Fig. 5 when plotted against the data for the wavelength quoted above. The shift to the shorter wavelength in the case of an acidic solution is said to be due to the decrease in the conjugation between the NH_2 group and the benzene ring, resulting from the interaction of the substituent with the acid. Thus, this result supports the first assumption that such an effect of acidic substances will cause a marked change in the C–H bond moment and, therefore, in the magnitude of A_0.

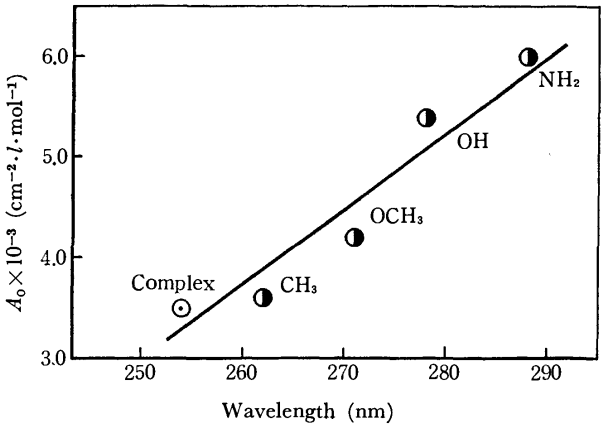

Fig. 5. The comparison of A_0 of aniline with that of its complex in terms of the correlation with UV spectra.

A similar decrease in intensity has been observed when different acidic substances are added to acetone. Table 2 lists the data for A_0 of aniline interacting with various carboxylic acids having similar pK_a values. These results show that there is no wide difference among these acids in their effects on the aniline molecule, regardless of the substituents attached to the COOH group.

Quite different phenomena have been observed in the molar ratio range (a), where the existing acetic acid molecules are much fewer than the aniline molecules. First, a considerable amount of time is required until the interaction reaches the equilibrium state (about two hours after sampling). The change of the spectra with the time is demonstrated in Fig. 6. Second, the group characteristic intensity, A_0, is 4500 ± 200 cm$^{-2}\cdot l\cdot$mol^{-1}, considerably larger than that in the (b) range. Third, the molar concentration of aniline molecules interacting with the acid is much greater than that of the added acid molecules. From these experimental facts, it can be guessed that the state of the aggregation of aniline, acid, and acetone molecules is different from that in the case of (b).

In the molar ratio range (c), where a very large quantity of the acid is added to acetone, the following phenomena can be observed, although, in this case, the observed spectra are not clear enough for a precise estimation of the intensities. The new bands attributable to aniline interacting with the acid can no longer be observed in this case, and the intensity sum, A_0, estimated roughly from the observed bands becomes near to that of aniline not interacting with the acid. These experimental results show clearly that, in this concentration range, the acid becomes almost inactive to the aniline molecule.

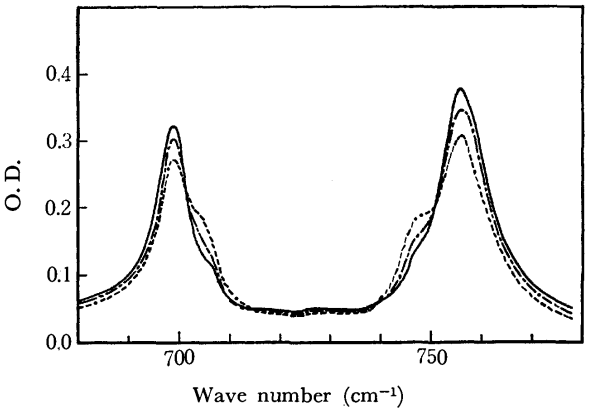

Fig. 6. The change of spectra with time, ——: immediately after sampling, – – – –: 30 min. after sampling, ……: 120 min. after sampling.

3. *The Relation between the Behavior of A_0 and the State of Aggregation for the Molecular Systems in Question.* The above-mentioned experimental results clearly suggest that the factor determining the behaviour of A_0 is the state of aggregation for the molecular systems in question. Therefore, in this paragraph, we will try to present some details on the state of molecules in the solutions, expressed so far in the rather ambiguous term "interacting", and will discuss the changes in A_0 from that viewpoint. The molecular systems treated here are very complex, and there are several kinds of possible molecular associations. That is, the following five kinds of combinations of the molecules are considered to be possible in this case; (1)

4) H. H. Jaffé and M. Orchin, "Theory and Applications of Ultraviolet Spectroscopy", John Wiley and Sons, Inc., New York London (1962), p. 257.

aniline-aniline, (2) aniline-acetone, (3) aniline-acid, (4) acid-acid, and (5) acid-acetone. Since, in general, primary amines are very weak proton donors, the (1) and (2) associations are, if present at all, weak. On the other hand, the (3), (4) and (5) associations may be inferred to be considerably stronger. In the solutions, these molecular associations are considered to be in certain equilibrium states, resulting from complicated mutual interferences among them.

First, we will consider the state of aggregation when no acetic acid is added; here the only possible molecular associations are (1) and (2). The information on the formation of such a state of aggregation will be given by the spectra in the wavenumber region of NH_2 stretching vibrations. Those spectra are shown in Fig. 7. It can be seen that the NH_2 stretching bands of aniline in the acetone solvent show no shift of wavenumbers, even when the concentrations of the solute are made about twenty five times smaller than those used in the measurements of the intensities of the out-of-plane bending vibrations in question. This fact proves that there is no self-association (1) among aniline molecules. However, it is also observed that the wavenumbers in the case of the acetone solvent are about 20 cm^{-1} lower than those in the case of carbon tetrachloride, suggesting that there occurs a weak association (2) by hydrogen bonding between the aniline and the acetone molecules. In fact, it has been reported in the literature that amines associate with carbonyl compounds by weak hydrogen bonding.[5,6] Thus, it can be concluded that the state of aggregation in this case is the associated complex of a certain number of aniline molecules with carbonyl groups between them. Since, in the formation of this type of complex, the hydrogen atoms of the NH_2 group act the principal role, while the *n*-electrons on the group do not, this interaction has no effect on the intensity sum, A_0, resulting in no marked changes in A_0 among the different solvents, as is demonstrated in Table 1 and Fig. 1.

When acetic acid is added to the acetone solvent,

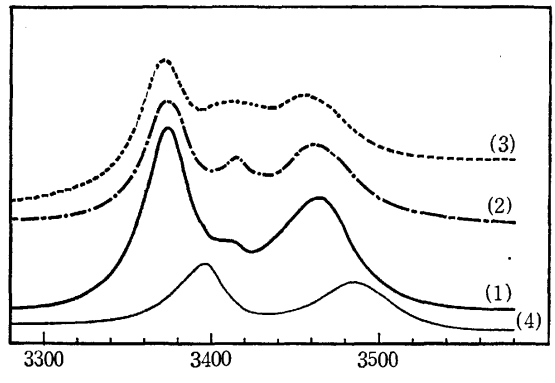

Fig. 7. The spectra of aniline in NH_2 stretching region, (1), (2), (3): in acetone, (4): in carbon tetrachloride, rough concentrations: (1) 0.5 mol/*l*, (2) 0.1 mol/*l*, (3) 0.02 mol/*l*.

three molecular associations, (3), (4), and (5), may all be realized. In this case, it is natural to consider that the acid added to the solvent interacts with the NH_2 groups involved in the complex originally formed between the aniline and the acetone molecules, and that, in this interaction, *n*-electrons on the NH_2 group act the principal role, resulting in the great changes in A_0 described in the foregoing paragraph. At the same time, the added acid molecules will associate with themselves (4) and with acetone molecules (5). These three associations, (3), (4), and (5), will reach some equilibrium state determined by the relative concentration of each of the component molecules. Since the A_0 values of the aniline interacting with the acid change with the concentration of the acid, as is demonstrated in Fig. 4, the strength of the (3) interaction can be thought to change with the alterations in the equilibrium relations among the (3), (4), and (5) associations. In a very simple picture, however, it may safely be said that the degree of the interaction, which has appeared as the change in the A_0 of aniline, is regulated by the degree of the competing associations, (4) and (5), in the equilibrium state at each concentration of the acid. On the basis of this simple model, the following qualitative interpretations of the behaviours of A_0 shown in Fig. 4 are possible, though no quantitative discussion of the chemical equilibria in question here are possible at present. As has already been mentioned, the interaction determining the behaviour of A_0 is between the acid and the associated complex of a certain number of aniline molecules with carbonyl groups between them. In the molar ratio range (b), where there is enough of the acid, each of the NH_2 groups in the complex undergoes sufficient interaction with the acid, resulting in the lowest magnitude of A_0. The experimental results demonstrated in Fig. 5 and Table 2 suggest that, in this case, aniline molecules interacting with the acid exist in the solutions as anilinium ions or a similar state of molecular aggregation. As the concentrations of the acid become higher, the dimerization of the acid (4) gradually becomes pronounced. However, at least in the concentration range (b) examined in the present study, the effect of this dimerization does not appear in the values of A_0; A_0 keeps approximately constant within the limits of experimental error. This suggests that, in this range of concentration of the acid, the dimerization of the acid molecules competes only with the association between the acid and acetone molecules (5), and that the association (3) is not much influenced until the concentration of the acid becomes much higher, though no quantitative and decisive discussion of this phenomenon can be given here.

In relation to the above discussions, the phenomenon observed in the molar ratio range (c), where a very large amount of the acid is added to acetone, can be interpreted easily. That is, in this concentration range, the effect of the dimerization of the acid is extremely pronounced; as a result, the acid molecules become inactive not only to acetone, but also to aniline molecules, resulting in the disappearance of the bands attributable to aniline interacting with the acid.

As has already been mentioned, the results for the

5. E. A. Cutmore and H. E. Hallam, *Trans. Faraday Soc.*, **58**, 40 (1962).

6. J. Lauransan, P. Pineau, and M. L. Josien, *Ann. Chim.* (Paris), **9**, 213 (1964).

molar ratio range (a) suggest that the state of aggregation of the molecules in this case is different from that in the case of (b). Also, in this case, the interaction in question is considered to occur between the associated complex [aniline-acetone] and the acid molecules. However, there is a difference in this case in that there does not exist enough of the acid as compared with aniline. From the experimental results, it may be supposed that, in the (a) range, NH_2 groups in the complex exist not as a state similar to anilinium ions (1 : 1 association), as in the case of (b), but as a state such as when one acid molecule interacts with several NH_2 groups simultaneously. On the basis of this model, the relatively greater values of A_0 observed in this concentration range can be understood easily, for, under such circumstances, the action of the acid which the *n*-electrons of each of the NH_2 groups in the complex receive in the equilibrium state becomes weaker on the average. Although a more detailed microscopic image of the molecular associations in this case cannot be given at present, the assumption of the possibility of the above-mentioned state of aggregations is consistent with all the phenomena observed in the (a) range. Be that as it may, it can at least be said that the experimental facts presented here are very suggestive as to the elucidation of the state of molecules in solutions similar to those in question here.

Conclusion

It has been demonstrated that the present experimental results are all consistent with the concept that the n-π conjugation between the substituent and benzene ring is the major factor in determining the magnitude of the C–H bond moment. The conclusion was drawn originally from the studies of the substituent effect; this time, it has been confirmed by discussion of the state of aggregation of the solute and solvent molecules. The authors realize that more detailed experimental and theoretical research over a wide range of related compounds is required before a more general rule as to the influences of media on the intensities in question can be set up. We realize also that there remain considerable ambiguities concerning the explanations of the state of molecules in the solutions in question. However, we believe that the experimental results demonstrated in this paper will be of value in stimulating the advancement of more detailed and exact studies of this subject.

The authors would like to thank Mr. K. Yamamoto of Tokyo Research Center, Bridgestone Tire Co., Ltd. for giving us permission to use a Du Pont 310 Curve Resolver belonging to his laboratory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3016—3020 (1972)

Vibration Spectra and Molecular Structures of *n*-Butyl Chloride and *n*-Butyl Bromide in Relation to Parallel (1 : 3) Interactions

Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University af Tokyo, Bunkyo-ku, Hongo, Tokyo

(Received February 15, 1972)

The vibration spectra of liquid *n*-butyl chloride and *n*-butyl bromide are observed in the region of 1500—100 cm^{-1}. From the analyses of spectra corresponding to the skeletal deformation vibrations, the molecular configurations are determined for both molecules. All the possible rotational isomers, the TT, GT, TG, GG, and GG′ forms, are observed for *n*-butyl chloride, while four isomers, the TT, GT, TG, and GG forms, are observed for *n*-butyl bromide. The results are compared with those of the electron-diffraction methods. It is shown that unfamiliar interactions must be considered for the parallel (1 : 3) interaction between methyl and chlorine substituents.

Ukaji and Bonham[1] studied the structures of *n*-butyl chloride by an electron-diffraction method and found that the concentration of the GG′ form is twenty-four percent in the gas phase at room temperature. This result is very important because the GG′ form is the most highly coiled among the five possible rotational isomers. Figure 1 shows the possible rotational isomers for $CH_3CH_2CH_2CH_2X$ type molecules. It can naturally be assumed from the figure that the GG′ form is the most unstable because of methyl/chlorine interactions.

The infrared spectra of this molecule have been studied by Snyder[2] for the crystalline state from the point of view of the molecular force field. Snyder concluded that the stable form in the crystalline state is the TT form.

The present work will be concerned with the confirmation of the electron-diffraction results through analyses of the vibration spectra of liquid *n*-butyl chloride and *n*-butyl bromide. The skeletal deformation vibrations will be discussed mainly, because they are characteristic in molecular geometry and are sensitive to any change in molecular configuration.[3]

Experimental

The samples used in the present work were commercial products. After fractional distillation, the purity was checked

by gas chromatography.

The Raman spectra were recorded using a laser Raman spectrometer which was designed and constructed in our laboratory.[4] Figures 2 and 3 show the Raman spectra of *n*-butyl chloride and *n*-butyl bromide in the region of 100—1000 cm^{-1}. The Raman spectra of crystalline samples observed at the temperature of liquid nitrogen are illustrated in Figs. 4 and 5. The spectrometer was operated under a resolution of 5—10 cm^{-1}. The temperature dependence of the Raman spectra of *n*-butyl chloride was observed at low temperatures; the results are shown in Fig. 8. The temperature was observed by means of a thermocouple directly inserted in the sample.

The infrared spectra of liquid *n*-butyl chloride and *n*-butyl bromide in the region of 200—600 cm^{-1} are illustrated in Figs. 6 and 7. A Hitachi EPI-GII infrared spectrometer was used for the measurements. The observation of the infrared spectra at low temperatures reproduced the results of a previous author[2] quite well; therefore, those results are not illustrated here.

Normal Coordinate Treatment

In confirming the vibrational assignment, normal frequencies of *n*-butyl chloride and *n*-butyl bromide were calculated for all the possible rotational isomers by using the force constants obtained for a series of alkanohalides.[5] The method of calculation may be found described in the references.[6] In the present report, the results of the calculation will not be discussed in detail, but they are available upon request from the author.

Vibrations Spectra and Molecular Configuration

A molecule of the $CH_3CH_2CH_2CH_2X$ type can have the five rotational isomers of Fig. 1, because it

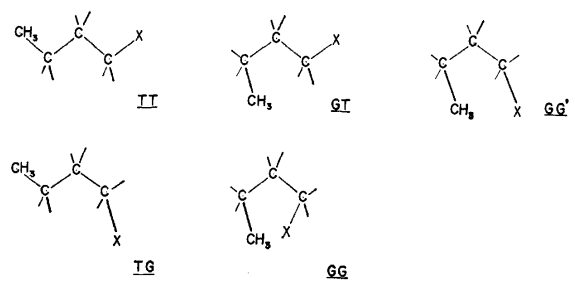

Fig. 1. Possible rotational isomers for the $CH_3CH_3CH_2CH_2X$ type molecules.

has two axes of internal rotation. We define the two axes as:

$$CH_3CH_2\text{-(I)-}CH_2\text{(II)-}CH_2X$$

and call them the I axis and the II axis. In the case of *n*-butyl chloride or *n*-butyl bromide, configurations about the II axis can easily be determined by referring to the well known empirical rule of a stretching-vibration frequency of a carbon-halogen bond.[7] An empirical rule was previously proposed by the present author for the relationship between skeletal deformation vibrations and the molecular configurations of rotational isomers.[3] Based upon this rule, the molecular configuration will be discussed below.

n-Butyl Chloride. Among the three skeletal deformation vibrations of *n*-butyl chloride, the so-called A type vibration is expected to occur in the region of about 350—500 cm^{-1} in this frequency order:[3]

$$\nu(GG') > \nu(GG) > \nu(TG) > \nu(GT) > \nu(TT),$$

where ν(TG) refers to, for example, a frequency of the A type vibration corresponding to a rotational isomer whose configurations is *trans* and *gauche* about the I axis and the II axis respectively.

In Figs. 2 and 5, we can see five Raman lines, at 529, 476, 465, 438, and 382 cm^{-1}, and seven infrared counterparts, namely, the 525, 472, 456, 435, 399, 388, and 375 cm^{-1} bands. The Raman shift at 382 cm^{-1} can be explained as an unresolved band which corresponds to the infrared bands at 399, 388, and 375 cm^{-1}. The observed bands may be assigned to molecular configurations of *n*-butyl chloride if the location of the TT form band is determined, because it occurs at the lowest frequency of all the five bands.

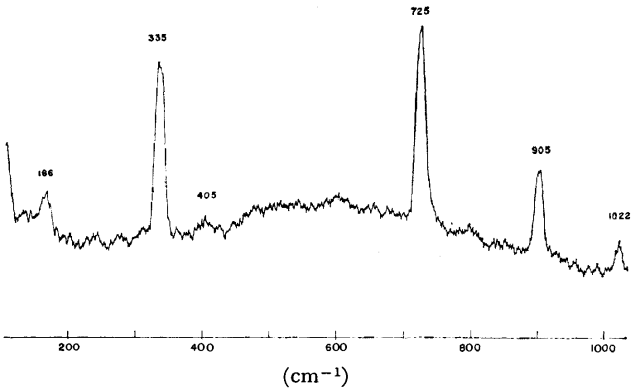

Fig. 4. Raman spectra of crystalline *n*-butyl chloride at −160°C.

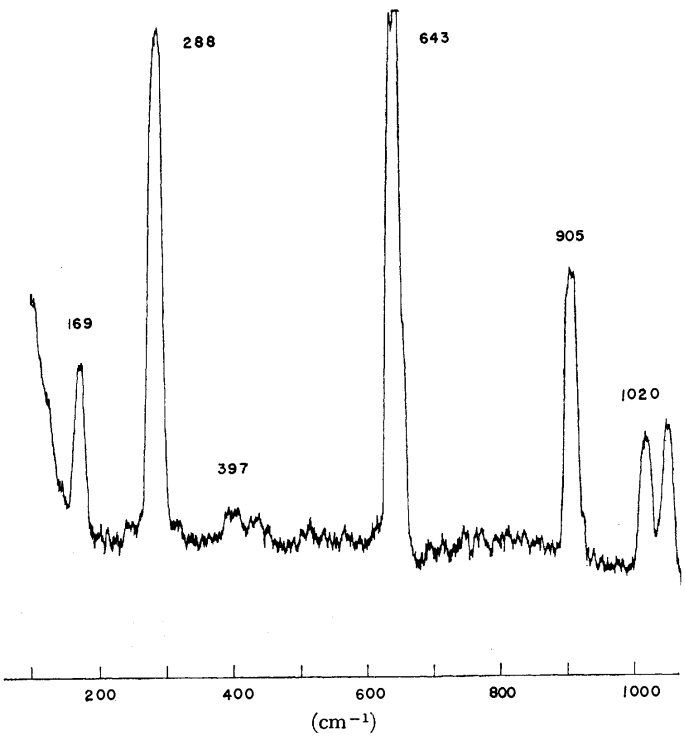

Fig. 5. Raman spectra of crystalline *n*-butyl bromide at −162°C.

Snyder[2] reports a band at 411 cm^{-1} observed in the infrared spectra of crystalline *n*-butyl chloride. The band corresponds clearly to the Raman line at 405 cm^{-1} of Fig. 6. The results of the normal coordinate treatment of Snyder and of the present work show that the Raman shifts at 405, 355, and 166 cm^{-1} of Fig. 6 can be definitely assigned to the skeletal deformation vibrations of the TT form in the crystalline state.

A little observation of Figs. 2 and 6 leads to the conclusion that the remaining four bands can be assigned to the remaining four rotational isomers. The band at 405 cm^{-1} of Fig. 6 is assumed to be buried in the wing part of the Raman shift at 382 cm^{-1} of Fig. 2. By referring to the frequency order of the empirical rule, the four bands at 438, 465, 476, and 529 cm^{-1} of Fig. 2 can be assigned to the GT, TG, GG, and GG′ forms respectively.

n-*Butyl Bromide.* The vibration spectra of *n*-butyl bromide may be analyzed in a manner similar to that used for *n*-butyl chloride. The frequencies of the A type skeletal deformation vibrations of this molecule can be expected to be slightly lower than those of *n*-butyl chloride. In Figs. 3 and 7, we see four Raman lines, at 460, 452, 419, and 394 cm^{-1}, and four infrared counterparts, at 460, 448, 417, and 394 cm^{-1}.

The Raman lines at 169, 288, and 397 cm^{-1} of Fig. 5 can be expected to correspond to the three skeletal deformation vibrations of the TT form from analogy with the results obtained for *n*-butyl chloride. Actually, the normal frequencies of these vibrations are calculated to be 155, 267, and 381 cm^{-1}. Thus, *n*-butyl bromide takes the TT form in the crystalline state and the band at 394 cm^{-1} of Fig. 5 can definitely be assigned to the A type skeletal deformation vibration of the TT form. The remaining three bands, at 460, 452, and 419 cm^{-1}, can reasonably be assigned to the GG, TG, and GT forms of *n*-butyl bromide respectively. The close similarity of the spectral patterns observed for *n*-butyl chloride and *n*-butyl bromide in the region of 350—500 cm^{-1} probably support the validity of the above-described assignments (see Figs. 2 and 3).

Discussion

The GG' Form and the Parallel (1 : 3) Interaction. It may be concluded from the spectral analyses that the numbers of rotational isomers observed in the vibration spectra of liquid *n*-butyl chloride and *n*-butyl bromide are five and four respectively. Only the TT form remains in the crystalline state of both molecules. The most remarkable finding is the existence of the GG' form of *n*-butyl chloride in the liquid state. In the GG' form, strong methyl/chlorine interactions are assumed to occur, because substituents on the carbon atoms, 1 and 3, give rise to parallel C–Cl and C–CH_3 bonds on the same side of the carbon skeleton. Actually, it has been widely agreed to reject the possibility of the existence of molecular configurations in which parallel (1 : 3) interactions are involved. We call those interaction by the term "parallel (1 : 3) interactions" following the suggestion of Sheppard.[8]

Table 1 shows the isomer percentage of the $CH_3CH_2CH_2CH_2X$-type molecules (X–CH_3, Cl, and Br) observed by the gas electron diffraction methods.[1,9,10] It may be seen from the table that these good agreement between the electron diffraction data and the present results in the senses that the GG' form of *n*-butyl chloride is present in a considerable concentration and that the GG' form of *n*-butyl bromide is not present in a readily measurable concentration. The qualitative agreement between the two sets of experimental results, namely, for the gas and liquid phases, is naturally accepted because the change in a dipole moment due to the change in molecular configuration is very small for the $CH_3CH_2CH_2CH_2X$ type molecules; therefore, the relative stabilities of the rotational isomers change little on passing from the vapour to the liquid phase. This only emphasizes that parallel (1 : 3) interactions between methyl and chlorine groups do not satisfy the criterion for rejecting the presence of a certain rotational isomer.

Table 1. Isomer percentages for the $CH_3CH_2CH_2CH_2X$ type molecules (After Bonham *et al.* (1, 9, 10))

Isomer	Concentration (per cent)		
	n-Pentane	*n*-Butyl chloride	*n*-Butyl bromide
TT	43	11	36
GT	25	11	24
TG	25	37	24
GG	7	17	16
GG'	—	24	—

Relative Stabilities of Rotational Isomers. All attempts to obtain the energy differences between rotational isomers were unsuccessful because of the poor S/N ratios of the spectra. From the temperature dependence of the Raman spectra of Fig. 8, however, a few conclusions may be drawn. The relative Raman intensities do not change remarkably; this indicates that the energy differences between the rotational isomers of *n*-butyl chloride are rather small. The relative intensity of the 438 cm^{-1} line of Fig. 2 decreases rapidly as the temperature goes down. This result supports the conclusion of the gas-phase data that GT form is the most unstable form. Two Raman lines are seen at 405 and 476 cm^{-1} in the spectra observed at about −160°C; they may correspond to an unannealed glassy solid. This indicates that both TT and GG forms coexist in the glassy solid. The most important conclusion may be drawn from the relative intensity change in the Raman line at 529 cm^{-1}. Although the temperature changes from 27°C to 70°C, its relative intensity changes little. Thus, we can conclude that the GG' form is as stable as the other rotational isomers. It is of some interest to add that the relative stability of the five rotational isomers of vapour *n*-butyl chloride is calculated from the percentage concentrations of Table 1 to be in this order:

$$TG > TT > GG' > GG > GT\text{-form},$$

where the contribution of the entropy term to the concentrations is taken into account in the calculation.

In order to emphasize the anomalous feature of the present results (or those of Ref. 1.) for *n*-butyl chloride, a rough estimation of internal energies of rotational isomers will be made for $CH_3CH_2CH_2CH_2X$-type molecules. If we assume that the magnitude of the internal-energy difference between *trans* and *gauche* isomers of *n*-butane or *n*-propyl chloride can be transferred to *n*-butyl chloride, the internal-energy difference between the TT isomers and others may be estimated to a zero-th order approximation;

$$\Delta E(\text{TT-TT}) = 0,$$

8) A. B. Dempster, K. Price, and N. Sheppard, *Spectrochim. Acta*, **25A**, 1381 (1969).
9) F. A. Monany, R. A. Bonham, and W. H. McCoy, *J. Amer. Chem. Soc.* **85**, 3077 (1963).
10) R. A. Bonham, L. S. Bartell and D. A. Kohl, *ibid.*, **81**, 3491 (1959).

$$\Delta E(\text{GT-TT}) \simeq 0,$$

$$\Delta E(\text{TG-TT}) \simeq 0.75,$$

$$\Delta E(\text{GG-TT}) \simeq 0.75,$$

and $\Delta E(\text{GG'-TT}) \simeq 0.75 + E$ (parallel (1 : 3) interactions)

in units of kcal/mol, as the internal-energy differences of *n*-butane[11] and *n*-propyl chloride[12,13] are

$$\Delta E(C_4H_{10}) \simeq 0.75$$

and $$\Delta E(C_3H_7Cl) \simeq 0,$$

where $\Delta E = E(gauche) - E(trans)$. In other words, the relative stability of the rotational isomers may be in this order:

$$\text{TT} \simeq \text{GT} > \text{TG} \simeq \text{GG} > \text{GG'-form.}$$

These results are quite different from those obtained from Table 1 (see the preceding paragraph).

Similar calculations can be performed for *n*-butyl bromide using $\Delta E(C_4H_{10}) = 0.75$ kcal/mol and $\Delta E(C_3H_7Br) \simeq 0$[12-14], or for *n*-pentane using $\Delta E(C_4H_{10}) = 0.75$; the results agree well with those obtained from Table 1. In the cases of *n*-pentane and *n*-butyl bromide, the absence of the GG' form can be accounted for if we consider large enough parallel (1 : 3) interactions between two methyl groups or between methyl and bromine substituents. In order to stabilize the GG' form of *n*-butyl chloride, however, we have to consider some unfamiliar parallel (1 : 3) interactions whose interaction energy is negative, that is, attractive rather than repulsive.

Conclusion

It was ascertained that liquid *n*-butyl chloride is a mixture of the TT, GT, TG, GG, and GG' isomers, while liquid *n*-butyl bromide is a mixture of the TT, GT, TG, and GG isomers. Only the TT isomer remains in the crystalline state of *n*-butyl chloride or *n*-butyl bromide. These conclusions confirm the results obtained by means of the electron-diffraction method by Ukaji and Bonham.

The existence of the GG' form in a redily measurable concentration leads to the conclusion that we cannot deny the possibility of the presence of certain rotational isomers by the reason that there are expected parallel (1 : 3) interactions between methyl and chlorine substituents in the configurations. The results also indicate that the parallel (1 : 3) interactions between methyl and chlorine substituents might be attractive rather than repulsive in nature.

Absorption Band Shapes and Molecular Reorientation of Liquid Methyl Cyanide

Masao KAKIMOTO and Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received March 27, 1972)

The shapes and intensities of the fundamental bands of liquid methyl cyanide were observed by conventional transmittance method. Using the refractive indices observed by the ATR method, the observed absorption indices were corrected for the dielectric-field effect. The band shapes were analyzed from the point of view of moment analysis or correlation-function analysis. The results indicate that the shapes of a_1-type vibrations are good Lorentzian shapes, while those of the *e*-type can be explained as superpositions of Lorentzian and Gaussian functions. It is also found that the band-widths of the *e*-type vibrations were quite different from each other. Taking into account the effect of vibration-rotation interaction on the band-widths, the disagreement could be explained well. From the analyses of the band shapes of ν_7 and ν_8, the life-time function, $\phi(t)$, was obtained; it represents the decay of the fraction of freely-rotating molecules.

It has been widely accepted that an infrared absorption band shape of a liquid molecule is the Fourier transform of a dipole-correlation function, as was first pointed out theoretically by Shimizu[1] and Gordon.[2] Since a dipole-correlation function describes the time correlation of a transition-dipole moment related to the vibrational transition concerned, precise measurements of band shapes are expected to afford information about the anisotropic rotational motion of molecules in liquids. Based upon this principle, a number of experimental studies have been undertaken in order to elucidate the nature of molecular motions in liquids. Some of them have achieved fairly successful results,[3] but various difficulties have confronted spectroscopists at the same time. One of the most striking of them is seen in the spectra of liquid carbon disulfide; that is, an apparent reorientational relaxation time has a negative value if we follow the theory literally. It has been shown that this peculiarity can be resaonably explained by taking into account the contribution of vibrational relaxation to the observed band-widths.[4]

Another difficulty is found in the spectra of liquid methyl cyanide; that is, the shapes or half-widths of absorption bands belonging to the same symmetry species do not agree with each other, as was first pointed out by Vincent *et al.*[5] Vibrational transitions of particular symmetry species have their transition moments in the same direction in the molecular-fixed coordinate system; therefore, the corresponding correlation functions must be the same. No theoretical explanation of these experimental results had been found until Yamashita and Shimizu recently emphasized the effect of vibration-rotation interaction on the band-widths.[6] They calculated the change in a correlation function on varying a Coriolis constant, ζ, and showed that a correlation function decays more rapidly with an increase in $(1-\zeta)$. They also presented algebraic expressions of the second and fourth moments of vibrational bands for symmetric-top molecules, where a Coriolis coupling constant is explicitly included.

In the present work, an attempt is made to interpret the peculiarity observed for the band shapes of liquid methyl cyanide using the idea of Yamashita and Shimizu. An attempt is also made to describe the details of molecular reorientation quantitatively and to establish a general procedure for obtaining rotational diffusion constants from observed spectral information.

Experimental

The methyl cyanide used in the present work was a commercial product and was used after fractional distillation. No trace of any impurity was found in the infrared spectra covering the range of 400—4000 cm^{-1}.

All the infrared absorption spectra except for that of ν_8 were recorded by the use of a Perkin-Elmer 112G single-beam infrared spectrometer. A Perkin-Elmer 12C sinlge-beam infrared spectrometer mounted with a CsBr prism was used for the measurement of ν_8. These spectrometers had been carefully modified to eliminate the effect of stray light or thermal emission originating from the spectrometers themselves. The photometric effects and the nature of the noise spectra have also been thoroughly studied for these particular spectrometers.[7] The spectrometers were operated under a resolution of about 2 cm^{-1} and at room temperature (25°C). The effect of the finite slit-width on the observed band shapes was ascertained to be very small.

It has been recognized that an ATR method has many advantages for the precise measurements of the optical constants of liquid samples.[8] At the same time, the method is not particularly powerful for the study of absorption bands with weak intensities. Though the absorption bands of methyl cyanide were measured by the use of the transmittance method in this work, the agreement of the present data and those of the ATR method[9] was found to be excellent, probably because the absorption intensities of methyl cyanide are rather weak.

The observed light-energy distribution curve, $I(\nu)$ and $I_0(\nu)$, were reduced to the absorption index curve, $k(\nu)$, through the relation:

$$k(\nu) = \frac{1}{4\pi l\nu} \ln(I_0(\nu)/I(\nu)) \quad (1)$$

where ν is the wave number in cm^{-1} and l is the thickness of the sample cell in cm. The thickness of the sample cell was determined by the interference-fringe method.

The observed $k(\nu)$ curves were corrected for the dielectric-field effect[10] using the observed $k(\nu)$ curve and the refractive index data obtained by the ATR method.[9] The observed $k(\nu)$ and/or the corrected $k_c(\nu)$ curves are shown in Figs. 1 through 4, 7, and 8. As may be seen from Fig. 1, for example, the effects of the dielectric field on the band shape are very small for these weak absorption bands. Throughout the following sections, the intensity distribution function, $I(\omega)$, should be understood as a normalized function of $k(\nu)$ and/or $k_c(\nu)$.

It is ascertained that the effects of the vibrational relaxation of the resonance type[4] are negligibly small for all the observed bands of methyl cyanide because of their weak intensities. The experimental fact that the shapes of ν_4 and ν_7 do not change essentially in a carbon tetrachloride solution (4 wt%) is another piece of evidence for this point of view.

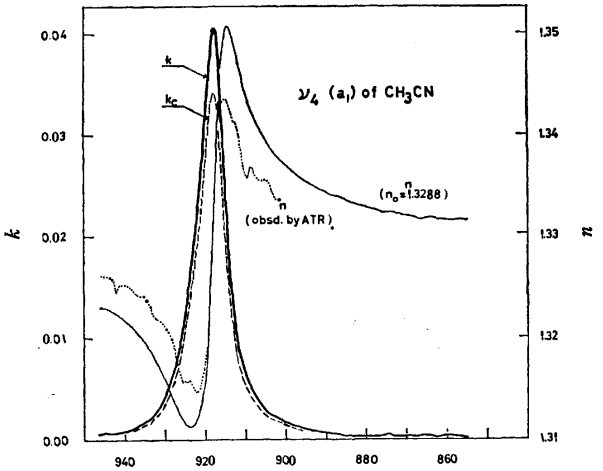

Fig. 1. $\nu_4(a_1)$ of liquid methyl cyanide. k: observed absorption index, n(solid line): refractive index calculated from k through Kramers-Kronig's formula, n(dotted line): refractive index observed by ATR method, k_c: corrected absorption index.

Discussion

Half-band-width. The half-band-widths, $\Delta\nu_{1/2}$'s, estimated from the observed $k_c(\nu)$ curves are summarized in Table 1. There is a relatively large uncertainty as to the $\Delta\nu_{1/2}$-values of ν_5 and ν_6 because they overlapped other bands considerably. It may clearly be seen from the table that the $\Delta\nu_{1/2}$'s of absorption bands

belonging to the same symmetry species do not agree with each other, especially for those of the *e*-type.

The observed values of Coriolis constants, ζ's, reported in the references[11,12] are also included in Table 1. It can quickly be observed in the table that there is apparent correlation between the $\Delta\nu_{1/2}$'s and the ζ's; this qualitatively coincides with the conclusion of Yamashita and Shimizu[6] that $\Delta\nu_{1/2}$ becomes larger with an increase in $(1-\zeta)$.

Moment Analysis and Mechanism of Molecular Reorientation. Corresponding to an absorption band's shape, $I(\omega)$, its n-th moment, M_n, is defined as [2,13]:

$$M_n = \int_{-\infty}^{\infty} I(\omega)\omega^n d\omega \qquad (2)$$

where ω is the angular frequency displacement from a band origin and where $I(\omega)$ is normalized to unity. Among the moments, the second moment, M_2, is the most important in the present discussion. As has been emphasized by Jones *et al.*,[14] the plotting of a second moment of an absorption band against its integration range is a useful tool in seeing if the band shape is a Lorentzian or a Gaussian function. This arises from the fact that a second moment plotted against the integration range diverges if $I(\omega)$ is a Lorentzian function, while it converges to a definite value if $I(\omega)$ is a Gaussian function. From the viewpoint of molecular rotation, a Gaussian band shape corresponds to a free-rotor model, while a Lorentzian band shape corresponds to a model of diffusional reorientation.[15]

The second-moment plottings for the bands of the a_1-type (ν_2 and ν_4) and of the *e*-type (ν_7 and ν_8) are shown in Figs. 5 and 6 respectively. It may be seen from the figures that the second moments of a_1-type bands go to infinity as the integration range increases, while those of *e*-type bands seem to converage to certain values. These facts indicate that the bands of the a_1-type have Lorentzian shapes, while those of *e*-type do not have simple Lorentzian shapes, but are presumably superpositions of Lorentzian and Gaussian curves. In other words, the molecular reorientational motion around an *x*- or *y*- axis may be described by diffusional reorientation, while molecular reorientation around a *z*-axis must be explained by a mechanism such as one in which both free and diffusional rotations take place simultaneously. The molecular symmetry axis coincides with the *z*-axis in the discussion.

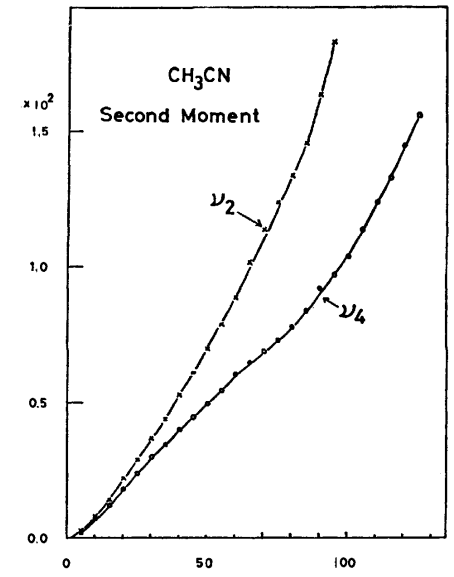

Fig. 5. Second moment plottings *vs.* integration range for ν_2 and $\nu_4(a_1)$ of liquid methyl cyanide.

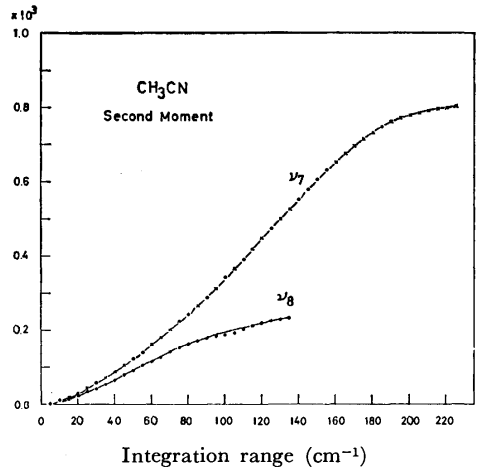

Fig. 6. Second moment plottings *vs.* integration range for ν_7 and $\nu_8(e)$ of liquid methyl cyanide.

Based upon a free-rotor model, Yamashita and Shimizu[6] proposed this algebraic expression of a second moment for a symmetric-top molecule:

$$M_2 = \begin{cases} kT\dfrac{2}{I_x}(\text{sec}^{-2}), \text{ for } a_1\text{-type} & (3a) \\ kT\left(\dfrac{1}{I_x}+\dfrac{1}{I_z}(1-\zeta)^2\right)(\text{sec}^{-2}), \text{ for } e\text{-type} & (3b) \end{cases}$$

where k is the Boltzmann constant; T, the absolute temperature, and I_i, the moment of inertia around the i-th axis. Equation(3) is essentially the same as the second-moment expression proposed by Gordon[13]

TABLE 2. CALCULATED AND OBSERVED SECOND MOMENTS OF LIQUID METHYL CYANIDE IN 10^2 cm^{-2}

	Gordon[13]	Yamashita[6] Shimizu	Obsd
$\nu_2, \nu_4(a_1)$	2.53	2.53	diverge
$\nu_7(e)$	23.0	4.32	8.1
$\nu_8(e)$		0.80	2.5

if we put ζ equal to zero. In Table 2, the observed and the calculated M_2's are compared for a few fundamental bands of methyl cyanide. Since the calculations of Gordon and Yamashita-Shimizu are clearly based upon free-rotor models, it is rather natural that the magnitude of M_2 calculated from Eq.(3) does not agree with the observed values.

Band-shape Analysis and Life-time Function, $\psi(t)$.
It was concluded in the preceding section that molecular reorientational motion around the z-axis of methyl cyanide may be interpreted as an intermediate state of free-rotation and rotational diffusion. The next problem is to analyze the observed band-shape data in a more quantitative way.

Theoretical expressions for a time-correlation function corresponding to the intermediate state may be found in the reports of Bratoz *et al.*[16] and of Shimizu.[1] Bratoz's formula is:

$$\Phi(t) = (1-\xi)\Phi_F(t) + \xi\Phi_D(t) \tag{4}$$

where $\Phi_F(t)$ and $\Phi_D(t)$ refer to time-correlation functions corresponding to free-rotation and rotational diffusion respectively, and where ξ is a constant which represents the fraction of molecules whose reorientational motion is diffusional. Shimizu expresses a time-correlation function as:

$$\Phi(t) = \psi(t)\Phi_F(t) + (1-\psi(t))\Phi_D(t) \tag{5}$$

Eqs.(4) and (5) differ only in whether the coefficients of $\Phi_F(t)$ and $\Phi_D(t)$ are time-dependent or not. In Eq.(5), $\psi(t)$ is a function of time and represents the decay of the fraction of freely-rotating molecules. We will call it a "life-time function" hereafter.

If we grant Eq.(4), then a band shape can be expressed as:

$$I(\omega) = (1-\xi)I_F(\omega) + \xi I_D(\omega) \tag{6}$$

where:

$$I_F(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi_F(t)e^{-i\omega t}dt \tag{7}$$

and:

$$I_D(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\Phi_D(t)e^{-i\omega t}dt \tag{8}$$

$I_F(\omega)$ is a Gaussian function, and its half-width may be different for different vibrational transitions, while $I_D(\omega)$ is a Lorentzian function whose half-width is considered to be the same for all the bands belonging to the same symmetry species. Therefore, the decomposition of an observed band shape, $I(\omega)$, into Lorentzian and Gaussian functions can be expected to confirm the validity of the theory of Bratoz. Two e-type

16) S. Bratoz, J. Rios, and Y. Guissani, *J. Chem. Phys.*, **52**, 439 (1970).

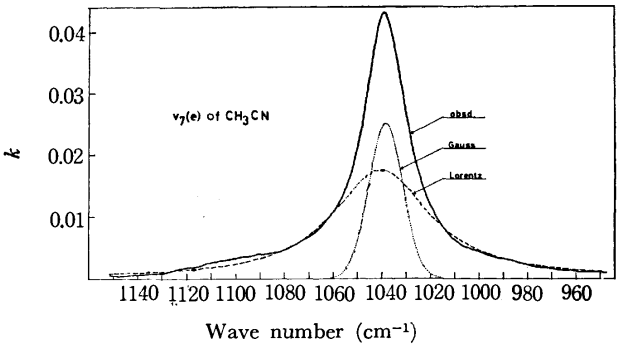

Fig. 7. Result of least-squares decomposition of $\nu_7(e)$ of liquid methyl cyanide into Lorentzian and Gaussian curves. Resultant Lorentzian and Gaussian components are shown by broken line and dotted line, respectively.

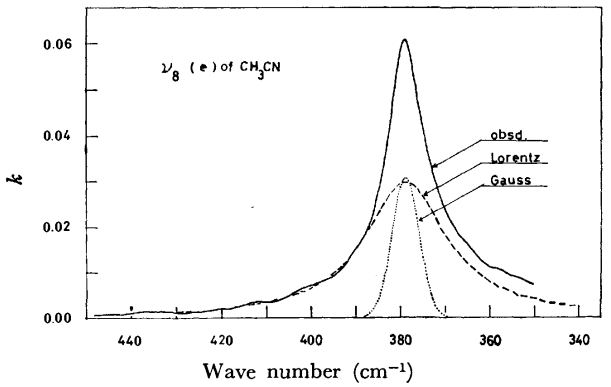

Fig. 8. Result of least-squares decomposition of $\nu_8(e)$ of liquid methyl cyanide into Lorentzian and Gaussian curves. Resultant Lorentzian and Gaussian components are shown by broken line and dotted line, respectively.

bands, ν_7 and ν_8, were decomposed into Lorentzian and Gaussian functions by the method of least-squares; the results are illustrated in Figs. 7 and 8 respectively. Unfortunately, the attempt was unsuccessful, because the shapes of the resultant Lorentzian components of ν_7 and ν_8 did not agree with each other. Therefore, Bratoz's model must be discarded.[17]

As the Fourier transform of Shimizu's formula of Eq. (5) is rather complicated to deal with, an attempt was made to analyze the correlation function obtained through the Fourier transformation of the observed band shapes of ν_7 and ν_8.

Let $\Phi_F(t)$ be a Gaussian function that will give a second moment of Yamashita and Shimizu (cf. Eq. (3b)):

$$\Phi_F(t) = \exp[-(M_2/2)t^2] \tag{9}$$

$\Phi_D(t)$ takes, as usual, an exponential form of the diffusion type:[14]

$$\Phi_D(t) = \exp[-D_e|t|] \tag{10}$$

where D_e is a rotational diffusion constant related to the e-type vibrations. Both $\Phi_D(t)$ and $\psi(t)$ are considered to be the same for all the vibrations of the e-type. Now that two sets of data, correlation functions for ν_7 and ν_8, are available, the form of $\psi(t)$ can be readily

17) The least-squares fitting did not result in a unique solution. However, the conclusion drawn here was the same for all sets of converged parameters.

estimated. A preliminary calculation showed that $\psi(t)$ is somewhat like an exponential function initiating from 1 at time zero. This fact may support the treatment of Shimizu,[1] who assumed the life-time function to be:

$$\psi(t) = \exp[-(1/\tau_L)|t|] \tag{11}$$

By employing the same form for $\psi(t)$, Eq.(5) is reduced to the form:

$$\Phi(t) = \exp[-(1/\tau_L)|t|]\cdot\exp[-(M_2/2)t^2] + (1-\exp[-(1/\tau_L)|t|])\cdot\exp[-D_e|t|] \tag{12}$$

Finally, the least-squares fitting of the correlation function of Eq.(12) to the observed correlation functions for ν_7 and ν_8 leads to the values of:

$$1/\tau_L = 1.8 \pm 0.7\ \text{psec}^{-1}$$

and:
$$D_e = 1.34 \pm 0.15\ \text{psec}^{-1} \tag{13}$$

In Figs. 9 and 10, the observed correlation functions for ν_7 and ν_8 are compared with those reproduced by Eq.(12) and the D_e and $1/\tau_L$ values thus obtained. The agreement of the two sets of correlation functions is fairly good. The standard errors attached to the parameters of Eq.(13) are estimated from the deviations between the observed and the calculated correlation functions. A rotational diffusion constant related

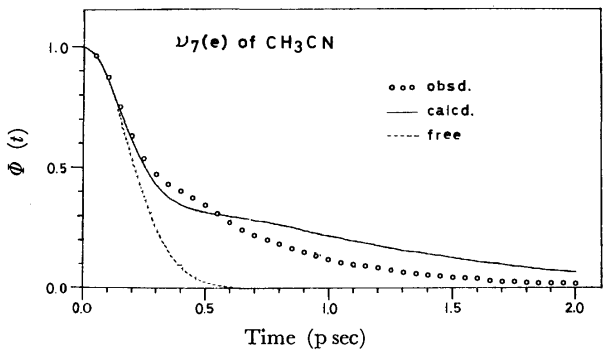

Fig. 9. Time-correlation function for $\nu_7(e)$ of liquid methyl cyanide. Open circles: Fourier transform of observed absorption index, solid line: calculated by Eq. (12), broken line: time-correlation function for a free-rotor of the form of Eq. (9).

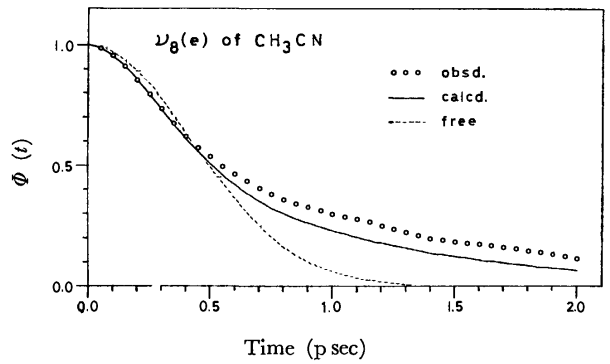

Fig. 10. Time-correlation function for $\nu_8(e)$ of liquid methyl cyanide. Open circles: Fourier transform of observed absorption index, solid line: calculated by Eq. (12), broken line: time-correlation function for a free-rotor of the form of Eq. (9).

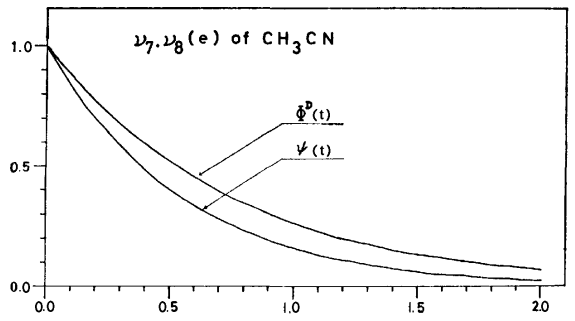

Fig. 11. Time-correlation function for diffusional reorientation, $\Phi_D(t)$, and life-time function, $\psi(t)$, obtained from time-correlation functions for ν_7 and $\nu_8(e)$ of liquid methyl cyanide.

with vibrations of the a_1-type, D_{a_1}, is directly obtained from the half-width of ν_2 or ν_4, namely:

$$D_{a_1} = 0.76 \pm 0.02\ \text{psec}^{-1} \tag{14}$$

because the shapes of a_1-type bands are good Lorentzian shapes. Using the values of D_e and D_{a_1}, the rotational diffusion constants about the x-and z-axes (D_x and D_z respectively) are calculated to be:

$$D_x = 0.38 \pm 0.01\ \text{psec}^{-1}$$

and:
$$D_z = 0.96 \pm 0.16\ \text{psec}^{-1}.$$

The correlation function related to the rotational diffusion, $\Phi_D(t)$, and life-time function, $\psi(t)$, are illustrated in Fig. 11. A comparison of Fig. 11 and Fig. 9 or 10 shows that $\Phi_D(t)$ and $\Phi(t)$ are essentially the same after about 1.0 psec; this corresponds to the situation in which $\psi(t)\Phi_F(t)$ decays very rapidly. In other words, almost all the molecules in the system follow diffusional reorientation at long times even if they behave like free-rotors at $t=0$. This result is consistent with that of a general theory of stochastic processes,[18]—that is, the finding that a correlation function of a random variable approaches a Markoffian exponential form at long times if the distribution of the variable is Gaussain.

Conclusion

The preceding discussion may be summarized as follows.

(1) The molecular reorientational motion of liquid methyl cyanide is diffusional around the x- and y-axes. The rotation around the z-axis must be understood as an intermediate state between free and diffusional ones.

(2) The vibration-rotation interaction affects the apparent correlation time.

(3) The intermediate state between free rotation and rotational diffusion may be described by the correlation function of Eq.(5).

(4) Rotational diffusion constants can safely be obtained if we can calculate a time-correlation function over a long period from the observed absorption spectra.

19) S. R. Polo and M. K. Wilson, *J. Chem. Phys.*, **23**, 2376 (1955).

This conclusion supports the description of a reference.[3)]
(5) Incidentally, a life-time function can be calculated if we have enough absorption data, which conversely describes the details of the molecular reorientation process.

CNDO Calculations on the Electronic Spectra of Several Saturated Compounds

Naoto OHMICHI, Akio TAJIRI,* and Takeshi NAKAJIMA
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received April 10, 1972)

CNDO calculations of the excited states were performed on the first three members of paraffinic hydrocarbons —methane, ethane, and propane, and on three compounds of saturated three-membered rings—cyclopropane, ethylenimine, and ethylene oxide. The method gives a reasonable interpretation of the electronic spectra of both kinds of compounds.

Most of the molecular orbital calculations on excited electronic states of organic compounds have so far been confined to π-electronic systems. There have been very few systematic and quantitative studies of electronic spectra on saturated compounds either theoretically or experimentally. One reason for this has been that the energy range of the electronic transitions in saturated compounds lies in the vacuum ultraviolet region, so that we had to wait until the spectroscopes of this energy range became avialabe for chemists.

Recently many experimental results on the electronic excitations in this energy region have been reported. Raymonda and Simpson[1] observed the vacuum ultraviolet absorption spectra of alkanes, while Lassettre *et al.*[2] and Brongersma *et al.*[3] reported the results of their electron-impact experiments on methane, ethane, and cycloalkanes. Particularly, the low-energy electron-impact excitation spectra observed by Brongersma *et al.* provide information about the singlet-triplet transitions in saturated hydrocarbons.[3] Moreover, Basch *et al.* reported very important experimental results in which they distinguished Rydberg transitions from valence-shell absorptions by making a condensed-phase vacuum ultraviolet experiment.[4]

As for theoretical treatments, several new molecular orbital methods, in which all valence electrons are treated and which can be applied to saturated molecules, have been proposed, one after another. Particularly, the CNDO method first proposed by Pople, Santry and Segal[5-7] has recently been used by many authors for MO calculations, mainly of the ground states of molecules. On the other hand, Del Bene and Jaffé[8-10] succeeded in reproducing experimental results on the electronic spectra of π-electronic systems including heteroatoms by using a modified version of this method. There have been however, few studies of the electronic spectra of σ-systems within the framework of the CNDO method.[11,12]

In view of these circumstances, we previously proposed[13] an approximate method with a new parametrization for the bonding parameter, β_A^0, and the two-center electron repulsion integral, γ_{AB}, within the framework of the CNDO/2 method; this method can be applied to the calculation of the electronic spectra of both saturated and unsaturated molecules.

In the present paper, we will apply this method to a series of paraffinic hydrocarbons and to a series of saturated three-membered ring compounds. We will compare the calculated electronic spectra of these molecules with those of Katagiri and Sandorfy,[14] who used the Pariser-Parr-Pople-type method on paraffinic hydrocarbons, and with those of Clark, obtained using the Pople-Segal CNDO/2 method[11] on ring compounds.

Method of Calculation

As we mentioned in the previous paper, our method is a compromise between the methods of Bene-Jaffé[8]

and of Sichel-Whitehead.[15] The F matrix elements are given in this method as:

$$F_{\mu\mu} = U_{\mu\mu} + \left(P_{AA} - \frac{1}{2}P_{\mu\mu}\right)\gamma_{AA} + \sum_{B \neq A}(P_{BB} - Z_B)\gamma_{AB}, \quad (1)$$

$$F_{\mu\nu} = \kappa/2(\beta_A^0 + \beta_B^0)S_{\mu\nu} - \frac{1}{2}P_{\mu\nu}\gamma_{AB}, \quad (2)$$

where μ and ν denote atomic orbitals centered on the A atom and the B atom respectively. The empirical parameter, κ, is taken as 0.75 for the π-bonds and as 1.0 otherwise. $U_{\mu\mu}$ is the diagonal matrix element of the atomic orbital, ϕ_μ, for the core Hamiltonian of the A atom. $P_{\mu\nu}$ is the charge density and bond-order matrix. P_{AA} is the total charge on the A atom. γ_{AB} is an average interaction energy between an electron in any valence atomic orbital of the A atom with another in an orbital of the B atom. β_A^0 is the bonding parameter, which depends only on the nature of the A atom.

For $U_{\mu\mu}$ and γ_{AA}, we used the values of Sichel and Whitehead.[15] In evaluating the interatomic electron repulsion integral, γ_{AB}, we employed Mataga-Nishimoto's formula;

$$\gamma_{AB} = 1/(R_{AB} + a), \qquad a = 2/(\gamma_{AA}^* + \gamma_{BB}^*), \quad (3)$$

where γ_{AA}^* is the "extrapolated" one-center electron repulsion integral.[15] The empirical parameter, κ, and the bonding parameters, β_H^0 and β_C^0 were so reparametrized that they reproduce the experimental spectra of the reference molecules—methane, ethylene, and benzene.[13] The values of β_N^0 and β_O^0 needed for calculating ethylenimine and ethylene oxide were determined using pyrole and furan as reference molecules. In Table 1, the parameter values used in this work are compared with those used in other methods.

The geometries of methane, cyclopropane, ethylenimine, and ethylene oxide were taken from Sutton's tables.[16] For ethane and propane, all the angles are assumed to be tetrahedral, and the bond lengths of C-C and C-H are assumed to be 1.54 Å and 1.09 Å respectively; this is done for convenience in calculation and in comparison of the results. For ethane, we adopted two thermally-probable conformers, staggered (D_{3d}) and eclipsed (D_{3h}).

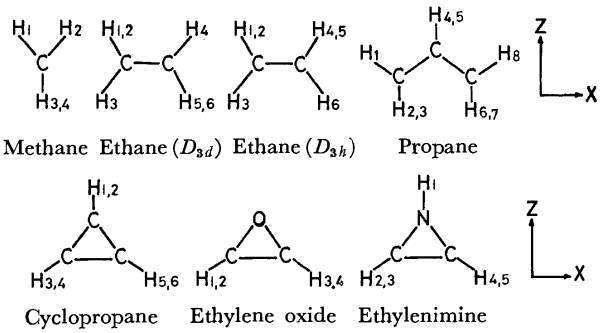

Fig. 1. Co-ordinate systems for calculated molecules.

The calculations were carried out on the NEAC 2200 Model 500 computer of Tohoku University, using the program of our modified CNDO method including configuration interactions restricted to 30 lowest singly-excited configurations.

Results and Discussion

Electronic Spectra of Paraffinic Hydrocarbons.

Methane: Table 2 shows the calculated and observed energies of excited states of methane. The calculated $T_2 \leftarrow A_1$ transition at 10.64 eV was used, together with some transitions in ethylene and benzene, for the parametrization of κ, β_H^0 and β_C^0.[13] The next higher allowed transition is calculated to be 13.42 eV($T_2 \leftarrow A_1$). This value is too high to be associated with the observed second transition at 11.7 eV.[3] We may, therefore, reasonably assign this observed band to one of the quintuply-degenerate forbidden transitions, $E \leftarrow A_1$ and $T_1 \leftarrow A_1$, at 12.27 eV. These forbidden transitions may be perturbed by vibrations belonging to the T_2 symmetry and may become vibronically-allowed by borrowing intensity from the $T_2 \leftarrow A_1$ transition at 13.42 eV, which is very intense.

Using the low-energy electron impact as a spectroscopic tool, Brongersma *et al.*[3] observed excitation spectra for saturated hydrocarbons considerably different from the optical ones. The difference arises from the fact that the selection rules for electronic excitation by electron impact differ fundamentally from those encountered in light-absorption spectroscopy. In the case of low-energy electron impact, in particular, as it is thought that the exchange between the incident electron and a molecular electron is possible, the difference between the two types of spectra may mainly be a result of singlet-triplet transitions. For methane, Brongersma *et al.* reported a low-energy electron impact excitation spectrum—a trapped electron (TE) spectrum—showing singlet-triplet transitions at 8.8 and 11.0 eV.[3] Our results on the triplet states of methane are in good agreement with their experimental data.

Ethane: Table 3 shows the calculated and observed excited states of ethane. The difference in predicted spectrum between the conformational isomers of ethane, staggered and eclipsed, turned out to be very small. We assign the observed values to the predicted values for the staggered ethane, thermally-most-probable conformer. According to Lassettre *et al.*, [2] three transitions are observed, at 8.5, 9.4, and 10.68 eV (third column). They may be assigned to the $E_u \leftarrow A_{1g}$ transition predicted at 8.81 eV (0.26), the $A_{2u} \leftarrow A_{1g}$ transition at 9.55 eV (0.32), and the $E_u \leftarrow A_{1g}$ transitions at 11.02 eV (0.15) and 11.43 (0.57) respectively. Thus, a good agreement between theory and experiment is obtained.

For triplet states, the present calculation predicted the first transition at 7.88 eV with a transition type of $E_u \leftarrow A_{1g}$. Brongersma *et al.*[3] observed the first peak at 9.3 eV, one with an onset at 7.1 eV, by using the low-energy electron-impact technique. In the optical[1] and high-energy electron-impact[2] spectra, the onset is at 8.1 eV. According to Brongersma *et al.*, the difference between these two types of spectra suggests that the contribution of singlet-triplet transitions is important. It is likely that the absorption between 7.1 eV and 8.1 eV observed in the TE spectrum is due mainly to the singlet-triplet transition, which is predicted at 7.88 eV by our method.

Propane: The results of the calculation of the elec-

tronic-transition energies of propane are given in Table 4, together with the experimental results. We calculated the excited states of propane, assuming an all-*trans* C_{2v} conformation. Actually, however, the propane molecule is not fully in an all-*trans* conformation; rather, it takes various *gauche*-type forms. Although each conformer will have excitation energies different from those of other conformers, the difference, may be guessed from the results concerning ethane conformers, may be very small. Thus, we may tentatively give the assignments shown in Table 4.

The lowest singlet-singlet transition ($B_2 \leftarrow A_1$) was calculated to be at 8.37 eV, with the very large oscillator strength of 0.35. From the experimental data given by Raymonda *et al.*[1] and by Lassettre *et al.*,[2] however, we can read the weak absorption at 8.1 eV as the first band. According to Salahub *et al.*[12] and Katagiri *et al.*,[14] the symmetry of the predicted first transition for propane is B_1. Our method, on the other hand, predicts the lowest $B_1 \leftarrow A_1$ transition at 8.40 eV (0.16), higher by 0.03 eV than the lowest calculated transition. This energy difference is so small that the order of these two predicted transitions is not essential for this type of calculation. We may thus assign the weak band observed at 8.1 eV as a shoulder to the $B_1 \leftarrow A_1$ transition predicted at 8.40 eV and the next strong absorption band observed at 8.9 eV to the group transitions including the $B_2 \leftarrow A_1$ transition calculated at 8.37 eV.

The transitions predicted by Katagiri and Sandorfy[14] seem, in general, to be too low to be assigned to the observed spectrum.

Electronic Spectra of the Saturated Three-membered Rings. Several discussions of the electronic structures of saturated three-membered rings have been reported; the earlier works focussed on the bonding nature,[17,18] and the more recent works, on their spectral properties.[4,11,19-22] Walsh has discussed the olefin-like structures of cyclopropane and ethylene oxide.[18] The results of our calculations of the electronic spectra of these molecules seem to support the study of Walsh,[18] since all the first singlet-singlet transitions of these molecules are predicted to be in about the 7 eV energy region, considerably lower than in the case of ususal saturated molecules and rather close to those met with in the case of olifins.

Cyclopropane: The calculated excited states of cyclopropane are shown in Table 5, alobg with the experimental values. Our calculations provide results very close to those predicted by Clark.[11] He associated the calculated transitions with the experimental ones obtained by Wagner and Duncan, including Rydberg transitions.[20] Recently Basch *et al.*[4] have reported new spectral data on cyclopropane: they proposed the values of 7.4, 8.6, and 10.3 eV for the N→V transitions. These values were obtained by comparing the gas-phase and condensed-phase spectra.

This is based on the fact that Rydberg bands do not appear in condensed phases. We may assign these observed transitions to the predicted 7.39 eV (E'←A_1' (0.06), 8.87 ev(E'←A_1') (0.17), and 9.73 eV (A_2''←A_1') (0.67) transitions respectively.

The TE spectrum of cyclopropane reported by Brongersma *et al.*[3] is quite different from the optical spectrum in the region of about 6—7.5 eV, suggesting that there is an important contribution of the singlet-triplet transition in the TE spectrum. In addition, Wagner *et al.*[20] observed a weak absorption centered around 6.79 eV for cyclopropane. The calculation by Brown *et al.*[21] suggests that this absorption is due to a singlet-triplet transition. In accordance with these peices of evidence, our calcualtion gives the A_2'←A_1' transition at 6.76 eV as the first singlet-triplet transition. The corresponding value calculated by Clark[11] is 5.95 eV (E'—A_1').

Ethylene Oxide: The calculated and observed excited states of ethylene oxide are listed in Table 6. Our method and Clark's method[11] give quite different results. Moreover, his assignments seem to be inadequate, for, according to Bash *et al.*,[4] some experimental values to which Clark assigned his calculated values come from Rydberg transitions. For example, the observed values of 7.23, 7.89, 8.64, and 8.96 eV[22] with which Clark associated his calculated values turned out to be due to Rydberg transitions.[4] The results of our calculation of ethylene oxide agree fairly well with the new experimental results.

Our calculation predicts three low-lying triplet states at 6.43 eV (A_2←A_1), 6.80 eV (B_1←A_1), and 7.23 eV (B_2←A_1); they are higher than Clark's results by ca. 1 eV.

Ethylenimine: In Table 7 we show the calculated and observed excited states of ethylenimine. Here again our method gives results quite different from those obtained usnig Clark's method.[11] This molecule belongs to the point group C_s, so that all singlet-singlet transitions are allowed. According to Basch *et al.*,[4] the lowest N→V transition is observed at 7.4 eV, so Clark's values[11] seem to be too low. The two rather close transitions predicted using our method, the A''←A' transition at 7.13 eV (0.03) and the A'←A' transition at 7.91 eV (0.02), may be associated with the observed first transition at 7.4 eV. In the energy region above 8 eV, our method predicts a large number of transitions very close to each other. We may associate these predicted transitions with the two bands observed at 9.0 and 10.5 eV, which are very broad, probably because of the overlapping of transitions.

The authors are greatly indebted to Professor S. Katagiri of Hirosaki University for many helpful discussions.

Properties of Water in Macromolecular Gels. IV. Proton Magnetic Resonance Studies of Water iu Macromolecular Gels

Masuo AIZAWA, Jun MIZUGUCHI, Shuichi SUZUKI, Shoichi HAYASHI*, Teruo SUZUKI*, Noriko MITOMO*, and Hiroshi TOYAMA*

(Received November 11, 1971)

Electrochemical and dilatometric studies have indicated that at least three states of water exist in macromolecular gels. The properties of each state of water in gels such as agarose gels were investigated by high-resolution and broadline PMR over the temperature range from +50 to −60°C. The linewidth of water protons in gels was found to depend markedly on the water content of gels, and the linewidth *vs.* water content curve gave two inflection points. One of the inflection points can be attributed to the so-called bound water, but the other cannot be explained unless three states of water are assumed in gels. Three kinds of transition temperatures were confirmed by anomalous changes in the PMR linewidth below 0°C. The so-called bound water exhibited no transition temperature between 0 and −20°C, and free water gave the transition temperature at 0°C. Moreover, the transition temperature of a quantity of water was distributed in the range from 0 to −20°C. On the basis of the transition temperature, the properties of water in macromolecular gels are discussed.

A solid-like state of a biopolymer adsorbing a small amount of water and an aqueous solution of biopolymer have been taken as the samples in most of the investigations of the properties of water in biopolymers, such as proteins, starch, and cellulose.[1] These two states of biopolymers investigated, however, seem to be somewhat different from that of native biotissues, which include a large quantity of water in their network. Macromolecular gels, such as polysaccharide and protein, have been used as the samples during the present investigation. Especially the results on agarose gels will be described in this report.

Two states of water, a so-called bound water and free water, are accepted to be present in macromolecular gels. Electrochemical[2,3] and dilatometric studies of the properties of water in macromolecular gels[4] have made it clear that free water in macromolecular gels should be classified into at least two groups. Furthermore, the properties and states of water in agarose gels were investigated by PMR in this investigation.

The nuclear magnetic resonance linewidth is known to be related with the spin-spin relaxation time, T_2, indicating the motional state of a nuclear spin.[5] Therefore, the motional state of water can be estimated by means of the PMR linewidth of water protons. In recent years, the technique of nuclear magnetic resonance has been used with some success to characterize distinct types of the molecular motion of water adsorbed on biopolymers.[6-10] Several PMR studies of water in agar have been carried out. Woessner[11] used pulse PMR to study the temperature hysteresis in agar sol-gel transitions of both the agar macromolecules and water in the agar–water system; his results indicate that the major portion of the water molecules (in the agar–water system) is not in an "ice-like" or modified state. These applications of PMR, however, have been limited to investigations on the state of water adsorbed by macromolecules containing either small amounts of water or a large quantity of water. In order to obtain additional information concerning molecular motions of water in macromolecular gels, the high-resolution and broad-line PMR spectra of water in agarose gels were measured over the full range of water content from 0 to 100% by weight. Additionally, the solid-liquid transition of water in gels was investigated by studying the temperature dependence on the PMR linewidth of the water proton in the agarose–water system to clarify the properties and the states of water in gels.

Experimental

Materials. The agarose for immuno-electrophoresis use was purchased from the Nakarai Chemicals Co., Ltd., and was assayed for its ash content by the atomic-absorption analysis method. The agarose contained Mg 0.04, Ca 1.01, K 0.09, and Na 1.75 mg/g dry agarose.

A series of samples was obtained by varying the mixing ratio of water and agarose; they were sealed in a standard PMR sample tube (5 mm O.D.). The water content of the sample was determined by drying it at 105°C for 24 hr and by then weighing the dried matter.,

PMR-spectra Analysis. The proton NMR spectra were obtained using a JNM-C-60HL high-resolution NMR spectrometer and a MW-40 broad-line NMR spectrometer operating at 60 MHz and 40 MHz respectively, with an external NMR lock system. Since the signals were wider than those normally seen in high-resolution work, it was necessary to operate at optimum rf power levels, just below signal saturation. The spectrometer was equipped with a variable-temperature controller which maintained the sample within ±0.5°C of the desired temperature. The temperature

of a sample was calibrated by means of a copper-constantan thermocouple placed inside the sample tube. The linewidth of the spectra was expressed in terms of half linewidth, *i.e.*, the linewidth at half of the maximum peak height.

Results

Broad-line PMR Spectra of Agarose Gels. The broad-line PMR spectra of agarose gels were measured in order to distinguish the signal of the water proton from that of the agarose protons. For the agarose-water system containing 10% of water by weight, the spectra are shown in Fig. 1, with the abscissa expressed

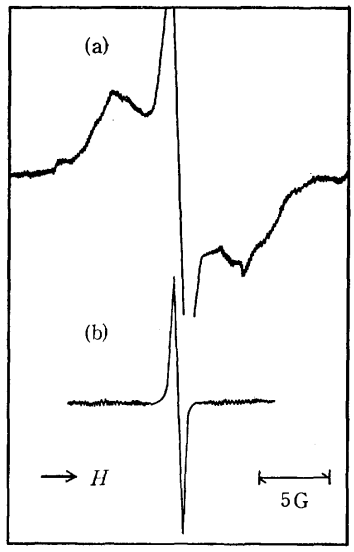

Fig. 1. Broad line PMR spectra of agarose containing 10% of water.
(a): Gain 1.0×100, Response 2, Mod. width 1G; (b): Gain 1.0×10, Response 1, Mod. width 1G, (25±0.5°C).

in Gauss units. Two components, namely, a broad one which can be attributed to the agarose proton and a narrow one attributable to the water proton, were detected, though the broad component disappeared in the (b) spectrum. The linewidth for the agarose proton in the (a) spectrum is evaluated as approximately 9 gauss. Therefore, it is reasonable to assign the signal in high-resolution PMR spectra to the water proton.

PMR Linewidth of water in Various Water Contents of Agarose Gel. PMR measurements showed that the line shape and width of the water proton are independent of the orientation of the gels in the magnetic field; this means that there is no preferential orientation of water molecules with respect to the gel structure when this technique is used.

The PMR spectra for agarose gels containing 98 and 80% water at room temperature are illustrated in Fig. 2; the spectra are attributed to protons of water in agarose gels.

The PMR linewidth of water in agarose gels was measured for the full range of water content from 0 to 100%. The results are presented in Fig. 3, where the linewidth is given as the linewidth at half of the maximum peak height. In the water-content range from 100 to 60% and from 30 to 0%, the linewidth was found to increase with a decrease in the water content.

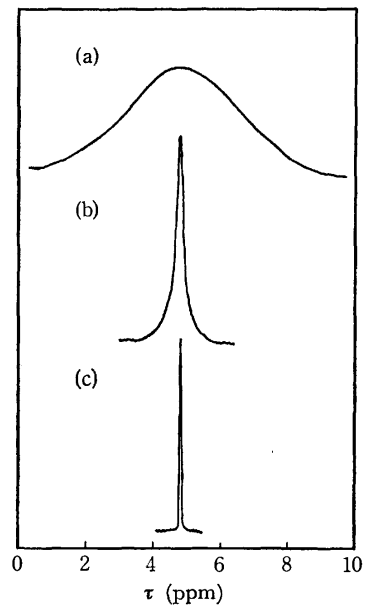

Fig. 2. PMR spectra of water in agarose gels; water content.
(a): 80%, (b): 98%, (c): pure water (H_2O), (25±0.5°C).

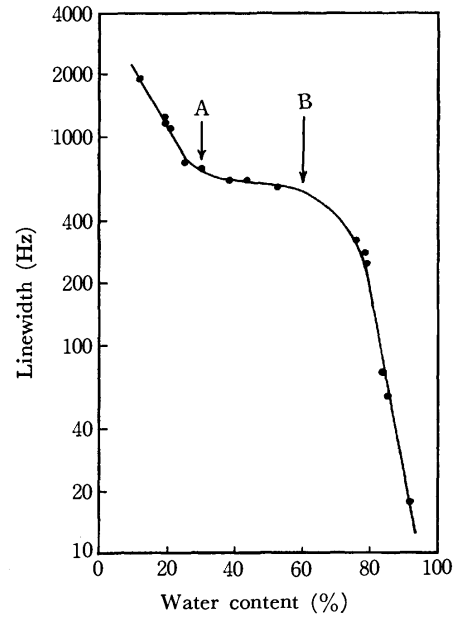

Fig. 3. Water content dependence of the linewidth of water proton in an agarose gel (25±0.5°C).

On the other hand, the linewidth of water protons is seen to be independent of the water content in the water-content range approximately from 60 to 30%.

Temperature Dependence of the PMR Linewidth of Water at Lower Temperatures. It has been known that ordinary water exhibits a transition at 0°C, which is accompanied with a marked change in the NMR linewidth of its proton. On the other hand, the water in gels is considered to give a transition temperature different from that of the ordinary water.

The transition temperature at lower temperatures was determined in accordance with the relationship between the temperature and the NMR linewidth of the water proton.

Agarose gels with various amounts of water were classified into three groups, A, B, and C. Group A

contains less than approximately 30% of water, most of which may be dominantly contributed to a motional state of the so-called bound water. The water content of Group B ranges from approximately 30 to 60%, while that of Group C is above about 60%.

The PMR spectrum for each sample was at first measured with an elevation of temperature in the range from 0 to 50°C, and then in the range from −60 to 0°C after a sufficient precooling of the sample in liquid nitrogen.

The PMR spectra of a sample containing 78.5% of water (by weight) at various temperatures are shown in Fig. 4. Each linewidth increases markedly with a decrease in the temperature.

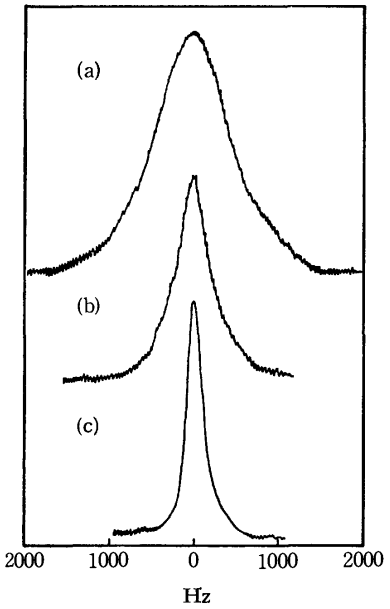

Fig. 4. PMR spectra of agarose gel (water content 78.5%); (a): −50°C, (b): −14°C, (c): 25°C.

The temperature dependence of the linewidth for Group A is shown in Fig. 5, where the abscissa represents the reciprocal of the absolute temperature (1/°K) and where the coordinate represents the half-linewidth (Hz). The PMR linewidth for Group A increases linearly with a decrease in the temperature up to approximately −20°C ($1/T=3.95\times10^{-3}$); the increase in the rate is found to change slightly at this temperature. In other words, an inflection point (T_γ) is found in Fig. 5.

The temperature dependence of the linewidth for Group B is presented in Fig. 6, and that for Group C, in Fig. 7. In contrast with Group A, the linewidth for Group B decreases with a decrease in the temperature up to approximately −20°C ($1/T=3.95\times10^{-3}$), though the inclination is changed in the range approximately from 0°C to −20°C ($1/T=3.66$ to 3.95×10^{-3}). On the other hand, the linewidth for Group C was found to change markedly at 0°C ($1/T=3.66\times10^{-3}$) in addition to the marked change at −20°C ($1/T=3.95\times10^{-3}$).

Discussion

We expected to detect one inflection point in the linewidth-water content curve, because two states of

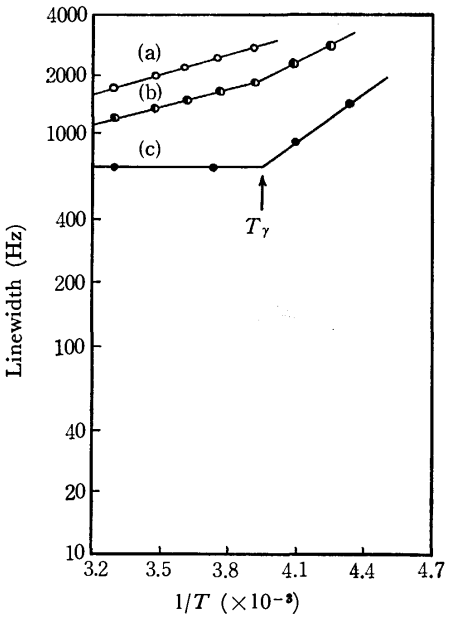

Fig. 5. PMR linewidth of water in agarose gels (Sample belonging to Group A) as a function of temperature. Water content; (a): 12%, (b): 19%, (c): 26%.

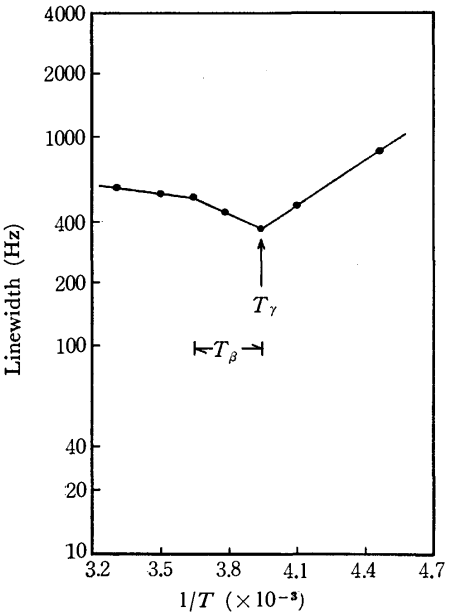

Fig. 6. PMR linewidth of water in agarose gel containing 48% of water (Sample belonging to Group B) as a function of temperature.

water are generally considered to exist in gels. We found, however, two inflection points, A and B, on the curve, as is shown in Fig. 3. The water content at the A inflection point can be attributed to the amount of so-called bound water in an agarose gel. Whereas the B inflection point is a new finding. From the independence of the linewidth of the water content, it seems reasonable to suppose that the water molecules in agarose gels containing 30 to 60% of water are in comparable motional states, for the curve is flat in the water-content range from 30 to 60% shown in Fig. 3.

On the other hand, the results obtained in previous electrochemical and dilatometric studies[2-4] can not be explained without supposing three states of water

in gels.

Therefore, it can be concluded that there are at least three states of water molecules in macromolecular gels. These states of water may be named W_1, W_2, and W_3, of which W_1 and W_2 are comparable to conventional free water, and W_3 to the so-called bound water.

The transition of water is expected to be accompanied by a marked change in the PMR linewidth. Each agarose gel was found to exhibit marked changes in PMR linewidth at lower temperatures, as is shown in Figs. 5, 6 and 7. In addition, these changes depend on the water content of agarose gel, as is presented in Fig. 8. Therefore, the marked changes in Figs. 5, 6 and 7 may be presumed to be caused by the transition of water in gels.

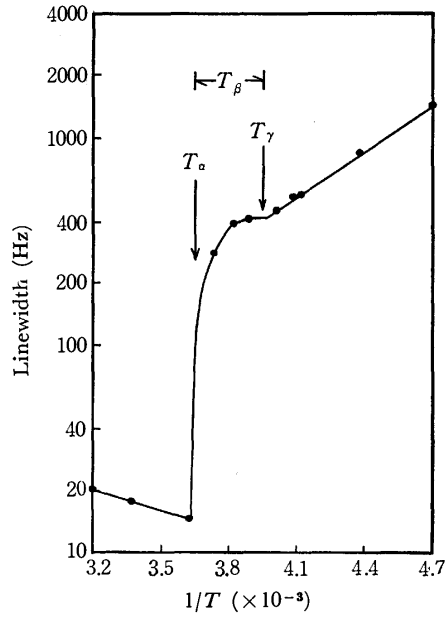

Fig. 7. PMR line width of water in agarose gel containing 92% of water (Sample belonging to Group C) as a function of temperature.

When these inflection points for Group C are named T_α, T_β, and T_γ respectively, as is presented in Fig. 7, the two in Fig. 6 may be T_β and T_γ, and the one in Fig. 5 may be T_γ, because the corresponding temperatures at the inflection points agree with each other.

The electrochemical studies have shown that the transition temperature of water in a gel was distributed from 0°C to approximately −20°C, but no transition temperature for a gel containing a small amount of water was confirmed at lower temperatures. Those results agree with those of nuclear magnetic resonance studies. As is shown in Fig. 7, the transition temperature is distributed from T_α to T_γ, *i.e.*, in the range of T_β. On the other hand, an agarose gel containing a very small amount of water exhibits no transition temperature.

On the basis of these results, the properties of W_1, W_2, and W_3 in gels can be presumed to be as follows.

As is shown in Fig. 7, the linewidth changes abruptly at T_α; W_1 may exhibit a transition between the liquid and the solid states corresponding to ordinary water at 0°C ($1/T=3.66\times10^{-3}$), *i.e.*, free water, though W_1 in gels is hindered from flowing out.

W_3, corresponding to the so-called bound water, may be oriented on agarose by the interaction between the H_2O molecule and the OH group of agarose, since the W_3 content almost agree with the OH-group content of agarose, which is calculated according to the proposed structure[12] of agarose shown in Fig. 9. Therefore, W_3 should exhibit solid-like behavior if such interaction is strong. Since the linewidth of W_3 is of the order of 1000 Hz, W_3 is supposed to be in a solid-like state, even at room temperature, due to the strong interaction between the H_2O molecule and the OH group of agarose. On this supposition, it is reasonable that the transition temperature for W_3 cannot be confirmed in the range of temperature investigated here.

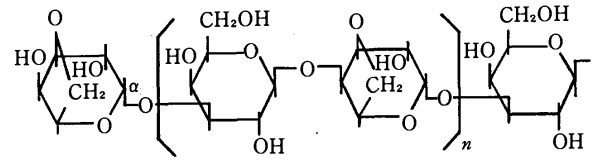

Fig. 8. Structural formula of agarose[12]

The properties of W_2 have not yet been clarified except that the linewidth of W_2 is several hundred Hz, and except that the transition temperature of W_2 may be distributed from 0°C to approximately −20°C. As one would expect, the molecules of water in gels are hydrogen-bonded; W_1, W_2 and W_3 cannot be sufficiently discriminated, but each of them shows dominant properies related to the restriction of water in the potential fields which exist in cavities of the gel. The properties of W_2 described above, however, indicate that W_2 is more fixed than W_1, but more mobile than W_3. It should be emphasized that W_2 is presumed to play an important role in the structure and properties of macromolecular gels because its properties are intermediate compared to those of W_3 and W_1. The detailed properties and the states of W_2 are under the investigation.

Conclusion

The properties of three states of water in agarose gels were investigated by high-resolution PMR over the temperature range from +50 to −60°C.

The transition temperature for water in agarose gels was confirmed to be distributed from 0°C to approximately −20°C by the anomalous temperature-dependence of the PMR linewidth. The transition temperature at 0°C is attributed to that of W_1, and the transition temperature of W_2 may be distributed from 0°C to approximately −20°C. On the other hand, W_3 may give no transition tempersture in this temperature range. Therefore, W_1 may be ordinary water, though it is prevented from flowing out. W_2 may be more fixed than W_1, but more mobile than W_3, and W_3 may be in a solid-like state even at room temperature due to a strong interaction with the OH group of agarose.

Molecular Vibrations, Conformational Analyses, and Force Fields of Normal and Monodeuterated (Methylthio)methanethiol

Masaru OHSAKU, Yuji SHIRO,* and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

**Shinonome Branch School, Faculty of Education, Hiroshima University, Shinonome-3-chome, Hiroshima*

(Received December 6, 1971)

(Methylthio)methanethiol, CH_3SCH_2SH, and (methylthio)methanethiol-d_1, CH_3SCH_2SD, were prepared, and their infrared spectra were obtained in the gaseous, liquid, and solid states. The obtained spectra have been assigned. The frequency shifts by D-substitution, gaseous-liquid transition. and liquid-solid transition have also been discussed. The normal coordinates of these thiols have been treated by a modified Urey-Bradley force field. The force constants used in the computation have been transferred from those previously reported, but we adjusted them to produce the experimental wave numbers. The calculated wave numbers correspond well with those observed. The stable molecular conformations of the normal and deuterated species have been determined by the aid of the normal coordinate treatment. In the gaseous and liquid states, at least three to four forms from among TT, TG, GT, GG, and GG′ have been confirmed to exist. In the solid state, though, CH_3SCH_2SH or CH_3SCH_2SD exists in only one form: GG.

Recently, the molecular vibrations and conformations of alkanethiols have been extensively studied.[1-6] At present, however, we can find no report on the vibrational and structural analysis of (methylthio)methanethiol. In this paper we will discuss the vibrational assignments; we prepared CH_3SCH_2SH and CH_3SCH_2SD and recorded their infrared spectra. From the vibrational data thus obtained, we will first treat the molecular vibrations of these molecular species in detail. (Methylthio)methanethiol, CH_3SCH_2SH has a molecular unit in common with CH_3SCH_2–D and CH_3SCH_2–SCH_3. We previously reported the existence of rotational isomers on the CH_3SCH_2D species.[7] As for the $CH_3SCH_2SCH_3$ species, we also postulated the existence of rotational isomers around the C–S bond.[8] Therefore, we will now try to establish the existence of rotational isomers on the CH_3SCH_2SH and CH_3SCH_2SD species. In order to determine the molecular conformation and confirm the vibrational assignment, the normal coordinate treatment has also been carried out for normal and monodeuterated (methylthio)methanethiol. For the organo-sulfur compounds without the SCS skeleton, Scott and El-Sabban carried out[5] the normal coordinate treatment by the use of the valence force field; they thus obtained a set of valence force constants. In the present study, the molecular vibrations were treated with a modified Urey-Bradley-type potential function, and the force constants were determined on a part of the SCS skeleton. The obtained force constants were then compared with Scott and El-Sabban's force constants.

Experimental

(Methylthio)methanethiol, CH_3SCH_2SH, was prepared by the method of Fehér and Vogelbruch.[9]

Bp 61°C/47 mmHg, (reported[9] bp 60°C/47 mmHg). The purity of the sample was above 98%, as estimated by gas chromatography. The deuterated species, CH_3SCH_2SD, was prepared from normal (methylthio)methanethiol by the direct exchange of thiol-hydrogen with D_2O in the presence of a small amount of catalytic potassium carbonate. The gaseous spectra (4000—550 cm^{-1}) were recorded by means of a 10-cm gas cell equipped with KBr windows under an appropriate vapour pressure. The liquid spectra (4000—200 cm^{-1}) were recorded by means of a liquid cell equipped with CsI windows. The solution spectra (4000—550 cm^{-1}) were recorded in carbon disulfide. The solid spectra (4000—200 cm^{-1}) were recorded near the temperature of liquid nitrogen with a low-temperature cell. The instrument used for the infrared measurement was a Perkin-Elmer Model 621 Spectrophotometer.

Vibrational Assignment

Tables 1 and 2 show the vibrational data obtained for CH_3SCH_2SH and CH_3SCH_2SD respectively. In the obtained spectra of the 3000—1000 cm^{-1} region,

there appeared nearly the same number of bands as we expected for one conformation. In the 1000—200 cm^{-1} region, however, a fairly larger number of bands appeared than that expected for one form. Therefore the question of the existence of rotational isomers comes to mind.

Now we can see five possible molecular conformations of (methylthio)methanethiol: TT (C_s), TG (C_1), GT (C_1), GG (C_1), and GG′ (C_1), all of which are shown in Fig. 1. All of the fundamental vibrations of each conformation are infrared-active.

Liquid-state Spectra. The liquid-state spectra of CH_3SCH_2SH and CH_3SCH_2SD are shown in Figs. 2 and 3 respectively. The obtained spectra of normal (methylthio)methanethiol are similar to those of bis-(methylthio)methane.[8]

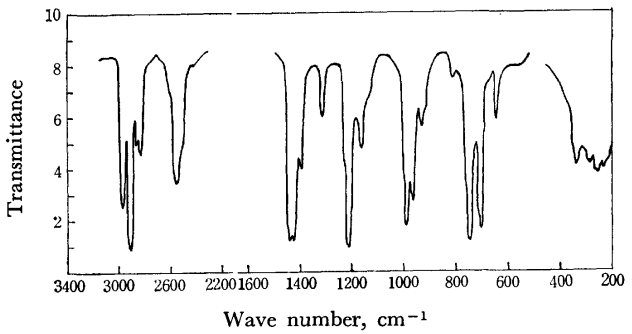

Fig. 2. Infrared spectra of (methylthio)methanethiol in the liquid state.

Five C-H stretching vibrations are expected for one conformation. In this region, we observed five bands. The bands at 2854 and 2829 cm^{-1} (2828 cm^{-1} in D-species), however, may not be due to the fundamentals. The characteristic bands of normal thiols (or deuterated thiols) are expected in the 2600—2500 cm^{-1} (or 1900—1800 cm^{-1}) region. The very broad bands around 2540 and 1860 cm^{-1} are assigned to the S-H

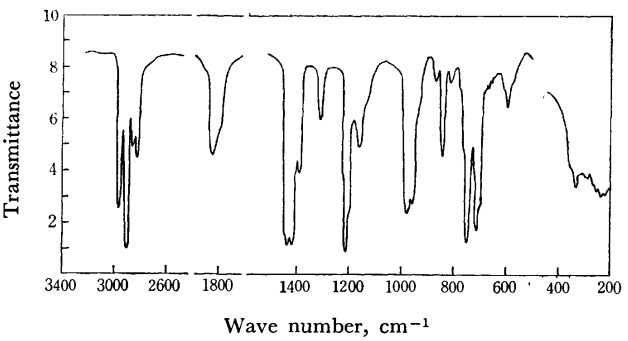

Fig. 3. Infrared spectra of (methylthio)methanethiol-d_1 in the liquid state.

and S-D stretching vibrations respectively. From the assignments of dimethylsulfide and $CH_3S(CH_2S)$-CH_3 (n=1—3),[8] the bands appearing around 1430 cm^{-1} are assigned to the CH_3 degenerate deformation, and a band around 1390 cm^{-1} is assigned to the CH_2 bending vibrations, although, these vibrations are not independent of each other. For the CH_3 symmetrical deformation, the band at 1318 cm^{-1} of the normal species and the band at 1317 cm^{-1} of the deuterated species are assigned. The band maxima at 1214 and 1164 cm^{-1} of the normal species, and at 1210 and 1158 cm^{-1} of the deuterated species, are assigned to the CH_2 wagging and twisting vibrations respectively. The CH_2 wagging and twisting bands are shifted in *ca.* 5 cm^{-1} to the lower-frequency region by D-substitution. The two shoulder bands around 1210 cm^{-1} of both the normal and deuterated species may be due to the rotational isomerism. The strong bands accompanied by weak shoulder bands at 988 and 960 cm^{-1} of the normal species and at 974 and 961 cm^{-1} of the deuterated species are assigned to the CH_3 rocking vibrations. The CSH bending vibration is expected around 900—800 cm^{-1}. Nothing appears in this region. Although the medium bands with weak

s, -strong; m, -medium; w, -weak; v, -very; sh, -shoulder; br, -broad; and ~, poorly estimated bands.
a) Above 3100 cm^{-1}, 2800—1950 cm^{-1}, and 1800—1500 cm^{-1} regions are omitted.
b), c) See b), c) of Table 1.

shoulders around 930 cm^{-1} are fairly higher than those expected, these bands may be assigned to the CSH bending vibrations. In the deuterated species, a band accompanied by two shoulders around 600 cm^{-1} is assigned to its also. The bands appearing in this region are many more than those expected for one conformation. The obtained band at 805 cm^{-1} of the normal species, and the 840 and 808 cm^{-1} bands of the deuterated species may be assigned to the CH_2 rocking vibrations. The C–S stretching vibrations may appear in the 800—600 cm^{-1} region. Three bands are expected for each conformation. In the infrared measurements, eight bands were observed—at 755, 745, 740, 705, 697, 693, 669, and 639 cm^{-1}—for the normal species, and nine bands—at 774, 758, 746, 725, 707, 695, 670, 661, and 658 cm^{-1}—for the deuterated species. The numbers of observed bands show the possibility of rotational isomerism. In this region, the bands of the normal species are shifted to a higher-frequency region by D-substitution. In the 400—200 cm^{-1} region, we observed eight bands, including very weak shoulder bands, for both the normal and deuterated species. In this region, the bands obtained are also many more than those expected for one form.

Gaseous-state Spectra. The gaseous-state spectra of CH_3SCH_2SH and CH_3SCH_2SD are shown in Figs. 4 and 5 respectively. We could not observe the S–H stretching, S–D stretching, CH_2 twisting, or CH_2 rocking vibrations. In the C–H stretching region, the resolution was fairly good. In both species, very strong and sharp PQR bands were obtained around 2930 cm^{-1}. Those bands are shifted by *ca.* 20 cm^{-1} to a higher frequency region than that in the liquid state. In the CH_3 degenerate deformation and the CH_2 bending region, rotational bands of the water vapor in the atmosphere are overlapped. Therefore,

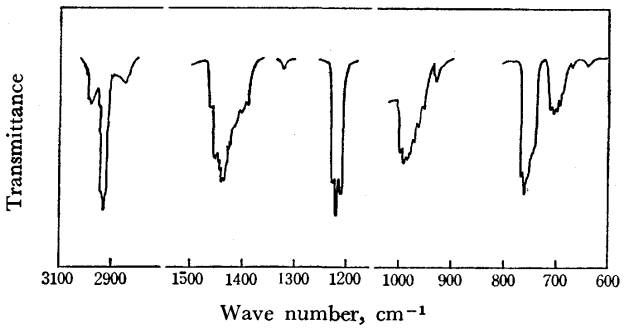

Fig. 4. Infrared spectra of (methylthio)methanethiol in the gaseous state.

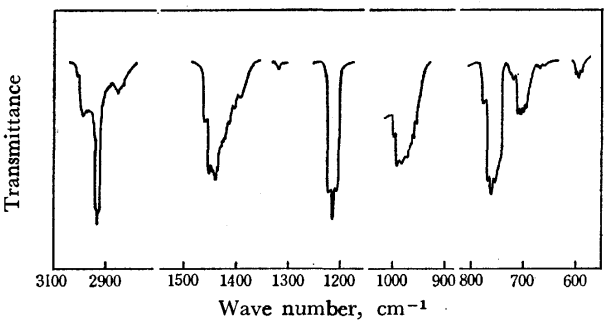

Fig. 5. Infrared spectra of (methylthio)methanethiol-d_1 in the gaseous state.

the band assignments are very difficult. In the CH_2 wagging region around 1200 cm^{-1}, very strong RQP peaks appeared at 1224, 1219, and 1211 cm^{-1} for the normal species, and at 1219, 1213, and 1207 cm^{-1} for the deuterated species. The Q-branch of the D-species shifts lower 6 cm^{-1} than that of the normal species. In the CH_3 rocking region, a lower-frequency

shift upon D-substitution is also observed. In the C-S stretching region, fairly complex spectra were obtained. The bands in this region may be mutually overlapped. In this region, a higher-frequency shift upon D-substitution was observed. In order to confirm the existence of the rotational isomers on CH_3SCH_2SH species, we attempted to investigate the temperature dependence of the intensity of the gaseous bands in the 850—600 cm^{-1} region (33—124°C). However, we could not obtain intensity changes sufficient to decide the energy differences because of the rotational isomerism in this temperature region.

Solid-state Spectra. Near the temperature of liquid nitrogen, we obtained the solid-state spectra of CH_3SCH_2SH and CH_3SCH_2SD shown in Figs. 6 and 7 respectively. Although we repeated annealing above and below their melting points, the samples were not completely crystallized. In the C-H stretching region, the difference between the liquid and solid spectra was not observed. In the S-H or S-D stretching region, a large lower-frequency shift due to the liquid-solid transition was observed. The reason for this lower frequency shift is not clear. In the solid state, however, it is supposed that the intermolecular hydrogen bonding is formed more strongly than the liquid, and that the S-H (S-D) stretching band is shifted lower on a weakening of the S-H or S-D bond. In the CH_3 degenerate deformation, CH_3 symmetrical deformation, CH_2 wagging, CH_2 twisting, CH_3 rocking, CSH or CSD bending, CH_2 rocking, and the skeletal deformation regions, the liquid-solid transition shifts stay within *ca.* 10 cm^{-1}. In the C-S stretching region, the frequency shift due to the liquid-solid transition was not so clear.

From the infrared spectra we have obtained, the following questions arise. The first concerns the extraordinary breadth of the S-H and S-D stretching bands. The second concerns the very large lower-frequency shift (*ca.* 330 cm^{-1}) of the CSH bending vibration upon D-substitution. The third concerns the large higher-frequency shift (*ca.* 35 cm^{-1}) of the CH_2 rocking vibration upon D-substitution. The first can be explained as the result of the rotational isomerism; it may also be due to the hydrogen bond just as in the alcohols. As for the second and third problems, these large frequency shifts will be explained in the following section.

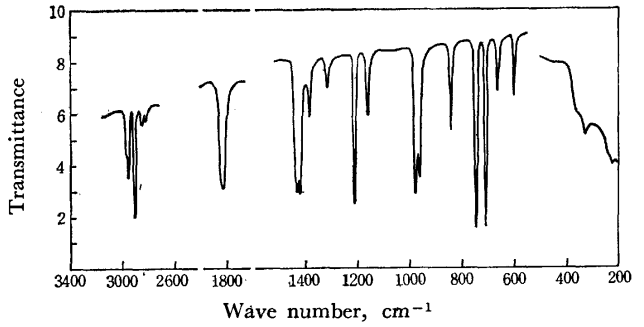

Fig. 7. Infrared spectra of (methylthio)methanethiol-d_1 in the solid state.

Normal Coordinate Treatment

We made the normal coordinate treatment for the five most probable forms: TT, TG, GT, GG, and GG'. The molecular parameters used in the computations were as follows:

r(C-H)=1.09Å, ϕ(CSC)=99°,
r(C-S)=1.81Å, ϕ(CSH)=96.5°,
r(S-H)=1.335Å.

c) Bands disappeared in the solid state.

The other bond angles were tetrahedral. The force field used was one in which we added some correction terms to the simple Urey-Bradley force field. The correction terms are: the bond-interaction constant of C–H bonds (p), the bond-interaction constant of C–S bonds (p'), the angle-interaction constant between ∠HCS and ∠HCH in the CH_3 group (n), the *trans* and *gauche* coupling constants between ∠HCS and ∠CSC in the CH_3 group (t and g), and the angle-interaction constant between SCH angles in the CH_2 group (l). Most of the force constants relating to the CH_3 group were transferred from those of dimethyl sulfide.[7] Some of the force constants relating to the CH_3 group were used by being changed within their dispersion.[10] The other force constants were referred to those of 1,2-ethanedithiol,[11] *n*-propanethiol,[12] polymethylene disulfide,[13] and bis(methylthio)-methane.[14] It has been supposed that the potential constants of CH_3SCH_2SH and CH_3SCH_2SD are common except for the S–H or S–D stretching constant.

The force constants of (methylthio)methanethiol obtained in the present study are listed in Table 3. The calculated wavenumbers are listed in Tables 4 and 5, together with the observed wavenumbers. Figs. 8 and 9 show the observed and calculated frequencies (1250—200 cm^{-1}), together with the observed band intensities. The calculated frequencies, in general, reproduced the observed frequencies well. The problems described in the previous section, that is, the very large lower-frequency shift of the CSH (CSD) bending and the large higher-frequency shift of the CH_2 rocking upon D-substitution, can also be well explained in the calculated wavenumbers.

C–H Stretching Region. The calculated C–H stretching frequencies did not reproduce the observed frequencies so well. The reason may be that we assumed the values of all the C–H stretching constants to be equal. This poor agreement might be overcome by distinguishing between two K(C–H) force constants in relation to the CH_3 and CH_2 groups.

S–H and S–D Stretching Regions. The S–H or S–D stretching vibration mainly depended on the S–H or S–D stretching constant, K(S–H) or K(S–D), and the CSH or CSD repulsion constant, on F(CSH) or F(CSD). We at first used the common value

for the S-H and S-D stretching constants, which gave higher S-H and lower S-D stretching frequencies than the observed ones. This phenomenon is known[15] to be common when the stretching constants of K(X-H) and K(X-D) are used. Therefore, we assumed that the K(S-D) to be 1.026 times[16,17] the K(S-H) constant, that is, K(S-H)=3.500 and K(S-D)=3.591 mdyn/Å; we thus obtained adequate calculated results.

1500—550 *cm*$^{-1}$ *Region.* Two calculated CH_3 degenerate deformation frequencies were fairly higher (5—20 cm^{-1}) than the observed values; also the spacing of the calculated wavenumbers did not explain the observed spacing. The CH_3 degenerate deformation vibrations depend mainly on the potential constants, H(HCS), F(HCH), and $\kappa(CH_3)$, and on the angle interaction constant, n. Each of these four constants relates almost equally to both frequencies. The observed CH_2 wagging vibration in the liquid spectra is shifted 4 cm^{-1} by the D-substitution. In the calculated frequency, this tendency is also seen. The calculated CH_3 rocking vibrations are mainly due to the potential constants, H(HCS), H(HCH), and $\kappa(CH_2)$. They depend on the two rocking bands nearly equally. The CH_3 rocking vibration of normal and monodeuterated band maxima were obtained in the liquid spectra at 988 and 960 cm^{-1}, and at 974 and 961 cm^{-1}, respectively. The spacings of the observed spectra are 28 and 13 cm^{-1} for the normal and deuterated species. In the calculated wavenumbers, however, these spacings were not reasonably explained. The potential field of the CH_3 group of the molecule may not have a C_3 symmetry. The similar spacing of dimethyl sulfide was explained[7] in terms of the non-bonded interaction between two CH_3 groups. In this treatment, however, such interactions were not taken into consideration, since the constants could not be directly transferred. The calculated wavenumbers of the CH_2 rocking and the C-S stretching changed fairly much according to their molecular conformations.

Skeletal Deformation Region. The skeletal bending vibrations are mainly affected by the force constants, H(CSC), H(SCS), F(CSC), and F(SCS). The calculated frequencies fairly well reproduced the observed ones.

Molecular Forms

From the results of the calculated frequencies, we have seen that the CH_2 wagging, CH_3 rocking, CSH (CSD) bending, CH_2 rocking, C-S stretching, and skeletal deformation vibrations are fairly much affected by the internal rotation angles. In the observed spectra, there appeared three bands for the CH_2 wagging, four bands for the CH_3 rocking, three bands for the CSH bending, eight bands for the C-S stretching, and eight bands for the skeletal deformation regions on the normal species. On the deuterated species, we have seen three bands for the CH_2 wagging, three bands for the CH_3 rocking, two bands for the CH_2 rocking, nine bands for the C-S stretching, three bands for the CSD bending, and eight bands for the skeletal deformation regions. One CH_2 wagging, two CH_3 rocking, one CSH or CSD bending, three C-S stretching, and two to three bands for the skeletal deformation can be expected for each conformation. Therefore, if all of the observed bands are fundamentals, we can expect at least three or four conformations to coexist in the liquid and gaseous states.

The numbers of the bands appearing in the solid state suggest that only one form stays in the solid state. It was seen from the calculated results for the various molecular conformations that, in the region below

1500 cm^{-1}, their rotational angles affect the wave numbers. The calculated wave numbers themselves, however, are not definite enough for us to decide the molecular conformation, since the force constant has an arbitrary value. The isotopic frequency shifts, however, give us more information about the molecular conformations if we compare the calculated results with the observed results, because the isotopic shifts of the calculated frequencies are, in general, little affected by the ambiguity of the force field.

In the obtained spectra, we observed frequency shifts in the S-H (S-D) stretching, CH_2 wagging, CH_2 twisting, CH_3 rocking, CSH (CSD) bending, CH_2 rocking, C-S stretching, and skeletal deformation regions. The calculated results have also shown shifts. Table 6 shows the observed results in the solid spectra and the calculated frequency shifts upon deuteration. In Table 6, the plus signs of Δ show the lower frequency shifts, while the minus signs show the higher ones, upon D-substitution. In the wagging region, the observed frequency shift is 7 cm^{-1}; the calculated frequency shifts are: TT (4 cm^{-1}), TG (0 cm^{-1}), GT (4 cm^{-1}), GG (0 cm^{-1}), GG' (0 cm^{-1}). The observed frequency shift of the CH_2 twisting vibration is 7 cm^{-1}. On the other hand, the shift is not seen in the calculated frequencies. In the CH_3 rocking region, one of the observed shifts is 15 cm^{-1}; we can see the calculated frequency shift in the TG and GG' conformations—1 cm^{-1}. In the CSH (CSD) bending region, we observed a frequency shift of 328 cm^{-1} upon deuteration. The calculated shifts of the TT, TG, GT, GG, and GG' conformations are 356, 351, 357, 357, and 362 cm^{-1} respectively. In the CH_2 rocking region, the observed frequency shift is −35 cm^{-1}; the calculated frequency shifts are: TG (−32 cm^{-1}), GT (−1 cm^{-1}), GG (−27 cm^{-1}), and GG' (−35 cm^{-1}). The shift of the TT form is in the reverse direction—1 cm^{-1}. The higher frequency shifts of the observed results in the C-S stretching bands become wide, ——2, −10, and −20 cm^{-1}, from short to long wavelengths. The conformations of TG, GG, and GG' show the above-mentioned tendency. In the skeletal deformation region, the shifts of the five forms of the calculated results show nearly the same behavior. Above all, the calculated frequency shifts of the TG, GG, and GG' conformations explain well the observed frequency shifts due to D-substitution. On the other hand, in the skeletal deformation region, the calculated wave numbers of the GT, GG, and GG' conformations correspond well to the observed wave numbers in the solid state. The calculated wave numbers of the TG form do not explain the observed wave numbers of the skeletal vibrations. In the case of the GT form, the isotopic shifts are not reasonably explained either. Therefore, we excluded the TG and GT forms from the stable form in the solid state. There, the possibility of the GG and GG' forms remains. In the cases of the GG and GG' forms, the repulsion forces between the S-H (S-D) and CH_3 groups may be stronger in the GG' form than in the GG form, so long as a strong hydrogen bond is not formed between S-H (S-D) and CH_3 groups. We, therefore, postulated the stable conformation in the solid state to be the GG form.

The molecular conformations existing in the liquid and gaseous states were also taken into consideration among the five conformation. Since the distance between S-H (S-D) and CH_3 groups is not so close in the GG' conformation, we did not neglect the GG' form, unlike the case of bis(methylthio)methane.[8] The molecular form in the solid state, GG, also exists in the gaseous and liquid states. Therefore, we will discuss mainly the liquid and gaseous band which disappear in the solid state. In the CH_2 wagging region of the liquid and gaseous spectra, we observed three bands of the normal species and also of the deuterated species. Among these three bands, two shoulder bands disappeared in the solid state. According to the calculated results of the normal species, the band at 1220 cm^{-1} corresponds to the TT and/or GT conformation, and the band at 1200 cm^{-1} corresponds to the TG and/or GG' conformation. In the deuterated species, the band at 1217 cm^{-1} corresponds to the TT and/or GT form, and the band at 1200 cm^{-1} corresponds to the TG and/or GG' conformation. In the CH_3 rocking region, two very weak shoulders and one very weak shoulder band are observed in the normal and deuterated species respectively. These shoulder bands correspond to the TT, TG, and/or GG' conformations.

a) Figures are listed in order: Urey-Bradley, valence; matrices are symmetrical; and the non-listed parts are all zero; valence constants from Ref. 5.
b) See an appended map.

In the CSH or CSD bending region, two shoulders of three bands disappeared in the solid state. On the normal species, the weak shoulder band at 934 cm^{-1} may be due to the TG and/or GG′ form, and the band at 917 cm^{-1}, to the TT and/or GT form. The bands at 600 and 587 cm^{-1} of the deuterated species correspond to the TG, and to the TT, GT, and/or GG′ form, respectively. In the CH_2 rocking region, we can expect more than one band in view of the calculated frequencies. We obtained one band for the normal species and two for the deuterated species. The band at 808 cm^{-1} of the deuterated species corresponds well to the TT and/or GT conformation. In the C–S stretching region, we observed that five (or six) bands of the normal (or deuterated) disappeared in the solid state. The calculated frequencies of the TT, TG, GT, and GG′ forms correspond well to the bands which disappeared in the solid state. In the skeletal deformation region, eight bands were observed in both the normal and deuterated species. If all of these eight bands are due to the fundamentals, more than four conformations coexist in the gaseous and liquid states. Since the most stable GG form in the solid state has two bands in both the normal and deuterated species, the remaining six bands may due to the other conformations: TT, TG, GT, and GG′.

We have discussed the conformations coexisting in the liquid and gaseous states. In the liquid and gaseous spectra, the isotopic frequency shift cannot be used for the conformational analysis, since the selection of the corresponding pairs from among many bands is difficult. We can postulate that at least three to four conformations, including the GG form, coexist in the liquid and gaseous states. However, we cannot decide, from the results we have obtained, how many conformations, and which conformations among the TT, TG, GT, and GG′ forms, persist, except for the GG form, which exists in all three states. The existence of the GG′ form cannot now be denied.

Force Constants

In order to confirm the reasonableness of our obtained Urey-Bradley force constants, we attempted to compare these Urey-Bradley constants and Scott and El-Sabban's force constants.[5] Scott and El-Sabban reported valence force constants for various organosulfur compounds which did not have the SCS skeleton. Table 7 shows the non-zero parts of both types of ***F***-matrix elements. The coordinate numbering is shown

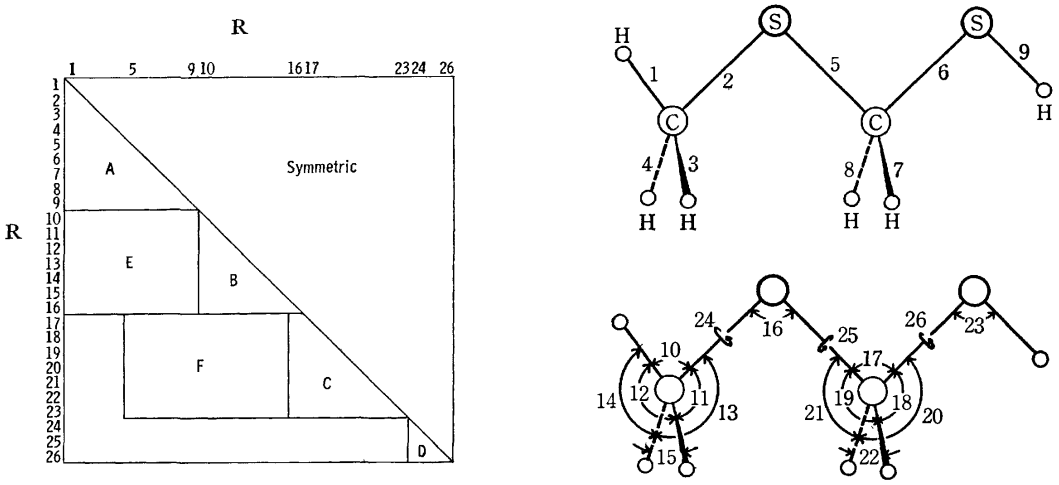

Fig. 10. Coordinates numbering for (methylthio)methanethiol.

in Fig. 10. The figures are listed in this order: Urey-Bradley, and valence force constants. No angle constant of ϕ(SCS) in the valence force field was obtained. In the diagonal elements, f_{ii} (i=1—26), our values agree well with Scott and El-Sabban's. Even for the off-diagonal parts, f_{ij} ($i \neq j$), the modified Urey-Bradley force elements and valence elements are in fairly good agreement. This shows that there is a good transferability of the obtained force constants for a wide range of organo-sulfur compounds. The newly-determined values for the SCS angle may be used on the valence force-type potential, *e.g.*, $f_{\mathrm{scs,scs}}$=1.141 and $f_{\mathrm{cs,scs}}$=0.384 mdyn/Å.

The authors wish to express their gratitude to Assistant Professor Michiro Hayashi of our University for his encouragement throughout this work. One of the authors (M. O.) is also greatly indebted to the foundation of the Kumura Syogakukai (Teijin Co., Tokyo).

Electrochemical Behaviour of the Lithiated Nickel Oxide Crystal

Hiroshi YONEYAMA and Hideo TAMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 26, 1971)

The electrochemical properties of lithiated nickel oxide were studied using a single-crystal (100) face and a sintered body. The I–V curves of the Fe^{2+}/Fe^{3+} system on the single-crystal electrode were almost the same as those on the sintered-body electrode when the electric resistivities of the crystals were equal. However, a high amount of charge was obtained at the sintered-body electrode compared with the single-crystal electrode when the crystals were oxidized anodically. The effect on these reaction rates of the space charge depletion layer formed on the electrode surface will be discussed. The dependence of the reaction rates on the electric resistivity of the crystal can be understood to a certain extent through this discussion.

Charge transfer reactions of some redox systems on sintered-body lithiated nickel oxide electrodes were studied previously[1], and it was concluded that the electric resistivity of the crystal influences the charge-transfer reaction rates. It was also found[2] that the resistivity of the crystal affects the quantity of higher-valency nickel oxides formed by anodic oxidation. It is often pointed out that the grain boundaries of the crystal act as peculiar defect sites, such as charge-trapping or -generating centers. According to Morin,[3] sintered-body nickel oxide contains cation vacancies, the number of which is influenced by the preparation conditions. Taking account of this information, the electrochemical behaviour of the crystal may be said to be influenced by the grain boundaries. One purpose of this paper is to present the difference in the electrochemical behaviour of lithiated nickel oxide between the single crystal and the sintered body. Another purpose is to discuss the electrochemical behaviour of the material from the semiconductor's point of view.

Experimental

Electrodes. The single-crystal lithiated nickel oxide was prepared by the method of Rouse and Weininger,[4] using commercial lithiated nickel oxide (Nakazumi Crystal Co. Ltd.). Electroless plating nickel was chosen as the electrical contact. The contact prepared by this method showed good ohmic behaviour. The electrode surface was the (100) face. The sintered-body lithiated nickel oxide electrode was prepared by a method described in a previous paper.[1] It was prepared by firing at 1350°C in the air. The distribution of the grain size of nickel oxide powder as a raw material is shown in Fig. 1; it was determined by the Andreasen pipet method. The electric resistivity of the electrode was estimated by means of the voltage drop between the end faces of the crystal.

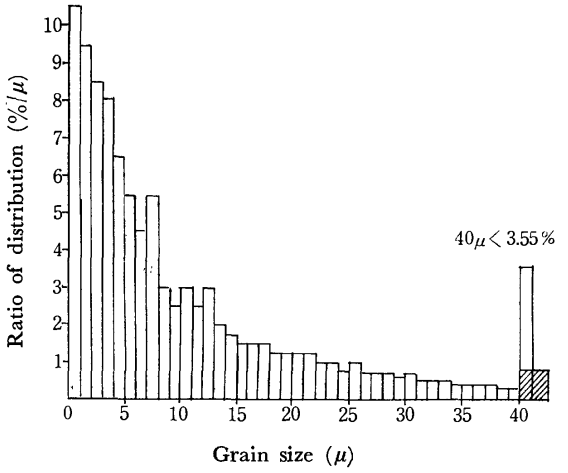

Fig. 1. Distribution of grain of NiO powder as a raw material.

Effective Surface Area of the Electorde. The effective surface area of the sintered-body electrode was determined by comparing the space charge capacitance of the depletion layer of the electrode with that of the single-crystal eleetrode in the following way.

Electrode surfaces of various single crystals and sintered bodies were polished with No. 2000 emery paper, followed by immersion in a mixed solution of conc. H_2SO_4 and conc. HNO_3 (1 : 1); then it was pretreated with a conc. HCl solution. After the electrode had been thoroughly washed with de-ionized water, the electric capacitance of the electrodes was measured in a 1N H_2SO_4 solution as a function of the electrode potential by means of the bridge arrangement shown in Fig. 2. Then the nominal carrier densities of various single-crystal electrodes were estimated usnig the relationship which can be applied for the depletion layer of the semiconductor:[5,6]

$$d(1/C^2)/dV = 2/(q\varepsilon\varepsilon_0 N) \quad (1)$$

In this equation, $q,\varepsilon,\varepsilon_0,N$, and C represent the elementary charge of the electron, the dielectric constant of the semiconductor, that of the vacuum, the carrier density of the semiconductor, and the capacitance of the depletion layer per unit of surface area of the semiconductor electrode. Typical examples are shown in Fig. 3. In the estimation of the nominal carrier densities of the various single crystals, the apparent geometric dimension was adopted as the effective surface area and the dielectric constant of the semiconductor was assumed to be 12.[7] Figure 4 shows the nominal carrier densities of the single-crystal electrodes as a function of their

resistivities.[8]

Let it be assumed that the carrier density of the sintered body is eventually equal to that of the single crystal of the same resistivity. Then, the slope of the plots of $1/C^2$ *vs.* V should be equal to each other for the electrodes of the same resistivity when the effective areas of the electrodes are equal. The effective surface area of the sintered-body electrode was determined by correcting the area of the measured capacitance so as to have the same slope of $1/C^2$ *vs.* V plot as that of the single-crystal of the corresponding resistivity.

Measurement of I–V Curves and V–t Curves. *I–V* curves of the redox system were obtained potentiostatically. *V–t* curves during the anodic oxidation and cathodic reduction of the electrode were obtained by means of an electrometer connecting to a voltage recorder. Measurements were made for current densities in which the ohmic drop across the electrode could be almost negligible. Commercial dry nitrogen gas was bubbled into the electrolyte thermostated at 25±0.5°C during the measurements. Electrolytes were prepared by the use of reagent-grade chemicals and deionized water. The electrolytic cell was a conventional H-type cell.

Results

Redox Reaction of the Fe^{2+}/Fe^{3+} System. Figure 5 shows the anodic portions of the *I–V* curves of the Fe^{2+}/Fe^{3+} system (5×10^{-3} M Fe^{2+}, 5×10^{-3} M Fe^{3+}, in 1 N H_2SO_4) on single-crystal and sintered-body electrodes of the same resistivity. It is evident from this figure that no difference in the *I–V* curves can be observed between these two electrodes. The *I–V* curves of this system on various single-crystal electrodes are shown in Fig. 6.[9] The apparent exchange current

—●— sinterd body, —○— single crystal, solution: 5×10^{-3} M Fe^{2+}, 5×10^{-3} M Fe^{3+}/1 N H_2SO_4.

8) As has previously been observed by Rouse and Weininger, the nominal carrier density, as estimated from the $1/C^2$ *vs.* V plot, does not accord with the lithium content in the crystal. However, the use of this nominal carrier density in the estimation of the effective surface area of the sintered-body electrode will not introduce any trouble.

TABLE 1. APPARENT EXCHANGE CURRENT DENSITIES OF Fe^{2+}/Fe^{3+} SYSTEM ON VARIOUS SINGLE CRYSTAL ELECTRODES

Resistivity of electrode (Ω-cm)	580	1600	3800
Apparaent exchange current (A/cm²)	2.2×10^{-6}	1.1×10^{-6}	8.5×10^{-7}

Solution: 5×10^{-3} M Fe^{2+}, 5×10^{-3} M Fe^{3+} in 1 N H_2SO_4

densities of the system were estimated by the extrapolation of the anodic portion of the *I–V* curves in Fig. 6 to a redox potential of the system; they are shown in Table 1. According to Fig. 6, a linear slope was observed in the log I *vs.* V plot of the *I–V* curves of the anodic process, while the current showed a tendency to become saturated with the cathodic polarization. On the other hand, it can be seen in Table 1 that the exchange current densities of the system are influenced by the resistivity of the electrode. Such observations have previously been reported[1] for sintered-body electrodes. Therefore, they seems to be connected with the genuine properties of the lithiated nickel oxide.

Anodic Oxidation. Figure 7 shows the electrode potential behaviour of various electrodes during the 1st oxidation and reduction cycle. 10 μA/cm² and 1 μA/cm² were chosen as the anodic and cathodic current densities respectively. In this figure, the effective area of the 25 Ω·cm sintered-body electrode was estimated by a different method.[1] The cathodic *I–V* curves obtained in the electrolyte into which oxygen gas was bubbling are also shown in Fig. 7 for two kinds of electrodes, that is, the 180 Ω·cm sintered body and the 64 Ω·cm single crystal. A plateau of the potential was observed in the cathodic *V–t* curves. This poten-

9) Judging from the *I–V* curves in a system of Ni–NiO–Ni, where V is the applied voltage between nickel contacts and where I is the current, the voltage drops across the crystal per 1 μA/cm² were as follows: 580 Ω·cm: 0.075 mV, 1.6 kΩ·cm: 0.34 mV 3.8 kΩ·cm: 0.36 mV. *I–V* curves which have been corrected on the basis of thse voltage drops are presented in Fig. 6.

tial which appeared in the oxygen-bubbling electrolyte was by far more noble than that in the nitrogen-bubbling electrolyte. Figure 7 shows that the oxygen gas pressure has no influence on the V–t curves in the reduction process before the plateau of the potential due to oxygen reduction appears. From a comparison of the V–t curves under oxygen-bubbling conditions with those under nitrogen-bubbling conditions, it may be expected that V–t curves during the reduction in the noble potential region, more noble, say, than 0V, are mainly the result of the charge retained by anodic oxidation.[10] Hence, it follows from Fig. 7 that the

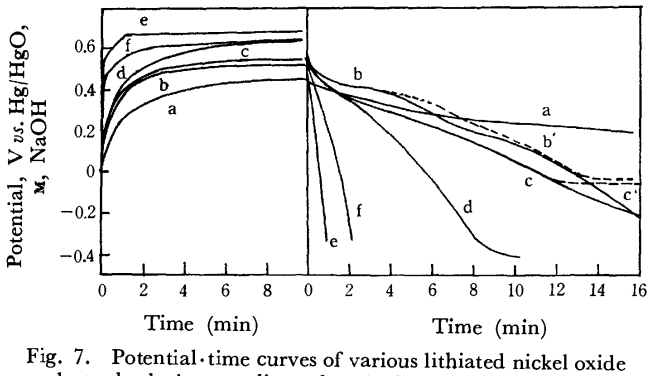

Fig. 7. Potential-time curves of various lithiated nickel oxide electrode during anodic and cathodic polarization.
anodic current density: 10 μA/cm^2, cathodic current density: 1μA/cm^2. solid line: in N_2 gas bubbling, dotted line: in O_2 gas bubbling, a: 25 Ω·cm, b: 64 Ω·cm single crystal, c: 180 Ω·cm. d: 580 Ω·cm, e: 580 Ω·cm single crystal, f: 2300 Ω·cm, b': 64 Ω·cm single crystal, c': 180 Ω·cm. solution: 1 M NaOH.

charge retained by anodic oxidation is high for an electrode of low resistivity. This conclusion is supported by the previous report[2] as well. Figure 7 suggests that the single crystal is less active in the anodic oxidation than the sintered body.

Discussion

Charge-transfer Reaction on the Lithiated Nickel Oxide Electrode. The rate equation of the charge-transfer reaction on the lithiated nickel oxide electrode will be presented first.

As only the positive hole participates in the charge-transfer process, the electrode reaction of the redox couple of Fe^{2+}/Fe^{3+} can be represented as[1];

$$Fe^{2+} + p \rightleftarrows Fe^{3+}$$

The positive hole concentration at the electrode surface, P_s, is related to the bulk concentration, P_b, according to the formulation by Myamlin and Pleskov[11]:

$$P_s = P_b \exp(F\phi_{sc}/\boldsymbol{R}T) \quad (2)$$

where ϕ_{sc} is the potential drop in the surface of the semiconductor and has a negative value when the space charge depletion layer is formed. The anodic current, J_a, and the cathodic current, J_c, can be expressed as:

$$J_a = kC_{Fe^{2+}}P_s \exp(\alpha F\phi_e/\boldsymbol{R}T) = kC_{Fe^{2+}}P_b \times \exp(F\phi_{sc}/\boldsymbol{R}T)\exp(\alpha F\phi_e/\boldsymbol{R}T) \quad (3)$$

$$J_c = k'C_{Fe^{3+}}\exp(-\beta F\phi_e/\boldsymbol{R}T) \quad (4)$$

where ϕ_e is the potential drop in the Helmholtz double layer. The exchange current density, J_o, is:

$$J_o = kC_{Fe^{2+}}P_b \exp(F\phi_{sc}^\circ/\boldsymbol{R}T)\exp(\alpha F\phi_e^\circ/\boldsymbol{R}T) = k'C_{Fe^{3+}}\exp(-\beta F\phi_e^\circ/\boldsymbol{R}T) \quad (5)$$

where ϕ_{sc}° and ϕ_e° are, respectively, the potential drop in the space charge layer of the electrode surface and that in the Helmholtz double layer when the electrode is in equilibrium with the redox couple. By substituting Eq. (5) into Eq. (3) and Eq. (4), we obtain:

$$J_a = J_o \exp[\{F(\phi_{sc}-\phi_{sc}^\circ) + \alpha F(\phi_e-\phi_e^\circ)\}/\boldsymbol{R}T] \quad (6)$$

$$J_c = J_o \exp\{-\beta F(\phi_e-\phi_e^\circ)/\boldsymbol{R}T\} \quad (7)$$

The potential drop in the Helmholtz double layer may be neglected when a distinct space-charge layer exists on the surface of the electrode. Then, ϕ_{sc}° and ϕ_{sc} relate to the flat-band potential, E_{fb}, the redox potential of the redox couple, E_{redox}, and the electrode potential, E, all of which are measurable values:

$$\phi_{sc}^\circ = E_{redox} - E_{fb} \quad (8)$$

$$\phi_{sc} = E - E_{fb} \quad (9)$$

In this case, the total current, J, is formulated as:

$$J = J_a - J_c = J_0 \exp\{(E-E_{redox})/\boldsymbol{R}T - 1\} \quad (10)$$

In the above formulation, $C\mathrm{Fe}^{2+}$ and $C\mathrm{Fe}^{3+}$ are used as the concentrations of the ferrous and ferric ions in the electrolyte. The concentration of the redox couple at the energy level of the positive hole of the electrode surface is truly determined by the product of the concentration of the redox couple and the distribution function of the couple, which is approximately a function of the energy difference between the positive hole level at the electrode surface and the Fermi energy of the redox couple.[12] The effect of the distribution function on the charge-transfer reaction rate is contained in the rate constants, k and k' in Eq. (3) and Eq. (4) respectively.

Figure 3 suggests that the flat-band potential of the electrode in 1 N H_2SO_4 is 0.85 V *vs.* SCE, while Fig. 6 shows that the equilibrium potential of the redox couple and the electrode is by far less noble. Judging from these pieces of information, there must be a space-charge depletion layer on the surface of the electrode. Figure 8 shows an energy diagram[13] of the electrolyte/electrode interface; the potential drop in the Helm-

10) The difference in the charge value between this and the previous paper is due to the anodic oxidation conditions. In the previous experiments, the electrode had been exposed to a high anodic current density in the first oxidation cycle, while in the subsequent cycles the total charge supplied during the oxidation as well as the oxidation current density had not exceeded the value of the first cycle. For this reason, an almost constant charge was obtained regardless of the anodic oxidation conditions. In this sence, the previous description that the charge corresponding to the higher-valency nickel oxides formed by anodic oxidation is constant, regardless of the anodic oxidation current density, is inadequate. Hence, all the data presented previously should be understood to those for electrodes which had been exposed to the first oxidation conditions (10 mA/cm^2 × 5 min).

13) The energy diagram presented in a previous paper (Ref. 1) contains a fault.

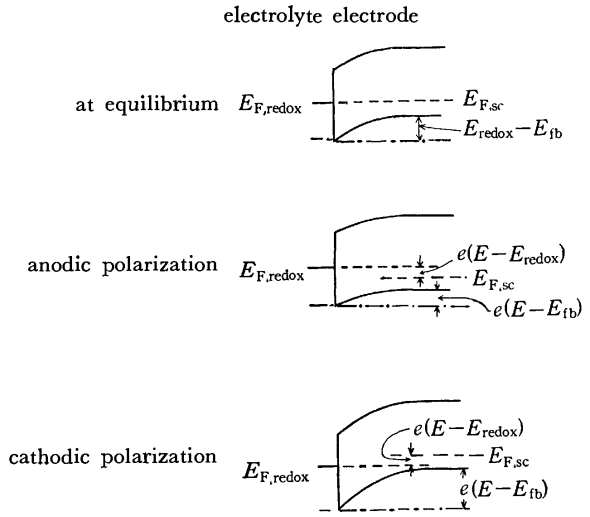

Fig. 8. Energy diagram of the electrode/electrolyte interface when the electrode contacts with a redox solution of Fe^{2+}/Fe^{3+} system.

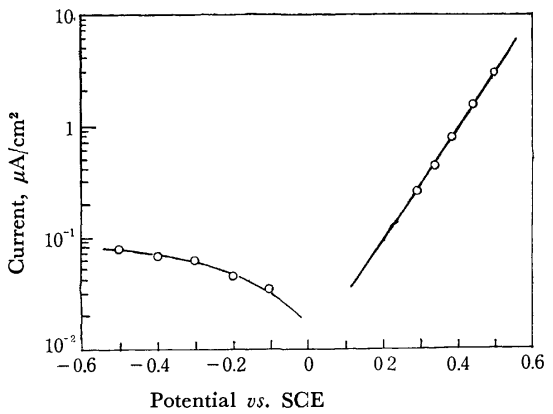

Fig. 9. *I-V* curves of Ti^{3+}/Ti^{4+} system in 1 N HCl solution on 580 Ω·cm single crystal electrode. Solution: 0.9 M Ti^{3+}, 0.1 M Ti^{4+} 1 N HCl.

holtz double layer is neglected. The solid lines of the energy diagram of the semiconductor shown in Fig. 8 denote the energy level of the positive hole and the electron respectively.[14,15] The experimental results which are shown in Fig. 6 for the Fe^{2+}/Fe^{3+} and in Fig. 9 for the Ti^{3+}/Ti^{4+} suggest that the ideal case, which is illustrated in Fig. 8, was not realized, for the anodic Tafel slope was not 59 mV/decade. However, the dependence of the exchange-current density on the resistivity of the electrode and the appearence of the Tafel slope in the anodic process can be understood by means of Eq. (5) and Eq. (6).

Anodic Oxidation. The charge retained by the anodic oxidation is possibly due to the formation of higher-valency nickel oxides. The phenomenon that the resistivity of the crystal affects this charge can not be explained on the basis of the atom arrangement of the crystal, since the dimensions of the unit cell decrease with increase in the lithium content.[16]

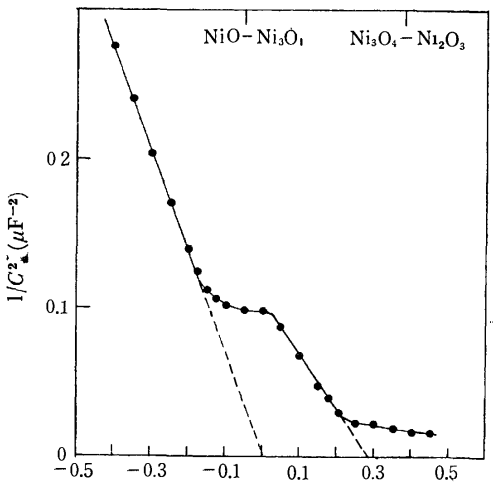

Fig. 10. $1/C^2$ *vs.* V plot for the sintered body of 580 Ω·cm. solution: 1 M NaOH, electrode area: 0.183 cm².

According to the above discussion, a potential drop in the space-charge depletion layer influences the electrochemical behaviour of the lithiated nickel oxide. Figure 10 shows the $1/C^2$ *vs.* V plot for the 580 Ω·cm sintered-body electrode in a 1 M NaOH solution. The thermodynamically-calculated equilibrium potentials of various nickel oxides[17] are also shown in this figure. Figure 10 clearly shows that the inflection of the $1/C^2$ vs. V plot occurs around the potential at which surface oxidation begins to occur, and that the flat-band potential shifts towards a more noble potential after beginning of surface oxidation. The shift of the flat-band potential towards a more noble potential may be brought about by the formation of the surface state, which is due to oxide formation. At any rate, Fig. 10 implies that there is a space-charge depletion layer on the electrode surface in the less noble potentials below 0.3 V (*vs.* Hg/HgO, M NaOH). According to Fig. 7, anodic oxidation proceeds to a certain extent in the potentials below 0.3 V. Therefore, the anodic oxidation mechanism below the flat-band potential will be discussed first.

When the space-charge layer exists on the electrode surface, the field strength across the space-charge layer will be different according to various resistivities of the electrode at the same polarization potential. The electric capacitance in Eq. (1) is related to the depth of the space-charge layer, d:

$$C = \varepsilon\varepsilon_0/d \qquad (9)$$

The potential drop in the space-charge layer corresponds ideally to the electrode potential as measured from the flat-band potential, $E-E_{fb}$. By replacing V in Eq. (1) with $(E-E_{fb})$ and by combining Eq. (1) with Eq. (9), we finally obtain the electric-field strength across the space-charge layer, which is shown in Eq. (10):

$$F = (E-E_{fb})/d = \{qN(E-E_{fb})/2\varepsilon\varepsilon_0\}^{1/2} \qquad (10)$$

Figure 11 shows the calculated field strength across

17) M. Pourbaix, "Atlas of Electrochemical Equilibria in Aqueous Solutions," Pergamon Press, Oxford (1966), p. 330.

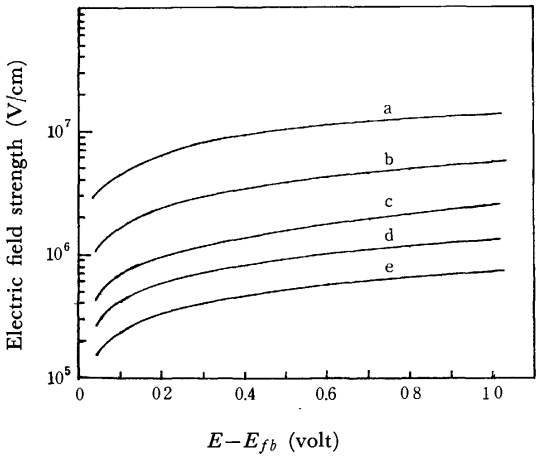

Fig. 11. Calculated electric field strength across the space charge in the electrode surface as a function of $E-E_{fb}$ a: 5.6 Ω·cm, b: 25 Ω·cm, c: 180 Ω·cm, d: 560 Ω·cm, e: 2300 Ω·cm.

the space-charge layer of the various electrodes as a function of $E-E_{fb}$. In the calculation, the value of N was estimated from the relationship between the lithium content and the resistivity of the crystal.[2] Figure 11 shows that the electric-field strength across the space-charge layer is high for the electrode of low resistivity.

The ionic current, I, in the anodic film formation process is generally expressed as:[18]

$$I = A \exp(\beta F) \tag{11}$$

where A and β are constants and where F is the electric-field strength. During the film formation process, an order of 10^6 V/cm is required for the value of F. According to Dewald's theoretical treatment of the mechanism of the formation of anodic oxide film at a high field,[19] there is a case where the contribution of the space charge layer to the F is predominate and where the rate of oxidation is determined almost entirely by the bulk properties of the film. If it is accepted that Dewald's theory is suitable for the anodic oxidation of the lithiated nickel oxide, it can be seen that the electrode of low-bulk resistivity suffers anodic oxidation more easily, although, in a strict sense, the precise estimation of various parameters in Dewald's theory is necessary in order to determine the applicability of the theory to this case.

The above mechanism of the anodic oxidation is probably restricted in the potential region below the flat-band potential, because the polarization potential is almost entirely concentrated in the Helmholtz double layer in the potential region above the flat-band potential of the electrode. The anodic oxidation above the flat-band potential will be influenced by the properties of the oxides formed by that time. Unfortunately, the properties of the oxides formed can not be elucidated at present becaue of its thinness.

Difference in Quantity of Higher-valency Oxides between Single Crystal and the Sintered Body. According to Fig. 7, the charge retained by the anodic oxidation seems to be different between the single crystal and the sintered body of the same resistivity. If the anodic oxidation mechanism ascribed above is valid, the difference should not be observed. The fact that the difference does appear suggests that other factors control the formation of the higher-valency oxides as well.

The following factors may influence the formation of the higher-valency oxides: 1) The sintered body prepared in the air presumably contained many cation vacancies.[3] The existence of vacancies is favorable for the ion movement in the crystal. 2) The gain in crystal-field stabilization energy on the chemisorption of oxygen on nickel oxide is high for the (110) face rather than the (100) face of the crystal.[20] This suggests that the (110) face is more active than the (100) face in the anodic oxidation. In the case of the sintered-body electrode, various crystal faces came in contact with the electrolyte. 3) Grain boundaries are considered to be high in surface free energy.[21] It has been pointed out that the surface free energy of a solid influences the rate of the anodic film formation process[22] as well as crystal growth.[23,24] Further study is necessary to elucidate which factor is most effective for the anodic oxidation of the nickel oxide crystal.

The Preparation of Divalent Cation Non-permselective Cation Exchange Membrane by Coating with Vinylon Film[1]

Reizo DOHNO, Takatugu AZUMI, and Shiro TAKASHIMA
Himeji Institute of Technology, Shosha, Himeji

(Received December 16, 1971)

The preparation of non-permselective membrane for the divalent cation was attempted by coating it with thin vinylon film on one side of a commercial cation-exchange membrane. When the coating surface of the cation-exchange membrane was set on the concentration-compartment side (cathode side), the permselectivity coefficient of the calcium ion to the sodium ion was equal to that of untreated cation-exchange membrane and no effect of the selective treatment was recognized. However, when the coating sufrace was directed to the desalting-compartment side (anode side), an effect of the selective treatment was observed; in this case, the permeability of the calcium ion was more depressed, corresponding with the formalation degree of the selective-treatment membrane; for example, the permselectivity of the calcium ion for the membrane which was formalated for 180 min at 30°C decreased about one half compared with the untreated membrane. The electric resistance of the cation-exchange membrane increased upon the coating with the vinylon film, and especially the resistance of the calcium ionic-form membrane indicated a remarkable increase.

In the concentration of sea-water by electrodialysis through an ion-exchange membrane, the preparation of a non-permselectivity membrane for the divalent cation is one of the important subjects in connection with the increase in the current efficiency of sodium chloride and the prevention of scaling. At present, with regard to the procedure of increasing the non-permselectivity for the divalent cation, several papers have been published as to either the synthesis of new kinds of base membranes[2] or the addition of surfactants as selective improvement agents to sea water during electrodialysis.[3]

The present authors[4–6] studied the mechanism of the permselectivity between same-charge ions across the cation-exchange membrane and recognized that the divalent cation show a large permselectivity in spite of their small mobility in a cation-exchange membrane because they have a much larger separation factor than the sodium ion in the ion-exchange equilibria. Also, as has been described in a previous paper,[7] the permselectivity between ions of the same charge across a vinylon membrane is predominantly effected by the mobility ratio of both ions in the membrane, regardless of the total concentration or of the composition ratio in the original solution. On the other hand, the ion-transport numbers for membranes with a very low ion-exchange capacity approximate to a neutral membrane have been reported by Kumins and London,[8] and other workers,[9] but these membranes can not be used as practical as diaphrams in an electrodialysis concentration because the transport number decreases remarkably in a highly concentrated solution.

In this paper, vinylon-coated ion-exchange membranes were prepared by the following method. A thin film of polyvinyl alcohol (PVA) was smeared on the surface of one side of a commercial cation-exchange membrane, and then it was formalated under various conditions. Then the permselectivities of the calcium ion to the sodium ion across these selective-treatment membranes were measured, and the mechanism was discussed.

Experimental

Selective Treatment of Cation-exchange Membrane. A commercial cation-exchange membrane (exchange capacity, 1.79 meq/g dry; water content, 33.5%; membrane thickness, 0.16 mm) was used as the base membrane; a 10% aqueous solution of polyvinyl alcohol (polymerization degree 2400—2500) was smeared on one side of this membrane and it was dried in an air bath at room temperature for 24 hours. The dried membrane was then formalated under various conditions of time and temperature in a solution composed of concentrated H_2SO_4 200 g/*l*, Na_2SO_4 200 g/*l* and 135 g/*l* of 37% formalin, and it was washed in deionized water. These formalated membranes were used for the experiments.

The symbols of all the selective-treatment membranes and the formalation conditions are listed in Table 1.

Apparatus and Procedure of Electrodialysis. The cation-exchange membrane and anion-exchange membrane used in this experiment were strongly acidic and basic membranes. The electrodialysis apparatus was a cell with eight compartments separated by a cation-exchange membrane and an anion-exchange membrane, each with an area of 13×4 cm^2; the selective-treatment membrane was placed between the 5th compartment and the 6th compartment (Fig. 1).

In this cell, a mixed solution of a 0.35N-NaCl solution and a 0.03 N-$CaCl_2$ solution, as the original solution (20 *l*), was circulated in order from the 4th through the 6th to 2nd compartment at about 500 ml/min. at 30 ± 1°C, and the 3rd, 5th, and 7th compartments were filled with a 0.1N-$NaNO_3$ solution. The left- and the right-side compartments, separated by a cation-exchange membrane, were cathode and anode compartments respectively, and in both electrode compartments a 0.3 N-Na_2SO_4 solution was circulated. The electrodialysis was carried out at a constant quantity of elec-

tricity by alternating the current density and the time respectively, and then the transfer eqivalents of the calcium ion and the sodium ion were determined from the concentrations of these ions in the 3rd and 5th compartments respectively. From these values, the permselectivity coefficients of the calcium ion to the sodium ion were calculated by means of Eq. (1):

$$T_{Na}^{Ca} = (E_{Ca}/E_{Na})/(C_{Ca}/C_{Na}) \quad (1)$$

where E is the transfer equivalent and where C is the concentrantion in the original solution. The analysis of the chloride ion and the calcium ion was done by Mohr's method and the EDTA method, while the sodium ion was determined by calculation.

Membrane Resistance. The untreated membrane (*i. e.*, the cation-exchange membrane) and the selective-treatment membranes were equilibrated with a 0.5N-NaCl or 0.5N-$CaCl_2$ solution for 50-hr. A cell with two compartments equipped with platinized platinum electrodes was used for the measurement, and the resistances were measured by means of a 1000-cycle AC bridge (Yokogawa Electric Works Ltd. BV-Z-103 B) at 30±0.5°C. The membrane resistance was obtained as the difference between the reading with the membrane and without the membrane.

Results and Discussion

Direction of Treatment Surface. The permselectivity coefficients in each case of the treatment surface of a cation-exchange membrane placed in the direction of the concentration-compartment side and in that of the desalting-compartment side are shown in Table 2.

When the selective-treatment surface was directed at the concentration-compartment side, the permselectivity coefficients were equal to that of the untreated membrane; that is, no effect of selective treatment was recognized. However, when it was directed to the desalting-compartment side, the values of the permselectivity coefficients decreased in comparison with

that of the untreated membrane. From these results, it can be concluded that the permselectivity of the calcium ion varies with the direction of the treated surface. Therefore, in the subsequent experiments, the permselectivities were measured for the treated surface directed to the desalting-compartment side.

Change of Permselectivity with the Formalation Conditions. Figures 2 and 3 show the change in the permselectivity coefficients due to the formalation conditions at each current density.

The permselectivity coefficients of the treated membrane decrease with an increase in the formalation time. It is presumed that the transfer of the calcium ion, which possesses a larger hydration radius,[10] was more depressed than that of the sodium ion because the vinylon phase came to have a fine structure upon formalation.[11] However, when the formalation time is over a certain length, the permselectivity coefficient does not decrease, because the transfer of the sodium ion is depressed as well as that of the calcium ion. For example, the permselectivity of the calcium ion to the sodium ion across the A-180 membrane is nearly equal to that of the A-120 membrane, but these values were about half that of the untreated membrane. On the other hand, at a constant formalation time, the permselectivity coefficient appears to have a tendency to increase somewhat with a rise in the formalation temperature (Fig. 3).

Membrane Resistance. The effective resistance of the treatment membrane in a calcium ionic form and in a sodium ionic form *vs.* the formalation time and the temperature are shown in Figs. 4 and 5 respectively.

In all cases, the resistance of the calcium ionic-form membrane was larger than that of the sodium ionic-form membrane. The resistance of both ionic-form membranes increased with an increase in the formalation time and temperature; the resistance of the calcium ionic-form membrane indicated an especially remarkable increase. This suggests that the transfer of the calcium ion is depressed by the vinylon-film coat on the cation-exchange membrane. Also, the degree of the increase in resistance due to the formalation conditions is greater with the formalation temperature than with the formalation time.

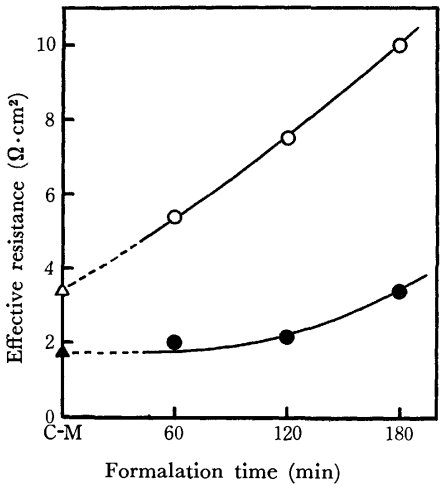

Fig. 4. Change of resistance by formalation time.
(Formalation temperature: 30°C)
○: 0.50 N-$CaCl_2$ ●: 0.50 N-NaCl, △▲: C-M

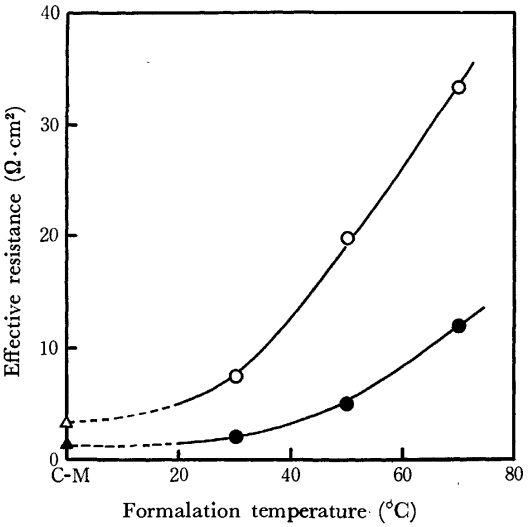

Fig. 5. Change of resistance by formalation temperature.
(Formalation time: 120 min.)
○: 0.50 N-$CaCl_2$, ●: 0.50 N-NaCl, △▲: C-M

It can be considered that, at low temperatures, the formalation proceeds with the increase of time until the PVA phase, because the formalation reaction does not proceed very fast; a fine structure will thus be formed. However, at high temperatures, a layer of a higher formalation degree will be formed on the surface of the PVA phase in even a short reaction time and the formalation can not succeed until within this phase.

Mechanism of Permselectivity for Treatment Membrane. The permselectivity between the same-charge ions across an ion-exchange membrane is split into two terms, the mobility term and the concentration term, as is shown by Eq.(2);

$$T_A^B = (\bar{U}_B/\bar{U}_A)S_A^B \qquad (2)$$

where $\bar{U}$ is the mobility in the ion-exchange membrane and S_A^B is the separation factor of the B ion to the A ion the cation-exchange membrane which is defined by Eq. (3);

$$S_A^B = (\bar{C}_B/\bar{C}_A)/(C_B/C_A) \qquad (3)$$

where $\bar{C}$ is the concentration in the ion-exchange membrane and C is the concentration in the solution.

Usually, the mobility ratio and the separation factor of the calcium ion to the sodium ion for the cation-exchange membrane are established experimentally as follows:

$$(\bar{U}_{Ca}/\bar{U}_{Na})<1,\ S_{Na}^{Ca}>1$$

The permeability of the calcium ion is larger than the sodium ion because the effect of S_{Na}^{Ca} is larger than the $(\bar{U}_{Ca}/\bar{U}_{Na})$ term. *i. e.*, $T_{Na}^{Ca}>1$. Thus, it is possible that the permselectivity of the calcium ion de-

10) T. Yamabe and M. Seno, "Ion Kokan Jushimaku," Gihodo, Tokyo, Japan (1964), p. 47.
11) N. Takahashi and K. Onozata, *Kogyo Kagaku Zasshi*, **63**, 1540 (1960).

pressed by a decrease in the concentration of the calcium ion in the cation-exchange membrane, *i. e.* $S^{Ca}_{Na}<1$.

On the other hand, the permselectivity for the vinylon membrane is given by Eq. (4) as well as for the cation-exchange membrane:

$$V^{Ca}_{Na} = (\overline{U}'_{Ca}/\overline{U}'_{Na})S'^{Ca}_{Na} \quad (4)$$

where $\overline{U}'$ is the mobility in the vinylon membrane and where S'^{Ca}_{Na} indicates the selective adsorption of the calcium ion to the sodium ion for the vinylon membrane, as defined by Eq. (5):

$$S'^{Ca}_{Na} = (\overline{C}'_{Ca}/\overline{C}'_{Na})/(C_{Ca}/C_{Na}) \quad (5)$$

where $\overline{C}'$ is the concentration in the vinylon membrane and where C is in accordance with that in Eq.(3).

Table 3 shows the values of S'^{Ca}_{Na} measured for the vinylon membrane formalated under various conditions. These values indicate that $S'^{Ca}_{Na}\fallingdotseq 1$ within the experimental error; that is, the concentartion ratio of the calcium ion to the sodium ion in the vinylon membrane is equal to that of the original solution. Also, $(\overline{U}'_{Ca}/\overline{U}'_{Na})<1$ is deduced from Figs. 4 and 5. Accordingly, $V^{Ca}_{Na}<1$. That is to say, the permselectivity for the vinylon membrane is primarily ruled by the mobility ratio of both ions in the vinylon phase, and this ratio is closely related to the fine structure of vinylon.

Table 3. S'^{Ca}_{Na} of vinylon membrane

Symbol of membrane	A-60	A-120	D-60	D-120
S'^{Ca}_{Na}	1.3	1.0	0.8	1.0

Now, in the case of the treatment membrane obtained by combining a cation-exchange membrane and vinylon film, the value of V^{Ca}_{Na} indicates the ratio of the transfer equivalent of the calcium ion to the sodium ion which is supplied to the cation-exchange membrane across the vinylon film coated on the desalting-compartment side. Since V^{Ca}_{Na} is smaller than that of the original solution, the concentration ratio of the calcium ion to the sodium ion in the cation-exchange membrane phase will decrease compared with the untreated membrane. Consequently, the permselectivity of the calcium ion across the treatment membrane decreases. However, when the treatment surface was directed to the concentration-compartment side, the concentration ratio of the two ions in the cation-exchange membrane phase become the same value as that of the untreated membrane because the cation exchange membrane directly contacts the original solution. Accordingly, no change in the permselectivity of the treatment membrane was observed.

On the other hand, the transport number of cations in the vinylon phase will be nearly equal to that in the original solution because the vinylon has no ion-exchange group, and the concentration polarization on the interface between the vinylon film and the original solution is negligibly small. Thus the deficiency of calcium ions and the accumulation of sodium ions will occur at the interface between the

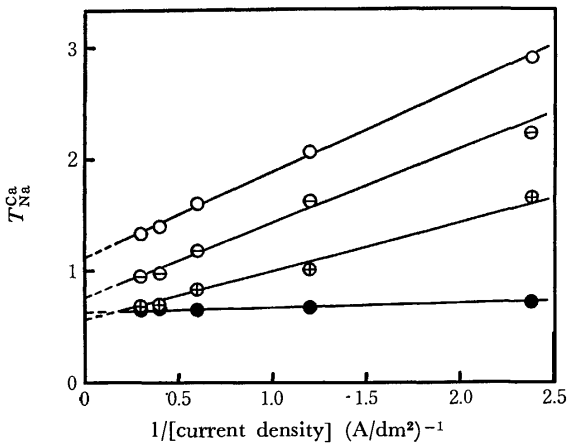

Fig. 6. Relationship between permselectivity and reciprocal of current density.

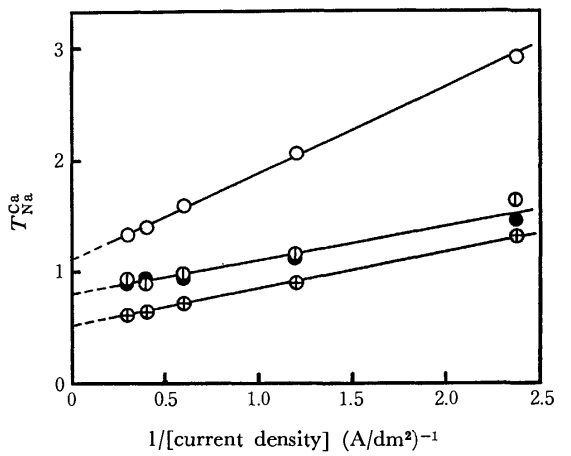

Fig. 7. Relationship between permselectivity and reciprocal of current density.
(Effect of formalation temperature)
○: C-M, ⊕: A-120, ●: B-50, ⊕: B-70

Table 4. Mobility ratio in vinylon phase

Symbol of membrane	A-60	A-120	A-180	B-50	B-70
$\overline{U}'_{Ca}/\overline{U}'_{Na}$	0.77	0.52	0.66	0.80	0.80

cation-exchange membrane and the vinylon film because $T^{Ca}_{Na}>1$ and $V^{Ca}_{Na}<1$. The value of $\overline{C}_{Ca}/\overline{C}_{Na}$ in the cation-exchange membrane decreases with an increase in the current density, and approaches $(\overline{U}'_{Ca}/\overline{U}'_{Na})S^{Ca}_{Na}$. That is, the permselectivity coefficient at infinity of a current density for the treatment membrane is equal to the mobility ratio $(\overline{U}'_{Ca}/\overline{U}'_{Na})$ of both ions in the vinylon phase by reason of $S'^{Ca}_{Na}\fallingdotseq 1$.

The relationship between the permselectivity and the reciprocal of the current density is shown in Figs. 6 and 7, while Table 4 shows the value of the permselectivity coefficient (*i. e.*, $\overline{U}'_{Ca}/\overline{U}'_{Na}$) obtained by an extrapolation to infinity of the current density in these figures.

For the untreated membrane the extrapolating value is 1.15; this value is consistent with the mobility ratio of both ions in a free solution, but for the other mem-

branes, which are formalated under various conditions, the values of $\bar{U}'_{Ca}/\bar{U}'_{Na}$ are smaller than that in solution; these results indicate that the mobility of the calcium ion to the sodium ion in the vinylon phase is depressed, as can be expected from Figs. 4 and 5.

From the above experimental results, it can be considered that the permeability of the divalent cation can be depressed by coating the desalting side of the cation-exchange membrane with vinylon film. However, in this case the electric resistance of the membrane increases; this problem may be resolved to a certain extent by making the vinylon-phase coat as thin as possible.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3058—3064 (1972)

Normal Vibrations and Far-infrared Spectra of Ammonium Chloride and Ammonium Chloride-d_4 Crystals

Kunio FUKUSHIMA and Hiroko YAMAMOTO

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka

(Received March 8, 1972)

The normal coordinate treatment of optically active lattice vibrations of ammonium chloride and ammonium chloride-d_4 at low temperature was made in order to elucidate the nature of the vibrations and obtain force constants in the potential in the crystals by the method of least squares. Using the constants, the optically active lattice vibrations of a crystal model for ammonium chloride and ammonium chloride-d_4 at room temperature were calculated. The far-infrared spectra obtained and the Raman and infrared spectra in literature were discussed.

Investigations of spectral change due to the phase transition in ammonium halides have been made by means of Raman and infrared spectroscopy.[1-11] Recently, by laser Raman spectroscopy, several weak Raman lines of the halides not detected in the Raman spectra obtained by use of mercury-vapor lamps as light sources, were observed. Assignments of some Raman lines to lattice vibrations were made, giving information on the lattice vibrations.[12,13] Neutron scattering expriments have given vibrational frequency data which Raman and infrared spectroscopy could not afford.[14-17] Studies on crystal structures of ammonium halides by means of X-ray, electron diffraction and neutron diffraction indicated an ordered structure for the low temperature phase.[18,19] However, no decisive conclusion has been obtained as regards the structure of the higher temperature phase.[18-21] We carried out a normal coordinate treatment of the optically active lattice vibrations of ammonium chloride and ammonium chloride-d_4 crystals in the low temperature phase in order to determine the force field in the crystals. The optically active lattice vibrations of a crystal model proposed as a model of ammonium chloride crystal at room temperature,[18] were calculated for interpretation of the infrared and Raman spectra of ammonium chloride and ammonium chloride-d_4 at room temperature.

Experimental

Ammonium chloride of the Wako Chemical Industries, Ltd. (JIS Special Grade) was recrystallized from its aqueous

solution. The deuterate was obtained by recrystallization of the ammonium chloride from its heavy water solution. Infrared spectra of Nujol mulls of the samples were measured in the region 4000—400 cm^{-1} with a Hitachi EPI-G3 spectrophotometer and in the region 400—30 cm^{-1} with a Hitachi FIS-3 Far-infrared spectrometer. The obtained spectra are shown in Figs. 1 and 2. The spectra in the region 4000—400 cm^{-1} are given in order to show the degree of deuteration by the relative intensities of N-H and N-D stretching bands.

Normal Coordinate Treatment

Normal coordinate treatments were carried out for the crystal structure of ammonium chloride at low temperature, which was confirmed by Goldschmidt and Hurst[18] (lattice parameter, a=3.820 Å; N-H=1.03 Å; space group, T_d^1; see Fig. 3) and for a crystal model[18] which might be related to the dominant structure in ammonium chloride crystal at room temperature (lattice parameter, a=7.73 Å; space group, O_h^5; see Fig. 4). Bravais lattice for the former structure is the cubic P lattice, to each lattice point of which a Bravais cell containing one NH_4Cl chemical unit belongs. That for the latter is a cubic F lattice, and the Bravais cell belonging to each lattice point contains two NH_4Cl

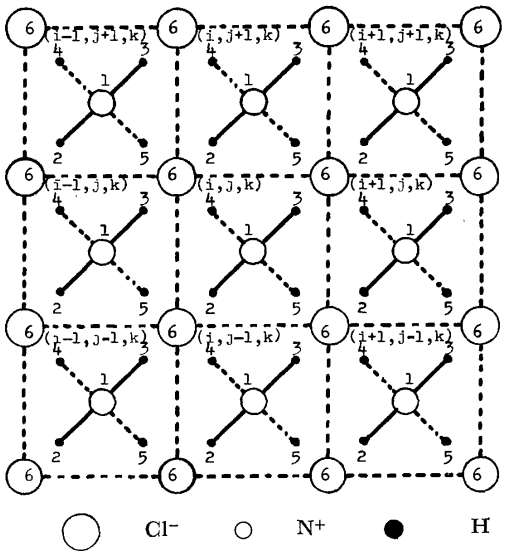

Fig. 3. A part of the structure of ammonium chloride and ammonium chloride-d_4 at low temperature (Cubic P lattice, number of chemical units per Bravais cell is one).

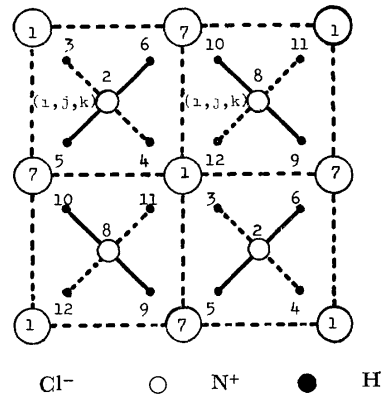

Fig. 4. A part of the unit lattice for a model of ammonium chloride and ammonium chloride-d_4 at room temperature.

chemical units as shown in Fig. 4. Cell repeating unit vectors are $(a_1+a_2)/2$, $(a_2+a_3)/2$, $(a_3+a_1)/2$, where a_1, a_2 and a_3 are the unit lattice vectors.

Calculation of optically acitve lattice vibrations was made according to the GF matrix method developed by Shimanouchi *et al.*[22] Optically active Cartesian and internal symmetry coordinate vectors, X_{op} and R^s_{op}, are expressed as follows:

$$X_{op} = \lim_{n_1,n_2,n_3\to\infty}(n_1n_2n_3)^{-1/2}\sum_{i=0}^{n_1}\sum_{j=0}^{n_2}\sum_{k=0}^{n_3}(X)^{i,j,k}_{\text{Bravais}}$$

$$R^s_{op} = \lim_{n_1,n_2,n_3\to\infty}(n_1n_2n_3)^{-1/2}\sum_{i=0}^{n_1}\sum_{j=0}^{n_2}\sum_{k=0}^{n_3}(R^s)^{i,j,k}_{\text{Bravais}}$$

Here, $(X)^{i,j,k}_{\text{Bravais}}$ and $(R^s)^{i,j,k}_{\text{Bravais}}$ represent, respectively, the Cartesian displacement coordinate vector and the internal symmetry coordinate vector, which belong to the Bravais cell (i,j,k). The internal coordinate vector belonging to the Bravais cell, (i,j,k), $(R)^{i,j,k}_{\text{Bravais}}$, and $(R^s)^{i,j,k}_{\text{Bravais}}$, are shown in Tables 1 and 2, respectively. In Table 1, R_1—R_{52}, R_{53}—R_{58}, R_{59}—R_{61} are coordinate of bond stretching, angle bending and NH_4^+ rotational motions, respectively. R^s_{op} and X_{op} are related by the optically active B matrix, B^s_{op} by

$$R^s_{op} = B^s_{op}X_{op}$$

Optically active F matrix, F_{op}, is expressed by F matrix associated with the Bravais cell, (i,j,k), F_{000}, and interaction matrices between the cell and the other cells surrounding it, F_{100},F_{010},F_{001}···

$$F_{op} = F_{000} + F_{100} + \tilde{F}_{100} + F_{010} + \tilde{F}_{010} + F_{001} + \tilde{F}_{001} + \cdots$$

Using X_{op}, R^s_{op} and F_{op}, optically acitve lattice vibrational frequencies were calculated by the equation

$$|M^{-1}F_{xs} - \lambda E| = 0, \quad F_{xs} = \tilde{B}^s_{op}F_{op}B^s_{op}$$

where M^{-1} is a matrix whose diagonal elements are constructed from the inverse of masses of atoms or ions in a Bravais cell.

The following potential was assumed for a Bravais cell.

$$V = V_{NH_4^+} + (1/2)\sum K(N^+\cdot Cl^-)(\Delta r_{N^+\cdot Cl^-})^2$$

22) T. Shimanouchi, M. Tsuboi, and T. Miyazawa, *J. Chem. Phys.*, **35**, 1597 (1961).

$$+ (1/2)\sum K(\mathrm{H\cdot Cl^-})(\Delta r_{\mathrm{H\cdot Cl^-}})^2$$
$$+ (1/2)\sum K_1(\mathrm{Cl^-\cdot Cl^-})(\Delta r_{\mathrm{Cl^-\cdot Cl^-}})_1^2$$
$$+ (1/2)\sum K_2(\mathrm{Cl^-\cdot Cl^-})(\Delta r_{\mathrm{Cl^-\cdot Cl^-}})_2^2$$
$$+ (1/2)\sum K_1(\mathrm{N^+\cdot N^+})(\Delta r_{\mathrm{N^+\cdot N^+}})_1^2$$
$$+ (1/2)\sum K_2(\mathrm{N^+\cdot N^+})(\Delta r_{\mathrm{N^+\cdot N^+}})_2^2$$
$$+ (1/2)\sum\sum_i K_i(\mathrm{H\cdot H})(\Delta r_{(\mathrm{H\cdot H})_i})^2$$
$$+ (1/2)\sum_{i=1}^{3} K_\theta \Delta(\theta_i)^2$$

where $V_{NH_4^+}$ represents the Urey-Bradley force field[23] for NH_4^+ ion, and the summation was taken over all atom(or ion)-atom(or ion) pairs of the same kind.

23) T. Shimanouchi, *ibid.*, **17**, 245 (1949).

Computations were carried out at the Computer Center, the University of Tokyo, using programs BGLZ and LSMB set up in the Shimanouchi laboratory, Dept. of Chem., Faculty of Science, the University of Tokyo, and also a program made by one of the authors (K. F.).

Optically active lattice vibrations of low temperature structure were calculated for the set I force constants in Table 3. The $Cl^-\cdot Cl^-$ or $N^+\cdot N^+$ interaction potential change due to displacement Δr of a Cl^- or N^+ ion in the crystal along $Cl^-\cdot Cl^-$ or $N^+\cdot N^+$ line consists primarily of that between the ion and the nearest neighbor ions at both sides. As the interaction is electronic and proportional to r^{-1}, the potential change is expected to be proportional to $r^{-3}\cdot\Delta r^2$. Thus, $K_2(Cl^-\cdot Cl^-)$ and $K_2(N^+\cdot N^+)$ were calculated from $K_1(Cl^-\cdot Cl^-)$ and $K_1(N^+\cdot N^+)$, assuming that the $Cl^-\cdot Cl^-$ and the $N^+\cdot N^+$ force constants are proportional to r^{-3}. Using the observed frequencies in Table 4, the set of force constants were revised to set II force constants by the method of least squares.[24] Of the force constants, $K_1(Cl^-\cdot Cl^-)$, $K_2(Cl^-\cdot Cl^-)$, $K_1(N^+\cdot N^+)$ and $K_2(N^+\cdot N^+)$ were not adjusted since the optically active lattice vibrations do not change by them. By use of the set II force constants except for $K_i(H\cdot H)$ and K_θ, optically active lattice vibrations of the model for the structure of ammonium chloride at room temperature were calculated. The atom(or ion)-atom(or ion) interactions taken into account in the calculation are shown in Table 5. $K_i(H\cdot H)$ force constants for H.H length greater than 3 Å were assumed to be zero and that for 2.67$_6$ Å was set to 0.008 on the basis of the $K_i(H\cdot H)$ values in the set II and the H·H force constant values.[25] It was found by obtaining

Cell indices are expressed *on the basis of the basic vectors*, a_1, $(a_1+a_2)/2$, $(a_1+a_3)/2$, for convenience, and the other necessary atom(or ion)-atom(or ion) sets, which can be produced from the corresponding ones in this table by either or both of the following operations, are omitted: 1) inversion with respect to the center of 2(N^+)-8(N^+) line in (i,j,k) cell; 2) C_2 operation around any one of axes passing through both 2(N^+) in (i,j,k) cell and any of 8(N^+)'s.

calculated frequencies for various values of K_θ that only the frequencies of F_{1g} and F_{2u} vibrations (NH_4^+ rotational vibrations) change by K_θ. Therefore, K_θ value of 0.0063 mdyn. Å giving the calculated frequencies of F_{1g} vibrations fitting the observed frequencies, 345 cm^{-1}($NH_4^+Cl^-$) and 220 cm^{-1}($ND_4^+Cl^-$), was used. Calculated frequencies of low temperature structure for the set II force constants and the dominant terms of potential energy distributions, $(F_{op})_{ii}(l_{ij})^2/\lambda_j(l_{ij}$; i-th element of eigenvector for eigen value of λ_j) are shown in Table 4. The calculated frequencies of the model of room temperature phase are shown in Table 6.

Discussion

For the crystal structures of ammonium chloride and ammonium chloride-d_4 at low temperature, which belong to the space group T_d^1, the optically active lattice vibrations are classified into nine internal vibrational modes ($1A_1+1E+2F_2$) and six external modes ($1F_2$(translational vibrations)$+1F_1$(rotational vibrations)) by factor group analysis. Fundamental frequencies of these vibrations were selected (Table 4) on the basis of the assignments.[4,6,12,13] The F_1 vibration is both Raman and infrared inactive. The frequency value in the table is determined from combination bands by Bovey.[9] The frequency is considered to be reliable by the fact that it is in line with neutron scattering data.[14,16,17] We see from Table 4 that ν_1 is almost pure N-H(or N-D) stretching vibtations, and ν_2 and ν_5 are almost pure H-N-H(or D-N-D) bending vibrations. ν_6 vibrations of F_2 species (185 cm^{-1}, NH_4Cl; 177 cm^{-1}, ND_4Cl) are the translational lattice vibrations, in which NH_4^+ and Cl^- vibrate each other as shown in the large potential energy distribution values in Table 4, which are associated with the coordinates, s_4-s_{12}($N^+\cdot Cl^-$ stretching coordinates and $H\cdot Cl^-$ stretching coordinates). The assignment is also confirmed by the fact that shift of frequency, 185 cm^{-1}, to 177 cm^{-1} on deuteration corresponds well to the calculated shift, 187 cm^{-1} to 175 cm^{-1}. In the infrared and Raman inactive vibration ν_3, the potential energy is concentrated largely in the coordinates s_4,s_5,s_6(rotational motion coordinate of NH_4^+) and also in H·H stretching coordinates s_1,s_2,s_3. This suggests that the vibration may change its frequency on order-disorder transition. Actually, it has been found that the frequency of ν_3 vibration decreases during phase change caused by elevation of temperature.[14,16]

The set II force constants (Table 3) obtained by the method of least squares can explain the observed frequencies. The force constants except for K_i(H·H)'s and K_θ are considered to be applicable to calculations of the optically active lattice vibrations of the structure model in the room temperature phase, in which the atom(or ion)-atom(or ion) distances (Table 5) except for H·H distances are very close to those of the low temperature structure.

It has been concluded by laser Raman spectroscopic investigation[13] that among the Raman lines having frequency shifts 171 cm^{-1}, 345 cm^{-1} (NH_4Cl); 176 cm^{-1}, 220 cm^{-1} (ND_4Cl), those having frequency shifts 171 cm^{-1} and 176 cm^{-1} are due to the translational lattice vibrations corresponding to the optically active lattice vibrations (185 cm^{-1}, NH_4Cl; 177 cm^{-1}, ND_4Cl) of the low temperature phase. The Raman line with frequency shift of 345 cm^{-1} changes the shift to 220 cm^{-1} on deuteration.[13] This is clearly assigned to NH_4^+ rotational vibration. On the other hand, the infrared bands of the translational vibrations have been observed at 172 cm^{-1} (NH_4Cl) and at 166 cm^{-1} (ND_4Cl).[12] However, the bands are very broad and asymmetrical. Each band might be composed of two or more overlapped bands. Precise measurement of the purified sample of ammonium chloride in the present investigation revealed that there are at least two bands at about 240 cm^{-1} and at 170 cm^{-1}. The corresponding bands of ammonium chloride-d_4 are at about 230 cm^{-1} and at 160 cm^{-1} (Fig. 2). The results

IR: infrared absorption R: Raman scattering, a) Ref. 13. b) Ref. 4. c) Present investigation.

conclude that there are one Raman line due to translational lattice mode and two infrared bands of the corresponding modes in the Raman and infrared spectra of both ammonium chloride and ammonium chloride-d_4 at room temperature.

For the structure of ammonium chloride at room temperature three models have been proposed: (a) the free rotation model by Pauling[27] (b) the disordered model by Frenkel[28] (c) a model having the space group symmetry of O_h^5.[18,20] The possibility of (a) has been denied on experimental results. Goldschmidt and Hurst examined the validity of the models, and denied either of the models,[18] but revised their conclusion,[20] and (b) and (c) still remain as possible models. Levy and Petersen have deduced a disordered structure from their experimental results.[21] In (c), each NH_4^+ is either of two locations corresponding to its potential minima, and the nearest neighbor NH_4^+ ions surrounding one NH_4^+ are all in the same structural relation with respect to the NH_4^+. It is likely that the structural units of the model might exist as the dominant structure in (b) at higher temperature. 33 optically active lattice vibrations of (c) are classified into one A_{1g}, one A_{2u}, one E_g, one E_u, one F_{1g}, four F_{1u}, three F_{2g} and one vibrations. Among these, there are translational vibrations $(2F_{1u}+1F_{2g})$, rotational vibrations $(1F_{1g}+1F_{2u})$ and internal vibrations $(1A_{1g}+1A_{2u}+1E_g+1E_u+2F_{1u}+2F_{2g})$. The translational vibrations of F_{1u} species are infrared active and the translational vibration of F_{2g} species is Raman active. If fraction of these structural units becomes dominant in the disordered crystal, at least two infrared bands and one Raman line are expected to appear for translational vibrations. In the observed spectra, two bands which can be assigned to translational vibrations appear at 240 cm^{-1} and 170 cm^{-1} in the case of ammonium chloride, and two corresponding bands appear at 230 cm^{-1} and 160 cm^{-1} for ammonium chloride-d_4. In the Raman spectra observed by Rimai *et al.*[13] one Raman line having frequency shift of 171 cm^{-1} appears and has been assigned to a translational vibration. The rotational vibrations of NH_4^+ are both Raman and infrared inactive for the model itself. However, the corresponding vibrations of the structure in the disordered crystal, in which fraction of the structural units of the model is large, may become both Raman and infrared active because of the absence of O_h^5 symmetry in the crystal as a whole. In this case, one infrared band and one Raman line due to rotational lattice vibrations are expected to appear. Rimai *et al.* observed a Raman line having frequency shift of 345 cm^{-1}. This is reduced to 220 cm^{-1} for ammonium chloride-d_4.[13] In the infrared spectra of ammonium chloride (Fig. 2), a very weak band appears at about 360 cm^{-1} which shifts to a lower frequency on deuteration.

The calculated frequencies of the vibrations 255 cm^{-1}, 166 cm^{-1} (NH_4Cl), 237 cm^{-1}, 161 cm^{-1} (ND_4Cl) (infrared active translational vibrations) correspond to the observed frequencies of the above mentioned infrared bands (Table 6). The frequency shift expected from calculation on deuteration also corresponds to the observed shift. The calculated frequency of F_{2g} translational vibration of the model also corresponds to the observed Raman shift frequency of 171 cm^{-1} (Table 6). The results suggest that in the disordered structure of ammonium chloride in the room temperature phase, its dominant structure consists of the model units of (c).

Cotton Effect Induced in Optically Inactive Molecules and Molecular Complexes by Optically Active Environment. I. Pyrene, TCNNQ, and Their Molecular Complex in Acetylcellulose Film

Yasumasa J. I'HAYA and Toru YUNOKI*

Department of Materials Science, The University of Electro-Communications, Chofu-shi, Tokyo

(Received April 6, 1972)

Ultraviolet absorption spectra, induced optical rotatory dispersion and circular dichroism of pyrene, TCNNQ, and their molecular complex were measured in acetylcellulose film and solution. The Cotton effect corresponding to each absorption maximum of these systems appeared. A perturbation of excited states of these molecules and their complex due to an asymmetric environment of acetylcellulose might be of paramount importance in producing a non-zero rotational strength in the corresponding molecular absorption region. The second charge-transfer band was clearly detected in the differential optical rotatory dispersion spectrum of the TCNNQ-pyrene molecular complex embedded in an acetylcellulose film. The method was shown to be promising in detecting very weak and closely overlapped transitions in various molecules.

Several works have appeared demonstrating the Cotton effect induced in various optically inactive molecules by optically active solvents.[1-5] Racemic or symmetric metal complexes were found to exhibit pronounced circlular dichroism (CD) sepctra in the region of their *d-d* absorptions when they were dissolved in optically active alcohols, usually diols.[1,2] In similar solvents, ketones, both aliphatic and aromatic, were also investigated in detail and confirmed to have a single (sometimes a double or more) CD spectrum induced around their $n\rightarrow\pi^*$ transition region.[3-5]

The precise mechanism of the phenomenon is still unkown but certain inferences have been made. One is that CD may be induced by a dissymmetric potential due to a solvent. Originally, hydrogen bonding was supposed to be the main origin,[1-3] but later it was found that such associative forces including hydrogen bonding are not a prerequisite since induced CD is observed also in the $n\rightarrow\pi^*$ absorption region of some nitrite or nitrate dissolved in optically active solvents.[4,5] The other explanation was that molecules like ketones are probably solvated into some dissymmetric configurations making themselves optically active.[3]

In this paper, we show that aromatic hydrocarbons in acetylcellulose film and solution also exhibit induced Cotton effect in their $\pi\rightarrow\pi^*$ absorption region. To the best of our knowledge no work has been reported on the induced optical activity for $\pi\rightarrow\pi^*$ transitions of aromatic molecules. Furthermore, we show that similar effects can be observed for a donor-acceptor type molecular complex in their charge-transfer absorption region.

Experimental

Pyrene, commercial reagent grade, was purified by recrystallization and sublimation. TCNNQ (11,11,12,12-tetracyano-1,4-naphthaquinodimethane) was synthesized by the method reported by Chantterjee[6] and purified by repeated recrystallization from methanol and methylenechloride, followed by vacuum sublimation. The pyrene-TCNNQ molecular complex was prepared from the purified pyrene and TCNNQ by simultaneous sublimation onto a heated glass plate.

The materials were first added to an acetone solution of acetylcellulose of commercial grade used as a matrix without further purification. The viscous solution was then drawn onto a fused quartz plate and baked in an oven to remove actone. Films approximately 5—15 μ in thickness with excellent transparency were obtained. The sample concentration in a film state was estimated from the measured density of acetylcellulose and was held in the range 10^{-2}–10^{-3} M. The film thickness was roughly estimated from birefringence and retardation using a polarizing microscope.

A Jasco ORD/UV/CD-5 spectrophotometer was used for the measurement of electronic absorption, ORD, and CD spectra of the samples. In each measurement, the ORD datum was calibrated with reference to the base line of the pure acetylcellulose film whose thickness was identical with that of the sample film. This was because acetylcellulose itself has a large negative rotatory dispersion. Similar measurements were carried out for the samples dissolved in an acetone solution of acetylcellulose.

Results and Discussion

The ultraviolet absorption (UV), ORD, and CD spectra of pyrene in an acetylcellylose film are shown in Fig. 1. The sample film used was 5μ in thickness and estimated to contain 5.3×10^{-2} M pyrene. The scales of the ordinate are the optical density(a vertical bar shown in the figure), the angle of rotation in degree (ϕ) and the circular dichroic optical density (ΔD), respectively, for the UV, ORD, and CD spectra. These quantities were not converted into the corresponding molecular characteristics, *i. e.*, molecular extinction coefficient, molecular rotation, and molecular ellipticity, since the concentration and thickness of each sample film could not be determined accurately.

The over-all UV spectrum shown in Fig. 1 is displaced to the red approximately by 300 cm^{-1}, compared to that observed in an ethanol solution. This suggests that the pyrene molecule embedded in an acetylcellulose film is in the same and/or the like surroundings as that in solution. Corresponding to each absorption maximum, namely to each vibrational

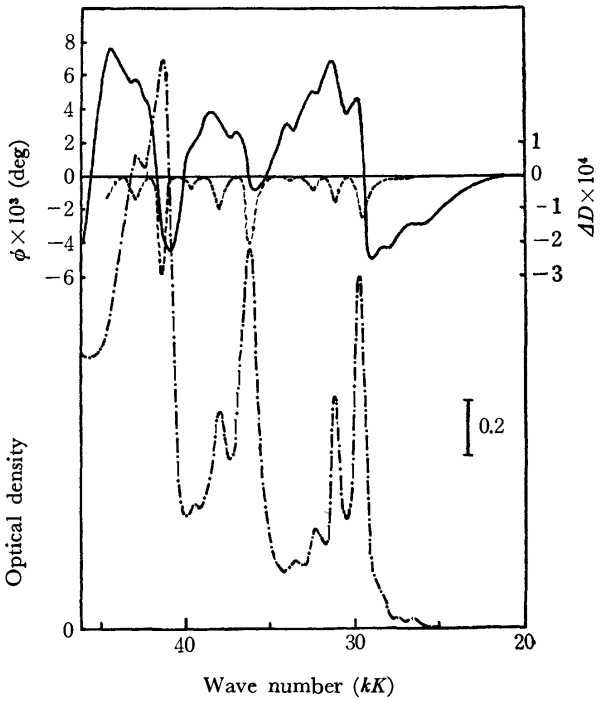

Fig. 1. UV (—·—·), ORD (——), and CD (·····) spectra of pyrene in acetylcellulose film. Film thickness: 5 μ; concentration of pyrene: 5.3×10^{-2} M. A vertical bar indicates the scale of optical density.

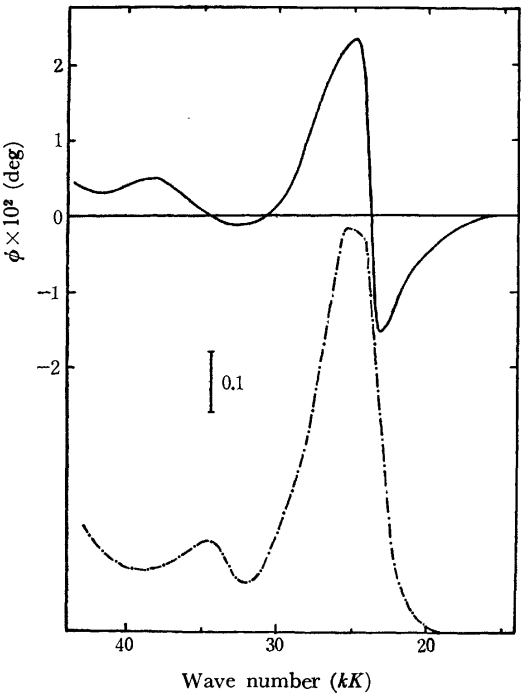

Fig. 2. UV (—·—·) and ORD (——) spectra of TCNNQ in acetylcellulose film. Film thickness: 14μ; concentration of TCNNQ: 1.5×10^{-2} M. A vertical bar indicates the scale of optical density.

spectrum of the ^1L_b, ^1L_a, ^1B_b, and ^1B_a bands of pyrene, a negative CD Cotton effect appears, the circular dichroic optical density of each minimum being roughly proportional to the intensity of the corresponding vibrational absorption maximum.

We have confirmed that the experimental ORD spectrum, though appearing somewhat complicated, can be well reproduced from the experimental CD spectrum, or *vice versa*, by the use of the Kronig-Kramers transform.[7] Only exception for this is the frequency region 26—29 kK where no CD spectral detail was detected as seen in Fig. 1. However, if more concentrated film of pyrene could be obtained, the respective vibrational transitions in this spectral region would show single negative CD absorptions.[8]

Fig. 2 shows the UV and ORD spectra of TCNNQ embedded in the acetylcellulose film of 14 μ thickness. The sample film contains approximatley 1.5×10^{-2} M TCNNQ. The UV absorption spectrum in this frequency region is in line with that observed in methylenechloride solution.[9] We have shown that the 25.3 kK absorption band corresponds to the lowest $\pi \rightarrow \pi^*$ B_2 transition polarized along the molecular longer axis (axis joining the carbon atoms of the 1- and 4-positions) and the weak 34.7 kK band to the next to the lowest $\pi \rightarrow \pi^*$ A_1 transition polarized along the molecular short axis.[9] As can be seen in Fig. 2, the respective $\pi \rightarrow \pi^*$ transitions show a sinlge negative Cotton effect, its rotational strength being roughly proportional to the corresponding dipole strength. A negative CD spectrum for each transition, which was originally expected to appear, was not detected under the present experimental conditions due to the low TCNNQ concentration. When the concentration of TCNNQ was increased, an induced CD spectrum, not a single negative but a double, was observed corresponding to each transition. It is thus found that the shape and intensity of the induced Cotton effect is markedly dependent on concentration. The situation is quite similar to that produced, for example, by nucleic acid-dye interactions in solution.[10,11] A monomer-dimer equilibrium of TCNNQ in sample films seems to play an important part.

The UV and ORD spectra of the pyrene-TCNNQ molecular complex in an acetylcellulose film are shown in Fig. 3. The thickness of the film was 10μ. In the lower frequency region beyond the strong 25.3 kK band of TCNNQ, the UV spectrum has one weak and broad band whose maximum is located at 15.3 kK and can be assigned to a charge-transfer band.[12] The ORD spectrum demonstrates the existence of some other bands at around 20 kK.

If we subtract the component ORD spectra of pyerne and TCNNQ from the ORD spectrum of the pyrene-TCNNQ complex, we obtain the plot in Fig. 4 (*differential* ORD spectrum), in which there remain two negative and one strong positive Cotton effect. This suggests that the first charge-transfer band is located at 15.5 kK, the second at around 23 kK, and the other strong band whose maximum is approximately at 27 kK is ascribed to an interaction between the component molecules.

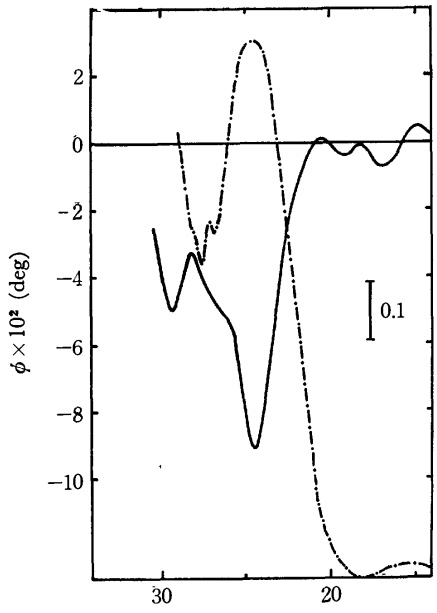

Fig. 3. UV (—·—·) and ORD spectra of the TCNNQ-pyrene molecular complex in acetylcellulose film. Film thickness: 10μ. A vertical bar indicates the scale of optical density.

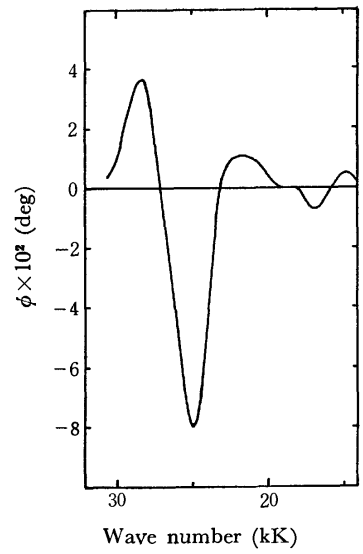

Fig. 4. The differential ORD curve for the TCNNQ-pyrene molecular complex.

According to our recent work on the polarized absorption spectrum of a pyrene-TCNNQ molecular complex crystal, the first charge-transfer band is found at 14.6 kK and the second charge-transfer band at 21.9 kK at room temperature.[13] The agreement is thus fairly good as to the location of the two charge-transfer bands, considering possible band shifts in solution and crystal. Though the 27 kK band can be seen as a tiny peak in Fig. 3, its origin is hard to guess. Even supposing that the peak is directly connected with the higher frequency side large Cotton component (negative and the absorption center is 27 kK) of the differential ORD spectrum (Fig. 4) and that this is induced from an inter-molecular interaction, it is inexplicable why such a large Cotton component is revealed.

The ORD and CD spectra of pyrene measured in an acetone solution of acetylcellulose were almost exactly the same as those in film, though whole spectral features were extremely obscure. It was confirmed that such optical activity is not induced for pyrene embedded in films of optically inactive polymers such as polyethylene and polystyrene. The situation is the same for the ORD spectra of TCNNQ and of the pyrene-TCNNQ molecular complex. These facts suggest that the induced optical activity is acribed *not* to distortion of molecular frames of the sample molecule and/or arrangement of the molecule in a crystalline state, but to dissymmetric potentials exerted by an optically active matrix.

Besides the fact that not only the intensity but also the shape of these induced ORD and CD spectra are strongly dependent on concentration, all their features remind us of the nucleic acid-dye interactions in solution.[10,11] If the induced Cotton effect in both cases is a general phenomenon caused by the same origin, the following interpretation might be right. A perturbation of molecular excited states (and possibly a ground state) due to an asymmetric environment of a matrix material may be of paramount imoprtance in producing non-zero matrix elements of electric and magnetic transition dipole moments for the molecule. The non-zero matrix elements yield a non-zero rotational strength at the molecular vibrational absorption region. Such an interaction more or less occurs whenever dissymmetric potentials exist, regardless of molecular species and molecular arrangement in matrix materials.[14] However, such problems as why the signs of all the CD bands of pyrene are negative, or why there is a sign reversal in the CD spectrum of TCNNQ, cannot be understood without consideration of the relative orientation of interacting units.[10]

The advantage of the present method is that many absorption bands in large molecules, even very weak and/or closely overlapped vibrational bands unresolved by the usual solution spectroscopy, may be observed in the corresponding induced CD and ORD spectra. In particular, very weak charge-transfer bands in donor-acceptor type charge-transfer complexes are detected with high probability and accuracy. A good example is the second charge-transfer band of the TCNNQ-pyrene molecular complex mentioned above, which was observed with difficulty in the single crystalline state of the complex.[12,13] The present method is thus considered superior to the usual microspectrophotometry, the technique for which is troublesome and a clear-cut spectrum rarely obtained.

The present work was supported in part by a grant from the Ministry of Education.

14) A rough estimate of molecular rotation of pyrene embedded in an acetylcellulose film gives an roder of 10^4 deg·mol.$^{-1}$ which is the same order of magnitude as met in the system of nucleic acid and dyes.

Activity Coefficients for the System Glycylglycine–Urea–Water

Hatsuho UEDAIRA

Research Institute for Polymeres and Textiles, Sawatari 4, Kanagawa-ku, Yokohama

(Received November 22, 1971)

Activity coefficients for the ternary system glycylglycine–urea–water were measured by the isopiestic vapor pressure method at 25°C. The activity coefficients of glycylglycine were lowered by urea. The lowering increased with increasing concentration of urea and with decreasing concentration of the amino acid. It was dependent on amino acid concentration to a greater extent than in the system α-amino-*n*-butyric acid–urea–water. The activity coefficients of urea were also decreased by glycylglycine. The free energy of the transfer of glycylglycine from water to urea solutions in various concentrations was calculated. The values obtained were combined with enthalpy data to yield −3.9 e. u. as the entropy value for the transfer from water to 6 M urea solution. Results have been interpreted to support the existence of interaction between urea and glycylglycine.

The interaction of urea on amino acids or oligopeptides in aqueous solutions has been investigated for the purpose of elucidating the denaturing action of urea on globular protein.

The solubility of amino acids and peptides in water and aqueous urea solutions was measured by Whitney and Tanford,[1] and Nozaki and Tanford.[2] They showed that aqueous urea solutions are able to accomodate nonpolar amino acid side chains better than water and that urea also interacts favorably with peptide groups, so that urea stabilizes both nonpolar groups and peptide groups.

Robinson and Jencks[3] examined the effect of a series of denaturing agents on the solubility of acetyltetraglycine ethyl ester and three carbobenzoxyglycine derivatives. They suggested that a nonhydrophobic effect of urea makes a major contribution to its denaturing action on some proteins.

Heat of transfer of amino acids from water to 6 M urea solution was measured by Kresheck and Benjamin.[4] It was shown that the ordering of water molecules around a solute molecule is increased due to the presence of the nonpolar part of the solute molecules and that part of this ordering is removed by urea. It was also shown that there is evidence for the existence of specific interactions between urea and polar parts of the solute molecules including the peptide bond.

The change in interaction as a continuous function of urea and amino acid concentrations can be obtained from the activity coefficients measured by the isopiestic vapor pressure method. Cussler[5] measured activity coefficients for the system α-amino-*n*-butyric acid–urea–water by the isopiestic method. In this system, the activity coefficient of the amino acid decreased with increasing urea concentration and increased with amino acid concentration.

The activity coefficients for the system glycylglycine—urea—water were measured by the isopiestic method to examine their dependence on concentrations of both amino acid and urea. Hydrophobic interaction need not be taken into consideration, as the peptide has no hydrophobic side chain.

Experimental

Materials. Glycylglycine (G. R.) was decolorized and recrystallized twice from a water-ethanol solution. Urea (G. R.) was recrystallized twice from water, without being heated above 60°C. The peptide and urea were dried *in vacuo* over phosphorus pentoxide at room temperature. Potassium chloride of analytical grade (Merck Co.) was not purified further and was dried in vacuo over phosphorus pentoxide at 110°C. Solutions were prepared with deionized water freed of air by boiling.

Measurements and calculation of the activity coefficients for the ternary solutions. Osmotic and activity coefficients were determined with an apparatus[6] similar to that used by Robinson and Stokes.[7] Four or five ternary peptide–urea solutions with varying compositions were put in silver dishes. Reference potassium cholride solutions were present in triplicate or quadruplicate. The dishes were placed on a flat copper block in a glass vacuum desiccator set in a thermostat bath at 25°C and controlled within 0.01°C. All the solutions were prepared afresh for each measurement. The intial concentrations in the solutions were adjusted to be sufficiently close to their equilibrium concentrations by the method reported previously.[8] The time required for attainment of equilibrium was 4—7 days. Equilibrium concentration was measured by weighing, all weights being corrected to those in vacuum.

An experimental quantity Δ is defined[7] by

$$\Delta = 2m_R\phi_R - m_1\phi_1 - m_2\phi_2 \quad (1)$$

where m_1 and m_2 are the molalities of glycylglycine (solute 1) and urea (solute 2), respectively, in aqueous ternary solutions. ϕ_1 and ϕ_2 are the osmotic coefficients of binary aqueous glycylglycine and urea solutions at a molality of m_1 and m_2, respectively. m_R and ϕ_R are the molality and osmotic coefficient, respectively, of reference potassium chloride solution which is in vapor pressure equilibrium with a ternary solution containing glycylglycine and urea at molalities m_1 and m_2.

The value of Δ is thus obtained experimentally from the concentrations m_R, m_1, and m_2, provided that the osmotic coefficients of reference solution and binary solutions of glycylglycine and urea are known.

The value of Δ/m_1m_2 is given by the equation

$$\Delta/m_1m_2 = A + Bm_1 + Cm_2 + Dm_1^2 + Em_1m_2 + Fm_1m_2^2 + Gm_1^3 + Hm_1^2m_2 + Im_1m_2^2 + Jm_2^3 \quad (2)$$

By means of Eqs. (1) and (2), the activity coefficient for glycylglycine in the ternary solution is given[9,10] by

$$\ln \gamma_1 = \ln \gamma_{10} + Am_2 + Bm_1m_2 + \frac{C}{2}m_2^2 + Dm_1^2m_2 + \frac{2E}{3}m_1m_2^2 + \frac{F}{3}m_2^3 + Gm_1^3m_2 + \frac{3H}{4}m_1^2m_2^2 + \frac{I}{2}m_1m_2^3 + \frac{J}{4}m_2^4 \quad (3)$$

and that of urea by

$$\ln \gamma_2 = \ln \gamma_{20} + Am_1 + \frac{B}{2}m_1^2 + Cm_1m_2 + \frac{D}{3}m_1^3 + \frac{2E}{3}m_1^2m_2 + Fm_1m_2^2 + \frac{G}{4}m_1^4 + \frac{H}{2}m_1^3m_2 + \frac{3I}{4}m_1^2m_2^2 + Jm_1m_2^3 \quad (4)$$

where γ_1, and γ_2 are the molal activity coefficients of solutes 1 and 2 in a ternary solution containing solute 1 and 2 with molalities m_1 and m_2, respectively. γ_{10} and γ_{20} are the molal activity coefficients, respectivley, of binary solutions containing only solute 1 at molality m_1 or solute 2 at molality m_2. The values of osmotic and activity coefficients for reference potassium chloride solutions were taken from the values given by Robinson and Stokes.[11] The values of osmotic and activity coefficients for glycylglycine solutions were taken from the data of Ellerton *et al.*,[12] and the values for urea solutions, from Ellerton and Dunlop.[10]

Results and Discussion

The isopiestic data for the system glycylglycine—urea—water are given in Table 1. The values of Δ/m_1m_2 (calcd) were calculated by the least-squares treatment of Eq. (2) and Table 2. The percentage

TABLE 2. COEFFICIENTS IN EQ. (2) FOR TERNARY SOLUTIONS GLYCYLGLYCINE–UREA–WATER AT 25°C

Coefficients		Coefficients	
A	−0.099457	F	0.002963
B	0.099905	G	0.007619
C	0.009731	H	0.004752
D	−0.047333	I	0.000847
E	−0.017318	J	−0.000434

error in the molality of the reference solution is defined by[7,13]

$$\text{diff. } \% = \frac{m_R(\text{calcd}) - m_R(\text{exptl})}{m_R(\text{exptl})} \times 100 \quad (5)$$

where

$$m_R(\text{calcd}) = \frac{m_1\phi_1 + m_2\phi_2 + \Delta(\text{calcd})}{2\phi_R} \quad (6)$$

The coefficients of Eq. (2) were calculated from the experimental values of Δ/m_1m_2 by the method of least-squares with a HITAC 8400 computer, and are given in Table 2.

Substituting the numerical values into Eqs. (3) and (4), we have for glycylglycine

$$\ln \gamma_1 = \ln \gamma_{10} - 0.099457m_2 + 0.099905m_1m_2 + 0.004865m_2^2 - 0.047333m_1^2m_2 - 0.011546m_1m_2^2 - 0.000988m_2^3 + 0.007619m_1^3m_2 + 0.003564m_1^2m_2^2 + 0.000424m_1m_2^3 - 0.000109m_2^4 \quad (7)$$

and for urea

$$\ln \gamma_2 = \ln \gamma_{20} - 0.099457m_1 + 0.049952m_1^2 + 0.009731m_1m_2 - 0.015778m_1^3 - 0.011546m_1^2m_2 + 0.002963m_1m_2^2 + 0.001905m_1^4 + 0.002376m_1^3m_2 + 0.000636m_1^2m_2^2 - 0.000434m_1m_2^3 \quad (8)$$

The activity coefficients of glycylglycine at various concentrations of urea in ternary solutions are shown in Fig. 1. The solid line shows the activity coefficients in binary solutions. The activity coefficients of glycylglycine decreased with the increase in concentration of urea. The lowering effect of urea was more marked at smaller concentrations of glycylglycine.

The activity coefficients of urea at various concentrations of glycylglycine are shown in Fig. 2. The activity coefficients of urea also decreased with the increase in concentration of glycylglycine.

Unlike the activity coefficients of glycylglycine, those of α-amino-*n*-butyric acid in aqueous solution are greater than unity and increase with concentration.[5] Addition of urea to aqueous solution of α-amino-*n*-butyric acid, however, also decreases the activity coefficients of the amino acid.[5] Urea decreases hydrophobic bonding of amino acids having larger hydrocarbon residues, resulting in an increase in

solubility.[2] The decrease in activity coefficient of α-amino-*n*-butyric acid is caused by the decrease in hydrophobic bonding.[5]

On the contraty, as there is no hydrophobic part in glycylglycine, the decrease in activity coefficient is due to some factor other than hydrophobic interaction.

Robinson and Jencks[3] showed that the increase in solubility of acetyltetraglycine ethyl ester by urea is not caused by hydrophobic interaction.

At lower concentrations of amino acids, urea decreases the activity coefficient of glycylglycine to a greater extent than that of α-amino-*n*-butyric acid, the degree of decreases being reversed at relatively high concentrations ($\gtrsim 1.2\ m$). The decrease in activity coefficients of glycylglycine in urea solutions is due to the factor which is more dependent on the concentration of amino acid than hydrophobic interaction.

The activity coefficients of solute i in urea solutions are all relative to unity in the standard state in water and do not refer to the standard state in a water-urea solvent,[14] because of the method of calculation adopted in isopiestic measurements.[9,10] Thus, the free energy of transfer ΔG_t of solute i at constant concentration of the solute, from water to urea solution, is given by an equation containing only the term of the change in activity coefficients. When urea is treated as a component of solvent, the appropriate concentration scale for solute i is the mole fraction. The free energy of transfer ΔG_t for solute i is given by

$$\Delta G_t = RT \ln(f_i/f_{i0}) \tag{9}$$

where f_{i0} and f_i are the activity coefficients in mole fraction scale of solute in binary and ternary solutions, respectively, both at mole fraction N_{i0}. The activity coefficient in the molality scale was calculated at a certain molality in a binary solution from the data referred to before. The activity coefficients of the solute were calculated at the same concentration in mole fraction scale in a ternary solution, by Eq. (7). The activity coefficients in the molality scale were then converted into the rational activity coefficients by the equation[11]

$$f = \gamma(1 + 0.001 m_i W_A) \tag{10}$$

where W_A is the molecular weight of solvent. In a binary solution, W_A is equal to the molecular weight of water. In a ternary solution, W_A is the molecular weight of mixed solvent (water-urea) defined by

$$W_A = \frac{55.51 W_{A0} + W_u m_u}{55.51 + m_u} \tag{11}$$

where W_{A0} is the molecular weight of water, and W_u and m_u are the molecular weight and molality of urea, respectively, in the mixed solvent.

The free energy of transfer of glycylglycine from water to urea solutions at various concentrations is shown in Table 3. At comparatively small concentrations of glycylglycine, the free energy of transfer becomes more negative with increasing concentration of urea, and at higher concentrations, the value changes a little with urea concentration and rather tends to approach zero at higher concentrations of urea. In addition, at the same concentration of urea, the values of ΔG_t approach zero with increasing concentrations of glycylglycine. The values of ΔG_t for glycylglycine (Table 3) have neither maximum not minimum as observed by Nozaki and Tanford[2] from measurement of solubility.[15]

The values of ΔG_t at $m_1=0$ are the free energy change when a mole of glycylglycine is transferred from water with a given mole fraction to the mixture urea-water of the same mole fraction in the limit $m_1=0$. Consequently, they can be compared with the enthalpy of transfer of the solute from water to aqueous urea at infinite dilution ΔH_t which is the difference between partial molal enthalpy of the solute at infinite dilution

14) H. S. Harned and R. A. Robinson, "Multicomponent Electrolyte Solutions," Pergamon Press Inc., London (1968), p. 94.

15) The values of transfer free energy for glycylglycine from water to various urea solution were: −5, to 2 M urea; −12, to 4 M urea; −1, to 6 M urea; and −4 (cal/mol), to 8 M urea.[2]

in ternary and binary solutions.

The enthalpy of transfer of the solute from water to aqueous 6 M (molarity scale) urea solution at infinite dilution was obtained by Kresheck and Benjamin.[4] The value obtained was −1425 cal/mol. Concentration of urea in the molality scale was converted into that in the molality scale by means of density of solution,[16] *i. e.* 6 molarity urea solution is 8.2402 molality. The corresponding values of ΔG_t of glycylglycine at infinite dilution is obtained by extrapolating Eq. (7). The extrapolated value for activity coefficient gives $\Delta G_t = -259$ cal/mol.[17] The entropy of transfer ΔS_t was thus calculated to be −3.9 e. u. Kresheck and Benjamin[4] calculated it with the ΔG_t of Nozaki and Tanford,[2] giving −4.8 e. u. Though the two values are not the same, their signs are negative in both calculations. The transfer of glycylglycine from water to urea solution is accompanied by negative free energy change, negative enthalpy change and negative entropy change. The negative value of free energy of transfer is caused by the large negative value of enthalpy of transfer which surpasses the unfavorable entropy decrease.

It is known that urea destroys the ordered structure of water in aqueous solution.[18] The self diffusion coefficients of water in aqueous glycylglycine solution were measured at 25—50°C by Altunina *et al.*[19] Glycylglycine decreases the activation energy of self diffusion of water. The peptide molecule shifts the equilibrium between ordered and free structures of water to the disordered structure by decreasing activation energy of self diffusion of water. Glycylglycine is ranked thus as a sturcture breaker (negative hydration), that is, water molecules move more easily in glycylglycine solution than in pure water.

In the case of a ternary system containing two sturcture breaking solutes, their activity coefficients are lowered by each other as a result of sturcture salting in,[20,21] occuring in the system, *e. g.*, sodium benzenesulfonate-urea-water.[8] The proportion of free water thus should increase and entropy of transfer should be positive. The data of partial molar heat capacity, obtained with dipeptides by Kresheck and Benjamin,[4] show that the peptide unit has no conspicuous effect on the solvent structure in water, but the negative value of partial molar heat capacities at infinite dilution, associated with transfer of glycylglycine from water to 6 M urea, suggests a peptide-urea interaction resulting in less ordered water structure. The explanations are in line with the lowering of activity coefficients in ternary systems, and with the negative free energy of transfer. However, the entropy of tansfer of glycylglycine from water to urea solutions is negative.

Thus, the interaction between glycylglycine and urea might be the main cause of decreasing activity coefficient and negative free energy of transfer. In order to confirm interaction such as complex formation between glycylglycine and urea, X-ray refraction intensity curves were obtained for the crystalline complex crystallized from aqueous glycylglycine and urea solution (mole ratio, 1 : 4), and soild mixture of glycylglycine and urea of the same mole ratio as crystallized from solution. A difference was found between the curves for the crystalline and solid mixture of glycylglycine and urea.[22] Thus, even in aqueous solution, glycylglycine and urea may form a certain complex aggregation.

Swenson and Koob[23] found by NMR study that rates of exchange for the peptide proton of glycylglycine and triglycine were smaller in aqueous urea than in water. They stated that urea might decrease the base-catalyzed rate by specifically interacting with the peptide hydrogen bond. Their data suggest an interaction between glycylglycine and urea in aqueous solution.

Robinson and Jencks[3] showed that an increase in the number of amide bonds in carbobenzoxyglycine derivatives has no appreciable influence on the effect of urea on the solubility of peptides and that solubility of acetyltetraglycine ethyl ester increases linearly with urea concentration. They pointed out that the evidence is more easily explained in terms of complex formation.

The interaction between urea and glycylglycine increases with urea concentratoin and decreases with glycylglycine concentration. In a relatively small concentration (at about 0.1 M amino acid residue) at which the usual investigations on denaturation of protein by urea are carried out, the decrease in the activity coefficient of glycylglycine is greater than that of α-amino-*n*-butyric acid. These results suggest that urea interacts with polar parts of amino acids, and the effect is important at relatively small concentrations of amino acids. The denaturation of globular protein by urea may thus be caused by the interaction of polar parts of amino acids and urea besides the weakening of hydrophobic bonding between hydrophobic side chains of constituent amino acid residues.

The author thanks Dr. Hisashi Uedaira for discussions. She is also indebted to Mr. Mitsuhiro Kikuchi for his assistance in measurements, and to Mr. Toshio Kurita for his help with the measurements of X-ray refraction.

17) The values of ΔG_t differ from those of Nozaki and Tanford.[2] The results in this paper show that activity coefficients of glycylglycine in urea solutions are a function of the concentrations of both urea and glycylglycine, containing their cross terms. It is therefore thought that the main cause of difference is that Nozaki and Tanford assumed the activity coefficients of glycylglycine in aqueous urea solutions to be dependent on the concentration of glycylglycine only and independent of the concentration of urea.

Formation Constants of Some Bivalent Metal Chelates of *N*-Phenylbutyrohydroxamic Acid

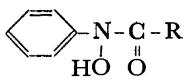
J. P. SHUKLA* and S. G. TANDON

Department of Chemistry, Government College of Science, Raipur, M.P., India

(Received December 25, 1970)

The formation constants for the metal chelates of Mn(II), Ni(II), Zn(II), and Cu(II) with *N*-phenylbutyrohydroxamic acid have been determined in 50 volume per cent dioxane–water mixture following the Bjerrum-Calvin pH titration technique and maintaining the titration medium at a constant salt background (0.1 M $KClO_4$) and a temperature 25±0.1°C. The formation constants found are log K_1=9.68(Cu), 6.85(Zn), 6.67(Ni), 5.25(Mn), and log K_2=8.58(Cu), 5.52(Zn), 5.21(Ni), and 4.09(Mn), the stability order being Mn<Ni<Cu>Zn.

Substitution of different groups at different positions of aryl nuclei of the parent compound influences the stabilities of the resulting metal complexes. A more or less quantitative survey of the effects of substitution in the aryl nuclei on the stability constants of metal chelates of the ligand was first carried out by Calvin and Wilson.[1] Such studies are important in as much as they help predict what type of substituents in the molecule might enhance its use for a particular purpose. Several *N*-arylhydroxamic acids represented by the general formula have been synthesised during the last



few years and their possible analytical applications examined. Recently, the stabilities of metal chelates of some aryl substituted *N*-arylhydroxamic acids (R= aryl), mainly of *N*-phenylbenzohydroxamic acid (PBHA) have been reported.[2,3] But so far no attempt seems to have been made except for a few instances[2,4] to elucidate the stability of metal chelates of alkyl substituted *N*-arylhydroxamic acids (R=alkyl). The present paper deals with the determination of formation constant of Cu(II), Ni(II), Zn(II), and Mn(II) chelates with *N*-phenylbutyrohydroxamic acid, P(n)BHA, by employing Calvin and Melchior's method,[5] commonly referred to as Bjerrum-Calvin pH titration technique. Titrations were carried out in duplicate in a medium of salt background 0.1 M adjusted with $KClO_4$, at 25± 0.1°C. A ratio 10: 1 of the ligand to metal ion concentration was used in order to satisfy the highest possible coordination number namely, 6, of the metal ions under study. Since evaluation of the formation constant required knowledge of the acid dissociation constant not found in literature, it was also determined under similar experimental conditions. As both the ligand and its complexes are fairly insoluble in water, 1: 1 dioxane–water was used as the solvent medium.

Experimental

B.D.H. *p*-dioxane was purified by the procedure of Weissberger and Proskauer.[6] Carbonate free KOH was prepared following the method of Vogel[7] and diluted to 0.1 M; the proportion of dioxane and water in the final solution was 1: 1. It was standardized against analytical grade potassium hydrogen phthalate.

Measurements of pH were made with a Radiometer pHM-4c pH meter, saturated calomel reference electrode and a glass electrode. Buffer solutions of pH 4.01 (at 25°C) and 9.18 (at 25°C), prepared from potassium hydrogen phthalate and borax respectively, were used for standardization of the pH meter, which was done at the beginning of each titration and checked after completion.

Chelating Agent. P(n)BHA was synthesised by the method of Priyadarshini and Tandon.[8] This was recrystallised before use from a mixture of benzene and petroleum ether and dried in a vacuum over P_2O_5. Purity of the compound was checked by elemental analyses, mp, UV and IR spectra.

Metal Perchlorates. Metal salt solutions were prepared by dissolving the respective metal carbonates or oxides in a known volume of perchloric acid. The concentration of the metal ion in each of the metal perchlorates was determined by EDTA titration.[9] Finally, these solutions were suitably diluted before use. In the case of copper perchlorate, however, no further dilution of the stock solution was made since the pH of hydrolysis for Cu(II) is rather low, *i.e.* 5.3.[10]

Determination of Acid Dissociation Constant (pK_a). The titration procedure for determination of pK_a was essentially the same as that given by Albert and Serjeant.[11] A half millimoles of the compound was transferred to a four-necked, flat bottomed titration cell and dissolved in known volumes of dioxane and water. Five milliliters of 1 M $KClO_4$ was added to maintain a constant salt background of 0.1 M. The total volume of the contents was made to 47.5 m*l* by adding dioxane and water in such proportion that it finally became 1: 1 dioxane–water mixture. Before performing the titration

the contents of the titration vessel were thermostated at 25±0.1°C. Pre-saturated nitrogen (with 50 volume per cent aqueous dioxane) was continuously bubbled through the solution. After about 15 min, the titration was started by adding 0.5 ml increments of 0.1M KOH each time and noting the highest pH-meter reading which remained steady. Titrations carried out in duplicate were reproducible within±0.01 pH unit. The results of the titration are recorded in Table 1.

Determination of Formation Constants. A weighed quantity of P(n)BHA, corresponding to 0.01M in the final solution of 50 ml was transferred to the titration cell and 25 ml of dioxane was added to it. Next, 10 ml of about 0.005M solution of the metal perchlorate, 5 ml of 1M $KClO_4$ and 10 ml of water were added to yield a 1:1 dioxane-water mixture. The titration procedure followed was exactly the same as that described above except that KOH was added in small aliquots of 0.25 ml until the pH of the titre solution crossed the hydrolysis point. The results of the copper(II)-ligand titration are summarized in Table 2. For the sake of brevity, results of titrations of Ni(II), Zn(II), and Mn(II) are not given here. The first and second stepwise stability constants, K_1 and K_2, were evaluated by the method of least squares as illustrated by Albert and Serjeant.[12]

Results and Discussion

Log K_1, log K_2, and log (K_1/K_2) of the complexes of Cu(II), Ni(II), Zn(II), and Mn(II) are given below. All the constants reported here including pK_a may be termed concentration (or stoichiometric) constants because they were obtained without applying activity corrections. It is quite evident from Table 3 that all the metal chelates are fairly stable. P(n)BHA is believed to react with these metal ions as leading to the formation of a five membered ring in the chelate. On the basis of published data, it has been assumed that P(n)BHA yields 1:2 complex with the aforesaid metal ions. In the present experiments $\bar{n}$ (average number

Cu	9.68	8.58	1.10
Zn	6.85	5.52	1.33
Ni	6.67	5.21	1.46
Mn	5.25	4.09	1.16

12) Ref. 11, p. 165.

of ligand molecules attached per metal ion) gradually reached a value of nearly 2 before precipitation. So our assumption of 1 : 2 complex formation in solution seems to be valid.

Order of Stability Constants or log K Values. From Table 3 it can be seen that the order Mn<Ni<Cu>Zn is in agreement with that of Irving and Williams.[13] In all the cases $K_1 > K_2$. The values of $\log(K_1/K_2)$ is the highest for the nickel complex. Furthermore, it is observed that the values of log K_2 are lower than log K_1 by approximately 1.1—1.5 units. This suggests that in these systems not only the statistical effect (which gives the value of log K_1—log K_2=0.60 units) should be considered but the electrostatic effect also becomes important.[14]

Values of log K for copper differs considerably from those for other metals and values for Zn are greater than Ni. The enormously higher log K value for copper chelate may be due to its possible square planar structure. The order Zn>Ni has been observed earlier,[15] where the relatively low value of Ni is attributed to steric hindrance preventing the formation of a square planar structure. Again the hydrolysis constant for Zn is greater than that of Ni indicating a greater affinity of Zn(II) for OH ions. These factors seem to account for the order Zn>Ni.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3075—3077 (1972)

Order of Quencher Participation in Photochemistry. II. Quenching Action of Ethanol on the Photoreduction of *p*-Aminobenzophenones

Mikio HOSHINO and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai

(Received March 21, 1972)

The effect of the addition of ethanol (quencher of the reaction) on the photoreduction of *p*-aminobenzophenone (NH_2BP) and dimethyl-*p*-aminobenzophenone in cyclohexane and in ether has been studied. The order of quencher participation for ethanol has been found to be two for the former and one for the latter. The results were interpreted to be due to the formation of intramolecular C–T state during excitation, promoted by the attachment of one ethanol (or ether) molecule to the NH_2-group and one ethanol molecule to O=C of NH_2BP.

We previously reconfirmed[1] the view that proton transfer is a cause of the quenching action of ethanol on the photoreduction of *p*-hydroxybenzophenone (HOBP). This was in line with the work of Porter *et al.*[2] It was found, however, from the measurement of relative quantum yields in the mixed solvents of cyclohexane and alcohols, that the participation of several alcohol molecules is required for the eventual proton transfer to occur from HOBP in cyclohexane. An approach of the same type will enable us to attain a dynamic aspect of the quenching action not obtained with pure solvents. We have extended similar sutdies to the quenching action of alcohols on the photoreduction of *p*-aminobenzophenone (H_2NBP) and dimethyl-*p*-aminobenzophenone ($(CH_3)_2NBP$).

H_2NBP is photoreduced in cyclohexane with a quantum yield of 0.2 but not at all in ethanol.[3] The difference was explained to be due to the different character of the lowest triplet state. Thus in cyclohexane, the lowest triplet is $T(n\text{–}\pi^*)$ whereas in ethanol it is an intramolecular C–T state. However, from analogy of HOBP, the quenching action of ethanol in the case of H_2NBP is also expected to be dynamic in nature, and studies in the mixed solvents should give more detailed information. In particular, we thought it possible that in cyclohexane containing a suitable amount of ethanol, intramolecular C–T state of H_2NBP might be stabilized during the lifetime of the excited state by a suitable reorientation of alcohol molecules around $^+NH_2$ and $C{=}O^-$ group, notwithstanding the lack of C–T type absorption spectrum. Our results indicate that this is actually the case.

Experimental

H_2NBP was prepared by the reduction of 4-nitrobenzophenone with zinc powder and glacial acetic acid. $(CH_3)_2NBP$ was obtained by the hydrolysis of 4-dimethylaminobenzophenone anil. These aminobenzophenones were recrystallized twice from ethanol. Mp=97—98°C (lit,98°C) for $(CH_3)_2NBP$ and 123°C (lit, 123~124°C) for H_2NBP. Cyclohexane and ethanol were purified by the usual method. Ether was refluxed on sodium metal for 24 hrs before dis-

tillation. The spectral change was followed with a Hitachi EPS-3T spectrophotometer. A 6W germicidal lamp was used as a light source of 2537 Å.

Results and Discussion

p-Aminobenzophenone (H_2NBP). The peak of the absorption at 303 nm in cyclohexane shifts to 335 nm in ethanol. The spectral change with the increase in ethanol concentration is shown in Fig. 1.

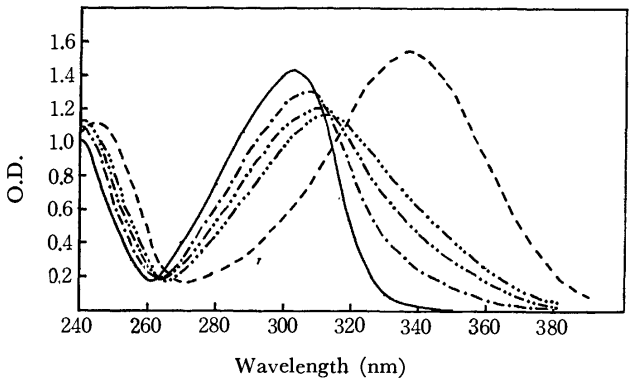

Fig. 1. Spectral change of H_2NBP (8.0×10^{-5} M) in cyclohexane with the addition of ethanol.
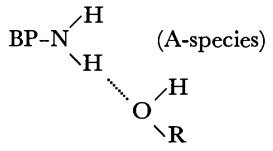
—— in cyclohexane
concentration of ethanol:
—·— 1.72×10^{-1} M, —··— 3.44×10^{-1} M, —···— 5.16×10^{-1} M, ---- in pure ethanol

A gradual *red* shift with no isosbestic point suggests that the interaction between NH_2-group and ethanol is hydrogen bonding of the type

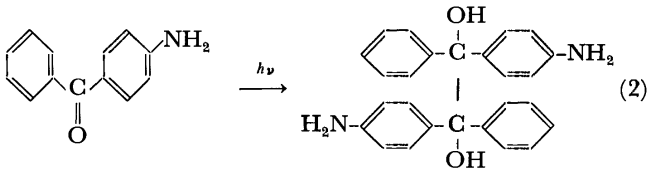


(A-species) (1)

which the general solvent effect is superposed. By analogy with a similar H-bonding species in the case of HOBP the photoreactivity of A-species was not expected to be reduced remarkably as compared with free H_2NBP.

It was found on the contrary that the relative quantum yield Φ_{rel} of the photoreduction decreases with the addition of ethanol much more rapidly than the spectral change.

The spectral change of H_2NBP in cyclohexane upon irradiation by 2357 Å is shown in Fig. 2. The change is due to the reaction



(2)

The analysis was made by the equation

$$-\frac{dC_A}{dt} = \Phi I_0(1-10^{-D})\frac{D_A}{D} \quad (3)$$

where D and D_A are the optical density of the irradiated solution and that due to H_2NBP at 2537 Å, respectively.

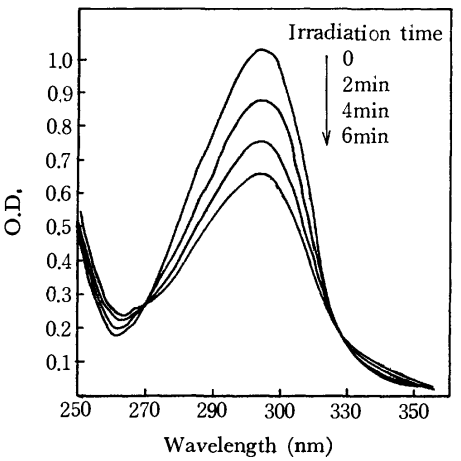


Fig. 2. Spectral change of H_2NBP containing ethanol (5.16×10^{-2} M) upon UV irradiation.

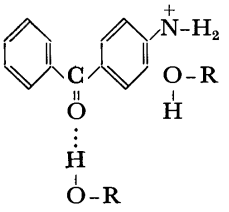
The other notations are the usual ones. Integrating we have

$$-\frac{1}{\varepsilon}\ln C_A = \Phi I_0 \int \frac{(1-10^{-D})}{D}dt \quad (4)$$

Because of a small change in optical density at 2537 Å, C_A was determined from the change at ~303 nm. The values of Φ_{rel} thus obtained at various ethanol concentrations [S] can be reproduced by the equation

$$\Phi_{rel} = \frac{1}{1+K[S]^n} \quad (5)$$

where $n=2$ and $K=3.03\times10^2$ M^{-2}. The plot of $1/\Phi_{rel}$ against $[S]^2$ gives a very good straight line as shown by curve a in Fig. 3. The value of 2 as the order of quencher participation suggests that another ethanol molecule is attached to C=O by H-bonding thus stabilizing the C-T state.



(6)

This is reasonable since the electron donating power of amino-group is much greater than that of the hydroxy

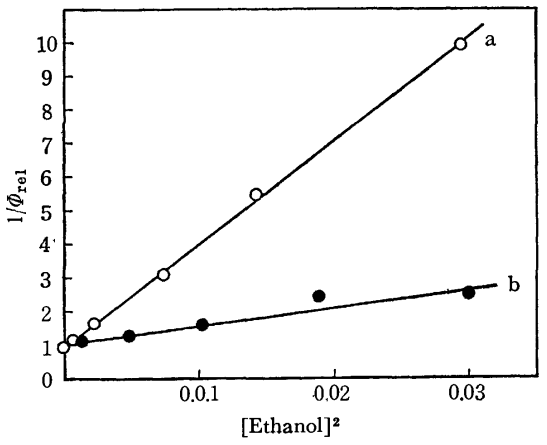


Fig. 3. Plots of $1/\Phi_{rel}$ *vs.* [ethanol]^2, ○: H_2NBP, ●: $(CH_3)_2NBP$.

group, for which such an electronic configuration is not so prominent. The interaction between $^{+}NH_2$ and ethanol in this state would be mainly due to a dipole-dipole one instead of H-bonding.

p-Dimethylaminobenzophenone ($(CH_3)_2$NBP). The absorption spectrum of $(CH_3)_2$NBP has a peak at 332 nm in cyclohexane and at 358 nm in ethanol, but it scarcely changes upon addition of ethanol up to about 1.7×10^{-1}M. However, the relative quantum yield of photoreduction obtained by the above analysis decreased to 40% at this ehtanol concentration.

$(CH_3)_2$NBP with no amino-hydrogen cannot form a H-bonded species as in the case of H_2NBP and it is quite natural that no spectral change occurs. Thus it is concluded that the decrease in Φ_{rel} in H_2NBP as well as in $(CH_3)_2$NBP is not related to the spectral change and accordingly the hydrogen bonding between NH_2 and alcohol.

The polt of $1/\Phi_{rel}$ against $[S]^2$ ($S=C_2H_5OH$) is linear as shown by curve b in Fig. 3 and the value of K was evaluated as 0.61×10^2 M^{-2}. All the results are similar to those of H_2NBP at least qualitatively and the mechanism of quenching is considered to be the same.

It is interesting that the K-value of $(CH_3)_2$NBP is much smaller than that of H_2NBP. Judging from a larger electron releasing power of dimethyl-group than hydrogen, structure (6) is expected to be more stable for $(CH_3)_2$NBP than for H_2NBP. The opposite result might be due to the kinetics of the phenomenon. Thus for H_2NBP, an ethanol molecule is in intimate interaction with H_2NBP molecule by H-bonding already in the ground state while no such an interaction takes place in $(CH_3)_2$NBP. However, there is a possibility that the structure itself is more stabilized by H-bonding in H_2NBP than in $(CH_3)_2$NBP.

The order of quencher participation of two could be interpreted by structure (6). It is conceivable that the quenching is caused by a dimeric ethanol molecule although this is less likely. The following experiment was carried out to clarify the mechanism.

Effect of the Addition of Ethanol on the Quantum Yield of the Photoreduction of H_2NBP in Ether. Ether is expected to interact with the amino group of H_2NBP in a similar way to ethanol, acting as a H-acceptor of H-bonding, but differing from ethanol in that no hydrogen bond formation occurs with carbonyl of H_2NBP. If by analogy to HOBP, a hydrogen bonded species of the type $\overset{R}{R}\!>\!O\cdots\overset{H}{H}\!>\!N$-BP and $\overset{H}{R}\!>\!O\cdots\overset{H}{H}\!>\!N$-BP (A-species (1)) is reactive, then the photoreduction of H_2NBP is expected to occur in pure ether as in HOBP. But when a small amount of ethanol is added, formation of species (6) becomes possible and the reaction may be suppressed. If this is the actual mechanism for the quenching of reaction, the order of quencher participation is now expected to become one. On the other hand, the mechanism due to ethanol dimer should result in the order of quencher participation of two. Thus it will be easy to discriminate the two mechanisms experimentally. From such a viewpoint, we have investigated the photoreduction of H_2NBP in ether.

The absorption peak of H_2NBP in ether lies at 320 nm compared with 303 nm in cyclohexane and 337 nm in alcohol. It was established that the photoreduction occurs in pure ether with a quantum yield about the same as or a little larger than in cyclohexane. This indicates that A-species (1) itself is reactive. The plot of Φ_{rel} and $1/\Phi_{rel}$ aganist the concentation of ethanol is shown in Fig. 4. It is evident that the quenching action of ethanol occurs according to the equation

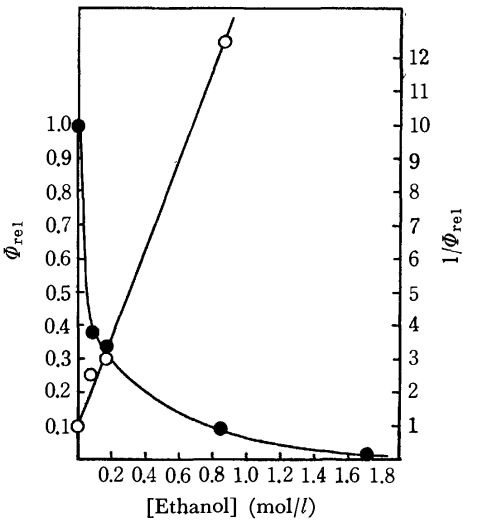

Fig. 4. Plots of Φ_{rel} *vs.* [ethanol] (●) and $1/\Phi_{rel}$ *vs.* ethanol (○) in ether.

$$\Phi_{rel}=\frac{1}{1+K[S]} \tag{7}$$

where [S] is the concentration of ethanol. The value of K evaluated from the solpe of $1/\Phi_{rel}$ *vs.* [S] plot is 13.2 M^{-1}. The absorption spectrum of H_2NBP in ether changes gradually to longer wavelength with the addition of ethanol, but the magnitude of change is very small at the ethanol concentration where the value of Φ_{rel} becomes about 1/10. This is reasonable in view of the fact that the effect of the hydrogen bond of this type on the π–π absorption spectra is rather small.[4]

It is thus concluded that the formation of intramolecular C-T state during the excitation by a solvent interaction as written in (6) is a cause for the quenching of reaction.

Heat Capacities of Antimony Trichloride and Tribromide

Kuniko TAKEYAMA and Tetsuzo ATODA
The Institute of Physical and Chemical Research, Hirosawa, Wako-shi, Saitama

(Received March 24, 1972)

Heat capacities of liquid antimony trichloride and tribromide saturated with their respective vapors were determined with an adiabatic calorimeter as follows: 35.2 cal K^{-1} mol^{-1} in the range, 90—210°C, for trichloride, and 34.6 cal $K^{-1}mol^{-1}$ in the range, 130—270°C, for tribromide.

For thermodynamic consideration on vaporization of antimony trichloride ($SbCl_3$) and tribromide ($SbBr_3$) at moderately high temperature, heat capacities of both halides in liquid state, which have never been determined, were required to be known, and the present authors measured them with an adiabatic calorimeter. Measurements were carried out for $SbCl_3$ in the range, 90—210°C, and for $SbBr_3$, 130—270°C, respectively.

Experimental

Apparatus and Procedure of Measurement. The calorimetric apparatus is shown schematically in Fig. 1. A capsule made of fused quartz, 5—6 cm^3 in volume, 0.8 mm in wall thickness, 5—6 g in weight, and provided with a well for an internal heater at its center was used as a sample container. Two alumel-chromel thermocouples, one for measuring the temperature of a capsule and another for adiabatic control, were fastened tightly with fine alumel wire at the middle part of the outside wall of the capsule to make a junction point of each couple touch surely to the wall surface. For measurements on $SbCl_3$, a thermocouple of 0.3 mm in diameter, and on $SbBr_3$, another of 0.2 mm in diameter were used. Calibration of each thermocouple was made by measuring the ice-point and melting points of In,[1] Sn,[2] and Pb[2] metals, the nominal purities of these metals being higher than 99.99%.

On heat capacity measurements, the pressure of argon gas filled in a nickel ball enveloping a capsule was kept at about 50 mmHg. Each sample was heated at a rate of 1°C/min with an internal heater to which practically constant wattage, the fluctuation being within ±0.5%, was supplied by a watt-stabilizer. Adiabatic control was made to make the temperature of the nickel ball equal to the temperature of the outer surface of the capsule with a heater equipped outside of the nickel ball. The heater was controlled by a proportional, integral, and differential heating device. The control fluctuation indicated by thermal emf of the alumel-chromel thermocouple was within ±1μV. Time required to elevate the temperature of a capsule containing a sample by 10°C was measured by a stop watch or a timer in error of less than 0.2%.

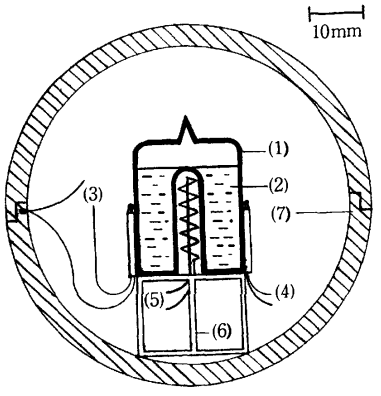

Fig. 1. The calorimetric apparatus
(1): Quartz capsule, (2): Sample, (3): Thermocouple for adiabatic control, (4): Thermocouple for measuring temperature of a capsule, (5): Internal heater, (6): Quartz stand, (7): Nickel ball.

Each sample in a reservoir was heated at a temperature between 100 and 150°C for several tens of minutes in reduced pressure (10^{-2}–10^{-3} mmHg) to remove any dissolved gas and volatile impurities prior to a distillation of the sample into a capsule through a vacuum line connecting the reservoir and the top of the capsule. The amount of the sample in the capsule was 4—5 cm^3. When the distillation was finished, the vacuum line was disconnected from the capsule by fusion. After heat capacity measurements were over, the top of the capsule was cut off to make the sample evaporate out of the capsule. After washed and dried, the empty capsule together with the cut tip was weighed. By subtracting the weight from that of the capsule containing the sample, a net weight of the sample was obtained. Buoyancy correction, less than 0.1% of total weight, was made for that purpose.

Materials. *$SbCl_3$*: $SbCl_3$,[3] the nominal purity being, higher than 99%, was purified with five times' vacuum distillation. $SbCl_3$ thus prepared was analyzed chemically; obsd. Sb, 53.36; Cl, 46.55 wt% calcd. Sb, 53.37; Cl, 46.63 wt%. Any impurities were not found by the emission spectrophotometric analysis. Mp 73.4°C.

$SbBr_3$: $SbBr_3$ was prepared at 250°C by direct reaction of metallic Sb,[1] the nominal purity six nines, with bromine,[4] the nominal purity higher than 99.5%. The reaction product thus prepared was then distilled five times in vacuum. The chemical composition of the purified $SbBr_3$ is: obsd. Sb, 33.70; Br, 66.19 wt% calcd. Sb, 33.68; Br, 66.32 wt%. The emission spectrophotometric analysis indicated very weak spectrum lines of Cu and Si on the purified $SbBr_3$. Mp 96.4°C. Liquid densities observed in the range, 100—250°C, by the pycnometric method were estimated to be: $3.95-2.67\times10^{-3}t$ (g/cm^3), where t is °C.

Hg: Hg,[5] the nominal purity being higher than 99.9%, was washed with dilute aqueous HNO_3, and then distilled five times in vacuum. Any impurities were not found by the emission spectrophotometric analysis on Hg thus purified.

Phenylether: Phenylether of special grade[6] was once distilled in reduced pressure of 7 mmHg, and then purified with five times' fractional recrystallization and two times' vacuum distillation. Any impurities were not found on phenylether thus prepared by the gaschromatographic technique. Mp 26.9°C.

6) Tokyo Kasei, GR.

mined according to the following equation:

$$P = (m_c/M_c)C_c + (m_s/M_s)C_s + E \quad (1)$$

where P is the input energy required to elevate the temperature of a calorimeter by 1°C, m weight in gram, M molecular weight in gram, C heat capacity per mole and E the sum of energies for thermocouples, protective tubes, an internal heater, a stand for a capsule and small heat exchange between the capsule containing a sample and the surroundings. c refers to a capsule and s to a sample. The amount of heat exchange varies depending on the stray emf of a thermocouple used for adiabatic control, on the heating rate, on the amount of a sample and on its thermal properties defining the extent of heat transfer. Except for thermal properties of a sample used, it is possible to keep all experimental conditions almost invariable in every heat capacity measurement. Therefore, when E, which is determined by measuring known heat capacity of a material chosen as a standard in strictly the same condition as in measurements on a sample, heat capacity of which is unknown, is used for determining heat capacity of the sample, the systematic error of heat capacity thus determined is caused principally by the difference in thermal properties between the standard and the sample.

The authors determined E on Hg, heat capacity of which is well-established,[7] for heat capacity calculation on antimony halides. To estimate the accuracy of heat capacity thus determined, heat capacity of phenylether determined by Furukawa *et al.*[8] with the probable error of ±0.25% was chosen as a relative standard, and was compared with that measured by the present authors in the same way as described above. Difference between the two would indicate the upper limit of accuracy of heat capacity on halides; thermal conductivity of a molten salt is, in general, smaller than that of Hg and larger than that of phenylether, hence, its heat capacity can be measured more accurately than that of phenylether by the adiabatic calorimetric technique.

In each work, heat capacity of two-phase system (C'), *i. e.* heat capacity of saturated vapor plus heat capacity of liquid in equilibrium with saturated vapor (C_{sat}), was observed, and C_{sat}/mol was obtained by calculation according to the following equation[9]:

$$C_{sat} = C' - \{(\Delta Hv_2 \cdot x_2 - \Delta Hv_1 \cdot x_1)/\Delta\theta - (\Delta Hv \cdot x/T)_m\} \quad (2)$$

where $\Delta\theta$ is the difference between initial and final temperature of a capsule containing a sample, T the absolute temperature, ΔH_v the latent heat of vaporization per mole, x the mass ratio of vapor to the total sample. 1, 2, and m refer to initial, final, and intermediate stages upon rise of temperature. In Eq. (2), values of ΔH_v and x were quoted from the following references: Ref. 10 and Ref. 11 on Hg; Ref. 12 on phenylether; Ref. 11 and Ref. 13 on $SbCl_3$; ΔH_v from Ref. 14 and x from liquid densities measured here and Ref. 14 on $SbBr_3$. The vapor correction was made to be: less than 0.1% of C_{sat} at 265°C on Hg; less than 0.2% of C_{sat} at 245°C on phenylether; less than 0.3% of C_{sat} at 205°C on $SbCl_3$; less than 0.2% of C_{sat} at 265°C on $SbBr_3$.

Heat capacities[7] of Hg and quartz at constant pressure (C_p) are:

$$C_p = 6.44 + 0.19\times10^5 T^{-2} \text{ (cal K}^{-1}\text{ mol}^{-1}\text{)(Hg)}:$$

$$C_p = 13.38 + 3.68\times10^{-3}T - 3.45\times10^5 T^{-2} \text{ (cal K}^{-1}\text{ mol}^{-1}\text{)(quartz)}.$$

These values were used here without conversion into C_{sat}, because the difference between the two is very small on both materials in the range of temperature in which the present work was carried out.

Results

Heat capacity measurements were made three to five times on one sample at each temperature, and values of P observed were within ±1% at each temperature. In every case, P was around 3 cal K^{-1} and its 60—70% was for heat capacity of a sample.

$SbCl_3$. Heat capacity measurements were made on Hg and $SbCl_3$ alternately, then on Hg and phenylether alternately in the range, 90—210°C, at each interval of 10°C. The value of E in every case is about 1% of P in the vicinity of 100°C and about 4% of P in that of 200°C. Seven samples of $SbCl_3$ were used for measurements. Mean heat capacity obtained at each temperature is shown in Table 1 and Fig. 2. Mean error of each value, about 1% of C_{sat}, is also given in Table 1. As shown in Fig. 2, the temperature dependency of heat capacity seems to be negative. When one, however, takes mean error on the measurements into account, the dependency should be disregarded. Therefore, averaging mean heat capacity obtained at each temperature in the range, 90—210°C, 35.2 cal $K^{-1}mol^{-1}$ is determined as the heat capacity of saturated liquid $SbCl_3$.

Mean heat capacities obtained on two samples of phenylether in the range, 90—210°C, are shown in Fig. 3 and compared with those determined by Furu-

225	—	—	34.6	0.9
235	—	—	34.8	1.0
245	—	—	34.6	0.9
255	—	—	34.7	1.1
265	—	—	34.8	0.9

a) Mean value obtained in the range $t \pm 5$°C.
b) Mean error $(\sqrt{\sum(C_{sat\ mean}-C_{sat\ obsd})^2/n(n-1)})/C_{sat}$ (%).

kawa *et al.* The present authors' are higher than Furukawa *et al.*'s, the discrepancy within 3% of C_{sat} in overall temperature range. As mentioned before, 3% is regarded as the accuracy of heat capacity on $SbCl_3$.

$SbBr_3$. Heat capacities of Hg, $SbBr_3$, and phenylether were measured alternately in the range, 110—270°C. For the measurements on $SbBr_3$, finer thermocouples, 0.2 mm in diameter, and protective tubes were used, resulting easier and more reproducible setting of the capsule and thermocouples. The value of E in every case is about −5% of P in the vicinity of 110°C and −2% of P in that of 250°C. Five samples of $SbBr_3$ were used for measurements. Mean heat capacity obtained at each temperature is shown in Table 1 and Fig. 4. Mean error of each value, about 1% of C_{sat}, is also shown in Table 1. As shown in Fig. 4, heat capacities which practically do not vary with temperature are obtained in the range, 130—270°C, however, higher values below 130°C; the reason remains unexplained. Except for those obtained below 130°C, mean heat capacity obtained at each temperature in the range, 130—270°C, was averaged, and 34.6 cal $K^{-1}mol^{-1}$ is determined as the heat capacity of saturated liquid $SbBr_3$.

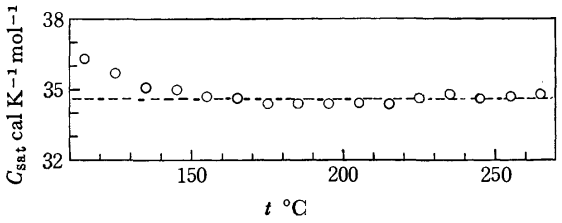

Fig. 4. Heat capacity *vs.* temperature on $SbBr_3$.

Mean heat capacities obtained in this run on three samples of phenylether in the range, 110—250°C, are also shown in Fig. 3. The present authors' agreed with Furukawa *et al.*'s within 1%, indicating that the accuracy of heat capacity on $SbBr_3$ is 1%.

Conclusion

Heat capacities of $SbCl_3$ and $SbBr_3$ saturated with their respective vapors are determined as follows:

$SbCl_3$: 35.2 cal $K^{-1}mol^{-1}$ in the range, 90—210°C. Accuracy is 3%, mean error 1%.

$SbBr_3$: 34.6 cal $K^{-1}mol^{-1}$ in the range, 130—270°C. Accuracy is 1%, mean error 1%.

Studies of Ruthenium Complexes. III. Kinetics of Isotopic Ligand-Exchange Reactions of Halogenopentaammineruthenium(III) Complexes in Aqueous Solution

Tetsuo SHINOHARA, Takato YAMADA, Noriyuki TAKEBAYASHI, Shun-ichi HIRAKI and Akira OHYOSHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received January 24, 1972)

Kinetic studies of isotopic ligand-exchange reactions, $[Ru(NH_3)_5X]^{2+}+X^{*-}=[Ru(NH_3)_5X^*]^{2+}+X^-$, where X=Cl, Br, and I, have been made in aqueous solutions. The effects of the hydrogen- and halide-ion concentrations, and of the ionic strength of the aqueous solution on the exchange rate had not been observed under certain definite experimental conditions. The rate constants were determined to be 3.15×10^{-4} sec^{-1} for the chloropentaammine 3.63×10^{-4} sec^{-1} for the bromopentaammine, and 1.1×10^{-4} sec^{-1} for the iodopentaammine at 80°C. The energies of activation were 20 kcal/mol (chloropentaammine), 23 kcal/mol (bromopentaamine), and 30 kcal/mol (iodopentaammine). The reactions proceed through the following two steps:

$$[Ru(NH_3)_5X]^{2+} + H_2O \longrightarrow [Ru(NH_3)_5H_2O]^{3+} + X^-$$

$$[Ru(NH_3)_5H_2O]^{3+} + X^{*-} \longrightarrow [Ru(NH_3)_5X^*]^{2+} + H_2O$$

The first step is regarded as the rate-determining one.

There have been several investigations of the direct replacement of a halide ligand by a free halide ion in solutions of metal halides[1,2] and halogenoammine complexes[3,4]. In most instances of this type of isotopic replacement, especially with octahedral complexes, the rate of exchange has been found to be controlled by the rate of aquation of the complex. For halogenopentaammineruthenium(III) complexes, however, no research has been done, as far as we know.

The results of the present kinetic study were compared with the results for d^6-metal halogenopentaammines, and the mechanism of the isotopic exchange reaction was explained on the basis of the kinetic data.

Expermental

Reagents. All the chemicals used were of a reagent grade. The radio-isotopes, ^{36}Cl(HCl), ^{82}Br(NH_4Br), and ^{131}I(NaI), were obtained from the Japan Radioisotope Association, Tokyo, and were used as radioactive tracers. Distilled water was used in all the kinetic runs. The ionic strength and the acidity of the reaction mixture were adjusted with p-toluenesulfonic acid and its sodium salt. The sodium salt was prepared by the neuralization of the acid with sodium hydroxide.

Halogenopentaammineruthenium(III) Complexes. The $[Ru(NH_3)_5X]X_2$ (X=Cl, Br, I) complexes were prepared by the method described by Allen.[5] One gram of ruthenium trichloride mono-hydrate was dissolved in distilled water (6 ml), and then hydrazine (85%, 10 ml) was added. The mixture was stirred for 17 hr at room temperature, and then filtered several times. To this filtrate, concentrated hydrohalogenic acid was added to make the solution strongly acidic. After this solution had been refluxed for three hours, the respective complexes were obtained. The complex was collected by filtration and washed with ethanol and ether. The final product was obtained by three recrystallizations from the distilled water.

Found: H, 5.08; N, 23.75%. Calcd for $[Ru(NH_3)_5Cl]Cl_2$: H, 5.13; N, 23.93%.

Found: H, 3.30; N, 16.48%. Calcd for $[Ru(NH_3)_5Br]Br_2$: H, 3.52; N, 16.44%.

Found: H, 2.50; N, 12.11%. Calcd for $[Ru(NH_3)_5I]I_2$: H, 2.65; N, 12.35%.

Kinetic Runs. A reaction vessel containing a solution of p-toluenesulfonic acid, sodium halide, and the respective halogenopentaammine complex was kept in a water bath at a constant temperature. A small amount of a solution of radioactive halide was added, and the exchange reaction was initiated. For the cases of the chloro- and the bromocomplex, aliquots of the reaction mixture were pipetted out at appropriate intervals and added to the ice-cooled silver nitrate solution. The free halide ion was precipitated as the silver halide. In the case of the iodocomplex, however, the decomposition of the complex was observed when the reaction mixture was added to the silver nitrate solution; therefore, we used an anion-exchange resin (Amberlite IR-4B) to collect free iodide ions.

In all cases, the supernatant containing the redioactive halogenopentaammine complex was separated and the radioactivity was measured.

The beta-activity of ^{36}Cl was measured by means of a G.M. counter while the gamma-activities of ^{83}Br and ^{131}I were measured by means of a well-type NaI(Tl) scintillation counter.

Results and Discussion

The recovery yields of the free halide ion in reaction solutions were determined, by a series of preliminary experiments, to be: Cl^-: 100%, Br^-: 98.5%, and I^-: 99.5%. Therefore, the exchange rates were calculated using these corrected values.

The reactions have been carried out for a period 8—10 times half-time, and the exchange rates were calculated by McKay's equations,[6] (1) and (2):

$$\ln(1-X/X_\infty) = -[(a+b)/ab]Rt \quad (1)$$

$$R = 0.693\,ab/[(a+b)\cdot T_{1/2}] \quad (2)$$

where R, exchange rate; t, time; a and b, the initial concentrations of the complex and the halide ion and X and X_∞, the radioactivity of the halogenopentaam-

mine complex at time t and at an infinite time. From Eq. (1), it can be expected that the plot of $\ln(1-X/X_\infty)$ *vs.* the reaction time will give a straight line with a slope of $-(a+b)R/ab$. From the plots in Fig. 1, the half-time of the exchange reaction was determined.

As is shown in Fig. 2, it is found that the exchange reaction is first-order with respect to the concentration of the complex.

As is shown in Fig. 3, there is no influence of the initial concentration of the halide ion on the reaction rate. This suggests that the bond formation between the halide and complex ion is not connected with rate-determining step in the exchange reaction.

No influence of the hydrogen ion on the reaction rate was observed under the present experimental conditions, as is shown in Fig. 4. Thus, the reaction rate, R, and rate constant, k_{ex}, can be expressed as follows:

$$R = k_{ex}[\text{complex}] \quad (3)$$

$$k_{ex} = 0.693\, b/[(a+b)\cdot T_{1/2}] \quad (4)$$

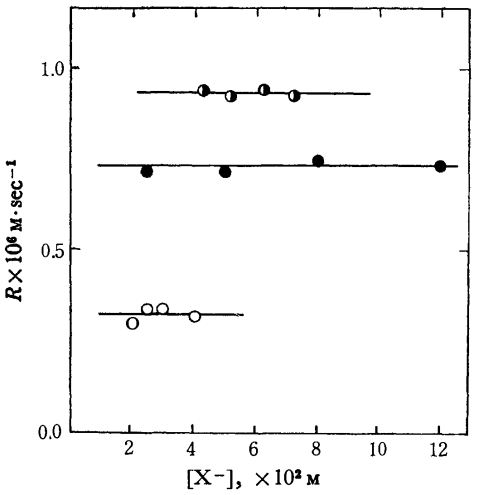

Fig. 3. Effects of halide-ion concentration on the rate

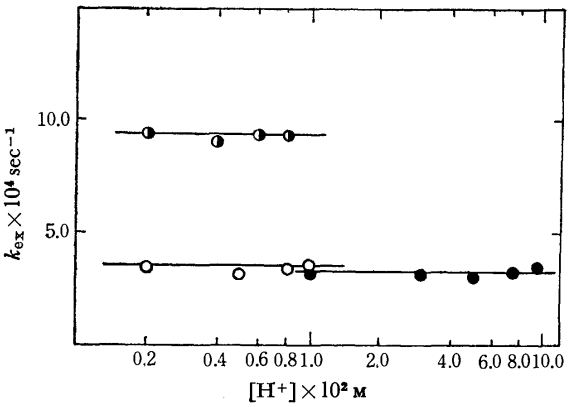

Fig. 4. Effects of hydrogen-ion concentration on the rate constants.
●: Chlorocomplex, ◑: Bromocomplex, ○: Iodocomplex

To know the dependence of the rate on the ionic strength, experiments were carried out while varying the ionic strength of the aqueous solution from 0.04 to 0.4 using sodium *p*-toluenesulfonate. The results are shown in Fig. 5. No practical effect of the ionic strength on the rate is found, this fact suggests that the charged species do not participate in the rate-determining process.

Figure 6 shows the Arrhenius plots, while the activation energies are listed, along with those of analogous and reference reactions, in Table 1.

The values of the rate constants of the exchange reactions are nearly the same as those of the acid-hydrolysis reactions. The values of both activation energies are also the same in the two kinds of the reactions except in the case of the iodopentaammine. From these facts, it may be concluded that the exchange reaction proceeds through the aquation process (5), and that the anation reaction (6) follows. The former step is presumably the rate-determining one.

$$[Ru(NH_3)_5X]^{2+} + H_2O = [Ru(NH_3)_5H_2O]^{3+} + X^- \quad (5)$$

$$[Ru(NH_3)_5H_2O]^{3+} + X^{*-} = [Ru(NH_3)_5X^*]^{2+} + H_2O \quad (6)$$

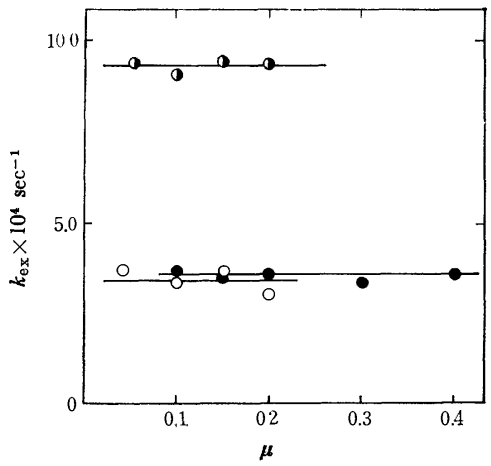

Fig. 5. Dependence of ionic strength on the rate constant.
●: Chloro-, ◑: Bromo-, ○: Iodocomplex

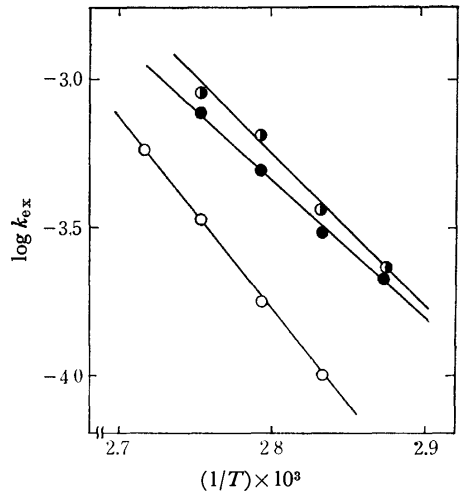

Fig. 6. Arrhenius plots for isotopic ligand exchange reactions.
●: Chloro-, ◑: Bromo-, ○: Iodocomplex

As the exchanging group is varied from chloride to bromide or iodide, the exchange rates are found to be in the order; Br>Cl>I for the halogenopentaammineruthenium(III) complexes. Similar trends have been found by Schmidt[4] for the halide-ion exchange rates of rhodium(III) and iridium(III) pentaammines.

If the mechansim for the aquation reaction (5) were of the dissociative (S_N1 lim) type, then the iodocomplex would be expected to be faster than the others. The present slower rate may be attributed to the higher activation energy term (Table 1) and indicates that bond breaking alone is not of major importance in Reaction (5).

A soft base such as an iodide ion tends to make a covalent bond, and the effective charge of the central metal may be decreased. If Reaction (5) proceeds through an S_N2 path, the exchange rate increases with an increase in the effective charge of the central metal ion.

Table 1. Rates and activation energies of isotopic ligand exchange reactions of $[M(NH_3)_5X]$ complexes

Complex	k_{ex}[a] 10^{-4} sec^{-1}	E_a kcal mol^{-1}	k[b] 10^{-4} sec^{-1}
$[Ru(NH_3)_5Cl]^{2+}$	3.15	20.0±0.5	3.28[c]
$[Ru(NH_3)_5Br]^{2+}$	3.63	23.2±0.9	3.99[f]

d) from Ref. 3.
e) from Ref. 7.
f) from Ref. 8.

Broomhead and Maguire[8] cited the ideas of Pearson and Songstad[9] to interpret their experimental results on the hydrolysis of analogous complexes. The replacement of the hard base, H_2O, by bases such as Cl^-, Br^-, or I^-, where the hardness is decreasing, should lead to a destabilization of the transition state in an S_N2 process and, consequently, to a slower reaction with a high E_a value. The slower rate and the higher activation energy for the iodocomplex are in good agreement with the predictions, assuming the presence of an S_N2 mechanism.

As is shown in Table 1, the exchange rate constants, k_{ex}, are generally smaller than those of acid hydrolyses. This would seem to suggest that Reaction (6) may be partly concerned with the over-all reaction rate; however, these differences are too small for another reaction mechanism to be considered.

Table 1 shows the isotopic exchange reaction rates of the three metal complexes for comparative purposes. It can be seen that the relative rate constants for the isotopic ligand exchange at 80°C are Ru(III)> Rh(III)>Ir(III) for all the halogenopentaammine complexes. This order is also in agreement with that predicted from the crystal-field consideration by Broomhead *et al.*,[7] assuming a seven-coordinated intermediate in an acid hydrolysis reaction corresponding to Eq. (5).

An NMR Study of Metal Complexes Containing Acetylacetone and Related Compounds. IV. The NMR Spectra and the Ligand-exchange Reaction of Cobalt(III) Complexes Containing *N,N'*-Ethylenebis(acetylacetonimine) and Amino Acid

Yuki Fujii

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito, Ibaraki

(Received January 26, 1972)

A series of mixed cobalt(III) complexes with the general formula of K[Co(baen)(amino acid anion)$_2$]·nH$_2$O (baen=dianion of *N,N'*-ethylenebis(acetylacetonimine); amino acid =glycine, β-alanine, L-alanine, D-alanine, D,L-alanine, L-valine, D-valine D,L-valine, L-leucine, L-isoleucine, and L-phenylalanine) were newly prepared from a reaction mixture of *trans*-*N,N'*-ethylenebis(acetylacetoniminato)diaquocobalt(II), [Co(baen)(H$_2$O)$_2$], and the amino acids. Also prepared were mixed cobalt(III) complexes having the general formula of [Co(baen)(X)$_2$]-ClO$_4$(X=glycine ethyl ester, L-alanine ethyl ester, L-leucine ethyl ester, L-phenylethylamine, D-phenylethylamine, and D,L-phenylethylamine). From the elemental analyses, and the IR and NMR spectra, the amino acid anions were found to coordinate as a unidentate ligand, and the structures of all the complexes were determined to be *trans* with respect to the two nitrogen atoms of the coordinated amino groups. The NMR spectral behavior of the complexes containing D,L-amino acid anions and D,L-phenylethylamine was well interpreted in terms of the existence of the following three species in a relative ratio of 1 : 2 : 1; [Co(baen)(L-form ligand)$_2$]$^{\pm n}$, [Co(baen)(L-form ligand)(D-form ligand)]$^{\pm n}$, and [Co(baen)(D-form ligand)$_2$]$^{\pm n}$. A rapid intermolecular exchange reaction of the apical amino acid anion groups was newly found in water: [Co(baen)(A)$_2$]$^-$+[Co(baen)-(B)$_2$]$^-$⇌2[Co(baen (A)(B)]$^-$ (where A and B indicate the apical amino acid anions). Also found was a rapid exchange reaction of the apical amino acid anion groups between the complex and free amino acid anion. Strong support for the rapid inter molecular exchange reaction was obtained in a CD spectral study of them.

It has been well established that the cobalamine ($V_{B_{12}}$) and its related compounds are labile for the apical ligand substitution reactions, even though the cobalt(III) complexes are generally inert.[1-3] Many anomalous properties of the cobalamines, as compared with the usual cobalt(III) complexes, have been reported by many investigators, and these anomalous properties have been explained in terms of the coordination of the macrocyclic unsaturated corrin to the cobalt(III) ion.[4]

Costa *et al.* found that the cobalt(III) complexes containing *N,N'*-ethylenebis(acetylacetonimine) (baen) and *N,N'*-bis(salicylidene)ethylenediamine (salen) had chemical properties similar to those of the cobalamines.[5-9] Cobalt(III)-baen,-salen complexes make cobalt-carbon bonds, and they show unusual stability in the lower valence state.[10]

In these circumstances, it seemed that it would be very interesting to study the lability of the apical ligands of the cobalt(III)-baen complexes. In this series of studies,[11,12] we found that the cobalt(III)-bean complexes show a rapid intermolecular exchange reaction of the apical ligands. In this paper, we will report the preparation, the NMR spectra, and the rapid intermolecular exchange reaction of the cobalt-(III)-baen complexes containing amino acid anions.

Experimental

Preparation of the Complexes. 1) *Complexes with the General Formula of K[Co(baen)(amino acid anion)$_2$]·nH$_2$O.* *N,N'*-Ethylenebis(acetylacetoniminato)diaquocobalt(II), *trans*-[Co-(baen)(H$_2$O)$_2$][13] (6.3 g, 0.02 mol), was dissolved in 200 m*l* of methanol. Amino acid (0.04 mol) neutralized with an equimolar amount of potassium hydroxide in 100 m*l* of water was then added. After air had been sucked through the solution for three hours, the solution was concentrated to a volume of about 100 m*l*. Acetone (100—200 m*l*) was added, and the mixture was allowed to stand for two days in a refrigerator. Brown crystals separated out; they were subsequently recrystallized from water and acetone. The yield was about 60—80%. The formulas and the elemental analyses data are listed in Table 1.

Complexes with the General Formula of [Co(baen)(amino acid ethyl ester)$_2$]ClO$_4$. Amino acid ethyl ester hydrochloride (0.022 mol), neutralized with an equimolar amount of potassium hydroxide in 50 m*l* of water, was added to a methanol solution (200m*l*) of *N,N'*-ethylenebis(acetylacetoniminato)-diaquocobalt(II) (3.1 g, 0.01 mol). Then, a hydrogen peroxide solution (5%, 5 m*l*) and sodium perchlorate monohydrate (5 g, 0.36 mol) were added to the solution, and the resulting solution was concentrated to about 100—150 m*l*.

(XVII)	[Co(baen)(DL-phenylethylamine)$_2$]ClO$_4$	53.87 (53.97)	6.54 (6.48)	8.88 (8.99)

When the solution was cooled to 0°C, brown crystals separated out; they were subsequently recrystallized from methanol-water. The yield was about 80%. The formulas and the elemental analyses data are summarized in Table 1.

3) *Cobalt(III)-baen Complexes Containing* D-, L-, *and* D,L-*phenylethylamine.* These complexes were prepared by the method employed for the preparation of the complexes containing the amino acid ethyl ester. The yeild was about 80—90%. The phenylethylamine was prepared by a known method[14] and was resolved with acetyl-L-leucine.[15] The (+)-amine had $[\alpha]_D^{25}$+39.1°(without solvent), lit. +39.2°, and the (−)-amine had $[\alpha]_D^{25}$−33.4°, lit. −33.6°. The formulas and the elemental analyses data are listed in Table 1.

Measurements. All the NMR spectra were recorded with a Hitachi R-20 spectrometer (60 MHz) at 35°C. The NMR spectra were measured in D_2O or deuterated DMSO, with NaTMS as the internal reference. The IR spectra were measured with a Hitachi EPI-S2 spectrometer, using a potassium bromide disk. The CD spectra were recorded with a Jasco Optical Rotatory Dispersion Recorder, Model ORD/UV-5. All the visible and ultraviolet absorption spectra were recorded with a Hitachi EPS-3 spectrometer.

Results and Discussion

Amino Acid in Unidentate Coordination. It is well known that an amino acid coordinates to a metal ion as a chelate ligand. In some particular complexes, however, the amimo acid acts as a unidentate ligand.[16-18] In the present study, the analytical values of the complexes (in Table 1) suggest that the amino acid in these complexes coordinates to the cobalt(III) ion as a unidentate ligand. Amino acid can coordinate to the cobalt(III) ion as a unidentate ligand in two ways; one is with the oxygen atom of the carboxylate group, and the other, with the nitrogen atom of the amino group. In the present case, the IR spectra suggest that the amino acid anions coordinate in the latter way. All the complexes with the general formula of K[Co(baen)(amino acid anion)$_2$] show the C-O stretching band of the free carboxylate group at about 1600 cm^{-1}, as is shown in Table 2. The carboxylate group of the amino acid anion coordinated to the cobalt(III) ion shows asym. ν_{COO-Co} band at about 1650 cm^{-1},[19] and the amino acid anions in these complexes obtained here seem to coordinate to the cobalt(III) ion, with their amino groups. Their absorption and CD spectra give further evidence for the cobalt(III)-nitrogen linkage in the complexes. The absorption and CD spectra of the K[Co(baen)-(amino acid anion)$_2$] complexes are very similar to

those of the [Co(baen)(amino acid ethyl ester)$_2$]ClO_4, in which the amino acid ethyl ester coordinated to the cobalt(III) ion, with its amino group.

An attempt to prepare a cobalt(III)-baen complex in which unidentate amino acid coordinates to the cobalt(III) ion with its carboxylate group was not successful. It is well known that the amino acid in a unidentate coordination generally prefers the formation of a bond to the cobalt(III) ion with its carboxylate group than one with its amino group.[20] Therefore, this unusual chemical property of the cobalt(III)-baen complex that the cobalt(III)-baen complex prefers the coordination-bond formation with an amino group of the amino acid anion, may be thought to be due to the anomalous chemical properties of the cobalt(III) complexes containing an unsaturated planar quadridentate ligand.

NMR Spectra of Complexes I, II, III, V, VI, VII, IX, X, XI, XII, XIII, XIV, XV, and XVI. The NMR spectral data of all the complexes are summarized in Tables 3 and 4, while some typical NMR spectra are shown in Fig. 1.

All the complexes except IV, VIII, and XVII show NMR spectral patterns with one C=CH and two CH_3 signals in a relative ratio of 1 : 3 : 3. Although there are three possible geometrical structures, *trans*-planar, *cis*-α, and *cis*-β, these spectral patterns clearly correspond to the *trans*-planar or *cis*-α structures. Since the cobalt(III)-baen complexes containing such unidentate ligands as ammonia, pyridine, and nitro group take the *trans*-planar structure,[12] we can safely assign the *trans*-planar structure to the complexes synthesized in this study.

NMR Spectra of Complexes IV, VIII, and XVII. The NMR spectra of the complexes IV, VIII, and XVII, however, show split patterns for the C=CH and two CH_3 signals of baen. The C=CH signal splits into three peaks with a relative intensities of 1 : 2 : 1, and, the two CH_3 signals, into a pair of three peaks with relative intensities of 3 : 6 : 3 respectively. Since these complexes were prepared by using D,L-racemic amino acid or amine as the starting materials, if the reaction between [Co(baen)$(H_2O)_2$] and the D,L-racemic ligand proceeded statistically it can be thought that Complexes IV, VIII, and XVII are obtained as a 1 : 2 : 1 mixture product of the following three species: [Co(baen)(L-form ligand)$_2$]$^{\pm n}$, [Co(baen)(L-form ligand)(D-form ligand)]$^{\pm n}$, and [Co(baen)(D-form ligand)$_2$]$^{\pm n}$. Complexes II and III, Complexes VI and VII, and Complexes XV and XVI show the same NMR spectra with one another, and the central peak of the C=CH signal and the two central peaks of two CH_3 signals of Complexes IV, VIII, of and XVII coincide with the corresponding peaks Complexes II, VI, and XV respectively. Therefore, we can assign these signals to those based on the [Co(baen)(L-form ligand)$_2$]$^{\pm n}$ and [Co(baen)(D-form ligand)$_2$]$^{\pm n}$ complexes. Thus, we can conclude that the split of two C=CH peaks and the split of four CH_3 peaks of Complexes IV, VIII, and XVII are based on the [Co(baen)(L-form ligand)(D-form ligand)]$^{\pm n}$ complex. The relative ratio between the central C=CH peak and the split of the two C=CH peaks of these complexes is estimated to be 1 : 1. Therefore, we can determine the relative ratio of the three species, [Co(baen)(L-form ligand)$_2$]$^{\pm n}$, [Co(baen)(L-form ligand)(D-form ligand)]$^{\pm n}$, and [Co(baen)(D-form ligand)$_2$]$^{\pm n}$, to be 1 : 2 : 1, which is in agreement with the above statistical considerations. The origin of the peak splitting is thought to be based on the asymmetric

nature of these complexes, as will be mentioned latter.

Exchange Reaction of the Apical Amino Acid Anions in Cobalt(III)-baen Complexes. The NMR spectra of 1 : 1 mixtures of Complexes II and III and of Complexes VI and VII are shown in Fig. 2, while their numerical values are tabulated in Tables 5 and 6. Both NMR spectra show peak splitting for C=CH and two CH_3 signals respectively, and the NMR spectra are the same as those of Complexes IV and VIII respectively. If there were no intermolecular interaction between the complexes, the NMR spectrum of the 1 : 1 mixture should be a superposition of the spectra of their original complexes. Therefore, some kind of intermolecular interaction is thought to occur in these complexes in water.

Since the split peaks of the C=CH and CH_3 signals are based on the [Co(baen)(L-form ligand)(D-form ligand)]$^{\pm n}$ complex, as mentioned above, we can interpret the NMR spectral behavior of the 1 : 1 mixtures of Complexes II and III and of Complexes VI and VIII by assuming that the following intermolecular exchange reaction of the apical amino acid anions occurs rapidly and that the corresponding three species exist as a 1 : 1 : 2 equilibrium mixture:

$$[\text{Co(baen)(L-from amino acid anion)}_2]^- + [\text{Co(baen)(D-form amino acid anion)}_2]^- \rightleftharpoons 2[\text{Co(baen)(L-form amino acid anion)-(D-form amino acid anion)}]^- \quad (1)$$

NMR Spectra of 1 : 1 Mixtures of the Complexes. In order to confirm the above assumption in detail, we measured the NMR spectra of 1 : 1 mixtures of the complexes. The NMR spectral data are summarized in Tables 5, 6, 7, and 8, while some representative NMR spectra are shown in Fig. 3.

The NMR spectra of the 1 : 1 mixtures of [Co(baen)$(A)_2]^-$ and[Co(baen)$(B)_2]^-$ complexes (where A and B indicate the apical amino acid anions) show peaks based on the two original complexes. Furthermore, when the optical forms of A and B are different, the peaks of the [Co(baen)(A)(B)]$^-$ complex also appear. Therefore, these experimental facts strongly support the above assumption. When the optical forms of A and B are identical, however, the peaks of the [Co(baen)(A)(B)]$^-$ complex can not be clearly distinguished except in the cases of the complexes containing the phenylalanine anion. In phenylalanine complexes, [Co(baen)-

(phenylalanine anion)(A)]$^-$, a large peak splitting resulting from the large magnetic anisotropy effect of a phenyl group is observed regardless of the optical form of A. Therefore, when the optical forms of A and B are identical, the formation of the [Co(baen)-(A)(B)]$^-$-type complexes can also be assumed.

Table 8. The NMR spectra of 1 : 1 mixtures (in δ, ppm)

Mixture of complexes	C=CH	CH_2-CH_2	CH_3(C=O)	CH_3(C=N)

NMR Spectra of the Mixtures of the Complexes and the Free Amino Acid Anion. If the exchange reaction of the apical amino acid anions occur rapidly and if all the possible products exist as equilibrium mixtures, we can expect that the following reactions between the complex and the free amino acid anion also occur rapidly, and that the corresponding products exist as equilibrium mixtures:

$$[Co(baen)(A)_2]^- + B^- \rightleftharpoons [Co(baen)(A)(B)]^- + A^- \quad (2)$$

$$[Co(baen)(A)(B)]^- + B^- \rightleftharpoons [Co(baen))B)_2]^- + A^- \quad (3)$$

We can confirm the above assumption by observing the peaks of the free amino acid anion A^-.

In order to confirm this again, we measured the NMR spectra of mixtures of the complex and the free amino acid anion. The NMR spectral data of 1 : 2 mixtures are listed in Tables 9 and 10, while some typical NMR spectra are shown in Fig. 4.

Through these measurements, we can clearly observe the peaks corresponding to A^-. The following facts are also observed. When the ratio between the complex and the free amino acid anion is kept at 1 : 2, the observed NMR spectra for these mixtures coincide with the corresponding NMR spectra of the 1 : 1 mixtures of the complexes, except for the additional peaks of the free amino acid anions. In these cases, the NMR spectra correspond to those of the possible species in the relative ratio of 1 : 2 : 1 : 4 : 4; [Co-

(baen)$(A)_2]^-$, $[Co(baen)(A)(B)]^-$, $[Co(baen)(B)_2]^-$, A^-, and B^-. When the ratio is kept at 1 : 20, the observed NMR spectra are the same as those of the complexes corresponding to $[Co(baen)(B)_2]^-$, except for the additional peaks of the free amino acid anions. These facts indicate that Reactions 1, 2, and 3 occur and that the corresponding equilibria are made up at the same time; the equilibrium constants in Reactions 1, 2, and 3 are all estimated to be about 1 for all the cases.

Peak Splitting and the Conformation of the Apical Amino Acid Anions. The fact that the NMR spectra of the complexes containing L-form amino acid anions are the same as those of the corresponding complexes containing D-form amino acid anions indicates that both complexes have the same symmetrical nature (C_2) and that both complexes have the same conformation for the apical ligand groups, although they are in the relation of an optical isomer. From the molecular-model test, it is found that the mobility of the apical ligand groups is somewhat restricted by the steric hindrance between the apical ligand groups and the coordinated baen. Although, in the cases of Complexes II, III, VI, VII, XV, and XVI, the symmetry of these complexes belongs to C_2, in the cases of Complexes IV, VIII, and XVII, in which both D- and L-form ligands are present, as the configurational effect of the optically-different forms of the apical ligands are not averaged because of the restriction of the mobility of the apical ligand groups, the symmetry of these complexes belongs to C_1. Perhaps this lowering of the symmetry from C_2 to C_1 may make

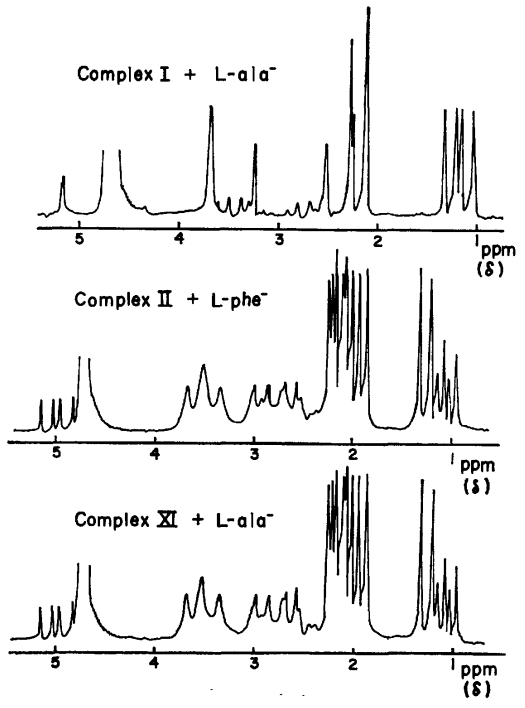

Fig. 4. The NMR spectra of 1 : 2 mixture of complex and potassium salt of amino acid in D_2O. The solution pH is adjusted to about 13 by adding NaOD solution. The compounds are referred to Table 1.

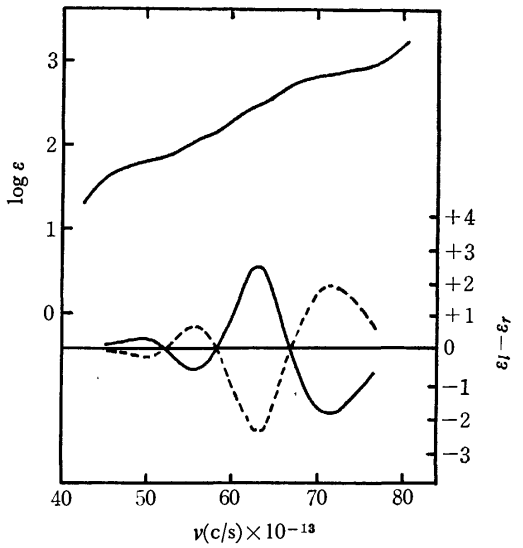

Fig. 5. The AB and CD spectra of K[Co(baen)(L-ala)$_2$] (——) and) K[Co(baen)(D-ala)$_2$] (----) in water.

the main contribution to the peak splitting for the NMR spectra of the complexes containing both D- and L-form ligands. The [Co(baen)(A)(B)]$^-$ complexes (where A and B have the same optical form) show no distinctive peak splitting in their NMR spectra, except when A or B is a phenylalanine anion. These facts indicate that the contribution of the conformation of the apical ligand groups for the peak splitting is bigger than that of the variation in the alkyl group of the amino acid groups. When the complexes contain phenylalanine and the other amino acid anions, because of the big magnetic shielding effect of the phenyl group, the peak splitting is observed in their complexes regardless of the optical forms of the apical ligands. For these complexes, the peak splitting is observed not only in the C=CH and CH_3 signals, but also in the CH_2-CH_2 signal.

On the other hand, when the complexes contain gylcine and β-alanine anions, there is no optically-active form in them. Therefore, no peak splitting is observed for the NMR spectra concerning those of glycine and β-alanine anions.

The data of complexes I, II, III, IV, V, VI, VII, VIII, IX, X, and XI are those in water.
The data of complexes XII, XIII, XIV, XV, XVI, and XVII are those in methanol.

CD Spectra of the Complexes. Some typical AB and CD spectra of the complexes are shown in Figs. 5 and 6, while their numerical data are listed in Tables 11 and 12.

The absorption and CD spectra of all the complexes are very complicated because of the π-π^* transition of the baen and charge-transfer transitions,[21-23] and so we can not make band assignemnts at this stage. However, since the CD spectra of the complexes containing L-form ligands are symmetric with those of the corresponding complexes containing D-form ligand, and since the two CD spectra differ only in their signs, by using this CD spectral behavior, we can obtain evidence for the rapid intermolecular exchange reaction of the apical amino acid groups. The CD spectra of mixtures of the complexes containing the L-alanine anion and the free D-alanine anion were measured. When the ratio between the L-alanine complex and the free D-alanine anion was kept at 1 : 1, the observed CD spectrum is that of one-half of the L-alanine complex only. When it was 1 : 2, no CD peaks were observed. When it was 1 : 20, the observed CD spectrum corresponded to that of the D-alanine complex only. These CD spectral changes are found to occur within a few sec. Therefore, it can be concluded that the exchange reactions are very rapid for the cobalt(III) complex, but it is sufficiently slow for all the species in the equilibrium condition to be distinguished separately in the NMR spectra.

These exchange reactions are observed in water, but not in dimethylformamide and dimethylsulfoxide;

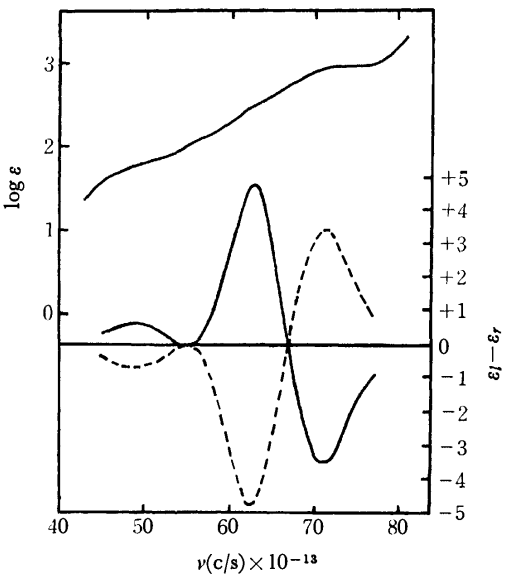

Fig. 6. The AB and CD spectra of K[Co(baen)(L-val)$_2$] (——) and K[Co(baen)(D-val)$_2$] (----) in water.

this is in agreement with the results of the polarographic study.[10] These exchange reactions are thought to be based on the unusual chemical properites of the cobalt(III) complexes containing an unsaturated planar quadridentate ligand.

The author wishes to express his deep thanks to Professor M. Shibata and Mr. K. Kawasaki of Kanazawa University and Professor M. Hatano of Tohoku University for their kind help in the CD spectral measurements. The author also wishes to express his deep thanks to Dr. M. Kodama of Ibaraki University for his encouragement.

The Kinetics of Electron-transfer Reactions between Oxalato-Cobalt(III) Complexes and Iron(II) in Acid Aqueous Solutions

Kousaburo Ohashi

Department of Chemistry, Ibaraki University, Mito

(Received February 18, 1972)

An investigation of the Fe^{2+} reductions of $Co(ox)(NH_3)_4^+$, $Co(ox)(en)_2^+$, $Co(ox)(trien)^+$, $Co(ox)(dip)_2^+$, $Co(ox)_2(en)^-$, and *cis*-$Co(ox)_2(NH_3)_2^-$ has been carried out spectrophotometrically. The rate constants of $Co(ox)N_4^+$-type complexes increase in this order: $Co(ox)(phen)_2^+ > Co(ox)(dip)_2^+ > Co(ox)(NH_3)_4^+ > Co(ox)(en)_2^+ > Co(ox)(trien)^+$, and these of $Co(ox)_2N_2^-$-type complexes, *cis*-$Co(ox)_2(NH_3)_2^- > Co(ox)_2(en)^-$. The variation in reactivity is mainly ascribed to a change in the enthalpy of activation. The rate constants of $Co(ox)(NH_3)_4^+$, $Co(ox)(en)_2^+$, *cis*-$Co(ox)_2(NH_3)_2^-$, and $Co(ox)_3^{3-}$ increase with the values of the half-wave potential of the polarographic reduction ($Co^{III} \rightarrow Co^{II}$) and with the decrease in the wave number of the maxima of the absorption spectra of the complexes.

The effect of a variation in the nonbridging ligand on the Fe^{2+} reductions of Co(III) complexes containing chloride, bromide, and azide ions as the bridging ligands has been investigated extensively[1-8] It has been demonstrated that the reactivities of *trans*-$CoN_3X(en)_2^{n+}$ ($X=H_2O$, Cl^-, N_3^-) with Fe^{2+} are affected by the free energy of activations required to stretch the *trans*-ligand of X away from the Co(III) center before electron-transfer occurs.[2]

Link found that a change in the nonbridging ligands has the same effect on the reaction of *cis*- and *trans*-$CoClY(en)_2^{2+}$ ($X=H_2O$, NH_3) with Fe^{2+} as it does on the reactions with *cis*- and *trans*-$CoBrY(en)_2^{2+}$.[8]

Recently, the kinetics of the Fe^{2+} reductions of *trans*-(O,Cl)-CoCl(am)(dien)$^+$ (am=amino acid ion and dien=diethylenetriamine) and *trans*(N)-$Co(am)_2(ox)^-$ (ox=oxalate ion) were studied. The effect of amino acids as the nonbridging ligands on the reduction rate of the former is not essentially different from that observed in the reductions of the latter.

In this connection the kinetics of the Fe^{2+} reductions of *cis*-$Co(ox)_2(NH_3)_2^-$, $Co(ox)_2(en)^-$, $Co(ox)(NH_3)_4^+$, $Co(ox)(en)_2^+$, $Co(ox)(trien)^+$, $Co(ox)(dip)_2^+$, and $Co(ox)(phen)_2^+$, (trien=triethylenetetramine, dip=2,2′-dipyridyl, phen=1,10-phenanthroline) were studied. The correlation between the reactivity and the activation parameters, and also the half-wave potential of the polarographic reduction ($Co^{III} \rightarrow Co^{II}$) will be reported here. The effect of an unsaturated nonbridging ligand, such as 2,2′-dipyridyl or 1,10-phenanthroline, on the Fe^{2+} reduction rate of Co(III) complexes will also be discussed.

Experimental

Preparations of Co(III) Complexes. $[Co(ox)NH_3)_4]Cl$,[9] $[Co(ox)(en)_2]Cl \cdot H_2O$,[10] $[Co(ox)(trien)]Cl$,[11] $NH_4[Co(ox)_2(NH_3)_2]H_2O$,[12] $Na[Co(ox)_2(en)]$,[13] and $[Co(ox)(phen)_2]Cl \cdot 4H_2O$ were prepared by methods similar to those described in the references cited. Found: C, 9.11; H, 4.62; N, 21.94%; Calcd for $[Co(ox)(NH_3)_4]Cl$: C, 9.58; H, 4.83; N, 22.36%. Found: C, 22.55; H, 5.65; N, 16.92%; Calcd for $[Co(ox)(en)_2]Cl \cdot H_2O$: C, 22.47; H, 5.65; N, 17.47%. Found: C, 28.18; H, 5.99; N, 16.55%; Calcd for $[Co(ox)(trein)]Cl$: C, 28.89; H, 5.47; N, 16.85%. Found: C, 15.69; H, 4.01; N, 13.20%; Calcd for $NH_4[Co(ox)_2(NH_3)_2] \cdot H_2O$: C, 15.75; H, 3.97; N, 13.78%. Found: C, 22.44 H, 2.31; N, 8.79%: Calcd for $Na[Co(ox)_2(en)]$: C, 22.66; H, 2.54; N, 8.81%. Found: C, 50.84; H, 3.72; N, 9.42%: Calcd for $[Co(ox)(phen)_2]Cl \cdot 4H_2O$: C, 50.80: H, 3.90; N, 9.10%.

Preparation of $[Co(ox)(dip)_2]ClO_4$.[15] To a hot water solution (100 *ml*) containing 2.1 g of *cis*-$[CoCl_2(dip)_2]Cl$, we added 2.0 g of sodium oxalate dissolved in 50 *ml* of hot water; the mixture was then heated on a water bath (60~70°C) for 30 min. The solution was filtered, and the sodium perchlorate was added to the filtrate. The orange crystals which precipitated were filtered. The crude complex was recrystallized from hot 5 N sulfuric acid by the addition of sodium perchlorate. Found: C, 47.93; H, 2.78; N, 10.08%: Calcd for $[Co(ox)(dip)_2]ClO_4$: C, 47.29; H, 2.89; N, 10.21%.

Materials. The preparation of the iron(II) solution and the determinations of the iron(II), the sulfate ion, and the hydrogen ion were carried out by a method similar to that described in a previous paper.[3] The concentration of the sulfate ions of all the reaction mixtures except for *cis*-$Co(ox)_2(NH_3)_2^-$ and $Co(ox)_2(en)^-$ was adjusted to 1.5 M by the addition of sulfuric acid. The reductions of *cis*-$Co(ox_2)(NH_3)_2^-$ and $Co(ox)_2(en)^-$ were carried out in perchloric acid media. All the other reagents used for the preparation of the stock solutions were of a guaranteed reagent quality.

Kinetic Measurements. The cobalt(III) and the iron(II) solutions, both of which contained the necessary amount of sulfuric acid, were kept in a thermostat. The desired volume of the iron(II) solution was added to the cobalt(III) solution. The solution was then transferred into a 1-cm cell compartment of a Hitachi Model EPS-3 type recording

c) Wavelength for the first absorption maxima. d) Wavelength for the second absorption maxima.

spectrophotometer.[16] The absorbance at the wavelengths corresponding to the first absorption maxima for the complexes was measured automatically. All the kinetic experiments except for that of $Co(ox)(dip)_2^+$ were run under pseudo-first order conditions with respect to $[Fe^{2+}]$. For $Co(ox)(dip)_2^+$, the rate constants were obtained under second-order conditions. The second-order rate constants were obtained by the usual method.

Results

Reductions of Co(III) Complexes. The reduction rates of all the Co(III) complexes except for *cis*-$Co(ox)_2(NH_3)_2^-$ and $Co(ox)_2(en)^-$ were first-order with respect to both the Fe^{2+} and Co(III) concentrations. Therefore, the rate equation may be represented as follows: $-d[Co(III)]/dt=k[Co(III)]\,[Fe^{2+}]$. The rate constants and the activation parameters are summarized in Table 1.

As may be seen from the kinetic data of $Co(ox)_2(en)^-$ listed in Table 2, the second-order constants increase slightly with the Fe^{2+} concentration under the conditions of constant perchlorate-ion and hydrogen-ion concentrations. Similar results were obtained in the reaction of *cis*-$Co(ox)_2(NH_3)_2^-$. The ionic strength increases with the Fe^{2+} concentration, though the perchlorate-ion concentration remains constant (Table 2). The increase in the ionic strength must be one of the reasons for the increase in the second-order rate constant with the Fe^{2+} concentration. No further experiments were carried out in order to investigate the effect of the Fe^{2+} concentration on the reduction rate.

Table 2. The kinetic data for the Fe^{2+} reductions of $Coox_2(en)^-$ under the conditions of $[H^+]=0.50$ M, 25±0.1°C and $\Sigma[ClO_4^-]=2.0$ M.[a]

Fe(II), M	Ionic-strength	Rate constant, M^{-1} sec^{-1}
0.136	2.14	3.60×10^{-3}
0.271	2.27	4.08×10^{-3}
0.407	2.41	4.58×10^{-3}
0.541	2.54	4.83×10^{-3}
0.679	2.69	5.50×10^{-3}

a) The perchlorate ion concentration was adjusted by the addition of lithium perchlorate.

16) A 10-cm cell was used for the reaction of $Co(ox)(phen)_2^+$, because the solubility of this complex into sulfuric acid is small.

The activation parameters for *cis*-$Co(ox)_2(NH_3)_2^-$ and $Co(ox)_2(en)^-$ were obtained from the temperature dependence of the rates, which were obtained under the conditions of a constant Fe^{2+} concentration (Table 1).

Discussion

An oxalate-bridged mechanism was demonstrated for the Fe^{2+} reductions of $Co(ox)_3^{3-}$ and $Coox(H_2O)(NH_3)_3^{+}$[17] by observing the spectrum of the Fe(III) product and by determining its rate of formation. Therefore, the present author thinks that all the reactions occur *via* similar mechanisms.

The relative reactivity for the Fe^{2+} reductions of $Co(ox)(NH_3)_4^+$ and *cis*-$Co(ox)_2(NH_3)_2^-$ decreased upon the replacement of the ammonia molecules with ethylenediamine and triethylenetetramine molecules (Table 1). A similar chelate effect was also observed in Fe^{2+} reductions of $CoCl_2N_4^+$ and $CoCl(H_2O)N_4^{2+}$ (N=$(NH_3)_4$, $(en)_2$ and trien).[3] It was demonstrated that the reactivity of chloro-cobalt(III) with Fe^{2+} is affected by the effects of a) and b) : a) the ligand-field strength of the *trans*-ligand,[1,18,19] and b) the energy required to stretch the *trans*-ligand away from the Co(III) center. The rate constants of $Co(ox)N_4^+$-type complexes (N=saturated ligand) increase with a decrease in the wavenumber of the first absorption band of the complexes.

It is of interest to note here that the reactivities of $Co(ox)N_4^+$-type complexes (N=$(NH_3)_4$, $(en)_2$, trien, $(dip)_2$, $(phen)_2$) and $Co(ox)_2N_2^-$-type complexes (N=$(NH_3)_2$, and (en)) decreases remarkably with an increase in the enthalpy of activation, and that there is a certain degree of compensation effect between $\Delta H^{\neq}$ and $T\Delta S^{\neq}$ for the Fe^{2+} reductions of these complexes (Table 1). Figure 1 shows the good linearity between the logarithm of the rate constant and the enthalpy of activation of $Co(ox)N_4^+$-type complexes. This illustrates that the variation in reactivity is mainly due to the change in the enthalpy of activation.

The reactivity of $Co(ox)(dip)_2^+$ and $Co(ox)(phen)_2^+$ is

very much larger than that of $Co(ox)(en)_2^+$. The larger reactivity of the former must result from the following factors: a) the efficiency of the mediators for the electron-transfer increases by the coordination of 2,2'-dipyridyl and 1,10-phenanthroline to the Co(III) ion, b) the oxidation-reduction potentials of $Co(ox)(dip)_2^+$, and $Co(ox)(phen)_2^+$ are very different from that of $Co(ox)(en)_2^+$, and c) the free energy of activation required to remove 2,2'-dipyridyl and 1,10-phenanthroline from the Co(III) center is smaller than that of ethylenediamine. However, no further, more detailed discussion could be made on the basis of the present limited kinetic data.

The rate constants of $Co(ox)_{3-n}(NH_3)_{2n}^{(3-2n)+}$ (n= 0, 1, 2) shown in Table 3 increase with the number of oxatate ion coordinated to Co(III). It is also of interest that the reactivity of $Co(ox)_{3-n}(NH_3)_2^{(3-2n)+}$ with Fe^{2+} increases with the decrease in the wavenumber of the first absorption band of the complexes.

It can be seen from Table 3 that the reactivities of $Co(ox)(NH_3)_4^+$, $Co(ox)(en)_2^+$, *cis*-$Co(ox)_2(NH_3)_2^-$, and $Co(ox)_3^{3-}$ with Fe^{2+} increases with the values of the half-wave potential of the polarographic reduction ($Co^{III}\rightarrow Co^{II}$). It has already been demonstrated that there is a relation between the half-wave potentials of polarographic reduction waves and the wavenumbers of the maxima of the absorption spectra of Co(III)-oxalato complexes.[20] The relation between the values of the half-wave potential and the logarithm of the rate constants is shown in Fig. 2. This linear behavior suggests that the reduction potential ($Co^{III}\rightarrow Co^{II}$) affects the reactivity of complexes with Fe^{2+}. No attempt was made to explain quantitatively the relation between the reactivity of complexes and the half-wave potential because of the present lack of much kinetic data.

The author wishes to thank Professor Katsumi Yamamoto and Professor Yoshimi Kurimura for their helpful advice and encouragement.

A Kinetic Study of the Monomer-dimer Reaction in Propionic Acid by Means of Ultrasonic Absorption Measurements

Nobuhide TATSUMOTO, Takayuki SANO, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September 16, 1971)

Second ultrasonic absorptions with relaxation frequencies of 26, 36, 53, and 70 MHz could be observed in 0.27, 0.47, 1.0, and 2.0 M cyclohexane solutions respectively of propionic acid at 20°C. The consideration of the variations in the sound absorption, the sound velocity, and the chemical shift with the concentration leads us to the conclusion that the relaxation is attributable to the perturbation of the equilibrium between the open dimer and the monomer of propionic acid. The backward rate constant in this reaction is estimated to be about 10^9 sec^{-1} M^{-1}.

The present authors[1,2] have previously reported that the cyclic and open dimers of propionic acid in several solvents are formed by an intermoleuclar hydrogen bond between carboxylic groups over the concentration range from 4 to 13.4 M(100%). In other ultrasonic studies[3] it has been discussed how the mechanism is associated with the equilibrium between the cyclic dimer and monomer. On the other hand, it has been reported by investigations of NMR,[4] the dielectric constant, and the sound velocity[5] that the monomer is scarcely detected at all in 100% carboxylic acid, but is detected in dilute solutions. The purpose of this paper is to study the kinetics of the reaction system containing the monomer. The ultrasonic absorption was measured in cyclohexane solutions of propionic acid over the concentration range from 0.27 to 13.4 M.

Experimental

The measurement of the ultrasonic absorption in a cyclohexane solution of propionic acid was made over the frequency range from 2.5 to 95 MHz at 20°C by the pulse method, while the sound velocity was measured at 3.00 MHz 20°C by using an ultrasonic interferometer. The chemical shift of the carboxylic proton in propionic acid was measured relative to protons in tetramethylsilane at 34°C. The propionic acid and cyclohexane were of a guaranteed grade. The propionic acid was purified once by fractional distillation at reduced pressure, while the cyclohexane was used without further purification.

Results

The ultrasonic absorptions in 3.9, 7.0, 10.1, and 13.4 M solutions are expressed by the equation for a single relaxation in the experimental frequency range, and the relaxation frequencies are 1.8, 2.4, 3.3, and 4.5 MHz respectively, as can be seen in Fig. 1a. On the other hand, in the 0.27, 0.47, 1.0, and 2.0 M solutions the absorptions are expressed by the equation for a double relaxation, in which the higher relaxation frequencies are 26, 36, 53, and 79 MHz respectively, as can be seen in Fig. 1b. These relaxations are represented by Eqs. (1) and (2):

tively, and f_{m_1} and f_{m_2} are the first and second relaxation frequencies respectively. The variation in the relaxation frequency with the concentration of propionic acid is shown in Fig. 2.

The variation in the sound velocity with the conecntration is expressed in the next equation for an ideal solution[6]:

$$V = \{V_1 p + V_2(100-p)\}/100, \quad (3)$$

where V is the sound velocity of the solution, V_1 and V_2 are those in the solute and the solvent respectively, and p is weight percentage of the solute. The experimental values of the sound velocity, as plotted against p in Fig. 3, however, deviate from the straight line. In Fig. 4, the values of $\Delta V/p$ are plotted against the molarity, where ΔV represents the deviation from the straight line in Fig. 3; the dependence of the proton shift on the concentration is also shown in Fig. 4.

Discussion

The first relaxation frequencies in the concentration range from 0.27 to 2.0 M, as estimated roughly from the absorption data in the frequency range from 5.5 to 15 MHz, are less than 10 MHz. The mechanism of the first relaxation in the dilute solutions, therefore, seems to be the same as that in the concentration range from 4 to 13.5 M, the mechanism of which is due to the perturbation of the equilibrium between cyclic and open dimers of propionic acid.[2] On the other hand, the second relaxation mechanism can be assigned to the perturbation of the equilibrium which might exist in the dilute solutions, provided the relaxation is chemical.

This behavior, the fact that $\Delta V/p$ decreases gradually first and then rapidly below 1 M with a decrease in the concentration, indicates the existence of a monomer in the dilute solution of propionic acid, because the decrease in the molecular weight is one of the factors lowering the sound velocity. The absorption in NMR, moreover, shifts to a lower magnetic field at first, and then to a higher field below 0.7 M, with a decrease in the concentration. This indicates that two equilibria exist between cyclic and open dimers and the polymer in a concentrated solution of propionic acid[4] and that the proportion of the number of cyclic dimers to that of open dimers or polymers increases with a

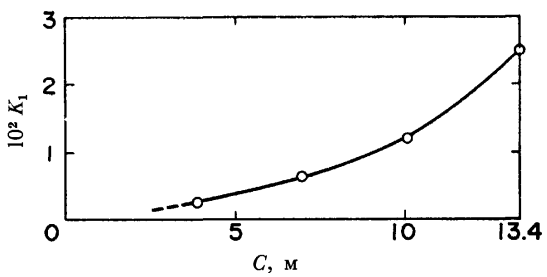

Fig. 5. Variation of equilibrium constant for the reaction between cyclic dimer and open dimer with concentration of propionic acid in cyclohexane at 20°C.

decrease in the concentration. This can also be understood by the change in the equilibrium constant for the reaction between open and cyclic dimers, as calculated from ultrasonic and other data,[2] with the concentration as shown in Fig. 5. That is, the decrease in the equilibrium constant means a relative decrease in the number of the open dimer. Below 0.7 M, the number of the hydrogen bond decreases rapidly, that is, the monomer becomes predominant in the solution. Hence, over the concentration range from 0.27 to 2 M there exist two equilibria between cyclic and open dimers and the monomer:

$$\text{cyclic dimer} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{open dimer} \underset{k_4}{\overset{k_3}{\rightleftarrows}} \text{monomer}$$

$$\bar{C}_c \qquad\qquad \bar{C}_o \qquad\qquad \bar{C}_M$$

where k_1, k_2, k_3, and k_4 are the forward and backward rate constants for the reactions between the cyclic and open dimers and between the open dimer and the monomer, and where $\bar{C}_C$, $\bar{C}_O$, and $\bar{C}_M$ are the equilibrium concentrations of cyclic and open dimers and the monomer respectively. The above considerations lead us to the conclusion that the second relaxation is due to the perturbation of the equilibrium between the open dimer and the monomer.

Davies *et al.*[7] have obtained the equilibrium constant between the monomer and the dimer of propionic acid in light petroleum, carbon tetrachloride, and benzene below 1 M by the measurement of the distribution, although they have not separated the open dimer from the cyclic dimer. In this case, the expression of the equilibrium constant is as follows:

$$K = \frac{[\text{monomer}]^2}{[\text{dimer}]} = \frac{(\bar{C}_M)^2}{\bar{C}_c + \bar{C}_o}. \tag{4}$$

From the literature values,[7] the value of K would be expected to be about 10^{-2} M in cyclohexane. On the other hand, the equilibrium constant between open and cyclic dimers is given by:

$$K_1 = \frac{k_1}{k_2} = \frac{\bar{C}_o}{\bar{C}_c}. \tag{5}$$

Equation (4) can, then, be rewritten as in the following equation:

$$K = \frac{(\bar{C}_M)^2}{\bar{C}_c(1+K_1)}. \tag{6}$$

The rough extrapolation of the previous data[2] of K_1 to 1 M gives about 10^{-3}; then:

$$K = \frac{(\bar{C}_M)^2}{\bar{C}_c}. \tag{7}$$

The total concentration of the acid in the monomer unit is expressed as:

$$C = 2\bar{C}_c + 2\bar{C}_o + \bar{C}_M, \tag{8}$$

and Eq. (8) is rewritten as Eq. (9) when K and K_1 are much smaller than unity:

$$C \simeq 2\bar{C}_c, \tag{9}$$

and K_1 is given by:

$$K_1 = \frac{2\bar{C}_o}{C}. \tag{10}$$

The values of $\bar{C}_M$ and $\bar{C}_O$ at C=0.27—2 M are listed in Table 1.

TABLE 1. THE EQUILIBRIUM CONCENTRATIONS OF MONOMER AND OPEN DIMER

C, M	2	1	0.49	0.27
$\bar{C}_M$, 10^{-2} M	10	7.1	5.0	3.7
$\bar{C}_o$, 10^{-4} M	10	5.0	2.5	1.4

The second relaxation frequency is given by:

$$2\pi f_{m_2} = 1/\tau_2 = 4k_4\bar{C}_M - k_2, \tag{11}$$

for $k_1 \ll (k_2 \text{ and } k_3) \ll 4k_4\bar{C}_M$,

and $$2\pi f_{m_2} = 1/\tau_2 = k_2 + k_3, \tag{12}$$

for $4k_4\bar{C}_M \ll k_1 \ll k_2$ and k_3, where τ_2 is the second relaxation time. The variation in $1/\tau_2$ with $\bar{C}_M$ is described in Fig. 6 (see Appendix). The variation in $1/\tau_2$ with $\bar{C}_M$ in this experiment is shown in Fig. 7,

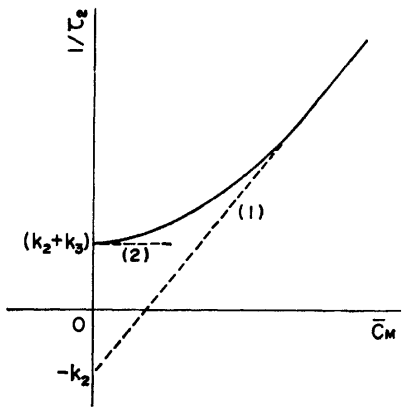

Fig. 6. Theoretical curve of variation of $1/\tau_2$ with equilibrium concentration of monomer, (1) according to Eq. 11; (2) to Eq, 12.

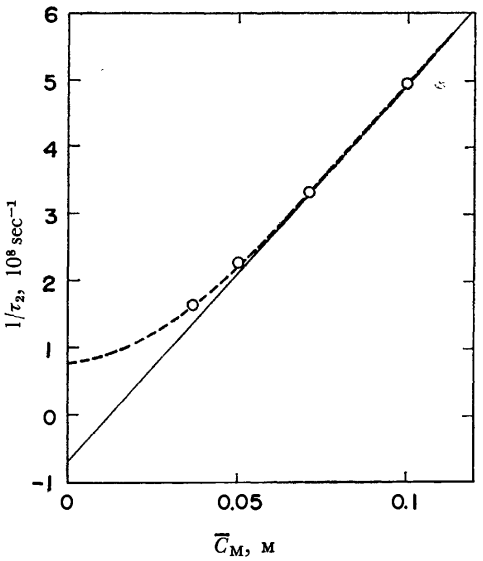

Fig. 7. Variation of $1/\tau_2$ with equilibrium concentration of monomer at 20°C.

○: $H_{21}^{\neq}$; ◑: H_{12}; ◐: k_1; ●: k_2

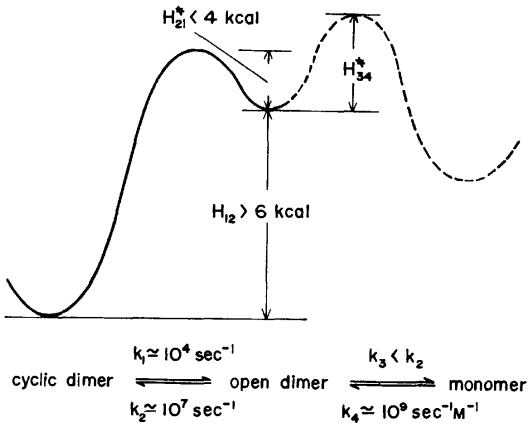

Fig. 9. Energy diagram for propionic acid in cyclohexane in the concentration range of 0.27 to 2 M at 20°C.

and an intercept of the tangent to the curve gives a value of k_2 which is about 7×10^7 sec^{-1}. This is in fair agreement with the value, 10^7 sec^{-1}, estimated approximately from the previous experimental values,[2] which are plotted against the concentration in Fig. 8. If the value of $1/\tau_2$ changes with the concentration, as in Fig. 7, k_2+k_3 can be estimated by the extrapolation of the curve to the intercept. The value of k_2+k_3 is nearly equal to that of k_2; therefore, k_3 is less than k_2. The value of k_4, moreover, is determined to be approximately 10^9 sec^{-1}M^{-1} by the slope of the curve. In order to illustrate the approximate energy diagram for propionic acid in the concentration range from 0.27 to 2.0 M, the values of the activation enthalpy of the backward reaction, $H_{21}^{\neq}$, and the enthalpy change of the reaction, H_{12}, in the reaction between the cyclic dimer and the open dimer, were estimated, along with those of k_1 and k_2, by the extrapolation of the curved $H_{21}^{\neq}$, H_{12}, k_1, and k_2 *vs.* C plots (Fig. 8) to approximately 1 M; the estimated values are listed in Table 2. The comparison between the magnitude of the equilibrium concentrations of the monomer and the open dimer informs us that the monomer is probably more stable than the open dimer. The fact that the activation enthalpy of the forward reaction between the open dimer and the monomer, $H_{34}^{\neq}$, is greater than $H_{21}^{\neq}$ is revealed by taking account of the magnitude of the corresponding rate constant. The energy diagram, consequently, may be described as in Fig. 9. More

Table 2. The kinetic parameters for the first reaction at $C\simeq1$ M and at 20°C

detailed kinetic values of the reaction between the open dimer and the monomer can be determined by the change in the ultrasonic absorption with the temperature, but the relaxation strength is too small to determine f_{m_2} and $(\alpha\lambda)_{m_2}$ with accuracy, where λ is the wavelength of sound.

In liquid acetic acid and solutions of acetic acid, a second relaxation similar to that in the solution of propionic acid has been observed,[8] and the perturbation of the equilibrium between the open dimer and the monomer has been proposed as one of the mechanisms. There is no direct evidence for the existence of monomeric acid in liquid acetic acid, but the fact that the second relaxation could be detected in these monocarboxylic acids is very interesting. Finally, it can be expected that the second relaxation will be observed in other monocarboxylic acids and that the mechanism can be assigned more precisely and in more detail in the near future.

Appendix

Variation in $1/\tau_2$ with the Equilibrium Concentration. In the case of the coupled mechanism, the reciprocal relaxation times, $1/\tau_i$, are the eigenvalues, λ_{ii}, of the characteristic equation, which, in the determinant form, reads:

$$\begin{vmatrix} (k_1-\lambda) & -k_2 & 0 \\ -k_1 & (k_2+k_3-\lambda) & -4k_4\bar{C}_M \\ 0 & -k_3 & (4k_4\bar{C}_M-\lambda) \end{vmatrix} = 0 \qquad \text{(A1)}$$

The relaxation times then reduce to:

$$\text{I)}\quad \lambda_1 = 1/\tau_1 = 2\pi f_{m_1} = k_1 + k_2 \simeq k_2, \qquad \text{(A2)}$$

and:

$$\lambda_2 = 1/\tau_2 = 2\pi f_{m_2} = 4k_4\bar{C}_M - (k_2+k_1) \simeq 4k_4\bar{C}_M - k_2, \qquad \text{(A3)}$$

for $k_1 \ll (k_2 \text{ and } k_3) \ll 4k_4\bar{C}_M$ (here, if $k_4/k_2 \leqq 10^3$, $\bar{C}_M$ is relatively large), and to

$$\text{II)}\quad \lambda_1 = 1/\tau_1 = 2\pi f_{m_1} \simeq \frac{k_1k_3}{k_2+k_3}, \qquad \text{(A4)}$$

and:

$$\lambda_2 = 1/\tau_2 = 2\pi f_{m_2} = k_2 + k_3, \qquad \text{(A5)}$$

for $4k_4\bar{C}_M \ll k_1 \ll k_2$ and k_3 (here, if $k_4 \gg k_1$, $\bar{C}_M$ is very small). This consideration holds only in the extremely high or low concentration ranges of $\bar{C}_M$. One, accordingly, should examine whether or not the function, $\lambda_2(\bar{C}_M)$, is represented by a continuous and monotonous increase in the middle concentration range. From Eq. (A1), $\bar{C}_M$ is given by:

$$\bar{C}_M = \frac{\lambda_2{}^2 - (k_1+k_2+k_3)\lambda_2 + k_1k_3}{4k_4\{\lambda_2-(k_1+k_2)\}}, \qquad \text{(A6)}$$

8) J. E. Piercy and J. Lamb, *Trans. Faraday Soc.*, **52**, 930 (1956), F. Bader and K. G. Plass, *Ber. Bunsenges. Physik. Chem.*, **75**, 553 (1971).

where $\lambda_2 \neq k_1+k_2$.

1) The derivative of $\overline{C}_M$ with respect to λ_2 is:

$$\frac{\partial \overline{C}_M}{\partial \lambda_2} = \frac{1}{4k_4} \cdot \frac{\{\lambda_2^2 - 2\lambda_2(k_1+k_2) + (k_1+k_2)(k_1+k_2+k_3) - k_1k_3\}}{(\lambda_2-k_1-k_2)^2}. \tag{A7}$$

A discriminant for a numerator in Eq. (A7) is negative, so that the tangent of a plot of $\partial \overline{C}_M/\partial \lambda_2$ *vs.* λ_2 is always positive.

2) The second derivative of $\overline{C}_M$ with respect to λ_2 is:

$$\frac{\partial^2 \overline{C}_M}{\partial \lambda_2^2} = \frac{-1}{2k_4} \cdot \frac{k_2k_3}{(\lambda_2-k_1-k_2)^3}. \tag{A8}$$

Considerable simplification is possible for two conditions:

i) $$\frac{\partial^2 \overline{C}_M}{\partial \lambda_2^2} < 0, \quad \text{for} \quad \lambda_2 > k_1 + k_2, \tag{A9}$$

and:

ii) $$\frac{\partial^2 \overline{C}_M}{\partial \lambda_2^2} > 0, \quad \text{for} \quad \lambda_2 < k_1 + k_2. \tag{A10}$$

From the definitions of τ_1 and τ_2, $f_{m_1} < f_{m_2}$, and hence $\lambda_2 > k_1+k_2$. Consequently, the $\overline{C}_M(\lambda_2)$ function can be represented by a continuous and monotounous increase, as is shown in Fig. 10.

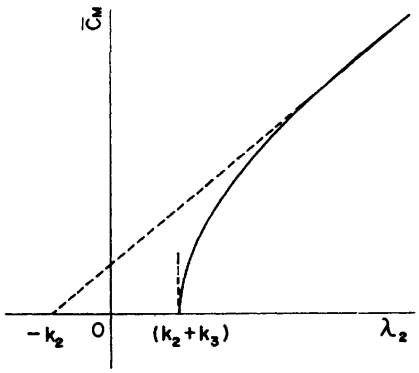

Fig. 10. Theoretical curve of variation of $\overline{C}_M$ with λ_2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3100—3104 (1972)

Stereoselectivity in Mixed Tris-type Complexes of Cobalt(III) with Glycine and L-Glutamic Acid[1]

Kiyoshi KAWASAKI and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received February 19, 1972)

The following ten complexes have been isolated from a reaction mixture of the $[CoCO_3(gly)_2]^-$ ion and L-glutamate in the presence of active charcoal: *mer*-[Co(gly)$_2$L-glutH] (two isomers), *mer*-Cogly(L-glutH)$_2$], *mer*-*Λ*-[Co(L-glutH)$_3$], *fac*-*Λ* and *Δ*-[Co(gly)$_2$(L-glutH], *fac*-*Λ* and *Δ*-[Cogly(L-glutH)$_2$], and *fac*-*Λ* and *Δ*-[Co(L-glutH)$_3$]. These complexes have been characterized by various spectral data. The *Δ*/*Λ* ratios in the *fac* isomers have been estimated to be ca. 60/40, 68/32, and 75/25 for the bis(glycinato), bis(L-glutamato) and tris(L-glutamato) complexes respectively, while no appreciable stereoselectivity has been found in the corresponding *mer* isomers.

Several works on the stereoselectivity in mixed-ligand complexes of cobalt(III) containing L-aspartic acid as a ligand have been made in our laboratory; the complexes studied were of the tris(glycinato-L-aspartato),[2] tris(L-or D-alaninato-L-aspartato),[3] tris-(l-propylenediamine-L-aspartato)[4] and tris(ethylene-diamine-L-aspartato)[5] series. Through these works, it has been found that the stereoselectivity observed can be explained in terms of the favorable interaction of the dangling *β*-carboxylate group in the chelated L-aspartate ion with the amino group in the adjacent chelated ligand.

In the present work, L-glutamic acid (L-glutH_2), with a *γ*-carboxyl group, was taken in order to make a comparison with previous works. That is, a series of tris(glycinato-L-glutamato) complexes, $[Co(gly)_{3-n}(L\text{-glut})_n]^{n-}$ ($n=1, 2, 3$), have been prepared and their diastereoisomers have been isolated. On the basis of the absorption, the circular dichroism, and the proton magnetic resonance spectral data, the isolated isomers have been characterized; then the degree of the stereoselectivity has been evaluated on the basis of the spectral data of the characterized isomers.

By the way, Gillard et al. have recently reported a more detailed study[6] than the previous one[7] on the reaction of L-glutamic acid with the $[CoCO_3(en)_2]^+$ ion.

described in the previous work[2]; potassium carbonatobis(glycinato)cobaltate(III) (6.4 g, 0.02 mol) was used as the starting material. The L-glutamic acid (5.9 g, 0.04 mol) and sodium hydroxide (1.6 g, 0.04 mol) used were of a reagent grade. Dowex 1-X8 resin in the chloride form was used for the chromatographic separation, and an aqueous solution of calcium chloride (0.05 M) was used as the eluting solution.

When chromatographed on a column of the resin, the reaction mixture finally gave six bands colored alternatively violet and red. These bands were separately collected in fractions labelled from E-1 to E-6 according to the elution order. By careful elution, the first band was further separated into two bands, which were then collected in fractions labelled Nos. 1 and 2. Each fraction, stored up to a certain amount, was concentrated under reduced pressure; ethanol was then added to the concentrate to precipitate the desired complex as its calcium salt. This crude salt was dissolved in a minimum amount of water, and then the solution was acidified with 6 *N* hydrochloric acid in order to convert the calcium salt into the less soluble hydrogen compound. From each fraction corresponding to the red bands (E-2, E-4, E-6), a pair of diastereoisomers (Δ and Λ) was obtained by means of the solubility difference. As for the other fractions, those corresponding to the violet bands (E-1, E-3, E-5), only the E-5 fraction gave one isomer of the diastereomeric pair in the course of crystallization, while the other fractions gave mixtures of the diastereoisomers. The compounds were purified by dissolving them in slightly alkalined water and by then acidifying the solutions with diluted hydrochloric acid. However, one isomer of the pair in E-4 was purified from a large amount of hot water, because it was sparingly soluble in water. For all of the optically-pure compounds, the purification procedure was repeated until the main CD peak of the compound showed a constant intensity ($\Delta\varepsilon$ value).

The results of the elemental analyses of the isolated compounds will be shown below (Table 1).

Formation Ratios. A similar but smaller-scale reaction was carried out; the starting complex (1.71 g, 0.005 mol), L-glutamic acid (1.47 g, 0.01 mol), sodium hydroxide (0.40 g, 0.01 mol), and active charcoal (0.5 g) were used. The temperature in the reaction was kept at *ca.* 60°C, but the reaction time was varied—0.5, 1 and 3 hr. Each reaction mixture, under different conditions, was chromatographed on a small column in a way similar to that described above. From the spectral data of the fractions, the percent compositions among the six bands were evaluated. Moreover, the percent compositions of the Δ isomers in the red bands were calculated on the basis of the spectral data of the isolated diastereomers.

Similar experiments were also carried out with the reaction times of 2 and 5 hr without sodium hydroxide.

Measurements. The absorption spectra were measured with a Hitachi Perkin-Elmer Model 139 UV-VIS spectrophotometer. The circular dichroism spectra were recorded on a JASCO Model ORD/UV-5 spectropolarimeter. The proton magnetic resonance spectra were all measured in deuterium oxide containing an equivalent Na_2CO_3, with a JEOL Model C-60H spectrometer using sodium 3-(trimethylsilyl)-1-propanesulfonate as the internal reference.

Results and Discussion

Characterization of the Isomers. It was apparent, from the absorption spectra and the elution order, that both types of bands, those colored violet and those colored red, consisted of *mer* and *fac* isomers in the *tris*(glycinato-L-glutamato) series, $[Co(gly)_{3-n}(L\text{-glut})_n]^{n-}$ $(n=1, 2, 3)$; A total of ten compounds were crystallized from the fraction. The six compounds obtained from the E-2, E-4, and E-6 fractions were pairs of diastereoisomers of the *fac* complexes. The compound obtained from E-5 was the Λ isomer of *mer*-$[Co(L\text{-glut})_3]^{3-}$, while the corresponding Δ isomer was not isolated, although the existence of the species

had been evidenced by the CD spectral change in the process of crystallization. The compound obtained from the No. 1 fraction of E-1 was a mixture of the *Λ* and *Δ* isomers of the *mer*-$[Co(gly)_2L\text{-glut}]^-$ complex, while the compound obtained from No. 2 was the *Λ* isomer contaminated with a small amount of the *Δ* isomer. The compound obtained from the E-3 fraction was also a mixture of the paired isomers of *mer*-$[Cogly(L\text{-glut})_2]^{2-}$. The results of the elemental analyses and the absorption spectral data in 60% perchloric acid are summarized in Table 1.

Structure of mer *Isomers.* In general, the *mer* form of a tris-chelated complex with two kinds of α-aminoacidates has three possible geometrical isomers concerned with the arrangement of two identical ligands (Fig. 1). In the previous works, at least two isomers have been found to exist in the *mer*-$[Cogly(L\text{-asp})_2]^{2-}$[2] amd *mer*-$[CoL\text{-ala}(L\text{-asp})_2]^{2-}$[3] complexes. The spectra of the present *mer*-$[Co(gly)_2\text{-}L\text{-glut}]^-$ complexes are shown in Fig. 2. The CH_2 resonance of the glycinate rings is observed in the 3.3~3.7 ppm region as a single line for the compound obtained from the No. 1 fraction, while it is observed as two lines of the compound obtained from No. 2. The weak lines near the CH_2 resonance are due to the CH resonance of the glutamate ring.

Denning and Piper[8] have reported the PMR spectra of the *mer*-$[Co(L\text{-ala})_3]$ and *mer*-$[Co(L\text{-leu})_3]$ complexes; these spectra show only two sets of doublets, with the ratio of 1 : 2, in the CH_3 resonance region; this fact can be related to the near equivalence of the two chelated rings with respect to the pseudo-three fold axis compared to the third ring. If analogous consideration is made of the present *mer* mixed complexes by disregarding the side group ($-CH_2CH_2COOH$) of the chelated glutamate, the two glycinate rings in the *cis*(N)*cis*(O) isomer seem to be near equivalent and can be expected to show a single CH_2 resonance line. For the remaining two isomers, two resonance lines would be expected. Thus, the complex isolated from the No. 1 fraction can tentatively be identified as the *cis*(N)*cis*(O) isomer, and the other one, obtained from No. 2, as either the *trans*(N)*cis*(O) or the *cis*(N)-*trans*(O) isomer. The above supposition seems to be realistic judging from the evidence that the CH_2 resonance of the *Λ* and *Δ* mixture of *fac*-$[Co(gly)_2L\text{-glut}]^-$ exhibited only one peak, indicating little influence of the side group of the chelated glutamate (Fig. 2, (c)).

CD Spectra. The additivity rule of the vicinal effects on the CD spectra has been reported for several cobalt(III) complexes.[9] Figure 3 shows the CD

spectra of the six *fac* compounds in 60% perchloric acid. The spectra for the *Λ* and *Δ* isomers are not mirror images of each other and change in a regular way with the number of the chelated L-glutamate because of the vicinal effect of the ligand. Figure 4 shows the vicinal curves of the three *fac* complexes and also the configurational curve of the tris-(L-glutamato) complex, all of which were calculated from the observed spectra of the pairs of *Λ* and *Δ* isomers. The configurational curves of the bis(glycinato) and bis(L-glutamato) complexes accord with that of the tris(L-glutamato) complex. The magnitude of the vicinal effects obtained for each complex is estimated to be 1 : 2 : 3 in proportion to the number fo the chelated glutamato ligand. This proves not only the additivity between the vicinal and configurational effects, but also the additivity within the vicinal effects themselves.

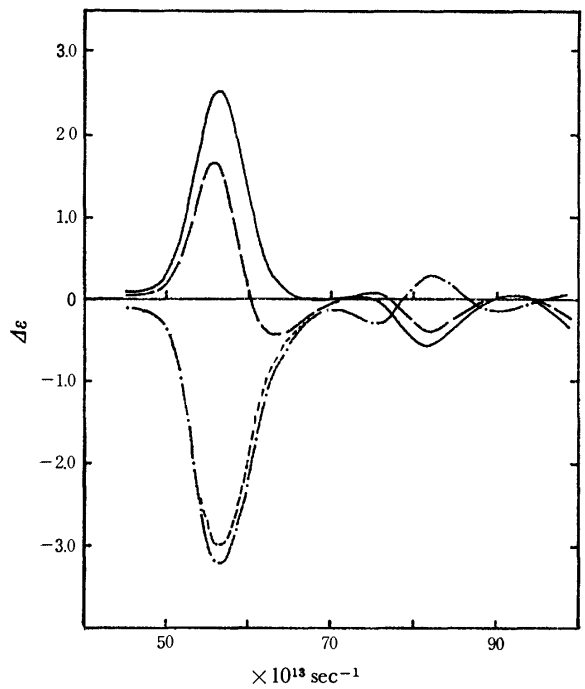

Fig. 5. CD spectra of *fac*-[Co(L-glutH)$_3$].
——, —·—: in 0.1 N NaOH aq. soln.
----, ---: in 0.5 N Na_3PO_4 aq. soln.

Figure 5 shows the CD spectra of *fac*-[Co(L-glut)$_3$]$^{3-}$ measured in 0.1 N sodium hydroxide and 0.5 N trisodium phosphate solutions. The spectrum of the *Λ* isomer in the sodium hydroxide solution shows a single peak with a positive sign in the first absorption band region. When the same sample is measured in a trisodium phosphate solution, the small negative peak appears on the shorter wavelength side and the positive peak decreases in its intensity to a large extent. The spectra of the *Δ* isomer, however, do not show such a large difference between the above two solvents. A similar effect on the CD spectrum by the phosphate ion was observed for *Λ*-[Co(en)$_3$]$^{3+}$ and *Λ*-[Co(*l*-pn)$_3$]$^{3+}$ and was studied in detail by Mason *et al.*[10] The reason for such an effect on the CD spectrum in our case seems to be that it is hard for the phosphate ion to interact with the amino groups in the *Δ* isomer by the repulsion with the *γ*-carboxylate groups, since the chelated glutamate ring seems to be near-planar in the isomers concerned. The spectrum of the *Λ* isomer measured in the trisodium phosphate solution very similar to that in 60% perchloric acid, implying that the latter medium interacts with the complex as the phosphate ion.

Figure 6 shows the CD spectra of the *mer*-*Λ*-[Co(L-glut)$_3$]$^{3-}$ in 60% perchloric acid, 0.1 N sodium hydroxide, and 0.5 N trisodium phosphate solutions. The spectra in an alkaline solution are not influenced very much by the presence of the phosphate ion. The similarity of the spectra in the perchloric acid and trisodium phosphate solutions was not observed for this isomer. The *mer* arrangement of the amino groups seems to inhibit the outer-sphere complexation.

Stereoselectivity. Figure 7 shows the CD spectra in the first absorption band region for the E-1, E-3, and E-5 fractions. Each spectrum exhibits a rather weak Cotton effect curve similar to the vicinal curve for such a complex as *mer*-[Co(L-ala)$_3$].[9] This indicates that the stereoselective formation of one diastereoisomer has scarcely occurred for the *mer* isomers. (By the way, the corresponding spectra for the *mer* fractions of the L-aspartato complexes showed strong Cotton effect curves, indicating the stereoselective formation of the *Λ* isomers.)[2]

The percent compositions of the *Λ* isomers in the E-2, E-4, and E-6 fractions are given in Table 2, together with the data on the corresponding fractions of the L-aspartato complexes.[2] The results in both sets of data show the preferential formation of the *Λ* isomers, but the degree of the selectivity in the L-glutamato complexes is considerably less than that in the L-aspartato complexes.

TABLE 2. PERCENT COMPOSITIONS OF *Λ* ISOMERS FOR *fac* FORMS

Reaction time (hr)	Complexes		
	E-2 $[Co(gly)_2$L-glut$]^-$	E-4 $[Cogly($L-glut$)_2]^{2-}$	E-6 $[Co($L-glut$)_3]^{3-}$
0.5	60%	67%	74%
1	60	68	75
3	60	68	75
2[a]	59	66	69
5[a]	50	50	50
	$[Co(gly)_2$L-asp$]^-$	$[Cogly($L-asp$)_2]^{2-}$	$[Co($L-asp$)_3]^{3-}$
1	89	95	95

a) These two reactions were performed at acidic condition (pH *ca.* 6). The others were all performed at pH *ca.* 10.

The stereoselectivity in the L-aspartato complexes has been interpreted in terms of an enhanced stability through hydrogen-bonding between the *β*-carboxylate group of the coordinated L-aspartate ion and the amino group in the adjacent ligand.[2] By the same interpretation, the weaker stereoselectivity in the L-glutamato complexes may be said to be due to the lower ability of the *γ*-carboxylate group of the coordinated L-glutamato ion to interact with the adjacent group. Indeed, there are some cobalt(III) complexes containing the L-aspartate ion as a terdentate ligand,[11] but no such glutamato complexes have yet been found. All of several attempts to make bis(L-glutamato)cobaltate-(III) were unsuccessful.

The percent compositions of the *mer* and *fac* isomers in the reaction mixture are given in Table 3. Similar data[2] on the related complexes are also cited in the table.

TABLE 3. PERCENT COMPOSITIONS OF THE REACTION MIXTURE

Reaction time (hr)	Complexes					
	$[Co(gly)_2$L-glut$]^-$		$[Cogly($L-glut$)_2]^{2-}$		$[Co($L-glut$)_3]^{3-}$	
	mer	*fac*	*mer*	*fac*	*mer*	*fac*
1	22%	16%	26%	20%	10%	5%
	Complexes					
	$[Co(gly)_2$L-asp$]^-$		$[Cogly($L-asp$)_2]^{2-}$		$[Co($L-asp$)_3]^{3-}$	
	mer	*fac*	*mer*	*fac*	*mer*	*fac*
1	17%	15%	22%	30%	6%	10%

In the present complexes, more of the *mer* isomers are formed than the *fac* isomers, whereas more *fac* isomers are formed than the *mer* isomers in the *tris*- and bis(L-aspartato) complexes. The larger formation of the *fac* isomer in the *tris*(L-aspartato) complex can be attributed to the possible hydrogen bonding. That is, the amounts formed increased in the order of *fac-Λ*<*mer-Λ*<*mer-Δ*<*fac-Δ*; this order agrees with the order of the number of the possible hydrogen bonding for for these isomers (their numbers are 0, 1, 2 and 3). This is not true for the isomers of the tris(L-glutamato) complexes, because their amounts increased in the order of *fac-Λ*<*fac-Δ*<*mer-Δ*≃*mer-Λ*. The formation ratio of each *fac-Δ* isomer against the *Λ* isomer was kept constant at various reaction times when the reaction mixture had been prepared as an alkaline solution with sodium hydroxide (pH∼10). On the other hand, with the reaction mixture without sodium hydroxide (pH∼6), the formation ratio was estimated to be nearly 1.0 for the 5-hour reaction. That is, the stereoselectivity disappeared when the reaction was prolonged under such acidic conditions. This fact seems to suggest that the *γ*-carboxylate groups of the chelated glutamates protonate partially in an acidic medium and are less able to form hydrogen bonds with the adjacent groups. Thus, it may be concluded that the polar interaction of the dangling (*β*- or *γ*-) carboxylate groups with adjacent coordinated groups plays an important part in the stereoselectivity in complexes containing optically-active aspartic or glutamic acid. The lower selectivity in the L-glutamato complexes may be responsible for the longer side group ($-CH_2CH_2COO^-$).

Derivatographic Studies on Transition Metal Complexes. VIII.[1] Thermal Deaquation-Anation Reaction of *cis*-$[CoX(H_2O)N_4]Y_2$ Type Complexes in Solid Phase

Ryokichi Tsuchiya, Masatatsu Suzuki,* and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa
**Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka*

(Received May 15, 1972)

The deaquation-anation reaction of *cis*-$[CoX(H_2O)N_4]Y_2$ type complexes, where X is chloride or bromide ion, N_4 is tetraammine or bis(ethylenediamine), and Y is chloride, bromide or nitrate ion, was investigated by means of both derivatographic and isothermal methods. Some of these reactions were found to include the stereochemical changes, the structure of reaction products formed by deaquation-anation reaction being considerably affected by the counter ionic species: the chloride complexes, where Y=Cl, were deaquated with retention of *cis*-structure, whereas the bromide complexes, where Y=Br, underwent *cis*-to-*trans* stereochemical change. According to the isothermal measurement in the isomerization of *cis*-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$, *cis*-$[CoCl(H_2O)en_2]Br(NO_3)$ and *cis*-$[CoBr(H_2O)en_2]Br_2\cdot H_2O$, these rates were found to obey the first-order rate law and the activation energies, E_a, were obtained to be 38 ± 5, 68 ± 6 and 37 ± 5 kcal mol^{-1} and the enthalpy changes, ΔH, 13.5 ± 2.0, 7.5 ± 2.0 and 13.3 ± 2.0 kcal mol^{-1} for the respective complexes.

Several studies on the thermal deaquation-anation reactions containing the exchange between coordinated water and a counter ion without the displacement of the other ligands in the solid phase are known for $[Co(H_2O)(NH_3)_5]X_3$,[2] $[Cr(H_2O)(NH_3)_5]X_3$,[3] where X is halide, nitrate or sulfate ion, and for *cis*-$[CoX(H_2O)en_2]Y_2$ type complexes,[4] where X and Y are both halide ions.

In the thermal isomerization reaction, *cis,trans*-$[CoCl_2(NH_3)_2en]Br\cdot H_2O \rightarrow$ *trans,cis*-$[CoCl_2(NH_3)_2en]Br$,[5] *cis*-$[CoCl(H_2O)(NH_3)_2en]ClBr$ was presumed to present as an intermediate on the basis of the "aquation-anation" mechanism, the following reaction pathway being deduced,

$$\begin{aligned} &\textit{cis, trans}\text{-}[CoCl_2(NH_3)_2en]Br\cdot H_2O \longrightarrow \\ &\quad \textit{cis}\text{-}[CoCl(H_2O)(NH_3)_2en]ClBr \longrightarrow \\ &\quad \textit{trans, cis}\text{-}[CoCl_2(NH_3)_2en]Br + H_2O. \end{aligned} \quad (1)$$

Since the stereochemical change is considered to occur in the deaquation-anation of *cis*-$[CoCl(H_2O)(NH_3)_2en]ClBr$ in the above pathway (1), it is very interesting to investigate the thermal behavior of halogenoaquo complexes as an intermediate in the isomerization reaction. The aim of this study will be placed on attempting the elucidation of nature for these thermal deaquation-anation reaction involving the stereochemical change and investigating the reaction mechanism thermochemically and kinetically. Such studies on the thermochemical change in the deaquation-anation step will indirectly support the rationality of the reaction pathway (1).

Experimental

Preparation of Complexes. cis-$[CoCl(H_2O)en_2]Br\cdot H_2O$: This complex was prepared by the known method,[6] being purified by the recrystallization from a small amount of concentrated hydrobromic acid.

cis-$[CoCl(H_2O)en_2]Br(NO_3)$. A cold solution of *cis*-$[CoCl(H_2O)en_2]Br_2\cdot H_2O$ obtained above was treated with saturated solution of lithium nitrate to precipitate the desired reddish violet crystals.

cis-$[CoClBren_2]Br\cdot H_2O$ *and* trans-$[CoClBren_2]NO_3$. These compounds were synthesized according to the same method as described in Ref. 6.

cis-$[CoBr_2en_2]Br\cdot H_2O$. $[Co(CO_3)en_2]Br$ was treated with alcoholic hydrogen bromide according to the method of Werner[7] to obtain the desired complex.

cis-$[CoBr(H_2O)en_2]Br_2\cdot H_2O$. This compound was prepared by the method of Werner.[7]

cis-$[CoCl(H_2O)(NH_3)_4]Cl_2$, cis-$[CoCl(H_2O)(NH_3)_4]Br_2$, cis-$[CoBr(H_2O)(NH_3)_4]Br_2$ *and* cis-$[CoBr(H_2O)(NH_3)_4]Cl_2$: These compounds were synthesized according to the literature.[8]

Derivatographic Measurement. The apparatus and techniques for derivatography used in this work were the same as described in the earlier paper.[3] The heating rate was 1°C min^{-1}.

Isothermal Measurement. A Shimadzu TM-1A Thermanobalance and Abderhalden apparatus were used for the isothermal measurement. The procedure of measurement and analytical method for the experiments are similar to those already described.[9] In order to determine the change of the conversion ratios in the thermal reactions of *cis*-$[CoBr(H_2O)en_2]Br\cdot H_2O$, the visible and UV absorption spectra of the complexes were measured consecutively with a Hitachi R-3 Spectrophotometer with 1.0 cm cell: the ratio of *cis*-$[CoBr(H_2O)en_2]Br\cdot H_2O$, *cis*-$[CoBr_2en_2]Br\cdot H_2O$ and *trans*-$[CoBr_2en_2]Br$ were estimated by using the following three simultaneous equations,

$$\begin{aligned} 9.5X + 37.0Y + 55.1Z &= D_{530} \\ 85.0X + 111.1Y + 13.4Z &= D_{554} \\ 102.6X + 101.0Y + 14.2Z &= D_{655}, \end{aligned}$$

cis-$[CoBr(H_2O)(NH_3)_4]Br_2$	100—135	*trans*-$[CoBr_2(NH_3)_4]Br$

where X, Y and Z are the respective concentrations (mol l^{-1}) of the above three complexes, and D_{530}, D_{554} and D_{655} are the observed absorbancies at 530 nm, 554 nm and 655 nm, respectively.

Results and Discussion

When a number of aquo complexes of *cis*-$[CoX(H_2O)N_4]Y_2 \cdot nH_2O$ type are heated, the following reaction takes place,

cis-$[CoX(H_2O)N_4]Y_2 \cdot nH_2O$

$\longrightarrow$ *cis*- or *trans*-$[CoXYN_4]Y + (n+1)H_2O$.

The aquo complexes prepared in the present work listed in Table 1, together with their reaction products and the range of the reaction temperatures.

Derivatography. *(a)* cis-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$: The complex undergoes the following reaction upon heating,

cis-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$

$\longrightarrow$ *cis*- + *trans*-$[CoBr_2en_2]Br + 2H_2O$.

The derivatogram for this reaction is shown in Fig. 1, together with those of the other two complexes, *cis*-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$ and *cis*-$[CoCl(H_2O)en_2]Br(NO_3)$, which will be described in the following sections. The TG curve indicates that the liberation of one mole of lattice water and one mole of coordinated water simultaneously begins to appear at about 70°C and ceases completely at 130°C, where the color change from violet to grayish green was observed, and no further mass loss is detected until about 210°C. The DTA curve shows one endothermic peak centered at 80°C, corresponding to the deaquation-anation process, and one more sharp exothermic peak centered at 170°C: in the latter peak region, no change of weight is detected in TG curve.

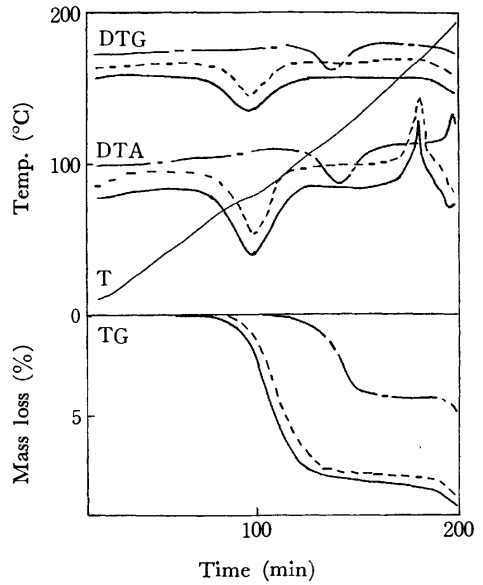

Fig. 1. Derivatograms of *cis*-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$ (——), *cis*-$[CoCl(H_2O)en_2]Br(NO_3)$ (– – –) and *cis*-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$ (----).

In order to compare the thermal behavior of halogenoaquo complexes with that of dihalogeno complexes, derivatograms of dihalogeno complexes, *cis*-$[CoBr_2en_2]Br \cdot H_2O$, *cis*-$[CoClBren_2]Br \cdot H_2O$ and *trans*-$[CoBr_2en_2]Br$, are shown in Fig. 2.

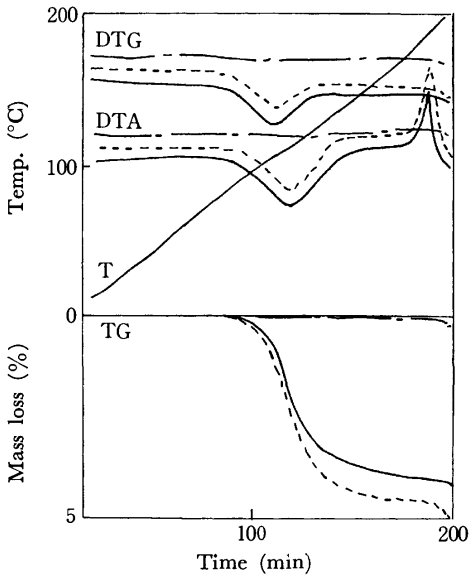

Fig. 2. Derivatograms of *cis*-$[CoBr_2en_2]Br \cdot H_2O$ (——), *cis*-$[CoClBren_2]Br \cdot H_2O$ (– – –) and *trans*-$[CoBr_2en_2]Br$ (— — —).

When *cis*-$[CoBr_2en_2]Br \cdot H_2O$ was heated, the dehydration reaction began to take place at about 90°C. The TG curve exhibits the mass loss of lattice water in the temperature range of 90 to 160°C and no further mass loss was detected until 210°C. The DTA curve exhibits a large endothermic peak at 120°C and a sharp exothermic peak at 185°C. This curve is approximately the same as that for *cis*-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$ in the temperature range of 160 to 210°C. During the dehydration process, the color change from blue to grayish green was observed. This change may be attributed to the *cis*-to-*trans* isomerization,

cis-$[CoBr_2en_2]Br \cdot H_2O \rightarrow$ *trans*-$[CoBr_2en_2]Br + H_2O$.

The isomerization could be also interpreted in terms of "aquation-anation" mechanism.[9]

When the trans-complex obtained in the above thermal reaction was cooled to room temperature, the reverse *trans*-to-*cis* isomerization occurred; *i.e.*, the *trans*-complex absorbed one mole of water as shown in the following reaction,

trans-[$CoBr_2en_2$]Br + H_2O → *cis*-[$CoBr_2en_2$]Br·H_2O,

the color change from grayish green to blue being observed.

In the derivatogram of *trans*-[$CoBr_2en_2$]Br shown in Fig. 2, differing from the corresponding *cis*-complex, no change was found in the DTA curve until the genuine decomposition began to appear at about 210°C. And even when the *trans*-complex was cooled to room temperature after heating, no *trans*-to-*cis* isomerization was observed.

(b) cis-[*CoCl*(H_2O)*en*$_2$]*Br*$_2$·H_2O: The complex undergoes the following reaction upon heating,

cis-[CoCl(H_2O)en_2]Br_2·H_2O
⟶ *cis*- + *trans*-[CoClBren_2]Br + H_2O.

The derivatogram for this change is very similar to that for the corresponding bromoaquo-bromide (a) as shown in Fig. 1. The TG curve indicates that the mass loss of lattice water begins to appear at approximately 65°C. An endothermic peak is observed at 85°C in the DTA. The deaquation-anation was completed at 130°C, and the mass was kept constant until 180°C, whereupon the genuine decomposition began to occur as shown in the TG curve. The DTA curve exhibits a sharp exothermic peak at a similar temperature, 175°C, to that seen in the corresponding bromoaquo-bromide complex.

The sharp exothermic peak is also found or *cis*-[CoClBren_2]Br·H_2O at the same temperature as shown in Fig. 2. The thermochromism was also observed in the dehydration process,

cis-[CoClBren_2]Br·H_2O → *trans*-[CoClBren_2]Br + H_2O,

in the temperature range of 95 to 155°C. The *trans*-complex obtained above was hygroscopic and completely turned back to *cis*-complex again under cooling.

(c) cis-[*CoCl*(H_2O)*en*$_2$]*Br*(*NO*$_3$): The complex undergoes the following reaction upon heating at 110—140°C, *cis*-[CoCl(H_2O)en_2]Br(NO_3) → *trans*-[CoClBren_2]NO_3+H_2O, as shown in Fig. 1, the color change from violet to green being found. The DTA curve exhibits an endothermic peak at 130°C and an exothermic peak at 200°C, which correspond to the deaquation-anation and the genuine decomposition reactions respectively.

(d) cis-[*CoCl*(H_2O)(*NH*$_3$)$_4$]*Cl*$_2$: The derivatogram of *cis*-[CoCl(H_2O)(NH_3)$_4$]Cl_2 is shown in Fig. 3, together with those of *cis*-[CoCl(H_2O)(NH_3)$_4$]Br_2 and *cis*-[CoBr(H_2O)(NH_3)$_4$]Br_2. The TG curve indicates that the deaquation-anation reaction proceeds in the temperature range of 135 to 170°C, and the DTA curve exhibits an endothermic peak corresponding to the deaquation-anation at 150°C. During the dehydration process, the color change from violet to bluish violet was first observed and then the bluish violet was gradually converted to green by heating for a long time, suggesting the formation of *trans*-complexes. From these results, the following stepwise reactions occur,

cis-[CoCl(H_2O)(NH_3)$_4$]Cl_2 → *cis*-[$CoCl_2$(NH_3)$_4$]Cl
→ *trans*-[$CoCl_2$(NH_3)$_4$]Cl.

The thermal behavior of *cis*-[CoBr(H_2O)(NH_3)$_4$]-Cl_2 was analogous to that of *cis*-[CoCl(H_2O(NH_3)$_4$]-Cl_2, so far as the initiation temperature and the reaction product of the deaquation-anation reaction are concerned.

(e) cis-[*CoCl*(H_2O)(*NH*$_3$)$_4$]*Br*$_2$ *and* cis-[*CoBr*-(H_2O)(*NH*$_3$)$_4$]*Br*$_2$: When these were heated, the following reactions were considered to occur,

cis-[CoCl(H_2O)(NH_3)$_4$]Br_2 → [CoClBr(NH_3)$_4$]Br (green)

cis-[CoBr(H_2O)(NH_3)$_4$]Br_2 → [$CoBr_2$(NH_3)$_4$]Br (green).

The color change from violet to green was found in both cases. The TG curves in Fig. 3 indicate that

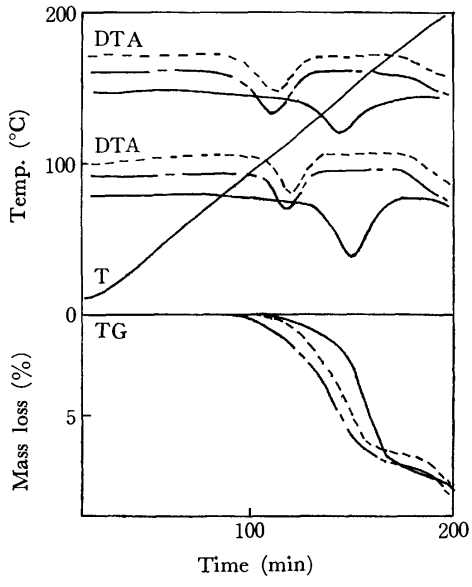

Fig. 3. Derivatograms of *cis*-[CoCl(H_2O)(NH_3)$_4$]Cl_2 (——), *cis*-[CoCl(H_2O)(NH_3)$_4$]Br_2 (– – –) and *cis*-[CoBr(H_2O)-(NH_3)$_4$]Br_2 (----).

the mass loss of the bromoaquo-bromide and of the chloroaquo-bromide was completed at 130 and 135°C, respectively, whereupon the produced *trans*-complexes were decomposed. A single endothermic peak was observed at 120°C in both DTA curves, where the deaquation-anation reaction occurred.

Electronic Spectra. Deaquation-anation reactions of the complexes were followed and the reaction products were identified by measuring the electronic spectra. The electronic spectra of *cis*-[CoBr(H_2O)en_2]-Br_2·H_2O and of the related complexes are shown in Fig. 4.

When *cis*-[CoBr(H_2O)en_2]Br_2·H_2O is heated, the first absorption maximum is gradually shifted from 530 nm (ε=102.0) to considerably lower frequency side. After the deaquation-anation was completed, the reaction product gave the broad absorption band at 554 nm with less intense shoulder at 630—650 nm. This suggests the superposition of spectra of *cis*-[$CoBr_2$-

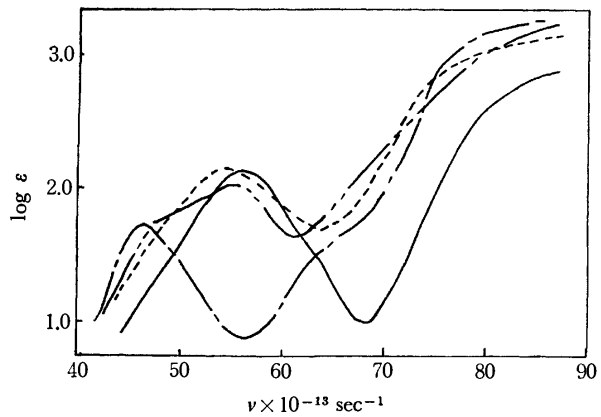

Fig. 4. Electronic spectra of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$ (——), *cis*-[$CoBr_2en_2$]$Br\cdot H_2O$ (----), *trans*-$CoBr_2en_2$]Br (———) and of thermal reaction product of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$ (—·—·—).

$en_2]^+$ and *trans*-[$CoBr_2en_2]^+$, which showed the first absorption maxima at 554 nm (ε=101.0) and at 655 nm (ε=55.1), respectively, as shown in Fig. 4. In the present work, no attempt was made to isolate the two isomers from the mixture.

The absorption spectra of *cis*-[CoCl(H_2O)en_2]-$Br_2\cdot H_2O$ and of the related complexes are shown in Fig. 5, which displays that the heating of *cis*-[CoCl-(H_2O)en_2]$Br\cdot H_2O$ also gives the formation of the mixture of *trans*-[CoClBren_2]Br and *cis*-[CoClBren_2]-Br as similar as that of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$.

When the bromide-nitrate complex, *cis*-[CoCl(H_2O)-en_2]$Br(NO_3)$, was heated, the first absorption peak of *cis*-complex disappeared and the same absorption spectrum as found for *trans*-[CoClBren_2]NO_3 was obtained.

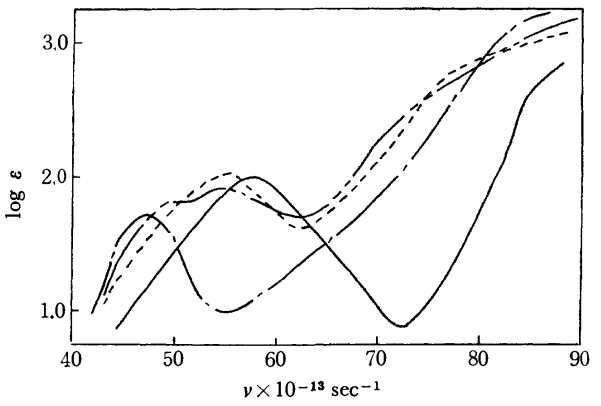

Fig. 5. Electronic spectra of *cis*-[CoCl(H_2O)en_2]$Br_2\cdot H_2O$ (——), *cis*-[CoClBren_2]$Br\cdot H_2O$ (----), *trans*-[CoClBren_2]Br (———) and of thermal reaction product of *cis*-[CoCl(H_2O)-en_2]$Br_2\cdot H_2O$ (—·—·—).

The deaquation-anation reactions for the ammine-complexes, (d) and (e), were only followed by the observation of their color change.

Rate Studies. Isothermal dehydration of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$ was followed by using a thermobalance at several constant temperatures in the range of 92 to 120°C and the conversion ratios this complex to *cis*-[$CoBr_2en_2$]Br and to the corresponding *trans*-complex were determined spectrophotometrically by the method described in the experimental section.

The dehydration reactions of all the monoacidoaquo-complexes treated in the present work were found to proceed in the first order. For example, the rate constant for the deaquation-anation reaction of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$ is expressed by,

$$k_a = \frac{1}{t}\ln\frac{a}{a-x}$$

the rate constant concerning the formation of *cis*-[$CoBr_2en_2$]Br by,

$$k_b = \frac{1}{t}\cdot\frac{y}{x}\ln\frac{a}{a-x}$$

and that concerning the formation of *trans*-[$CoBr_2en_2$]-Br by

$$k_c = \frac{1}{t}\cdot\frac{z}{x}\ln\frac{a}{a-x}$$

where a denotes the initial amount of the starting complex, *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$, x is the amount of the complex that has disappeared, y is the amount of *cis*-[$CoBr_2en_2$]Br formed, and z is the amount of *trans*-[$CoBr_2en_2$]Br formed in the time t. Since the plots, $\log a/(a-x)\sim t$, $(y/x)\log a/(a-x)\sim t$ and $(z/x)\log a/(a-x)\sim t$, give straight lines at each temperature as shown in Fig. 6, the above three reactions are considered to proceed in parallel with each other and in the first order respectively.

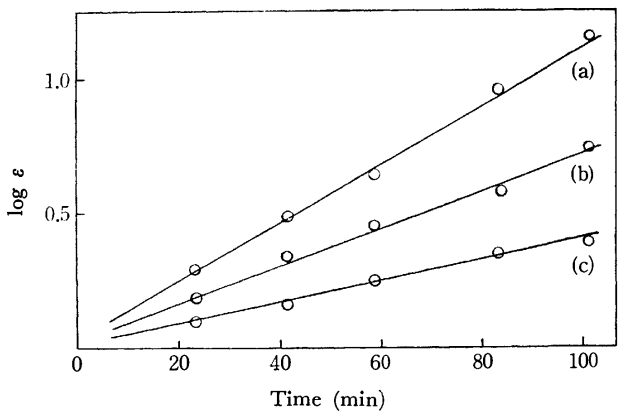

Fig. 6. The relationships of $\log a/(a-x)$ (a), $y/x\cdot\log a/(a-x)$ (b) and $z/x\log a/(a-x)$ (c) against t for deaquation-anation of *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$.

Rate constants calculated for *cis*-[CoBr(H_2O)en_2]-$Br_2\cdot H_2O$ are listed in Table 2, together with those for only the dehydration of *cis*-[CoCl(H_2O)en_2]$Br_2\cdot H_2O$. The activation energies (E_a) were obtained from the temperature dependency of the rate constant, and entropies of activation (ΔS_a) were calculated by using "absolute rate theory", which are given in Table 3.

Taking into account for the data of the initiation temperatures of deaquation-anation reaction in Table 1 and those of the activation energies in Table 3, the order of the thermal stability is deduced to be, *cis*-[CoCl(H_2O)en_2]$Br(NO_3)$ > *cis*-[CoBr(H_2O)en_2]$Br_2\cdot H_2O$ ≈ *cis*-[CoCl(H_2O)en_2]$Br_2\cdot H_2O$ for halogenoaquo ethylenediamine complexes, and *cis*-[CoCl(H_2O)$(NH_3)_4$]Cl_2 > *cis*-[CoCl(H_2O)$(NH_3)_4$]Br_2 ≈ *cis*-[CoBr(H_2O)$(NH_3)_4$]-

TABLE 2. RATE CONSTANTS OF DFAQUATION-ANATION OF *cis*-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$ AND DEHYDRATION OF *cis*-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$

Temp. (°C)	k_a (sec^{-1})	k_b (sec^{-1})	k_c (sec^{-1})	k_d [a] (sec^{-1})
92	$(1.9\pm0.3)\times10^{-4}$	$(1.2\pm0.3)\times10^{-4}$	$(7.2\pm0.3)\times10^{-5}$	$(2.4\pm0.3)\times10^{-4}$
100	$(2.3\pm0.3)\times10^{-4}$	$(1.4\pm0.3)\times10^{-4}$	$(8.5\pm0.3)\times10^{-5}$	$(2.8\pm0.3)\times10^{-4}$
110	$(1.3\pm0.2)\times10^{-3}$	$(7.5\pm0.3)\times10^{-4}$	$(4.8\pm0.3)\times10^{-4}$	$(1.7\pm0.2)\times10^{-3}$
120	$(3.5\pm0.4)\times10^{-3}$	$(2.2\pm0.4)\times10^{-3}$	$(1.2\pm0.4)\times10^{-3}$	$(4.0\pm0.3)\times10^{-3}$

TABLE 3. THE THERMOCHEMICAL FUNCTIONS FOR DEAQUATION-ANATION REACTIONS

Complex	E_a (kcal/mol)	ΔH (kcal/mol)	ΔS_a^a (e. u.)	ΔS_a^b (e. u.)	ΔS_a^c (e. u.)
cis-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$	38±5	13.5±2.0			
cis-$[CoCl(H_2O)en_2]Br(NO_3)$	68±6	7.5±2.0			
cis-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$	37±5	13.3±2.0	16±5	15±5	15±5

ΔS_a^a: the disappearance for *cis*-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$, ΔS_a^b: the formation of *cis*-$[CoBr_2en_2]Br$, ΔS_a^c: the formation of *trans*-$[CoBr_2en_2]Br$.

Br_2 for halogenoaquoammine complexes.

The ratios of *cis*-$[CoBr_2en_2]Br$ to *trans*-$[CoBr_2en_2]Br$ in the products at all temperatures investigated were found to be 62 : 38 at the end of deaquation-anation.

The reaction products produced by the deaquation-anation reactions are considerably affected by the entering groups: *i.e.*, *cis*-$[CoCl(H_2O)en_2]Br_2 \cdot H_2O$, *cis*-$[CoBr(H_2O)en_2]Br_2 \cdot H_2O$ and *cis*-$[Co(H_2O)_2en_2]Br_3 \cdot 2H_2O$ gave the mixture of *cis*- and *trans*-complexes, while *cis*-$[CoCl(H_2O)en_2]Cl_2$ and *cis*-$[Co(H_2O)_2en_2]Cl_3 \cdot 2H_2O$ gave *cis*-$[CoCl_2en_2]Cl$ with retention of structure.

As for the ammine-complexes, the reactions proceeded in the same manner as found for ethylenediamine-complexes: *i. e.*, *cis*-$[CoCl(H_2O)(NH_3)_4]Cl_2$ and *cis*-$[CoBr(H_2O)(NH_3)_4]Cl_2$ were deaquated with retention of structure to give the corresponding *cis*-complexes as reaction products, whereas *cis*-$[CoCl(H_2O)(NH_3)_4]Br_2$ and *cis*-$[CoBr(H_2O)(NH_3)_4]Br_2$ underwent *cis*-to-*trans* stereochemical change to give the corresponding *trans*-complexes as reaction products.

From these facts, it is concluded that, when the entering group is chloride ion, deaquation-anation reaction proceeds with the retention of structure, while, when it is bromide ion, the stereochemical change occurs during the deaquation-anation process. In addition, *cis*-$[CoCl(H_2O)en_2]Br(NO_3)$ was found to undergo the complete conversion into *trans* form. As seen in these complexes, the kind of counter ions in the outer coordination sphere affects the geometrical structure of deaquation-anation reaction products, though the kind of acidic ligands coordinated does not so much affect it.

Kinetics and Stoichiometry of Nitrogen Fixation with $TiCl_3$-Mg and VCl_3-Mg in Tetrahydrofuran

(Received May 15, 1972)

The kinetics and stoichiometry of nitrogen fixation with $TiCl_3$–Mg and VCl_3–Mg in tetrahydrofuran (THF) systems were studied. The systems react with molecular nitrogen at room temperature and normal pressure giving magnesium dichloride and nitrogen-containing complexes of compositions $[MNMg_2Cl_2(THF)]$, where M= Ti and V, according to the stoichiometry: $MCl_3(THF)_3 + \frac{5}{2}Mg + \frac{1}{2}N_2 \rightarrow [MNMg_2Cl_2(THF)] + \frac{1}{2}MgCl_2(THF)_2$. Properties of the isolated nitrogen-containing complexes were examined. Reactions under argon and hydrogen gave hydride-containing complexes. The initial rate of nitrogen fixation was first order with respect to the amounts of MCl_3, Mg, and nitrogen pressure. A mechanism involving the complexation of N_2 with dimeric M(II) species followed by rate-determining process to react with magnesium is proposed and discussed.

Since the discovery of Vol'pin and Shur that molecular nitrogen can be fixed under mild conditions by mixed systems of transition metal compounds and reducing agents,[1] there have been reported a number of systems which react with molecular nitrogen.[2] Among these systems, early transition metal compounds in combination with reducing agents contrast in their ability to fix molecular nitrogen with later transition metal compounds which often form stable dinitrogen complexes but the coordinated N_2 ligand can not be readily reduced. A variety of N_2-fixing systems based mostly on titanium compounds have been reported and the mechanism of nitrogen fixation has been studied to some extent. As the apparently simplest N_2-fixing systems we have selected the $TiCl_3$–Mg[3] and VCl_3–Mg systems in tetrahydrofuran (THF) and studied the mechanism of nitrogen fixation by kinetic as well as preparative methods.

Results

Stoichiometry and Kinetics of Nitrogen Fixation. $TiCl_3(THF)_3$ and $VCl_3(THF)_3$ in the presence of magneiusm in tetrahydrofuran react at room temperature and normal pressure with molecular nitrogen. The amounts of molecular nitrogen absorbed by the $TiCl_3$–Mg and VCl_3–Mg systems were equivalent to the amounts of ammonia formed after the hydrolysis of the system. Figure 1 shows typical kinetic runs of N_2 fixation with $TiCl_3$–Mg system; the VCl_3–Mg system behaves similarly but with much slower absorption. In no case the amount of ammonia formed per mole of $TiCl_3$ or VCl_3 exceeded one mole at ambient temperature and pressure. Figure 1 also indicates that the N_2 absorption starts after an induction period. This induction period can be shortened to some extent by using fine powder of magnesium or by pretreatment of magensium with iodine but can not be removed completely. As will be described later this induction period can be ascribed to the period of reduction of Ti(III) to Ti(II) or V(III) to V(II).

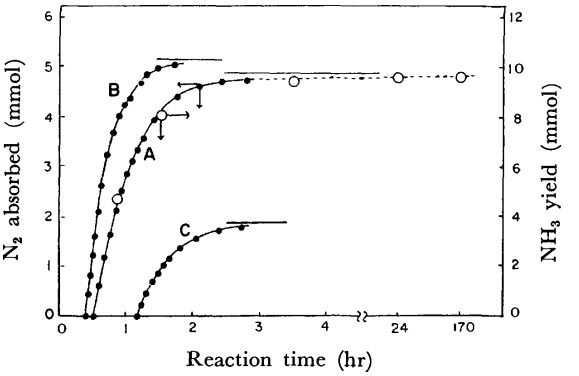

Fig. 1. N_2 absorption and ammonia formation by $TiCl_3$–Mg system at 20°C. ●: Amount of N_2 absorbed in mmol; ○: Amount of ammonia formed after hydrolysis. Curve A: $TiCl_3$, 1.50 g, reduced with 2.0 g of Mg. B: $TiCl_3$, 1.58 g; Mg, 4.0 g. C: $TiCl_3$, 0.57 g; Mg, 3.0 g. Horizontal lines for the curves indicate the calculated values for absorption of 0.5 mol of N_2 per titanium.

The kinetic experiment were carried out mostly with the $TiCl_3$–Mg system which absorbs nitrogen more rapidly than the VCl_3–Mg system. The kinetic curves shown in Fig. 1 have been replotted in Fig. 2 to indicate that the rate of N_2 absorption is first-order with respect to the concentration of a titanium species which is able to combine with molecular nitrogen.

$$r = d[NH_3]/dt = k[Ti] \quad (1)$$

Figure 3 illustrates the kinetic curves of magnesium consumption by the $TiCl_3$–Mg sytem under nitrogen and under argon. Evidently the rate of magnesium consumption under nitrogen is much faster than that under argon after the first 0.5 g-atom of magnesium per titanium was consumed, although the ultimate

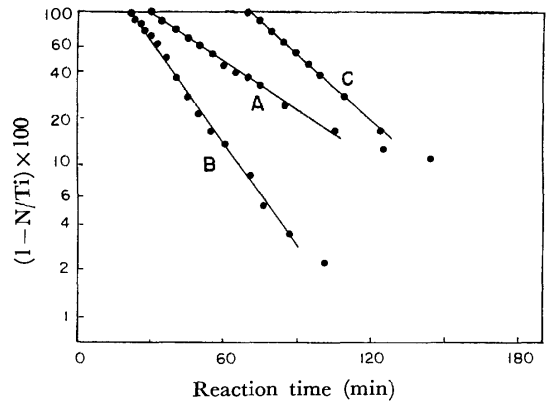

Fig. 2. First order plots of Fig. 1. Legends are the same with Fig. 1. N/Ti in the ordinate represents the number of moles of NH_3 produced per mol of $TiCl_3$ added.

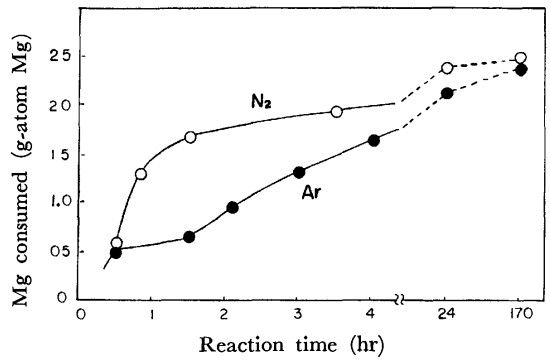

Fig. 3. Consumption of magnesium with time by $TiCl_3$-Mg system. $TiCl_3$, 1.50 g; Mg, 2.0 g, 20°C.
○, under nitrogen; ●, under argon.

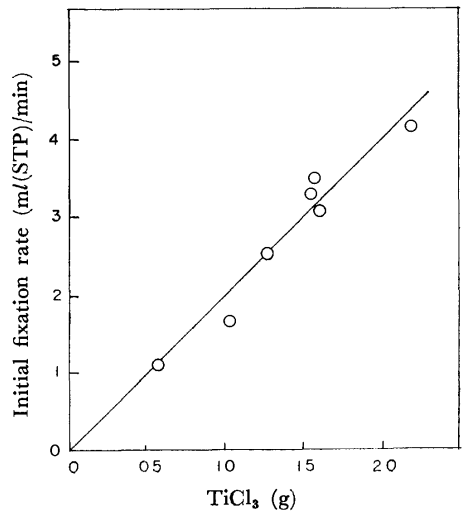

Fig. 4. Relationship between the initial rate of nitrogen fixation and the amount of $TiCl_3$ used.

amount of magnesium consumed is almost the same in either case. (2.5 g-atoms Mg per Ti or V.)

Figures 4, 5, and 6 show the dependences of the initial rate of N_2 fixation on the amount of $TiCl_3$ used, the amount of Mg consumed in the nitrogen fixation (the amount consumed in the induction period is excluded) and on the nitrogen pressure. It can be seen that the initial rate of N_2 fixation is first order with respect to these quantities. From the result

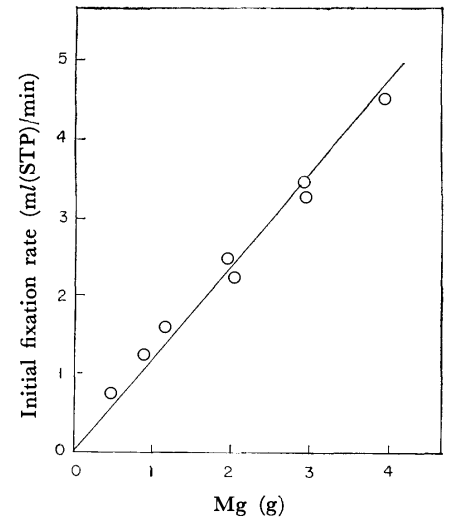

Fig. 5. The dependence of the initial rate of nitrogen fixation on the amount of Mg. The amount of Mg in the abssisae indicates the amount of Mg used for nitrogen fixation, *i.e.*, the amount of Mg consumed in the induction period is substracted from the total amount of Mg used. $TiCl_3$, 1.50 g; P_{N_2}, 62 cmHg; temperature, 20°C.

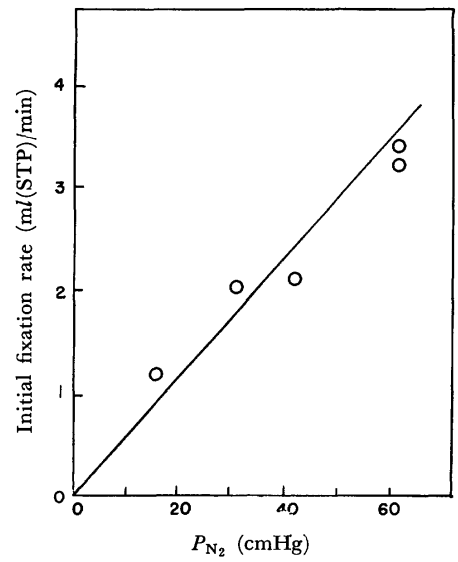

Fig. 6. The dependence of the initial rate of nitrogen fixation on nitrogen pressure at 20°C. $TiCl_3$, 1.50 g; Mg, 3.0 g; total pressure, 76 cmHg with argon as diluent.

of the temperature dependence of the initial rate, the activation energy for this process was estimated as 5 kcal/mol.

In both cases of $TiCl_3$-Mg and VCl_3-Mg the total amounts of magnesium consumed per mole of $TiCl_3$ or VCl_3 did not exceed 2.5 g-atoms but there was some difference observed between the $TiCl_3$-Mg and VCl_3-Mg systems in the relationships between the amount of N_2 fixed and the amount of Mg consumed. As Fig. 7 shows, in both cases with $TiCl_3$ and VCl_3, no N_2 absorption takes place until 1/2 g-atom of magnesium is consumed, and beyond this stage the amount of N_2 fixed increases linearly with the Mg consumption. In the case with $TiCl_3$-Mg system, 1 mol of NH_3 is produced by consumption of 2 g-atoms of Mg, and the system consumes further 0.5 g-atom of Mg without

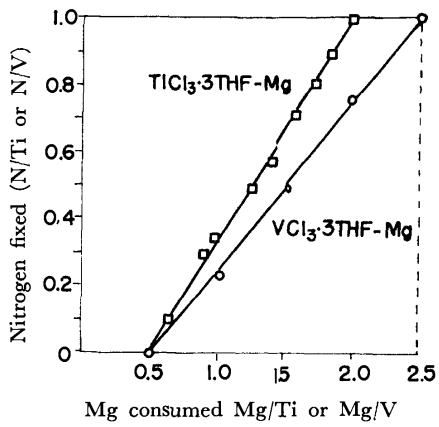

Fig. 7. The relationships between the amount of Mg consumed and the amount of nitrogen fixed by $TiCl_3(THF)_3$-Mg (□) and $VCl_3(THF)_3$-Mg system (○).

N_2 absorption. On the other hand, for VCl_3-Mg system the production of 1 mol of NH_3 is performed by consumption of 2.5 g-atoms of magnesium.

Taking into account the amounts of magnesium chloride formed and of nitrogen-containing titanium and vanadium complexes isolated from the reaction systems *(vide infra)*, the stoichiometries of the overall reactions for $TiCl_3$-Mg and VCl_3-Mg systems can be expressed by:

$$TiCl_3(THF)_3 + \frac{5}{2}Mg + \frac{1}{2}N_2 \rightarrow \underset{\mathbf{1}}{[TiNMg_2Cl_2(THF)]} + \frac{1}{2}MgCl_2(THF)_2 \quad (2)$$

$$VCl_3(THF)_3 + \frac{5}{2}Mg + \frac{1}{2}N_2 \rightarrow \underset{\mathbf{3}}{[VNMg_2Cl_2(THF)]} + \frac{1}{2}MgCl_2(THF)_2 \quad (3)$$

When these N_2 fixing systems are reduced with magnesium prior to contact with N_2 under argon beyond the oxidation state of Ti(II) and V(II), the ability of the systems to fix nitrogen is reduced as illustrated in Fig. 8. When $VCl_3(THF)_3$ is reduced with magnesium until 0.5 g-atom of Mg is consumed, no loss in the N_2 fixing ability is observed. Further usage of magnesium reduces the ability of the system to fix nitrogen and after consumption of 2.5 g-atoms of Mg the system does not show any more reactivity toward nitrogen. Similarly the titanium system which has been reduced with 2.5 g-atoms of magnesium does not react with nitrogen any more. The presence of other ligands such as triphenylphosphine and 2,2'-dipyridyl hinders the nitrogen fixation. The system containing $TiCl_2(acac)(THF)_2$[4] and magnesium in THF did not react with nitrogen.

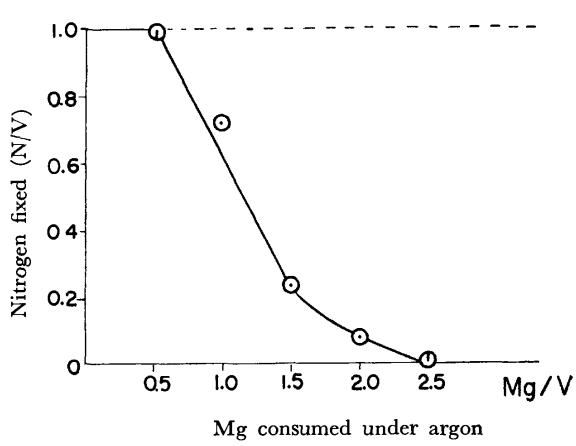

Fig. 8. Residual N_2-fixing capability of $VCl_3(THF)$-Mg system after controlled reduction of $VCl_3(THF)_3$ with limited amount of Mg under argon.

$TiCl_3(THF)_3$-Mg and $VCl_3(THF)_3$-Mg systems react with molecular hydrogen with the similar color change of the systems to the reduction under nitrogen or argon. The reactivity of the $TiCl_3(THF)_3$-Mg system was higher than that of the $VCl_3(THF)_3$-Mg system: The $TiCl_3(THF)_3$-Mg system absorbed 2.7 mol of H_2 per titanium in 18 hr whereas the latter system absorbed the same amount of hydrogen per vanadium in 3 weeks. The addition of hydrogen gas to the nitrogen gas competitively inhibits the nitrogen fixation: in an experiment with a 1 : 1 mixture of N_2 and H_2 2.6 mol of the gas was absorbed but only 0.25 mol of N_2 was fixed per titanium without formation of NH_3 in the gas phase.

The $TiCl_3(THF)_3$-Mg system reacted with propylene, absorbing 1.6 mol of propylene per titanium in 40 hr at room temperature and atmospheric pressure. Formation of propylene dimers including 2-methylpentane, 1-hexene and 2-hexene in a ratio of 4 : 2 : 1 was confirmed by gas chromatography. Under similar conditions the system absorbed 4 mol of ethylene in 15 hr yielding mainly ethane along with 1-butene, *n*-butane, and other hydrocarbons.

Separations of Low Valent Titanium and Vanadium Complexes. (i) Titanium Complexes: From the reaction system containing $TiCl_3(THF)_3$, magnesium and molecular nitrogen, a titanium complex containing nitrogen was isolated. After the system absorbed 0.5 mol of N_2 per titanium consuming 2.5 g-atoms of magnesium with the color change from blue through green to black, unreacted magnesium was removed and black benzene soluble diamagnetic powder of a composition $[TiNMg_2Cl_2(THF)]$ (**1**) was separated from benzene-insoluble crystals of $MgCl_2(THF)_2$. Complex **1** and other titanium or vanadium complexes to be described later were not obtained as crystals and we can not claim that they are unequivocally pure. However, they were homogeneous as far as one can judge from column chromatography of the THF solutions using sucrose, $MgCO_3$ or Na_2CO_3 and from the analytical data which always gave the same compositions. The titanium complex **1** contained a small amount of titanium hydride as detected by evolution of hydrogen on reaction of **1** with iodine. Complexes **1** gave one mole of ammonia per titanium on reactions with water and ethanol. The reaction of **1** with dry hydrogen chloride proceeded as follows:

$$[TiNMg_2Cl_2(THF)] + 6HCl \xrightarrow[THF]{} NH_4Cl + TiCl_3(THF)_3 + 2MgCl_2(THF)_2 + H_2$$

4) A. Yamamoto, M. Murai, N. Oshima, and S. Ikeda, unpublished.

The nitrogen bound in complex **1** can not be removed readily except by treatment with protic reagents. On heating the complex at 200°C no dinitrogen was released. The gas evolved by the thermal decomposition of the complex contained THF as the main decomposition product together with 1-butene, 2-butene, ethylene, propylene, ethane, butane and hydrogen which may be generated by decomposition of THF bound in complex **1**. The pyrolysis residue contained still 1 atom of nitrogen per titanium and some THF.

In order to find how nitrogen is bound in the complex, the following reactions of **1** were carried out. A part of magnesium contained in **1** was removed on reaction of **1** with pyridine yielding $MgCl_2(Py)_2$ and a black complex with a composition of $[TiNMgCl_{0.5}(THF)]$. The complex obtained by the reaction of **1** with pyridine released one mole of ammonia per titanium on hydrolysis.

A part of magnesium in **1** was removed also as a zerovalent complex with addition of 2,2′-dipyridyl. On reaction of **1** with 2,2′-dipyridyl in THF, reddish purple crystals which are soluble in THF were obtained and identified as $Mg(dipy)_3$ by elemental analysis. After the removal of $Mg(dipy)_3$, a THF-insoluble residue with a composition of $[TiNMg_{1.5}Cl_2(dipy)_{1.5}(THF)]$ remained. Further removal of magnesium from this residue by reaction with pyridine gave $MgCl_2(Py)_2$ and a black powder with a composition of $[TiNMgCl(Py)_2]$. THF in **1** was not replaced by a soft base such as triphenylphosphine.

Complete removal of magnesium component from **1** was achieved by using benzoyl chloride in THF. The reaction yielded $MgCl_2(THF)_2$, some polymer of THF and a dark green substance with an approximate composition of $[TiNCl(C_6H_5CO)_{1.5}]$. The polymer of THF is considered to be formed by cationic polymerization. The mode of combination of benzoyl chloride component with titanium was not clear. In none of the complexes which were obtained by various treatments of **1** the decrease of the nitrogen to titanium ratio was observed.

Complex **1** dissolved in THF showed no reactivity toward nitrogen but still reacted with hydrogen in the presence of magnesium. The system slowly absorbed hydrogen and the reaction continued as long as excess magnesium was present. From the system excess magnesium and a gray powder which are insoluble in THF were separated. The gray powder released hydrogen on reaction with iodine and probably contains magnesium hydride beside unreacted magnesium. As described in the preparation of **1**, $MgCl_2(THF)_2$ was separated from the system and a black powder of a composition of $[TiH_2NMg_3Cl_{1.5}(THF)_2]$ (**2**) was isolated. The reaction of iodine with **2** released one mole of H_2 per titanium. The nitrogen in **2** is still bonded with titanium after the reaction of **1** with hydrogen as revealed by the formation of 1 mol of ammonia and of ammonium chloride respectively on reactions of **2** with water and hydrogen chloride.

(ii) Vanadium Complexes. *a. Under Nitrogen:* In a similar manner to the $TiCl_3$–Mg system, $VCl_3(THF)_3$ was reduced in THF with magnesium under nitrogen. The color of the THF solution changed from red through green to black. $MgCl_2(THF)_2$ and a vanadium complex of a composition $[VNMg_2Cl_2(THF)]$ (**3**), were separated from the system. Complex **3**, diamagnetic ($\chi = 0.0113 \times 10^{-6}\ g^{-1}$) and very sensitive to air, gave 1 mol of ammonia per vanadium on hydrolysis. On iodolysis **3** released 0.026 mol of H_2 per vanadium thus showing the presence of a small amount of hydride ingredient as in titanium complex **1**. Thermal decomposition of **3** over 200°C for 10 hr released no nitrogen but hydrogen together with THF, 1-butene, *n*-butane, *trans*- and *cis*-2-butenes, propylene, ethylene, ethane, and methane were detected in the gas evolved. These products may be formed by decomposition of THF in **3**. The pyrolysis residue still contained nitrogen as proved by the formation of 1 mol of ammonia per vanadium on hydrolysis of the residue.

b. Under Argon: From the $VCl_3(THF)_3$–Mg system reacted under argon a diamagnetic vanadium complex of composition $[VHMg_2Cl_{1.5}(THF)]$ (**4**) and $MgCl_2(THF)_2$ were separated. The presence of hydride was deduced from the amount of H_2 produced on iodolysis of **4**. The IR spectrum of **4** was very similar to that of **3** and no band ascribable to ν(V–H) was detected.

c. Under Hydrogen: When $VCl_3(THF)_3$ was reduced with magnesium in THF under hydrogen at ambient temperature and pressure, the system absorbed hydrogen slowly but steadily over a long period; 3.5mol of H_2 was absorbed per mol of the vanadium complex in 35 days. The diamagnetic vanadium complex separated from the system has the composition of $[VH_2MgCl(THF)_2]$ (**5**). The amount of hydridic hydrogen in the complex was deduced from the amount of hydrogen produced on iodolysis.

Chemical Properties of $[VNMg_2Cl_2(THF)]$ ***3***. In order to examine the properties of **3**, the following reactions of **3** were carried out. Complex **3** dissolved in THF reacted in the presence of magnesium with hydrogen at room temperature and atmospheric pressure. The reaction proceeded slowly but steadily as long excess magnesium was present. More than 10 mol of H_2 per the vanadium complex was absorbed in a month. From the system black powder with a composition of $[VN(H)_2Mg_5Cl_2(THF)_2]$ (**6**) and magnesium hydride were separated.

Complex **3** as well as other vanadium complexes prepared under argon and hydrogen reacts with ethylene forming ethane. In the presence of hydrogen complex **3** catalyzes the hydrogenation of ethylene. The formation of amine was not detected.

Complex **3** reacted with various organic halides. The reaction of benzyl chloride with **3** took place with evolution of heat, and $MgCl_2(THF)_2$, dibenzyl, and a vanadium complex with a composition of $[VNMgCl_{1.5}(THF)]$ were formed. By the reaction of **3** with chlorotriphenylmethane, a part of magnesium in **3** was removed as $MgCl_2(THF)_2$ and a black complex of a composition $[VNMgCl_2(THF)]$ was obtained. A similar reaction with methyl iodide released 0.5 mol of methane per vanadium with partial removal of

magnesium chloride from **3**. A part of magnesium in **3** was also removed as magnesium chloride on reaction with benzoyl chloride accompanied by the formation of a polymer of THF.

Discussion

Comparison of the reductions of $TiCl_3(THF)_3$ and $VCl_3(THF)_3$ with magnesium under nitrogen, argon, and hydrogen clearly indicates the striking similarity of the two systems belonging to the IVth and Vth groups in the periodic table. The stoichiometries of the N_2-fixation reactions given by Eqs. (2) and (3) are satisfactorily substantiated from the analyses of the products as well as from kinetic studies. Clearly the induction periods observed in the nitrogen fixation with these systems are due to the one electron reductions of $TiCl_3(THF)_3$ and $VCl_3(THF)_3$ with 0.5 g-atom of Mg accompanied by the formation of 0.5 mol of $MgCl_2$. Similar induction period has been reported in the nitrogen fixation by $VCl_3(THF)_3$–lithium naphthalide system.[5] Examination of the visible spectrum of the $VCl_3(THF)_3$–Mg system after the one electron reduction revealed the formation of a divalent vanadium species as shown by the presence of absorption maxima at 410 and 650 nm which can be compared with the spectrum of known $VCl_2(THF)_2$ at 407 and 643 nm.[6] Similarly the absorption band at 380 nm observed in the induction period of the N_2-fixing $TiCl_3$–Mg system may be due to the divalent titanium species. Accompanying the change of the electronic spectrum the ESR spectrum of the $VCl_3(THF)_3$–Mg system changed with increasing amount of magnesium added to the system. Vanadium having the nuclear spin of 7/2 gives 8 hyperfine splittings but the shape of the ESR spectrum changed depending on the amount of Mg consumed. The ultimate reduction products of VCl_3–Mg system which consumed 2.5 g-atoms of magnesium per vanadium were diamagnetic and showed no ESR absorption. The ESR spectra of the intermediate reduction products prepared under nitrogen and argon were identical. The ultimate oxidation states of titanium and vanadium complexes after absorption of 2.5 g-atoms of Mg (**1** and **3**) are difficult to assign, since the magnesium contained in the complexes can be removed by reactions with organic nitrogen bases as Mg(II) in one case and as Mg(0) in the other, although the diamagnetism of **1** and **3** suggests Ti(0) and V(I) as the formal oxidation states. Some ESR studies on VCl_3–alkali naphthalide system have been reported.[5,7]

From the kinetics of nitrogen fixation by $TiCl_3$–Mg system, the initial rate of nitrogen absorption after the induction period was shown to be first order with respect to the amounts of $TiCl_3$, of Mg and the pressure of nitrogen, whereas the stoichiometry of the nitrogen fixation (Eq. 2) shows that half a molecule of nitrogen combines with mole of titanium and vanadium. As a reasonable explanation compatible with these results we assume a dimeric titanium or vanadium species which combines with molecular nitrogen and the N_2 complex thus formed is further reduced reacting with magnesium in the succeeding rate determining step:

$$[M]_2 + N_2 \rightleftarrows [MN_2M] \quad (4)$$
$$M = Ti, V$$

$$[MN_2M] \xrightarrow{Mg} [MN_2M] \xrightarrow{3Mg} M_2N_2Mg_4Cl_4(THF)_2$$
$$\vdots$$
$$Mg$$

$$\text{or } MNMg_2Cl_2(THF) \quad (5)$$

As the N_2-binding species, divalent and univalent transition metal may be considered but the latter appears to be less probable. The experiment shown in Fig. 8 indicates that VCl_3–Mg which reacted with 1.0 g-atom of Mg per vanadium under argon has the N_2-fixing ability of about 70%. This system would be expected to show the full N_2-fixing ability if V(I) formed by stepwise reduction of V(III) should be responsible as the N_2-binding species.

Therefore we propose the divalent vanadium and titanium compounds as the N_2 binding species. Negligible absorption of nitrogen in the divalent state of vanadium and titanium at room temperature and normal pressure may be understood if the equilibrium (4) is on the side of dissociation. Recent isolations of titanium[8–10] and molybdenum[11] complexes with N_2, as the bridging ligand between two metal atoms, lend support to the assumption. We are presently investigating the possibility of identifying the species with a composition $[Ti(II)\cdot N_2\cdot Ti(II)]$ or $[V(II)\cdot N_2\cdot V(II)]$. We do not have at present any information about the state of aggregation of the divalent titanium and vanadium species to combine with nitrogen but $TiCl_3(THF)_3$ is reported to be dimeric.[12]

Alternative pathway to the above mechanism is that a monomeric species combines with N_2 followed by a rapid combination with another monomeric species forming a bridged N_2 complex. Van Tamelen presented evidence to indicate the formation of TiN_2 type complex.[2h,13]

The linear relationship between the amount of magnesium consumed and the amount of N_2 fixed (Fig. 7) suggests that stepwise change of the oxidation states of titanium and vanadium is not involved during the consumption of Mg between 0.5 and 2.0 g-atoms in the titanium system and between 0.5 and 2.5 g-atom in the vanadium system. Probably the reaction of

magnesium with the previously assumed N_2-bridged species (Eq. 5) is irreversible and once the nitrogen is partially reduced in the titanium or vanadium complex, further reaction with magnesium would take place preferentially with the nitrogen bound, partially reduced species, leaving the other species the full capacity to combine with molecular nitrogen. This assumption is supported by Fig. 3 which shows much faster rate of Mg consumption under nitrogen than under argon and by Fig. 8 which demonstrates that the system reacted with 1.5 g-atoms of Mg under argon still shows considerable capacity to combine with nitrogen.

When $TiCl_3(THF)_3$ was reduced with sodium amalgam under nitrogen, the system became heterogeneous when 2.7 equivalents of Na was consumed with the N_2 fixation of 0.35 mol per titanium. In a similar experiment with $VCl_3(THF)_3$ using 5 equivalents of sodium amalgam per vanadium the fixation of nitrogen after 1 day was almost negligible. These results show the suitability of magnesium in the N_2 fixation and suggest its particular role in the reduction of the combined nitrogen.

The mode of combination of magnesium with titanium or vanadium presents a difficult problem to explain. The magnesium content in the benzene-soluble vanadium complexes **3**—**6** varies depending on the preparative conditions and magnesium in $[TiNMg_2Cl_2(THF)]$ **1** can be removed either in zerovalent or in divalent state as described earlier. Magnesium is supposed in these complexes to be present in the vicinity of titanium or vanadium and of chlorine, and can be driven in different ways depending on the reagent to attack magnesium. It is clear that the nitrogen in these complexes is not present in the form of magnesium nitride since the removal of magnesium takes place leaving the nitrogen in the complexes intact.

Evidently the nitrogen in the complexes is bound with titanium or vanadium but we can not conclude from the available data whether it is in the form of nitride or exists as the bridging ligand. The absence of the N_2 stretch band in the IR spectrum above 1600 cm^{-1} excludes the possibility of the presence of N_2 ligand as in later transition metal-N_2 complexes.[2] No distinct band assignable to metal-nitride stretch was observed above 400 cm^{-1} and the possibility of N_2-bridged binuclear structure with low N-N bond order can not be excluded, although the failure of detection of hydrazine after hydrolysis of the nitrogen-containing complexes favors the nitride structure.

Tetrahydrofuran in complexes **1**—**6** appears to be bonded with titanium or vanadium. Symmetric and antisymmetric stretching bands of C-O-C bond of THF were observed at 860 and 1015 cm^{-1} for titanium complex **1** and at 875 and 1026 cm^{-1} for vanadium complex **3** in comparison with those of free THF at 910 and 1075 cm^{-1} and of $MgCl_2(THF)_2$ at 890 and 1040 cm^{-1}. The tetrahydrofuran is bonded with titanium very strongly in complex **1** and thermal decomposition of **1** at 200°C could not remove all THF in the complex and the decomposition was accompanied by partial decomposition of the THF ligand whereas THF in $MgCl_2(THF)_2$ was easily removed.

The presence of a small amount of hydridic hydrogen in complexes **1** and **3** and of one hydridic hydrogen in complex **4** prepared under argon should be explained by hydrogen abstraction from THF by titanium or vanadium. This result may be understood as the indication of the reactivity of the low valent vanadium and titanium complexes toward hydrogen in the absence of nitrogen.

The high reactivities of the low valent titanium and vanadium complexes are reflected in their reactions with various reagents. The reactions with organic halides may probably proceed through oxidative addition reactions which yield unstable transition metal-alkyl complexes. The formations of dibenzyl in the reaction of benzyl chloride and of methane in the reaction of methyl iodide with **3** support the above assumption.

The catalytic activities of the low valent complexes in the dimerization and hydrogenation of olefins may be understood by assuming titanium and vanadium hydrides as the active species which can be formed by the reaction with molecular hydrogen and also by hydrogen abstraction from THF.

The $TiCl_3$-Mg and VCl_3-Mg systems described here react with molecular nitrogen and hydrogen respectively but no ammonia was formed in the presence of both reactants except after hydrolysis. Previously we considered necessary conditions for ammonia synthesis from N_2 and H_2 by a transition metal complex to proceed including the activation of N_2 and H_2 and transfer of hydrogen from the activated hydrogen to nitrogen.[14] The present systems are capable to activate both N_2 and H_2 but apparently the conditions for hydrogen transfer to occur are not fulfilled. Interestingly complexes **1** and **3** containing nitrogen catalyze the hydrogenation of magnesium to magnesium hydride. Complex **1** or **3** containing reduced nitrogen reacts with hydrogen forming a titanium hydride or vanadium hydride complex but the hydride formed is passed to magnesium, not to nitrogen, giving magnesium hydride despite the high reactivity of the bound nitrogen toward protonic reagents. Apparently the bound nitrogen in the complex has anionic nature and so does the hydride formed by the reactions of titanium or vanadium complex with molecular hydrogen, thus the hydrogen transfer of the hydride to the bound nitrogen may be hindered. Finding a proper method to make this hydrogen transfer possible seems a key problem for the catalytic formation of NH_3 from N_2 and H_2 to proceed under mild conditions.

Experimental

Materials. Titanium trichloride was used by dissolving in THF or after conversion to $TiCl_3(THF)_3$ by refluxing in THF for several hours and then purifying by recrystallization from THF.

Found: C, 39.2; H, 6.6; Cl, 28.0; Ti, 13.2% μ_{eff} 1.91 B. M. Calcd for $C_{12}H_{24}O_3Cl_3Ti$: C, 38.9; H, 6.5; Cl, 28.7; Ti, 12.9%.

14) A. Yamamoto, S. Kitazume, L. S. Pu, and S. Ikeda, *ibid.*, **93**, 371 (1971).

Vanadium trichloride was always used as $VCl_3(THF)_3$. VCl_3 which was prepared by the reaction of V_2O_5 with S_2Cl_2[15] was converted to the THF adduct which was purified by recrystallization from THF.

Found: C, 37.7; H, 6.2; Cl, 28.0; V, 13.9% μ_{eff}, 2.95. B. M. Calcd for $C_{12}H_{24}O_3Cl_3V$: C, 38.6; H, 6.5; Cl, 28.5; V, 13.9%.

Nitrogen, hydrogen, and argon gases were dried and deoxygenated by passing through columns of $CaCl_2$, P_2O_5, and activated copper. Solvents were dried by usual methods and deoxygenated by distillation under nitrogen or argon. Granular or powder magnesium was used; in some experiments granular magnesium was pretreated with iodine and washed with THF. Sodium amalgam was prepared by the reaction of sodium with mercury in Nujol; the sodium content was 0.2%.

Analytical Methods. Analysis of Ti, V, Mg, and Cl was carried out after hydrolysis of a sample (0.1—0.6 g) with 20% sulfuric acid. Titanium was precipitated by Cupferron (nitrosophenylhydroxylamine) and determined as TiO_2 by gravimetric method. Vanadium was determined in a similar method as V_2O_5. Magnesium was analyzed after removal of titanium or vanadium component from the sample by titration with ethylenediaminetetracetic acid. Chlorine content was determined by Mohr method with silver nitrate. The amount of nitrogen fixed by the complex was determined by Kjeldahl method and referred to as N* in analytical data to distinguish when necessary from the amount of total nitrogen content N obtained by microanalysis. The microanalysis was performed by Mr. T. Saito of our laboratory.

The amount of coordinated THF in complexes was determined by displacing the coordinated THF with 2,2'-dipyridyl and by analyzing the liberated THF by gas chromatography. This method is not quite quantitative but can be used as a measure to estimate the number of the coordinated THF approximately. In the case of $TiCl_2(acac)(THF)_2$[4] we have confirmed that 85% of THF for the theoretical value was released.

Because the complexes obtained are very air-sensitive, considerable difficulties were encountered in analysis. Furthermore, since the amount of THF contained in complexes varied, the absolute percentage of the analytical data can not be regarded as the criteria for purity. Therefore the empirical composition based on the ratio of atoms and THF in the complexes will be given below in most places.

IR spectra were recorded in KBr discs with Hitachi EPI-G3 and Shimadzu IR 27C spectrophotometers. Electronic spectrum was measured with a Shimadzu SV-50 spectrophotometer and ESR spectra was recorded on a Jeolco JES 3B-X.

Kinetic Studies. Kinetics studies were carried out using a 1-liter glass flask with a magnetic stirrer in a thermostatted bath regulated within 0.1°C. $TiCl_3$ was added to 100 m*l* of THF containing Mg and the time was measured from the point of addition. Previous dissolution of $TiCl_3$ somewhat shortened the induction period but no change in the essential feature of the N_2 absorption rate was observed. The absorption rate was followed by a gas flow meter, keeping the pressure constant by an oil seal and removing the moisture of the flowing gas by passing through a P_2O_5 column. The reaction with argon diluent was carried out as follows; after all the reagents were introduced into the reactor under argon, the pressure of argon was adjusted to a given pressure and N_2 was introduced. The reaction was terminated by removing the gas and solvent *in vacuo*. The amount of nitrogen fixed was determined as ammonia after hydrolysis with sulfuric acid and the amount of magnesium consumed was measured by weighing the unreacted magnesium which was separated from the solution, washed with THF and dried *in vacuo*.

Isolation and Reactions of Complexes. Since the complexes were isolated in a similar way some typical examples will be given.

1. [*$TiNMg_2Cl_2(THF)$*] **1**: $TiCl_3(THF)_3$ (18 g, 50 mmol) was dissolved in 150 m*l* of THF under nitrogen and the solution was added to 12 g of magnesium. The color of the solution changed slowly from blue through green to black with evolution of heat and absorption of N_2 which was measured by a gas burette. The absorption of N_2 stopped after several hours but the contact of the solution with nitrogen was continued for 24 hr to complete the reaction. The total amount of nitrogen absorbed was 0.5 mol per titanium. Unreacted magnesium was separated by filtration and the black THF solution was evaporated to dryness at room temperature. The residue was extracted with benzene *in vacuo* until no benzene-soluble dark substance remained. The white residue (5.7 g) was recrystallized from THF-hexane mixture as white needles. The benzene soluble fraction was dissolved again in THF and precipitated by addition of a controlled amount of hexane. The dark precipitate thus obtained was dried *in vacuo* to yield black very air-sensitive powder (11.2 g).

The white needles readily lose THF on drying and the amount of THF varied depending on the extent of drying. The ratio of magnesium to chlorine of the powder obtained on drying the crystals was 1 : 1.94, thus indicating the compound as $MgCl_2$ probably coordinated with 2 mol of THF in the crystalline state.

The benzene soluble fraction obtained as black powder analyzed as follows: Ti, 18.3; Mg, 17.6; Cl, 23.8; N, 4.7; THF, 24.5; C, 21.6; H, 4.5%. The empirical composition based on the ratio of atoms and THF: $TiMg_{1.9}Cl_{1.8}N_{0.94}(THF)_{0.89}$.

Reactions of **1** *a. Iodolysis* of this complex (0.32 g) released 1.89 m*l* at STP of H_2 which was measured by a Toepler pump and identified by mass spectrometry. The amount of H_2 evolved corresponded to 6.34% per titanium.

b. With HCl: **1** dissolved in THF (0.439 g, 1.67 mmol as calculated from the Ti content) reacted with dry hydrogen chloride consuming 10.07 mmol (6.02 mmol/Ti) and evolved 1.26 mmol (0.76 mol/Ti) of H_2.

c. With Pyridine: The reaction of **1** (2.3 g) in 100 m*l* of THF with pyridine (13.2 g) caused the precipitation of a black substance. Extraction of the system with THF and recrystallization from THF gave colorless crystals.

Found: C, 47.4; H, 4.0; N, 10.8; Cl, 28.3; Mg, 9.65%. Calcd for $MgCl_2(C_5H_5N)_2$: C, 47.4; H, 4.0; N, 11.1; Cl, 28.1; Mg. 9.60%.

Analysis of the black precipitate purified by repeated reprecipitation from pyridine-THF-hexane mixture: Ti, 22.7; Mg, 13.6; Cl, 8.62; N*, 6.31. Empirical composition: $TiMg_{1.2}CI_{0.5}N^*_{0.95}$

d. With 2,2'-Dipyridyl: Addition of THF solution of dipyridyl (20 g) to the black THF solution containing 5.2 g of **1** caused the color change to reddish violet and a precipitate was formed. Extraction of a THF soluble fraction from the system gave dark reddish violet crystals which are very sensitive to air.

Found: Mg, 4.6; C, 69.5; H, 5.7; N, 15.9%; Atomic ratio: Mg, 1.0; C, 30; H, 26; N, 6.0.

The THF insoluble fraction could not be purified because of the lack of appropriate solvent.

15) H. Funk and C. Muller, *Z. Anorg. Allg. Chem.*, **244**, 94 (1940).

Found: Ti, 9.9; Mg, 7.2; Cl, 13.9; N*, 2.9; C, 46.7; H, 4.8; N, 10.4%. Empirical formula: $TiMg_{1.4}Cl_{1.9}M^*_{1.0}C_{19}H_{23}(N\text{-}N^*)_{2.6}$.

Reaction of the THF-insoluble fraction with pyridine gave homogeneous black solutiom. Addition of THF formed the black precipitate which was separated from the solution and analyzed after reprecipitation from pyridine-THF mixture.

Found: Ti, 17.6; Mg, 0.87; Cl, 10.1; N*, 4.4; C, 36.4; H, 3.7; (N-N*), 9.2%. Empirical formula: $TiMg_{0.87}Cl_{0.78}N^*_{0.86}C_{8.3}H_{10}(N\text{-}N^*)_{1.8}$. From the solution white crystals of $MgCl_2(C_2H_5N)_2$ were isolated.

e. With Benzoyl Chloride: $[TiNMg_2Cl_2(THF)]$ **1** (2.1 g, 8.2 mmol) was dissolved in 50 m*l* of THF and a THF solution containing 3.5 g of benzoyl chloride was added at room temperature. The black solution turned dark green with addition of benzoyl chloride. On cooling the mixture with addition of *n*-hexane colorless plates of $MgCl_2(THF)_2$ separated out. After removal of the white crystals, all the titanium complex was precipitated with addition of *n*-hexane and the precipitate was washed to remove excess benzoyl chloride. The precipitate was extracted with benzene, purified and analyzed as usual.

Found: Ti, 17.6; Cl, 10.9; N*, 4.89; C, 48.5; H, 4.0%. Empirical formula: $TiCl_{0.84}N_{0.95}C_{11}H_4$.

f. With Hydrogen and Magnesium: Complex **1** (2.35 g, 9.2 mmol) dissolved in THF (50 m*l*) was put in contact with 2.3 g of magnesium under hydrogen at room temperature. The system absorbed 3.33 mol of H_2/Ti in 90 hr and still showed ability to react with hydrogen. From the system black powder was separated as the benzene-soluble fraction.

Found: Ti, 13.0; N*, 3.4; Mg, 26.6; Cl, 14.6; C, 25.0 H, 5.0; N, 3.8%. Iodolysis of the powder 0.1164 g (0.318 mmol based on Ti content) in benzene gave 0.318 mmol of H_2 (98.5% based on Ti content). Empirical formula: $TiN_{1.0}(H)_2Mg_{4.0}Cl_{1.5}C_{7.7}H_{16}$(**2**).

2. Preparation of Vanadium Complexes. 2.1 Under Nitrogen: Complex **3** was prepared in a similar way to titanium complex **1** from 28.7 g (75.9 mmol) of $VCl_3(THF)_3$ in 200 m*l* of THF and 18.7 g (0.77 mol) of Mg under nitrogen. The absorption of nitrogen took 15—20 hr at room temperature and the color of the solution turned from red through green to black.

Found: V, 17.5; Mg, 15.9; Cl, 25.5; N, 4.9; C, 21.5; H, 3.8%. Empirical formula: $VMg_{2.1}Cl_{2.1}N_{1.0}C_{5.2}H_{11.0}$. Iodolysis of the complex, 0.311 g, released 0.615 m*l* of H_2 which corresponded to 2.75 mol% of vanadium.

2.2 Under Argon: $VCl_3(THF)_3$ (17.3 g, 46.3 mmol) in 150 m*l* of THF was reduced under argon with 11.4 g (0.47 mol) of magnesium at room temperature. After the reaction for 3 days with the color change of the solution as observed in the reaction under nitrogen, the argon was replaced with nitrogen but no absorption was observed. $MgCl_2(THF)_2$ and benzene-soluble black powder were separated.

Found: V, 20.4; Mg, 18.5; Cl, 21.3; C, 25.6; H, 4.4%. Empirical formula: $VH_{0.6}Mg_{1.9}Cl_{1.5}C_{5.3}H_{10.0}$. Iodolysis of the complex 0.258 g (1.03 mmol) gave 0.303 mol of hydrogen per vanadium.

2.3 Under Hydrogen: $VCl_3(THF)_3$ (22.6 g, 60.4 mmol) dissolved in 200 m*l* of THF was stirred with 29.2 g of Mg under hydrogen at room temperature for 1 month and the system absorbed 3.5 mol of hydrogen per vanaduim. Magnesium chloride and benzene soluble black powder were separated.

Found: V, 19.6; Mg, 17.8; Cl, 11.6; C, 32.8; H, 6.2%. Empirical formula: $V(H)_{1.8}Mg_{1.9}Cl_{0.81}C_{7.1}H_{14.2}$. Hydride content was determined by iodolysis which relaesed 0.90 mol of H_2 per vanadium.

Reaction of **3**. *a. With Hydrogen and Magnesium*: Complex **3** (2.8 g, 9.7 mmol) was dissolved in 80 m*l* of THF and stirred with 4.7 g (0.19 mol) of magnesium at room temperature under hydrogen. The solution absorbed 10 mol of H_2 per vanadium in 40 days. Black powder was recovered from the solution.

Found: V, 11.6; Mg, 28.6; Cl, 16.8; N, 3.0; C, 21.6; H, 4.2%. Empirical formula: $V(H)_{1.9}Mg_{5.2}Cl_{2.1}N_{0.94}C_{7.9}H_{18.5}$. Hydride content was determined by iodolysis which released 0.95 mol of H_2 per vanadium.

b. With Benzyl Chloride: Benzyl chloride 4.8 g (38 mmol) in THF (80 m*l*) was added to **3**(3.7 g, 12.7 mmol) and the reaction took place with evolution of heat. The solution was evaporated to dryness, washed with *n*-hexane and ether, and extracted with benzene. In the ether washing the presence of dibenzyl, mp 51—53.5°C, was detected and identified by comparison of the IR spectrum with authentic sample. As the benzene insoluble residue magnesium dichloride remained and from the benzene extract a nitrogen containing vanadium complex was recovered.

Found: V, 23.2; Mg, 8.8; Cl, 19.3; N, 5.9; C, 27.8; H, 4.6%. Empirical formula: $VMg_{0.79}Cl_{1.2}N_{0.92}C_{5.1}H_{10.1}$. The IR spectrum of this complex was similar to that of **3**.

c. With Chlorotriphenylmethane: Reaction of **3** (4.2 g, 14.4 mmol) with chlorotriphenylmethane (9.4 g, 33.6 mmol) in 60 m*l* of THF took place with evolution of heat and a black benzene soluble powder with a similar IR spectrum to **3** was obtained.

Found: V, 18.4; Mg, 10.3; Cl, 24.6; N, 4.7; C, 22.3; H, 4.1%. Empirical formula: $VMg_{1.1}Cl_{1.9}N_{0.93}C_{5.1}H_{11.4}$. White benzene insoluble crystals were identified as magnesium chloride.

d. With Methyl Iodide: A THF solution containing 8.6 g (60.5 mmol) of methyl iodide was added to 4.5 g (15.5 mmol) of **3**. Reaction took place with evolution of gas. As the benzene soluble powder a vanadium complex was obtained.

Found: V, 18.1; Mg, 15.7; Cl, 23.6; N, 4.8; C, 21.6; H, 3.9%. Empirical Formulas: $VMg_{1.8}Cl_{1.9}N_{0.96}C_{5.2}H_{10.9}$. The IR spectrum of the complex was similar to **3**. By an independent experiment the gas evolved was identified as methane (0.5 mol/V) and traces of ethane and ethylene by mass spectroscopy and gas chromatography.

Kinetics of Liquid-phase Hydrogenation of Aliphatic α,β-Unsaturated Aldehyde over Raney Cobalt Catalyst Modified with Co-, Mn-, Ni-, and $PdCl_2$

Kazuhiko HOTTA and Teruo KUBOMATSU

The Osaka Municipal Technical Research Institute, Kita-ku, Osaka

(Received May 4, 1971)

Kinetic studies were carried out on the hydrogenation of the α,β-unsaturated aldehyde, 2-methyl-2-pentenal (UD), over the Raney cobalt catalyst modified with various amounts of Co-, Mn-, Ni- and $PdCl_2$ in *n*-hexane under atmospheric pressure at 40 and 20°C. Initial rates of formation of the saturated aldehyde (r_{SD}), saturated alcohol(r_{SA}) and unsaturated alcohol(r_{UA}) were determined in the concentration range of UD(C_{UD}) 0.018—0.263 mol/*l*. It was found that ($r_{SD}+r_{SA}$) obeyed a Langmuir-type rate equation and r_{UA} a different one. The rate equations are as follows.

$$r_{SD} + r_{SA} = \frac{k_1 \cdot b_1 \cdot C_{UD}}{(1+b_1 \cdot C_{UD})^2}, \qquad r_{UA} = \frac{k_2 \cdot b_2 \cdot C_{UD}}{(1+b_2 \cdot C_{UD})^2}$$

where k and b denote the rate constant of the surface reaction and parameter for the adsorption of UD and hydrogen, respectively, the subscripts 1 and 2 representing the formation of SA and SD and that of UA, respectively. Kinetic parameters k_1, k_2, b_1 and b_2 were found to vary with the amount and kind of modifier. The variation of b_1 and b_2 was irregular. The rate constant k_1 decreased with increasing amount of Co-, Mn- and $NiCl_2$ added; it increased remarkably with the addition of $PdCl_2$. The variation of k_2 was more complicated. Addition of a small amount of the modifiers did not decrease k_2. Further addition of Co- and $MnCl_2$ made k_2 decrease, while that of $NiCl_2$ made it increase. Mechanism of the modification with these metal chlorides is discussed on the basis of the active site hypothesis.

In the course of studies on selectivities of Raney-type catalysts modified with various compounds in the liquid phase hydrogenation of the α,β-unstaturated aldehyde, we have found that the formation of the saturated aldehyde and alcohol over the Raney cobalt catalyst was inhibited by the addition of $FeCl_2$ and that of the unsaturated alcohol was retarded only slightly.[1]

Kishida *et al.* have studied the modifier effect of some organic compounds in the liquid phase hydrogenation of acetone over the Raney nickel catalyst and found that the addition of tripropylamine decreased the rate of hydrogenation at low concentrations of acetone but increased at high concentrations.[2] The effect of the modifier depends on the concentration of the reactant at which the rate measurement was carried out.

Thus in studying the modifier effect on a solid catalyst, it is advisable to determine the kinetic parameters for the adsorption of reactants and for surface reaction, both being independent of the concentration of reactants, and to examine the variation of the two parameters. Such a treatment has seldom been performed on the modifier effect of metal chlorides. In the present paper, kinetics of the liquid phase hydrogenation of the α,β-unsaturated aldehyde, 2-methyl-2-pentenal, over the Raney cobalt catalyst modified with manganese(II)-, cobalt(II)-, nickel(II)- and palladium(II) chlorides are described. Variation of the rate constant and adsorption coefficient with the amount and kind of modifier is examined. Mechanism of uneven poisoning of the catalyst observed when Co- and $MnCl_2$ were added, is discussed on the basis of the active site hypothesis. The promoter effect of $PdCl_2$ on the reaction of the carbon-carbon double bond is also discussed.

Experimental Methods

Catalyst. A Raney cobalt-aluminum alloy(50 wt% Co) was developed with a sodium hydroxide solution and washed with distilled water and then with 2-propanol.[3] The catalyst thus obtained was stirred with specified amounts of anhydrous metal chlorides in 2-propanol for 1 hr in a hydrogen atmosphere. The amount of metal chlorides adsorbed was determined by measuring polarographically the amount of metal ions remaining in 2-propanol solution. It was found that these ions were completely adsorbed on the catalyst when the amount of metal chlorides added was less than 0.10 mmol/g-Co. When metal chloride of 0.15 mmol/g-Co was used, the amount of adsorbed ion was 0.14 mmol/g-Co.

It was observed that the brown color of $PdCl_2$ solution faded by stirring for a few minutes. Absorption of hydrogen was observed, and the blue color of Co(II) ion appeared and then disappeared completely by stirring for 5 min. This indicates that $PdCl_2$ is adsorbed on the catalyst and reduced to the metal according to the following equations

$$PdCl_2 + Co \longrightarrow Pd + CoCl_2$$

$$PdCl_2 + H_2 \longrightarrow Pd + 2HCl$$

and HCl formed reacts with cobalt atom to give $CoCl_2$ and $CoCl_2$ formed is also adsorbed on the catalyst surface.

The modified catalyst thus obtained was washed twice with 2-propanol and 10 times with *n*-hexane and then dried in a hydrogen atmosphere. The resulting catalyst was weighed and stored in the portion containing *ca.* 500 mg of cobalt.[3]

Apparatus, Procedure, and Materials. Hydrogenation was carried out as described previously.[3] Over the catalyst modified with $PdCl_2$, however, it was carried out at 20°C since a too rapid reaction took place at 40°C. Reaction products were analyzed by glc. Adsorbed metal chlorides were not removed during the reaction. Substrate: 2-methyl-2-pentenal, cylinder hydrogen, 2-propanol, and

Unit of initial rate: 10^{-2} mmol/min·g-Co, C_{UD}: concentration of UD.

n-hexane were the same as those described previouly. Commercial anhydrous metal chlorides of extra pure grade were used without further purification.

Determination of Initial Rate of Formation of Product. The initial rate of formation was determined by extrapolating the plot, rate of formation *vs.* reaction time, to zero.[3]

Results

Initial Rate of Formation of Product. Products of the reaction were found to be the saturated aldehyde 2-methylpentanal(SD), saturated alcohol 2-methylpentan-1-ol(SA) and unsaturated alcohol 2-methyl-2-penten-1-ol(UA). Isomerization of UA to SD, and dehydrogenation of UA to UD and of SA to SD and/or UA were not observed under the conditions studied.

Initial rates of the formation of SD(r_{SD}), SA(r_{SA}), and UA(r_{UA}) are given in Tables 1 and 2 for the catalyst modified with $CoCl_2$, abbreviated as R-Co-(Co), the one with $PdCl_2$ as R-Co(Pd), respectively. R_{UA} decreased by the addition of 0.025 mmol/g-Co of $CoCl_2$ at low concentrations of UD and increased at high concentrations. r_{UA} decreased by the further addition of the modifier. On the other hand, r_{SD} and r_{SA} decreased with increasing amount of $CoCl_2$. A similar behavior was observed for the catalyst modified with Ni- and $MnCl_2$. The behavior of the initial rates mentioned above is not contradictory to that reported by other workers.[4,5]

r_{UA} increased by the addition of 0.025 mmol/g-Co of $PdCl_2$ at low concentrations of UD and decreased at high concentrations, and decreased by the further addition of the modifier. r_{SD} increased by the addition of $PdCl_2$ more remarkably than r_{SA}.

Rate Equation and Kinetic Parameters. The data in Table 1 were analyzed by means of the equation

$$r = \frac{k \cdot b \cdot C_{UD}}{(1 + b \cdot C_{UD})^2} \quad (1)$$

where k denotes the rate constant, C_{UD} the concentration of UD, and b is the ratio of the adsorption equilibrium constant of UD to that of hydrogen, divided by the liquid phase concentration of hydrogen *i.e.* $b = K_{UD}/$

	0.10	0.091	20	0.17	14
	0.15	0.032	22	0.13	13
$NiCl_2$	0.025	0.54	15	0.38	12
	0.050	0.53	23	0.39	12
	0.10	0.44	27	0.40	12
$PdCl_2$	0.0	0.44	11	0.17	6.1
	0.025	1.4	17	0.17	20

$K_H \cdot C_H$ and called adsorption coefficient. As the rate measurement was carried out under the constant pressure of hydrogen, and the solubility of hydrogen is assumed to be independent of the composition of reaction mixture, C_H is constant at a given temperature, and b depends only on the adsorption equilibrium constants of UD and hydrogen.

Rearranging Eq. (1), we obtain: $(C_{UD}/r)^{1/2}=1/(k\cdot b)^{1/2}+(b/k)^{1/2}\cdot C_{UD}$. This gives a linear relation between $(C_{UD}/r)^{1/2}$ and C_{UD} when $(C_{UD}/(r_{SD}+r_{SD}))^{1/2}$ *vs.* C_{UD} for R-Co(Co) are plotted (Fig. 1), and $(C_{UD}/r_{UA})^{1/2}$ *vs.* C_{UD} (Fig. 2). From these plots, the values of kinetic parameters k and b were determined (Table 3). The values of the kinetic parameters for R-Co-(Mn), R-Co(Ni) and R-Co(Pd-0.025) determined similarly are also given.

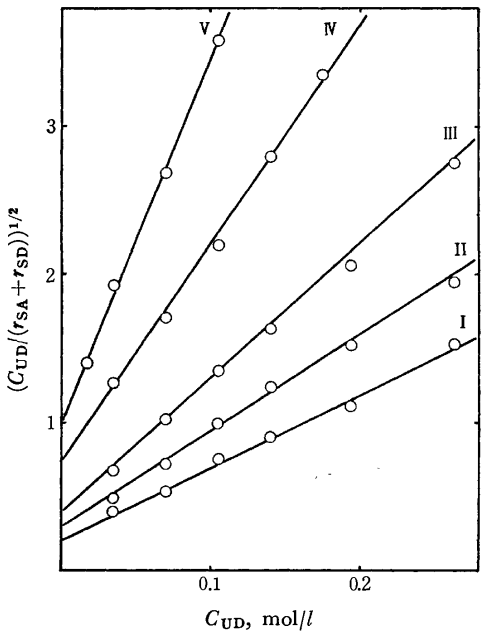

Fig. 1. $(C_{UD}/(r_{SA}+r_{SD}))^{1/2}$ *vs.* C_{UD} plots for R-Co catalyst modified with $CoCl_2$ of 0.0 mmol/g-Co, I; 0.025, II; 0.050, III; 0.10, IV; 0.15, V.

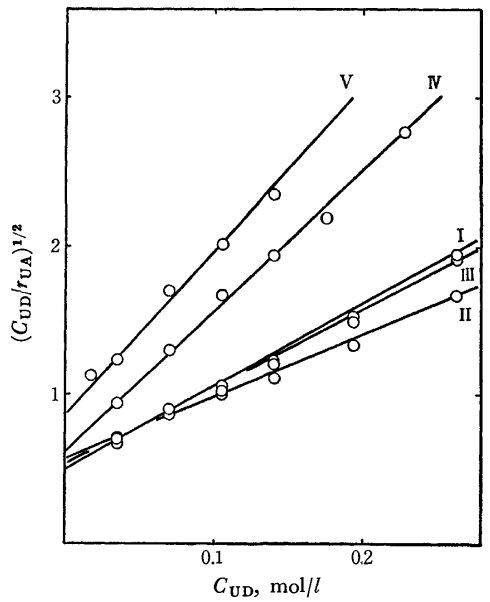

Fig. 2. $(C_{UD}/r_{UA})^{1/2}$ *vs.* C_{UD} plots.

The rate data over R-Co(Pd-0.050 and 0.10) were not analyzed by the same method since SA was supposed to be formed through both SD and UA. Variation of the values of b_1 and b_2 is irregular (Table 3). Variation of the rate constant with the amount of metal chlorides is shown in Fig. 3. The rate constant for the formation of SA and SD (k_1) decreases with increasing amount of Co-, Mn- and $NiCl_2$, but it increases with the addition of $PdCl_2$.

Addition of a small amount of these modifiers does not decrease the rate constant for the formation of UA (k_2). Further addition of Co- and $MnCl_2$ decreases k_2, while that of $NiCl_2$ makes it increase.

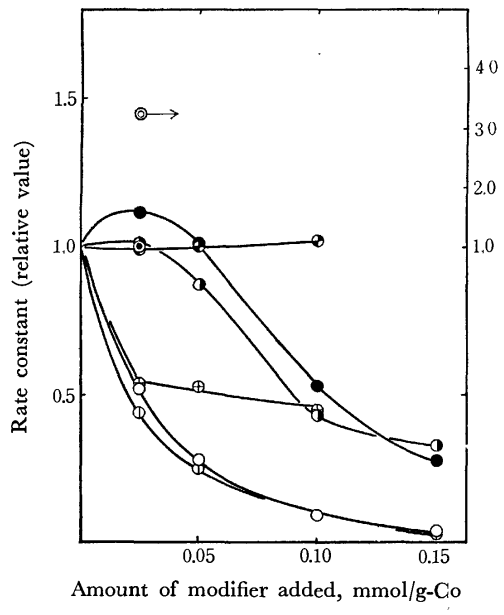

Fig. 3. Variation of rate constant with amount of modifier added, for k_1 with $CoCl_2$, ○; $MnCl_2$, ◑; $NiCl_2$, ⊕; $PdCl_2$, ◎; k_2 with $CoCl_2$, ●; $MnCl_2$, ◑; $NiCl_2$, ◒; $PdCl_2$, ⊙

Discussion

It has been reported[1] that, in the hydrogenation of a mixture of SD and UA (mole ratio 1 : 1) over the Raney cobalt catalyst in the absence and in the presence of $FeCl_2$, SD was preferentially hydrogenated. Since the initial rates of formation of the three products varied with the addition of Co-, Mn- and $NiCl_2$ in a similar way to that observed when $FeCl_2$ was added, it can be considered that the hydrogenation of UA to SA does not occur over the catalyst modified with Co-, Mn-, and $NiCl_2$ in the period in which the concentrations of SD and UA are comparable. Thus, the reaction scheme,[3] in which the formation of UA and that of SA and SD were separately treated, can also be valid for the present systems over the catalyst modified with Co-, Mn-, and $NiCl_2$.

When the mixture of UA and SD was hydrogenated over the Raney cobalt catalyst modified with $PdCl_2$ (0.050 and 0.10 mmol/g-Co), both SD and UA were hydrogenated simultaneously. Thus in the hydrogenation of UD over the $PdCl_2$-modified catalyst the reaction path of the hydrogenation of UA to SA has to be considered, and the formation of SD and SA and that of UA can not be treated separately. This is considered to be due to the formation of metallic palladium which is active for the hydrogenation of the carbon-carbon double bond. This is supported by the result where r_{SD} over the $PdCl_2$-modified catalyst increased remarkably. Promotion in the activities of the Raney nickel and cobalt catalysts by the addition of platinum-metal compounds was reported by several workers.[6-8]

The decrease of k_1 over R-Co(Co) and R-Co(Mn) (Fig. 3), can be explained as being due to the poisoning of active sites. The variation of k_2 over R-Co(Mn) might indicate that the formation of UA, SA and SD takes place on different sites of catalyst surface and the site responsible for the formation of UA is not occupied with $MnCl_2$ when 0.025 mmol/g-Co of the modifier was used.

Modification of the catalyst with $CoCl_2$ of 0.025 mmol/g-Co caused the increase of k_2. Promotion in the rate constant can not be explained by a simple active site hypothesis. As the number of active sites responsible for the formation of UA can not be considered to increase with the addition of 0.025 mmol/g-Co of $CoCl_2$ although k_2 was found to increase, the specific rate constant defined as the rate constant per unit active site must increase. This suggests a promoting effect which is induced onto a site by the modifier adsorbed on another site. The fact that k_2 begins to decrease can be explained by considering that further addition of the modifier causes the adsorption of $CoCl_2$ even on the site responsible for the formation of UA and, hence, the increase in the number of sites covered by the modifier overcomes an increase in the specific rate constant. A similar behavior of rates has also been observed in acetone hydrogenation over the Raney nickel catalyst by the addition of a small amount of triethylamine.[2]

The ratio k_2/k_1 increased with the amount of Co- and $MnCl_2$, and decreased with the addition of $PdCl_2$. Although behaviors of k_1 and k_2 over R-Co(Ni) differ somewhat from those over R-Co(Co) and R-Co(Mn), the ratio k_2/k_1 over R-Co(Ni) increased with the amount of $NiCl_2$ added, as found for the modification with Co- and $MnCl_2$. It can therefore be considered that $NiCl_2$ acts as the modifier in the original form and is not reduced to the metal on the catalyst surface.

The Photolysis of Ethoxycarbonylmethyltriphenylphosphonium Salts[1]

Yoshihiro NAGAO, Kensuke SHIMA, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka
(Received October 28, 1971)

Irradiation of ethoxycarbonylmethyltriphenylphosphonium salts (IV) gave products expected to be derived from the homolytic fission of the P-CH_2CO_2Et or P-Ph bond. The rate of the product formation was dependent strongly on the anion species and on the solvent polarity; an oxidizable anion was effective for the photolysis and the less polar the solvent the faster the rate became. It was found through the measurement of the electrical conductance that the degree of electrolytic dissociation of IV was very low at the concentration employed in the photolysis. On the basis of these results, the photolysis of IV was confirmed to proceed through a direct charge transfer from an anion to a cation.

A fair number of works have been reported on the photochemistry of the compounds containing nitrogen or sulfur atoms.[2] However, little attention has been paid to the photochemical behavior of organophosphorus compounds.[3]

We found previously that the P-Ph bond was broken at the primary step of the photolysis of the phosphonium ylids,[4] I and II, and that the mode of the bond fission of III depended on the wavelength of exciting light used.[5] Now, we studied the photolysis of ethoxycarbonylmethyltriphenylphosphonium salts (IV).[6] Although it has been reported that phosphonium salts are decomposed by ultraviolet irradiation.[7] the mechanism is not yet established. In the present paper the effect of the anion species and solvent polarity on the rate of the product formation were examined in detail and the possibility of four different paths leading to the decomposition of IV was discussed. Further, we discussed briefly on the differences of the modes of the bond fission in the photolysis of I,[4] IV, and ammonium[8] and sulfonium salts.[9]

$Ph_3P{=}CHCO_2Et$ (I), $Ph_3P{=}CHCOR$ R=Me or Ph (II),
$Ph_3P{=}CPh_2$ (III),
$Ph_3P^+CH_2CO_2Et\ X^-$
X=Cl, Br, I, BF_4, ClO_4, or NO_3 (IV).

Results

Acetonitrile solutions of IV (X=Cl, Br, or I) (3.5 mmol in 10 m*l*) in quartz tubes were degassed by three cycles of the freeze-pump-thaw method and irradiated with a high pressure mercury lamp for 150 hr. Triphenylphosphine (TPP), ethoxycarbonylmethyldiphenylphosphine (EDP), diphenyl, halobenzenes, diethyl succinate, ethyl phenylacetate, benzene, and ethyl acetate were detected by gas chromatographic analysis. The yields of the products are shown in Table 1.

$$Ph_3P^+CH_2CO_2Et\ X^- \xrightarrow{h\nu} Ph_3P + Ph_2PCH_2CO_2Et + Ph\text{-}Ph + PhX + EtO_2CCH_2CH_2CO_2Et + PhCH_2CO_2Et + PhH + CH_3CO_2Et$$
X=Cl, Br, or I

In order to see the effect of the nature of the anion species on the rate of the formation of the product, the quantum yields for the formation of TPP, EDP, benzene, and ethyl acetate (ϕ_{TPP}, ϕ_{EDP}, ϕ_{PhH}, and $\phi_{CH_3CO_2Et}$) from the phosphonium halides and tetrafluoroborate were determined at 253.7 nm using ferrioxalate actinometry.[10] As shown in Table 2, ϕ_{TPP} and $\phi_{CH_3CO_2Et}$, or ϕ_{EDP} and ϕ_{PhH} were approximately

Table 1. Photolysis of IV in acetonitrile[a]

equal for each salt except in the case of the iodide, where ϕ_{TPP} and ϕ_{EDP} were extremely low. It is noteworthy that both ϕ_{PhH} and $\phi_{CH_3CO_2Et}$ were increased in the order, chloride<bromide<tetrafluoroborate<iodide.

The photochemical stability of IV (X=NO_3, Cl, Br, BF_4, or I) was estimated from the amount of the recovered salt after the photolysis. The results are shown in Table 3. The rate of the photodecomposition of IV was increased with the change of the anion in the order, $NO_3^-<Cl^-<Br^-<BF_3^-<I^-$. This order was essentially the same as obtained in the quantum yields measurements. Thus, the photolysis of IV in acetonitrile solution was found to be very sensitive to the nature of the anion species.

The effect of the solvent polarity on the rate of the product formation was examined in the photolysis of the bromide. The data shown in Table 4 indicate that with decreasing solvent polarity the yields of TPP and EDP were increased and the yield ratio TPP/EDP was decreased. These tendencies might suggest that a direct relation exists between solvent polarity and the rate of the product formation. More definitive evidence indicating the relation was obtained when the photolysis was carried out in benzene–ethanol mixed solvent in quartz tube. As shown in Fig. 1, the yields of TPP and EDP were increased linearly

with the increase in the ratio of benzene to ethanol. Similar results as shown in Fig. 1 were also obtained when the photolysis was done in Pyrex tube.[11)] This result indicates that the absorption of the light by benzene does not contribute to the acceleration of the rate of the formation of phosphines (that is, benzene does not sensitize the photodecomposition of IV). Thus, it was found that the rate of the product formation was sensitive to the solvent polarity and less polar solvents were effective for the photolysis.

As it was suggested through the examination of the solvent effect that the degree of the interaction between an anion and a cation in a solution may be an important factor in the photolysis of IV, the degree of the electrolytic dissociation of IV were determined through the measurements of electrical conductances of the acetonitrile solutions of IV. The degree of dissociation ($\alpha=\Lambda/\Lambda_\infty$) at 0.32 M (this concentration is close to that at which the photolysis was done; 0.37 M) was calculated to be 0.24 for the bromide and 0.26 for the iodide. Under such circumstances an appreciable interaction between an anion and a cation may be possible.

Table 5 shows the effects of the additives on the yields of the products in the photolysis of the bromide. The addition of iodine strongly inhibited the formation of all the products. Lithium nitrate also showed the inhibition. Oxygen and phenyl iodide enhanced the rate of the photodecomposition of IV.

Discussion

Four different paths are possible for the photochemical decomposition of the ionic compounds, RY^+X^-.

$$X^- \xrightarrow{h\nu} X\cdot + e^-$$
$$RY^+ + e^- \longrightarrow R\cdot + Y \qquad (A)$$

11) Since a Pyrex tube eliminates wavelengths below 280 nm, benzene does not absorb the light energy in this case.

TABLE 5. PHOTOLYSIS OF IV IN THE PRESENCE OF THE ADDITIVES[a)]

a) IV (1.6 mmol) in 4 m*l* of acetonitrile. b) Not determined.

$$RY^+ \xrightarrow{h\nu} R\cdot + Y^+\cdot \quad (B)$$

$$RY^+ \xrightarrow{h\nu} R^+ + Y \quad (C)$$

$$RY^+X^- \xrightarrow{h\nu} R\cdot + Y + X\cdot \quad (D)$$

A solvated electron is involved in Path A. Path B involves a homolytic cleavage of a bond to produce a cation radical. Path C involves a heterolytic bond cleavage to produce a carbonium ion. Both Path B and Path C predict no anion dependency. Path D represents a direct charge transfer reaction under the interaction between an anion and a cation.

All the products shown in Table 1 can be expected to be derived from radical reactions because the rates of their formation were retarded markedly by the addition of iodine, a radical scavenger (Table 5). Path C (a heterolytic bond cleavage) can be ruled out on the basis that phenetole could not be detected at all when the photolysis was carried out in ethanol.

Tables 2, 3, and 5 show that the photochemical reactivity of IV depends strongly on the anion species. The quantum yields of the products (Table 2) and the rate of the photodecomposition of IV (Table 3) were increased with the change of the anion in the order, ClO_4^-, $NO_3^-<Cl^-<Br^-<BF_4^-<I^-$. An oxidizable anion was shown to be more effective except for BF_4^-.[12] This result indicates that Path A and/or Path D may be operative in the photolysis. However, Path A can be safely ruled out on the basis that any anion does not absorb the light above 250 nm,[13] and that a Brønsted acid which is a good scavenger of the solvated electron[14] is generated during each overall reaction (Table 5). Consequently, Path D may be most likely among the four paths.

The observation that no more than 30% of IV is ionized in solution at the concentration employed in the photolysis may be a further support for the direct charge transfer mechanism (Path D) because at such a low degree of dissociation the electron transfer from an anion to a cation should be easy. Further, as shown in Table 6, an absorption band which may be due to the charge transfer was observed at 245 nm in the UV spectrum of the iodide.[15]

The solvent effect on the rates of the formation of the phosphines can also be explained well by the charge transfer mechanism. That is, the degree of dissociation of IV in benzene–ethanol mixed solvent may be decreased with increasing proportion of benzene to ethanol. As a result, an anion may transfer an electron to a cation more easily at high concentration of benzene. TPP and EDP may be obtained in better yields under these conditions. It may be reasonable to explain the solvent effect in this way since the degree of dissociation of $Ph_4P^+I^-$ in solution has been reported to be increased with increasing solvent polarity in the order, $MeCN<MeOH<H_2O$.[16] It is not yet clarified why the ratio TPP/EDP was decreased with solvent polarity in this experiment.

As shown in Table 5, the addition of lithium nitrate retarded the photodecomposition. This may be due to that the charge transfer became difficult as a result of an increase in ionic strength of the medium. The acceleration of the reaction by the addition of oxygen may be accounted for by the oxidative decomposition of the phosphonium salts. Such accelerative effect of oxygen has been observed also in the pyrolysis of I in cyclohexene, producing triphenylphosphine oxide instead of TPP.[17] Formation of neither TPP nor EDP could be detected in the photolysis of the nitrate or perchlorate. This may be due to the interaction of oxygen atoms in a nitrate or perchlorate anion with the resulting phosphines. Further, the observation that ϕ_{TPP} and ϕ_{EDP} were very low for the iodide may be attributable to the formation of the diiodophosphorane (Ph_2PRI_2) by the reaction of TPP or EDP with an iodine molecule, which is formed by the dimerization of iodine atoms.

$$2I\cdot \rightarrow I_2$$

$$Ph_2PR + I_2 \rightarrow Ph_2PRI_2, \quad R=Ph \text{ or } CH_2CO_2Et$$

14) L. E. Orgel, *Quart. Rev.*, **8**, 422 (1954).

15) The assignment of the band should be reasonable since it has been reported that the absorption bands at 233 nm in the UV spectra of tris-*p*-tolylalkylphosphonium iodides are attributable to the charge transfer: M. A. A. Beg and Samiuzzaman, *Tetrahedron*, **24**, 191 (1968).

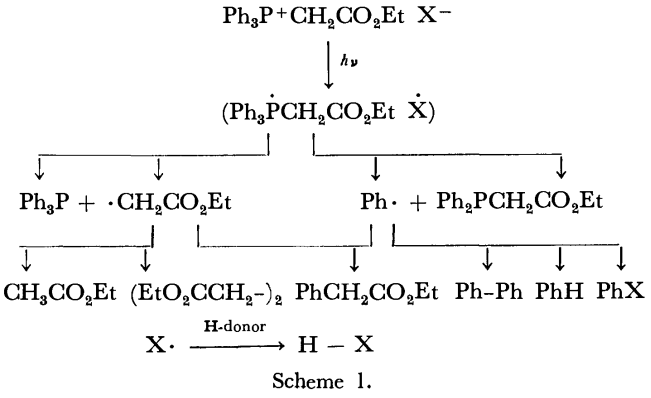
17) Y. Nagao, K. Shima, and H. Sakurai, This Bulletin, **43**, 1885 (1970).

On the basis of the above discussion, we can conclude that the photolysis of IV proceeds through the charge transfer from an anion to a cation. The processes shown in Scheme 1 may account for the observations in the photolysis of IV.



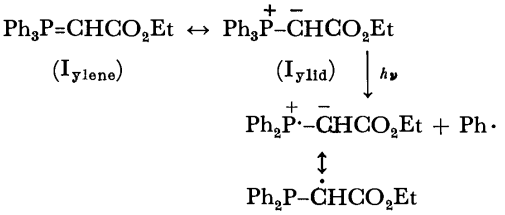
Scheme 1.

In this scheme, the phosphoranyl radical ($Ph_3\dot{P}CH_2CO_2Et$)[18] formed by one electron transfer decomposes mainly to TPP and an ethoxycarbonylmethyl radical, and partly to EDP and a phenyl radical. Radicals such as Cl· or Br· may abstract hydrogen atoms from solvent molecules, yielding hydrogen halides.

The photolysis of the tetrafluoroborate is the only one case where the charge transfer mechanism may not be operative. That is, the tetrafluoroborate was photolyzed more easily than the bromide although a tetrafluoroborate ion is less oxidizable than a bromide ion. Probably Path B, a direct cation excitation mechanism, may be important in this case.

Now, as the photolysis of IV has been confirmed to proceed through the charge transfer mechanism, we have compared the results with those of the photolysis of I and sulfonium and ammonium salts.

Owing to the important contribution of the ylid structure,[19] the compound I would have a positively charged phosphorus atom in its ground state. However, the mode of the photodecomposition of I differs significantly from that of IV. In the photolysis of I, a homolytic fission of a P-Ph bond may take place in the first stage by the direct absorption of light at a triphenylphosphinyl moiety. The charge transfer mechanism may not be important in this case.[20] On the other hand, a homolytic fission of a $P-CH_2CO_2$-Et bond took place preferentially through the electron transfer from the counter-anion to the associated acceptor cation in the photolysis of IV.



The charge transfer mechanism has also been proposed to take place in the direct[8a] and acetone sensitized photolysis[8b] of trimethylphenylammonium salts. However, a less stable radical (a phenyl radical) has been formed exclusively in these photolyses. In contrast, a more stable radical (an ethoxycarbonylmethyl radical) was produced preferentially in the photolysis of IV. Such a difference may arise from whether the *d* orbitals of the phosphorus or the nitrogen atom can participate or not in the photodecomposition. In the photolysis of IV, the phosphoranyl radical may be formed as an intermediate by the participation of the *d* orbitals of the phosphorus atom after the charge transfer. It is, thus, reasonable that a more stable ethoxycarbonylmethyl radical is produced preferentially from this intermediate. On the other hand, the energy level of the *d* orbitals of the nitrogen atom is so high that the *d* orbitals cannot participate in the photolysis of the ammonium salts. Possibly the direct electron transfer from an anion to the lowest antibonding orbital of the phenyl group of the cation might result in the exclusive cleavage of the N-Ph bond.

The photolysis of triarylsulfonium salts in alcohol[9] has been reported to involve both a charge transfer

(Path D) and a direct excitation of a cation yielding an aryl radical and a sulfinium cation radical (Path B). It has been considered that triarylsulfur radicals (sulfur analogs of phosphoranyl radicals) are formed by the participation of the *d* orbitals of the sulfur atom as the intermediate in the charge transfer process. Although the photolysis of dimethylphenacylsulfonium salts[9b,c] has been found to form a phenacyl radical (more stable than a methyl radical), the *d* orbitals may not participate in this system since this reaction proceeds through the direct cation excitation mechanism (Path B) only.

Experimental

All melting points are uncorrected. UV spectra were recorded on a Hitachi 124 Spectrophotometer. Gas chromatographic analysis were performed on a Shimadzu Gas Chromatograph, GC-3AF (carrier gas; N_2).

Preparation of Phosphonium Salts. Phosphonium salts were prepared by the following two methods, A and B.

Method A: A solution of 0.06 mol of TPP in 30 m*l* of benzene was treated with a solution containing an equivalent amount of ethyl α-haloacetate in 30 m*l* of benzene. The salt was filtered, washed with benzene, dried, and recrystallized from methylene chloride–ether.

Method B: A solution of 0.01 mol of AgX (X=ClO_4, NO_3 or BF_4) in water was added dropwise with stirring to a solution containing an equivalent amount of phosphonium bromide in methanol and the mixture was washed with methanol, and the filtrate and washing were combined and concentrated to a residue that was recrystallized from methylene chloride–ether.

Melting points and the UV spectral data of the salts are shown in Table 6.

Ethoxycarbonylmethyldiphenylphosphine (EDP). This compound was prepared by the method of Issleib and Thomas.[23] Hydrolysis of this compound gave carboxymethyldiphenylphosphine, mp 121—122°C (lit,[23] mp 120—121°C).

Photochemical Studies. A solution of 3.5 mmol of IV (X=Cl, Br, or I) in 10 m*l* of acetonitrile was placed in a quartz tube and degassed by three cycles of the freeze-pump-thaw method. The solution was irradiated with a quartz Eikosha PIH 350-W water-cooled, high pressure mercury lamp for 150 hr. After the irradiation the tube was opened and the contents were analyzed directly by gas chromatography. Four different columns were used in order to separate the peaks of the products: (1) a 1-m 15% SE-30 column for TPP and EDP, (2) a 3-m 25% DEGS column for most of the volatile components, (3) a 3-m 25% Silicone-DC column for halobenzenes, and (4) a 3-m 25% PEG column for benzene and ethyl acetate. Cyclohexane, α-methyl naphthalene and ethyl succinate were used as the internal standards in determining product yields.

Kinetic Experiments. Solutions containing 1.6 mmol of IV and equimolar amounts of the appropriate additives in the appropriate anhydrous solvents (4 m*l*) were degassed in quartz or Pyrex tubes and irradiated with the same high pressure mercury lamp as used above. Samples in quartz tubes were irradiated for 45 min. Within such irradiation time the yields of the products increased linearly. Samples in Pyrex tubes needed longer irradiation. The amounts of unreacted salts were found by adding ether to the reaction mixture slowly. The crystals formed were filtered, washed with ether, dried, and weighed. The concentrations of Brønsted acids were determined by titrating the reaction mixture with 0.1 N potassium hydroxide solution.

Quantum yields were measured by use of a 4 m*l* of quartz spectrophotometric cell. Acetonitrile solutions of IV (0.5 M) were degassed and irradiated at 253.7 nm. Potassium ferrioxalate was used as an actinometer. The yields of the products were determined by gas chromatography.

The Measurement of the Electrical Conductance. Resistances were measured with a Yokokawa On-Ichi-Go Impedencemeter at a frequency of 1000 Hz. An oscilloscope, Yokokawa OL-51C, and an oscillator, Matsushita VP-706 were used. The cell constant was 0.393 cm^{-1}.

Brominations of Aliphatic Ketones by Copper(II) Bromide in Organic Solvents. II. The Reaction of Acetone with Copper(II) Bromide in *N,N*-Dimethylformamide

Yoshitane KOJIMA, Kimiko USUI, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received November 25, 1971)

Because of a long induction period, the reaction between acetone and copper(II) bromide does not occur readily in pure DMF. However, in the presence of an acid, it proceeds readily. The initial rate is proportional to the product of the concentration of acetone and perchloric acid, but independent of the concentration of copper-(II) bromide. The acid-catalyzed bromination of acetone by bromine has also been studied in DMF and found to obey the same second-order rate law as that in water. Both bromination reactions of acetone in DMF by copper(II) bromide and bromine were interpreted to be controlled by the enolization process of acetone.

In a previous paper[1] we reported on the reaction of copper(II) bromide with acetone in methanol. In the presence of copper(II) bromide, the reaction of acetone with methanol to form acetone dimethylacetal attained equilibrium quickly even at 0°C, making the reaction system complicated. Water produced in the acetal formation made the acid-catalyzed reaction so complicated that the observed dependence of the rate upon the acetone concentration could not be explained quantitatively.

To avoid such troubles the reaction between copper-(II) bromide and acetone has been studied in *N,N*-dimethylformamide (DMF) and found not to proceed at room temperature unless assisted by an acid catalyst. The acid-catalyzed reaction is reported in this paper.

Experimental

Materials. DMF was boiled with benzene (5 vol%) to eliminate water as an azeotrope and distilled twice under reduced pressure (bp 27—29°C/5mmHg). Contamination with the free amine was examined by means of a saturated ethanol solution of 2,4-dinitrofluorobenzene.[2] Bromine was washed with water repeatedly to eliminate chlorine and iodine, and then dissolved in a solution of pure potassium bromide and distilled over zinc oxide. The distillate was again distilled over calcium oxide and finally dried with phosphorus pentoxide. Acetone was purified by a standard method.[3] Purity of organic solvents was checked by vapor phase chromatography.

Identification and Determination of Reaction Products. After the reaction mixture was kept standing at room temperature for a few days, volatile substances were distilled under reduced pressure. In one experiment to determine the amount of copper(I) bromide, the residue was dissolved in a sulfuric acid solution containing iron(III) ammonium sulfate, and iron(II) produced was titrated with an aqueous solution of cerium(IV) ammonium sulfate.[4] In another experiment, the residue was dissolved in aqueous ammonia, and total copper was determined by electrolysis, and bromine gravimetrically as silver bromide.

Monobromoacetone in the distillate was identified by comparing the infrared spectrum and gas-chromatogram with those of the authentic specimen. A 3 m column (4 mm in diameter) containing Diglycerol (5%) and Silicone Grease (5%) on Neosorb NCS was used at 63°C with hydrogen as a carrier gas at a flow rate of 20 cc/min. Content of monobromoacetone in the distillate was determined by iodometry, and that of hydrogen bromide by titration with an aqueous solution of sodium hydroxide.

Kinetics. Acetone and perchloric acid were added to a DMF solution of copper(II) bromide in a three-necked flask equipped with a stirrer, a nitrogen gas inlet tube and an outlet tube containing calcium chloride. At appropriate time intervals, aliquots were withdrawn from the flask and quenched in cold sulfuric acid solutions of iron(III) ammonium sulfate and titrated with cerium(IV) solutions as described above.

The reaction of acetone with bromine in DMF was also followed in a similar fashion without the nitrogen flow. Each aliquot was quenched in a potassium bromide solution buffered with acetic acid and sodium acetate, and the liberated iodine was titrated with a thiosulfate solution.[5] Monobromoacetone does not liberate iodine under these conditions.

In spite of careful purification of DMF, fluctuation in the reaction rate with the change of solvent was inevitable. Hence the dependence of the reaction rate on concentration was examined with DMF in the same bottle.

Results

Stoichiometry of the Reaction. Acetone was allowed to react with copper(II) bromide at room temperature for several days, and then the mixture was analyzed by the methods described in the Experimental Section. As shown in Table 1, the mole ratio of copper(I) bromide to monobromoacetone in the first experiment was close to 2 : 1 in conformity with the following equation.

$$CH_3COCH_3 + 2CuBr_2 = CH_3COCH_2Br + 2CuBr + HBr \quad (1)$$

The very low acid content in the distillate is due to the formation of a non-volatile adduct $(CH_3)_2NCHO \cdot HBr$.[6] This was proved by the second set of data in Table 1 which shows that sum of bromine gram-atoms in the residue and in the distillate is colse to twice moles of copper(II) bromide employed.

Kinetics. When acetone was mixed with a DMF solution of copper(II) bromide at 30°C, an in-

duction period longer than 100 min was observed before the reaction started (curve 1, Fig. 1). This result suggests that copper(II) bromide does not react with acetone in pure DMF and the reaction after the induction period might be caused by the catalytic effect of hydrogen bromide produced by side reactions. In fact when perchloric acid was added to the system, the reaction started without the induction period (curve 2, Fig. 1). However, the disturbing influences of reaction products made the kinetic run too difficult to analyze, and the effects of various factors were investigated by the initial rate method.

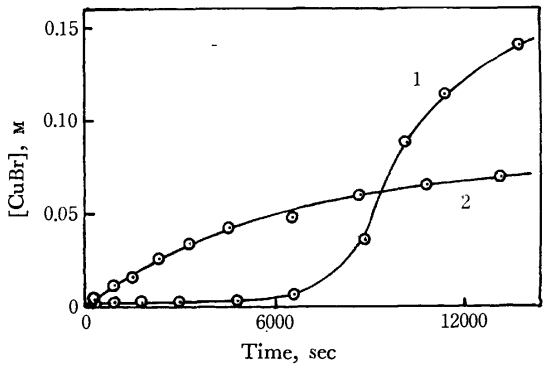

Fig. 1. Rates of reactions between acetone and copper (II) bromide in the absence (Curve 1) and presence (Curve 2) of perchloric acid. Curve 1: $[CuBr_2]=0.310$ M, [acetone] $=3.45$ M, 30°C. Curve 2: $[CuBr_2]=0.227$ M, [acetone] $=1.73$ M, $[HClO_4]=0.115$ M, 25°C.

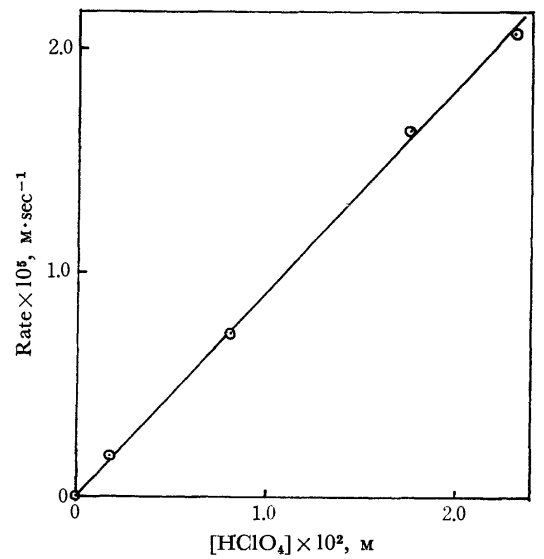

Fig. 2. The dependence of the reaction rate on the perchloric acid concentration at 23.2°C. $[CuBr_2]=0.284$ M, [acetone] $=1.73$ M.

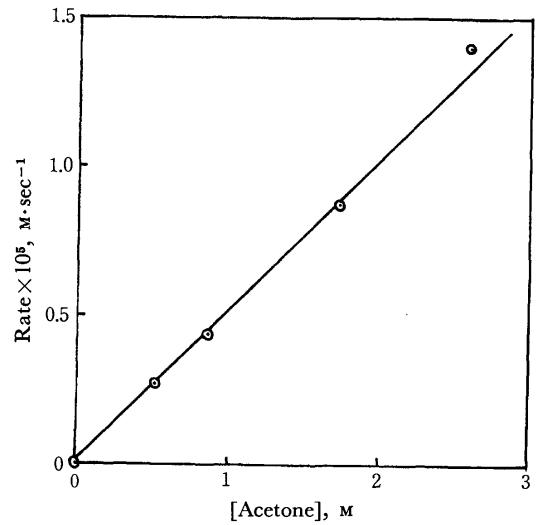

Fig. 3. The dependence of the reaction rate on the acetone concentration at 23.2°C. $[CuBr_2]=0.284$ M, $[HClO_4]=0.0115$ M.

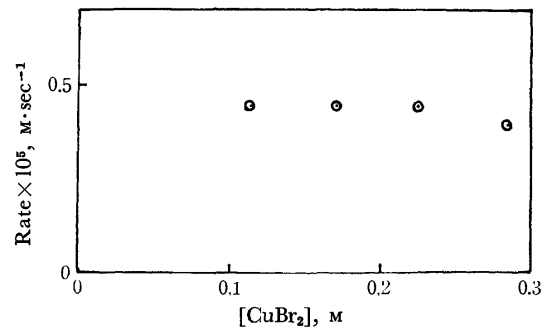

Fig. 4. The independence of the reaction rate from the copper(II) bromide concentration at 23.2°C. [acetone] $=0.875$ M, $[HClO_4]=0.0115$ M.

As shown in Figs. 2, 3, and 4 the initial rates of the reaction of acetone with copper(II) bromide in DMF at 23.2°C are proportional to the products of perchloric acid and acetone concentrations and independent of the copper(II) bromide concentration, providing the following equation.

$$d[CuBr]/dt = k[\text{acetone}][HClO_4] \quad (2)$$

The second order rate constant was obtained as $k=4.60\times10^{-4}M^{-1}sec^{-1}$ at 23.2°C. In these experiments perchloric acid was added as a 60% aqueous solution. The effect of water on the reaction rate was confirmed in advance to be negligible.

At 0°C, however, the rate of the acid-catalyzed reaction of acetone with copper(II) bromide was not independent of the latter concentration. As shown in Table 2 the pseudo second-order rate constant k in-

Table 2. Rate data of the acid-catalyzed reaction between acetone and copper(II) bromide in DMF at 0°C

$[CuBr_2]$, M	[acetone], M	$[HClO_4]$, M	Initial rate $\times 10^6$ M·sec^{-1}	Pseudo 2nd-order rate const. $\times 10^5$ M^{-1} sec^{-1}
0.038	1.75	0.046	0.88	1.1
0.075	1.75	0.046	1.18	1.5
0.113	1.75	0.046	1.75	2.2
0.200	1.75	0.046	2.27	2.8
0.225	0.87	0.023	0.52	2.9

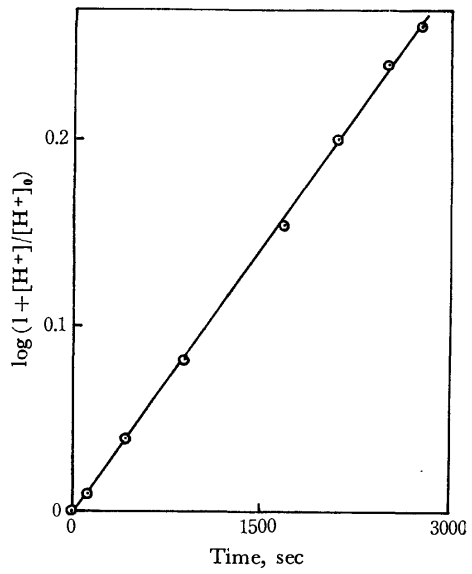

Fig. 5. The pseudo first-order plot of a kinetic run of the reaction of acetone with bromine in DMF at 23.2°C. [acetone]=1.144 M, $[Br_2]$=0.189 M, $[HClO_4]$=0.096 M.

creased with the concentration of copper(II) bromide, but no simple relationship between them could be found.

The Acid-catalyzed Bromination of Acetone by Bromine. For the sake of comparison, the acid-catalyzed bromination of acetone by bromine was followed in DMF solutions. With a large excess of acetone the reaction proceeded according to the pseudo first-order rate law as evidenced by the linear plot of $\log(1+[H^+]/[H^+]_0)$ *vs.* time in Fig. 5. Values of the second-order rate constant k_{Br} in the equation

$$-d[Br_2]/dt = d[H^+]/dt = k_{Br}[\text{acetone}]([H^+]_0 + [H^+]) \quad (3)$$

were 2.2×10^{-5}, 6.1×10^{-5}, and 19.0×10^{-5} M^{-1}sec^{-1} at 0.0, 11.0, and 23.2°C, respectively. From these data kinetic parameters were calculated as E_a=14.8 kcal·mol^{-1} and A=1.65×10^7 M^{-1}sec^{-1}.

Although the reaction of acetone with copper(II) bromide was followed by measuring the copper(I) bromide concentration according to Eq. (1), that with elemental bromine was followed by measuring the bromine concentration according to the following equation.

$$CH_3COCH_3 + Br_2 \rightarrow CH_3COCH_2Br + HBr$$

Thus k_{Br} defined by Eq. (3) should be compared with one half of k in Eq. (2). The value of k_{Br}, 19.0×10^{-5} M^{-1}sec^{-1} at 23.2°C is close to one half of k at the same temperature.

Discussion

Kosower *et al.*[7] reported reactions of various ketones with copper(II) chloride or copper(II) bromide at temperatures higher than 80°C. However, the present investigation revealed that copper(II) bromide does not react readily with acetone in pure DMF at room temperature, a long induction period being observed before the reaction starts. Dissolution of copper(II) bromide in DMF is very exothermic and the solutions were usually prepared with cooling in an ice-bath. If a copper(II) bromide solution in DMF prepared without cooling and heated spontaneously is allowed to react with acetone, the induction period almost disappears. On heating, DMF tends to decompose to dimethylamine and carbon monoxide,[8] and dialkylamine is known to react with copper(II) halides.[9] In fact it was confirmed that copper(II) bromide reacts with dimethylamine much faster than with acetone in DMF. Thus the following reactions may occur during the induction period of the reaction between copper(II) bromide and acetone in DMF, and hydrogen bromide produced may catalyze the latter reaction.

$$(CH_3)_2NCHO \rightarrow (CH_3)_2NH + CO \quad (4)$$

$$CuBr_2 + (CH_3)_2NH \rightarrow CuBr + HBr + \text{oxidation products of the amine} \quad (5)$$

Ichikawa *et al.*[10] noticed that about 20% of copper(II) chloride was consumed when heated with DMF at 80—90°C for 10 hr. These results are also interpreted to be caused by reactions similar to (4) and (5).

Copper(II) bromide reacts with acetone in methanol, playing dual roles as the catalyst which activates acetone and also as the brominating agent.[1] On the contrary the same reaction does not occur in DMF possibly because DMF is a stronger ligand to copper(II) than acetone, and the following ligand substitution equilibrium is very unfavorable to the latter.

10) K. Ichikawa, S. Uemura, T. Hiramoto, and Y. Takagaki, *Kogyo Kagaku Zasshi*, **71**, 1657 (1968).

$$CuBr_2(DMF)_n + n \text{ acetone} \rightleftharpoons CuBr_2(\text{acetone})_n + n \text{ DMF} \quad (6)$$

However, copper(II) bromide still retains brominating ability and reacts with acetone even in DMF if an acid is added to catalyze the enolization of acetone.

It has been well established that the rate of acid-catalyzed halogenation of acetone by elemental halogen in an aqueous solution is controlled by the enolization step.[5] The bromination of acetone in DMF proceeds according to the same rate law (3) as that in water, and is represented by the following steps.

$$HA + DMF \rightarrow DMFH^+ + A^- \quad (7)$$

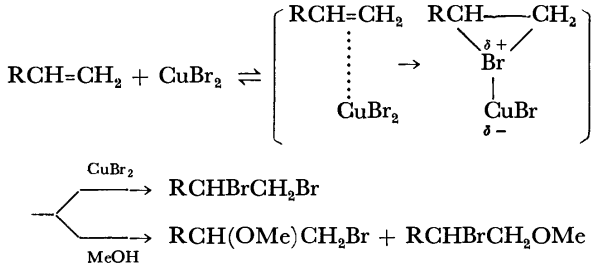
$$(CH_3)_2CO + DMFH^+ \rightleftharpoons (CH_3)_2COH^+ + DMF \quad (8)$$

$$(CH_3)_2COH^+ + DMF \xrightarrow{\text{slow}} CH_3C(OH)=CH + DMFH^+ \quad (9)$$

$$CH_3C(OH)=CH_2 + Br_2 \xrightarrow{\text{fast}} CH_3COCH_2Br + HBr \quad (10)$$

The second order rate constant k_{Br} at 25°C obtained by extrapolation of data at three temperatures is 2.2×10^{-4} M^{-1}sec^{-1} which is several times larger than 2.8×10^{-5} M^{-1}sec^{-1} in water.[5] This seems to reflect the higher basicity of DMF than that of water which functions as the proton acceptor in the rate-determining step (9).

By analogy the reaction of acetone with copper(II) bromide at around room temperature is also considered to be controlled by the enolization step (9). It is not certain, however, whether copper(II) bromide or bromine liberated therefrom brominates enolic molecules of acetone in the succeeding step (10). Castro *et al.*[11] found the formula rate$=k[CuBr_2]^2$ for the reaction between allyl alcohol and copper(II) bromide at 64°C and attributed the rate law to the rate determining dissociation of the latter followed by bromination of the unsaturated alcohol by bromine. Barnes and Hume[12] also reported that elemental bromine was distilled from a boiling solution of copper(II) bromide in acetonitrile. On the other hand, Koyano[13] has recently reported that the bromination of olefins with copper(II) bromide in methanol at 40°C may be represented by the following polar mechanism.



At such lower temperatures as employed in the present investigation, the following equilibrium concentration of elemental bromine produced by the dissociation of copper(II) bromide may not be enough to explain the observed overall rates.

$$2CuBr_2 \rightleftharpoons 2CuBr + Br_2 \quad (11)$$

It might be preferable to consider that copper(II) bromide plays a role of the brominating agent.

At 0°C the initial rate shows some dependence on the copper(II) bromide concentration. This may indicate that the brominating step is slower than the preceding enolization steps (7)—(9) at 0°C. The detailed mechansim is not clear.

Reactions of Cuprous Acetate with Organic Halides

Takao KAWAKI and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo
**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received December 18, 1971)

Cuprous acetate was prepared from phenylcopper and acetic acid, and its reactivity for organic halides was investigated. The mixed anhydrides containing an acetyl group are formed easily from cuprous acetate and acyl halides. The reaction of cuprous acetate with CH_3I, C_2H_5I, CH_2=$CHCH_2Br$, and $PhCH_2Cl$ in acetonitrile gives the corresponding ester. The addition of ethylenediamine converts the above reaction to a reductive coupling reaction, resulting in bibenzyl (50% yield) from benzyl chloride and 1,5-hexadiene (95—98% yield) from allyl chloride or bromide. The reaction of cuprous acetate-ethylenediamine with aryl bromide or iodide in DMF gives a reductively dehalogenated product, *i.e.*, the corresponding hydrocarbon, in a small yield.

Although numerous copper salts have been utilized in organic syntheses, little has been investigated about cuprous acetate. Cuprous acetate was first prepared from cuprous oxide and acetic anhydride by Calvin.[1] Recently, Sheppard[2] reported to obtain this compound quantitatively from *m*-(trifluoromethyl)phenylcopper octamer and acetic acid. It has also been reported that cuprous acetate activates the molecular hydrogen in quinoline,[1,3] and that cuprous acetate executes

a reductive dehalogenation on aryl halides in nitrogen heterocyclic solvents.[4] However, the reaction of cuprous acetate with organic halides has not yet been fully investigated. Therefore, we prepared cuprous acetate from phenylcopper and acetic acid, and examined its reactions with acyl halides and some aliphatic and aromatic halides.

Results and Discussion

Although Sheppard used *m*-(trifluoromethyl)phenylcopper as an organocopper, we found that cuprous acetate can be synthesized quantitatively from phenylcopper and acetic acid;

$$PhCu + CH_3COOH \rightarrow Cu(OCOCH_3) + PhH$$

As cuprous acetate was easily decomposed by both oxygen and moisture, it was isolated and characterized as a complex with triphenylphosphine according to the usual procedures for Cu(I) complexes.[5,6] It is a white crystalline oxygen-stable compound, is soluble in an organic solvent and has the composition of $CuOAc\text{-}(PPh_3)_2$.

Reactions of Cuprous Acetate with Acyl Halides. Cuprous acetate similar to cuprous alkoxides reacted with acyl halides to produce the corresponding anhydrides in fairly good yields, as is shown in Table 1. The yield of anhydride diminishes with the increase in the carbon chain in the acyl group. This fact may be attributable to the increase in the electron-releasing ability in the order of $-CH_3 < -C_2H_5 < -C_3H_7$. Mixed anhydrides have been synthesized from carboxylic acid or its metal salts[7] and acyl halide. Recently, Taylor[8] reported that mixed anhydrides could be prepared in high yields by utilizing Tl(OCOR). Considering that thallium salts are very toxic, the above reaction seems to be a useful method of synthesizing mixed anhydrides containing acetyl group.

Reactions of Cuprous Acetate with Aliphatic Halides. The halogen-exchange reactions of copper salts with organic halides have been studied by many investigators. Therefore, the reactions of cuprous acetate with organic halides were examined, as is shown in Table 2.

It is clear from Table 2 that all alkyl halides except bromobenzene and iodobenzene are converted to the corresponding esters in acetonitrile. Cohen[9] reported that cuprous benzoate reacts with aryl halides in diglyme to produce aryl benzoate in good yields and that organocopper ArCuOCOPh is an intermediate in the reaction. Cuprous phenoxide[10] also reacted with aryl halides in diglyme to produce aryl phenyl

ether. However, cuprous acetate did not react with aryl halides under similar experimental conditions. As toluene has not been detected in the reaction of cuprous acetate with benzyl chloride, the reaction of cuprous acetate with organic halide seems not to proceed through an organocopper intermediate of the RCuOAc type, but seems to proceed through the four-centered mechanism proposed by Bacon.

The Effect of Ligands on the Reactions with Aliphatic Halides. Although cuprous acetate was expected to have more reducing power than the other cuprous salts, it could not dehalogenate organic halides. It has been reported that the reducing power of cuprous chloride is remarkably enhanced by the addition of ethylenediamine in acetonitrile[11] and that the resulting complex dehalogenates benzyl chloride. Table 3 shows the effects of the addition of ligands on the reactions of the cuprous acetate with halides in acetonitrile. In the reaction with benzyl chloride, the addition of 1 mol of ethylene diamine enhanced the reducing power of cuprous acetate, resulting in a higher yield of bibenzyl. Dipyridyl would stabilize cuprous acetate too strongly resulting in a much smaller yield of bibenzyl. Allyl chloride and bromide were converted to 1,5-hexadiene quantitatively without any formation of the ester. Cuprous acetate–ethylenediamine is expected to have more reducing power in DMF because ethylenediamine stabilizes the higher valent state of copper. However, even under these conditions, the reductive coupling product of iodo- and bromobenzene could not be prepared, although the reductively dehalogenated products were obtained in low yields, as is shown in Table 4.

Because the coupling products were not detected when oxygen was bubbled into the reaction mixture prior to hydrolysis, it seems that organocopper is not an intermediate in this reaction. Bacon and his coworkers[4] proposed the following mechanism in the reaction of cuprous acetate with aryl halides in pyridine or quinoline;

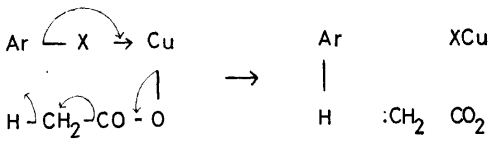

Fig. 1

The reaction of cuprous acetate–ethylenediamine with aryl halides in DMF may also proceed through a similar process.

TABLE 4. REACTIONS OF CuOAc-ETHYLENEDIAMINE WITH ARYL HALIDES IN DMF[a]

Experimental

Preparation of Cupous Acetate and its Characterization as the Triphenylphosphine Complex. Phenylcopper was prepared according to the direction of Costa.[12] To the phenylcopper (0.1 mol) suspended in fresh ether under nitrogen was added a slight excess of acetic acid at 0—20°C, after which the mixture was stirred for 4 hr. The resulting white solid of CuOAc was washed several times with ether and dried under nitrogen. CuOAc is so air-sensitive that we failed in elemental analysis under the usual conditions.

Triphenylphosphine (0.02 mol) was added to CuOAc (0.01 mol) suspended in benzene under nitrogen, and the mixture was refluxed for 5 hr. The reaction mixture was then decanted, and the supernatant solution was concentrated to deposit $CuOAc(PPh_3)_2$.

Found: C, 70.81; H, 5.20; Cu, 10.06%. Calcd for $CuOAc(PPh_3)_2$: C, 70.53; H, 5.13; Cu, 9.80%.

Reactions of Cuprous Acatate with Oraganic Halides. Organic halide or acyl halide (0.01 mol) was added to CuOAc (0.01 mol) suspended in acetonitrile or ether under nitrogen, and the mixture was heated under the conditions shown in Tables 1 and 2. The yields of the products were determined by gas chromatography.

The Effect of Addition of Ethylenediamine. Ethylenediamine (0.01 mol) was added to CuOAc (0.01 mol) suspended in acetonitrile under nitrogen, and the mixture was refluxed for 0.5 hr, after which organic halide (0.01 mol) was dropped in. Then, the mixture was stirred under the conditions shown in Table 3. The reactions in DMF were also conducted in a manner similar to the experiment described above.

Effects of Substituents on the Smiles Rearrangement of *O-s*-Triazinyl-2-aminophenols

Norio MAENO, Takeshi ITAGAKI, Seiichi UNO, and Kohji MATSUI
Department of Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu, Gunma
(Received December 22, 1971)

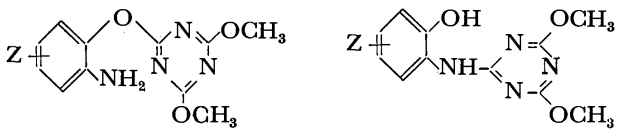
Several 4- or 5-substituted *O*-(*s*-triazinyl)-2-aminophenols were synthesized, and the kinetics of the Smiles rearrangement of these compounds have been studied spectrophotometrically in methanol, ethanol, and 2-propanol in order to make clear the effects of substituents on the rearrangement. Substituents in the *s*-triazine nucleus were found to affect the progress of the reaction to a great extent by changing the positive character of the triazine-ring carbon. On the other hand, a substituent in the aminophenol moiety affects both the nucleophilic reactivity of the attacking amino group and the stability of the leaving phenoxide anion or the reactivity of the *s*-triazinyl group, but the effect on the amino group was found to be predominant, the effect of a substituent in the aminophenol moiety was smaller than that of the substituents in the *s*-triazine nucleus.

In previous papers[1] we reported that *O-s*-triazinyl-2-aminophenols rearrange under various conditions, especially readily in the presence of acid, to give *N-s*-triazinyl-2-aminophenols. The migration of the triazinyl group was thought to proceed through an intramolecular nucleophilic attack by the amino group on the ring carbon of an *s*-triazinyl group, and substituents in *O-s*-triazinyl-2-aminophenol were found to affect the progress of the reaction to a great extent. The electronic effects of substituents on the Smiles rearrangement have already been studied, especially with the derivatives of *O*-nitrophenyl-2-aminophenols.[2] However, these studies have been limited to qualitative discussions and the details of the substituent effects have not been made clear. Therefore, it was of interest to study quantitatively the electronic effects of substituents upon the Smiles rearrangement with *O-s*-triazinyl-2-aminophenols.

In preliminary experiments, it was found that solvents affect the progress of the rearrangement. *O-s*-Triazinyl-2-aminophenols are stable in aprotic solvents, such as cyclohexane, benzene, carbon tetrachloride, butyl ether, and acetone, but most of the *O-s*-triazinyl-2-aminophenols were found to rearrange readily to give *N-s*-triazinyl-2-aminophenols in protic solvents, such as water and lower alcohols. This paper will report the effects of substituents on the rearrangement with *O-s*-triazinyl-2-aminophenols in methanol, ethanol, and 2-propanol.

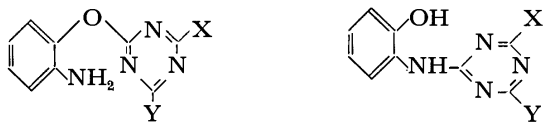
Results and Discussion

Syntheses of O-s-*triazinyl-2-aminophenols and* N-s-*triazinyl-2-aminophenols.* *O-s*-Triazinyl-2-aminophenols and *N-s*-triazinyl-2-aminophenols of the following general formulas—(I), (II), (III), and (IV)—were prepared according to Schemes 1 and 2:



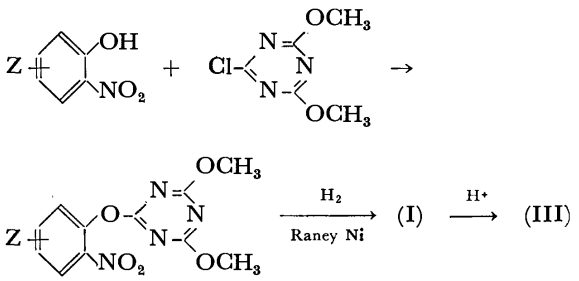
(I) (III)

Z=H, 4-CH_3, 4-Cl, 4-OCH_3, 4-$COCH_3$, 5-CH_3, 5-Cl, 5-OCH_3



(II) (IV)

(II-1), (IV-1), X=OCH_3, Y=$N(CH_3)_2$
(II-2), (IV-2), X=Y=$N(CH_3)_2$
(II-3), (IV-3), X=C_6H_5, Y=$N(CH_3)_2$
(II-4), (IV-4), X=NH_2, Y=OCH_3



Scheme 1.

The compounds (I) were prepared by the condensation of *o*-nitrophenol or substituted *o*-nitrophenols with chloro-dimethoxy-*s*-triazine, followed by catalytic hydrogenation in the presence of Raney nickel. On the other hand, *o*-nitrophenol was converted with 2,4-dichloro-6-methoxy-*s*-triazine or cyanuric chloride into 2-chloro-4-methoxy-6-(2-nitrophenoxy)-*s*-trizine or 2,4-dichloro-6-(2-nitrophenoxy)-*s*-triazine, which, with dimethylamine or ammonia, gave 2-dimethylamino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine, 2-amino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine, or 2,4-bis(dimethylamino)-6-(2-nitrophenoxy)-*s*-triazine. Compounds (II-1), (II-4), and (II-2) were obtained by the hydrogenation of 2-dimethylamino-4-methoxy-6-(2-ni-

II-1	19.0	−30.3	16.8	−34.4

of the rearrangement, and the rates of the rearrangement of *O*-*s*-triazinyl-2-aminophenols can be measured spectrophotometrically. For example, a plot of $-\log(D_\infty-D_t)/(D_\infty-D_0)$ against the reaction time, t, for the rearrangement of (I-1) in methanol gave a straight line, as is shown in Fig. 2.

Accordingly, the first-order rate constant for the rearrangement can be calculated using Eq. (1):

$$k_1 = -2.303\cdot\frac{1}{t}\cdot\log\frac{D_\infty-D_t}{D_\infty-D_0} \quad (1)$$

where D_0=initial optical density of a solution of *O*-*s*-triazinyl-2-aminophenol.
D_t=optical density of a solution at time t.
D_∞=optical density of a solution at an infinite time.

In Table 5 are listed the first-order rate constants for the rearrangements of (I-1), (I-2), (I-4), (II-1), (II-2), (II-3), and (II-4) at 10, 20, 40, 50, and 60°C in methanol, while in Table 6 are listed those in 2-propanol; the energies and entropies of activation thus obtained are listed in Table 7. Table 8 compares the rate constants of these compounds in methanol, ethanol, and 2-propanol.

As is shown in Table 8, the rate of the rearrangement varied with the dielectric constant of the alcohol used, and in methanol the rearrangement took place most rapidly. However, no simple relation between the dielectric constant of the solvent and the rate constant has been observed. On the other hand, from a comparison of the rate constants, activation energies, and activation entropies in methanol and 2-propanol, it is apparent that, in the rearrangement of *O*-*s*-triazinyl-2-aminophenols, in spite of the counteracting change in the entropy of activation, the change in the activation energy dominates the rate change. These results can be explained as follows:[3] because the transition state of the reaction may be assumed to be more polar than the initial state, in a more polar solvent the rearrangement can be expected to proceed more rapidly by lowering activation energy under the formation of a stronger solvated transition state than in a less polar solvent.

Effects of Substituents on the Rearrangement. In Table 9, the rate constants for the rearrangement of 4- or 5-substituted *O*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminophenols in methanol at 20°C are listed. From Tables 5 and 9, it is apparent that the substituents in *O*-*s*-triazinyl-2-aminophenol affect the rate of the rearrangement to a great extent, and that the effects

3) C. K. Ingold, "Structure and Mechanism in Organic Chemistry," Cornell University Press. Itaca and London 2nd ed (1969) p. 457.

of substituents differ according to the nature and the position of substituents. The effect of the substituents in the triazine nucleus may become clear from a comparison of the rate constants of (I-1), (II-1), (II-2), (II-3), and (II-4). Although the rate of the rearrangement of (II-2) in methanol was too slow to measure, the facility of the rearrangement was found to vary in the following order:

$$\text{II-2} \ll \text{II-3} < \text{II-1} < \text{II-4} < \text{I-1}$$

In *s*-triazine compounds, it was found that the Hammett σ_m values of the benzene series are applicable in studying the effects of substituents and that the total effect of two substituents in the *s*-triazine ring on the reaction center is given by the summation of the two substituent constants, $\sum\sigma_m$.[4] Therefore, the sensitivity of the rearrangement towards the substituents in a triazine ring can be evaluated by a reaction constant which is calculated from the rate constants of (I-1), (II-1), (II-3), and (II-4) using the respective $\sum\sigma_m$ values. In the case studied, the reaction constant (ρ) thus obtained was 6.43, with a correlation coefficient of 0.987. As will be described later, this ρ value is considerably larger than those of the reactions attributable to the substituent in the aminophenol moiety.

Although it is yet uncertain whether this migration proceeds by the S_N2 mechanism or by the intermediate-complex mechanism, the effect of a substituent in the aminophenol moiety may reasonably be considered in view of the following two points: the influence of the substituent upon the nucleophilic reactivity of the attacking amino group, and the influence upon the reactivity of the migrating *s*-triazinyl group towards the amino group (the positive character of the ring carbon of the *s*-triazine nucleus) or the stability of the leaving phenoxide anion. In the former, an electron-releasing effect of a substituent favors the rearrangement, while an electron-attracting effect is favored in the latter. Therefore, the Hammett equation for reactions like this rearrangement may be expressed by Eq. 2, which consists of a sum of two terms.[5]

$$\log k/k_0 = \sigma\rho' + \sigma\rho'' \qquad (2)$$

where the reaction constants, ρ' and ρ'', are attributable to the effect of a substituent on the reactivity of the migrating triazine nucleus through the -O- bridge or the stability of the leaving phenoxide anion and the effect of a substituent on the nucleophilicity of the amino group respectively.

Using the rate constants (in the case of 4-$COCH_3$, the σ^- value was used), the ρ' and ρ'' values calculated by the method of least squares were:

$$\rho' = 2.86; \qquad \rho'' = -4.15$$

respectively, and the ρ''/ρ' ratio was -1.45. A Hammett plot of $\log k_1$ against $\sigma_m - 1.45\sigma_p$ when a substituent is in the 5-position or $\sigma_p - 1.45\sigma_m$ when a substituent is in the 4-position gave a straight line, with a correlation coefficient of 0.990, as is shown in Fig. 3.

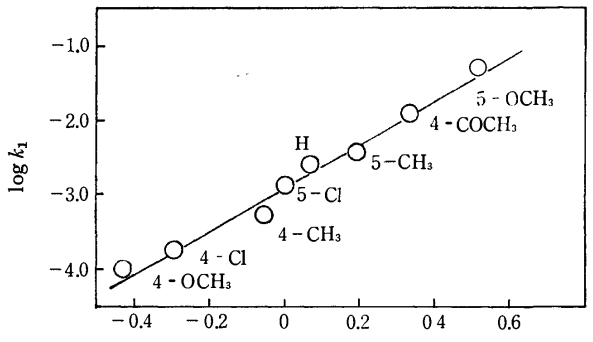

Fig. 3. Hammett plot for the rearrangement of 4- or 5-substituted *O*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminophenols in methanol (20°C).

However, a linear relation between the substituent constants and log k_1 was not obtained by using a usual Hammett equation, involving only one term.

Therefore, a substituent in the 5-position affects the nucleophilic reactivity of the attacking amino group as a *para*-substituent and, simultaneously, the reactivity of the migrating *O*-*s*-triazinyl group as a *meta*-substituent. Such a situation holds for a substituent in the 4-position. As a result, the logarithm of the rate constants apparently depends upon a composite effect of these two. These results indicate that, in 4- or 5-substituted *O*-*s*-triazinyl-2-aminophenols, a substituent in the aminophenol moiety affects the nucleophilic reactivity of the free amino group more effectively than the reactivity of the *s*-triazinyl group or to stability of the leaving phenoxide anion. Moreover, as has been described previously, it has become apparent from a comparison of the value of ρ with those of ρ' and ρ'' that, in the Smiles rearrangement of *O*-*s*-triazinyl-2-aminophenols, the effect of the substituents in the *s*-triazine nucleus is larger than that of a substituent in the aminophenol moiety.

Experimental

All the melting points are uncorrected. The ultraviolet spectra were recorded on a Hitachi-124 UV-VIS spectrophotometer. The elemental analyses were performed in the Micro-analytical Center of the Gunma University.

Materials. *Aryloxy-4,6-dimethoxy-s-triazines*: A typical preparation is the case of 2,4-dimethoxy-6-(4-methoxy-2-nitrophenoxy)-*s*-triazine. Into a solution of 4.1 g (0.024 mol) of 2-nitro-4-methoxyphenol and 1.2 g(0.03 mol) of sodium hydroxide in 40 m*l* of acetone, we stirred, drop by drop, a solution of 5.0 g (0.028 mol) of 2-chloro-4,6-dimethoxy-*s*-triazine in 50 m*l* of acetone. After an additional 24 hrs' stirring at 40°C, the mixture was poured into 500 m*l* of ice water, filtered, and dried.

4- or 5-Substituted O-(4,6-dimethoxy-s-triazin-2-yl)-2-aminophenols (I). A typical run is shown in the case of *O*-(4,6-dimethoxy-*s*-triazin-2-yl)-4-methoxy-2-aminophenol. A mixture containing 50 m*l* of dioxane, 5.0 g (0.016 mol) of 2,4-dimethoxy-6-(4-methoxy-2-nitrophenoxy)-*s*-triazine, and 3 g of Raney nickel was stirred for 2 hr at room temperature under a pressure of 60 kg/cm² of hydrogen. After the

catalyst had then been removed by filtration, the solution was poured into 500 m*l* of ice water containing a small amount of sodium hydroxide. The precipitate was filtered, washed with water, and dried.

O-(4-Dimethylamino-6-methoxy-s-triazin-2-yl)-2-aminophenol (II-1). i) 2-Chloro-4-methoxy-6-(2-nitrophenoxy)-s-triazine: A solution of 139 g (1.0 mol) of *o*-nitrophenol and 45 g (1.1 mol) of sodium hydroxide in 500 m*l* of water was stirred, drop by drop, over 3-hr period and at 0—5°C, into a solution of 180 g (1.0 mol) of 2,4-dichloro-6-methoxy-*s*-triazine in 1 *l* of acetone. After an additional 2 hrs' stirring at room temperature, the mixture was poured into 2 *l* of ice water. The precipitate was then filtered and dried to give 270 g (quantitative) of crude 2-chloro-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine (mp 116—120°C). Recrystallization from benzene-ligroin gave an analytical sample; mp 122—123°C.

Found: C, 42.29; H, 2.47%; Calcd for $C_{10}H_7ClN_4O_4$: C, 42.49; H, 2.47%.

ii) 2-Dimethylamino-4-methoxy-6-(2-nitrophenoxy)-s-triazine: Into a solution of 230 g (0.84 mol) of 2-chloro-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine in 1 *l* of acetone, we stirred 190 m*l* of a 40% dimethylamine solution (1.7 mol) drop by drop over a 2-hr period at 10°C. Stirring was continued for 5 hr at 40°C; then the mixture was refluxed for 3 hr and poured into 2 *l* of ice water. The precipitate was filtered and dried to give 226 g (quantitative) of crude 2-dimethylamino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine; mp (116—120°C). Recrystallization from benzene–ligroin gave an analytical sample.

iii) O-(4-Dimethylamino-6-methoxy-s-triazin-2-yl)-2-aminophenol (II-1): This was obtained in a 54% yield by the hydrogenation of 2-dimethylamino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine in dioxane in the presence of Raney nickel. Recrystallization from benzene–ligroin gave an analytical sample; mp 104—105°C.

O-[4,6-Bis(dimethylamino)-s-triazin-2-yl]-2-aminophenol (II-1). i) 2,4-Dichloro-6-(2-nitrophenoxy)-s-triazine: This compound was obtained in a 94% yield by the condensation of *o*-nitrophenol with cyanuric chloride in the presence of sodium hydroxide in acetone at 0—5°C. Recrystallization from benzene–ligroin gave an analytical sample; mp 136—137°C.

Found: C, 37.93; H, 1.51%; Calcd for $C_9H_4Cl_2N_4O_3$: C, 37.65; H, 1.40%.

ii) 2,4-Bis(dimethylamino)-6-(2-nitrophenoxy)-s-triazine: Into a solution of 75 g (0.26 mol) of 2,4-dichloro-6-(2-nitrophenoxy)-*s*-triazine in 300 ml of acetone, we stirred 130 ml of a 40% dimethylamine solution drop by drop over a 2-hr period at 10°C. The mixture was then processed according to the procedure used for 2-dimethylamino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine. Yield, 99%. Recrystallization from benzene–ligroin gave an analytical sample; mp 169—170°C.

iii) O-[4,6-Bis(dimethylamino)-s-triazin-2-yl]-2-aminophenol (II-2): The compound (II-2) was obtained in a 75% yield by the catalytic reduction of 2,4-bis(dimethylamino)-6-(2-nitrophenoxy)-*s*-triazine, using Raney nickel as the catalyst in dioxane. Recrystallization from benzene gave an analytical sample of (II-2); mp 134—135°C.

O-(4-Dimethylamino-6-phenyl-s-triazin-2-yl)-2-aminophenol (II-3). 2-Chloro-4-phenyl-6-(2-nitrophenoxy)-*s*-triazine was obtained by treating *o*-nitrophenol with 2,4-dichloro-6-phenyl-*s*-triazine in acetone in the presence of sodium hydroxide; mp 152—153°C (benzene-ligroin)

Found: C, 54.75; H, 3.07%; Calcd for $C_{15}H_9ClN_4O_3$; C, 54.81; H, 2.76%.

it was then condensed with dimethylamine in acetone to give 2-dimethylamino-4-phenyl-6-(2-nitrophenoxy)-*s*-triazine; mp 193—195°C (benzene-ligroin). The compound (II-3) was obtained in an 88% yield by the catalytic hydrogenation of 2-dimethylamino-4-phenyl-6-(2-nitrophenoxy)-*s*-triazine in dioxane, using Raney nickel as the catalyst. Mp 149—150°C (benzene-ligroin).

O-(4-Amino-6-methoxy-s-triazin-2-yl-2-aminophenol (II-4). 2-Amino-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine obtained by treating 2-chloro-4-methoxy-6-(2-nitrophenoxy)-*s*-triazine with ammonia in acetone [mp 179—181°C (benzene)] was hydrogenated using Raney nickel as the catalyst in dioxane. Recrystallization from benzene then gave an analytical sample of (II-4); mp 185—186°C.

N-(s-Triazinyl)-2-aminophenols (III, IV). A typical run is the case of (IV-1). To a solution of 1.0 g (II-1) in 50 m*l* of acetone we added one drop of concentrated hydrochloric acid at room temperature, and then the mixture was stirred for 12 hr. After the mixture had been poured into 200 m*l* of ice water, the precipitate was filtered and dried to give 0.9 g of crude (IV-1) (mp 213—214°C).

Kinetic Measurements. Kinetic measurements were carried out spectrophotometrically by measuring the increase in the absorbance at 280—310 nm of an alcoholic solution of *O-s*-triazinyl-2-aminophenol at 10, 20, 30, 40, 50, and 60°C; the first-order rate constant for the rearrangement was calculated using Eq. 1.

The $N^1 \rightarrow N^2$ Migration of the *s*-Triazinyl Group of 4-Substituted N^1,N^1-Bis-(*s*-triazinyl)-*o*-phenylenediamines

Kenji NAKAMURA, Noboru NOHARA, and Kohji MATSUI

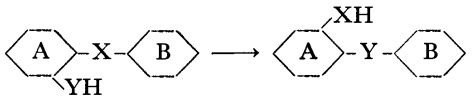
(Received December 22, 1971)

Several 4-substituted N^1-[bis-(diethylamino)-*s*-triazinyl]-N^1-(dimethoxy-*s*-triazinyl)-*o*-phenylenediamines were synthesized, and the migrations of the *s*-triazinyl group were investigated in these compounds. In methanol, every 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine gave only 4-substituted N^1-[bis-(diethylamino)-*s*-triazinyl]-N^2-(dimethoxy-*s*-triazinyl)-*o*-phenylenediamine by the migration of the dimethoxy-*s*-triazinyl group; the rearrangement was assumed to proceed through an intramolecular nucleophilic attack by the *ortho* amino group upon the ring carbon of the dimethoxy-*s*-triazinyl group. However, in the presence of a small amount of acid, the $N^1 \rightarrow N^2$ migration of the bis(diethylamino)-*s*-triazinyl group occurred preferentially, and two kinds of rearranged products were obtained. The kinetics of the rearrangement have also been studied spectrophotometrically in methanol, and the effects of the substituents on the rearrangement have been discussed.

Rearrangements involving intramolecular nucleophilic substitutions as are shown in Eq (1) are well known as Smiles rearrangements:[1]



(1)

(I) (II)

where X=O, S, CO_2, SO_2, *etc.*

YH=-OH, $-NH_2$, $-CONH_2$, -NH-Acyl, and -SH

A=substituted phenyl or other aromatic group

B=substituted phenyl or nitrogen heteroaromatic group

As for the Smiles rearrangement involving aryl migrations between two functional groups of the same kind, several examples of an oxygen-oxygen displacement have been reported.[2]

Recently, $N^1 \rightarrow N^2$ migrations of the aryl group have been observed in the reactions of *N*-phenyl derivatives of *o*-phenylenediamine or hydrazine[3] with alkyllithium and α-bromoacetanilides with amines.[4] However, little is known about the Smiles rearrangement of the nitrogen-nitrogen type. It was, therefore, of interest to study the $N^1 \rightarrow N^2$ migration of an aromatic system with *s*-triazinyl derivatives of *o*-phenylenediamine or other diamines in which the *s*-triazinyl group migrates as an aromatic system. For this purpose, 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines were found to be suitable substrates; the present work will report the $N^1 \rightarrow N^2$ migration of the *s*-triazinyl group and the effect of substituents on the rearrangement with these compounds.

4-Substituted 2-nitroanilines were converted with cyanuric chloride into 2,4-dichloro-6-(4-substituted 2-nitrophenylamino)-*s*-triazines (IV), which, with sodium methoxide, then gave 2,4-dimethoxy-6-(4-substituted 2-nitrophenylamino)-*s*-triazines (V). The substances (V) were converted with cyanuric chloride into 4-substituted *N*-(4,6-dichloro-*s*-triazin-2-yl)-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-nitroanilines(VI), which, with diethylamine, then gave 4-substituted *N*-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-nitroanilines (VII); 4-substituted N^1-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-N^1-(4,6-dimethoxy-*s*-triazin-2-yl)-*o*-phenylenediamines (III) were obtained by the hydrogenation of VII, using

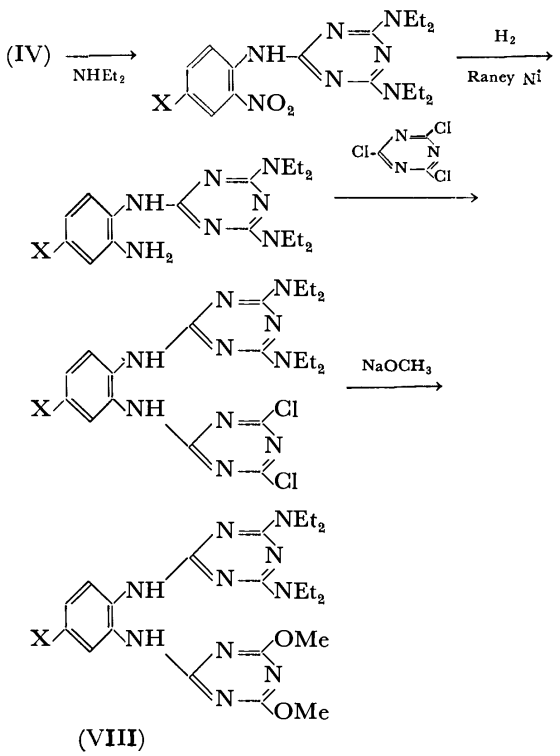
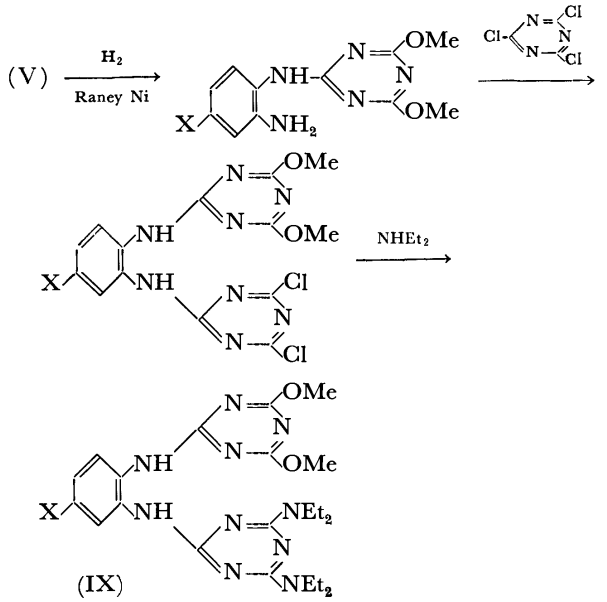
Raney nickel as the catalyst. However, in the case of every hydrogenated product, the presence of N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamine (VIII), which is assumed to be produced by a rearrangement of preformed N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine (III), was observed. The formation of N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamine (VIII) during the hydrogenation shows that the rearrangement of N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine (III) occurred fairly readily.

The intermediates IV, V, VI, VII, and N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines (III) thus obtained are listed in Tables 1, 2, 3, 4, and 5.

Rearrangement of N¹,N¹-*Bis(*s*-triazinyl)-*o*-phenylenediamines.* Because of the presence of two different *s*-triazinyl groups in these 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines (III), it is assumed that each compound may rearrange to give two kinds of 4-substituted N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines, depending upon whether the migrating group is the dimethoxy-*s*-triazinyl or bis(diethylamino)-*s*-triazinyl group. Authentic samples of these rearranged compounds were synthesized from IV or V as follows:





The N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines (VIII and IX) thus obtained are listed in Tables 6 and 7.

In preliminary experiments, it was found that the compounds III are stable in such aprotic solvents as benzene, cyclohexane, carbon tetrachloride, and acetone, but that they rearrange to give N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines (VIII) in methanol and ethanol, and somewhat more readily in the presence of sodium hydroxide in these protic solvents, as will be described kinetically later. However, an intermolecular reaction between III-1 and aniline to give 2,4-dimethoxy-6-anilino-*s*-triazine or 2,4-bis(diethylamino)-6-anilino-*s*-triazine did not take place. Moreover, *N*-[bis(diethylamino)-*s*-triazinyl]-*N*-(dimethoxy-*s*-triazinyl)-2-nitroaniline (VII-1), whose *s*-triazinyl groups are expected to be more reactive towards a nucleophilic reagent than those of III-1 because of the presence of a nitro group, did not react with aniline or *p*-anisidine under similar reaction conditions. From these results, it is obvious that the rearrangement of N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine (III) is intramolecular.

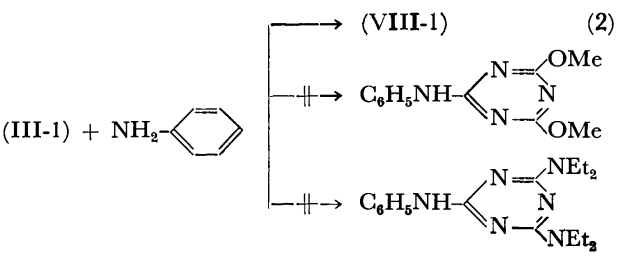


TABLE 6. 4-SUBSTITUTED N^1-[4,6-BIS(DIETHYLAMINO)-*s*-TRIAZIN-2-YL]-N^2-(4,6-DIMETHOXY-*s*-TRIAZIN-2-YL)-*o*-PHENYLENEDIAMINES (VIII)

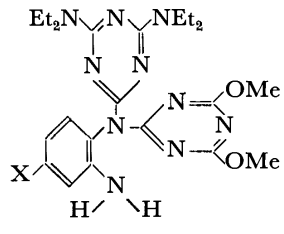
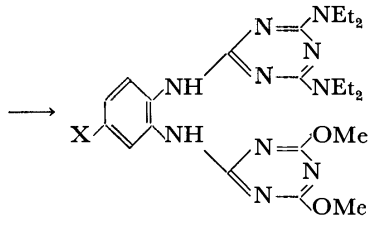
When 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine was heated in methanol in either the presence or absence of sodium hydroxide, only one kind



(III)



(3)

(VIII)

X = -H, $-CH_3$, $-OCH_3$, -Cl

of 4-substituted N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamine was obtained, regardless of the substituent in the 4-position; in every case the rearranged product was proved to be 4-substituted N^1-[bis(diethylamino)-*s*-triazinyl]-N^2-(dimethoxy-*s*-triazinyl)-*o*-phenylenediamine (VIII) by a mixed-melting-point test with an authentic sample. These results show that, in these 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines, a migration of the dimethoxy-*s*-triazinyl group occurs under these reaction conditions.

Effects of Substituents on the Rearrangement of 4-Substituted N^1,N^1-*bis(s-triazinyl)-o-phenylenediamines.* Table 8 lists the yields of the rearranged products of several 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines when they are heated at 50°C for 50 hrs in methanol in the presence of a small amount of sodium hydroxide. From these figures, it is apparent that the facility of the rearrangement varies with the substituent according to the following order:

$$H > CH_3 > Cl > OCH_3$$

TABLE 8. YIELDS OF REARRANGED PRODUCTS OF 4-SUBSTITUTED N^1-[4,6-BIS(DIETHYLAMINO)-*s*-TRIAZIN-2-YL]-N^1-(4,6-DIMETHOXY-*s*-TRIAZIN-2-YL)-*o*-PHENYLENEDIAMINES (III) IN METHANOL IN THE PRESENCE OF SODIUM HYDROXIDE (50°C)

Substituent	H	CH_3	Cl	CH_3O
Yield (%)	53	48	25	21

As has been described above, the compounds III gave 4-substituted N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines in alcohols. In methanol, both N^1,N^1-bis(*s*-triazinyl)- and N^1,N^2-bis(*s*-triazinyl)-*o*-phenylenediamines have absorption maxima at about 270 nm, but in every case the molar extinction coefficient of the original substance is much smaller than that of the rearranged product, as Table 9 shows. Therefore, the absorption in this region increases with the progress of the rearrangement, and the rate of the rearrangement can be measured spectrophotometrically. Since a plot of $-\log (D_\infty - D_t)/(D_\infty - D_0)$ against the reaction time, t, was found to give a straight line, as is shown in Fig. 1, the first-order rate constant for the rearrangement can be calculated using Eq. 6. (See Experimental section). Table 10 lists the first-order rate constants

TABLE 9. MOLAR EXTINCTION COEFFICIENTS OF 4-SUBSTITUTED N^1-[BIS-(DIETHYLAMINO)-*s*-TRIAZINYL]-N^1-(DIMETHOXY-*s*-TRIAZINYL)-*o*-PHENYLENEDIAMINES (III) AND 4-SUBSTITUTED N^1-[BIS(DIETHYLAMINO)-*s*-TRIAZINYL]-N^2-(DIMETHOXY-*s*-TRIAZINYL)-*o*-PHENYLENEDIAMINES (VIII) AT 270 nm

TABLE 11. EFFECT OF SODIUM METHOXIDE ON THE RATE OF THE REARRANGEMENT OF N^1-[BIS(DIETHYLAMINO)-*s*-TRIAZINYL]-N^1-(DIMETHOXY-*s*-TRIAZINYL)-*o*-PHENYLENEDIAMINE IN METHANOL (40°C)

Solvent	Rate constant (min^{-1})
Methanol	1.36×10^{-4}
Methanol–water (96.2 : 3.8 by volume)	1.34×10^{-4}
CH_3ONa methanolic solution (1.5×10^{-3} mol/*l*)	2.42×10^{-4}

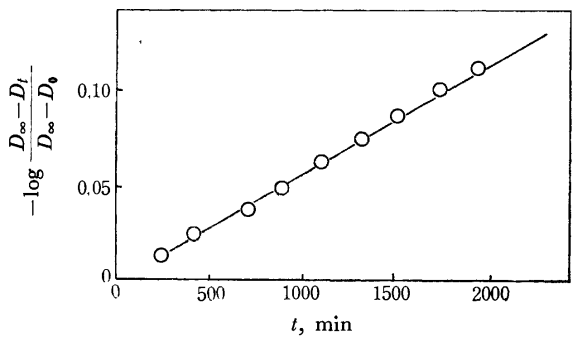

Fig. 1. First-order rate plot for the rearrangement of N^1-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-N^1-(4,6-dimethoxy-*s*-triazin-2-yl)-*o*-phenylenediamine (III-1) in methanol at 40°C.

and activation parameters for the rearrangements of III in methanol. From a comparison of these figures with those of the rearrangement of 4-substituted *O*-(dimethoxy-*s*-triazinyl)-2-aminophenols,[5)] it is apparent that these reactions proceed somewhat more slowly than those of the corresponding 4-substituted *O*-(dimethoxy-*s*-triazinyl)-2-aminophenols in methanol. However, *O*-(*s*-triazinyl)-2-aminophenols are also stable in aprotic solvents and rearrange readily in protic solvents, and the rearrangement is catalyzed by bases[6)] in a manner similar to that in the case of III. As an example, a catalytic effect of sodium methoxide on the rearrangement of III-1 in methanol is shown in Table 11. Moreover, both these reactions are intramolecular, and the activation energies and activation entropies of the rearrangements of III in methanol are close in magnitude to those of the rearrangement of *O*-(*s*-triazinyl)-2-aminophenols. Therefore, it may be assumed that the process of the rearrangement of N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenedi-

5) N. Maeno, T. Itagaki, S. Uno, and K. Matsui, submitted to This Bulletin.

6) T. Shiojima, Y. Hashida, and K. Matsui, details will be published elsewhere.

amines is very similar to that of *O*-(*s*-triazinyl)-2-aminophenols, involving an intramolecular nucleophilic attack by the *ortho* amino group upon the ring carbon of one of the *N*-*s*-triazinyl groups.

It can be seen from Table 10 that the substituents in N^1,N^1-(bis-*s*-triazinyl)-*o*-phenylenediamines affect the progress of the rearrangement to a great extent, but the effect of substituents differs according to the nature and the position of substituents. With respect to the substituents in the triazine nucleus, it is expected that an electron-withdrawing substituent will favor the nucleophilic attack by the amino group by lowering the electron density of triazine carbon atoms. In the cases studied, the dimethoxy-*s*-triazinyl group is anticipated to be more reactive towards nucleophiles than the bis(diethylamino)-*s*-triazinyl group. In fact, the formation of VIII from III indicates that, under the reaction conditions described above, the nucleophilic attack by the *ortho* amino group takes place preferentially upon the more electron-deficient ring carbon of the dimethoxy-*s*-triazinyl group.

Although it is still uncertain whether this migration proceeds by the S_N2 mechanism or by the intermediate-complex mechanism, the effect of a substituent in the *o*-phenylenediamine moiety may be considered from two points of view. One is the influence of the substituent upon the nucleophilic reactivity of the attacking amino group, and the other is the influence upon the reactivity of the migrating triazine nucleus through the nitrogen atom or the stability of the leaving amide anion. In the former, an electron-releasing effect of a substituent favors the rearrangement, while an electron-attracting effect favors the latter. In the cases studied, the position of the substituent was *meta* to the free amino and *para* to the bis-*s*-triazinylamino group, and it can be assumed that the more the σ_m value of a substituent becomes negative, and the more the σ_p value becomes positive, the more readily does the rearrangement occur. Therefore, the Hammett equation for reactions like this rearrangement may be expressed by Eq. (4), which consists of a sum of two terms:[7]

$$\log k/k_0 = \sigma_p\rho + \sigma_m\rho' \qquad (\rho \mp \rho') \tag{4}$$

where the reaction constants ρ and ρ' are attributable to the effect of a substituent on the reactivity of the migrating triazine ring or on the stability of the leaving amide anion, and to the effect of a substituent on the nucleophilicity of the amino group, respectively. Using the rate constants at 40°C and the Hammett substituent constants, the ρ and ρ' values calculated by the method of least squares were found to be:

$$\rho = 2.20, \qquad \rho' = -3.35$$

respectively; the ratio ρ'/ρ was -1.52, and a Hammett plot of log k_1 against $\sigma_p - 1.52\ \sigma_m$ gave a straight line, with a correlation coefficient of 0.993, as is shown in Fig. 2.

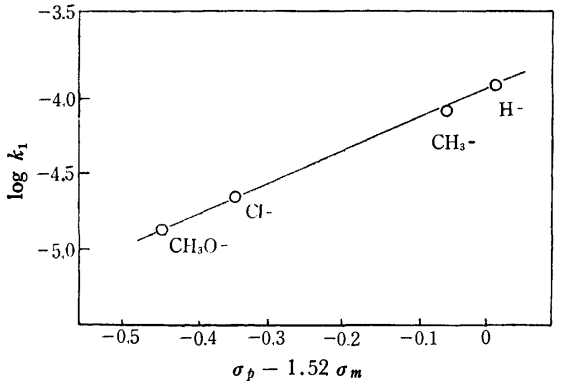

Fig. 2. Plot of log k_1 against $(\sigma_p - 1.52\ \sigma_m)$ for the rearrangement of 4-substituted N^1,N^1-Bis-(*s*-triazinyl)-*o*-phenylenediamines (III) in methanol. (40°C).

Thus, in this reaction, it became clear that, by using Eq. (4) instead of the usual Hammett equation, involving only one term, a good linear relationship is obtained between the substituent constants and the logarithm of the rate constants. These figures show that, in the rearrangement of 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines (III), the substituent affects the nucleophilic reactivity of the the free amino group more than the stability of the leaving amide anion or the reactivity of the triazinyl group.

Rearrangement of N¹,N¹-*Bis(s-triazinyl)-o-phenylenediamines in the Presence of Acid.* As has been mentioned in the preceding paragraph, 4-substituted N^1 - [bis(diethylamino) - *s* - triazinyl] - N^1 - (dimethoxy-*s*-triazinyl)-*o*-phenylenediamines (III) gave, in methanol, only 4-substituted N^1-[bis(diethylamino)-*s*-triazinyl]-N^2-(dimethoxy-*s*-triazinyl)-*o*-phenylenediamines (VIII). In the presence of sodium hydroxide, the rearrangement was found to proceed more readily, as has been described above, but the compound VIII was the only product obtained in this case. However, in methanol in the presence of a small amount of hydrochloric acid (5×10^{-3} mol/*l*), 4-substituted N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine (III) (7×10^{-3} mol/*l*) gave two kinds of rearranged products, regardless of the substituent in the 4-position. One was 4-substituted N^1-[bis(diethylamino)-*s*-triazinyl]-N^2-(dimethoxy-*s*-triazinyl)-*o*-phenylenediamine (VIII), while the other was proved to be 4-substituted N^1-(dimethoxy-*s*-triazinyl)-N^2-[bis(diethylamino)-*s*-triazinyl]-*o*-phenylenediamine (IX), which is obviously produced by the migration of the bis(diethylamino)-triazinyl group. Under the present reaction conditions, the ratios of the yields of the two isomers (IX/VIII) were found to vary depending upon the substituentt in the 4-position; they were 1.1 when the substituent was the methoxyl group and 1.7 when the substituent was chlorine. Thus, in every case the major product was a compound of the IX type. These results indicate that the presence of acid accelerates the migration of the bis(diethylamino)-*s*-triazinyl group, and it can be assumed that the predominant rearrangement of the bis(diethylamino)-*s*-triazinyl group proceeds as follows. The initial stage of this reaction is a preferential lowering of the electron density of ring carbon atoms of the bis-diethylamino-*s*-triazinyl group by a protonation at the ring nitrogen atom[8] of this

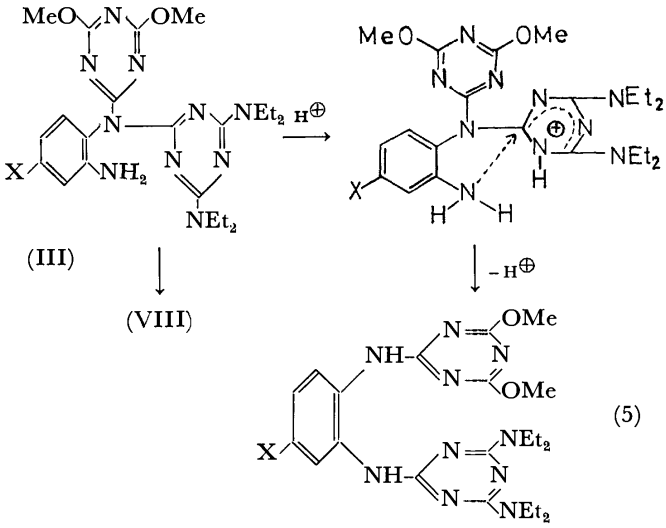
more basic *s*-triazine nucleus; the next step of the reaction is a nucleophilic attack by the *ortho* amino group upon the ring carbon of the activated triazine nucleus by protonation. A compound of the VIII type is anticipated to be produced by a non-catalytic process under the reaction conditions described above.

A study concerning the influences of solvents and bases on the rearrangement is in progress; it will be reported in the near future.



Experimental

All the melting points are uncorrected.

The ultraviolet spectra were recorded on a Hitachi-124 UV-VIS spectrophotometer. The NMR spectra were recorded on a Varian A-60D spectrometer. The elemental analyses were performed in the Micro-analytical Center of Gunma University.

Materials. *2-Arylamino-4,6-dichloro-s-triazines (IV)*: 2-Arylamino-4,6-dichloro-*s*-triazines were prepared by treating 4-substituted 2-nitroanilines with cyanuric chloride, as has been described in the case of 2-(*o*-carbomethoxyanilino)-4,6-dichloro-*s*-triazine.[9]

2-Arylamino-4,6-dimethoxy-s-triazines (V): 2-Arylamino-4,6-dimethoxy-*s*-triazines were prepared by treating 2-arylamino-4,6-dichloro-*s*-triazines with sodium methoxide in methanol, as has been described in the case of 2,4-dimethoxy-6-(2-nitroanilino)-*s*-triazine (V-1).[9]

N-(4,6-Dichloro-s-triazin-2-yl)-N-(4,6-dimethoxy-s-triazin-2-yl)-arylamines (VI): These compounds were prepared by treating 2-arylamino-4,6-dimethoxy-*s*-triazines (V) with cyanuric chloride under conditions similar to those used in the preparation of *N,N*-bis(4,6-dichloro-*s*-triazin-2-yl)-arylamines[9] from IV.

N-[4,6-Bis(diethylamino)-s-triazin-2-yl]-N-(4,6-dimethoxy-2-s-triazin-2-yl)-arylamines (VII): A typical preparation is shown below in the case of *N*-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-4-methoxy-2-nitroaniline (VII-3). A solution of 8.8 g (0.12 mol) of diethylamine in 50 m*l* of acetone was stirred drop by drop into a solution of 13.7 g (0.03 mol) of *N*-(4,6-dichloro-*s*-triazin-2-yl)-*N*-(4,6-dimethoxy-*s*-triazin-2-yl)-4-methoxynitroaniline (VI-3) in 200 m*l* of acetone at 0—5°C. Stirring was continued for 8 hr at 35—40°C, and then the mixture was refluxed for 2 hr and poured into 500 m*l* of ice-water. The oily precipitate was extracted with chloroform and the chloroform layer was dried and evaporated and the residue was collected (VII-3).

4-Substituted N¹-[4,6-bis(diethylamino)-s-triazin-2-yl]-N¹-(4,6-dimethoxy-s-triazin-2-yl)-o-phenylenediamines (III): A typical run is noted in the case of *N*¹-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-*N*¹-(4,6-dimethoxy-*s*-triazin-2-yl)-4-chloro-*o*-phenylenediamine (III-4). A mixture containing 30 m*l* of dioxane, 5.4 g (0.01 mol) of VII-4, and 3 g of Raney nickel was stirred for 5 hr at room temperature under a pressure of 100 kg/cm² of hydrogen. After the catalyst had then been removed by filtration, the solution was poured into 500 m*l* of ice water. The precipitate was then filtered and dried. The recrystallization of the product from benzene–ligroin gave 3.5 g (88%) of III-4. NMR (DMSO-d_6) δ 1.10 (t, 12H), 3.48 (q, 8H), 3.80 (s, 6H), 5.24 (s, 2H), 6.84 (m, 3H).

4-Substituted N¹-[4,6-bis(diethylamino)-s-triazin-2-yl]-N²-(4,6-dimethoxy-s-triazin-2-yl)-o-phenylenediamines (VIII). *i)* *N¹-[4,6-Bis(diethylamino)-s-triazin-2-yl]-N²-(4,6-dimethoxy-s-triazin-2-yl)-o-phenylenediamine (VIII-1).* A mixture containing 5.6 g (0.02 mol) of V-1, 40 m*l* of dioxane, and 3 g of Raney nickel was stirred for 7 hr at 50°C under a pressure of 60 kg/cm² of hydrogen. The mixture was processed according to the procedure for III-4 to give 4.8 g (97%) of crude *N*-(4,6-dimethoxy-*s*-triazin-2-yl)-*o*-phenylenediamine. Recrystallization from benzene gave an analytical sample. Mp 150—151°C. Found: C, 53.72; H, 5.20%. Calcd for $C_{11}H_{13}N_5O_2$: C, 53.43; H, 5.30%.

Compound VIII-1 was prepared by treating the *N*-(4,6-dimethoxy-*s*-triazin-2-yl)-*o*-phenylenediamine thus obtained with cyanuric chloride, followed by treatment with diethylamine according to the procedures used in the preparation of VII-3. Recrystallization from methanol gave an analytical sample. Mp 127.5—128.5°C. NMR (DMSO-d_6) δ 1.09 (t, 12H), 3.51 (q, 8H), 3.83 (s, 6H), 7.48 (m, 4H), 8.31 (s, 1H), 9.66 (s, 1H).

ii) *N¹-[4,6-Bis(diethylamino)-s-triazin-2-yl]-N²-(4,6-dimethoxy-s-triazin-2-yl)-4-methyl-o-phenylenediamine (VIII-2).* Compound VIII-2 was prepared in a manner similar to that to be described below, the preparation of VIII-3 from IV-2 without any purification of the intermediates. Mp 155—155.5°C. NMR (DMSO-d_6), δ 1.10 (t, 12H), 2.31 (s, 3H), 3.52 (q, 8H), 3.87 (s, 6H), 7.29 (m, 3H), 8.31 (s, 1H), 9.60 (s, 1H).

iii) *N¹-[4,6-Bis(diethylamino)-s-triazin-2-yl]-N²-(4,6-dimethoxy-s-triazin-2-yl)-4-methoxy-o-phenylenediamine (VIII-3).* 2,4-Bis(diethylamino)-6-(4-methoxy-2-nitroanilino)-*s*-triazine obtained by treating IV-3 with an excess of diethylamine [mp 95.5—96°C (ethanol), Found: C, 55.54; H, 7.32%. Calcd for $C_{18}H_{27}N_7O_3$: C, 55.51; H, 6.98%] was hydrogenated in dioxane in the presence of Raney nickel. The resulting oily product [crude 2,4-bis(diethylamino)-6-(2-amino-4-methoxyanilino)-*s*-triazine] was treated with cyanuric chloride and then with sodium methoxide in methanol. Recrystallization from methanol gave an analytical sample of VIII-3. Mp 106—107°C, NMR (DMSO-d_6) δ 1.08 (t, 12H), 3.50 (q, 8H), 3.76 (s, 3H), 3.87 (s, 6H), 7.15 (m, 3H), 8.32 (s, 1H), 9.58 (s, 1H).

iv) *N¹-[4,6-Bis(diethylamino)-s-triazin-2-yl]-N²-(4,6-dimethoxy-s-triazin-2-yl)-4-chloro-o-phenylenediamine (VIII-4).* 2,4-Bis(diethylamino)-6-(4-chloro-2-nitroanilino)-*s*-triazine obtained by treating IV-4 with an excess of diethylamine in acetone [mp 128—129°C (benzene) Found: C, 51.50; H, 5.80%, Calcd for $C_{17}H_{24}ClN_7O_2$: C, 51.84: H, 6.14%] was hydrogenated in dioxane in the presence of Raney nickel to give 2,4-bis(diethylamino)-6-(2-amino-4-chloroanilino)-

9) N. Nohara, S. Sekiguchi, and K. Matsui, *J. Heterocycl. Chem.*, **7**, 519 (1970).

s-triazine [mp 122—122.5°C (methanol)]. Found: C, 55.80; H, 7.02%. Calcd for $C_{17}H_{26}ClN_7$: C, 56.11; H, 7.20%.

The 2,4-bis(diethylamino)-6-(2-amino-4-chloroanilino)-*s*-triazine thus obtained was treated with cyanuric chloride and then with sodium methoxide in methanol. The recrystallization of the reaction product from methanol gave an analytical sample of VIII-4; mp 161—162°C. NMR (DMSO-d_6)δ 1.09 (t, 12H), 3.51 (q, 8H), 3.86 (s, 6H), 7.33 (m, 3H), 8.41 (s, 1H), 9.70 (S, 1H).

4-Substituted N¹-*(4,6-Dimethoxy-*s*-triazin-2-yl)*-N²-*[4,6-bis-(diethylamino)-*s*-triazin-2-yl]-o-phenlyenediamines (IX).* A typical run, that in the case of N^1-(4,6-dimethoxy-*s*-triazin-2-yl)-N^2-[4,6-bis(diethylamino)-*s*-triazin-2-yl]-4-methyl-*o*-phenylenediamine (IX-2), will be described. A mixture containing 3.5 g (0.012 mol) of V-2, 30 m*l* of dioxane, and 3 g of Raney nickel was stirred for 5hr at 60—70°C under a pressure of 100 kg/cm² of hydrogen. After the catalyst had then been removed by filtration, the solution was evaporated *in vacuo*. The residue was, without purification, treated with cyanuric chloride and then with diethylamine. The subsequent recrystallization of the product from methanol gave an analytical sample of IX-2. Mp 130—131°C. NMR (DMSO-d_6),δ 1.12 (t, 12H), 2.30 (s, 3H), 3.49 (q, 8H), 3.85 (s, 6H), 7.29 (m, 3H), 8.18 (s, 1H), 9.56 (s, 1H).

Identification and Quantitative Determination of Rearranged Products. A typical example is shown below in the case of III-3. A solution of III-3 in methanol (0.1009 g/30 m*l* $=2\times10^{-4}$ mol/30 m*l*) containing a small amount of sodium hydroxide (1×10^{-4} mol/30 m*l*) was warmed for 20 hr at 50°C. To the mixture, 0.0498 g (2.89×10^{-4} mol) of 4-chloro-2-nitroaniline was added as an internal standard, after which the mixture was developed on a silica-gel layer, using a mixture of benzene and acetone (40 : 3 by volume) as the developing solvent. From the thin-layer chromatogram thus obtained, the original substance, a rearranged product, and the internal standard were eluted with ethanol separately and afterward diluted to a constant volume, the concentration of each solution being determined by measuring the absorbance at 280 nm (original substance), 270 nm (rearranged product), and 410 nm (4-chloro-2-nitroaniline). The rearranged product was identified by a mixed-melting-point test with an authenitc sample after the rearranged product had been separated from the original and other substances by tlc and purified by recrystallization.

Kinetic Measurements. The kinetic measurements were carried out spectrophotometrically by measuring the increase in the absorbance at 270 nm of a methanolic solution of III (*ca.* 10^{-4} mol/l) at 40, 45, and 50°C; the first-order rate constant for the rearrangement was calculated using Eq. 6:

$$k_1 = -2.303\frac{1}{t}\log\frac{D_\infty - D_t}{D_\infty - D_0} \qquad (6)$$

where D_0=initial optical density of a solution of N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamine (III) in methanol.

D_t=optical density of a solution at time t.

D_∞=optical density of a solution at an infinite time.

Syntheses of Isoprenoids from Isoprene. III. The Dimerizations of Dimethylcyclopropanes[1]

Juntaro TANAKA, Takao KATAGIRI, Kunihiko TAKABE, and Tadashi SAKAMOTO

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received December 27, 1971)

1,1-Dimethylcyclopropane(I) was found to dimerize selectively by the action of boron trifluoride etherate. In the products, compound (III), which had been presumed, and the reaction intermediates (VII and VIII) were identified. The reaction mechanism was discussed. 1,2-Dimethylcyclopropane(VI) gave the same products.

1,1-Dimethylcyclopropane(I) has been reported to polymerize.[2-4] However, the oligomers have not been studied in detail. We will reported here, however, that I is dimerized selectively by the action of boron trifluoride etherate to give 3,4,5,5-tetramethyl-2-hexene(II), 2,3,4,4-tetramethyl-1-hexene(III), 3,5,5-trimethyl-2-heptene(IV), and 3,4,4,5-tetramethyl-2-hexene(V). Furthermore, the reaction intermediates were confirmed, and the reaction mechanism was discussed. 1,2-Dimethylcyclopropane(VI) was also reacted by the same catalyst.

Experimental

Materials. 1,1-Dimethylcyclopropane(I) was synthesized from isoprene by our method.[5] Bp 21°C, NMR(τ); 8.97(6H, s), 9.80(4H, s). 1,2-Dimethylcyclopropane(VI) was prepared from 2-butene by a modification of Doering and Hoffmann's method.[6] Bp 28—37°C, NMR(τ); 9.00(d), 9.01(d), 9.20—9.91(m).

Measurements. The products were analyzed after glc fractionation (15% Apiezon grease L/Celite 545, 4 mmϕ $\times$2.5 m, H_2: 45ml/min, 90°C). The IR spectra were recorded on a Perkin Elmer Model 337 infrared spectrophotometer. The NMR spectra were run on a Hitachi-Perkin Elmer Model R-20 (60 MHz) spectrometer, using tetramethyl-

silane as the internal reference and carbon tetrachloride as the solvent, at an ordinary temperature. The mass spectra were recorded on a Hitachi RMU-7U mass spectrometer.

Procedure. In a 30-ml flask, which was controlled at a fixed temperature, we placed 2 g of I, and then 1 g of boron trifluoride etherate was stirred on, drop by drop. After the reaction, the catalyst was deactivated with water and the reaction mixture was extracted with ether. The ether layer was washed with a saturated NaCl aqueous solution and dried over K_2CO_3. VI was reacted in the same manner.

3,4,5,5-Tetramethyl-2-hexene(II). RT: 10.5 min. IR(cm^{-1}): 1670, 820. Mass(*m/e*): 140(M^+, 22%), 84 ($M^+-C_4H_9$, 100%), IR(cm^{-1}): Mass(*m/e*): 140($M^+-C_4H_9$, 1670, 820. 100%), 57($C_4H_9^+$, 60%). NMR(τ): 4.89(1H, q, J=6.0 Hz), 8.09(1H, q, J=6.8 Hz), 8.45(3H, s), 8.49 (3H, d, J=6.0 Hz), 9.04(3H, d, J=6.8 Hz), 9.16(9H, s). n_D^{20} 1.4377(lit,[7] n_D^{20} 1.4360).

2,3,4,4-Tetramethyl-1-hexene(III). RT: 12.5 min. IR(cm^{-1}): 1650, 890. Mass(*m/e*): 140(M^+, 2%), 70($C_5H_{10}^+$, 100%), 43($C_3H_7^+$, 77%). NMR(τ): 5.23(1H, s), 5.39(1H, s), 7.94(1H, q, J=7.0 Hz), 8.30(3H, s), 8.81(2H, q, J=7.0 Hz), 9.03(3H, d, J=7.0 Hz), 9.19(3H, t, J=7.0 Hz). n^{20} 1.4389.

3,5,5-Trimethyl-2-heptene(IV) and 3,4,4,5,-Tetramethyl-2-hexene(V). IV and V had the same RT (14.0 min) and could not be identified. Therefore, these two compounds were confirmed after an ozonolysis of the glc fraction (RT: 14.0 min) carried out in chloroform. *3,3,4-Tetramethyl-2-pentanone*[8] (which was derived from V). RT: 12.9 min. IR(cm^{-1}): 1710. NMR(τ): 7.79(3H, s), 7.75—8.50(1H, m), 9.02(6H, s), 9.18(6H, d, J=6.8 Hz). *4,4-Dimethyl-2-hexanone* (which was derived from IV). RT: 11.7 min. IR(cm^{-1}): 1710. NMR(τ): 7.77(2H, s), 7.99(3H, s), 8.75(2H, q, J=6.8 Hz), 9.07(6H, s), 9.07(3H, t, J=6.8 Hz).

Results and Discussion

The yields of IV were not seriously affected by the reaction periods or times, as is shown in Tables 1 and 2. Therefore, the reaction path to produce IV seems to

7) F. C. Whitmore and A. Mosher. *J. Amer. Chem. Soc.*, **63**, 1120 (1941).

8) This compound was identical with the authentic sample synthesized by the method of the literature (J. W. Baker, *J. Chem. Soc.*, **1950**, 1302.

be different from the path to give other dimers, such as II, III, and V. Furthermore, the components in the volatile fraction of the reaction mixture were confirmed to be 2-methyl-2-butene(VII) and 2-methyl-1-butene (VIII). Since these seemed to be the reaction intermediates, mixtures of these compounds obtained from *t*-amyl alcohol by dehydration (VII: VIII=6 : 1) were reacted by the same catalyst. The results (Table 3) were very similar to those for I, while the reactivity to the dimers was superior to that of I.

From these results, the mechanism to produce II, III, V, and IV may be as follows. The cation(IX) formed from I was deprotonated to give VII and VIII, and then coupled with VII to give the cation(X). From this cation, III was obtained by deprotonation. The formation of II and V from the cation(X) can be explained by the mechanism of the carbonium-ion rearrangements:[9-11] these rearrangements were clarified by the reaction of III.[12] That is, the confirmation of III clarified the existence of X predicted by Whitmore and Mosher.[9] The other dimer, IV, was formed through the cation(XI), which was formed by the coupling of the above-mentioned cation (IX) and VIII.

Since scarcely VII and VIII could be obtained in the reaction of III,[12] the two reaction paths seem to be largely independent. The reaction scheme is illustrated in Fig. 1.

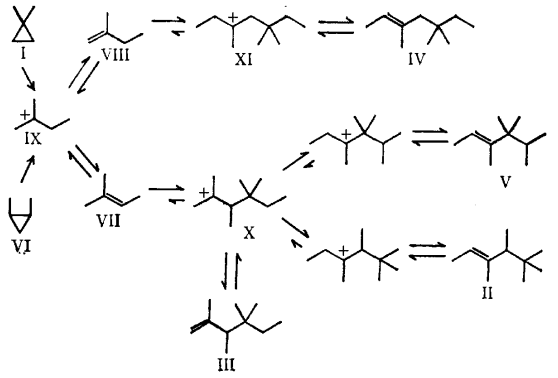

Fig. 1. The reaction scheme.

When 1,2-dimethylcyclopropane(VI) was reacted by the same catalyst (Table 3), the results were very similar to those for I, but the reactivity was inferior to that of I. The difference in the reactivities may be due to the relative difficulties of the cleavage of the cyclopropanes.[13,14]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3149—3155 (1972)

Syntheses and Reactions of Functional Polymers. LXVI. Activation of Carboxylic Acid by Means of Polymers Containing Hydroxamic Acid Residue and *N*-Hydroxysuccinimide Residue

Mitsuaki NARITA,* Takero TERAMOTO, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguroku, Tokyo

(Received January 20, 1972)

In order to achieve solid-phase acyl activation of carboxylic acid, the syntheses and reactions of polymers containing hydroxamic acid and *N*-hydroxysuccinimide residues were investigated. A polymer containing hydroxamic acid residue was obtained by the modification of cross-linked copolymer of *p*-nitrophenyl acrylate with styrene, and one containing *N*-hydroxysuccinimide residue was prepared by copolymerization of *N*-acetoxymaleimide with styrene followed by hydrolysis. These *N*-hydroxy polymers were allowed to react with *N*-protected amino acids by means of the dicyclohexylcarbodiimide method giving the activated polymer ester. While the polymer containing hydroxamic acid residue was inferior to that containing *N*-hydroxysuccinimide residue in activation of carboxylic acid, amino acid esters of the latter were active enough to react with another amino acid to yield dipeptides almost quantitatively without racemization.

Activation of carboxylic acid under mild conditions is a useful method for selective acylation in peptide syntheses. The utilization of polymers carrying the active ester group in stepwise syntheses of peptides has been described for the polymers containing *o*-nitrophenol,[1] *p,p'*-dihydroxydiphenyl sulfone[2] and *N*-hydroxysuccinimide[3] moieties.

In a study on polymeric reagents, we reported on

the preparation and use of polymers having *N*-hydroxysuccinimide unit in the chain.[4] Use of such polymers would facilitate synthetic procedure, *i.e.*, separation of reaction mixture, purification of product, and recovery of the original polymer. In this article, preparation of hydroxamic acid polymer and activation of carboxylic acid by means of polymers containing hydroxamic acid and *N*-hydroxysuccinimide residues are described.

Results and Discussion

Preparation of Polymer Containing Hydroxamic Acid Residue. A series of polymer modifications was carried out as shown in scheme 1. Copolymerization of *p*-nitrophenyl acrylate with styrene (St) in the presence of divinylbenzene (DVB) was carried out to obtain cross-linked copolymer (I). Polymer (I) was reacted with benzyloxyamine and debenzylated by treatment with hydrogen bromide in acetic acid to give insoluble polymer(III). Polymer(III) was acetylated with acetic anhydride to give polymer(IV). Nitrogen analysis of polymer(I) showed that the total molar fraction of the ester was 38%. The reaction of I with benzyloxyamine proceeded almost quantitatively at 130°C for 25 hr. A characteristic feature in its IR spectrum was the presence of bands of ester at 1760 cm^{-1} and of the nitro group at 1525 cm^{-1} and

1345 cm^{-1}. In the IR spectrum of polymer(II), these absorptions disappeared and characteristic absorptions of amide appeared at 1650 cm^{-1}.

The IR absorptions of polymers(I)—(IV) and those of model compounds are shown in Table 1. The acyl content in polymer(IV) was determined from the yield of *N*-cyclohexylacetamide obtained in the reaction with excess cyclohexylamine.

Similarly, copolymerization of *p*-nitrophenyl methacrylate with styrene in the presence of DVB yielded cross-linked polymer(I'). A series of polymer modifications (scheme 1) was carried out. Polymer(I') was less reactive than polymer(I). It was transformed into amide polymer(II') almost quantitatively by treatment with benzyloxyamine in DMF at 120—140°C for 100 hr. Polymer(II'), however, was not debenzylated by treatment with hydrogen bromide in acetic acid at 80°C for 10 hr.

In general, amino acid *p*-nitrophenyl esters are remarkably reactive, and have been used frequently for peptide bond formation.[5] In the case of polymers(I) and (I'), however, their reactivities are so reduced as to need high temperature and long reaction time probably due to their insolubility and steric hindrance of main chain.

The direct reaction of polymer(I) with hydroxylamine was also attempted. A DMF solution containing hydroxylamine was prepared by mixing hydroxylamine hydrochloride with equimolar anhydrous triethylamine in DMF. Polymer(I), which was swelled enough in DMF, was then combined with the above solution and kept at room temperature overnight. The IR spectrum of polymer(III") thus obtained, however, showed that it contained carboxylic acid residue in addition to hydroxamic acid residue[broad absorptions at 3400—2300 cm^{-1} and 1730—1600 cm^{-1}].

On the other hand, the reaction of ethylacrylate–styrene copolymer with hydroxylamine or benzyloxyamine was carried out under various conditions. However, the starting polymer was recovered in all cases.

In order to prepare polymers(III) and (III'), pre-

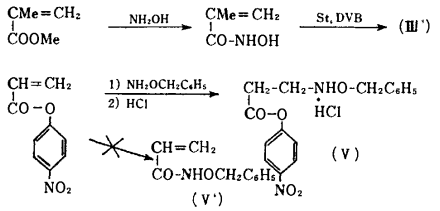
Acyl Content of Polymer(meq/g)[e]		1.08	1.06	0.74

a) Polymer(1.0 g) was reacted with 1.0 g of cyclohexylamine in 30 m*l* of methylene chloride at room temperature for 20 hr. b) Recrystallized from *n*-hexane-ethyl acetate. c) Recrystallized from ethyl acetate. d) Determined from the yield of *N*-cyclohexylacylamide. e) Determined from the increase in weight of the insoluble polymer as a result of the coupling reaction.

Table 3. The yields of dipeptides by the acylation of ethyl esters of amino acids with polymers(VIa) and (VIb)

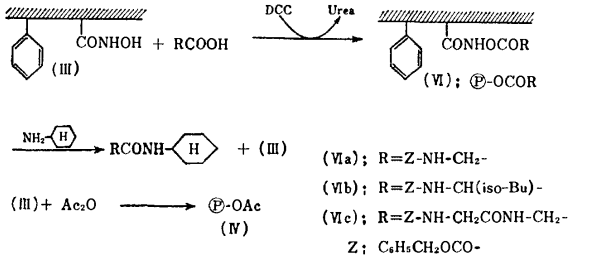
Polymer	HGlyOEt Yield of dipeptide (%)	H-L-LeuOEt Yield of dipeptide (%)
VIa	86	73
VIb	47	39

paration and polymerization of monomers having hydroxamic acid residue were attempted (scheme 2). Methacryloylhydroxamic acid was prepared by Smith's method,[6] but its copolymerization with styrene in the presence of DVB was not successful under various conditions. An attempt to prepare monomer(V') having protected hydroxy group was also carried out. However, the reaction of *p*-nitrophenyl acrylate with benzyloxyamine produced only the Michael type addition product, *p*-nitrophenyl ester of γ-(*N*-benzyloxyamino)-propionic acid(V).



Scheme 2.

Activation of Carboxylic Acid by Means of Polymer(III) Containing Hydroxamic Acid Residue. The acyl activation of amino acids with polymer(III) was investigated. Acylated polymers(VIa—c) were obtained (scheme 3) by the coupling reaction of polymer(III) with *N*-carbobenzoxy glycine(Z-GlyOH), -L-leucine(Z-LeuOH) or -glycylglycine(Z-GlyGlyOH) by



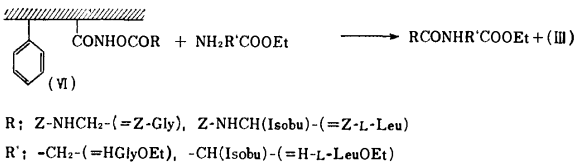
Scheme 3.

6) H. Smith, Brit. 852176 (1960); *Chem. Abstr.*, **55**, 9284[i] (1961).

use of dicyclohexylcarbodiimide(DCC) as a dehydration reagent in DMF at room temperature for 40 hr. The IR spectra of polymers(VI) exhibited characteristic absorptions similar to those of a model compound ($Z\text{-GlyONHCOCH}_3$) as shown in Table 1.

Determination of acyl contents of polymers(VIa—c) was made: (1) base on the yields of *N*-cyclohexylacylamides obtained by the reaction with excess of cyclohexylamine and (2) from the increase in weight of the polymer obtained. The results of the two methods agreed well, as shown in Table 2.

Acylation of ethyl esters of amino acids with acylated polymer (VIa, b) was carried out as shown in scheme 4.



Scheme 4.

The reaction was carried out by use of a slight molar excess of polymer(VI) in DMF at room temperature for 40 hr. The yield of acylation products was not always good as shown in Table 3. In particular, the yield of acylation with polymer(VIb) [Z-L-LeuO-Ⓟ] was low. This seems to be due to the fact that the steric hindrance reduced its reactivity as well as polymer(I) carrying active ester group adjacent to the polymer chain. This shows that the polymer used for activation of carboxylic acid should have the active ester group detached from the polymer backbone.

Although activation of carboxylic acid by means of a polymer containing hydroxamic acid residue was slightly inferior to reported polymer,[1-3] it was observed

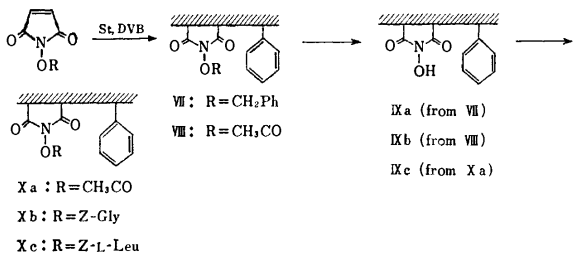
that insoluble polymeric reagents were useful for simplifying the procedures and making the separation of product easier.

Activation of Carboxylic Acid by Means of Polymer(IX) Containing N-*Hydroxysuccinimide Structure.* Several methods to prepare *N*-acyloxymaleimides were reported.[4c] *N*-Benzyloxymaleimide thus obtained was copolymerized with styrene(St) in the presence of DVB to afford cross-linked copolymer(VII), which contained 47 mol% of imide moiety according to nitrogen analysis.



Scheme 5.

Polymer(VII) was debenzylated by treatment with hydrogen bromide in acetic acid to give the intended polymer(IXa) containing *N*-hydroxysuccinimide structure as shown in scheme 5. Polymer(IX) was acylated with acetic anhydride to give *N*-acetoxy polymer (Xa) whose acyl content (3.19 meq/g) was determined by the cyclohexylamine method. The content shows that the debenzylation of polymer(VII) to (IXa) about 90%. Similarly, cross-linked copolymer(VIII) of *N*-acetoxymaleimide and styrene was prepared and hydrolyzed with 6 N-hydrochloric acid at 100°C for 10 hr in dioxane to give cross-linked polymer(IXb) with 3.12 meq/g of *N*-hydroxyimide moiety.

The coupling reaction of polymer(IXb) with Z-L-LeuOH by means of DCC was examined in various solvents. The amino acid content in the acylated polymer was determined from the yield of cyclohexylamide and the weight increase. Both results agreed well as shown in Table 4. Polymer(IXb) was swelled well in DMF and methylene chloride, but not in chloroform, dioxane and ethyl acetate. Thus, the acylation reaction proceeded effectively in good swelling solvents. Similarly, the coupling reactions of polymer(IXa) with Z-GlyOH and Z-L-LeuOH were performed in DMF by means of DCC method. The acyl contents of polymer(Xb, Xc) thus obtained were

Table 9. Optical rotation of dipeptide $[\alpha]_D^{18}$ ($c=0.2$, in ethanol)

Dipeptide	Prepared by using polymer(Xc)	Prepared by using the DCC method	Lit.
Z-L-LeuGlyOEt	−27.5	−25	−27.2
Z-L-Leu-L-LeuOEt	−37	−40.5	

determined by use of cyclohexylamine and the results are shown in Table 5 together with those of polymer (Xa). The regenerated *N*-hydroxyimide polymer(IXc) from X combined with cyclohexylamine (from IR data) as discussed in the preceding paper.[4c] The characteristic IR absorption data on these polymers are shown in Table 6.

For the sake of confirmation, polymer(IXc) was allowed to react with excess acetic anhydride. The acyl content in the polymer obtained was 3.19 meq/g, the same as in the above polymer(Xa).

The coupling of polymer(IXb) with various chain length acids was investigated. The acyl contents of polymer(XI) obtained are shown in Table 7. The DCC method was superior to the mixed anhydride method. The acyl content did not increase with prolonged reaction time. The fraction of reacted *N*-hydroxy group decreased with the increase of the number of amino acids in peptide. On the other hand, the fraction was higher in the case of glycine derivatives than in leucine derivatives for the same number of amino acids.

The acylation of ethyl esters of amino acids with polymer(X) was carried out. The reaction was carried out by using a slight excess of the acylated polymer in DMF at room temperature. The melting points and yields of the crude dipeptide derivatives obtained are shown in Table 8. The acylation with polymers (Xa—c) proceeded almost quantitatively. Crude products gave pure dipeptide derivatives by recrystallization. The optical rotations of Z-L-LeuGlyOEt and Z-L-Leu-L-LeuOEt obtained by the reaction of polymer (Xc) are shown in Table 9. The values agree with those in literature and those of the product obtained by the usual DCC method. Thus, acylation with polymer(Xc) seems to proceed without racemization.

In conclusion, the *N*-hydroxyimide polymer(IX) is superior to the hydroxamic acid polymer(III) in its

9) St. Goldschmidt, and M. Wick, *Ann.*, **575**, 217 (1952).
10) G. W. Anderson, J. Bloninger, and A. D. Welcher, *J. Amer. Chem. Soc.*, **74**, 5309 (1952).

effectiveness for acyl activation, probably because the former has a reactive site detached from the polymer backbone. The bulkiness of the amino acid derivative would also affect the reactivities of polymers both in their acylation and coupling processes.

Experimental

The melting points were uncorrected. The IR spectra were obtained as potassium bromide disks with a Hitachi Infrared Photometer Model EPI-S2. Solvents used for reactions were purified by the usual method.

Preparation of Polymer(I). *p*-Nitrophenyl acrylate (17.0 g, 0.088 mol), prepared by Morawetz's method,[11] 9.15 g(0.088 mol) of styrene, 5.72 g (0.044 mol) of DVB and 0.90 g(0.0055 mol) of AIBN were dissolved in 150 m*l* of dioxane. The polymerization tube was sealed off in a vacuum, and heated in a bath thermostatted at 80°C for 20 hr. The separated polymer(I) was washed with ether, and crashed to small species, and dried in a vacuum. The total yield was 26.5 g. Polymer(I) was pale yellow. Elemental analyses; Found; C 71.21, H 5.86, N 3.68%. Nitrogen analysis showed that total molar fraction of the ester was 38%.

Preparation of Polymer(II). Polymer(I) thus obtained (25.0 g) was swelled in 200 ml of DMF and 18.5 g(0.15 mol) of benzyloxyamine was added. The mixture was heated at 120—140°C for 25 hr. Polymer(II) thus obtained was filtered off, and washed with ether, DMF and ether. It was collected and dried in a vacuum. The yield was 16.6 g.

Preparation of Polymer(III). Polymer(II)(16.0 g) was suspended in 100 m*l* of 28% HBr-AcOH solution and heated at 80—85°C for 6 hr. Polymer(III) thus obtained was separated by decantation, and washed with ether and methanol several times. Soluble parts of polymer(III) was extracted with methanol by use of a Soxhlet extractor. The yield of polymer(III) was 12.4 g. Polymer(III) was light brown.

Polymers(I′) and (II′) were prepared in similar ways. Preparation of polymer(II′) was carried out in DMF at 120—140°C for 100 hr. The reaction of polymer(II′) with hydrogen bromide in acetic acid at 80—85°C for 10 hr recovered the starting polymer(II′).

Reaction of Polymer(I) with Hydroxylamine. Ten m*l* of DMF solution containing hydroxylamine was prepared by mixing 0.7 g (0.01 mol) of hydroxylamine hydrochloride (dried at 140°C/0.1 mmHg for 3 hr) with 1.0 g (0.01 mol) of triethylamine (free from water) in 10 m*l* of DMF. Polymer(I) was swelled in 10 m*l* of DMF, and then these were combined, and kept at room temperature for 24 hr. Polymer (III″), thus obtained, was filtered off, and washed by swelling in methanol, and dried in a vacuum. The yield was 0.71 g.

Polymerization of Methacryloyl Hydroxamic Acid. Copolymerization of methacryloyl hydroxamic acid (0.51 g) prepared by Smith's method,[6] with DVB (0.65 g) in 15 m*l* of dioxane with AIBN (0.08 g) in polymerization tube sealed in a vacuum at 80°C for 12 hr gave no polymer.

Reaction of p-*Nitrophenyl Acrylate with Benzyloxyamine.* *p*-Nitrophenyl acrylate (18.5 g, 0.096 mol) and 12.0 g (0.098 mol) of benzyloxyamine were dissolved in 100 m*l* of ether, and kept at room temperature for 12 hr. The ether solution was washed with water, 1 N hydroxy ammonium solution and water by means of a separation funnel, and then washed with 1 N hydrochloric acid solution to precipitate crystalline needles. This product was filtered off. The filtrate was washed with water and dried over sodium sulfate. Although the filtrate was evaporated in a vacuum, the desired *N*-benzyloxyacrylamide was not obtained. The yield of the crystalline was 17.3 g. The product was confirmed to be *p*-nitrophenyl ester hydrochloride of γ-(*N*-benzyloxyamino)-propionic acid by elemental analysis and IR data. The yield was 17.3 g (51%), Mp 132—134°C(recrystallized from acetonitrile). Found: C, 54.28; H, 4.79; N, 7.93; Cl, 10.08%. Calcd for $C_{16}H_{17}N_2O_5Cl$: C, 54.7; H, 8.43 N, 7.97; Cl, 10.1%.

Preparation of Acetylated Polymer(IV). Polymer(III) (2.0 g) was swelled in 25 m*l* of DMF and 1.0 g of acetic anhydride was added. The mixture was kept at room temperature for 40 hr. Polymer(IV) thus obtained was filtered off and washed sith methanol. Polymer(IV) was further washed with methanol by use of a Soxhlet extractor and dried in a vacuum. The yield was 2.18 g.

Preparation of Acylated Polymer(VI). Polymer(III) (2.5 g) was swelled in 25 m*l* of DMF and 3.14 g (15 mmol) of Z-GlyOH was added. DCC (4.2 g, 20 mmol) was added to the mixture with stirring under cooling with ice-cold water, and kept at room temperature for 40 hr. The reaction mixture was diluted with methanol and precipitated *N,N′*-dicyclohexylurea was separated by decantation, and then polymer(VIa) was filtered off and washed with methanol. Polymer(VIa) was further washed with methanol by use of of a Soxhlet extractor and dried in a vacuum. Similar reaction were carried out with the use of 3.98 g (15 mmol) of Z-L-LeuOH and 3.74 g (15 mmol) of Z-GlyGlyOH. The yields of polymers(VIa), (VIb,) and (VIc) were 3.16 g, 3.38 g, and 3.07 g, respectively.

Preparation of N-*Acetyl*-O-*(*N-*carbobenzoxy)-glycyl Hydroxylamine[The Model Compound for Polymer(VI)].* Acetohydroxamic acid (4.50 g, 0.051 mol) and 10.45 g (0.05 mol) of Z-GlyOH were dissolved in 100 m*l* of DMF. DCC (10.3 g) was added to the solution with stirring under cooling with ice-cold water. The reaction mixture was kept for 2 hr with stirring under cooling with ice-cold water, and then at room temperature for 12 hr. *N,N′*-Dicyclohexylurea precipitated was filtered off and the filtrate was concentrated in a vacuum to give *N*-acetyl-*O*-(*N*-carbobenzoxy)-glycyl hydroxylamine. It was recrystallized from the mixture of hexane and ethyl acetate (1 : 1). The yield was 5.71 g (43%). Mp 137—139°C. Found: C, 53.87; H, 5.38; N, 10.44%. Calcd for $C_{12}H_{14}N_2O_5$: C, 54.13; H, 5.30; N, 10.52%.

Acylation of Cyclohexylamine with Polymers(IV) and (VI). One gram of polymer(IV) or (VI) was swelled in 30 m*l* of methylene chloride and 1.0 g of cyclohexylamine was added. The reaction mixtrue was kept at room temperature for 20 hr. The polymer recovered was filtered off and washed with ethyl acetate and methanol. The filtrate and the washing were combined and concentrated in a vacuum to obtain *N*-cyclohexylacylamide. The results are shown in Table 2. The crude products gave pure products by recrystallization.

Acylation of Ethyl Ester of Amino Acid with Polymer(VI). Glycine ethyl ester hydrochloride (0.112 g, 0.8 mmol) or 0.156 g (0.8 mmol) of L-leucine ethyl ester hydrochloride and 0.081 g (0.8 mmol) of triethylamine were dissolved in 10 m*l* of DMF. Polymer(VIa) or (VIb) (1.0 g) was swelled in 15 m*l* of DMF. Both were mixed and kept at room temperature for 40 hr. The consumed polymer was filtered off and washed with methanol. The filtrate and washings were combined and concentrated in a vacuum. The residue was dissolved in ethyl acetate, and insoluble triethylamine

11) E. Gaetjens, H. Morawetz, *J. Amer. Chem. Soc.*, **83**, 1738 (1961); H. Morawetz, and P. E. Zimmering, *J. Phys. Chem.*, **58**, 753 (1954).

hydrochloride was filtered off. Ethyl acetate was evaporated in a vacuum, and the residue was worked up by the same procedure to obtain the crude products. The results are shown in Table 3.

Preparation of Polymer(VII). A mixture of 10.0 g (0.049 mol) of *N*-benzyloxymaleimide prepared by means of the method given previously,[4c] 10.0 g (0.096 mol) of styrene, 0.12 g (0.6 mol% contrary to all monomers) of DVB and 0.10 g of AIBN in 100 m*l* of benzene was heated at 40°C for 5 hr under a stream of nitrogen. The separated polymer (VII) was washed with benzene and methanol, and crashed to small species, and dried in a vacuum. The yield was 16.4 g. Found: C, 73.59; H, 5.18; N, 4.35%.

Preparation of Polymer(VIII). A mixture of 35.6 g (0.23 mol) of *N*-acetoxymaleimide prepared by means of the method given previously,[4c] 36.0 g (0.345 mol) of styrene, 1.5 g (0.0115 mol, 2 mol% toward all monomers) of DVB and 0.73 g (0.003 mol) of benzoyl peroxide in 150 m*l* of benzene was heated at 75°C for 6 hr under a stream of nitrogen. Separated polymer(VIII) was crashed to small species, and washed with methylene chloride by use of a Soxhlet extractor, and dried in a vacuum. The yield was 70.2 g.

Preparation of Polymer(IXa), A mixture of 15.0 g of polymer(VII) in 100 m*l* of 20% hydrogen bromide acetic acid solution was heated at 65—70°C for 15 hr. The reaction mixture was poured into ether. Polymer(IXa) was filtered off and washed with acetic acid, DMF, ether, and methanol. It was collected and dried in a vacuum. The yield was 10.95 g.

Preparation of Polymer(IXb). Polymer(VIII) was hydrolized with 6 N hydrochloric acid solution in dioxane to give polymer (IXb), and then subjected to the usual work-up.

Preparation of Polymer(Xa). Polymer(IXa) (5.0 g) was swelled in 50 m*l* of DMF and 20 m*l* of acetic anhydride was added. The mixture was kept at room temperature for 12 hr. Polymer(Xa) thus obtained was filtered off and with ether, tetrahydrofuran and ether. It was collected and under vacuum. The yield was 5.35 g.

Preparation of Peptide Derivatives. Z-GlyOH and Z-L-LeuOH were prepared according to the methods reported.[8,9] Z-GlyGlyOH and Z-GlyGlyGlyOH were prepared from Z-GlyOH and GlyOEt by the DCC method. Z-GlyGlyOH; mp 177—178°C (lit,[14] 175—176°C). Z-GlyGlyGlyOH; mp 197—198°C (lit,[15] 198°C). Z-L-Leu-L-LeuOH and Z-L-Leu-L-Leu-L-LeuOH were prepared from Z-L-LeuOH and L-LeuOEt by the DCC method. Z-L-Leu-L-LeuOEt; mp 86—88°C (recrystallized from *n*-hexane)., Found: C, 64.69; H, 8.43; N, 7.02%. Calcd for $C_{22}H_{34}N_2O_5$: C, 65.00; H, 8.43; N, 6.89%. Z-L-Leu-L-LeuOH; mp 117—119°C(recrystallized from *n*-hexane) (lit,[16] 99—99.5°C). Found: C, 63.16; H, 8.12; N, 7.38%. Calcd for $C_{20}H_{30}N_2O_5$: C, 63.47; H, 7.99; N, 7.40%. Z-L-Leu-L-Leu-L-LeuOEt; mp 137—139°C (recrystallized from carbon tetra chloride-ethyl acetate. Z-L-Leu-L-Leu-L-LeuOH; mp 150—152°C (recrystallized from carbon tetrachloride-ethyl acetate). Found: C, 63.28; H, 8.71; N, 8.49%. Calcd for $C_{26}H_{41}N_3O_6$: C, 63.52; H, 8.41; N, 8.55%.

Preparation of Polymers(X) and (XI). Polymers(Xb) and (Xc) were prepared by using polymer(IXa) as well as polymer(VI) [reaction time; 30 hr]. Polymer(X) washed with mathanol, DMF and methanol, and then dried in a vacuum. Polymer(Xb), 3.45 g, was obtained from 2.5 g polymer(IXa). Polymer(Xc), 3.84 g, was obtained from 2.4 g of polymer(IXa).

Polymer(XI) was prepared similarly in the reaction conditions shown in Table 9.

Acylation of Cyclohexylamine with Polymer(VIII), (X) and (XI). These reactions were performed as well as the reactions of cyclohexylamine with polymers(IV) and (VI). DMF was used as a solvent instead of methylene chloride. The results are shown in Table 5. In the case of polymer (XI), 1.0 g polymers(XIa—d) gave the corresponding acyl amides 490 mg, 540 mg, 530 mg, and 470 mg, respectively. These crude products offered pure products by recrystallization. Z-GlyNH-⟨H⟩; mp 108—109°C(lit,[8] 110°C). Z-GlyGlyNH-⟨H⟩; mp 179—179.5°C(lit,[8] 173°C). Z-L-LeuNH-⟨H⟩; mp 129—131°C(recrystallized from *n*-hexane-ethyl acetate). Found: C, 68.96; H, 8.92; N, 7.93%. Calcd for $C_{20}H_{30}N_2O_3$: C, 69.33; H, 8.73; N, 8.09%. Z-L-Leu-L-LeuNH-⟨H⟩; mp 194—195°C(recrystallized from ethyl acetate). Found: C, 67.36; H, 8.95; N, 8.93%. Calcd for $C_{26}H_{41}N_3O_4$: C, 67.94; H, 8.99; N, 9.14%.

Acylation of Ethyl Ester of Amino Acid with Polymer(X).

Glycine ethyl ester hydrochloride(0.182 g, 1.3 mmol) or 0.245 g (1.3 mmol) of L-leucine ethyl ester hydrochloride and 0.132 g (1.3 mmol) of triethylamine were dissolved in 10 m*l* of DMF. Polymer(X)(1.0 g) was swelled in 10 ml of DMF. Both of them were mixed and kept at room temperature for 12 hr, and then treated as above. The results are shown in Table 8. The optical rotations of products were measured in ethanol(c=0.2) at 18°C using a Japan Spectroscopic Co., Model ORD/UV-5 spectropolarimeter. The results are shown in Table 9.

The Stereochemistry of Nucleophilic Addition. V.[1] The Reformatsky Reaction of 2-Phenylpropanal with Methyl α-Bromopropionate

Takashi MATSUMOTO, Yūkei HOSODA, Kiyomi MŌRI, and Kenji FUKUI

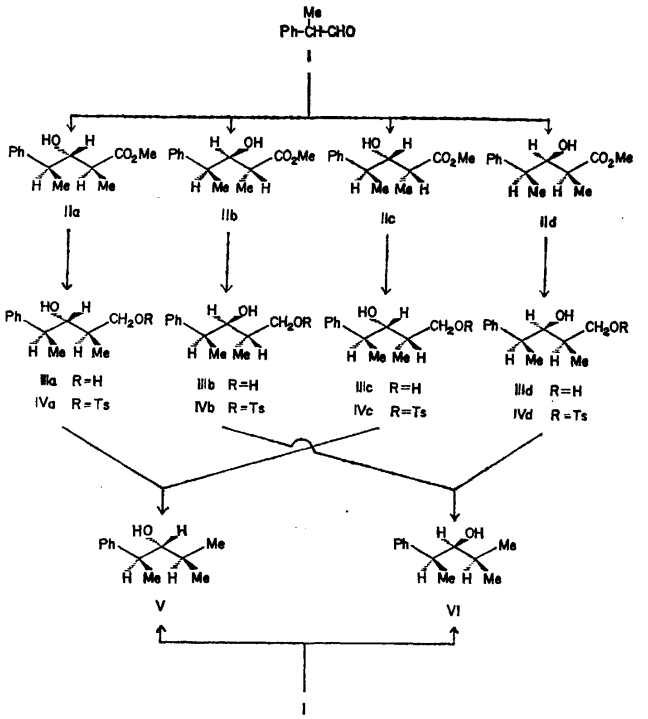
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received January 24, 1972)

The Reformatsky reaction of 2-phenylpropanal (I) with methyl α-bromopropionate gave the diastereomeric methyl 3-hydroxy-2-methyl-4-phenylvalerates, IIa, IIb, IIc, and IId, in a 5 : 24 : 16 : 55 ratio. The configurations of these β-hydroxy esters were assigned by the following experiments. The reduction of IIa—IId with $LiAlH_4$ gave the corresponding diols, IIIa—IIId, which were then converted to the monotosylates, IVa—IVd. The further reduction of IVa or IVc and IVb or IVd with $LiAlH_4$ gave the epimeric 2-methyl-4-phenyl-3-pentanols, V and VI respectively. Since V and VI were also obtained as minor and major products (20 : 80 ratio) of the Grignard reaction of I with isopropylmagnesium iodide, the configurations of the C-3 and C-4 positions in IIa—IId were assigned. The Wittig reaction of I with carbomethoxyethylidenetriphenylphosphorane gave methyl 2-methyl-4-phenyl-2-*cis*-pentenoate (VII) and its *trans*-isomer (VIII), which were then reduced to the corresponding alcohols, IX and X respectively. The *cis*-hydration of IX gave IIIc and IIId, while a similar treatment of X gave IIIa and IIIb. From this experiments, the relative configurations from the C-2 position to the C-3 position in IIa—IId were also assigned. These configurational assignments of IIa—IId were further confirmed by the ozonization of IIa—IId.

In previous papers,[2-4] we reported on the stereochemistry of the Reformatsky reaction of carbonyl compounds possessing an asymmetric α-carbon atom with methyl (or ethyl) bromoacetate. In these reactions the products had two vicinally-situated asymmetric carbon atoms, which led to two epimeric racemates. On the other hand, if methyl α-bromopropionate is used as a nucleophilic reagent in place of the bromoacetate, the product can be expected to have three asymmetric carbon atoms; therefore, four racemic isomers will be present. The present paper will describe the stereochemistry of the Reformatsky reaction of 2-phenylpropanal (I) with methyl α-bromopropionate.

The condensation of I with methyl α-bromopropionate in dry benzene in the presence of zinc gave a mixture of diastereomeric methyl 3-hydroxy-2-methyl-4-phenylvalerates in a 75% yield. The separation of these esters was subsequently carried out by means of column chromatography on silica gel to give, in the order of elution, the IIa, IIb, IIc, and IId esters in a 5 : 24 : 16 : 55 ratio. The configurations of these β-hydroxy esters (IIa—IId) were assigned in the following manner. The reduction of IIa, IIb, IIc, and IId with $LiAlH_4$ in ether afforded the corresponding 2-methyl-4-phenylpentane-1,3-diols, IIIa, IIIb, IIIc, and IIId respectively. Subsequently, the IIIa—IIId diols were subjected to tosylation with *p*-toluenesulfonyl chloride in pyridine to give the corresponding monotosylates, IVa, IVb, IVc, and IVd respectively. The reduction of IVa and IVc in dry tetrahydrofuran with $LiAlH_4$ gave the same alcohol, 2-methyl-4-phenyl-3-pentanol (V). Therefore, it is clear that IIa and IIc possess the same configuration at the C-3 and C-4 positions. On the other hand, the tosylates, IVb and IVd, were also reduced to another alcohol (VI). These findings mean that the configurations of IIb and IId at the C-3 and C-4 positions are the same. Furthermore, the Grignard reaction of I with isopropylmagnesium iodide gave the epimeric alcohols in a 20 : 80 ratio; these minor and major alcohols were shown to be identical with the above V and VI respectively by a comparison of their IR spectra.



Since the stereochemistry of the Grignard reaction is well known as Cram's rule[5,6] of asymmetric induction, the configurations of the C-3 and C-4 positions in

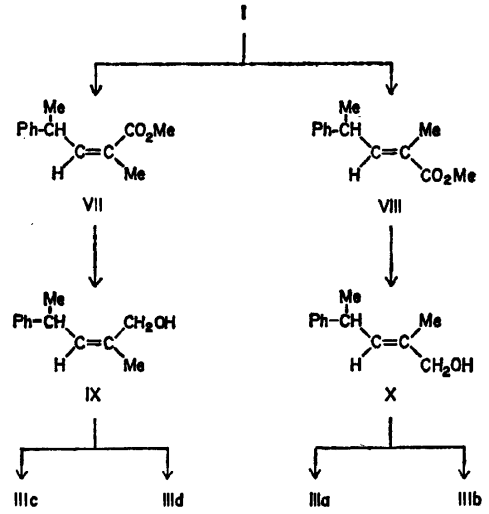
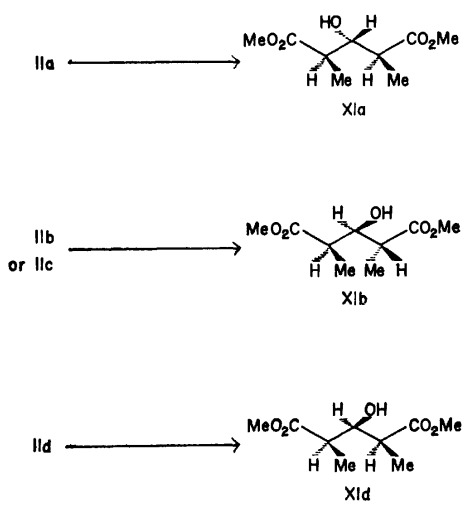
the β-hydroxy esters were assigned to as is shown in IIa—IId. To obtain the data on the configuration of the C-2 position relative to the C-3 position in IIa–IId, the following experiments were carried out.

The Wittig reaction of I with carbomethoxyethylidene triphenylphosphorane in dry benzene gave an 87% yield of a mixture of geometric isomers, which were then successfully separated by means of column chromatography on silica gel into two oily esters in a 3 : 97 ratio. It is well known[7,8] that the ylids stabillized by an adjacent carbonyl function yield, as the predominant product, an isomer in which the carbonyl function is *trans* to the larger group at the beta carbon atom. In the NMR spectra it is also known that the signal of a *cis*-vinyl proton to the methoxycarbonyl group appeares in a field lower than that of the corresponding *trans*-vinyl proton.



The chemical shifts of the vinyl protons in the above minor and major esters were observed at δ 5.88 ppm and at δ 6.78 ppm respectively. Therefore, the structures of the minor and major esters were identified as methyl 2-methyl-4-phenyl-2-*cis*-pentenoate (VII) and its *trans*-isomer (VIII) respectively. These assignments were further supported by the chemical shifts of the methine protons at the C-4 position in VII and VIII. That is, VII showed the signal of the methine proton at δ *ca.* 4.5 ppm, suggesting the presence of a *cis*-methoxycarbonyl group relative to the methine proton, because VIII showed the corresponding signal at δ *ca.* 3.7 ppm. The VII and VIII esters were then reduced with $LiAlH_4$ in ether to give the corresponding alcohols, IX and X respectively. The hydroboration of the *cis*-alcohol (IX), followed by oxidation with alkaline hydrogen peroxide, gave the diols (IIIc and IIId). This result means that the configurations of the IIIc and IIId diols differ only at the C-4 position. On the other hand, a similar treatment of the *trans*-alcohol (X) gave the IIIa and IIIb diols. Therefore, the difference between the configurations of the IIIa and IIIb diols is also at the C-4 position. Further, it is well known[9] that the hydration of the carbon-carbon double bond by the hydroboration-oxidation procedure proceeds in a *cis* manner.

On the basis of the above experiments, the configurations of all the asymmetric carbon atoms in the β-hydroxy esters were assigned as is shown in IIa—IId. These configurational assignments of IIa—IId were further confirmed by the following experiments. If the phenyl group in IIa—IId could be converted to the methoxycarbonyl group, it might be expected that IIa and IId would afford, respectively, two meso isomers, XIa and XId, while IIb or IIc would afford a racemate, XIb. Therefore, the ozonization of IIb and IIc in acetic acid, followed by the methylation of the resulting acids with diazomethane, was carried out; as would be expected, the same diester, XIb, was obtained. However, a similar treatment of IIa and IId afforded the corresponding diesters, XIa and XId.



An attempt will now be made to explain the ratio of IIa–IId. It is known[3] that the stereochemistry of the Reformatsky reaction of the carbonyl compound possessing an asymmetric α-carbon atom has been explained by Cram's rule of asymmetric induction. Further, the stereochemistry of this reaction has also been explained on the hypothesis of an enolate-anion mechanism[10] involving a cyclic transition state, as in the case of the Ivanov reaction.[11] Therefore, the four models (A, B, C, and D) of transition states for the Reformatsky reaction of I with methyl α-bromopropionate in the presence of zinc are as is shown in Fig. 1. The conformation of I in A and B is more stable than that in C and D, as has been reported by Karabatsos.[6] For the steric interaction between the methyl group at the C-2 position and the hydrogen at the C-3 position, the B and D transition states should be less stable than the corresponding A and C transition states. Thus, the stability of these transition states decreases in the order of A, B, C, and D, leading to the IId, IIb, IIc, and IIa esters respectively.

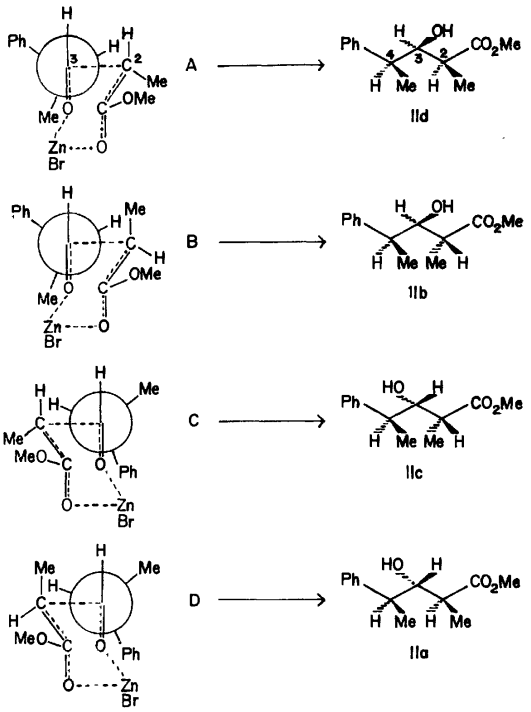

Fig. 1

Experimental

All the melting and boiling points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 MHz), using tetramethylsilane as the internal standard. The chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, dqa: double quartet, qi: quintet, m: multiplet. The column chromatography was performed on Merck silica gel (0.08 mm).

Methyl 3-Hydroxy-2-methyl-4-phenylvalerates (IIa, IIb, IIc, and IId). A solution of methyl α-bromopropionate (6.01 g) and 2-phenylpropanal (I: 3.22 g) in dry benzene (10 ml) was added, drop by drop at 80°C and over a period of 20 min, to a stirred suspension of purified zinc powder[12] (2.35 g) in dry benzene (3.0 ml); the temperature was kept at 80—85°C during the addition. After the addition was complete, the mixture was refluxed for 70 min, cooled, decomposed with dilute hydrochloric acid, and then extracted with benzene. The extract was successively washed with aqueous sodium hydrogen carbonate and water, dried over sodium sulfate, and then evaporated. The residue was distilled to give a mixture of methyl 3-hydroxy-2-methyl-4-phenylvalerates (IIa—IId) as an oil; bp 115—125°C/1 mmHg; yield, 4.80 g. The above oil was purified by means of column chromatography on silica gel (500 g), using benzene containing 1% ether and then 7% ether as the eluents. The first fraction gave IIa as a solid (199 mg) which was recrystallized from petroleum ether to give colorless crystals; mp 59—59.6°C. NMR in CCl_4: 1.13(d, J=6.5 Hz, $-CH(C\underline{H}_3)CO_2CH_3$), 1.31 (d, J=7 Hz, $-CH(C\underline{H}_3)C_6H_5$), 2.32(qi, J=6.5 Hz, $-C\underline{H}CO_2CH_3$), 2.75 (s, $-O\underline{H}$), *ca.* 2.8 (m, overlap, $-C\underline{H}-C_6H_5$), 3.53 (s, $-CO_2C\underline{H}_3$), *ca.* 3.6 (m, overlap, $-C\underline{H}OH$), 7.18 (s, $-C_6\underline{H}_5$).

Found: C, 70.32; H, 8.17%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

The second fraction gave IIb as an oil; yield, 954 mg. NMR in CCl_4: 1.15 (d, J=7 Hz, $-CH(C\underline{H}_3)CO_2CH_3$), 1.32 (d, J=7 Hz, $-CH(C\underline{H}_3)C_6H_5$), *ca.* 2.3 (m, $-C\underline{H}CO_2CH_3$), *ca.* 2.75 (m, overlap, $-C\underline{H}C_6H_5$), 2.85 (s, $-O\underline{H}$), *ca.* 3.4 (m, overlap, $-C\underline{H}OH$), 3.60 (s, $-CO_2C\underline{H}_3$), 7.16 (s, $-C_6\underline{H}_5$).

Found: C, 70.22; H, 8.16%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

The third fraction gave IIc as an oil; yield, 636 mg. NMR in CCl_4: 1.12 (d, J=7 Hz, $-CH(C\underline{H}_3)CO_2CH_3$), 1.24 (d, J=5 Hz, $-CH(C\underline{H}_3)C_6H_5$), 1.83 (d, J=5 Hz, $-C\underline{H}CO_2CH_3$), *ca.* 2.2—3.0 (m, $-C\underline{H}C_6H_5$), *ca.* 2.7 (overlap, $-O\underline{H}$), 3.60 (s, $-CO_2C\underline{H}_3$), *ca.* 3.9 (m, $-C\underline{H}OH$), 7.17(s, $-C_6\underline{H}_5$).

Found: C, 70.22; H, 8.17%. Calcd for $C_3H_{18}O_3$: C, 70.24; H, 8.16%.

The fourth fraction gave IId as an oil; yield, 2185 mg. NMR in CCl_4: 1.09 (d, J=7 Hz, $-CH(C\underline{H}_3)CO_2CH_3$, 1.32 (d, J=6.5 Hz, $-C\underline{H}(C\underline{H}_3)C_6H_5$), 2.22 (m, $-C\underline{H}CO_2CH_3$), *ca.* 2.7 (m, overlap, $-O\underline{H}$ and $-C\underline{H}C_6H_5$), 3.58 (s, $-CO_2C\underline{H}_3$), 3.95 (m, $-C\underline{H}OH$), 7.12 (s, $-C_6\underline{H}_5$).

Found: C, 70.31; H, 8.18%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

The total yield of IIa—IId was 3.974 g (75% from I).

Reduction of IIa, IIb, IIc, and IId with $LiAlH_4$. *a)*: A solution of IIa (523 mg) in dry ether (5.0 ml) was added, drop by drop over a period of 30 min, to a suspension of $LiAlH_4$(200 mg) in dry ether (15 ml) at room temperature, and then the mixture was refluxed for 2.5 hr. After cooling, the mixture was decomposed with dilute hydrochloric acid and extracted with ether. The extract was washed with an aqueous sodium chloride solution, dried over sodium sulfate, and then evaporated. The residue was chromatographed on silica gel (30 g), using benzene containing 20% ether as the eluent, to give 2-methyl-4-phenylpentane-1,3-diol (IIIa) as an oil; yield, 245 mg. NMR in $CDCl_3$: 0.90 (d, J=6.5 Hz, $-CH(C\underline{H}_3)CH_2OH$), 1.24 (d. J=7 Hz, $-CH(C\underline{H}_3)C_6H_5$), 1.55 (m, $-C\underline{H}CH_2OH$), 2.86 (qi, J=6.5 Hz, $-C\underline{H}C_6H_5$), 3.41 (s, $-O\underline{H}$), *ca.* 3.55 (m, overlap, $-C\underline{H}OH$ and $-CH_2\underline{O}H$), 7.23 (s, $-C_6\underline{H}_5$).

Found: C, 74.28; H, 9.57%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%).

b): The IIb ester (400 mg) was reduced with $LiAlH_4$ by a method similar to that used for IIIa. The crude product was recrystallized from petroleum ether to give IIIb as colorless crystals; mp 52—53°C; yield, 275 mg. NMR in $CDCl_3$: 0.95 (d, J=7 Hz, $-CH(C\underline{H}_3)CH_2OH$), 1.29 (d, J=7 Hz, $-CH(C\underline{H}_3)C_6H_5$), 1.75 (m, $-C\underline{H}CH_2OH$), 2.90 (s, $-O\underline{H}$), 3.0 (m, overlap, $-C\underline{H}C_6H_5$), *ca.* 3.7 (m, overlap, $-C\underline{H}OH$ and $-CH_2\underline{O}H$), 7.28 (s, $-C_6\underline{H}_5$).

Found: C, 74.36; H, 9.47%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

c): The IIc ester (749 mg) was also reduced with $LiAlH_4$ to give IIIc as colorless crystals (from petroleum ether); mp 70.5—71°C; yield, 452 mg. NMR in $CDCl_3$: 1.02 (d, J=7 Hz, $-CH(C\underline{H}_3)CH_2OH$), 1.19(d, J=7 Hz, $-CH(C\underline{H}_3)C_6H_5$), *ca.* 2.0 (m, overlap, $-C\underline{H}CH_2OH$), 2.02 (s, $-OH$), 2.84 (m, $-C\underline{H}C_6H_5$), 3.73 (d, J=5 Hz, $-CH_2\underline{O}H$),

3.88 (dd, overlap, J=9.5 and 2 Hz, -CHOH), 7.30 (s, -C_6H_5).

Found: C, 74.29; H, 9.48%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

d): Similarly, the IId ester (2.20 g) was reduced to IIId; colorless crystals (1.30 g); mp 98—98.5°C (from *n*-hexane containing ether). NMR in $CDCl_3$: 0.92 (d, J=6.5 Hz, -CH(CH_3)CH_2OH), 1.34 (d, J=6.5 Hz, -CH(CH_3)C_6H_5), *ca.* 1.4 (m, overlap, -CHCH$_2$OH), 2.39 (s, -OH), 2.8 (m, -CHC$_6$H$_5$), 3.62 (d, J=4 Hz, -CH_2OH), 3.97 (dd, J=9.5 and 2 Hz, -CHOH), 7.24 (s, -C_6H_5).

Found: C, 74.28; H, 9.53%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

The Tosylates (IVa, IVb, IVc, and IVd). a): A mixture of the IIIa diol (189 mg) and *p*-toluenesulfonyl chloride (186 mg) in dry pyridine (3.0 m*l*) was allowed to stand at room temperature for 72 hr. After a usual work-up, the crude product was chromatographed on silica gel (15 g). Elution with benzene containing 5% ether was then carried out to give IVa as an oil; yield, 133 mg.

Found: C, 65.72; H, 7.08%. Calcd for $C_{19}H_{24}O_4S$: C, 65.50; H, 6.94%.

b): The other tosylates (IVb, IVc, and IVd) were also prepared from the corresponding diols (IIIb, IIIc, and IIId) by a method similar to that used for IVa.

IVb; Found: C, 65.70; H, 7.04%. Calcd for $C_{19}H_{24}O_4S$: C, 65.50; H, 6.94%.

IVc; Found: C, 65.48; H, 6.95%. Calcd for $C_{19}H_{24}O_4S$: C, 65.50; H, 6.94%.

IVd; Found: C, 65.80; H, 7.15%. Calcd for $C_{19}H_{24}O_4S$: C, 65.50; H, 6.94%.

2-Methyl-4-phenyl-3-pentanols (V and VI). a) By the Grignard Reaction: A solution of I (1.960 g) in dry ether (5.0 m*l*) was added, drop by drop over a period of 30 min, to a Grignard reagent, prepared from magnesium (0.660 g) and isopropyl iodide (3.950 g) in dry ether (20 m*l*). The mixture was refluxed for 90 min, cooled, decomposed with a mixture of ice and dilute hydrochloric acid, and then extracted with ether. The extract was successively washed with aqueous sodium thiosulfate and water. After drying over sodium sulfate, the solvent was evaporated; the residue (2.032 g) was then chromatographed on silica gel (200 g), using benzene containing 3% ether as the eluent. The first fraction gave a minor alcohol (V) as an oil (327 mg).

Found: C, 80.64; H, 10.21%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

The second fraction gave a major alcohol (VI) as an oil (1142 mg).

Found: C, 80.81; H, 10.14%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

b) From the Tosylates (IVa and IVc): The tosylate (IVa: 133 mg) was reduced with $LiAlH_4$ (50 mg) in dry tetrahydrofuran (3.0 m*l*) by a method similar to that used for IIIa. The crude product was purified by column chromatography on silica gel (30 g), using benzene containing 2% ether as the eluent, to give an oil (36 mg); this oil was shown to be identical with the above minor alcohol (V) of the Grignard reaction by an IR spectral comparison.

By a similar reduction, IVc was converted to V; its identity was also confirmed by an IR spectral comparison.

c) From the Tosylates (IVb and IVd): The tosylates (IVb and IVd) were treated with $LiAlH_4$ by a method similar to that used in *b*). After chromatographic purification, the two products were shown by a spectral comparison to be identical with the major alcohol (VI) of the Grignard reaction.

*Methyl 2-Methyl-4-phenyl-2-*cis*-pentenoate (VII) and Its* trans*-Isomer (VIII).* A mixture of I (2.68 g), carbomethoxyethylidene triphenylphosphorane (6.96 g), and dry benzene (50 m*l*) was refluxed for 2 hr under a stream of nitrogen; the solvent was then evaporated under a vacuum. The residue was extracted with ether. The extract, after the removal of the ether, was chromatographed on silica gel (500 g), using benzene containing 1% ether as the eluent. The first fraction gave methyl 2-methyl-4-phenyl-2-*cis*-pentenoate (VII) as an oil (0.12 g). NMR in CCl_4: 1.31 (d, J=7 Hz, -CHCH_3), 1.83 (d, J=1.5 Hz, =CCH_3), 3.66 (s, -CO_2CH_3), *ca.* 4.5 (m, -CHCH_3), 5.88 (dqa, J=10 and 1.5 Hz, =CH), 7.15 (s, -C_6H_5).

Found: C, 76.66; H, 7.96%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

The second fraction gave methyl 2-methyl-4-phenyl-2-*trans*-pentenoate (VIII) as an oil (3.41 g), NMR in CCl_4: 1.36 (d, J=7 Hz, -CHCH_3), 1.83 (d, J=1.5 Hz, =CCH_3), 3.65 (s, -CO_2CH_3), *ca.* 3.65 (m, overlap, -CHCH_3), 6.78 (dqa, J=9 and 1.5 Hz, =CH), 7.18 (s, -C_6H_5).

Found: C, 76.35; H, 7.87%. Calcd for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

*2-Methyl-4-phenyl-2-*cis*-pentenol (IX) and Its* trans*-Isomer (X). a)*: A solution of VII (225 mg) in dry ether (5.0 m*l*) was added, drop by drop over a period of 10 min at —10—0°C, to a stirred suspension of $LiAlH_4$ (100 mg) in dry ether (4.0 m*l*). The mixture was further stirred for 1.5 hr at this temperature and then decomposed with a mixture of ice and dilute hydrochloric acid. The mixture was extracted with ether. The extract was washed with an aqueous sodium chloride solution, dried over sodium sulfate, and then evaporated. The residual oil was purified by column chromatography on silica gel (30 g). Elution with benzene containing 15% ether gave IX as an oil (118 mg). NMR in CCl_4: 1.24 (d, J=7 Hz, -CHCH_3), 1.71 (d, J=1.5 Hz, =CCH_3), 2.33 (s, -OH), 3.66 (m, -CHCH_3), 3.99 (s, -CH_2-), 5.31 (bd, J=9 Hz, =CH), 7.10 (s, -C_6H_5).

Found: C, 81.79; H, 9.21%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

b): By a method similar to that used for IX, the ester (VIII: 1.36 g) was also reduced with $LiAlH_4$ to give X as an oil (0.97 g). NMR in CCl_4: 1.26 (d, J=7 Hz, -CHCH_3), 1.58 (d, J=1.5 Hz, =CCH_3), 3.00 (bs, -OH), *ca.* 3.6 (m, overlap, -CHCH_3), 3.78 (s, -CH_2-), 5.44 (bd, J=9 Hz, =CH), 7.12 (s, -C_6H_5).

Found: C, 81.98; H, 9.27%. Calcd for $C_{12}H_{16}O$: C, 81.77; H, 9.15%.

*Hydroboration of 2-Methyl-4-phenyl-2-*cis*-pentenol (IX) and 2-Methyl-4-phenyl-2-*trans*-pentenol (X). a)*: A solution of the *cis*-alcohol (IX: 380 mg) in dry tetrahydrofuran (5.0 m*l*) was added to a solution of sodium borohydride (150 mg) in dry tetrahydrofuran (3.0 m*l*) at 0—5°C over a 10-min period. To the stirred and cooled solution, a solution of freshly-distilled boron trifluoride etherate (0.7 m*l*) in dry tetrahydrofuran (3.0 m*l*) was added at this temperature over a period of 5 min. After the sitrring had been continued for 3 hr at 0—10°C, a few drops of water, aqueous sodium hydroxide (12%: 3.0 m*l*), and then hydrogen peroxide (30%: 0.7 m*l*) were added successively. The mixture was stirred for 30 min, poured into an aqueous sodium hy-

droxide solution, and then extracted with ether. The extract was washed successively with aqueous sodium hydroxide and water. After the removal of the dried ether, the residue (368 mg) was chromatographed on silica gel (35 g), using benzene containing 15% ether as the eluent. The first fraction gave the recovered IX (150 mg). The second fraction gave colorless crystals (50 mg), which were shown to be identical with the above IIIc by a comparison of their IR spectra. The third fraction gave colorless crystals (88 mg), which were also shown to be identical with the above IIId by a comparison of their IR spectra.

b): The *trans*-alcohol (X: 3.75 g) was treated by a method similar to that used in *a)*. The crude product was purified by means of column chromatography on silica gel to give IIIa (256 mg) and IIIb (1787 mg), which were shown to be identical with the authentic samples by a comparison of their IR spectra.

Ozonolyses of IIa—IId. *a)* The ozone gas stream from a laboratory ozonator (Nihon Ozon Co.) was passed through a solution of IId (1.755 g) in acetic acid (40 m*l*) for 40 hr at room temperature. The mixture was allowed to stand at room temperature with hydrogen peroxide (30%: 10 m*l*). After the decomposition of the excess reagent with aqueous sodium hydrogen sulfite (25%: 40 m*l*), the solution was evaporated under a vacuum. The residue was extracted with ether, after which the extract was methylated with diazomethane. The crude ester, after the removal of the ether, was purified by means of column chromatography on silica gel (200 g). Elution with benzene containing 3% ether gave the recovered IId (574 mg). Further elution with benzene containing 7% ether gave XId (221 mg) as an oil. NMR in CCl_4: 1.19 (d, J=7 Hz, 2-$\underset{|}{C}HC\underline{H}_3$), 2.48 (qi, J=7 Hz, 2-$C\underline{H}CH_3$), 3.0 (bs, -O$\underline{H}$), 3.67 (s, 2-$CO_2C\underline{H}_3$), 3.98 (t, J=7 Hz, -$\underset{|}{C}\underline{H}OH$).

Found: C, 52.78; H, 8.07%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%,

b) The ozonization of the IIa ester (215 mg) was carried out, by a method similar to that used for XId, to give XIa (15 mg) as an oil. NMR in CCl_4: 1.18 (d, J=7 Hz, 2-$\underset{|}{C}HC\underline{H}_3$), 2.58 (qi, J=7 Hz, 2-$\underset{|}{C}\underline{H}CH_3$), 3.03 (bs, -O$\underline{H}$), *ca.* 3.6 (m, overlap, -$\underset{|}{C}\underline{H}OH$), 3.65 (s, 2-$CO_2C\underline{H}_3$).

Found: C, 52.91; H, 7.98%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

c) The IIb ester (497 mg) was treated, by a method similar to that used for XId, to give XIb (56 mg) as an oil. NMR in CCl_4: 1.18 (d, J=7 Hz 2-$\underset{|}{C}HC\underline{H}_3$), 2.48 (qi, J=7 Hz, 2-$\underset{|}{C}\underline{H}CH_3$), 2.81 (bs, -O$\underline{H}$), 3.67 (s, 2-$CO_2C\underline{H}_3$), 3.78 (m, overlap, -$\underset{|}{C}\underline{H}OH$).

Found: C, 52.81; H, 7.96%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

Similarly, the IIc ester (290 mg) was also treated by a method similar to that used for XId, thus giving an oil (43 mg) which was shown to be identical with XIb by a comparison of their IR spectra.

Oxidative Dimerization of Pyrrole Derivatives. II. The Formation and Structure of Dimers of 3-Alkoxycarbonyl-substituted Pyrryls[1,2]

Kuniyuki TOMITA and Norio YOSHIDA

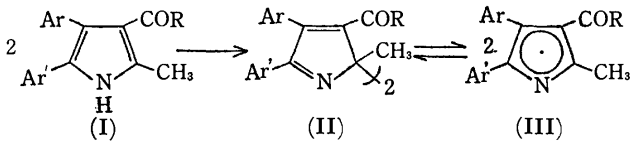
Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received January 31, 1972)

Oxidation of 3-alkoxycarbonyl-substituted pyrrolic compounds with aqueous potassium ferricyanide in the presence of potassium hydroxide afforded 2,2′- and 5,5′-bispyrrolenine derivatives, which were in equilibrium with each other in solution *via* radical intermediates. The substituent effects on the dimer formation will also be discussed in connection with the characters of the intermediate pyrryl radicals.

Several *N*-heteroaromatic compounds have been known to form dimers *via* oxidation, and some of these exist in equilibrium with dissociated radicals.[3a–h] However, the structures of such dimers have not been elucidated except in the case of bis-triarylimidazolyl radicals.[4a,b]

In the previous paper, we reported that some 3-acyl-substituted pyrrole derivatives (I) gave dimers (II) which were in equilibrium with stable pyrryl radicals (III) in solution, on oxidation with potassium ferricyanide.[5a,b]



The formation of such dimers seems to raise discussion connected with the characters of the radicals, since the intermediacy of the heteroaromatic radicals has been suggested for the oxidative dimerization of *N*-

heteroaromatic compounds with potassium ferricyanide.[3a])

This paper will discuss the formation and structure of the dimers of 3-alkoxycarbonyl-substituted pyrryl radicals obtained from the corresponding pyrrole derivatives. We will also discuss briefly the characters of these radicals on the basis of the substituent effects on the dimer formation.

Results and Discussion

Formation of Dimers. Oxidation of ethyl 4,5-bis(*p*-methoxyphenyl)-2-methylpyrrole-3-carboxylate (IV) with potassium ferricyanide under alkaline conditions afforded a crystalline precipitate (D-IV)[6] quantitatively. The results of an elemental analysis and the molecular weight of D-IV, listed in Table 1, support the formation of a pyrryl-radical dimer. The reduction of D-IV with hydroquinone affords the pyrrole derivatives IV quantitatively, which shows that the dimer still contains the intact pyrrole ring. The IR spectrum of D-IV is characterized by strong imine absorptions at 1610 cm^{-1} and carbonyl at 1720 cm^{-1} (appearing at 1675 cm^{-1} in IV) and an absence of NH absorptions.

The Occurrence of Equilibrium in D-IV. The NMR spectra of D-IV showed characteristic features, as is shown in Fig. 1.

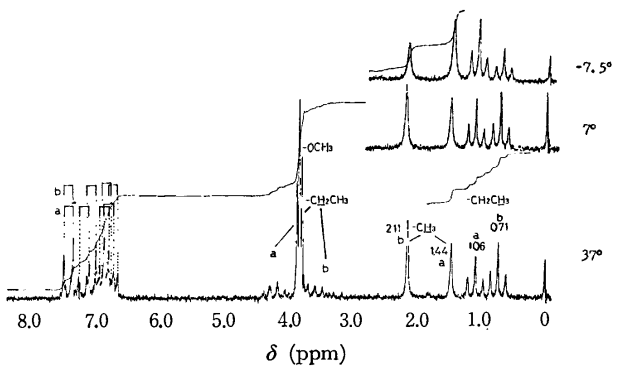

Fig. 1. NMR spectra of D-IV in $CDCl_3$.

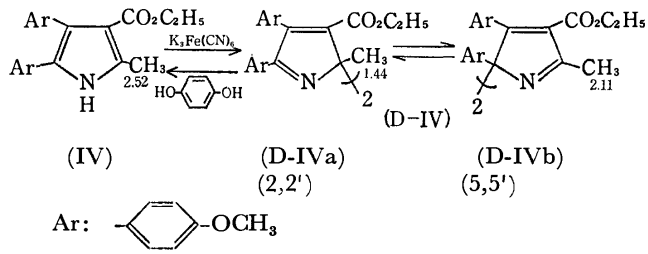
Since it shows the presence of the two ester, four *p*-methoxyphenyl, and two methyl groups in a ratio dependent on the temperature, D-IV seems to be a mixture of two dimers, (D-IVa) and (D-IVb) (assigned as *a* and *b* in Fig. 1), which are in equilibrium with each other in solution. In fact, as expected, one of the dimers D-IVa was isolated on the recrystallization of D-IV from acetone.[7] Its NMR spectrum, measured at −7.5°C immediately after D-IVa was dissolved in cold $CDCl_3$, showed only the signals, *a* in Fig. 1, corresponding to a single compound. With the passage of time, the spectrum showed the gradual appearance of the other isomer, D-IVb, from D-IVa, and after a long time afforded the same pattern of spectrum of a mixture of D-IVa and D-IVb, as is shown in Fig. 1. Those phenomena were also observed on a thin layer chromatogram (tlc); a tlc of D-IV showed two spots (R_f; 0.6 and 0.2, developed in a mixture of benzene and acetone (20 : 1) on a silicagel plate), while that of D-IVa showed one spot (R_f; 0.6) when it was developed immediately, and an additional spot (R_f; 0.2), developed after the solution of D-IVa was allowed to stand for a long time at room temperature.

These results strongly indicate the presence of the equilibrium, though attempt at the isolation and characterization of the other isomer, D-IVb, have thus far been unsuccessful.

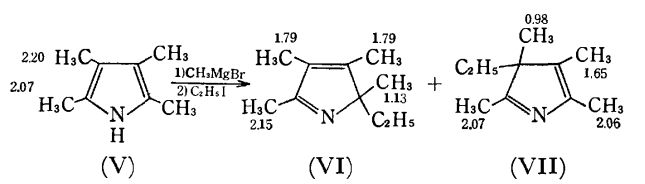
The Structures of D-IVa and D-IVb. The structures of D-IVa and D-IVb were determined to be 2,2′- and 5,5′-bispyrrolenine derivatives respectively, as is shown in Scheme 1, on the basis of the following results.



Scheme 1.

The single 2-methyl signal at 1.44 ppm in the NMR spectrum of D-IVa supported a symmetrical dimer structure, while the two overlapping A_2B_2-type signals in the aromatic region indicate that the phenyl rings were not involved in the dimerization-bond formation, as they are in the dimer of the triphenylmethyl radical.[8a–d] The IR spectrum of D-IVa shows the same absorptions as D-IV, and the strong imine absorptions at 1610 cm^{-1} indicate the pyrrolenine structure, eliminating the possibility of the formation of a 1,1′ (N,N′) bond. The absorptions at 1720 cm^{-1} show the presence of an α,β-unsaturated ester group, which also suggests that the formation of a 3,3′ bond is unlikely.

The 2-methyl proton signal in the NMR spectrum of tetramethylpyrrole (V) is markedly shifted upfield with further substitution at the 2-position,[9] as is shown in Compound (VI) in Scheme 2.



Scheme 2.

In the case of the dimer D-IVa, the methyl signal which appeared at 2.52 ppm in the pyrrolic compound, IV, underwent a remarkable upfield shift to

6) The dimer of compound (Y) is noted (D-Y) symbolically.

1.44 ppm. The 2,2′ bond formation was thus assigned for the dimer D-IVa; which was analogous to the dimers II of 3-acylpyrryls III.[5]

Although the other isomer, D-IVb, was not isolated, its NMR and IR spectra, deduced from a comparison of the spectra of D-IVa with those of the mixture D-IV, also support the symmetrical bispyrrolenine structure in which 1,1′ or 3,3′ bond formation is excluded. In this isomer, the methyl signal (2.11 ppm), which is not shifted upfield as in the case of D-IVa, allows for the possibility of two dimers, 4,4′ or 5,5′, by comparison with the results described by Wong *et al.* (Scheme 2); however the 5,5′ structure, as is shown in Scheme 1, seems reasonable on the basis of the following facts. When the oxidation of the 4-methyl-substituted analogue (VIII) was undertaken, a mixture of two dimers, (D-VIIIa) and (D-VIIIb), also resulted; the isomer isolated on the recrystallization from acetone, D-VIIIa, was identified as a 2,2′-dimer from the same consideration of NMR spectral data, postulated in Scheme 3, as in the case of D-IVa. The 4-methyl proton signal of the other isomer, D-VIIIb, was observed at 2.08 ppm;[10] this fact strongly supports the 5,5′ structure, since a much larger upfield shift would be expected if the carbon at the 4,4′-position is involved

10) Assigned on comparison with that of IXb, as shown in Table 1.

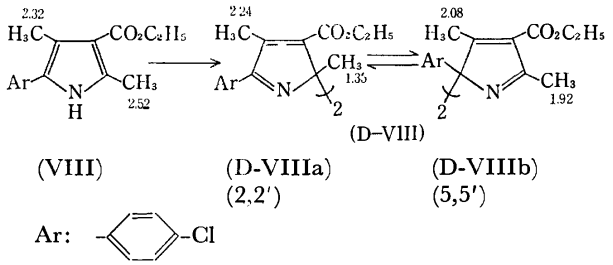
in the bonding, as is shown by the 4-methyl proton signal of (VII).



Scheme 3.

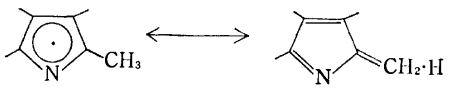
It was found that analogous reactions of some other derivatives (IX—XV) gave the corresponding dimers (D-IX—XV) quantitatively, and that each of them consisted of 2,2'- and 5,5'-bispyrrolenines. Their physical properties, spectral data, and occurrence ratio in equilibrium are summarized in Table 1. It is not clear why the 3-alkoxycarbonyl-substituted derivatives give a mixture of the dimers, while the 3-acyl analogues I afforded only 2,2' dimers II. It seems, however, that the steric effect of this difference is not important, since the 3-methoxycarbonyl-substituted compound (X) gives two dimers, while the sterically-not-so-unequivalent 3-propionyl derivative (I, Ar=Ar'=*p*-$CH_3OC_6H_4$-, R=C_2H_5) forms a single dimer.

The Mechanism of the Interconversion between the 2,2'- and 5,5'-Dimers. We consider that the interconversion of the 2,2'-dimers to 5,5'-isomers proceeds *via* a pyrryl radical as an intermediate, from the reasons described below.

Firstly, the conversion of 2,2'-dimers to 5,5'-dimers is inhibited by hydroquinone. A second reason is based on the substituent effects. Kinetic studies by means of NMR showed that the interconversion obeyed first-order kinetics, and the rate constants, $k_{a\to b}$ and $k_{b\to a}$, for the dimers D-IV and D-XIII were estimated to be 2.7×10^{-3}, 1.9×10^{-3} (D-IV) and 0.75×10^{-3}, 0.71×10^{-3} (D-XIII), both at 37.0°C. Thus, a significant increase in the rate constant was observed for the former; this was explainable from the radical stabilizing ability of the *p*-methoxy substituent, as was suggested by Zimmerman *et al.*[3g]

The Effect of Substituents on the Dimerization Reactions. In order to estimate the effect of 2-alkyl substituents on the dimerization reactions, Compounds (XVI—XIX) were examined; the results are listed in Table 2.

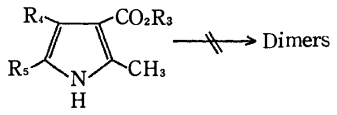
Table 2 indicates that the 2-alkyl groups have a direct influence on the yield of the dimers. It is likely that the oxidation of these compounds proceeds *via* pyrryl radicals, as was mentioned before; therefore, it seems reasonable to consider that the yield of the dimers depends mainly upon the reactivity of the intermediate pyrryl radicals. As is shown in Table 2, the order of the yields is as follows; $CH_3>C_2H_5>i$-C_3H_7, *t*-$C_4H_9\gg$H. This order is in accord with that of the stabilizing ability of the radicals by a hyperconjugation effect caused by the 2-alkyl substituents. Thus, in this series, the largest increase in resonance energy can be obtained when R_2 is CH_3 (IV), as is shown below;



On the other hand, in the case of XIX (R_2=H), which gave no dimer, the intermediate pyrryl radical is less stabilized. When R_2 is isopropyl (XVII) and *t*-butyl (XVIII), however, the remarkable decrease in the yield of the dimers can not be fully explained by a decrease in the hyperconjugation effect. These facts suggest that the dimerization is also markedly subject to steric hindrance by the bulky 2-substituents in the approach of two pyrryl radicals. An analogous steric effect was observed in the case of the acid-catalysed dimerization of 2-alkyl-indole and -benzofuran derivatives.[11,12]

The experimental results, which suggest the effects of substituents at other positions (4 and 5), are shown below.

11) G. F. Smith and A. E. Walters, *J. Chem. Soc.*, **1961**, 940.
12) T. Abe and R. Shimizu, *Nippon Kagaku Zasshi*, **91**, 753 (1970).



(XX—XXII)

	R_3	R_4	R_5
XX	$CH_2C_6H_5$	p-$CH_3OC_6H_4$	CH_3
XXI	C_2H_5	H	C_6H_5
XXII	C_2H_5	CH_3	CH_3

These results indicate that the 5-aryl substituent is more essential for the dimer formation than that of the 4-position, since 4-alkyl-5-aryl derivatives (VIII, IX and XV) afford the corresponding dimers in good yields, whereas the 4-aryl-5-alkyl compound (XX) gives no dimer and the starting material is recovered. (However, the effect of the 4-alkyl substituent is not entirely negligible, as is shown by the lack of dimerization of Compound XXI (R_4=H).) From this point of view, the fact that the 4,5-dimethyl-substituted compound (XXII) gives no dimer is very understandable.

Finally, these substituent effects show that the 2- and and 5-substituents play an important role in the stabilization of the pyrryl radicals. Similar substituent effects have been suggested in the case of tetraarylpyrryl radicals.[13a,b]

The Properties of the Dimers. Some of the dimers, for example, D-IV and D-XI, exhibit thermochromism in solution due to the reversible dissociation of the dimers into pyrryl radicals; this will be shown in detail in the following paper.

Experimental

All the melting points are uncorrected. The IR spectra were determined by means of Nujol mulls with a Hitachi EPI-S2 spectrophotometer; the mass spectra, with a JEOL-JMS-OIS mass spectrometer, and the NMR spectra, with a Varian A-60 NMR spectrometer, using tetramethylsilane as the internal standard.

Materials. The pyrrolic compounds were synthesized by the methods of Davidson[14] and Knorr[15),16]

Preparation of D-IV. To a stirred solution of IV (1.0 g) in 100 m*l* of ethanol was added gradually an aqueous solution (100 m*l*) of potassium ferricyanide (1.7 g) and potassium hydroxide (0.3 g) at room temperature. The precipitate which was thus formed was filtered and washed with water repeatedly and then dried at room temperature under reduced pressure. This precipitate of D-IV (0.95 g) was pure enough as to require no further purification. The recrystallization of D-IV from acetone gave D-IVa, while from the other solvents, ethanol or benzene-petroleum ether, a mixture of D-IVa and D-IVb was formed.

The oxidation reactions of other pyrrolic compounds were carried out in a similar way.

The Reaction of D-IV with Hydroquinone. To a solution of D-IV (174 mg) in 20 m*l* of benzene, hydroquinone (50 mg) was added, and then the mixture was heated at 80°C for 15 min under a stream of nitrogen. The solution was placed on an alumina column and eluted with benzene. The residue obtained by the evaporation of the solvent was recrystallized from benzene-petroleum ether, yielding 158 mg of colorless needles, mp 138°C, which were found to be identical with IV on a mixed melting point determination and by a comparison of their IR and UV spectra.

D-XIII and D-XIV also afforded the corresponding pyrrolic compounds, XIII and XIV respectively, both in quantitative yields.

The authors wish to thank Dr. G. Sunagawa, the Director of these Laboratories, and Dr. K. Tanabe for encouragement through the course of this work.

Studies of the Synthesis of Furan Compounds. XXVIII.[1] Syntheses and Steric Configurations of 3-(5-Nitro-2-furyl)-2-(2-furyl)acrylonitrile and Its Bromine Derivatives[2]

Yasuhiko KATO, Takashi KUBOYAMA, and Ichiro HIRAO

Laboratory of Organic Synthesis, Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kita-kyushu

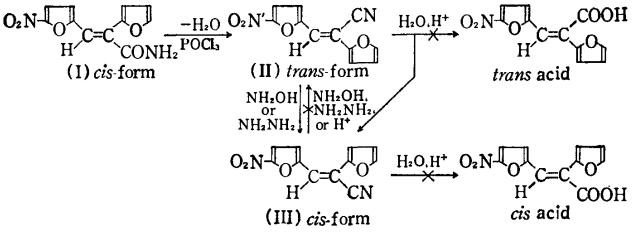
(Received February 2, 1972)

In continuing a previous report[3] concerning the syntheses and steric configurations of 3-(5-nitro-2-furyl)-2-(2-furyl)acrylic acid derivatives, *trans* and *cis* 3-(5-nitro-2-furyl)-2-(2-furyl)acrylonitrile and their related compounds have been synthesized. The isomerization was involved in the conversion of *cis*-3-(5-nitro-2-furyl)-2-(2-furyl)acrylamide (I) to *trans*-3-(5-nitro-2-furyl)-2-(2-furyl)acrylonitrile (II) upon the treatment of phosphoryl chloride. II was converted to its *cis* isomer (III) by treating it with hydroxylamine, hydrazine hydrate, or hydrochloric acid. II and III were treated with bromine at 5—10°C in carbon tetrachloride to afford dibromo compounds, (3*S* : 5*S* and 3*R* : 5*R*)-(IV) and (3*S* : 5*R* and 3*R* : 5*S*)-3-(5-nitro-2-furyl)-3-bromo-2-(5-bromo-2,5-dihydro-2-furylidene)propionitrile (V) respectively. When the bromination was carried out at a higher temperature (70—73°C), a monobromo compound, *cis*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile (VI), was obtained from both II and III. VI was also produced by heating IV or V in refluxing acetone. The structures and configurations of these compounds were discussed on the basis of their experimental and spectral data.

3-(5-Nitro-2-furyl)acrylonitrile has been prepared by various methods,[1,4-6] and it gives an amidoxime derivatives upon treatment with hydroxylamine.[1,7] In a similar treatment of 3-(5-nitro-2-furyl)-2-(2-furyl)acrylonitrile with hydroxylamine, the corresponding amidoxime-type compound was not obtained, but a configurational interconversion was observed. In this report, the systheses and steric configurations of *trans* and *cis* 3-(5-nitro-2-furyl)-2-(2-furyl)acrylonitrile and their bromine derivatives will be described.

Results and Discussion

3-(5-Nitro-2-furyl)-2-(2-furyl)acrylonitrile (II) was easily obtained in a good yield from 3-(5-nitro-2-furyl)-2-(2-furyl)acrylamide[8] (I) by treatment with phosphoryl chloride at 50—60°C according to the method described in a previous report.[1] When treated with hydroxylamine at 60—70°C, II was converted to its isomer (III); the results of an elemental analysis of this isomer agreed with the value calculated for II. In this isomerization, the hydroxylamine seems to serve as an isomerization catalyst, much like the hydrazine.[3] In fact, the same isomerization also occurred when II was treated with hydrazine hydrate. Further, the isomerization by a hydroxylamine or hydrazine catalyst was confirmed to be irreversible. In order to compare the structures of II and III with those of the corresponding mother acids and identify them, II and III were both heated with hydrochloric acid. The desired acids, however, were not obtained; II was converted to III, while III remained unchanged.



Scheme 1. Preparation and isomerization of II and III.

The IR spectra of II and III showed a C≡N stretching absorption band at about 2240 cm^{-1}. In the UV spectra, as is shown in Fig. 1, two absorption maxima of II, one near 300 mμ and the other near 400 mμ, were observed; the former one showed a hypsochromic shift upon comparison with the corresponding one of III. The extinction coefficient of the former was larger and that of the latter was smaller than in III. The NMR spectra (Fig. 2) indicate precisely that the olefinic proton and the CN group are on the same side of the ethylene double bond in the molecule of III, since the olefinic proton of III reveals a signal in a lower magnetic field than that of II (Δ_{tc} 0.44 ppm), as a result of the magnetic anisotropy of the C≡N bond. Thus, the configuration of III was determined to be *cis*, and that of II, to be *trans*, necessarily.[9] Saikachi *et al.*[8] gave a *trans* symbolism in the configurational nomenclature to the general 3-(5-nitro-2-furyl)-2-(2-furyl)acrylic acid and its amide, I, even though their two furan rings are on the same side of the ethylene bond. In a recent experiment, Kato prepared two isomeric 5-[2-(5-nitro-2-furyl)-1-(2-furyl)-vinyl]-2-amino-1,3,4-thiadiazoles from 3-(5-nitro-2-furyl)-2-(2-furyl)acrylic acid and determined the steric configurations of the 1,3,4-thiadiazoles, the starting acids, and their esters,[3] according to the nomenclature[8] mentioned above; it was necessary to correlate and/or compare the starting acids and esters with those described by Saikachi *et al.* We consider

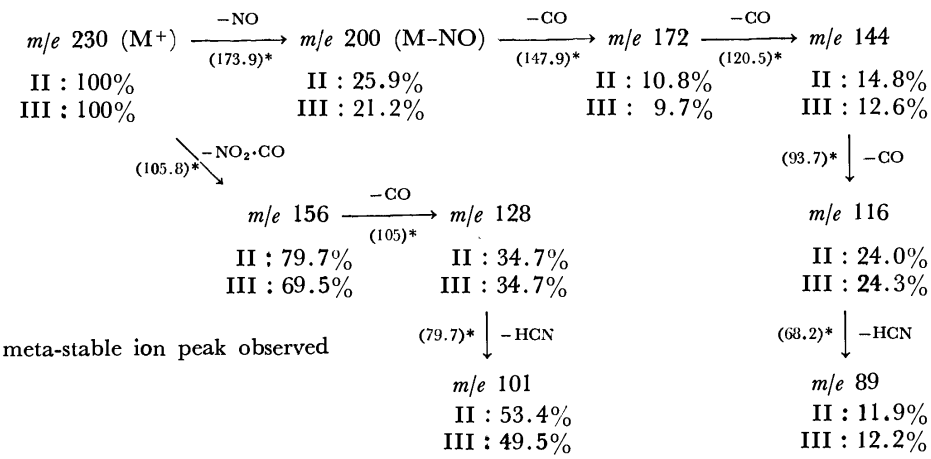
NF-4-H: C_4-H of 5-nitrofuran ring 
that it is most reasonable and suitable to conclude that the configurations of such an acid and I are *cis*. Furthermore, the symbolism of the compounds previously presented by Kato should also be corrected, changing *cis* to *trans*, and *trans*, to *cis*.

In the above dehydration reaction, it was found that a particularly facile isomerization[3,10] was involved in the conversion of I (*cis*) to II (*trans*) by the action of phosphoryl chloride.

The mass spectral data exhibited no difference between II and III. As is shown in Scheme 2, the molecular ion (M^+, *m/e* 230) is the most prominent (the base peak) and forms a distinct ion peak at mass 200 upon the elimination of NO. The M−NO ion successively loses three carbon monoxides to give the *m/e* 172, 144, and 116 ions. The ion with mass 89 results from the *m/e* 116 ion by the loss of HCN. On the other hand, the molecular ion loses NO_2 and CO fragments by a one-step process to give an ion at mass 156. This ion undergoes the elimination of CO and the subsequent loss of HCN to form *m/e* 128 and 101 ions successively.

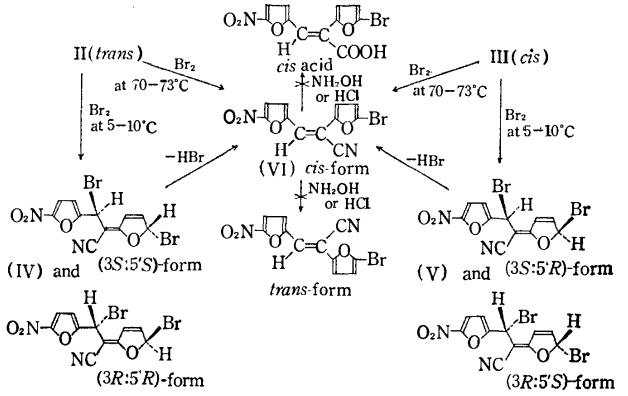
On the treatment of II and III with bromine at 5—10°C in carbon tetrachloride, two dibromo compounds, IV and V respectively, were obtained, while in the bromination carried out at 70—73°C a monobromo compound (VI) was produced from both II and III. Moreover, IV and V were found to be unstable both in air and in solvents, and they gave only VI, with the release of hydrogen bromide. For example, this elimination reaction occurred satisfactorily



Scheme 2. The fragmentation of II and III.

10) S. M. Kupchan and A. Afonso, *J. Org. Chem.*, **25**, 2217 (1960); see also R. E. Buckles, G. V. Mock, and L. Locatell, *Chem. Rev.*, **55**, 659 (1955).

when a dioxane solution of IV or V was left standing at room temperature or heated in refluxing acetone. The monobromo compound VI was stable, and it was recovered unchanged when heated with hydroxylamine in aqueous ethanol for 2 hr or with 36% hydrochloric acid for 12 hr.



Scheme 3. Preparation of bromo compounds from II and III.

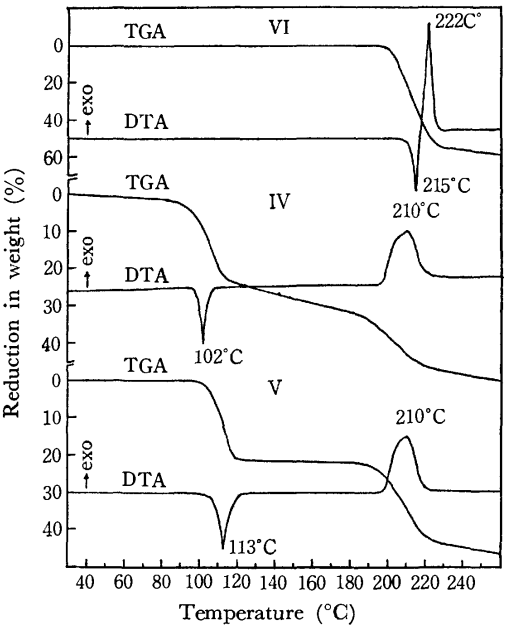


Fig. 3. The thermal analyses of IV, V, and VI at the heating rate of 3°C/min in a nitrogen stream.

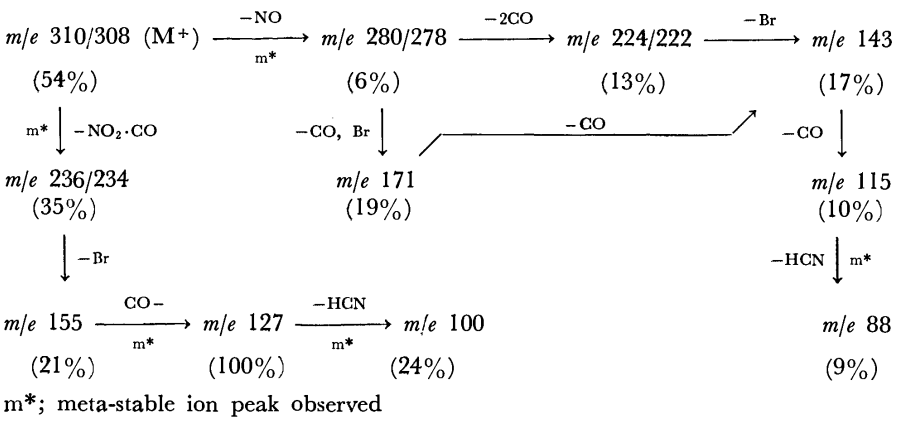
The thermostability of IV, V, and VI was investigated by thermogravimetric analysis (TGA) and differential thermal analysis (DTA) under a nitrogen atmosphere. As is shown in Fig. 3, the DTA curve of VI shows an endothermic peak and an exothermic peak at 215°C and 222°C respectively; these peaks coincide with the melting and decomposition points of VI. On the other hand, in the DTA curves of IV and V, the endothermic peak at 102°C for IV and that at 113°C for V, and the exothermic one (210°C for IV and V) are in agreement with the initial and the second stages (80—114°C and 180—220°C for IV, 100—120°C and 185—220°C for V) of the reduction in weight of the corresponding TGA curves. About 23% and 21% of the loss of weight occur for IV and V respectively in the initial stage; this corresponds to the loss of a hydrogen bromide molecule from both IV and V (theoretical: 20.8%). The second stage of the reduction in weight agrees with the decomposition point of VI during the pyrolysis.

The IR spectrum of VI showed two C–H stretching absorption bands and a weak C≡N stretching absorption band at 3150, 3063, and 2240 cm^{-1} respectively. In the spectra of IV and V, the absorbances of the C–H and C≡N stretching bands were more intense than those of VI, and the C–H absorption bands were observed at 3135 and 2985 cm^{-1} for IV, and at 3175, 3085, and 3025 cm^{-1} for V. The C≡N absorption bands appeared at 2220 cm^{-1}. The NMR spectra of IV and V were unsatisfactory because of their lower solubility and greater instability in solvents. On the other hand, VI was clearly determined to be *cis*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile by a comparison of its NMR spectrum with those of II and III (Fig. 2). The mass spectrum also supported the above structure. In Scheme 4, the molecular ion (M^+, *m/e* 310/308) peak is strong; this undergoes two modes of cleavage. One path is the loss of NO_2 and CO fragments by a one-step process to give an ion at mass 236/234, and the other is the loss of NO, giving rise to the *m/e* 280/278 ion. The following fragmentations are virtually identical with that of II or III, but the substituted position of bromine is demonstrated by the elimination porcess of a bromine atom previous to the loss of the last CO.

Considering the above experimental data and the



m*; meta-stable ion peak observed

Scheme 4. The fragmentation of VI.

rule of *trans*-addition in the usual bromination, IV and V can be presumed to be (3*S* : 5*S* and 3*R* : 5*R*)- and (3*S* : 5*R* and 3*R* : 5*S*)-3-(5-nitro-2-furyl)-3-bromo-2-(5-bromo-2,5-dihydro-2-furylidene)propionitrile respectively, though more precise data as to the confirmation of the configuration of IV and V could not be obtained. In conclusion, by the elimination of hydrogen bromide, as has been mentioned above, only a sort of monobromo compound, VI, was obtained from both IV and V. It can be suggested that the elimination is not a simple *trans*-one, but that the configurational interconversion is involved in the releasing process of a bromine anion after a proton has been pulled off.

Experimental

The melting and decomposition points are uncorrected. The elemental analyses were carried out with a Yanagimoto CHN Corder, MT-2 type. The ultraviolet absorption spectra (UV) were performed on a Perkin-Elmer Model 202 spectrophotometer. The infrared absorption spectra (IR) were measured with a JASCO Model IRA-2 grating infrared spectrophotometer. The nuclear magnetic resonance spectra (NMR) were determined with a Japan Electron Optics Lab. JNM-C-60HL spectrometer. All the spectra were measured in trichloroacetic acid at 60 MHz, with hexamethyldisiloxane as the internal reference; the chemical shifts are expressed in δ-values. The mass spectra were taken on a Hitachi RMU-6L mass spectrometer by means of a direct insertion (at 70 eV, 3.2 kV). The thermal analyses were carried out with a Chyo Balance and with a Rigaku Denki Thermoflex in a nitrogen stream.

trans-*3-(5-Nitro-2-furyl)-2-(2-furyl)acrylonitrile (II).* A mixture of *cis*-3-(5-nitro-2-furyl)-2-(2-furyl)acrylamide (10 g, 40 mmol), 40 m*l* of phosphoryl chloride, and 2 drops of *N,N*-dimethylaniline was heated at 50—60°C for 45 min, cooled, and then poured into crushed ice with agitation. The solidified crude product was collected and purified by recrystallization from methanol to afford 7.8 g (84.4%) of ochreous needles; mp 132—133°C. UV λ_{max}^{EtOH} mμ (ε): 302 (6800) and 396 (15000). IR (KBr) cm,$^{-1}$: 3143, 3050 (C–H), and 2232 (C≡N). NMR (CCl_3COOH) δ: 6.07 (q, 1H, J=1.7 Hz, furan ring C_4–H), 6.36 (s, 1H, olefinic proton), 6.66 (d, 1H, J=*ca.* 3.5 Hz, furan ring C_3–H; overlapped with nitrofuran ring C_3–H), 6.66 (d, 1H, J=4.0 Hz, nitrofuran ring C_3–H), 6.85 (d, 1H, J=4.0 Hz, nitrofuran ring C_4–H), and 7.07 (d, 1H, J=2.1 Hz, furan ring C_5–H). Mass: the spectral fragmentation is indicated in Scheme 2.

Found: C, 57.40; H, 2.57; N, 12.28%. Calcd for $C_{11}H_6N_2O_4$: C, 57.39; H, 2.61; N, 12.17%.

cis-*3-(5-Nitro-2-furyl)-2-(2-furyl)acrylonitrile (III).*

From the Conversion of II to III with Hydroxylamine: To a stirred, warmed (70—75°C) mixture of II (2 g, 8.7 mmol) and 2 drops of *N,N*-dimethylaniline in 50 m*l* of ethanol, we gradually added an aqueous solution of free hydroxylamine (16 mmol in 10 m*l* of water) during a period of 15—20 min. After the addition, the reaction mixture was heated under reflux for 5 hr. Cooling provided a crude product, and then recrystallization was carried out from methanol. Orange-yellow needles; mp 186—187°C. The yield was 1.96 g (98%). UV λ_{max}^{EtOH} mμ (ε): 316 (5900) and 398 (21800). IR (KBr) cm^{-1}: 3138, 3065 (C–H), and 2240 (C≡N). NMR (CCl_3COOH) δ: 6.03 (q, 1H, J=1.7 Hz, furan ring C_4–H), 6.31 (d, 1H, J=3.4 Hz, furan ring C_3–H), 6.66 (d, 1H, J=4.0 Hz, nitrofuran ring C_3–H), 6.80 (s, 1H, olefinic proton), 6.93 (d, 1H, J=4.0 Hz, nitrofuran ring C_4–H), and 6.98 (d, 1H, J=*ca.* 2 Hz, furan ring C_5–H; overlapped with nitrofuran ring C_4–H). Mass: shown in Scheme 2.

Found: C, 57.75; H, 2.61; N, 12.55%. Calcd for $C_{11}H_6N_2O_4$: C, 57.39; H, 2.61; N, 12.17%.

On the other hand, III was not converted to II under the above conditions.

From the Conversion of II to III with Hydrazine Hydrate: A mixture of II (0.6 g, 2.6 mmol), 80% hydrazine hydrate (0.63 g, 10 mmol), and methanol (100 m*l*) was stirred at 0—5°C for 1 hr, at room temperature for 3 hr, and then at 50—60°C for 3 hr. Cooling subsequently provided 0.5 g (83.3%) of a product which melted at 186—187°C. Recrystallization from methanol gave orange-yellow needles; mp 187—188°C. This product was identified as III by an admixture-test and by a comparison of its IR spectrum with that of the sample prepared by the above procedure. Compound III was not converted to II under the above conditions.

From the Conversion of II to III with Hydrochloric Acid: A mixture of II (1 g, 4.4 mmol) and 36% hydrochloric acid (50 m*l*) was heated under reflux for 50 min. Work-up as above gave 0.98 g (98%) of orange-yellow needles. Mp 186°C; undepressed upon admixture with a sample prepared by the above two methods. In a similar manner, III was recovered without any conversion.

(*3S* : *5S and 3R* : *5R*)-*3-(5-Nitro-2-furyl)-3-bromo-2-(5-bromo-2,5-dihydro-2-furylidene)propionitrile (IV).* To a stirred, cooled (5—10°C) mixture of II (5 g, 21.7 mmol) and carbon tetrachloride (250 m*l*) was added dropwise a solution of bromine (4 g, 22.3 mmol) in 50 m*l* of carbon tetrachloride. The mixture was stirred below 10°C until the bromine had been absorbed completely. The solid product was collected by filtration, washed with cooled dry petroleum ether, and dried on paraffin wax in a cold box. In this way, a 8.4-g portion (quantitative yield) of a pale yellow powder was obtained; it melted, with decomposition, at 102°C. However, the recrystallization of this product could not be achieved from the solvents or solvent mixtures, and the product could not be stored over 3 days; nevertheless, the freshly-prepared product was pure enough for elemental analysis and was used in the following experiments without further purification. IR (KBr) cm^{-1}: 3135, 2985 (C–H), and 2220 (C≡N).

Found: C, 34.27; H, 1.83; N, 6.82%. Calcd for $C_{11}H_6N_2O_4Br_2$: C, 33.86; H, 1.54; N, 7.18%.

(*3S* : *5R and 3R* : *5S*)-*3-(5-Nitro-2-furyl)-3-bromo-2-(5-bromo-2,5-dihydro-2-furylidene)propionitrile (V).* This was prepared by the method used for IV, using 5 g (21.7 mmol) of III. Work-up as above afforded 8.3 g (quantitative) of V as a pale yellow powder; mp 113°C (decomp.). This product was also unstable and gradually decomposed during storage. IR (KBr) cm^{-1}: 3175, 3085, 3025 (C–H), and 2220 (C≡N).

Found: C, 33.53; H, 1.53; N, 6.83%. Calcd: the same value as IV above.

cis-*3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile (VI).* *Procedure A*: A solution of bromine (0.8 g, 5 mmol) in 20 m*l* of carbon tetrachloride was stirred into a warmed (70°C) mixture of 1 g (4.4 mmol) of II (or III) and carbon tetrachloride (50 m*l*) and then the mixture was refluxed for 2 hr. After cooling, the precipitated product was collected, washed with carbon tetrachloride, and then dried. Recrystallization from acetone–dioxane gave 1.2 g (63%) of VI as an orange-red powder, which melted at 218—220°C with decomposition. IR (KBr) cm^{-1}: 3150, 3063 (C–H), and 2240 (C≡N). NMR (CCl_3COOH) δ: 6.00 (d, 1H, J=3.4 Hz, bromofuran ring C_4–H), 6.29 (d, 1H, J=3.4 Hz, bromofuran ring C_3–H), 6.71 (d, 1H, J=4.0 Hz, nitrofuran

ring C_3–H), 6.81 (s, 1H, olefinic proton), and 6.95 (d, 1H, J =4.0 Hz, nitrofuran ring C_4–H). Mass: shown in Scheme 4.

Found: C, 43.17; H, 1.63; N, 8.73%. Calcd for $C_{11}H_5N_2O_4Br$: C, 42.72; H, 1.62; N, 9.06%.

Procedure B: IV or V (each 1 g, 5 mmol) was heated in acetone under reflux for 1 hr, or was dissolved in dioxane and allowed to stand at room temperature for 2 hr. A work-up as above afforded 0.8 g (quantitative) of an orange-red powder; mp 218—220°C (decomp.). This product was identical in its infrared spectrum with an authentic sample of VI.

Found: C, 42.91; H, 1.63; N, 8.81%. Calcd: the same value as VI by *Procedure A*.

This compound, VI, could not be converted to its *trans*-isomer or carboxylic derivative by treatment with hydroxylamine at 70—80°C in aqueous ethanol for 2 hr or by refluxing with 36% hydrochloric acid for 12 hr.

The authors are indebted to Mr. A. Yamamoto and Mr. S. Iwasaki for their experimental assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3169—3171 (1972)

Solvent Shifts of Methyl Proton Resonances of Pinanols and Related Compounds[1]

Toshifumi HIRATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received February 14, 1972)

The chemical shifts of methyl protons of a number of bicyclo[3.1.1]heptanols and their acetates were measured on carbon tetrachloride and benzene in order to examine the correlation between the benzene-induced shifts and the spatial arrangements of the functional groups concerned. Thus, the shifts induced by benzene were found to be useful in establishing both the location and the stereochemistry of methyl protons situated in the vicinity of the hydroxyl or the acetoxyl function in a pinane skeleton.

It has been reported[3-10] that solvent shifts (Δ) of proton resonances can be used in the elucidation of stereochemical problems. Particularly, the empirical rule[3-6] for ketones has been useful in considering these problems. However, attempts to extend the rule to alcohols and their acetates and to find a generalization in these fields have not been successful. In connection with our studies of the stereochemistry and the reaction of pinane derivatives, significant solvent effects were found for the methyl protons of pinanols and their acetates. The author now wishes to report his findings regarding the benzene-induced shifts and to correlate the shifts with the stereochemistry of the functional groups concerned.

Results and Discussion

The benzene-induced shifts ($\Delta=\delta_{CCl_4}-\delta_{C_6H_6}$) were measured for three methyl protons in pinanols

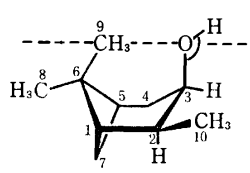
protons at the 9-position showed a different value of shifts, in dependence on the spatial arrangements between the functional group and the *gem*-dimethyl bridge. Shifts to a lower field were noted for a *cis*-form, and to a higher one, for a *trans*-form. The downfield shifts have been observed[9] for monohydroxy-steroids in which the hydroxyl and the methyl groups are 1,3-diaxial. We observed the same phenomena for 2- or 4-hydroxypinanes and their acetates respectively. For *cis*-3-hydroxypinanes and their acetates, also, downfield shifts or very small upfield shifts were observed, although the 9-methyl and the hydroxyl groups are not perfectly 1,3-diaxial but, rather, those are situated in a nearly diaxial arrangement, as is shown in **9a**. Therefore, it is very likely that the 9-methyl



9a

protons of *cis*-3-hydroxypinanes and their acetates suffer decreased shielding by benzene. These observations suggest that the unknown configuration of a hydroxyl or acetoxyl group of pinane derivatives can probably be determined by measuring the benzene-induced shifts of the methyl protons at the 9-position.

On the modification of the rule[3-6] established for ketones, an empirical rule can thus be proposed on the bases of the above observations and the data reported for hydroxy-steroids.[9] As an aid for predicting the benzene-induced shifts, a reference plane is imagined through the hydroxyl oxygen atom at right angles to the carbon-oxygen bond of the hydroxyl group. The Δ values are negative for protons lying on the reference plane; they become positive as they leave the plane. The bonzene-induced shifts of the hydroxylated or the acetoxylated pinane derivatives may be useful in establishing both the location and the stereochemical relationship of protons situated in the vicinity of the hydroxyl or the acetoxyl function.

Experimental

The NMR spectra were measured with a Varian Associates HA-100 spectrometer and a Hitachi Perkin-Elmer R-20 high-resolution spectrometer on the carbon tetrachloride and the benzene solution in a 5% (w/v) concentration at normal probe temperatures (*ca.* 30°C), using tetramethylsilane as the internal standard. The chemical shifts of the proton resonances of the 8-, 9-, and 10-methyl protons of pinanols and their acetates are shown in Table 2, expressed in δ-values (accuracies, $\pm$0.02 ppm). The purity of the samples used was checked by a combination of thin-layer chromatography with silica gel and vapor-phase chromatography using a Hitachi Perkin-Elmer F6-D Gas Chromatagraph with a stainless-steel column (3 mm$\times$1 m) packed with 20% PEG-6000 on Celite (60—80 mesh) at 120—150°C. All the spectral data (IR, NMR and MS) and physical properties of each sample coincided with those of the data reported in the literature and completely supported the structure depicted above.

The 2-hydroxypinanes, (**1**) and (**2**), were generously donated by Ohloff,[11] while the hydroxypinanes, (**5**), (**9**), (**10**), (**11**) and (**12**), had been previously synthesized in our laboratory by the reduction of the appropriate ketones.[12-14] Most of the acetates were prepared from the corresponding alcohols by treating them with acetic anhydride in pyridine, followed by purification with preparative thin-layer chromatography on silica gel, using a mixture of *n*-hexane and ethyl acetate as solvent.

*2-Hydroxyapopinanes (**3**) and (**4**).* A mixture of 1.0 g of (+)-nopinone ($[\alpha]_D^{25}$+20.3°, prepared from (−)-β-pinene by ozonization), 2.6 g of aluminum isopropoxide, and 20 m*l* of isopropyl alcohol was refluxed for 4 hr, and then worked-up following the method in the literature.[15] The oily product (910 mg) thus obtained was subjected to column chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane to give 334 mg of 2β-hydroxyapopinane (**3**) (mp 103.5—104.0°C, lit,[15] mp 101.5—102.0°C; $[\alpha]_D^{25}$−12.0° (*c* 0.75, MeOH); the phthalate, mp 131.0—131.5°C, lit,[15] mp 131.0—131.5°C) and 175 mg of the 2α-epimer (**4**) (mp 35—36°C, lit,[15] mp 37.0—37.5°C; $[\alpha]_D^{25}$−15.2° (*c* 0.67,

MeOH); the phthalate, mp 154—155°C, lit,[15] mp 155.8—156.2°C).

*4β-Hydroxy-pin-2-ene(**7**).* The reduction of 680 mg of (−)-verbenone ($[\alpha]_D^{25}$−208.6°, prepared from (−)-α-pinene by *t*-butyl chromate oxidation) with 200 mg of sodium borohydride gave 600 mg of a crude sample of Compound **7**; this sample was purified by recrystallization followed by preparative gas chromatography with a PEG-6000 column; mp 67—68°C (lit,[16] mp 68—70°C); $[\alpha]_D^{25}$−17.3° (*c* 0.75, MeOH) (lit,[16] $[\alpha]_D^{22}$−16.0°).

*4α-Hydroxy-pin-2-ene (**8**) and Its Acetate (**20**).* Following the procedure previously reported,[17] (−)-α-pinene (3.0 g; $[\alpha]_D^{25}$−39.9°) was oxidized with lead tetraacetate in dry benzene. The oxidation product (2.95 g) was isomerized with glacial acetic acid to give an oily product (2.90 g). Purification by column chromatography on silica gel gave the acetate (**20**) (1.55 g) ($[\alpha]_D^{25}$−128.1° (*c* 1.00, MeOH), lit,[16] $[\alpha]_D^{22}$−135.6°; IR (liq.) 1735 ($OCOCH_3$) and 1650 cm^{-1} (C=C)). The saponification of the acetate (**20**) (0.7 g) with methanolic sodium hydroxide gave the alcohol (**8**) (0.45 g) ($[\alpha]_D^{25}$−107.2° (*c* 0.78, MeOH), lit,[16] $[\alpha]_D^{22}$−112.7°; the *p*-nitrobenzoate; mp 98—99°C, lit,[16] mp 98—98.5°C).

*4α-Hydroxy-10β-pinane (**6**).* The hydrogenation of 4α-hydroxy-pin-2-ene (**8**) (250 mg) in the presence of the Adams catalyst (10 mg) in cyclohexane gave the pinanol (**6**) (249 mg); mp 85—86°C (lit,[12] mp 87°C).

*3β-Hydroxy-pin-2(10)-ene (**13**).* Following the procedure previously reported,[18] pinocarvone (7.0 g; bp 69.0—70.0°C (6.5 mmHg), $[\alpha]_D^{25}$+55.1°, n_D^{25} 1.4959, d_4^{25} 0.9952), which had been prepared from (−)-β-pinene by selenium dioxide oxidation,[18] was treated with bromine and then zinc powder in acetic acid to yield 3β-hydroxy-pin-2(10)-ene (**13**) (3.4 g); mp 49—50°C (lit,[18] mp 50—50.5°C), $[\alpha]_D^{25}$−37.4° (*c* 3.6, MeOH) (lit,[18] $[\alpha]_D$−41°).

*3α-Hydroxy-pin-2(10)-ene (**14**) and Its Acetate (**26**).* Lead tetraacetate (10 g) was added, over 10-min periods, to a stirred suspension of calcium carbonate (1.0 g) in dry benzene (50 m*l*) containing (−)-β-pinene (5.0 g; $[\alpha]_D^{25}$−20.0°); the mixture was then stirred at 60°C for a further 30 min. The reaction mixture was worked up as usual to afford an oily product, which was then subjected to column chromatography on silica gel with a mixture of *n*-hexane and ethyl acetate to give 3α-acetoxy-pin-2(10)-ene (**26**) (3.2 g) ($[\alpha]_D^{25}$−15.9° (*c* 12.8, MeOH), n_D^{25} 1.4739, d_4^{25} 0.9894). The saponification of the acetate (**26**) (0.6 g) with methanolic potassium hydroxide gave the alcohol (**14**) (0.4 g) ($[\alpha]_D^{25}$+60.7° (*c* 1.61, MeOH), lit,[18] $[\alpha]_D$+60°).

The author is thankful to Dr. Takayuki Suga of Hiroshima University for his guidance and encouragement, to Dr. E. von Rudloff of the National Research Council of Canada for measuring the NMR spectra with a Varian Associates HA-100 Spectrometer, and to Dr. G. Ohloff of the Max-Planck Institut for the gift of the samples of pinan-2-ols (**1**) and (**2**).

Syntheses and Reactions of Metal Organics. VII. Reactions of *n*-Butoxytitanium Chlorides with Saturated Cyclic Ethers

Norio Yoshino and Takeshi Yoshino

Department of Industrial and Engineering Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 7, 1972)

The reactions of *n*-butoxytitanium chloride, $TiCl_n(O^nBu)_{4-n}$ (n=0,1,2,3,4), with 1,4-dioxane, tetrahydrofuran, and tetrahydropyran have been studied. No adducts have been isolated when n=0,1,but the compounds $TiCl_2(O^nBu)_2\cdot O(CH_2CH_2)_2O$, $TiCl_2(O^nBu)_2\cdot C_4H_8O$, $TiCl_2(O^nBu)_2\cdot C_5H_{10}O$, $TiCl_3(O^nBu)\cdot O(CH_2CH_2)_2O$, $TiCl_3(O^nBu)\cdot 2C_4H_8O$, $TiCl_3(O^nBu)\cdot 2C_5H_{10}O$, $TiCl_4\cdot O(CH_2CH_2)_2O$, $TiCl_4\cdot 2C_4H_8O$ and $TiCl_4\cdot 2C_5H_{10}O$ have been isolated when n=2,3,4. Possible structures for these adducts were discussed on the basis of elemental analysis, IR spectra, NMR spectra, and molecular weights. The adducts undergo hydrolysis very quickly with moisture.

Tin and titanium tetrachlorides have been shown to readily form stable, solid adducts with various ethers, but not silicon and germanium tetrachlorides.[1-4] Formation of tin tetrachloride adducts was understood to result from Lewis acid-base reactions in which the metal atom expanded its valence shell by accepting a pair of electrons from an oxygen atom of each of two molecules of ether to form compounds of the type $MCl_4\cdot 2R_2O$. Failure of silicon and germanium tetrachlorides to form such compounds was attributed to the fact that the size of the chlorine atom causes four of these atoms to fill the coordination sphere of the silicon and germanium atoms so completely as to prevent any reaction with the ether. The effect of the replacement of the chlorine atoms in titanium tetrachloride by larger halogens was studied as regards the tendency for titanium tetrahalides to react with 1,4-dioxane, tetrahydrofuran, and tetrahydropyran. It was shown that the adducts $TiBr_4\cdot O(CH_2CH_2)_2O$, $TiBr_4\cdot 2C_4H_8O$, and $TiBr_4\cdot 2C_5H_{10}O$ have been isolated, but not the pure adduct of titanium tetraiodide with any ether.[4] The formulas were proposed only on the basis of elemental analysis.

It was shown that the reactions of alkoxy- and phenoxy-titanium chlorides with amides and other compounds involve the carbonyl group. The present investigation revealed that the effect of the alkoxy groups replaced the chlorine atoms of titanium tetrachloride in the reaction with ethers. We used saturated cyclic ethers which are more basic than aliphatic ethers.[5] Possible structures for these adducts were discussed on the basis of elemental analysis, IR spectra, NMR spectra, and molecular weights.

Experimental

All the experiments were carried out in a dry atmosphere or nitrogen.

Materials. Titanium tetrachloride (I) was purified by the method of Clabaugh *et al.*[6] Mono-*n*-butoxytitanium trichloride (II), di-*n*-butoxytitanium dichloride (III), tri-*n*-butoxytitanium monochloride (IV), and tetra-*n*-butyltitanate (V) were prepared by the methods of Bradley *et al.*[7,8] and Jennings *et al.*[9]).

1,4-Dioxane (DO) was purified by the method of Fieser.[10] Tetrahydrofuran (THF) and tetrahydropyran (THP) were dried over calcium chloride, and fractionated from over sodium in a dry nitrogen atmosphere using a 30 cm Widmer distilling column. A constant boiling middle fraction was retained. Boiling point data: DO, 100.3—100.5°C; THF, 65.2—65.5°C; THP, 87.5—88.0°C. To avoid the presence of peroxides, the ethers were purified immediately before use.

Apparatus. All-glass apparatus fitted with standard interchangeable joints was used and special precautions were taken to exclude moisture.

Instruments. The IR spectra were measured in a nujol or a liquid film with a Japan Spectroscopic Co. DS-403G Spectrophotometer. The NMR spectra were measured with a Varian A-60 Spectrometer in a solution of carbon tetrachloride with tetramethylsilane as an internal standard. The molecular weights were determined by the cryoscopic method in benzene.

Preparation of $TiCl_4\cdot O(CH_2CH_2)_2O$ (VI). To a stirred solution of I (3.5 g, 0.018 mol) in 30 m*l* of *n*-hexane was added dropwise a solution of DO (4.9 g, 0.054 mol) in 10 m*l* of *n*-hexane, under cooling at 0—5°C. The reaction, highly exothermic, rapidly yielded a yellow solid. After stirring for 1 hr at room temperature for completion of the reaction, the resulting precipitation of VI (5.1 g) was collected by filtration and washed with *n*-hexane and dried in a vacuum at room temperature, decompn. >200°C.

Found: Ti, 17.25; Cl, 50.82; C, 16.81; H, 2.88%. Calcd for $TiCl_4C_4H_8O_2$: Ti, 17.24; Cl, 51.04; C, 17.29; H, 2.90%. IR (nujol) 1044 (ν_{C-O-C}) cm^{-1}.

Preparation of $TiCl_4\cdot 2C_4H_8O$ (VII) and $TiCl_4\cdot 2C_5H_{10}O$ (VIII). The procedure for the preparation of VI was adopted. Yellow powder (8.2 g) of VII was collected by the reaction of I (4.7 g, 0.025 mol) with THF (5.4 g, 0.075 mol), mp 118—120°C.

Found: Ti, 14.53; Cl, 42.71; C, 28.59; H, 4.61%. Calcd for $TiCl_4C_8H_{16}O_2$: Ti, 14.34; Cl, 42.47; C, 28.78; H, 4.83%. IR (nujol) 990 (ν_{C-O-C}) cm^{-1}.

Yellow powder (2.9 g) of VIII was collected by the reaction of I (2.0 g, 0.010 mol) with THP (2.8 g, 0.030 mol), mp

a) s, singlet; *t*, triplet; m, multiplet. Internal standard TMS in *ca.* 20% CCl_4 solution.

130—132°C.

Found: Ti, 13.42; Cl, 38.99; C, 33.23; H, 5.61%. Calcd for $TiCl_4C_{10}H_{20}O_2$: Ti, 13.23; Cl, 39.18; C, 33.18; H, 5.57%. IR (nujol) 991 (ν_{C-O-C}) cm^{-1}.

Preparation of $TiCl_3(O^nBu)\cdot O(CH_2CH_2)_2O$ (IX). To a solution of II (4.7 g, 0.020 mol) in 30 m*l* of benzene was added dropwise a solution of DO (7.3 g, 0.080 mol) in 10 m*l* of benzene with stirring at 5—10°C. The reaction was slightly exothermic. A white precipitate was obtained after 25 hr of agitation at room temperature. After filtration, the precipitate was washed with benzene and dried in a vacuum at room temperature, mp 159—160°C.

Found: Ti, 15.28; Cl, 33.50; C, 30.33; H, 5.24%. Calcd for $TiCl_3C_8H_{17}O_3$: Ti, 15.18; Cl, 33.71; C, 30.46; H, 5.43%.

Preparation of $TiCl_3(O^nBu)\cdot 2C_4H_8O$ (X) and $TiCl_3(O^nBu)\cdot 2C_5H_{10}O$ (XI). Excess THF (1.9 g, 0.027 mol) in 10 m*l* of benzene was added to II (2.0 g, 0.009 mol) in 30 m*l* of benzene at 15—20°C. The reaction was not exothermic. No solid was obtained after 25 hr of agitation at room temperature. A brown viscous liquid (3.2 g) of X was obtained after the removal of THF and benzene in the mixture in a vacuum at room temperature. The drying in a vacuum was continued 48 hr, at the end of which time the unit was pressurized to one atmosphere with dry nitrogen.

Found: Ti, 12.99; Cl, 28.46; C, 38.77; H, 6.72%, mol wt, 348±20. Calcd for $TiCl_3C_{12}H_{25}O_3$: Ti, 12.89; Cl, 28.62; C, 38.79; H, 6.78%, mol wt, 371.6. IR (liquid film) 1012 (ν_{C-O-C}) cm^{-1}. NMR (Table 1).

Similarly, brown viscous liquid (7.5 g) of XI was obtained by the reaction of II (4.3 g, 0.019 mol) with THP (4.9 g, 0.057 mol) in benzene.

Found: Ti, 11.94; Cl, 26.49; C, 42.05; H, 7.12%, mol wt, 377±21. Calcd for $TiCl_3C_{14}H_{29}O_3$: Ti, 11.99; Cl, 26.61; C, 42.08; H, 7.31%, mol wt, 399.6. IR (liquid film) 1015 (ν_{C-O-C}) cm^{-1}. NMR (Table 1).

Preparation of $TiCl_2(O^nBu)_2\cdot O(CH_2CH_2)_2O$ (XII), $TiCl_2(O^nBu)_2\cdot C_4H_8O$ (XIII) and $TiCl_2(O^nBu)_2\cdot C_5H_{10}O$ (XIV). The procedure was the same as that for preparation of X. A brown jelly adduct (6.6 g) of XII was obtained from III (5 g, 0.019 mol) and DO (6.6 g, 0.075 mol) in benzene.

Found: Ti, 13.34; Cl, 19.94; C, 40.73; H, 7.44%, mol wt, 361±22. Calcd for $TiCl_2C_{12}H_{26}O_4$: Ti, 13.56; Cl, 20.08; C, 40.81; H, 7.42%, mol wt, 353.1. NMR (Table 1).

A brown viscous liquid (2.6 g) of XIII was prepared from III (2.0 g, 0.008 mol) with THF (4.4 g, 0.060 mol) in benzene.

Found: Ti, 14.36; Cl, 21.12; C, 42.66; H, 7.68%, mol wt, 318±25. Calcd for $TiCl_2C_{12}H_{26}O_3$: Ti, 14.21; Cl, 21.03; C, 42.75; H, 7.68%, mol wt, 337.1. IR (liquid film) 1020 (ν_{C-O-C})cm^{-1}. NMR (Table 1).

A brown viscous liquid (2.8 g) of XIV was obtained from III(2.1 g, 0.008 mol) and THP (2.0 g, 0.024 mol) in benzene.

Found: Ti, 13.63; Cl, 20.49; C, 44.19; H, 8.00%, mol wt, 342±30. Calcd for $TiCl_2C_{13}H_{28}O_3$: Ti, 13.46; Cl, 20.19; C, 44.46; H, 8.04%, mol wt, 351.2. IR (liquid film) 1020(ν_{C-O-C}) cm^{-1}. NMR (Table 1).

IV and V did not react with ethers.

Results and Discussion

The reactivity of I—V with acetanilide (Lewis base) and the IR measurement of the adducts of I—IV with the amide showed that the activity of Lewis acid decreased as reported.[11] I>II>III>IV>V. From this fact, it seems probable that no adducts have been isolated from the reaction of ethers with IV and V, which are less active Lewis acids.

The IR spectra of VII, X, and XIII indicated that the ν_{C-O-C} of THF (1068 cm^{-1}) indicate the shift toward the lower wave numbers, 990, 1012, and 1020 cm^{-1} respectively. The negative shifts of the ν_{C-O-C} of THF (1093 cm^{-1}) for VIII, XI, and XIV were observed at 991, 1015, and 1020 cm^{-1} respectively. The shifts indicate the order of the activity of the Lewis acids (I—III). The shifts of the ν_{C-O-C} of DO (1119 cm^{-1}) in IX and XII were not confirmed because of the mixing of their frequencies with that of the alkoxy group ν_{C-O} in alkoxytitanium chlorides, but we found adduct VI at 1044 cm^{-1}.

NMR spectra of adduct XIII indicate that, for ex-

11) N. Yoshino and T. Yoshino, *Kogyo Kagaku Zasshi*, **71**, 1025 (1968).

ample, the chemical shift of the proton H^5 (τ 5.78) should be lower than that of THF (τ 6.37).[12] Similar lower chemical shifts of the adducts of THF and THP were measured. Thus we conclude that the oxygen atom of THF or THP is coordinated to the titanium atom of each of the alkoxytitanium chlorides.

In the case of the adducts of DO, either two oxygen atoms of DO are coordinated to a titanium atom to form a five-membered-ring chelate, or only one oxygen atom of DO coordinated to a titanium atom, and otherwise two oxygen atoms of DO coordinate to two titanium atoms such as  . A comparison of the IR spectrum of DO with that of its adduct VI indicates that the ν_{C-O-C} of the latter is shifted to lower values; this indicates that the oxygen atom of DO is involved in coordination. Observation of the NMR spectra of XII indicates that, the intensity of H^1, $H^{2,3}$, $H^{5,6}$, and H^4 is 2 : 4 : 4 : 3, respectively the results indicate that the two oxygen of DO are on even conditions. Since the molecular weight determination of adduct XII gives a monomeric value, one can believe that two oxygen atoms of DO are coordinated to a titanium atom of III to form a chlate ring.

Sisler[3] and his co-workers have shown the molecular weight of the adduct VIII to be monomeric in benzene.

Molecular weight determination of all the liquid adducts and a jelly adduct indicate them to be monomeric in benzene. X and XI filled the coordination number of titanium 6, but XIII and XIV did not. Thus it seems reasonable to assume that the adducts in non-solution state are dimeric, but monomeric in solution.

The adducts undergo rapid hydrolysis with moisture.

The Reaction of Troponoid with Ylide. III.[1,2] The Reaction of Tropone with Pyridinium Compounds

Yukio SUGIMURA, Nobuo SOMA, and Yukichi KISHIDA

Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received March 13, 1972)

Phenacylpyridinium ylide (**2**) reacted with tropone (**1**) to afford 2-hydroxy-2-phenyl-3-phenacyl-2*H*-cyclohepta[*b*]furan (**3**) which was converted into 2-(1′,2′-dibenzoylethyl)tropone (**4**). The reactions of tropone with several kinds of pyridinium bromides (**7**) yielded 2-substituted tropones in the presence of amine, and 1-azaazulene derivatives (**9, 10, 11**) in a one-step formation in the presence of ammonium acetate.

Many reactions of tropone with nucleophiles have been reported since its unique conjugated cyclic trienone system is thought to exert a contribution of the 6π cation system. We earlier reported[3] on the reaction of troponoids with sulfur ylides. In this paper we describe the reactions of tropone with pyridinium salts and pyridinium ylides under various conditions giving 2-substituted tropones and resulting in some one-step azaazulene formations. The chemistry of pyridinium salts and the corresponding ylides has been extensively studied by Krohnke and his collaborator.[4] For example, pyridinium ylide reacted with conjugated carbonyl compounds giving stable pyridinium ylides by Michael addition. The newly formed ylides were utilized to synthesize some heterocyclic systems. Since tropone generally reacts with a nucleophile at 2-position, we at first presumed that the reaction of tropone with pyridinium ylide would give an ylide having tropone moiety or, in the presence of ammonium ion, 1-azaazulene derivatives.

Results

The Reactions of Tropone with Phenacylpyridinium Ylides. When tropone (**1a**) was treated in benzene with phenacylpyridinium ylide prepared by Krohnke's method, red crystals were obtained. Recrystallization gave a pure substance of cycloheptafuran derivative (**3**), mp 134.5—135.5°C in 58.4% yield. The IR showed absorption maxima at 3450 cm^{-1} (OH stretching) and 1680 cm^{-1} (C=O stretching) and the UV exhibited $\lambda_{max}^{ethanol}$ at 240, 320, 335, and 350 nm. The patterns of the spectra closely resembled those of heptafulvene. The elemental analysis and high resolution mass spectrum agreed with the formula $C_{23}H_{18}O_3$ for **3**. **3** was converted into 2-(1′,2′-dibenzoylethyl)tropone (**4a**) on silica gel column chromatography and into a tropylium salt (**5**), $C_{46}H_{34}O_4Cl_6Pt$, by treatment with platinic chloride. The IR of **4a** showed maxima at 1690, 1635, and 1585 but lacked the OH band at 3450 cm^{-1} originally observed in **3**, while the UV highly resembled that of tropone. The elemental analysis and mass spectra agreed with

3) Y. Sugimura and N. Soma, *Tetrahedron Lett.*, **1970**, 1721.

4) F. Krohnke, *Angew. Chem.*, **65**, 605 (1953). F. Krohnke and W. Zecher, *Angew. Chem. Int. Ed. Engl.*,, **1**, 626 (1962). F. Krohnke, *ibid.* **2**, 225 (1963), *ibid.* **2**, 380 (1963).

the formula for **4a** (equal to **3**). Analogously, *p*-bromophenacylpyridinium ylide reacted with tropone or 2-phenyltropone (**1b**) giving compounds of mp 195—197°C; $C_{23}H_{16}O_3Br_2$ (**4b**) in 44.5% and mp 191—193°C; $C_{29}H_{20}O_3Br_2$ (**4c**) in 54.5%, respectively. The molecular formulas were obtained by elemental analyses and mass spectra. The NMR (δ ppm, in $CDCl_3$) of **4b** exhibited ABX pattern at 3.20, 3.89, and 5.83 ($J_{AB}=18$, $J_{AX}=4$, and $J_{BX}=10$ Hz), and 6.8—7.4 (5H, protons of tropone ring), 7.5—8.0 (8H, phenyl protons). The spectroscopic data of **4c** were analogous to those of **4b**, except for the presence of one more phenyl group in the tropone system. **4c** was chosen as a representative for further hydrolysis to determine the structure; refluxing in an aqueous sodium hydroxide-methanol solution gave an oily compound (**6**), $C_{22}H_{17}O_2Br$ and *p*-bromobenzoic acid. The UV absorption maxima of **6** at 230, 255, and 330 nm in ethanol strongly suggested the presence of phenyltropone moiety in **6**. Its IR absorption maxima at 1690 (benzoyl C=O) and 1585 cm^{-1} (tropone C=O) and the NMR [in CCl_4: 2.8—3.5 (4H, A_2B_2; $-CH_2-CH_2-$), 6.8—7.0 (2H), and 7.2—7.4 (7H) ascribed to the phenyltroponyl protons, 7.48 (2H) and 7.77 (2H), ascribed to the benzoyl phenyl protons] suggested that **6** should have the structure of 2-(2′-*p*-bromobenzoylethyl)-7-phenyltropone. Mechanistic consideration together with all the evidence enabled us to assign the structure of 2-(1′,2′-di-*p*-bromobenzoylethyl)-7-phenyltropone for **4c**. Thus the structures of **4a** and **4b** were assigned to be 2-(1′,2′-dibenzoylethyl)tropone and 2-(1′,2′-di-*p*-bromobenzoylethyl)tropone, respectively. The assignments led to determination of the structures of **3** and **5** to be 2-hydroxy-2-phenyl-3-phenacyl-2*H*-cyclohepta[*b*]furan and 2-phenyl-3-phenacylcyclohepta[*b*]furanium hexachloroplatinate.[5] Analogously, tropone reacted with *p*-bromophenacylpyridinium bromide in the presence of K_2CO_3 in DMSO to give **4b** in 30% yield.

The Reactions of Pyridinium Salts with Tropone in the Presence of Amines. Application of the forementioned reactions was limited, since phenacylpyridinium ylides are so stable as to be isolated among pyridinium ylides. The use of pyridinium salts in the presence of amine was then attempted in order to extend the applicability of the reactions.

Tropone was added to a suspension of phenacylpyridinium bromide in tetrahydrofuran (THF) containing triethylamine. The reaction product obtained as a partially crystallized syrup was chromatographed to give 2-phenacyltropone (**8a**) in 61% yield. Identification was carried out by mixed melting point and spectroscopy with an authentic sample. Analogous treatments of tropone with *p*-bromophenacylpyridinium bromide (**7b**), ethoxycarbonylmethylpyridinium bromide (**7c**) and acetonylpyridinium

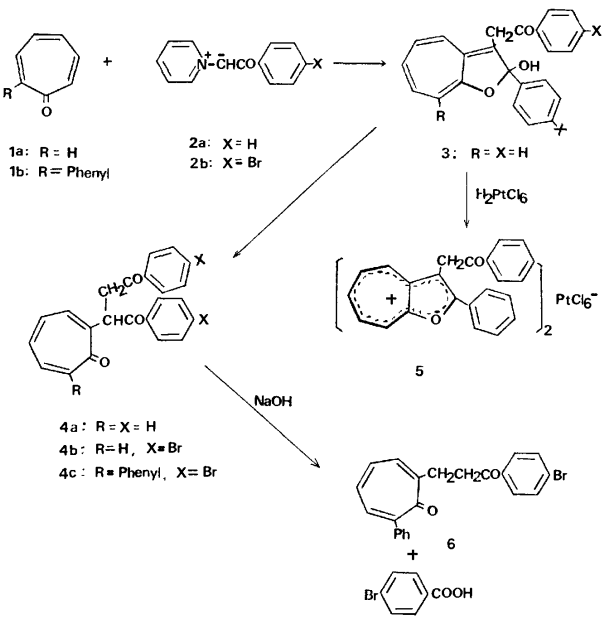

Chart 1.

bromide (**7d**) in the presence of triethylamine gave the corresponding 2-substituted tropones (**8b**, **8c**, and **8d**). Tropone did not react with *o*-cyanobenzylpyridinium bromide (**7e**) in THF–triethylamine, but reacted in ethanol–piperidine giving 2-(*o*-cyanobenzyl)tropone (**8e**) in 45.5% yield. The structure of **8e** was determined by physicochemical data (see Experimental). It is noteworthy that the reaction of tropone with *p*-bromophenacylpyridinium bromide (**7b**) gave only **8b** and not **4b** even when pyridinium bromide and amine were present in excess.

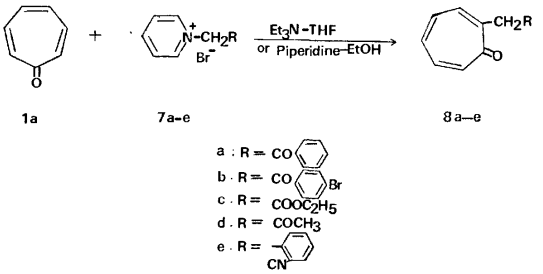

Chart 2.

Synthesis of 1-Azaazulenes. From the fact that the pyridinium ylides attack 2-position of tropone giving 2-substituted tropone, 1-azaazulene derivatives would be formed in the presence of ammonium ion. In fact 2-phenacyltropone (**8a**) was converted into 2-phenyl-1-azaazulene (**9a**) by treatment with ammonium acetate in acetic acid. **9a** was directly obtained by refluxing a mixture of tropone, phenacylpyridinium bromide (**7a**) and ammonium acetate in acetic acid. The principle of the procedure was exactly the same as in the pyridine synthesis by Krohnke.[6] Purple crystals of **9a** were obtained in 21% yield, mp 157—159°C. The structural confirmation was made by physicochemical data, especially the characteristic

5) 2-Phenylcycolhepta[*b*]furanium fluorosulfonate was isolated and the structure was determined (unpublished work). The UV absorption closely resembles that of **5** (see Experimental) and NMR suggests the hybridization of the charge in 10π system. UV: $\lambda_{max}^{ethanol}$ 255, 300, 425 nm. NMR (in DMSO): 7.94 (2H, A_2B_2), 8.25 (2H, A_2B_2), 8.33 (1H, s), 8.8—9.2 (3H. m), 9.3—9.5 (2H, m).

6) W. Zecher and F. Krohnke, *Chem. Ber.*, **94**, 690 (1961).

UV: $\lambda_{max}^{ethanol}$ 237.5 (log ε=4.20), 287.5 (4.58), 312 (4.45), 357 (4.08), and 373 (4.03) nm (the other data are given in Experimental). Analogously, tropone reacted with acetonylpyridinium bromide (**7d**) giving a blue oil of 2-methyl-1-azaazulene (**9b**), which was converted into its picrate, mp 196—198°C. A similar treatment of tropone with cyanomethylpyridinium chloride (**7f**) gave 2-imino-1,2-dihydrocyclohepta-[*b*]pyrrole (**10**), mp 177°C, in 14% yield. Identification of the structure was made by comparison of the spectroscopic data with those of an authentic sample.[7] Tropone also reacted with 2-oxo-3,4-benzocyclohexylpyridinium bromide (**7g**) in the presence of triethylenediamine (DABCO) and ammonium acetate in ethanol to give 12-aza-5,6-dihydronaphth[2,1-*a*]-azulene (**11**) as purple oil. This was dehydrogenated to 12-azanaphth[2,1-*a*]-azulene (**12**), mp 195—197°C, by refluxing with DDQ in benzene. The UV and visible light spectra of $\lambda_{max}^{ethanol}$ 337, 374, and 537 nm indicate characteristics of the structure.

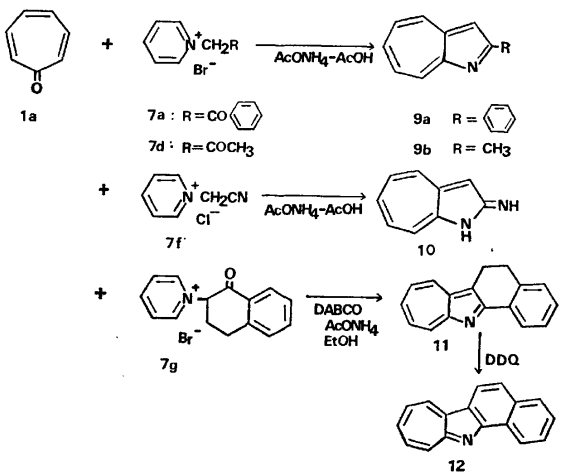

Chart 3.

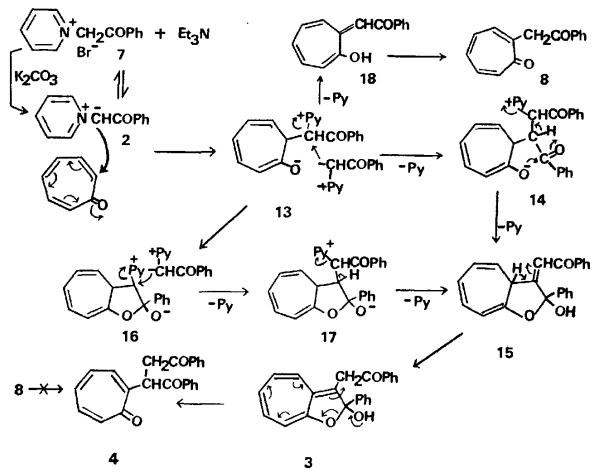
Discussions

Plausible mechanisms for the formation of **3**, **4**, and **8** are shown in Fig. 1. For **3**, two moles of pyridinium ylide participate in the reaction, such a mode of reaction being very rare.[8] Pyridinium betaine (**13**) formed at first is further attacked by the second ylide to give **14** with concomitant liberation of pyridine, subsequent cyclization affording **15**. By an alternative route, betaine **13** would first cyclize to give **16** which is succeedingly attacked by the second ylide to afford **15** *via* **17**. On the other hand, for the formation of **8**, *viz.*, in the reaction of tropone with a phenacylpyridinium bromide in the presence of amine, the ylide is not present in excess so as to be able to attack **13**, since an equilibrium between the ylide (**2**) and its conjugate acid (**7**) should exist under such reaction conditions and the ylide formed is immediately consumed by tropone to give betaine (**13**). Elimination of pyridine from **13** to give heptafulvene (**18**) would be reasonable because of the stability of **18**. Phenacyltropone (**8b**) thus obtained did not give **4b** by the reaction with ylide (**2b**). Thus a proton exchange between **8** and **2** would not be feasible. Recently Sasaki *et al.*[9] reported that the reaction of tropone with ethoxycarbonylaminopyridinium ylide gave 2-ethoxycarbonylaminotropone and they obtained no 1 : 2-adduct such as **4**. It is not certain whether the difference in reaction pattern is derived from the nucleophilicity of ylide or other factors.



Py: Pyridine Ph: Phenyl

Fig. 1.

The reaction mentioned in the second paragraph is valuable for the preparation of 2-substituted tropones which have hitherto been synthesized from oxaazulanone in lower yields.

Experimental

All melting points are uncorrected. The NMR spectra were taken on Varian A-60 (60 MHz) and HA-100 (100 MHz) spectrometers, and indicated in δ ppm using TMS as an internal standard.

2-Hydroxy-2-phenyl-3-phenacyl-2H-cyclohepta[b]*furan* (**3**). Tropone (2.05 g) was added dropwise under cooling with an ice-water bath to a suspension of phenacylpyridinium ylide (**2a**) in dry benzene (80 m*l*), obtained from phenacylpyridinium bromide (7 g) and potassium carbonate (23 g) by the method of Krohnke. The reaction mixture turned red when the orange crystals of ylide were dissolved. The precipitated white crystals were separated and washed with benzene. The filtrate and washing were combined and evaporated to dryness to give reddish yellow crystals. The crystals were washed with a small amount of benzene and recrystallized from benzene-chloroform to give 1.56 g of the compound, mp 134.5—135.5°C, in 58.6% yield. The mother liquor was chromatographed and the starting tropone (1.22 g) was recovered. Found: C, 80.77; H, 5.40%. Calcd for $C_{23}H_{18}O_3$: C, 80.68; H, 5.30%. IR: ν (Nujol) 3450, 1680 cm^{-1}. UV: $\lambda_{max}^{ethanol}$ 240, 320, 335, 350 nm; $\lambda_{max}^{0.1N\,HCl}$ 250 (log ε=4.51), 292 (4.36), 423 (4.27) nm. High

The reaction mixture was stirred for 2 hr at 0—10°C and the precipitated crystals were separated by filtration and washed with benzene. The filtrate and the washing were combined and evaporated to dryness to give colorless crystals. The crystals were recrystallized from benzene to give 1.87 g of the compound (**4b**), mp 195—197°C, in 44.5% yield. Found: C, 54.95; H, 3.30; Br, 31.94%. Calcd for $C_{23}H_{16}O_3Br_2$: C, 55.21; H, 3.22; Br, 31.95%. IR *ν* (Nujol) 1672, 1575 cm^{-1}. UV: $\lambda_{max}^{0.1N\,HCl}$ 258 (log ε=4.58), 314 (3.92) nm. NMR (in $CDCl_3$): 3.20 (1H, d of d, *J*=18 and 4 Hz), 3.89 (1H, d of d, *J*=18 and 10), 5.83 (1H, d of d, *J*=10 and 4), 6.8—7.4 (5H, m), 7.5—8.0 (8H, m, aromatic). Mass spectrum (*m/e*) 498 ($^{79}Br_2$, M^+), 480 ($^{79}Br_2$) 452 ($^{79}Br_2$), 315 (^{79}Br), 298 (^{79}Br), 183 (^{79}Br), 155 (^{79}Br).

*2-(1',2'-Di-*p*-bromobenzoylethyl)-7-phenyltropone (**4c**)* The compound (1.57 g) was obtained from *p*-bromophenacylpyridinium bromide (5 g) and 2-phenyltropone (910 mg) in 54.5% yield by a similar method to that for the preparation of **4b**, mp 191—193°C. Found: C, 60.34; H, 3.68; Br, 27.43%. Calcd for $C_{29}H_{20}O_3Br_2$: C, 60.44; H, 3.50; Br, 27.74%. IR $\nu_{C=O}$ (Nujol) 1685, 1585 cm^{-1}. UV: $\lambda_{max}^{ethanol}$ 259 (log ε=4.65), 312 (3.98) nm. NMR (in $CDCl_3$): 3.28 (1H, d of d, *J*=17.6 and 4 Hz), 3.93 (1H, d of d, *J*=17.6 and 9.4), 5.84 (1H, d of d, *J*=9.4 and 4), 6.75—7.05 (2H, m), 7.3—8.0 (15 H).

*2-(1',2'-Di-*p*-bromobenzoylethyl)tropone (**4b**) from the Pyridinium Salt.* A suspension of *p*-bromophenacylpyridinium bromide (3.5 g) and K_2CO_3 (0.7 g) in DMSO (30 m*l*) was stirred for 50 min at room temperature and then cooled to 0°C. Tropone (530 mg) was added to the suspension and the reaction mixture was stirred for two hours at 0°C. The reaction mixture was then poured onto ice-water and extracted with chloroform. The extract was washed with water, dried over magnesium sulfate and condensed to give oily residue (1.68 g) which partially crystallized. The crystals were collected by filtration and washed with benzene to give 120 mg of **4b**. The filtrate and washing were combined and subjected to silica gel column chromatography. The benzene-chloroform (1 : 1) eluate gave 190 mg of **4b**. Yield 30%.

*2-(2'-*p*-Bromobenzoylethyl)-7-phenyltropone (**6**).* **4c** (1 g) was added to a solution of sodium hydroxide (524 mg) in 50% aqueous methanol (50 m*l*) and the reaction mixture was refluxed for five hours. After removal of the solvents, the residual oil was extracted with chloroform. The extract was washed with water, dried over magnesium sulfate and condensed to give a partially crystallized syrup. The crystals were collected by filtration to recover the starting **4c** (350 mg). The filtrate was purified by silica gel column chromatography to afford 170 mg of compound (**6**) as syrup. Found: C, 66.70; H, 4.59; Br, 20.04%. Calcd for $C_{22}H_{17}O_2Br$: C, 67.17; H, 4.36; Br, 20.32%. IR $\nu_{C=O}$ (liquid) 1685, 1585 cm^{-1}. UV: $\lambda_{max}^{ethanol}$ 230, 255, 330 nm. NMR (in $CDCl_3$): 2.9—3.4 (4H, A_2B_2 pattern), 6.8—7.0 (2H, m), 7.2—7.4 (7H), 7.48 and 7.77 (each 2H, A_2B_2).

*2-Phenacyltropone (**8a**).* Triethylamine (1 m*l*) was added to a suspension of phenacylpyridinium bromide (**7a**, 2.78 g) in tetrahydrofuran (14 m*l*) and the reaction mixture was stirred for fifteen minutes at room temperature. To this was added a tetrahydrofuran solution of tropone (1.06 g/10 m*l*) and the whole mixture was stirred overnight at room temperature. The precipitated crystals were separated by filtration and the filtrate was condensed to give a syrup, which was purified by silica gel dry column chromatography to afford 2-phenacyltropone (**8a**, 1.43 g) in 61% yield. **8a**, mp 113—113.5°C, was identified with an authentic sample by spectrometry.

2-p-*Bromophenacyltropone (**8b**).* The compound (**8b**, 1.21 g) was obtained from *p*-bromophenacylpyridinium bromide (1.8 g), triethylamine (0.6 m*l*), and tropone (0.5 g) in 80% yield by a similar method to that for the preparation of **8a**, mp 102—104°C. Found: C, 59.45; H, 3.78; Br, 26.16%. Calcd for $C_{15}H_{11}O_2Br$: C, 59.40; H, 3.66; Br, 26.35%. IR: $\nu_{C=O}$ (nujol) 1685, 1585 cm^{-1}. NMR (in $CDCl_3$): 4.23 (2H, s), 6.9—7.3 (4H, m), 7.3—7.55 (1H, m), 7.67 (2H, A_2B_2), 8.00 (2H, A_2B_2).

*2-Ethoxycarbonylmethyltropone (**8c**).* The compound (**8c**, 0.95 g) was obtained from ethoxycarbonylmethylpyridinium bromide (**7c**, 2.46 g), triethylamine (1 m*l*), and tropone (1.0 g) in 63% yield (considering the recovery of the starting tropone, 0.42 g) by a similar method to that for the preparation of **8a**, mp 66°C (recrystallized from isopropyl ether). Found: C, 66.42; H, 6.93%. Calcd for $C_{11}H_{12}O_3$: C, 66.65; H, 6.71%. IR$\nu_{C=O}$ (Nujol) 1740, 1585 cm^{-1}. NMR (in $CDCl_3$): 1.27 (3H, t, *J*=7 Hz), 3.62 (2H, s) 4.20 (2H, q, *J*=7), 6.85—7.50 (5H, m).

*2-Acetonyltropone (**8d**).* The compound (**8d**, 1.47 g) was obtained from acetonylpyridinium bromide (**7d**, 2.16 g), triethylamine (1 m*l*), and tropone (1.06 g) in 95% yield by a similar method to that for the preparation of **8a**. **8d** was a yellow oil whose purity was checked by vpc. (PEG 10% column). Found: C, 71.54; H, 6.83%. Calcd for $C_9H_{10}O_2$: C, 71.98; H, 6.71%. IR: $\nu_{C=O}$ (liquid) 1715, 1585 cm^{-1}. NMR (in $CDCl_3$): 2.30 (3H, s), 3.68 (2H, s), 6.85—7.40 (5H, m).

2-o-*Cyanobenzyltropone (**8e**).* Piperidine (1 m*l*) was added to a solution of *o*-cyanotolylpyridinium bromide (**7e**, 2.77 g) in ethanol (10 m*l*) and the reaction mixture was stirred for ten minutes. Tropone (1.06 g) was then added. After being left to stand overnight at room temperature, the reaction mixture was poured onto ice-water and extracted with chloroform. The extract was washed with water, dried over magnesium sulfate, and condensed to give a syrup. The residual syrup was purified by silica gel dry column chromatography to afford 503 mg of the compound **8e** as colorless crystals which were recrystallized from chloroform-isopropyl ether, mp 110—112°C. Found: C, 81.40; H, 5.13; N, 6.18%. Calcd for $C_{15}H_{11}ON$: C, 81.43; H, 5.01; N, 6.33%. IR $\nu_{C=O}$ (Nujol) 1575, $\nu_{C\equiv N}$ 2220 cm^{-1}. NMR (in $CDCl_3$) 4.22 (2H, s), 6.9—7.8 (11H, m).

*2-Phenyl-1-azaazulene (**9a**).* Tropone (2.12 g) was added at room temperature to a solution of phenacylpyridinium bromide (**7a**, 5.6 g) and ammonium acetate (8 g) in acetic acid (40 m*l*) and the reaction mixture was stirred

and heated to refluxing. The reaction mixture turned dark red at about 80°C and black at refluxing temperature. After refluxing for two hours, the solvent was evaporated and the residual syrup was poured onto ice-water and allowed to stand overnight at room temperature. The precipitates were filtered off with the aid of celite and washed with chloroform. The filtrate and washing were combined and extracted with chloroform. The chloroform extract was washed with water, dried over magnesium sulfate and condensed to give reddish purple crystals of the compound (**9a**, 850 mg) in 21% yield, mp 157—159°C (recrystallized from benzene-cyclohexane). Found: C, 87.71; H, 5.61; N, 6.78%. Calcd for $C_{15}H_{11}N$: C, 87.77; H, 5.40; N, 6.82%. UV: $\lambda_{max}^{ethanol}$ 237.5 (log ε=4.20), 287.5 (4.58), 312 (4.45), 357 (4.08), 373 (4.03) nm. NMR (in $CDCl_3$): 7.3—7.9 (7H, m), 8.3—8.9 (4H, m). Mass spectrum (*m/e*): 205 (M^+), 190, 178, 176, 151, 127, 102.

*2-Methyl-1-azaazulene (**9b**).* Tropone (3.18 g) was added at room temperature to a solution of acetonylpyridinium bromide (**7b**, 6.48 g) and ammonium acetate (12 g) acetic acid (60 m*l*). The reaction mixture was stirred and heated to refluxing. The mixture then turned dark brown. After refluxing for one hour, the solvent was evaporated and the residual syrup was poured onto ice-water. The precipitate was filtered off with the aid of celite and washed with chloroform. The combined filtrate and washing were neutralized with 10% aqueous sodium hydroxide solution and extracted with chloroform. The extract was washed with water, dried over magnesium sulfate and condensed to give a dark green syrup which was subjected to alumina column chromatography. From the benzene eluate 970 mg of the compound (**9b**) was obtained as a blue syrup (23%). **9b** was converted into its picrate of green crystal, mp 196—198°C, by treatment with an ethanol solution of picric acid. Picrate of **9b**: Found: C, 51.54; H, 3.75; N, 14.61%. Calcd for $C_{16}H_{12}N_4O_7$: C, 51.62; H, 3.25; N, 15.05%.

2-Imino-1,2-dihydrocyclohepta[b]*pyrrole (**10**).* Tropone (2.12 g) was added at room temperature to a solution of cyanomethylpyridinium chloride (**7g**, 3.09 g) and ammonium acetate (8 g) in acetic acid (30 m*l*) and the reaction mixture was stirred and refluxed for seven hours. After evaporation of the solvent, the residue was poured onto ice-water and allowed to stand overnight at room temperature. The precipitates were filtered off with the aid of celite, and washed with water. The combined filtrate and washing were washed with chloroform, neutralized with 10%-aqueous sodium hydroxide solution and extracted with chloroform. The chloroform extract was washed with water, dried over magnesium sulfate and condensed to give the compound as brown crystals, mp 175—177°C (recrystallized from benzene), 0.4 g (yield 14%). Found: C, 74.80; H, 5.63; N, 19.36%. Calcd for $C_9H_8N_2$: C, 74.97; H, 5.59; N, 19.43%.

12-Aza-5,6-dihydronaphth[*2,1*-a]*azulene (**11**).* 2-Oxo-3,4-benzocyclohexylpyridinium bromide (3.04 g) was added to a solution of triethylenediamine (1.12 g) and ammonium acetate (1 g) in ethanol (20 m*l*) and the reaction mixture was stirred at 50°C for ten minutes. Tropone (1.06 g) was added and the whole mixture was refluxed for five hours. The precipitated crystals were then filtered off and the filtrate was condensed to give a partially crystallized syrup. The crystals were filtered off and washed with benzene. The combined filtrate and washing were subjected to silica gel dry column chromatography. After development with benzene-ethyl acetate (4 : 1), each fraction of R_f 0.2 and 0.1 was collected and extracted with chloroform. The starting tropone (0.7 g) was recovered from the former the compound **11** (170 mg) as a purple syrup from the latter. Mass spectrum (*m/e*): 231 (M^+, base peak), 230, 202, 121, 93. UV: $\lambda_{max}^{ethanol}$ 244, 292, 324, 502 nm. NMR (in $CDCl_3$): 3.13 (4H, s), 6.7—7.3 (6H, m), 8.1—9.0 (3H, m).

12-Azanaphth[*2,1*-a]*azulene (**12**).* A solution of **11** (140 mg) and DDQ (300 mg) in benzene (20 m*l*) was refluxed for two hours. The reaction mixture was then poured onto 10%-aqueous sodium hydroxide solution and extracted with chloroform. The chloroform extract was washed with water, dried over magnesium sulfate and condensed to give violet crystals of the compound (**12**) which were recrystallized from benzene-*n*-hexane, mp 195—197°C, 60 mg. Found: C, 89.13; H, 4.76; N, 6.02%. Calcd for $C_{17}H_{11}N$: C, 89.05; H, 4.84; N, 6.11%. Mass spectrum (*m/e*): 229 (M^+, base peak), 205, 203, 202, 200, 178, 177, 176, 175, 174. UV: $\lambda_{max}^{ethanol}$ 337, 374, 537 nm. NMR (in $CDCl_3$) 7.6—8.3 (8H, m), 8.7—9.2 (3H, m).

We are grateful to Professor T. Nozoe for his helpful discussion.

The Kinetic Study on the Reaction of Oxaziridine with Tri-*n*-Butylphosphine

Seizo TAMAGAKI, Keishi SAKAKI, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshiku, Osaka

(Received March 24, 1972)

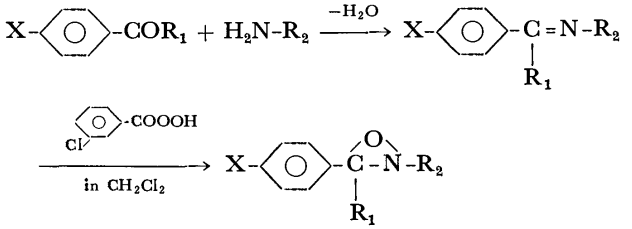
The mechanism of deoxygenation reaction of oxaziridine with trivalent phosphine was kinetically examined by changing substituents, solvents, and temperatures. The reaction proceeds through an attack of phosphine on oxgen in a concerted manner rather than on nitrogen or carbon, eventually producing the corresponding imine and phosphine oxide. The mechanism of the title reaction was compared with those of similar deoxygenations of epoxide and thioepoxide.

Oxaziridines are three-membered ring compounds bearing an active oxygen like organic peroxides and can be assayed iodometrically with potassium iodide in acetic acid. Generally, oxaziridine ring is cleavaged slowly by treatment with strong acids, but fairly stable to weakly basic reagents. The stability of the heterocycle varies sharply with the nature and number of substituents.[1] However, the reactions of oxaziridines with various nucleophiles have not been extensively explored.[2]

The present paper describes a detailed kinetic study on the reaction of oxaziridine with tervalent phosphorous compound in order to clarify the mechanism of the reaction in comparison with those of the epoxides and thioepoxides.[3]

Experimental

Materials. *Oxaziridines*: Oxaziridines were prepared by per-acid oxidation of Shiff's bases according to the method described previously.[4] The physical properties of Schiff's bases and oxaziridines are listed in Table 1 together with the NMR spectral data in Table 2.



Tri-n-butylphosphine: Commercial phosphine was purified by repeated distillation, bp 128—130°/27 mmHg (lit, 149.5°/50 mmHg).

Solvent: Commercial acetonitrile and special analytical grade *n*-hexane were dried over phosphorous pentoxide and distilled just before use.

Product Analysis. The reaction of 2-alkyl-3-aryloxaziridines with triphenylphosphine or tri-*n*-butylphosphine at room temperature quantitatively afforded the corresponding imines and the phosphine oxides. The product analysis was readily performed by measuring the NMR signals of the methyne protons of both oxaziridines and imines.

Kinetics. A typical procedure is as follows: 2-*t*-butyl-3-(*p*-chlorophenyl)oxaziridine (74.03 mg, 3.5×10^{-4} mol) was dissolved in 50 m*l* acetonitrile. Tri-*n*-butylphosphine (141.4 mg, 7×10^{-4} mol) was also dissolved in 50 m*l* of the same solvent. Five m*l* of each solution was mixed in a reaction vessel which was kept at 50.0°C in a thermostat. Accordingly, the concentrations of the oxaziridine and the phosphine at the initial reaction stage were 3.5×10^{-3} mol/*l* and 7×10^{-3} mol/*l*, respectively. Every ten minute an aliquot (1 m*l*) was withdrawn and poured into 50 m*l* of acetonitrile in order to stop the reaction. The rate was followed by measuring the concentration of the imine produced by means of UV spectrometer. The second-order rate constants were calculated by the integral form (2) of the differential equation (1), where a and b signify the initial concentrations of the oxaziridine and the phosphine, respectively,

$$dx/dt = k_2(a-x)(b-x) \quad (1)$$

$$1/(b-a)\ln(b-x)a/(a-x)b = k_2t \quad (2)$$

while, x is the amount of the imine formed at the given time (t) from the start and k_2 is the second-order rate constant. A typical run is shown in Fig. 2.

Results and Discussion

The second-order rate constants obtained in the deoxygenation reaction of a few substituted oxaziridines with tri-*n*-butylphosphine are given in Table 3 and the activation parameters are represented in Table 4.

A straight Hammett line was obtained by plotting log k values against sigma values as shown in Fig. 3 and a rho values of +1.12 in acetonitrile and +1.06 in *n*-hexane were obtained. Accordingly, the reactivity increases with an electron-withdrawing *para*-substituent in phenyl ring. This observation, together with the lack of reactivity of the poorly nucleophilic tri-

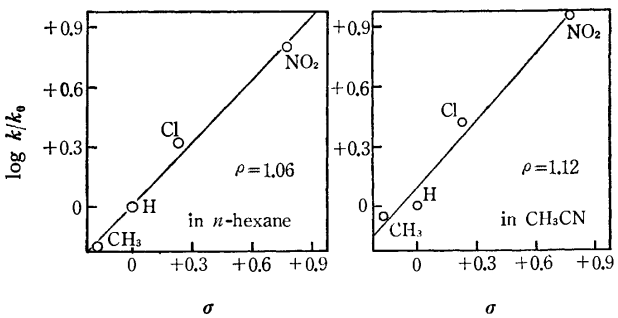

Fig. 3. Correlation of second-order rate constants with Hammett sigma values.

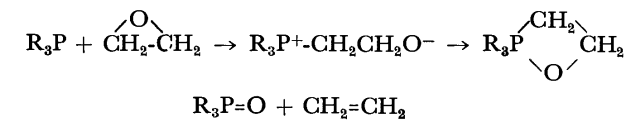
phenylphosphite in the deoxygenation, suggests that the reaction involves the nucleophilic attack of the trivalent phosphine on the oxaziridine ring.

In general, from these data we may conclude that the rate of reaction is not much affected by the change in the dielectric constants of the reaction media. Even in ethanol which is known to act as protonating solvent, the rate increase was only less than two fold as compared with that in acetonitrile, although the values of k_2 are not very accurate due to the decomposition of phosphine itself in ethanol.

In the reaction of the oxaziridine with a trivalent phosphorous compound which is usually a softer nucleophile and a good deoxygenating or desulfurizing reagent, the deoxygenation reaction takes place instantaneously even at room temperature in benzene, *n*-hexane, and actonitrile.

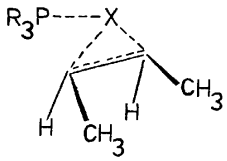
It has been well known that epoxides were also readily deoxygenated by trivalent phosphines to afford the corresponding phosphine oxides and olefins.[5] The mechanism of this reaction has been investigated extensively and is known to involve the nucleophilic attack of the phosphine on the carbon of the epoxide to form the betaine as an intermediate, as shown below.



$$R_3P=O + CH_2=CH_2$$

However, this mechanism can explain only one side of the reaction. Other stereochemical studies indicate that the reaction is better explained by the scheme involving the direct attack of the phosphine on the oxygen atom of the epoxide.[5]

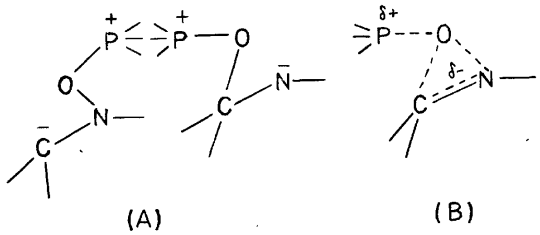
As for analogous reaction of episulfide, Neureiter *et al.*[6a] and Denney[6b] have concluded that both the direct attack of the phosphine on the sulfur atom and the subsequent desulfurization are completely stereospecific.[6]



X = O or S

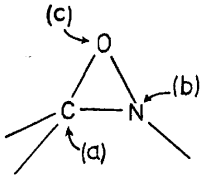
The results in Table 3 indicate that in the deoxygenation reaction of oxaziridines the effect of the change of the solvent from nonpolar to polar solvent on rate of the reaction is found insignificant like in the desulfurization reaction of the thioepoxide.[6] This fact is in a marked contrast to the results by Bartlett in the desulfurization reaction of elemental sulfur with trialkyl phosphine in which the increase in polarity of solvent resulted in a sharp increase in reaction rate by over several hundred fold.[7]

Therefore, based on these observations and considerations we may conclude that the structure of the transition state for the deoxygenation is assumed not to be like (A) which has a large charge separation, but like that (B) which is essentially non-polar. This is essentially a concerted process and dose not require any appreciable charge separation in the transition state.



(A) (B)

However, it should be open to question whether the phosphine exclusively attacks the oxygen atom rather than the carbon or nitrogen atom, because there are three possible attacking sites by a nucleophile in the oxaziridine ring at the initial step of the reaction, *i.e.*, either carbon (a) or nitrogen (b) or oxygen atom (c).



The following observation may be taken as evidence to confirm the attacking on oxygen. Substitution of *t*-butyl group on the nitrogen atom by the less sterically hindered *n*-propyl group results in the rate-increase of only 1.5. In a normal nucleophilic substitution reaction the difference in steric effects by changing the group from *n*-propyl to *tert*-butyl may be estimated as at least over ten.[8] Thus the attacking site can not be the nitrogen atom.

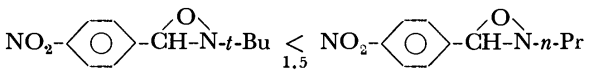
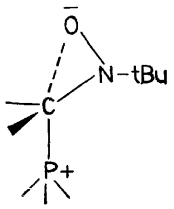
8) M. S. Newman, "Steric Effects in Organic Chemistry" John Wiley & Sons (1955), p. 205.



As for another alternative possibility involving the nucleophilic attack of the phosphine on the carbon atom, Pearson reported that in methanol various nucleophiles reacted with methyl iodide in the following decreasing rate-order:

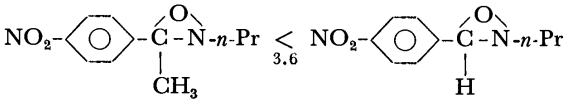
$$PhS^- > (n\text{-}Bu)_3P > Ph_3P > CN^- > P(OCH_3)_3$$
$$(17) \quad (1) \quad (2\times10^{-2}) \quad (1\times10^{-2}) \quad (3\times10^{-4})$$

where the numbers denote the relative rates.[9] Accordingly, if the initial nucleophilic attack would take place at the carbon atom, the reactivities of the nucleophiles in this reaction would fall in the same order as that found with methyl iodide. Contrary to the expectation, in the reaction of oxaziridine, PhS^-, I^-, and CN^- did not react at all even in dimethylformamide in which nucleophiles are known to be markedly activated. Meanwhile, triphenyl- and tri-*n*-butylphosphines can readily reduce the oxaziridine ring to the imine in a good yield. This cannot be account for by assuming the attack of the phosphine on the carbon atom. Moreover, the possibility of the carbon attack could not be compatible with the very small solvent dependency on the rate, because the carbon attack by phosphine must require a charge-separated structure for the transition state (C) due to C–O bond fission as shown below:



(C)

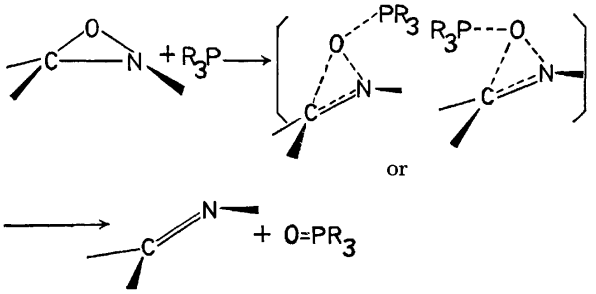
As Table 3 indicates, further striking negative evidences against nucleophilic carbon attack may be the very small influence on the rate produced by the replacement of methyne hydrogen attacked to the carbon by methyl group (D).



(D)

In usual S_N2 reaction retardation in rate caused by the change of steric crowdness from hydrogen to methyl groups has been reported to be larger than 10^2.[8] The lack of difference is markedly contrast to what one normally expects when hydrogen is replaced by methyl group in the S_N2 reaction on the carbon atom.

Such a small decrease in rate may better be explained in terms of the electron-donating nature of methyl group rather than the steric origin, since Fig. 3 indicates that the electron-donating substituents in the three-membered ring decrease the rate quite significantly. Consequently in view of these considerations, the posibility of either carbon or nitrogen attack by the trivalent phosphine seems unlikely. The remaining posibility, which is in harmony with the experimental results, is the rate-determining nucleophilic attack of the phosphine on the oxygen atom of the oxaziridine. Thus, we may conclude that deoxygenation reaction proceeds through nonpolar transition state, with subsequent synchronous deoxygenation.



The large negative entropies of the reaction in both *n*-hexane and acetonitrile can be also rationalized in terms of such a rigid and highly oriented transition state. The priority for attack on oxygen would be attributed to the large driving force of forming a strong P=O and a C=N double bond.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. IX. Syntheses and Elctronic Spectra of α,ω-Di-1-anthrylpolyenes*

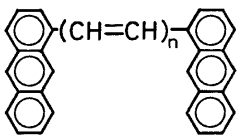
Yasuhira TAKEUCHI, Shuzo AKIYAMA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University Toyonaka, Osaka 560

(Received May 12, 1972)

Syntheses of α,ω-di-1-anthrylpolyenes have been carried out by the Wittig reaction for information on the role of aromatic terminal groups on the electronic spectral regularity of α,ω-diarylpolyenes. The reaction of phosphoranes derived from 1-anthrylmethyl-, 3-(1-anthryl)propenyl-, and 5-(1-anthryl)-pentadienyltriphenylphosphonium bromides with 1-formylanthracene, 3-(1-anthyrl)propenal, 5-(1-anthryl)pentadienal, and muconic aldehyde afforded a series of di-1-anthrylpolyenes (I_{1-6}) by a proper combination of the phosphorane and the aldehyde moiety. Owing to the broading of absorption bands in the long wavelength region, no discussion could be made on the electronic spectral regularity.

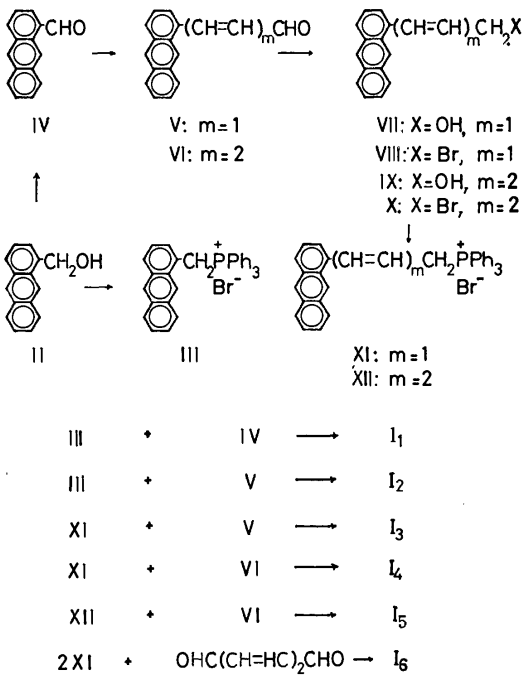
It has been generally accepted that the square of wavelength of the longest wavelength absorption maxima (λ^2_{max}) of a series of all-*trans* linear polyenes varies linearly with the number of double bond (n) [$\lambda^2_{max} \propto n$].[1] However, the linear relationship between the longest wavelength absorption maxima (λ_{max}) and the xth power of the number of acetylenic bond (n) [$\lambda_{max} \propto n^x$, $1 \leqq x \leqq 2$] observed in various kinds of diarylpoly-ynes[2-13] clearly indicates the marked influence of terminal groups on the electronic excitation of polyacetylene chromophore. This suggests that the aromatic terminal groups in α,ω-diarylpolyenes also exert a similar effect on the spectral regularity of linear polyenes. In order to clarify the effect, we have carried out the synthesis of α,ω-di-1-anthrylpolyenes (I_n) first, because anthryl groups have



I_n

been found to exert the most prominent effect in polyyne series.[2,4]

Syntheses. The reaction sequence of the syntheses of α,ω-di-1-anthrylpolyenes (I_n) is outlined in the Scheme. The starting material of syntheses of I_n is 1-hydroxymethylanthracene (II).[14] 1-Anthrylmethyltriphenylphosphonium bromide (III) was prepared



Scheme. Syntheses of Di(1-anthryl)polyenes (I_n)

from II *via* 1-bromomethylanthracene.[8] 1-Formylanthracene (IV) which was obtained from II was converted into 3-(1-anthryl)-2-propen-1-al (V) according to a modified J. F. Arens and van Dorp method.[15] 5-(1-Anthryl)-2,4-pentadien-1-al (VI) was synthesized from IV by the reaction of Grignard derivative of methoxybutenyne.[16] Reduction of V and VI with sodium borohydride afforded allyl alcohol derivatives, VII and IX, respectively. The bromides (VIII and X) obtained from VII and IX were treated with triphenylphosphine to give phosphonium bromides (IX and XII). The reaction of aldehyde (IV, V, or VI) with phosphorane derived from phosphonium bromide (III, XI, or XII) according to the combination shown in the Scheme afforded α,ω-di-1-anthrylpolyenes

(I_{1-5}). 1,12-Di-1-anthryldodecahexene (I_6) was obtained by the reaction of XI with muconic aldehyde.[17] The Wittig reaction was performed under shielding from light in anhydrous benzene or xylene. An ethereal solution of phenyllithium was used as a base for the conversion of phosphonium bromides to phosphoranes. The reaction product was extracted with hot benzene or toluene and percolated through a column of alumina. The first crop of crystals obtained from the concentrated filtrate was recrystallized from benzene or toluene. The pure specimen of I_n thus prepared was subjected to measurement of the electronic spectrum. 1,4-Di-1-anthryl-1,3-butadiene (I_2) was also prepared from di-1-anthryldiacetylene[18] by reduction with sodium in liquid ammonia and proved to be identical with I_2 obtained by the Wittig reaction.

The color of the crystals, melting points, and wave numbers of IR absorption due to CH out-of-plane deformation (δ) of *trans*-double bonds of I_n are summarized in Table 1. The polyenes (I_n) were found to be stable and exhibited definite melting points in contrast to the fact that almost all diarylpoly-ynes showed decomposition points. Regular increase in melting point with the increase in the number of ethylenic bonds reported in α,ω-diphenylpolyenes[19] could not be observed in I_n. The solubility of I_n in organic solvents decreases markedly with the increase of n. Shift of δ due to C–H out-of-plane deformation of the *trans*-double bond to a higher wave number and an increase in the absorption intensity with the increase of n were observed (Table 1).

Electronic Spectra. Absorption curves and numerical data of the electronic spectra of I_n are shown in Fig. 1 and Table 2. The intense and broad bands in the long wavelength region which presumably arise from an interaction of L_a band of anthracene nucleus with the polyene chromophore shift to a longer wavelength with the increase in the length of polyene chain. On the other hand, the length of polyene chain exerts no effect on the location of short wavelength bands. The bands with moderate intensity at medium wavelength region shift to longer wavelength with an increase in n. Owing to disappearance of the vibrational fine structure, exact estimation of wavelength of the maxima of long wavelength bands was difficult. However, the plots of the square of approximate wavelength of long wavelength absorption maxima (λ^2) against the number of double bonds (n) gave no straight line (Fig. 2). The fact that the widely accepted linear relationship ($\lambda^2 \propto n$) does not hold for di-1-anthrylpolyenes (I_n) indicates an appreciable effect of terminal groups on polyene chromophore. Disappearance of

Table 1. Physical properties of α,ω-di(1-anthryl)polyenes (I_n)

the vibrational fine structure is attributed to a steric interference between hydrogen atoms at ethylenic linkage and those at *peri*- and *o*-positions of anthracene nuclei.

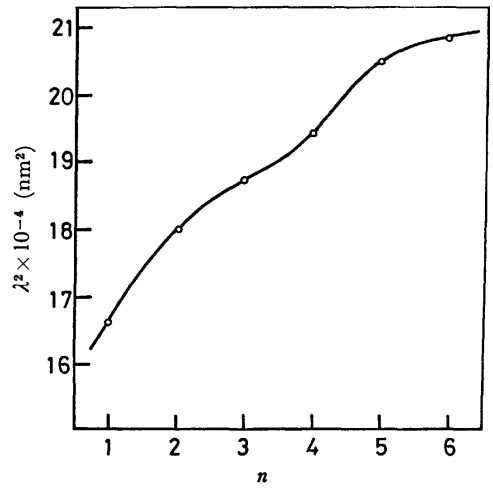

Fig. 2. Plot of λ^2_{max} against n for I_n

Experimental

All the melting points are uncorrected. The electronic spectra were obtained on a Hitachi EPS-3T spectrophotometer at room temperature using a well-matched pair of 1-cm cells, unless otherwise stated. The IR spectra were determined with a Hitachi EPI-2 infrared spectrophotometer by KBr-disk method.

3-(1-Anthryl)-2-propen-1-al (V). To a solution of lithium salt of ethoxyacetylene (prepared from 2-chlorovinyl ethyl ether (35.3 g, 0.33 mol) and lithium amide (lithium, 4.55 g, 0.66 g-atom)) in liquid ammonia (500 m*l*) was added a solution of 1-formylanthracene (IV, 13.6 g, 0.066 mol) in tetrahydrofuran (120 m*l*) over a period of 15 min. After the mixture had been stirred for 12 hr at the boiling point of liquid ammonia, a saturated solution of ammonium chloride (50 g) was added and the ammonia was allowed to evaporate. The organic layer was separated and combined with the benzene extract of aqueous layer. After washing and drying, the solvent was removed under reduced pressure. A benzene solution of the residue was passed through a thin layer of alumina. Dark red liquid (IR: 2260 (C≡CH), 3400 cm^{-1} (OH)) obtained by concentration of the filtrate *in vacuo* was dissolved in ether (110 m*l*). The ethereal solution was added under stirring to a suspension of lithium aluminum hydride (5.7 g, 0.15 mol) in ether (200 m*l*). After 4 hr, ethyl acetate (20 m*l*) and then 4 N sulfuric acid were added to the stirred mixture. After 30 min, the mixture was extracted with ether and the extract was washed with water and dried. The residue obtained by evaporating the solvent under reduced pressure was dissolved in benzene. The solution was percolated through a short column of alumina. The dark brown liquid obtained from the filtrate was triturated with a small amount of benzene-cyclohexane to yield yellow crystals (4.95 g). The crystals were recrystallized from cyclohexane to give pure V, yellow plates. V showed double melting point, mp 98—99°C and mp 119—120°C, IR: 2815 (CHO), 1690 (C=O), 965 (C=CH) cm^{-1}.

Found: C, 87.73; H, 5.22%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%.

5-(1-Anthryl)-2,4-pentadien-1-al (VI). A solution of 1-methoxy-1-buten-3-yne (12.5 g, 0.152 mol) in tetrahydrofuran (20 m*l*) was added to a stirred solution of ethylmagnesium bromide (prepared from ethyl bromide, 8.8 g and magnesium, 1.5 g) in the same solvent (38 m*l*) at 40°C. The mixture was stirred under nitrogen atmosphere for 30 min at 40°C and then 1 hr at room temperature. A solution of 1-formylanthracene (8.2 g, 0.04 mol) in tetrahydrofuran (90 m*l*) was added to the ice-cooled solution of Grignard derivative of methoxybutenyne over a period of 1 hr. After the mixture had been stirred overnight at room temperature, a saturated solution of ammonium chloride (90 m*l*) was added. The organic layer was separated, washed with water and dried. Brown liquid obtained by evaporation of the solvent *in vacuo* was dissolved in ether (100 m*l*) and added to a suspension of lithium aluminum hydride (4.5 g, 0.12 mol) in ether (65 m*l*). The mixture was stirred at room temperature for 2 hr and then ethyl acetate (18 m*l*), water (5 m*l*) and 4 N sulfuric acid (135 m*l*) were added successively. After the mixture had been stirred for 30 min at room temperature, the organic layer was separated and washed with water and dried. Fine orange crystals obtained by evaporation of the solvent under reduced pressure were dissolved in methanol and mixed with a saturated solution of sodium hydrogen sulfite. The adduct precipitated was filtered, washed successively with methanol and hot benzene. The adduct was decomposed with a solution of sodium carbonate, and the mixture was extracted with benzene. The extract was worked up according to the usual manner to yield orange yellow fine crystals (6.4 g, 63%). This material was recrystallized from cyclohexane to give pure VI as yellow plates, mp 147.5—149°C, IR: 1685 (C=O), 985 (C=CH) cm^{-1}.

Found: C, 87.90; H, 5.43%. Calcd for $C_{19}H_{14}O$: C, 88.34; H, 5.46%.

3-(1-Anthryl)-2-propen-1-ol (VII). A solution of sodium borohydride (0.23 g, 6.0 mmol) in methanol (22 m*l*) was added to a stirred solution of anthrylpropenal (V, 0.23 g, 1.0 mmol) in tetrahydrofuran (10 m*l*) and methanol (40 m*l*). Stirring was continued for 1.5 hr at room temperature. Dilute hydrochloric acid was then added to the reaction mixture. Pale yellow crystals (0.22 g, 92%, mp 138—140°C) obtained from the organic layer were recrystallized from benzene to afford pure VII as yellow needles, mp 141.0—141.5°C, IR: 3300 (OH), 995 (C–O), 980, 970 (C=CH) cm^{-1}.

Found: C, 87.38; H, 6.16%. Calcd for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

5-(1-Anthryl)-2,4-pentadien-1-ol (IX). A solution of sodium borohydride (0.40 g, 10 mmol) in methanol (20 m*l*) was added at room temperature to a stirred solution of anthrylpentadienal (VI, 0.90 g, 3.5 mmol) in tetrahydrofuran (13 m*l*) and methanol (20 m*l*). After 2 hr, dilute hydrochloric acid was added to the reaction mixture and the organic solvent was removed under reduced pressure. The solid deposited was filtered, washed and dried to give yellow fine crystals (1.0 g, mp 140—147°C). The crude alcohol (IX) thus obtained was recrystallized from benzene-cyclohexane, yielding pure IX as yellow plates, mp 159—160.5°C, IR: 3350 (OH), 1015 (C–O), 995, 980, 972 (C=CH) cm^{-1}.

Found: C, 87.44; H, 6.12%. Calcd for $C_{19}H_{16}O$: C, 87.66; H, 6.19%.

3-(1-Anthryl)-2-propen-1-yltriphenylphosphonium Bromide (XI). To a solution of anthrylpropenol (VII, 1.5 g, 6.4 mmol) in chloroform (60 m*l*) containing 2 drops of pyridine which was chilled on an ice-salt bath was added a solution of phosphorus tribromide (1.7 g, 6.5 mmol) in the same solvent (10 m*l*) and the mixture was stirred for 1 hr at room temperature. The reaction mixture was poured onto ice-water

and the organic layer was separated, washed and dried. Crude bromide (VIII) obtained as yellow fine crystals by evaporation of the solvent under reduced pressure was mixed with triphenylphosphine (1.9 g, 7.2 mmol) in benzene (26 ml). The mixture was refluxed overnight, and the crystals deposited were filtered and washed with benzene, yielding pale yellow crude phosphonium bromide (XI, 3.2 g, 89.5%, mp 256—260°C). Recrystallization of crude XI from ethanol afforded pure XI as yellow crystals, mp 260—262°C.

Found: C, 73.14; H, 5.45%. Calcd for $C_{35}H_{28}PBr \cdot C_2H_5OH$: C, 73.40; H, 5.62%.

5-(1-Anthryl)-2,4-pentadien-1-yltriphenylphosphonium Bromide (XII). A solution of phosphorus tribromide (0.97 g, 3.8 mmol) in chloroform (20 ml) was added to a strongly chilled (ice-salt bath) solution of anthrylpentadienol (IX, 0.465 g, 1.8 mmol) in chloroform (70 ml) containing 2 drops of pyridine. After stirring for 30 min at the same temperature, the reaction mixture was poured onto ice-water and the organic layer was separated. After washing and drying the organic layer was treated with active charcoal. Greenish yellow crystals obtained by evaporation of the solvent under reduced pressure were mixed with benzene (40 ml) and triphenylphosphine (0.54 g, 2.2 mmol) and the mixture was allowed to stand overnight at room temperature. Evaporation of the solvent under reduced pressure gave fine greenish yellow crystals. The crystals were washed with a small amount of benzene–cyclohexane (1 : 1) to give slightly crude XII, mp 140—143°C, 0.45 g (44%). The crude XII was used in the subsequent reaction without further purification.

1,2-Di(1-anthryl)ethylene (I_1). To a suspension of 1-anthrylmethyltriphenylphosphonium bromide[8] (III, 0.533 g, 1.0 mmol) in benzene (15 ml) was added 0.22 N ethereal solution of phenyllithium (4.6 ml) under nitrogen atmosphere. After stirring for 15 min, a solution of 1-formylanthracene[14] (IV, 0.206 g, 1 mmol) in benzene (10 ml) was added to the resulting red solution of phosphorane and the mixture was stirred overnight at room temperature. The crystals deposited were filtered and digested with boiling benzene. Yellow crystals (0.108 g, 28.5%, mp 267—279°C) obtained by concentration of the extract were recrystallized from benzene, yielding pure I_1 as greenish yellow crystals, mp 277—279°C, IR: 1615, 1540, 1455, 1430, 1325, 975, 967, 875, 795, 734 cm^{-1}.

Found: C, 94.38; H, 5.29%. Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%.

1,4-Di(1-anthryl)-1,3-butadiene (I_2). (a) By the Wittig Reaction: An ethereal solution of phenyllithium (0.84 N, 1.6 ml) was added to a suspension of 1-anthrylmethyltriphenylphosphonium bromide (III, 0.69 g, 1.3 mmol) in xylene (70 ml) under nitrogen atmosphere and the mixture was stirred for 30 min at 50—60°C resulting in a dark red solution of phosphorane. To this was added under shielding from light a solution of 3-(1-anthryl)-2-propen-1-al (V, 0.30 g, 1.3 mmol) in xylene (50 ml) and the mixture was stirred for 19 hr at room temperature. The crystals deposited were filtered and digested with hot toluene. The yellow crystals (0.256 g, 48%, mp 266—270°C) obtained by concentration of the extract were recrystallized from toluene to yield pure I_2 as yellow leaflets, mp 273—275°C, IR: 1613, 1538, 1455, 1300, 990, 874, 784, 728 cm^{-1}.

Found: C, 94.41; H, 5.46%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%.

(b) Reduction of Di-(1-anthryl)diacetylene: Sodium (0.4 g) was added to a solution of di-(1-anthryl)diacetylene[18] (0.603 g) in liquid ammonia (120 ml). After the mixture had been stirred for 5 hr, ammonium nitrate and then water were added. The insoluble material was collected by filtration, washed successively with water and ethanol and dried. The crude material was dissolved in benzene (90 ml). The crystals obtained by concentration of the solution up to 70 ml were recrystallized from benzene, yielding yellow leaflets, mp 273—275°C.

Found: C, 94.10; H, 5.65%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%.

The butadiene (I_2) thus prepared was found to be identical with that prepared by the Wittig reaction.

1,6-Di(1-anthryl)-1,3,5-hexatriene (I_3). 3-(1-Anthryl)-2-propen-1-yltriphenylphosphonium bromide (XI, 0.839 g, 1.5 mmol) in xylene (80 ml) was mixed with phenyllithium (0.5 N ether solution, 3 ml) under nitrogen atmosphere and the mixture was stirred at 50—60°C for 30 min. A solution of 3-(1-anthryl)-2-propen-1-al (V, 0.348 g, 1.5 mmol) in xylene (50 ml) was added to the dark violet solution of phosphorane under shielding from light. Stirring was continued for 5 days at room temperature, and the yellow crystalline powder deposited (0.214 g, 33%) was digested with hot toluene and the hot extract was passed through a short column of alumina. Concentration of the filtrate under reduced pressure yielded pure I_3 as orange yellow plates, mp 304—305°C, IR: 1610, 1454, 1297, 1001, 877, 788, 728 cm^{-1}.

Found: C, 94.33; H, 5.64%. Calcd for $C_{34}H_{24}$: C, 94.41; H, 5.59%.

1,8-Di(1-anthryl)-1,3,5,7-octatetraene (I_4). A solution of 5-(1-anthryl)-2,4-pentadien-1-al (VI, 0.260 g, 1.0 mmol) in xylene (20 ml) was added under shielding from light to a dark violet solution of phosphorane [prepared by stirring a mixture of 3-(1-anthryl)-2-propen-1-yltriphenylphosphonium bromide (XI, 0.560 g, 1.0 mmol) in xylene (22 ml) and phenyllithium (0.06 N, ether solution, 16.6 ml) for 1 hr under nitrogen atmosphere]. After the reaction mixture had been stirred overnight at room temperature, the solvent was removed under diminished pressure. The residue was digested with hot toluene and the hot extract was percolated through a thin layer of alumina. Concentration of the filtrate yielded fine orange crystals (0.065 g, 14%), mp 286—290°C which were recrystallized from toluene to give pure I_4, bright yellow plates, mp 289.5—290.0°C, IR: 1610, 1537, 1428, 1010, 880, 787, 732 cm^{-1}.

Found: C, 93.79; H, 5.69%. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%.

1,10-Di(1-anthryl)-1,3,5,7,9-decapentaene (I_5). A solution of 5-(1-anthryl)-2,4-pentadien-1-al (VI, 0.130 g, 0.5 mmol) in benzene (20 ml) was added to a solution of phosphorane prepared from 5-(1-anthryl)-2,4-pentadien-1-yltriphenylphosphonium bromide (XII, 0.290 g, 0.5 mmol) in benzene (20 ml) and an ethereal solution of phenyllithium (0.12 N, 8.3 ml). After stirring overnight at room temperature, the solvent was removed under reduced pressure. The residue was extracted with hot toluene and the hot extract was passed through a short column of alumina. Orange crystalline powder (0.044 g, 18%, mp 282—292°C) deposited on cooling the filtrate was recrystallized from toluene to give pure I_5 as orange plates, mp 290—292°C, IR: 1610, 1535, 1428, 1010, 990, 975, 878, 865, 790, 730 cm^{-1}.

Found: C, 93.85; H, 5.87%. Calcd for $C_{38}H_{28}$: C, 94.18; H, 5.82%.

1,12-Di(1-anthryl)-1,3,5,7,9,11-dodecahexaene (I_6). To a suspension of 3-(1-anthryl)-2-propen-1-yltriphenylphosphonium bromide (XI, 0.670 g, 1.2 mmol) in benzene (20 ml) was added an ethereal solution of phenyllithium (0.33 N, 3.6 ml) under nitrogen atmosphere. After the mixture had been stirred for 20 min at room temperature, a solution

of muconic aldehyde[17] (0.044 g, 0.4 mmol) in benzene (3 m*l*) was added and the mixture was stirred for 23 hr at room temperature. Crystalline orange powder deposited was digested with hot toluene. The extract was concentrated under reduced pressure to yield fine orange red crystals, 0.084 g, (41%), mp 273—280°C. The crude crystals were dissolved in hot toluene and the hot solution was passed through a short column of alumina, yielding pure I_6 as orange red plates, mp 279—280°C, IR: 1612, 1535, 1455, 1428, 1010, 995, 876, 868, 788, 730 cm^{-1}.

Found: C, 93.71; H, 5.87%. Calcd for $C_{40}H_{30}$: C, 94.08; H, 5.92%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3187—3191 (1972)

Compounds Related to Acridine. VIII.[1] Reaction of 9-Vinylacridine with *p*-Substituted Nitrosobenzenes

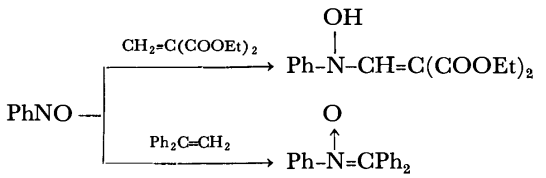
Otohiko Tsuge[2] and Akiyoshi Torii[3]

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812

(Received May 17, 1972)

In the presence of hydrochloric acid, 9-vinylacridine reacts with nitrosobenzenes having electron-donating groups such as *p*-nitroso-*N*,*N*-dialkylaminoaniline and *p*-methylnitrosobenzene to yield a four-membered oxazetidine, as the first example of a non-fluorinated oxazetidine ring system. A new 2 : 2 adduct, to which the perhydro-1,2,7-oxadiazepine structure is assigned tentatively, is formed in the reaction of 9-vinylacridine with nitrosobenzene or *p*-chloronitrosobenzene under similar conditions.

So far no report has been given on non-fluorinated oxazetidines.[4,5] Hepfinger *et al.*[6] have shown that the oxazetidines reported by Ingold and Weaver[7] from the reaction of nitrosobenzene with diethyl methylenemalonate and 1,1-diphenylethylene are diethyl *β*-*N*-hydroxy-*N*-phenylmethylenemalonate and triphenylnitrone as proposed by Lapworth *et al.*[8]



We reported[9,10] that hydrochloric acid (HCl) is an extremely effective catalyst for the condensation of *p*-substituted nitrosobenzenes with 9-methyl- and 9-ethylacridine. Furthermore, even 9-ethynylacridine undergoes condensation with two moles of *p*-nitroso-*N*,*N*-dialkylaniline in the presence of HCl to yield 1-(9-acridinyl)-1,2-bis(*p*-dialkylaminophenylimino)-ethane *N*,*N*-dioxide.[11]

We report herewith that in the presence of HCl, 9-vinylacridine reacts with nitrosobenzenes having electron-donating groups to give oxazetidine compounds as the first example of a non-fluorinated oxazetidine ring system. With nitrosbenzene or *p*-chloronitrosobenzene, a new 2 : 2 adduct was obtained.

Results and Discussion

From previous results,[9-11] *cis*- or *trans*-1-(9-acridinyl)-2-methylethylene (**1**) might be expected to react with *p*-nitroso-*N*,*N*-dialkylaniline to give the *α*,*β*-unsaturated anil and/or nitrone. Contrary to expectation, the reaction of **1** with *p*-nitroso-*N*,*N*-dimethylaniline (**2a**) in the presence of HCl in refluxing ethanol afforded acridine-9-carboxaldehyde-*N*-(*p*-*N*,*N*-dimethylaminophenyl)anil (**3a**), whose structure was confirmed by comparison with the authentic sample.[9] Olefin **1** did not react with **2a** in the presence of HCl at room temperature nor in the presence (or absence) of a basic catalyst such as potassium carbonate in ethanol.[12]

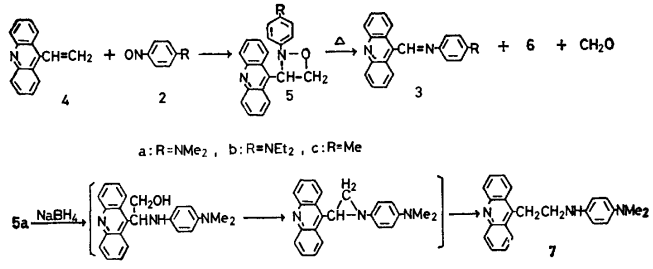
11) O. Tsuge and A. Torii, *ibid.*, **43**, 2920 (1970).

It is conceivable that **3a** might have been formed *via* the oxazetidine intermediate **A** with the elimination of acetaldehyde, although an attempt at isolation of **A** was unsuccessful (Scheme 1).

On the other hand, 9-vinylacridine (**4**) reacted easily with **2a** in the presence of HCl at room temperature to afford a 1 : 1 adduct **5a**, mp 156—157°C (decomp.), as violet prisms, while under reflux in ethanol **3a** was obtained.

The structure of the 1 : 1 adduct was established to be 3-(9-acridinyl)-2-(*p*-*N*,*N*-dimethylaminophenyl)-oxazetidine (**5a**) on the basis of spectra data and chemical conversions. The IR spectrum of **5a** showed a characteristic band ascribable to ν_{C-O-N} at 1050 cm^{-1}. The mass spectrum exhibited a parent peak (M^+) at *m/e* 355 together with major fragment peaks at *m/e* 341 (M^+-CH_2), 339 (M^+-O), 337 (M^+-H_2O), 325 (M^+-CH_2O), 324 (325^+-H), 221 (341^+- $-NMe_2$), 217 (337^+- $-NMe_2$), and 204 (324^+- $-NMe_2$). However, the NMR spectrum could not be obtained owing to the insolubility of organic solvents.

When a solution of **5a** in ethanol was refluxed, anil **3a**, a new compound **6** and formaldehyde were formed. This indicates that **3a** was formed from **5a** by the elimination of formaldehyde.[13] Reduction of **5a** with sodium borohydride gave 1-(9-acridinyl)-2-(*p*-*N*,*N*-dimethylanilino)ethane (**7**), whose structure was confirmed by spectral data as well as by microanalysis. Although the exact pathway for the formation of **7** is not clear, it seems to have been caused by the initial reductive cleavage of oxazetidine, followed by the formation of an aziridine by the loss of water and subsequent ring opening as shown in Scheme 2.

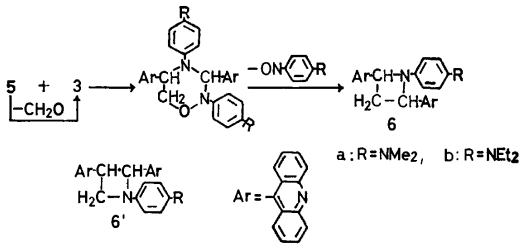


Scheme 2.

Similarly, the reaction of **4** with *p*-nitroso-*N*,*N*-diethylaniline (**2b**) or *p*-methylnitrosobenzene (**2c**) in the presence of HCl at 0°C afforded the corresponding oxazetidine compound **5b** or **5c**. Refluxing of an ethanol solution of **5b** or **5c** gave the corresponding anils **3b** and **3c**, and **6b**. In the case of **5c**, however, the compound of type **6** could not be isolated.

The results of microanalyses and mass spectra of **6a** and **6b** agreed with the molecular formulas of the corresponding 1 : 1 adduct of **4** and **3**. The IR spectra of **6a** and **6b** were very similar to each other, and showed no bands ascribable to ν_{NH}. The NMR spectrum of **6a** exhibited signals at δ 2.85 (2H, multiplet, CH_2), 2.95 (6H, singlet, $N(CH_3)_2$), and 6.7—8.7 ppm (22H, complicated, aromatic (20H) and two methine protons). It was thus deduced that the most reasonable structure for **6** is 2,4-di(9-acridinyl)-1-(*p*-*N*,*N*-dialkylaminophenyl)azetidine rather than the 2,3-di(9-acridinyl)azetidine compound **6'**.

The reaction of **4** with **3a** did not occur and starting materials were recovered. It is thus conceivable that the formation of **6** might have taken place from a secondary reaction of **5** with **3** by the elimination of nitroso compound **2**. Although no increase in the yield of **6a** was observed in the thermolysis of **5a** in the presence of **3a**, the formation of **6** can be viewed as proceeding by the initial formation of the perhydro-1,2,4-oxadiazine intermediate from the reaction of **5** with **3**, followed by the elimination of nitroso compound **2** as illustrated in Scheme 3.



Scheme 3.

4 reacted with nitrosobenzene (**2d**) in the presence of HCl to afford a 2 : 2 adduct **8d** as pale yellow prisms, accompanied by a large amount of tarry material. In a similar reaction of **4** with *p*-chloronitrosobenzene (**2e**), a 2 : 2 adduct **8e** was isolated together with a small amount of oxazetidine **5e**. However, *p*-nitronitrosobenzene did not react with **4** but was converted into *p*,*p'*-dinitroazobenzene.

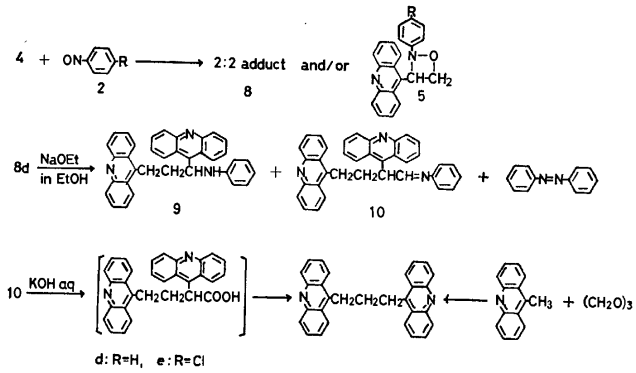
Although the formation of 1 : 2 adduct of styrene and trifluoronitrosomethane[5] and 1 : 2 adduct of styrene and nitrosobenzene[14] was observed in the reaction of styrene with the respective nitroso compound, formation of 2 : 2 adducts from olefin and nitroso compound has not been reported.

Although **8d** was stable against reduction with sodium borohydride and lithium aluminum hydride, its treatment with sodium ethoxide in ethanol afforded 1-anilino-1,3-di(9-acridinyl)propane (**9**) and 2,4-di-(9-acridinyl) butyraldehyde-*N*-phenylanil (**10**), accompanied by a trace amount of azobenzene. Structures of **9** and **10** were confirmed by their spectral data as well as by the results of microanalyses. **10** was hydrolyzed with aqueous potassium hydroxide to give 1,3-di(9-acridinyl)propane (**11**) *via* the carboxylic acid, which could not be isolated in a pure form; **11** was identified by comparison with an authentic sample prepared from the Mannich reaction of 9-methylacridine with paraformaldehyde (Scheme 4).

12) The reaction of *trans*-9-styryl- and *trans*-9-(*p*-nitrostyryl)-acridine with **2a** did not take place under various conditions.

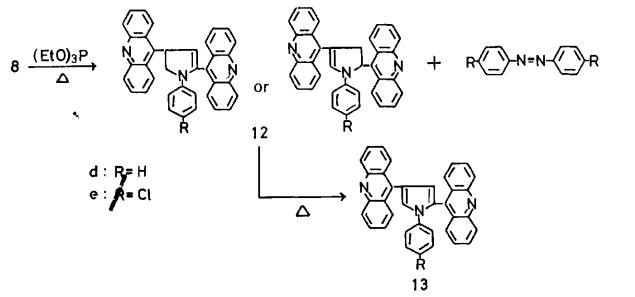
13) Formaldehyde in exhaust gas was identified by means of the fuchsin-sulfuric acid color test. It was reported that perfluoroxazetidine obtained from trifluoronitrosomethane and tetrafluoroethylene decomposed thermally to form perfluoromethylenemethylamine and carbonylfluoride.[4]

14) N. F. Hepfinger and C. E. Griffin, *Tetrahedron Lett.*, **1963**, 1361.



Scheme 4.

Contrary to oxazetidine **5**, 2 : 2 adducts **8d** and **8e** were stable in refluxing ethanol. Heating of **8d** in triethylphosphite for 10 hr afforded a new compound **12d**, mp 276—277°C, and azobenzene. On the basis of its spectral data and reaction with triethylphosphite, compound **12d** was assumed to be either 2,3-di(9-acridinyl)-1-phenyl-Δ^2- or -Δ^4-pyrroline. On heating with triethylphosphite, **12d** was converted into 2,3-di(9-acridinyl)-1-phenylpyrrole (**13d**), mp 280—281°C, whose structure was established by its spectral data. Similarly, treatment of **8e** with triethylphosphite gave the corresponding pyrroline **12e** and *p,p'*-dichloroazobenzene (Scheme 5).



Scheme 5.

The NMR spectrum of **8d** exhibited multiplets at δ 2.5 (2H, CH_2), 4.0 (2H, CH_2), 6.2 (2H, $\rightarrow$CH), and 6.7—9.5 ppm (26H, aromatic protons).

From the above NMR spectra and chemical conversions it is evident that the 2 : 2 adducts **8** have the moiety **B** in the molecule, while three types of arrangements **C**, **D**, and **E** are possible for the remainder of the adduct (Fig. 1). 1,2,3-Oxadiazolidin 3-oxide **F** and 1,2,5-oxadiazolidin 2-oxide **G** were proposed, respectively, for the 1 : 2 adducts of styrene with trifluoronitrosomethane[5] and with nitrosobenzene.[14] Structures **F** and **G** correspond to **E** and **C**, respectively.

The results of reduction and deoxygenation of **8** eliminate the possibility of a structure incorporating **E**. Thus, perhydro-1,2,7-oxadiazepin 1-oxide **8-1**, 7-oxide **8-2** (from **B** and **C**), and perhydropyridazine 1,2-dioxide **8-3** (from **B** and **D**) are possible structures for adducts **8**. From the spectral data it could not be decided which type of structure **8-1**—**8-3** would be most reasonable for **8**. However, perhydro-1,2,7-oxadiazepine structure **8-1** or **8-2** was assumed to be

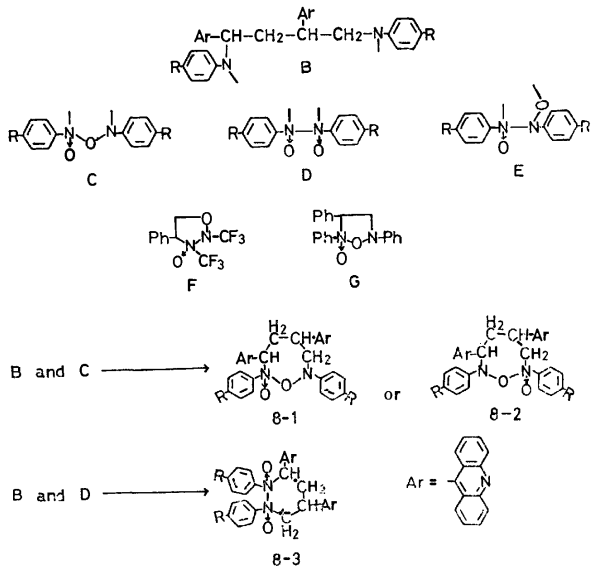


Fig. 1.

more reasonable than perhydropyridazine structure **8-3**, because pyrrole **13** was obtained on deoxygenation of **8** but no pyridazine. Furthermore, hydrolysis of **8d** with hydrochloric acid afforded the 1-(*p*-chlorophenyl)pyrroline compound **12e**; formation of **12e** seems to take place by the hydrolytic cleavage of -N-O- bond in the ring, followed by the Orton rearrangement. This seems to support the proposed structure **8-1** or **8-2** for **8**.

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets and the UV spectra were determined in ethanol solutions. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV. The NMR spectra were determined at 60 MHz with a Hitachi R-20 NMR spectrometer, with TMS as an internal reference. The microanalyses were carried out by Miss M. Akita.

Materials. 1-(9-Acridinyl)-2-methylethylene (**1**)[15] (*cis*: mp 56—58°C; *trans*: mp 98—99°C); *trans*-9-styrylacridine,[16] mp 184—185°C; *trans*-9-(*p*-nitrostyryl)acridine,[16] mp 291—292°C, and 9-vinylacridine (**4**),[15] mp 87—88°C, were prepared by our previous methods.

Nitrosobenzenes were prepared by methods described in literature: *p*-nitroso-*N,N*-dimethylaniline (**2a**), mp 93—94 °C (lit,[17] mp 92—95°C); *p*-nitroso-*N,N*-diethylaniline (**2b**), mp 84—85°C (lit,[17] mp 84°C); *p*-methylnitrosobenzene (**2c**), mp 49°C (lit,[18] mp 48.5°C); nitrosobenzene (**2d**), mp 65—66°C (lit,[19] mp 64—67°C); *p*-chloronitrosobenzene (**2e**), mp 90—91°C (lit,[18] mp 89.5°C); *p*-nitronitrosobenzene, mp 118°C (lit,[20] mp 118°C).

21) HCl used in this paper: d^{27} 1.1748.

*Reaction of **1** with **2a**.* A typical reaction is as follows. To a solution of 1.0 g of **1** (*trans*) and 0.8 g of **2a** in 20 m*l* of ethanol was added 0.05 m*l* of HCl[21] at room temperature, and the reaction mixture was heated under reflux for 8 hr. After it was allowed to stand overnight, filtration gave reddish crystals which on recrystallization from ethanol afforded 0.16 g (15%) of acridine-9-carboxaldehyde-*N*-(*p*-*N*,*N*-dimethylaminophenyl)anil (**3a**), mp 249—250°C (lit.,[9] mp 248°C). The structure of **3a** was established by identification with an authentic sample.[9]

*Reaction of **4** with **2a**.* To a solution of 1.0 g of **4** and 0.8 g of **2a** in 20 m*l* of ethanol was added 0.1 m*l* of HCl. The reaction mixture was then stirred at room temperature for 1 hr. Filtration gave 0.6 g (35%) of 3-(9-acridinyl)-2-(*p*-*N*,*N*-dimethylaminophenyl)oxazetidine (**5a**), mp 156—157°C (decomp.), as violet prisms, which was subjected to microanalysis without further purification.

Found: C, 77.31; H, 5.93; N, 11.75%. Calcd for $C_{23}H_{21}N_3O$: C, 77.72; H, 5.96; N, 11.82%.

UV λ_{max} nm (log ε): 253 (4.5), 537 (4.4).

The reaction of **4** with **2a** in refluxing ethanol gave anil **3a**. The effects of reaction conditions on yields of products are given in Table 1.

Table 1. Reaction of **4** with **2a**[a]

Run	Reaction conditions			Product, Yield (%)	
	2a/**4** (mol/mol)	Time (hr)	HCl (m*l*)	**3a**	**5a**
1	1	1	0.1	—	35
2	2	1	0.1	—	64
3	3	1	0.1	—	65
4	1	8	0.05	11	—
5	1	8	0.1	9	—
6	1	8	0.2	8	—
7	2	8	0.1	15	—
8	3	8	0.1	22	—

a) A mixture of 1.0 g of **4**, the specified amounts of **2a** and HCl in 20 m*l* of ethanol was stirred at room temperature (Runs 1-3) or under reflux (Runs 4-8).

*Reaction of **4** with **2b**.* One gram of **4** was reacted with 1.8 g of **2b** in the presence of 0.1 m*l* of HCl in 20 m*l* of ethanol at 0°C for 15 min to give 1.35 g (69%) of 3-(9-acridinyl)-2-(*p*-*N*,*N*-diethylaminophenyl)oxazetidine (**5b**) monohydrate, mp 112—113°C (decomp.), as violet prisms.

Found: C, 74.81; H, 6.73; N, 10.47%. Calcd for $C_{25}H_{25}N_3O \cdot H_2O$: C, 74.95; H, 7.07; N, 10.54%.

IR cm^{-1}: ν_{C-O-N} 1045. UV λ_{max} nm (log ε): 253 (4.8), 539 (4.2). Mass spectrum *m/e*: 383 (M^+), 369 ($M^+ - CH_2$), 367 ($M^+ - O$), 365 ($M^+ - H_2O$), 353 ($M^+ - CH_2O$), 205 ($M^+ - $**2b**).

Similarly, the reaction of 0.5 g of **4** with 0.6 g of **2c** in the presence of 0.05 m*l* of HCl in 10 m*l* of ethanol at 0°C for 2.5 hr gave 0.25 g (31%) of 3-(9-acridinyl)-2-(*p*-tolyl)oxazetidine (**5c**), mp 192—193°C (decomp.), as violet prisms.

Found: C, 80.60; H, 5.46; N, 8.54%. Calcd for $C_{22}H_{18}N_2O$: C, 80.98; H, 5.52; N, 8.59%.

IR cm^{-1}: ν_{C-N-O} 1045. UV λ_{max} nm (log ε): 253 (4.8), 524 (4.4). Mass spectrum *m/e*: 326 (M^+), 312 ($M^+ - CH_2$), 310 ($M^+ - O$), 308 ($M^+ - H_2O$), 296 ($M^+ - CH_2O$), 205 ($M^+ - $**2c**).

*Thermolysis of Oxazetidine **5**.* A solution of 2.0 g of **5b** in 20 m*l* of ethanol was refluxed for 8 hr, during which time evolution of formaldehyde was confirmed by means of fuchsin-sulfurous acid color test. The reaction mixture was concentrated *in vacuo* to leave a residue, which was then chromatographed on alumina using benzene as an eluent to obtain 0.42 g (23%) of anil **3b**, mp 168°C (lit,[9] mp 168—169 °C) and 0.4 g (15%) of 2,4-di(9-acridinyl)-1-(*p*-*N*,*N*-diethylaminophenyl)azetidine (**6b**), mp 295—296°C, as pale yellow prisms.

Found: C, 83.71; H, 5.94; N, 9.90%. Calcd for $C_{39}H_{34}N_4$: C, 83.84; H, 6.13; N, 10.03%.

UV λ_{max} nm (log ε): 247 (4.8), 365 (3.9).

NMR (in $CDCl_3$) δ ppm: 1.15 (6H, triplet, $-CH_2-CH_3$), 3.0—3.6 (6H, multiplet, CH_2), 6.7—8.55 (22H, complicated, aromatic (20H) and two methine protons).

Mass spectrum *m/e*: 558 (M^+).

Similarly, heating of **5a** or **5c** in ethanol afforded anil **3a** (22%) and azetidine **6a** (32%), or anil **3c** (22%), mp 180—181°C (lit,[22] mp 182—183°C), respectively.

Azetidine **6a**: mp 294—295°C, yellow needles.

Found: C, 84.02; H, 5.51; N, 10.63%. Calcd for $C_{37}H_{30}N_4$: C, 83.74; H, 5.70; N, 10.56%.

UV λ_{max} nm (log ε): 247 (4.7), 362 (3.7). Mass spectrum *m/e*: 530 (M^+).

*Reduction of **5a** with Sodium Borohydride.* A solution of 1.3 g of **5a** in 16 m*l* of ethanol-dioxane mixture (1 : 1) was stirred with 0.5 g of sodium borohydride at room temperature for 1.5 hr. To the reaction mixture was added 50 m*l* of water. The resulting solution was then extracted with 100 m*l* of diethyl ether. The extract was dried over anhydrous sodium sulfate and then evaporated to leave a reddish oily residue. The residue was chromatographed on alumina using benzene as an eluent to obtain 0.56 g (58%) of 1-(9-acridinyl)-2-(*p*-*N*,*N*-dimethylanilino)ethane (**7**), which on recrystallization from petroleum ether (bp 45—60°C) gave orange prisms, mp 131—132°C.

Found: C, 80.79; H, 6.81; N, 12.03%. Calcd for $C_{22}H_{23}N_3$: C, 80.90; H, 6.79; N, 12.31%. IR cm^{-1}: ν_{NH} 3280.

NMR (in $CDCl_3$) δ ppm: 2.8 (6H, singlet, $N(CH_3)_2$), 3.5 (2H, triplet, CH_2, J=6 Hz), 3.8 (2H, triplet, CH_2, J= 6 Hz), 3.55 (1H, singlet, NH), 6.6—8.4 (21H, multiplet, aromatic protons).

Mass spectrum *m/e*: 341 (M^+).

*Reaction of **4** with **2e**.* A solution of 1.0 g of **4** and 1.4 g of **2e** in 20 m*l* of ethanol containing 0.1 m*l* of HCl was stirred at room temperature for 24 hr. Filtration gave 0.31 g (18%) of 2 : 2 adduct **8e**, which on recrystallization from chloroform afforded pale yellow prisms, mp 212—213°C (decomp.).

Found: C, 72.80; H, 4.18; N, 7.93%. Calcd for $C_{42}H_{30}N_4O_2Cl_2$: C, 72.54; H, 4.32; N, 8.08%.

UV λ_{max} nm (log ε): 253 (4.2), 520 (4.1).

The mass spectrum of **8e** did not show a parent peak (M^+), but major fragment peaks at *m/e* 656, 658, 660 (9 : 6 : 1, $M^+ - 2H_2O$), 531, 533 ($M^+ - 2H_2O$ — Cl- -N), 316, 318 (3 : 1, 9-acridinyl-CH=N- -Cl^+), 315, 317, and other peaks appeared in the spectrum.

The filtrate was evaporated *in vacuo* to leave a residue, which was chromatographed on alumina using chloroform as an eluent to give 10 mg of oxazetidine **5e**, mp 191°C (decomp.), as violet prisms, together with a large amount of tar.

Found: C, 72.66; H, 4.33; N, 8.00%. Calcd for $C_{21}H_{15}N_2OCl$: C, 72.54; H, 4.32; N, 8.08%.

Mass spectrum *m/e*: 346, 348 (3 : 1, M^+), 330, 332 ($M^+ - O$), 316, 318 ($M^+ - CH_2O$).

22) N. S. Drozdov and E. V. Yavorskaya, *Zh. Obshch. Khim.*, **30**, 3421 (1960).

Similarly, the reaction of 1.0 g of **4** with 1.2 g of **2d** in 20 ml of ethanol containing 0.1 ml of HCl afforded 0.3 g (20%) of 2 : 2 adduct **8d**, mp 172—173°C, as pale yellow prisms.

Found: C, 81.03; H, 5.09; N, 8.90%. Calcd for $C_{42}H_{32}N_4O_2$: C, 80.76; H, 5.12; N, 8.97%.

Mass spectrum *m/e*: 588 (M^+-2H_2O), 497 (M^+-2H_2O-PhN), 282 (9-acridinyl-CH=N-Ph^+), 281.

Reduction of ***8d*** *with Sodium Ethoxide.* A solution of 3.0 g of **8d** in 20 ml of ethanol was stirred with 0.5 g of sodium at room temperature for 12 hr. Filtration afforded 0.4 g (23%) of 2,4-di(9-acridinyl)butyraldehyde-*N*-phenylanil (**10**), which on recrystallization from pyridine gave yellow prisms, mp 296—297°C.

Found: C, 85.66; H, 5.27; N, 9.13%. Calcd for $C_{36}H_{27}N_3\cdot 1/2C_5H_5N$: C, 85.55; H, 5.48; N, 8.95%. IR cm^{-1}: $\nu_{C=N}$ 1660.

NMR (in CF_3COOH) δ ppm: 3.5, 5.6 (each 2H, multiplet, CH_2), 7.3—8.8 (23H, multiplet, aromatic (21H) and two methine protons).

Mass spectrum *m/e*: 501 (M^+), 309 (M^+—9-acridinylmethyl, base peak), 295 (9-acridinyl-$\overset{+}{C}$HCH=NPh), 206 (9-acridinyl-$CH_2CH_2^+$).

The filtrate was concentrated *in vacuo* to leave a residue, which was chromatographed on alumina using benzene as an eluent to give 10 mg of azobenzene and 0.25 g (11%) of 1-anilino-1,3-di(9-acridinyl)propane (**9**). Recrystallization of **9** from pyridine afforded yellow prisms, mp 214—215°C.

Found: C, 85.79; H, 5.28; N, 8.76%. Calcd for $C_{35}H_{27}N_3$: C, 85.86; H, 5.56; N, 8.58%. IR cm^{-1}: ν_{NH} 3280.

NMR (in $CDCl_3$) δ ppm: 2.9, 3.5 (each 2H, multiplet, CH_2), 4.5 (1H, multiplet, NH), 6.0 (1H, multiplet, >CH), 6.5—8.7 (21H, multiplet, aromatic protons).

Mass spectrum *m/e*: 489 (M^+), 397 (M^+—PhNH), 297 (M^+—9-acridinyl-CH_2^+), 283 (9-acridinyl-CH=$\overset{+}{N}$HPh, base peak), 206 (9-acridinyl-$CH_2CH_2^+$).

Hydrolysis of ***10***. After 0.1 g of **10** in 4 ml of ethanol-concentrated potassium oxide aqueous solution (1 : 1) was stirred at 90°C for 30 min, filtration afforded 70 mg of crystals. The crystals were washed with diethyl ether to leave 60 mg (75%) of yellow crystals, which on recrystallization from benzene gave 1,3-di(9-acridinyl)propane (**11**), mp 201—202°C, as yellow prisms.

Found: C, 87.70; H, 5.53; N, 7.03%. Calcd for $C_{29}H_{22}N_2$: C, 87.40; H, 5.57; N, 7.03%. Mass spectrum *m/e* 398 (M^+).

NMR spectrum (in CF_3COOH) δ ppm: 2.7 (2H, multiplet, CH_2), 4.5 (4H, multiplet, CH_2), 7.9—8.9 (16H, multiplet, aromatic protons).

The ether-washings were concentrated to give a trace amount of pale yellow crystals, whose IR spectrum showed the bands ascribable to ν_{OH} and $\nu_{C=O}$ at 3400 and 1700 cm^{-1}, respectively. However, the carboxylic acid could not be isolated in pure state.

Preparation of ***11***. A mixture of 3.0 g of 9-methylacridine, 0.5 g of paraformaldehyde and 1.5 g of dimethylamine hydrochloride in 25 ml of ethanol was refluxed for 2 hr. The reaction mixture was neutralized with aqueous sodium hydroxide to give brown oily substance, which solidified on trituration with diethyl ether. The solid was recrystallized from benzene to afford 0.75 g (72%) of **11**. mp 201—202°C.

Reaction of ***8d*** *with Triethylphosphite.* A solution of 1.0 g of **8d** in 5 ml of triethylphosphite was refluxed for 10 hr. The reaction mixture was concentrated *in vacuo* and the residue was allowed to stand overnight to give 0.25 g (32%) of 2,3-di(9-acridinyl)-1-phenylpyrroline (**12d**), which on recrystallization from benzene afforded orange prisms, mp 276—277°C.

Found: C, 86.79; H, 4.91; N, 8.08%. Calcd for $C_{36}H_{25}N_3$: C, 86.54; H, 5.04; N, 8.41%.

NMR (in CF_3COOH) δ ppm: 4.7 (2H, multiplet, CH_2), 7.0—9.3 (23H, multiplet, aromatic (21H), >CH and =CH).

Mass spectrum *m/e*: 499 (M^+), 497 (M^+-H_2, base peak), 422 (M^+—Ph), 420, 406 (497^+—PhN), 393 (497^+—PhN=CH), 312 (M^+—9-acridinyl), 295 (M^+—9-acridinyl-CH=CH), 281 (9-acridinyl-C≡$\overset{+}{N}$Ph), 205 (9-acridinyl-CH=CH_2^+), 204.

The filtrate was further concentrated to leave a residue, which was chromatographed on alumina using chloroform as an eluent to give 0.1 g of azobenzene and tar.

Similarly, treatment of 0.5 g of **8e** with 3 ml of triethylphosphite yielded 0.12 g (38.5%) of pyrroline **12e**, mp 292—293°C, as orange prisms and a small amount of *p,p'*-dichloroazobenzene, mp 189°C (lit,[23] mp 187°C).

Found: C, 81.07; H, 4.19; N, 7.65%. Calcd for $C_{36}H_{24}N_3Cl$: C, 80.79; H, 4.49; N, 7.87%.

Mass spectrum *m/e*: 533, 535 (3 : 1, M^+).

Hydrolysis of ***8d***. A solution of 0.5 g of **8d** in 10 ml of 20% aqueous hydrochloric acid was stirred at 90°C for 10 min. The reaction mixture had been cooled and neutralized with ammonium hydroxide to precipitate crystals. Recrystallization from benzene afforded 0.17 g (40%) of **12e**, mp 292—293°C.

*2,3-Di(9-acridinyl)-1-phenylpyrrole (****13d****).* A solution of 0.5 g of pyrroline **12d** in 3 ml of triethylphosphite was refluxed for 15 hr. The reaction mixture was concentrated *in vacuo* to give 0.3 g (60%) of crystals. Recrystallization from benzene afforded **13d**, mp 280—281°C, as orange yellow prisms. The pine reaction color test of **13d** was positive.

Found: C, 86.90; H, 4.46; N, 8.26%. Calcd for $C_{36}H_{23}N_3$: C, 86.92; H, 4.62; N, 8.45%. Mass spectrum *m/e*: 497 (M^+). NMR (in CF_3COOH) δ ppm: 7.3—9.1 (multiplet, aromatic protons).

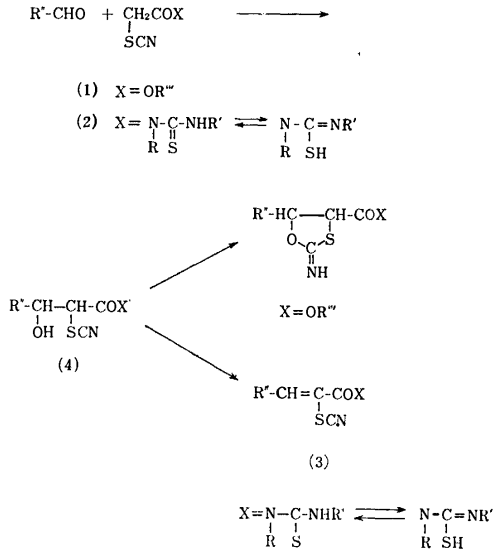
Thiocyanoacetate. IV. The Reaction of Ethyl Thiocyanoacetate with Aromatic Aldehydes in the Presence of Thioureas[1]

Satoshi KAMBE and Toshio HAYASHI*
Oyama Technical College, Oyamashi, Tochigi
**The Institute of Physical and Chemical Research, Wako-shi, Saitama*
(Received January, 31, 1972)

Ethyl thiocyanoacetate (**1**) reacts with anomatic aldehydes in the presence of *N,N'*-dialkylthiourea to give arylidene *N,N'*-dialkyl-*N*-thiocarbamoyl thiocyanoacetamides (**3**). On the other hand, the treatment of the ester (**1**) with benzaldehyde in the presence of thiourea or *N*-methylthiourea under the same conditions affords 5-benzylidene-2-imino-4-thiazolidinone (**5a**) or 5-benzylidene-3-methylthiazolidine-2,4-dione (**6a**).

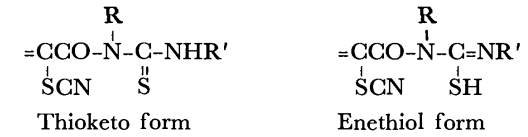
In the first paper of this series[2] it was shown that, in the presence of potassium carbonate or fluoride, thiocyanoacetic acid esters (**1**) and aldehydes undergo an Aldol-type condensation, followed by ring closure, to give *N*-carbamoyl-2-imino-1,3-oxathiolanes and α,β-unsaturated esters. However, we have found that *N,N'*-dialkyl-*N*-thiocarbamoyl thiocyanoacetamide (**2**) and aromatic aldehydes lead to a Knoevenagel-type condensation giving arylidene *N,N'*-dialkyl-*N*-thiocarbamoyl thiocyanoacetamides (**3**) in a good yield. This means that, in the case of the amide **2**, the dehydration rate of the intermediate **4** is larger than the rate of ring closure, whereas with the ester **1**, the reverse is true. It seems interesting that the modification of the ester group by the *N*-carbamoyl amide group causes a drastic change in the reaction course.



Scheme 1.

Results and Discussion

The reaction of the ester **1** with aromatic aldehydes in the presence of *N,N'*-dialkylthioureas gave arylidene *N,N'*-dialkyl-*N*-thiocarbamoyl thiocyanoacetamides (**3**), whose structures were confirmed on the basis of elemental analyses and spectral studies.



Thioketo form Enethiol form

Compounds **2** and **3** can exist in two tautomeric forms, the thioketo and enthiol forms, as is shown above. Product **3a**, for example, consisted of pale yellow needles with the structural formula $C_{13}H_{13}ON_3S_2$; mp 185—186°C. The IR spectrum of **3a** (KBr pellet) revealed the existence of the SH (near 2550 cm^{-1}), SCN (2050 cm^{-1}), C=O (1740 cm^{-1}), C=N (1640 cm^{-1}), and C=C (1600 cm^{-1}) groups. The NMR spectrum of **3a** (DMSO-d_6) showed the CH_3 proton signal δ at 3.25 and 3.30, =C<u>H</u> at 7.90, $C_6\underline{H}_5$ at 7.60, and a broad line with intensity of one proton at 8.85 ppm, a line which might be attributed to the SH proton. These facts suggest that **3** exists predominantly in the enethiol form.

The products (**3b—n**) could be obtained similarly from the reaction of substituted benzaldehyde with the ester **1** in the presence of *N,N'*-dialkylthiourea (see Table 1). However, the substituent effect was obscure in this case.

A plausible reaction sequence is illustrated in Scheme 2. Presumably, the reaction proceeds through the intermediacy of *N,N'*-dialkyl-*N*-thiocarbamoyl thio-

a) Decomp. All IR spectra were measured in KBr pellets.

cyanoacetamide (**2**), which subsequently condenses with aromatic aldehyde to give **3**.

Support for this may be supplied by the fact that the ester **1** reacted easily with *N,N'*-dialkylthiourea to give the amide **2**, and that the amide **2** thus isolated condensed with an aromatic aldehyde in the presence of *N,N'*-dialkylthiourea as a basic catalyst to give the product **3**. In contrast with the above reaction, when thiourea was used instead of *N,N'*-dialkylthiourea, the reaction of the ester **1** with benzaldehyde led to the formation of 5-benzylidene-2-imino-4-thiazolidinone (**5a**).[3]

The reaction of ester **1** with benzaldehyde in the presence of *N*-methylthiourea afforded 5-benzylidene-3-methylthiazolidine-2,4-dione (**6a**).[3] This compound is considered to be produced by the hydrolysis of 5-benzylidene-2-imino-3-methylthiazolidin-4-one (**5b**), which may be formed as an intermediate. Compound **6a** was obtained by the hydrolysis of the **3a** product with hydrochloric acid–ethanol. In addition, the reaction of the ester **1** with *N*-methylthiourea gave the corresponding amide (**2a**) (R=CH_3, R=H), but not 2-imino- or oxothiazolidinone. On the other hand, the treatment of **3a** with potassium carbonate or fluoride gave 5-benzylidene-2-methylimino-3-methyl-4-thiazolidinone (**5c**), which was identical with the authentic sample prepared by the alternative synthesis from benzaldehyde and 2-methylimino-3-methyl-4-thiazolidinone.[4] Furthermore, this compound (**5c**) was also obtained by the reaction of the amide **2b** (R=R'=CH_3) with benzaldehyde in the presence of potassium carbonate or fluoride. These facts suggest that, in the reaction of the amide **2** with aromatic aldehyde, the formation of a 4-thiazolidinone ring occurs after the condensation between the amide **2** and aromatic aldehyde has taken place. It is interesting that the ring closure of **3** might occur with the elimination of hydrogen thiocyanide, as is shown in Scheme 2.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Shimadzu IR-27G spectrometer. The NMR spectra obtained on a Nihondenshi JNM-C-60 high-resolution NMR spectrometer (60 MHz). Tetramethylsilane was used as the internal standard. The chemical shifts of the protons are presented in terms of δ values.

General Procedure for the Reaction of Ethyl Thiocyanoacetate. (1) With Aromatic Aldehyde in the Presence of N,N'-*Dialkylthiourea*: A mixture of the ester **1** (0.02 mol), an aldehyde (0.02 mol), and an *N,N'*-dialkylthiourea (0.02 mol) in ethanol (20 m*l*) was refluxed for a suitable period. After the reaction mixture had then been cooled, the resulting precipitates were filtered and washed with water. They were recrystallized from ethanol to give arylidene *N,N'*-dialkyl-*N*-thiocarbamoyl thiocyanoacetamide (**3**). The results are summarized in Table 1.

The Reaction of Ethyl Thiocyanoacetate (1) with Benzaldehyde in the Presence of N-*Methylthiourea.* A mixture of the ester **1** (0.02 mol), benzaldehyde (0.02 mol), and *N*-methylthiourea (0.02 mol) in ethanol (20 m*l*) was refluxed for 5 hr. After cooling, the resulting precipitate was filtered and washed with water. Recrystallization from ethanol gave 5-benzylidene-3-methylthiazolidine-2,4-dione (**6a**); yield, 48%; mp 133—134°C (lit,[3] 134—135°C).

The Reaction of Ethyl Thiocyanoacetate (1) with Benzaldehyde in the Presence of Thiourea. A mixture of the ester **1** (0.02 mol), benzaldehyde (0.02 mol), and thiourea (0.02 mol) in ethanol (20 m*l*) was refluxed for 3 hr. A crystalline precipitate was deposited during the reaction; this was collected on a filter and washed with ethanol. Recrystallization from dimethyl sulfoxide gave 5-benzylidene-2-imino-4-thiazolidinone (**5a**); yield, 37%; decomp. 282—284°C (lit,[3] decomp. 282—284°C).

The Reaction of Ethyl Thiocyanoacetate (1) with N-*Methylthiourea.* The ester **1** (0.02 mol) was added, drop by drop at approximately 60°C, to a mechanically-stirred solution of *N*-methylthiourea (0.02 mol) in 20 m*l* of ethanol. Stirring was continued for 3 hr. After the solvent had then been removed with a vacuum evaporater, the residue was allowed to stand overnight. The precipitate which thus formed was separated by filtration, washed with water, and recrystallized to give *N*-methyl-*N*-thiocarbamoyl thiocyanoacetamide (**2a**); yield, 25%; decomp. 175—178°C.

IR (KBr): near 3300 (NH), near 2500 (SH), 2050 (SCN), 1670 (C=O), 1650 (C=N) cm^{-1}.

Found: C, 31.71; H, 3.69; N, 21.43; S, 33.81%. Calcd for $C_5H_7ON_3S_2$: C, 31.75; H, 3.73; N, 22.22; S, 33.83%.

The Reaction of Ethyl Thiocyanoacetate (1) with N,N-*Dimethylthiourea.* A mixture of the ester **1** (0.02 mol) and *N,N'*-dimethylthiourea (0.02 mol) in ethanol (20 m*l*) was refluxed for 2 hr. The resulting precipitate was collected on a filter and washed with water. Recrystallization from ethanol gave *N,N'*-dimethyl-*N*-thiocarbamoyl thiocyanoacetamide (**2b**); yield, 68%; mp 174—175°C.

IR (KBr): near 2550 (SH), 2050 (SCN), 1750 (C=O, 1640 (C=N) cm^{-1}.

Found: C, 35.51; H, 4.50; N, 20.89; S, 31.67%. Calcd for $C_6H_9ON_3S_2$: C, 35.47; H, 4.47; N, 20.69; S, 31.50%.

The Reaction of Ethyl Thiocyanoacetate (1) with N,N'-*Diethylthiourea.* A solution which contained the ester **1** (0.02 mol) and *N,N'*-diethylthiourea (0.02 mol) in ethanol (20 m*l*) was refluxed for 4 hr. After the solvent had then been removed with a vacuum evaporator, the residue was allowed to stand for several days. The crystalline matter thus formed was collected, washed with water, and air-dried. Recrystallization from ethanol–water gave *N,N'*-diethyl-*N*-thiocarbamoyl thiocyanoacetamide (**2c**); yield, 21%; mp 96—97°C.

Found: C, 41.52; H, 5.66; N, 18.31; S, 27.73%. Calcd for $C_8H_{13}ON_3S_2$: C, 41.56; H, 5.67; N, 18.18; S, 27.73%.

The Reaction of Ethyl Thiocyanoacetate (1) with Thiourea. Thiourea (0.02 mol) was stirred in ethanol (20 m*l*) at approximately 60°C; the stirring was then continued until the thiourea was completely dissolved. To a stirred alcoholic solution there was then added, drop by drop, the ester **1** (0.02 mol) over a 0.5-hr period. After this addition, stirring was continued for an additional 4 hr, and then the reaction mixture was allowed to stand for several hours. The crystalline matter thus formed was collected and washed with ethanol. Recrystallization from acetic acid gave 2-imino-4-thiazolidinone; yield, 19%; decomp. 232—235°C (lit,[5] 233—238°C).

The Reaction of N,N'-*Dimethyl*-N-*thiocarbamoyl Thiocyanoacetamide (***2b***) with Benzaldehyde in the Presence of* N,N'-*Dimethylthiourea.* A solution of the amide **2b** (0.01 mol) benzaldehyde (0.01 mol), and *N,N'*-dimethylthiourea (0.0025 mol) in ethanol (30 m*l*) was refluxed for 4 hr. After cooling, a crystalline matter separated; this was recrystallized from ethanol to afford benzylidene *N,N'*-dimethyl-*N*-thiocarbamoyl thiocyanoacetamide (**3a**); yield, 65%.

The Reaction of N,N'-*Dimethyl*-N-*thiocarbamoyl Thiocyanoacetamide (***2b***) with Benzaldehyde in the Presence of Potassium Carbonate or Fluoride.* To a solution of the (**2b**) amide (0.01 mol) and benzaldehyde (0.01 mol) in ethanol (20 m*l*), potassium carbonate or fluoride (0.01 mol) was added, after which the mixture was refluxed for a suitable period. After standing overnight, the resulting precipitate was collected on a filter and washed with water. Recrystallization from ethanol gave 5-benzylidene-2-methylimino-3-methyl-4-thiazolidinone (**5c**); mp 109—110°C.

When potassium carbonate was used as the catalyst, the reaction time was 2 hr and the yield was 54%.

When potassium was used as the catalyst, the reaction time was 7 hr and the yield was 58%.

IR (Nujol): 1750 (C=O), 1660 (C=N), 1620 (C=C) cm^{-1}.

NMR (DMSO-d_6): δ 3.20, 3.40 (CH_3), 6.05 (C_6H_5), 6.15 (=CH) ppm.

Found: C, 61.89; H, 5.20; N, 12.04; S, 13.74%. Calcd for $C_{12}H_{12}ON_2S$: C, 62.06; H, 5.21; N, 12.06; S, 13.77%.

The Reaction of Benzylidene N,N'-*Dimethyl*-N-*thiocarbamoyl Thiocyanoacetamide (***3a***) in the Presence of Potassium Carbonate or Fluoride.* A mixture of the amide **3a** (0.01 mol) in ethanol (20 m*l*) containing potassium carbonate or fluoride (0.01 mol) was refluxed for a suitable period. After the mixture had then stood overnight, the precipitate formed was separated by filtration, washed with water, and recrystallized from ethanol to afford 5-benzylidene-2-methylimino-3-methyl-4-thiazolidinone (**5c**).

When potassium carbonate was used as the catalyst, the reaction time was 2 hr and the yield was 56%.

When potassium fluoride was used as the catalyst, the reaction time was 6 hr and the yield was 58%.

The Hydrolysis of Benzylidene N,N'-*Dimethyl*-N-*thiocarbamoyl Thiocyanoacetamide (***3a***).* To a solution containing concentrated hydrochloric acid (10 m*l*) and ethanol (10 m*l*), we added the amide **3a** (0.01 mol), and then the mixture was refluxed for 6 hr. After cooling, the reaction mixture was poured onto cracked ice. The crystalline matter thus formed was collected, washed with water, and air-dried. Recrystallization from ethanol gave 5-benzylidene-3-methylthiazolidin-2,4-dione (**6a**); yield, 52%; mp 133—134°C (lit,[3] 134—135°C).

The Hydrolysis of 5-Benzylidene-2-methylimino-3-methyl-4-thiazolidinone. The procedure used was essentially the same as that described above; yield, 53%; mp 133—134°C.

The Reaction of 2-Methylimino-3-methyl-4-thiazolidinonew ith Benzaldehyde. 2-Methylimino-3-methyl-4-thiazolidinone was prepared according to the procedure described in the literature.[4]

A mixture of 2-methylimino-3-methyl-4-thiazolidinone (0.01 mol) and benzaldehyde (0.01 mol) in ethanol (10 m*l*) containing potassium acetate (0.01 mol) was refluxed for 4 hr. After the solvent had been removed, the residue was allowed to stand overnight. The resulting crystals were collected on a filter. Recrystallization from ethanol gave 5-benzylidene-2-methylimino-3-methyl-4-thiazolidinone (**5c**); yield, 56%; mp 109—110°C.

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa and Heinosuke Yasuda for their kind advice and encouragement, and Dr. Haruo Homma and his staff for their microanalyses.

The Michael Reactions of Substituted 9,9′-Bifluorenylidenes with 2-Iodo- and 2,7-Diiodofluorene, and Some Other Reactions of Iodofluorenes[1,2]

Masahiro MINABE and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya

(Received September 28, 1971)

The Michael-addition reaction between 2-iodofluorene and 9,9′-bifluorenylidene gave exclusively the normal addition product. The same reaction of fluorene with 2,2′-diiodo-9,9′-bifluorenylidene, of 2,7-diiodofluorene with 9,9′-bifluorenylidene, and of fluorene with 2,7,2′,7′-tetraiodo-9,9′-bifluorenylidene afforded not only the normal adducts, but also some abnormal compounds. Some new iodo-substituted fluorenes, -9,9′-bifluorenylidenes, -9,9-bifluorenyls, and -1,4-bis(2,2′-biphenylylene)-1,3-butadienes, were synthesized. The hydrogenolyses of 2- or 2,7-di-iodofluorene with lithium aluminum hydride, Raney nickel, and hydriodic acid were performed relatively smoothly to give fluorene. The Grignard and the Ullmann reactions of 2- or 2,7-di-iodofluorene gave the usual, expected compounds, accompanied by some unusual products. The cyano-substituted fluorenes were prepared by the reaction of 2- or 2,7-diiodofluorene with potassium cyanide-cupric cyanide in *N,N*-dimethylformamide.

The Michael reaction[3] of 9,9′-bifluorenylidene (**7**) with 2,7-dibromofluorene gave an abnormal product, 2,7,2″,7″-tetrabromo-9,9′,9′,9″-terfluorenyl, as the main product, and the normal addition product, 2,7-dibromo-9,9′,9′,9″-terfluorenyl, as a by-product. The similar addition of fluorene (**1**) to 2,7,2′,7′-tetrabromo-9,9′-bifluorenylidene afforded three abnormal products, 2,7-dibromo-9,9′,9′,9″-terfluorenyl and 2,7,2″,7″-tetrabromo-9,9′,9′,9″-terfluorenyl, as the main products, and 9,9′,9′,9″-terfluorenyl (**22**), and the normal addition product, 2,7,2′,7′-tetrabromo-9,9′,9′,9″-terfluorenyl, as by-products.

An analogous reaction[2] of 2-fluorofluorene with **7** in the presence of a sodium hydroxide–pyridine solution or sodium ethoxide in ethanol gave exclusively the normal addition product, 2-fluoro-9,9′,9′,9″-terfluorenyl. Also, 2,2′-difluoro-9,9′,9′,9″-terfluorenyl, 2,7-difluoro-9,9′,9′,9″-terfluorenyl, and 2,7,2′,7′-tetrafluoro-9,9′,9′,9″-terfluorenyl were obtained as normal main products by similar reactions of **1** with 2,2′-difluoro-9,9′-bifluorenylidene, of 2,7-difluorofluorene with **7**, and of **1** with 2,7,2′,7′-tetrafluoro-9,9′-bifluo-renylidene respectively.

The present paper will deal with the Michael reaction of iodo-substituted 9,9′-bifluorenylidenes with fluorenes and will attempt to elucidate some effects due to the difference between iodo-substitutions. It will also compare a few reactions in 2-iodofluorene (**2**)[4] or 2,7-diiodofluorene (**3**)[4b,4c,4e,5] with other, corresponding halogeno derivatives.

The Michael reaction of **7** with **2** in the presence of potassium hydroxide–pyridine gave 2-iodo-9,9′,9′,9″-terfluorenyl (**15**), 2-iodofluorenone (**5**)[4a,4d,4e,4f] and fluorenone (**4**). The yield of **15** increased with the increase in the base concentration, as is shown in Table 1.

The same reaction of 2,2′-diiodo-9,9′-bifluorenylidene (**8**)[6] with **1** afforded 2,2′-diiodo-9,9′,9′,9″-terfluorenyl (**16**), 2,2″-diiodo-9,9′,9′,9″-terfluorenyl (**17**), **4**, and **5**. The yield of **17** increased as the base concentration increased, while, on the contrary, the yield of **16** decreased, as is shown in Table 2. Compounds **16** and **17** are isomeric, and their structures were estimated by comparing the fragmentation peaks in the mass spectra.

An analogous reaction between **7** and **3** yielded 2,7-diiodo-9,9′,9′,9″-terfluorenyl (**19**), 2,7,2″,7″-tetraiodo-9,9′,9′,9″-terfluorenyl (**21**), and **22** as both normal and abnormal addition products, and 2,7-diiodofluorenone (**6**)[4e,5] and **4** as elimination products, as is shown in Table 3. The yields of these reaction products are closely related with the base concentration and with the molar ratio of the reactants.

2,2′,2″-Triiodo-9,9′,9′,9″-terfluorenyl (**18**) and 2,7,2′,7′,2″,7″-hexaiodo-9,9′,9′,9″-terfluorenyl (**23**) were obtained by the reactions of **2** with **8**, and of **3** with 2,7,2′,7′-tetraiodo-9,9′-bifluorenylidene (**9**). These products could be obtained as normal products, but the stereoisomeric 9,9′,9′,9″-terfluorenyls[7] were not isolated.

In the reaction of **9** with **1**, 2,7,2′,7′-tetraiodo-9,9′,9′,9″-terfluorenyl (**20**), **19**, **21**, **22**, **3**, **4**, and **6** were separated.

The sequences for the formation of the compounds in these Michael reactions can be represented by the typical reaction of **9** with **1** as is illustrated in Scheme 1. A transitory carbanion (D) is formed by the nucleophilic attack of the fluorenyl carbanion (**1′**) generated from **1** on the highly-polarized ethylenic carbons of **9** in the presence of the base. Subsequently, D may be transformed to the normal addition product, **20**, by protonation, but then, the D dis-

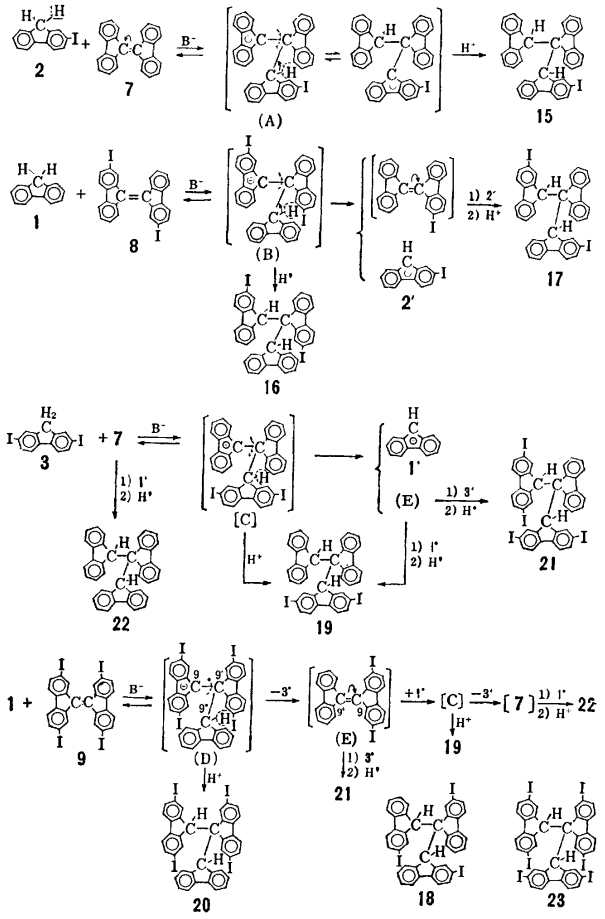
sociates into **3'** and the intermediate 2,7-diiodo-9,9'-bifluorenylidene (E)[8] by the fission of the 9-9' carbon-carbon bond, with the elimination of the 9''-proton. Therefore, the anomalous formation of **21** can be explained by a secondary Michael reaction of **3'** with (E), followed by protonation.

The reaction of E with **1'** gives the carbanion (C), which then yields an abnormal product, **19**. Further, the complete process of formation to the iodine-free compound, **22**, involves three additions and two eliminations through the two intermediates, (D and C), under consideration. Moreover, **3**, **4**, and **6** were also isolated by elimination or oxidation reactions in the process.[9]

Meanwhile, the 9-methylene hydrogen in 2-halo- or 2,7-dihalo-fluorenes are more reactive in forming fluorenyl carbanions than that in the parent fluorene in the Michael reaction. For this reason, the electron-withdrawing effect[10] of these substituents may operate on the 9-carbon atom in fluorenes. Moreover, the base concentration seems to be an important factor in the 9-methylene hydrogen.

In view of this effect, the ethylenic 9-carbon in E, for example, is more electronegative than the 9'-carbon,



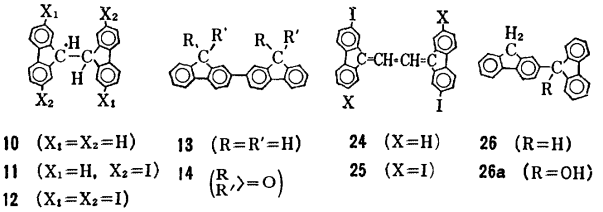
Scheme 1.

8) The Michael reaction of **7** with 2-bromofluorene afforded a trace amount of 2-bromo-9,9'-bifluorenylidene. And therefore, (E) or 2-iodo-9,9'-bifluorenylidene can be regarded as intermediates in this series. See K. Suzuki and M. Fujimoto, This Bulletin, **37**, 1833 (1964).

and the addition of **3'** is preferential in forming the 9'-carbon leading to **21** than the other possible way. These effects were supported experimentally by the corresponding bromo derivatives[3] in the analogous Michael reaction. The crowded carbanions, for example, C and D, which contain bulky iodine atoms, might be reactive because of the steric compression. Therefore, under reasonably mild reaction conditions, the addition products are chiefly normal compounds. However, the reaction is accelerated toward elimination upon an increase in the alkali concentration.

Because there is more active iodine than any other halogen on the 2- or 2,7-positions of fluorene, attempts at the step-by-step syntheses of iodine-substituted 9,9',9',9''-terfluorenyls were unsuccessful. However, we are able to estimate the positions of iodine by comparing the melting points and the mass and IR spectra of iodo-9,9',9',9''-terfluorenyls with those of the bromo-[3] and chloro-[11] analogues.

Barnett and others[4d] reported that 2,2'-bifluorenyl-9,9'-dione (**14**) was obtained by the Ullmann reaction of **5**, even though no 2,2'-bifluorenyl (**13**) was formed from **2**. The syntheses of these compounds were re-investigated by the Ullmann reaction; 42% of **14** was obtained from **5**, and 9% of **13** from **2**. In addition, a considerable amount of **1** was formed from **2**. The same reaction of **3** gave 15% of **1** instead of a polymeric substance upon dehalogenation.



10 ($X_1=X_2=H$) **13** ($R=R'=H$) **24** ($X=H$) **26** ($R=H$)
11 ($X_1=H$, $X_2=I$) **14** ($R,R'>C=O$) **25** ($X=I$) **26a** ($R=OH$)
12 ($X_1=X_2=I$)

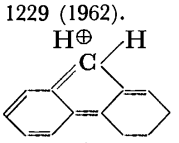
Scheme 2.

The iodine atoms in **2** and **3** were completely removed by reaction with Raney nickel, lithium aluminum hydride, or hydriodic acid. However, no reaction occurred at all for 2-bromofluorene and 2,7-dibromofluorene[12] under the same conditions.

The reaction of **2** with ethylmagnesium bromide afforded **1**, 2-ethylfluorene, and **13**. The yield of the anticipated compound, 2-ethylfluorene, was, however, very low, and **1** and **13** were unexpectedly ob-

9) A small amount of **3** can be oxidized to **6** under these reaction conditions.

10) The high reactivity of fluorene is due to the coplanarity enforced by the 9-methylene bridge. And the activation of 9-methylene group is attributable to enhanced hyperconjugation between the aromatic rings. See for example, P. B. D. de la Mare, D. M. Hall, M. M. Harris, and M. Hassan, *Chem. Ind.* (London), **1958**, 1086; H. C. Brown, M. Bubeck, and G. Goldman, *J. Amer. Chem. Soc.*, **84**, 1229 (1962).



11) K. Suzuki and M. Minabe, unpublished.

12) 2,7-Dibromofluorene, however, was reduced to **1** by refluxing with Raney nickel in xylene; see A. Schoenberg, K. H. Brosowski, and E. Singer, *Chem. Ber.*, **95**, 2984 (1962).

tained in relatively high yields. The formation of **1** and **13** can be regarded as occurring by means of the reaction between **2** and magnesium, which was activated by ethyl bromide, followed by hydrolysis or alkylation. **1** was obtained in a 60% yield from **2** following the procedure of Morrison.[13]

The synthesis of 2,9′-bifluorenyl (**26**)[14] was examined by interaction between 2-fluorenylmagnesium iodide and 9-bromofluorene, but 9,9′-bifluorenyl (**10**), **13**, and **1** were afforded. These results can be explained in terms of the reactions of 9-fluorenylmagnesium bromide with 9-bromofluorene and of 2-fluorenylmagnesium iodide with **2** respectively. The reaction of 2-fluorenylmagnesium iodide with **4** afforded **26**, but not 9′-hydroxy-2,9′-bifluorenyl (**26a**). The interpretation of the unusual formation is not yet clear.

The synthesis of α-cyanonaphthalene, as has been reported by House and Fischer,[15] was adapted to the syntheses of 2-cyanofluorene derivatives. The reaction of **2** with potassium cyanide–cupric cyanide gave 2-cyanofluorene[16] and a small amount of 2-cyanofluorenone. Similarly, 2,7-dicyanofluorene and 2,7-dicyanofluorenone were obtained from **3**. The melting point of 2-cyanofluorene was 91—92°C,[16a] slightly different from that of the literature;[16b,16c] the structure of this compound was assigned by elemental analysis and by means of the IR and mass spectra. If 2-cyanofluorene is contaminated by a small amount of impurities, **1** and/or **2**, the mass spectra can be expected to be 166 and 292 *m/e*. However, neither fragmentation was observed.

Experimental[17]

The IR spectra were recorded on KBr pellets using a JASCO model IR-G spectrophotometer (Japan Spectroscopic Co., Ltd.). The gas chromatograms were obtained by means of GCG-550T gas chromatograph (Yanagimoto Mfg. Co., Ltd.), using a column containing 5% of Silicone SE-30 on Celite 545-AW. The mass spectra were measured with a model RMU-6E apparatus (Hitachi, Ltd.) by means of the direct inlet system. The sample evaporating temper-

17) All the melting points are uncorrected. The identities of the compounds in this series were confirmed by mixed-melting-point determinations and by comparison of IR absorption spectra with those of authentic samples.

ature, chamber volt, total emission, and target current were maintained at 200°C, 80 V, 80 μA, and 50 μA respectively.

3 (mp 215—216.5°C) was synthesized in a 75% yield from **2** in a manner similar to that used for **2**[4a]; it was then converted to the corresponding ketone, **6** (80%); mp 207—208°C; IR (>C=O): 1716 cm^{-1}.

2-Iodofluorenol. A mixture of 5.2 g of **5**, 53 g of zinc dust, 220 m*l* of ethanol, and 5 g of calcium chloride in 10 m*l* of water was refluxed for 1 hr. The reaction mixture was then filtered, and the filtrate was poured into water. The precipitate was recrystallized from benzene-cyclohexane (1 : 1). Colorless needles; mp 121—123°C; yield 1.22 g (23%). IR (>OH): 3190 cm^{-1}. Found: C, 50.95; H, 2.88%. Calcd for $C_{13}H_9OI$: C, 50.68; H, 2.94%.

2,7-Diiodofluorenol. A 1.3-g portion of **6** was treated under the conditions described above to yield 1.02 g (78%) of 2,7-diiodofluorenol as fine, colorless needles; mp 201.5—203°C (decomp. to yellow). IR (-OH): 3270 cm^{-1}. Found: C, 36.13; H, 1.74%. Calcd for $C_{13}H_8OI_2$: C, 35.98; H, 1.86%.

2-Iodo-9-bromofluorene. a): A mixture of 8.76 g (0.03 mol) of **2**, 5.60 g of *N*-bromosuccinimide (NBS), and 50 m*l* of dry benzene was refluxed for 3 hr to afford 7.10 g (64%) of 2-iodo-9-bromofluorene; mp 126—127°C (from cyclohexane). Found: C, 42.36; H, 1.96%. Calcd for $C_{13}H_8BrI$: C, 42.09; H, 2.17%.

b): 2-Iodofluorenol (1.03 g) was brominated by hydrogen bromide in acetic acid to yield 0.75 g (53%) of the product; mp 126—127°C.

2,7-Diiodo-9-bromofluorene: a): A 2.1-g portion of **3** was worked up with NBS (1.0 g) to yield 1.6 g (64%) of 2,7-diiodo-9-bromofluorene; mp 204—205°C (from benzene and cyclohexane). Found: C, 31.43; H, 1.22%. Calcd for $C_{13}H_7BrI_2$: C, 31.42; H, 1.42%.

b): **3** (8.4 g; 0.02 mol) was dissolved in 150 m*l* of benzene, and then a trace amount of benzoyl peroxide was added. Into this boiling mixture there was stirred a solution of benzene containing 3.5 g (0.022 mol) of bromine under the irradiation with UV light for 15 min. After the mixture had been left standing to cool, 4.0 g of 2,7-diiodo-9-bromofluorene (mp 204—205°C) were collected by filtration. The mother solution was then treated as usual to afford an additional 2.3 g (total 6.3 g; 63%) of the product.

Furthermore, a small amount of 2,7-diiodo-9,9-dibromofluorene (mp 230—232°C) was isolated. Found: C, 27.30; H, 0.93%. Calcd for $C_{13}H_6Br_2I_2$: C, 27.56; H, 1.06%.

c): The bromination of 2,7-diiodofluorenol (15 g in 1 *l* of acetic acid) with hydrogen bromide yielded 7.7 g (45%) of the same compound; mp 204—205°C.

*1,4-Bis(4-iodo-2,2'-biphenylylene)-1,3-butadiene (**24**)*: A mixture of 1.46 g (0.005 mol) of **2**, 55 m*l* of ethanol, and 2.5 g of potassium hydroxide in 5 m*l* of water was refluxed under a gentle stream of air for 20 hr. The deposited product was then recrystallized from pyridine to yield 1.01 g (67%) of **24** (mp 405—405°C (decomp.)) as orange-red needles. Found: C, 55.50; H, 2.48%. Calcd for $C_{28}H_{16}I_2$: C, 55.47; H, 2.66%.

*1,4-Bis(4,4'-diiodo-2,2'-biphenylylene)-1,3-butadiene (**25**)*: The compound was prepared in a 54% yield by the same procedure; red needles; mp 455°C (decomp.). Found: C, 39.17; H, 1.25%. Calcd for $C_{28}H_{14}I_4$: C, 39.20; H, 1.64%.

*2,2'-Diiodo-9,9'-bifluorenylidene (**8**)*: An acetone solution (110 m*l*) containing 3.71 g (0.01 mol) of 2-iodo-9-bromofluorene was refluxed for 5 hr with potassium hydroxide-methanol (0.56 g/20 m*l*) to afford 1.91 g (66%) of red **8**; 262—263°C. Found: C, 53.48; H, 2.17%. Calcd for $C_{26}H_{14}I_2$: C, 53.82; H, 2.43%.

*2,7,2',7'-Tetraiodo-9,9'-bifluorenylidene (**9**)*: To a mixture of 10.0 g (0.02 mol) of 2,7-diiodo-9-bromofluorene and 3 *l* of methyl ethyl ketone, was added 30 m*l* of methanol containing equimolar sodium hydroxide at 5—8°C over a period of 15 min. Thereupon, the reaction mixture was worked up by the two following methods.

a) After stirring for 2 hr, the precipitate was filtered off, washed with water, dried, and washed with 50 m*l* of boiling benzene to afford 5.6 g (67%) of **9** (mp 425°C (decomp.)). Found: C, 37.51; H, 1.69%. Calcd for $C_{26}H_{12}I_4$: C, 37.54; H, 1.45%.

b) The other reaction mixture, which was prepared from 4.0 g of 2,7-diiodo-9-bromofluorene, was refluxed for 20 hr to yield 2.01 g (60%) of **9** (mp 423°C (decomp.)), 0.98 g (28%) of **6** (mp 206—207°C), and 0.01 g (0.3%) of **23** (mp 316—318°C (decomp.)).

*Reduction of **8**.* A mixture of 0.58 g (0.001 mol) of **8**, 700 m*l* of acetic acid, 10 g of zinc granule and 100 m*l* of concentrated hydrochloric acid was refluxed for 1.5 hr. The reaction mixture was evaporated to dryness, and the residue was recrystallized from ethyl acetate to afford 0.12 g (21%) of **8** (mp 260—262°C) and 0.18 g (31%) of 2,2'-diiodo-9,9'-bifluorenyl (**11**) (mp 287—288°C (decomp.) (from benzene)). Found: C, 53.77; H, 2.64%. Calcd for $C_{26}H_{16}I_2$: C, 53.64; H, 2.77%.

*The Michael Reaction of 9,9'-Bifluorenylidene (**7**) with 2-Iodofluorene (**2**).* A mixture of 2.19 g (1/150 mol) of **7**, 1.95 g (1/150 mol) of **2**, 28 m*l* of pyridine, and 3.0 g (10% for the solvent) of potassium hydroxide in 2 m*l* of water was placed in a sealed tube and heated at 97—100°C for 7 hr. The reaction mixture was then poured into 500 m*l* of water, and the precipitate was recrystallized from cyclohexane and then from benzene to give 3.02 g of **15** (mp 272—274°C (decomp.)). The analytical sample was recrystallized from *N,N*-dimethylformamide (DMF) and then from benzene. Found: C, 75.75; H, 3.90%. Calcd for $C_{39}H_{25}I$: C, 75.49; H, 4.06%.

The subsequent evaporation of the mother liquor *in vacuo* and chromatography on alumina in benzene gave an additional 0.04 g (total 3.06 g; 74%) of **15** (mp 271—274°C (decomp.)), 0.08 g (3%) of **4** (mp 81—82°C), and 0.10 g (5%) of **5** (mp 148—150°C).

*The Michael Reaction of 2,2'-Diiodo-9,9'-bifluorenylidene (**8**) with Fluorene (**1**).* A mixture of 2.32 g (0.004 mol) of **8**, 0.83 g (0.005 mol) of **1**, 28 m*l* of pyridine, and 3.0 g of potassium hydroxide in 2 m*l* of water was heated at 98—100°C for 8 hr in a sealed tube. The reaction mixture was then treated in a manner analogous to that described above to yield 0.90 g (30%) of **16** (mp 261—262°C (decomp.)) and 1.10 g (37%) of **17** (mp 281—282°C (decomp.)) from benzene and ethyl acetate. Anal for **16**. Found: C, 62.60; H, 3.07%. Calcd for $C_{39}H_{24}I_2$: C, 62.76; H, 3.24%. Mass (M^+): 746 *m/e*. For **17**. Found: C, 62.75; H, 3.47%. Calcd for $C_{39}H_{24}I_2$: C, 62.76; H, 3.24%. Mass (M^+): 746 *m/e*.

Although the compounds **16** and **17** are isomeric to each other, we have speculated on these structures by comparing the IR spectra, melting points, and relative intensities of the fragment ions in the mass spectra.

In addition, 0.08 g (10%) of **1** (mp 111—112.5°C) and 0.15 g (6%) of **5** (mp 149—150.5°C) were isolated by alumina column chromatography.

*The Michael Reaction of 2,2'-Diiodo-9,9'-bifluorenylidene (**8**) with 2-Iodofluorene (**2**).* A mixture of 2.32 g (0.004 mol) of **8**, 1.46 g (0.005 mol) of **2**, 28 m*l* of pyridine, and 1.5 g of potassium hydroxide in 2 m*l* of water was placed in a

sealed tube; then the mixture was heated in boiling water for 10 hr. The precipitate formed upon dilution with 400 ml of water was sublimed at 160°C. The sublimate afforded 0.15 g of **2** (mp 126—128°C) and 0.03 g of **5** (mp 146—147°C) by alumina-column chromatagraphy. The sublimation residue was recrystallized from ethyl acetate and then from benzene to afford 1.49 g (43%) of **18** (mp 281—282°C (decomp.)). Found: C, 54.06; H, 2.41%. Calcd for $C_{39}H_{23}I_3$: C, 53.70; H, 2.66%.

Further, 0.07 g of **8** (mp 258—261°C) was recovered from the mother solution.

*The Michael Reaction of 9,9'-Bifluorenylidene (**7**) with 2,7-Diiodofluorene (**3**).* A mixture of 2.2 g (1/150 mol) of **7**, 2.8 g (1/150 mol) of **3**, 28 ml of pyridine, and 0.3 g of potassium hydroxide in 2 ml of water was heated at 95—100°C for 2.5 hr. During this period, the reaction mixture turned dark and colorless crystals were deposited.

The crude product was recrystallized from benzene to afford 2.69 g of **19** (mp 286—288°C (decomp.)). The pyridine mother liquor was then poured into water, and the deposited product was separated by a combination of recrystallization, alumina-column chromatography, and vacuum sublimation to yield 1.00 g (total 3.69 g; 74%) of **19** (mp 287—288°C (decomp.)), 0.10 g (3%) of **21** (mp 307—307.5°C (decomp.)), 0.12 g of **6** (mp 205—207°C), 0.01 g of **4** (mp 81—82°C), 0.08 g of **3** (mp 213—214°C), and 0.13 g of **7** (mp 180—182°C). Anal for **19**. Found: C, 62.75; H, 3.15%. Calcd for $C_{39}H_{24}I_2$: C, 62.76; H, 3.24%. For **21**. Found: C, 46.86; H, 1.95%. Calcd for $C_{39}H_{22}I_4$: C, 46.93; H, 2.22%.

*The Michael Reaction of 2,7,2',7'-Tetraiodo-9,9'-bifluorenylidene (**9**) with Fluorene (**1**).* **1** (4.2 g, 0.025 mol) also underwent a similar reaction with **9** (4.2 g, 0.005 mol) in 112 ml of pyridine in the presence of potassium hydroxide (1.2 g; 1% for the solvent) in 8 ml of water at 95—100°C for 20 hr.

The following compounds were thus obtained; 0.47 g of **19** (mp 286—287°C (decomp.)), 0.09 g of **20** (mp 299—300°C (decomp.)), 0.17 g of **21** (mp 312—314°C (decomp.)), 0.02 g of **22** (mp 290—292°C (decomp.)), 0.89 g of **3** (mp 213—215°C), 0.23 g of **6** (mp 205—207°C), and 0.04 g of **4** (mp 83—84°C). In addition, 1.73 g of **1** (mp 113—114°C) and 0.03 g of **9** (mp 423—424°C (decomp.)) were recovered. Anal for **20**. Found: C, 46.84; H, 2.03%. Calcd for $C_{39}H_{22}I_4$: C, 46.93; H, 2.22%. For **21**. Found: C, 46.89; H, 2.31%. Calcd for $C_{39}H_{22}I_4$: C, 46.93; H, 2.22%. For **19**. Found: C, 63.11; H, 3.29%. Calcd for $C_{39}H_{24}I_2$: C, 62.76; H, 3.24%.

The **20** and **21** compounds are isomeric, and we estimated their structures by comparing the mass and IR spectra and melting points.

*The Michael Reaction of 2,7,2',7'-Tetraiodo-9,9'-bifluorenylidene (**9**) with 2,7-Diiodofluorene (**3**).* A 2.9-g portion of **3** was allowed to react with 1.11 g of **9** (mol. ratio 5/1), using 0.3 g of potassium hydroxide as a catalyst in 30 ml of pyridine for 55 hr. The reaction mixture was then worked up as usual. Thus, 0.14 g (9%) of **23** (mp 318—319°C (decomp.) and 1.00 g (90%) of recovered **9** (mp 424°C (decomp.)) were isolated. Also, 0.31 g (10%) of **6** (mp 207—207.5°C) and 2.20 g (76%) of **3** (mp 216—217°C) were obtained from the mother solution by alumina-column chromatography. Found for **23**: C, 37.70; H, 1.50%. Calcd for $C_{39}H_{20}I_6$: C, 37.47; H, 1.61%.

Under other conditions, **3** (1.67 g) was allowed to react with **9** (1.11 g) (mole ratio 3/1), using sodium ethoxide (10% for the solvent) in absolute ethanol (30 ml) for 40 hr; 0.66 g of **9** (mp 424°C (decomp.)) and a compound (mp 323—324°C (decomp.) (0.23 g)) were thus isolated. Found for compound with mp 323—324°C (decomp.): C, 37.63; H, 1.45%. Calcd for $C_{26}H_{14}I_4$: C, 37.44; H, 1.69%.

The IR spectrum of this compound resembles that of halogen-substituted 9,9'-bifluorenyl; hence, the compound is presumably a reduction product, 2,7,2',7'-tetraiodo-9,9'-bifluorenyl (**12**).

*The Ullmann Reaction of 2-Iodofluorene (**2**) and 2,7-Diiodofluorene (**3**).* *a)*: A mixture of 3.0 g of **2** and 6.0 g of activated copper bronze[18] was heated in a sealed tube at 150°C for 20 hr to give 0.15 g (9%) of **13** (mp 316°C (lit,[4d] mp 316.5—318°C)) and 0.36 g (22%) of **1** (mp 110—112°C).

In another reaction, in which a mixture of 1.5 g of **2**, 10 g of zinc-copper couple,[19] and 30 ml of dry xylene was refluxed for 19 hr, 0.225 g (27%) of **1** (mp 111—112.5°C) was isolated.

b): A mixture of 4.0 g of **3** and 8.0 g of a zinc-copper couple was treated in a sealed tube at 230°C for 20 hr to afford 0.25 g (15%) of **1** (mp 113—114.5°C).

*Hydrogenolyses of 2-Iodofluorene (**2**) and 2,7-Diiodofluorene (**3**).* *a)*: A suspension of 5.0 g of Raney nickel (W-7)[20] in 150 ml of ethanol containing 1.46 g of **2** was shaken under an atmospheric pressure of hydrogen at room temperature for 2 hr. The reaction mixture was then filtered from Raney nickel, and the nickel was washed with 100 ml of ethanol. The combined filtrate was concentrated to dryness under reduced pressure, and the residue was washed with water, dried, and recrystallized from ethanol to yield 0.73 g (88%) of **1** (mp 112—113°C).

b) A mixture of 2.09 g of **3**, 50 ml of tetrahydrofuran, and 10 g of Raney nickel was worked up in a manner similar to Method a) to give 0.70 g (84%) of **1** (mp 111—113°C).

*Reduction of 2-Iodofluorene (**2**) and 2,7-Diiodofluorene (**3**) with Lithium Aluminum Hydride.* *a)* To the stirring mixture of 0.38 g of lithium aluminum hydride and 40 ml of dry dioxane, was added, drop by drop, 2.92 g (0.01 mol) of **2** in 60 ml of dry dioxane at room temperature; the resulting solution was then refluxed for 4 hr. Upon concentration, the precipitate was decomposed with 100 ml of 10% hydrochloric acid, washed with water, dried, and recrystallized from ethanol; 1.36 g (47%) of recovered **2** (mp 124—125°C) and 0.84 g (51%) of **1** (mp 110—112°C (no halogen)) were thus obtained.

b) A 4.18-g portion (0.01 mol) of **3** was treated with 0.76 g of lithium aluminum hydride in 160 ml of dry tetrahydrofuran by the same procedure as in Method a); this afforded 0.48 g (29%) of **1** (mp 111—112°C), 1.43 g (49%) of **2** (mp 123—125°C), and 0.64 g (15%) of recovered **3** (mp 215—216°C).

*Reduction of 2-Iodofluorene (**2**) and 2,7-Diiodofluorene (**3**) with Hydriodic Acid.* *a)*: A mixture of 2.92 g (0.01 mol) of **2**, 5 ml of hydriodic acid, 2 g of red phosphorus, and 50 ml of acetic acid was refluxed for 22 hr. The resulting mixture was filtered, the filtrate was poured into 500 ml of water, and the precipitate was recrystallized from cyclohexane. This compound was confirmed to be **1** (mp 112—114°C; 1.61 g 97%).

b) A 2.09-g portion (0.005 mol) of **3** in 150 ml of acetic acid was allowed to react with 5 ml of hydriodic acid and 2 g of red phosphorus for 22 hr to yield 0.41 g (49%) of **1** (mp 111—113°C), 0.15 g (10%) of **2** (mp 123—125°C), and 0.57 g (27%) of recovered **3** (mp 213—215°C).

18) R. C. Fuson and E. A. Cleveland, "Organic Syntheses", Coll. Vol. III, p. 339 (1955).
19) E. Legoff, *J. Org. Chem.*, **29**, 2048 (1964).
20) H. Adkins and A. A. Pavlic, *J. Amer. Chem. Soc.*, **68**, 1471 (1946).

A 3.24-g portion (0.01 mol) of 2,7-dibromofluorene was worked up as in the case of **3**, but only 3.16 g (98%) of the starting material was recovered.

*Reaction of 2-Iodofluorene (**2**) with Ethylmagnesium Bromide.* A solution of ethylmagnesium bromide (from 0.02 mol of ethyl bromide and 0.04 g atom of magnesium) in ether (40 m*l*) was added to a solution of 2.92 g (0.01 mol) of **2** in 25 m*l* of dry tetrahydrofuran, and the mixture was gently refluxed for 5 hr. The reaction mixture was then worked up as usual, and the crude product was recrystallized from ethanol to yield 0.09 g (6%) of **13** (mp 316—318°C (from benzene)) and 1.03 g of recovered **2** (mp 124—126°C). The ethanol mother liquor was analyzed by means of gas chromatography; 0.16 g (10%) of **1**, 0.04 g (2%) of 2-ethylfluorene, and 0.25 g (total 1.28 g; 44%) of **2** were confirmed.

Reaction of 2-Fluorenylmagnesium Iodide. a) With 9-bromofluorene: To magnesium, which had been activated by ethylmagnesium iodide, in dry tetrahydrofuran (25 m*l*) was added a solution of 25 m*l* of dry tetrahydrofuran containing 2.92 g of **2**; this mixture was refluxed by stirring for 23 hr. Then, a mixture of 2.45 g (0.01 mol) of 9-bromofluorene and 25 m*l* of dry tetrahydrofuran was added, drop by drop, to the foregoing Grignard solution, and the mixture was refluxed for 3 hr.

The reaction mixture was worked up as usual; consequently, 0.52 g (32%) of **10** (mp 242—243°C), 0.46 g (28%) of **13** (mp 312—314°C), and 0.25 g of **1** (mp 113—115°C) were isolated. Found for **13**: C, 94.34; H, 5.41%. Calcd for $C_{26}H_{18}$: C, 94.55; H, 5.45%.

The sodium bichromate oxidation of **13** gave **14** (mp 290—291°C; IR (>C=O): 1710 cm^{-1}; lit,[4d] mp 295—297°C); this compound was identical in all respects with the product obtained by the Ullmann reaction of **5**.

*b) With **4***: 2-Fluorenylmagnesium iodide was prepared in the same manner as has been described above. A 1.80-g portion of **4** in 20 m*l* of tetrahydrofuran was added to the resulting Grignard solution, and the mixture was refluxed for 2 hr to afford 0.13 g (8%) of **26** (mp 224—225°C). In addition, a trace amount of a compound (mp 252—254°C (decomp.)) was isolated, but its structure is not clear at present.

*Reaction of 2-Iodofluorene (**2**) and 2,7-Diiodofluorene (**3**) with Potassium Cyanide-Cupric Cyanide in DMF. a)*: A mixture of 2.92 g of **2**, 1.30 g of potassium cyanide, and 1.79 g of cupric cyanide in 40 m*l* of freshly-distilled DMF was refluxed for 25 hr. During the period, the reaction mixture turned from brown to dark green.

The mixture was then cooled and poured into 500 m*l* of cold water, and 50 m*l* of hydrochloric acid was added. The precipitate was collected and sublimed *in vacuo* at 120°C. The sublimate was recrystallized from 20 m*l* of cyclohexane to yield 1.15 g (60%) of pure 2-cyanofluorene (mp 91—92°C) as colorless needles. (Lit, mp 88°C,[16a] 100.5—101.5°C,[16b] 105°C[16c]). Found: C, 87.82; H, 4.65; N, 7.49%. Calcd for $C_{14}H_9N$: C, 87.93; H, 4.74; N, 7.33%. IR (-CN): 2245 cm^{-1}. Mass: 191 (M^+); 186; 149 *m/e*.

The residual part was further sublimed at 170°C; the sublimate yielded 0.03 g (1%) of 2-cyanofluorenone (mp 175—177°C) as yellow needles (from benzene). Found: C, 82.13; H, 3.38; N, 6.47%. Calcd for $C_{14}H_7NO$: C, 81.94; H, 3.44; N, 6.83%. IR: (-CN) 2245; (>C=O) 1715 cm^{-1}. Mass (M^+): 205 *m/e*.

b): A mixture of 2.09 g of **3**, 1.30 g of potassium cyanide, and 1.79 g of cupric cyanide in 50 m*l* of DMF was refluxed for 25 hr. When the reaction products were sublimed *in vacuo* at 200°C, the sublimate afforded 0.11 g of 2,7-dicyanofluorene (mp 285°C), upon recrystallization from benzene. Found: C, 83.07; H, 4.05; N, 12.70%. Calcd for $C_{15}H_8N_2$: C, 83.32; H, 3.73; N, 12.95%. IR (-CN): 2245 cm^{-1}. Mass (M^+): 216 *m/e*.

The residue of the sublimation was extracted with four 40-m*l* portions of benzene, and 0.12 g of 2,7-dicyanofluorenone (mp 340°C (decomp.)) was obtained from the benzene extract. Found: C, 78.36; H, 2.87%. Calcd for $C_{15}H_6N_2O$: C, 78.26; H, 2.63%. IR: (-CN) 2245; (>C=O) 1715 cm^{-1}.

Photochemical Reactions of 3-Alkyl-4-phenylsydnones[1)]

Yoshiharu HUSEYA, Akiko CHINONE, and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 28, 1972)

Photochemical reaction of 3-cyclohexyl-4-phenylsydnone (**4**) in nitrogen atmosphere afforded 2-cyclohexyl-4,5-diphenyl-1,2,3-triazole (**5**), 1,2-biscyclohexylazo-1,2-diphenylethylene (**6**) and 4-cyclohexyl-2-phenyl-Δ^2-1,3,4-oxadiazoline-5-one (**7**). The results showed that the reaction of **4** in the presence of carbon dioxide, carbon disulfide and dimethyl acetylenedicarboxylate proceeded *via* nitrile imine intermediate. Irradiation of 3-*t*-butyl-4-phenylsydnone (**11**) afforded 1-benzoyl-2-*t*-butyl-4-phenyl-1,2-diazetidine-3-one (**12**). Variation of the absorbance of **4** at the longest wavelength with irradiation was affected by 1,3-pentadiene, but not that of **11**. This shows that the excited triplet state is responsible for the photochemical reaction of **4**.

We reported[2)] that photolysis of 3,4-diarylsydnones afforded 2,4,5-triaryltriazoles *via* bicyclic intermediate (**2**) and nitrile imine (**3**). In this report, we give details on the photolysis of 3,4-diphenylsydnone (**1**) and 3-alkyl-4-phenylsydnones.

From the consideration that the stability of the nitrile imine (**3**) controls the reaction, we investigated the photolysis of 3-alkyl-4-phenylsydnone. 3-Cyclohexyl-4-phenylsydnone (**4**) was prepared by treating α-(*N*-cyclohexyl-*N*-nitrosamino)phenylacetic acid with acetic anhydride. Irradiation of **4** in a dilute benzene solution was carried out with high pressure mercury lamp through a Pyrex filter under nitrogen atmosphere. The reaction was followed by withdrawal of a small aliquot at various time intervals and examination by means of UV spectroscopy. The products were separated by column chromatography and identified as 2-cyclohexyl-4,5-diphenyl-1,2,3-triazole (**5**), 1,2-biscyclohexylazo-1,2-diphenylethylene (**6**) and 4-cyclohexyl-2-phenyl-Δ^2-1,3,4-oxadiazoline-5-one (**7**). The structure of **5** was confirmed on its elementary analysis and spectral data, which were closely similar to those of 2,4,5-triphenyl-1,2,3-triazole. The structure of **6** was deduced from elementary analysis, spectral data and its characteristic red color, but the configuration was not defined unambiguously. The structure of **7** was deduced from its elementary analysis and spectral data. The IR spectrum of **7** exhibited a peak at 1780 cm^{-1} which was attributed to the CO group of 1,3,4-oxadiazoline-5-one. It is noteworthy that the yields of **5** and **6** showed correlation with the period of irradiation. The yield of **5** increased with the increase of the period of irradiation, and that of **6** decreased with the increase of the yield of **5**. The results are in line with the reaction mechanism postulated,[2-5)] in which triazole was originated from bisazoethylene formed by "head to head" interaction of nitrile imine. Additional support for this mechanism was obtained by following examination. In contrast to the photochemical reaction of **1** which did not afford the corresponding oxadiazoline, **7** was obtained predominantly by irradiation of a benzene solution of **4** under carbon dioxide atmosphere. Similarly, when a benzene solution of **4** was irradiated in the presence of carbon disulfide, 4-cyclohexyl-2-phenyl-Δ^2-1,3,4-thiadiazoline-5-thione (**8**) was obtained. Formation of **7** and **8** is explained by the reaction of *N*-cyclohexyl-*C*-phenylnitrile imine with carbon dioxide and carbon disulfide, respectively. It is evident that *N*-cyclohexyl-*C*-phenylnitrile imine is more reactive than *N,C*-diphenylnitrile imine toward dipolarophiles such as carbon dioxide and carbon disulfide. It seems that *N*-phenylnitrile imine, which is an intermediate of the photolysis of 3-phenylsydnone,[6)] reacted preferentially with carbon dioxide, giving no corresponding triazole. 1,3-Dipolar cycloaddition of **4** under irradiation was carried out in the presence of dimethyl acetylenedicarboxylate to give dimethyl 1-cyclohexyl-3-phenylpyrazole-4,5-dicarboxylate (**9**), whose structure was deduced from its composition ($C_{19}H_{22}O_4N_2$) and IR spectrum. Treatment of **4**

with dimethyl acetylenedicarboxylate at 120—140°C afforded a product **A** whose elementary analysis gave the same formula $C_{19}H_{22}O_4N_2$ as that of **9**. A mixed melting point measurement of **A** with **9** showed a depression, and the structure of **A** was assigned to dimethyl 1-cyclohexyl-5-phenylpyrazole-3,4-dicarboxylate (**10**).

The different course of the over-all photoreaction was observed in 3-*t*-butyl-4-phenylsydnone (**11**), prepared by treating α-(*N*-*t*-butyl-*N*-nitrosamino)phenylacetic acid with acetic anhydride. Exposure of a dilute solution of **11** in benzene to a high pressure mercury lamp gave 1-benzoyl-2-*t*-butyl-4-phenyl-1,2-diazetidine-3-one (**12**). Satisfactory analytical data were obtained for **12** whose mass spectral fragmentation pattern was consistent with that of the assigned structure. Compound **12** was obtained even in toluene under the same conditions. It is known that diazetidinones are prepared photochemically by the reaction of azo compounds with ketones.[7] Formation of **12** by the irradiation of **11** may be explained by the intermolecular addition of an excited >N-N- grouping to C=C=O grouping of sydnone, followed by an introduction of benzoyl group through ambiguous mechanism. Dipolar addition of **11** to carbon dioxide, carbon disulfide and dimethyl acetylenedicarboxylate was not successful under irradiation. However, **11** reacted with dimethyl acetylenedicarboxylate in refluxing toluene to give addition product **13**.

The absorption spectra of **1**,**4** and **11** in cyclohexane showed bands at 345 mμ (ε 9750), 325 mμ (ε 10890) and 312 mμ (ε 7090), respectively. A hypsochromic shift in a more polar solvent was observed as shown in Table 1. The absorptions might be assigned to *n*-π*

Table 1. UV spectra

Compound		1	4	11
λ_{max}(cyclohexene)	mμ(ε)	345(9750)	325(10890)	312(7090)
λ_{max}(methanol)	mμ(ε)	330(9140)	310(9490)	297(7800)

transition, though relatively high extinction coefficient are observed. Under irradiation, the variation of absorbances of **1**, **4** and **11** at the longest wavelength corresponded to their concentrations, since their photoreaction products showed no absorptions in these regions. The variations of absorbances at the longest wavelength of **4** and **11** in the absence or presence of 1,3-pentadiene, which is known as a quencher of triplet state, are plotted against irradiation time (Fig. 1 and 2). This shows that a sydnone (**4**) excited state transferred its energy to 1,3-pentadiene. Irradiation of a benzene solution of **4** in the presence of 1,3-pentadiene gave **5** in a low yield (6%). Colorless crystals whose structure was not determined were obtained with a mp of 201—202°C. On the other hand, variation of the absorbance of **11** was not appreciably affected by 1,3-pentadiene. The yield of **12** did not decrease even in the presence of 1,3-pentadiene.

From the results a mechanism is postulated which rationalizes the experimental observations. It seems

that the photochemical reaction of **4** is derived from the lowest triplet state, which has an *n*-π* configuration. The reaction proceeds from the triplet state *via* bicyclic intermediate, from which diazirine is formed by the extrusion of carbon dioxide as in the case of the photochemical reactions of 3,4-diarylsydnones. It is suggested that either the excited triplet state of **11** is not responsible for the conversion into **12**, or the triplet state has too low energy to be affected by 1,3-pentadiene. It seems that the photochemical reaction of **11** proceeds through an intermediate other than nitrile imine.

Experimental

3-Cyclohexyl-4-phenylsydnone (4). Mandelonitrile prepared from 30 ml of benzaldehyde was added dropwise to a mixture of cyclohexylamine (25 g), sodium acetate (0.5 g) and ethanol (25 ml) and the reaction mixture was heated at 60—70°C for a few minutes. After being stirred at room temperature for 2 hr, α-cyclohexylaminophenylacetonitrile precipitated, mp 57.5—58.5°C, 28.6 g (52%).

α-Cyclohexylaminophenylacetonitrile (5 g) was stirred in

15 ml of concentrated sulfuric acid for 2 days at room temperature. The reaction mixture was added to 75 ml of water, and concentrated aqueous ammonia was added until the pH became about 9, and α-cyclohexylaminophenylacetamide precipitated was collected, mp 115—117°C, 5.3 g (98%).

After refluxing a 10% hydrochloric acid solution (43 ml) of α-cyclohexylaminophenylacetamide (5.3 g) for 6 hr, the reaction mixture was cooled to room temperature, and concentrated aqueous ammonia was added until the pH became about 4. α-Cyclohexylaminophenylacetic acid precipitated as white crystals, mp (decomp.) 280°C, 4.5 g (85%).

An aqueous solution of sodium nitrite (1.5 g/10 ml) was added dropwise below 0°C to a solution of α-cyclohexylaminophenylacetic acid (4.7 g) in 10% hydrochloric acid (86 ml). The reaction mixture was kept below 0°C for 1 hr and allowed to stand overnight at room temperature. α-(*N*-Cyclohexyl-*N*-nitrosamino)phenylacetic acid precipitated as yellow crystals, mp 133—136°C, 3.5 g (66%). After being dried the acid was dissolved in 30 ml of acetic anhydride and kept at 60—70°C for 20 min. After cooling, the reaction mixture was poured into 100 ml of water and stirred vigorously. Precipitates were collected and recrystallized from ethanol to give colorless prisms with a mp of 161—162°C, 3 g (91%).

Found: C, 68.98; H, 6.58; N, 11.76%. Calcd for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%. IR: $\nu_{C=O}$ 1730 cm^{-1}.

Irradiation of **4**. *i) Under Nitrogen Atmosphere*: A solution of 1.0 g of **4** in 300 ml of benzene was irradiated with a 100 W high pressure mercury lamp using a Pyrex filter under nitrogen atmosphere. The reaction was followed by withdrawal of small aliquots at various time intervals and measurement of their UV spectra. After irradiation for 3 hr, the solvent was removed *in vacuo* and the resulting residue was placed on a silica gel column. A petroleum ether solution was used to elute the column. The first elute contained an oil whose structure was not determined. The next petroleum ether-benzene (2 : 1) solution contained a white solid, which was recrystallized from ethanol to give colorless needles, mp 131—132°C, 0.08 g (12%). This was identified as **5**.

Found: C, 79.46; H, 7.12; N, 14.15%. Calcd for $C_{20}H_{21}N_3$: C, 79.17; H, 6.89; N, 13.85%. IR: 3050; 2920, 1460, 1440, 1350, 1260, 1080, 990, 770, 700 cm^{-1}. UV: λ_{max}^{MeOH} 255 mμ (ε 9170).

The next petroleum ether-benzene (1 : 1) solution afforded a crude solid, which was recrystallized from methanol to give red needles, mp 100—101°C, 0.13 g (15%), and identified as **6**.

Found: C, 77.63; H, 7.77; N, 14.21%. Calcd for $C_{26}H_{32}N_4$: C, 77.96; H, 8.05; N, 13.99%. IR: 3030, 2910, 1490, 1440, 760, 710, 700 cm^{-1}. UV: λ_{max}^{MeOH} mμ(ε) 310 (6440), 253 (10900). NMR: τ_{Me_4Si} ($CDCl_3$) 2.6—2.9 (10H), 6.2—6.7 (2H), 8.1—9.1 (20H).

The next benzene solution contained a crude solid, which was recrystallized from methanol to give colorless prisms, mp 78—80°C, 0.15 g (15%), and identified as **7**.

Found: C, 68.78; H, 6.47; N, 11.64%. Calcd for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%. IR: 3060, 2920, 1780, 1450, 1350, 1020, 740, 700 cm^{-1}. UV: λ_{max}^{MeOH} 268 mμ (ε 7350).

ii) Under Carbon Dioxide Atmosphere: A solution of **4** (1.0 g) in benzene (300 ml) was irradiated under carbon dioxide atmosphere for 3 hr, and treated as mentioned above to give **7**, 0.47 g (47%).

iii) In the Presence of Carbon Disulfide: Compound **4** (1.0 g) was dissolved and irradiated in a mixture of 200 ml of benzene and 100 ml of carbon disulfide. After removal of the solvent in a vacuum, the residue was placed on a silica gel column and eluted with a petroleum ether-benzene (1 : 1) solution. The elute contained a crude solid, which was recrystallized from ethanol to give colorless silky crystals, mp 136—137°C, 0.19 g (20%), and identified as **8**.

Found: C, 60.61; H, 5.65; N, 10.03; S, 22.93%. Calcd for $C_{14}H_{16}N_2S_2$: C, 60.86; H, 5.84; N, 10.14; S, 23.16%. IR: 3050, 2910, 1490, 1450, 1350, 1280, 1210, 1060, 760, 690 cm^{-1}.

The starting material (0.15 g) was eluted with benzene-ethyl acetate (3 : 1).

iv) In the Presence of Dimethyl Acetylenedicarboxylate: A solution of **4** (1.0 g) and dimethyl acetylenedicarboxylate (1.2 g) in benzene (300 ml) was irradiated for 2.3 hr. The reaction mixture was treated as mentioned above and the resulting residue was eluted first with petroleum ether to give 0.7 g starting material and next with benzene to give a crude solid, which was recrystallized from methanol to give colorless needles, mp 92—93°C, 0.6 g (43%), and identified as **9**.

Found: C, 66.40; H, 6.32; N, 8.15%. Calcd for $C_{19}H_{22}O_4N_2$: C, 66.65; H, 6.48; N, 8.18%. IR: 3050, 2920, 1730, 1530, 1450, 1250, 1160, 790, 700 cm^{-1}.

Reaction of **4** *with Dimethyl Acetylenedicarboxylate*. A mixture of **4** (1.0 g) and dimethyl acetylenedicarbaxylate (2.0 g) was heated at 120—140°C for 4 hr, during which time evolution of carbon dioxide was observed. Excess dimethyl acetylenedicarboxylate was removed, and a small amount of methanol was added to the residue and the reaction mixture was kept in a refrigerator. Precipitates were collected and recrystallized from methanol to give colorless prisms, mp 98—99°C, 0.3 g (21%), identified as **10**.

Found: C, 66.60; H, 6.67; N, 8.32%. Calcd for $C_{19}H_{22}O_4N_2$: C, 66.65; H, 6.48; N, 8.18%. IR: 2940, 1730, 1550, 1500, 1440, 1220, 1170, 1080, 760, 700 cm^{-1}.

*3-t-Butyl-4-phenylsydnone (***11***)*. Mandelonitrile prepared from 75 ml of benzaldehyde was added to a mixture of *t*-butylamine (52 g), sodium acetate (1.3 g) and ethanol (60 ml) under ice cooling. The reaction mixture was kept at 50—60°C for 5 min, and allowed to stand overnight with stirring at room temperature. Unreacted *t*-butylamine and ethanol were removed *in vacuo*. To the residue was added 500 ml of 5% hydrochloric acid and the mixture was vigorously stirred, and the precipitates were filtered off. Filtrate was neutralized with aqueous potassium hydroxide and oily layer was extracted with ether. After drying the ether layer over sodium sulfate, ether was evaporated off and crude α-*t*-butylaminophenylacetonitrile (100 g) was obtained, which was added dropwise to 300 ml of concentrated sulfuric acid under ice cooling. After the solution was stirred for 2 days at room temperature, the reaction mixture was diluted with sixford amount of water and treated with activated charcoal and neutralized with concentrated aqueous ammonia until the pH became 8. Precipetates were collected and refluxed in 800 ml of 10% hydrochloric acid for 14 hr. The solution was treated with activated charcoal and hydrochloric acid solution of α-*t*-butylaminophenylacetic acid was subjected to subsequent reaction.

An aqueous solution of sodium nitrite (18 g/100 ml) was added dropwise below 0°C with vigorous stirring to a hydrochloric acid solution of α-*t*-butylaminophenylacetic acid. The reaction mixture was kept below 0°C for one hour, and stirred at room temperature for 24 hr. α-(*N*-*t*-Butyl-*N*-nitrosamino)phenylacetic acid precipitated as pale yellow crystals, mp 179—180°C.

To this was added 250 ml of acetic anhydride and the mixture was stirred at room temperature for 3 days in the dark. The resulting yellow solution was concentrated in a vacuum

to one-third of the total volume, and poured into 1 *l* of water with vigorous stirring to give colorless crystals. Recrystallization from ethanol afforded colorless prisms, mp 124—125.5°C, 23 g (19%).

Found: C, 65.82; H, 6.49; N, 13.10%. Calcd for $C_{12}H_{14}O_2N_2$: C, 66.03; H, 6.47; N, 12.84%. IR: $\nu_{C=O}$ 1750 cm^{-1}.

Irradiation of ***11****. i) Under Nitrogen Atmosphere*: After irradiation of a solution of **11** (1.0 g) in 300 m*l* of benzene for 1.5 hr, the solvent was removed *in vacuo* and the resulting residue was analyzed by column chromatography. A benzene-ethyl acetate (4 : 1) elute contained a solid, which was recrystallized from ethanol to give colorless needles, mp 114—115°C, 0.42 g (59%) and identified as **12**.

Found: C, 73.57; H, 6.52; N, 9.05%. Calcd for $C_{19}H_{20}O_2N_2$: C, 74.00; H, 6.54; N, 9.09%. IR: 2960, 1780, 1680, 1280, 750, 730, 700 cm^{-1}. NMR τ_{Me_4Si} ($CDCl_3$) 2.3—2.9 (m, 10H), 4.6 (s, 1H), 8.4 (s, 9H). Mass spectra M^+ *m/e* 308, C_6H_5CO *m/e* 105 (base peak), $C_6H_5CHNCOC_6H_5$ *m/e* 209 (70% of the base peak), C_6H_5CHCO *m/e* 118 (90%), $C_6H_5CH_2$ *m/e* 91 (84%).

Compound **12** was also obtained by irradiation of a solution of **11** in toluene with a yield of 68%.

ii) Under Carbon Dioxide Atmosphere: Irradiation of a solution of **11** under carbon dioxide atmosphere for 1.5 hr afforded **12** in a yield of 62%.

iii) In the Presence of Carbon Disulfide: A solution of **11** (0.8 g) in 200 m*l* of benzene and 100 m*l* of carbon disulfide was irradiated under the same conditions for 1.5 hr to give 0.08 g (14%) of **12**.

Reaction of ***11*** *with Dimethyl Acetylenedicarboxylate.* A solution of 0.75 g of **11** and 0.9 g of dimethyl acetylenedicarboxylate in 5 m*l* of toluene was refluxed for 1.5 hr. Analysis by column chromatography afforded **13**, which was recrystallized from methanol, mp 117—119°C, 0.84 g (77%).

Found: C, 64.09; H, 6.17; N, 8.41%. Calcd for $C_{17}H_{20}O_4N_2$: C, 64.54; H, 6.37; N, 8.86%. IR: 2980, 1730, 1240, 1200, 1080, 760, 710 cm^{-1}.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3206—3207 (1972)

The Chlorine Nuclear Quadrupole Resonance of *o*-, *m*-, and *p*-Chlorobenzamide

Seiichi KONDO, Hiroyuki INOUE, Akemi SAKAMOTO, and Haruo KATSUMATA
Laboratory of Physical Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka-shi

(Received November 6, 1971)

The nuclear quadrupole resonance of *o*-, *m*-, and *p*-chlorobenzamide has been studied in this laboratory; the results and their relation to the crystal structures of these materials, the various polymorphic modifications of which have been extensively studied by Sakurai, Takaki, and others,[1] will be reported in this paper.

The materials were synthesized by the reaction of monochlorobenzoic acid with thionyl chloride and then with ammonia. No impurity was seen in the X-ray powder diffraction patterns or in the infrared spectra of the materials purified by repeated recrystallization from the various solvents mentioned below. The melting points of the final samples are shown in Table 1. These samples were sealed *in vacuo* in glass ampules for the NQR measurement. We were not successful in growing a single crystal for the Zeeman measurement.

The NQR signal was searched for in the range from 28 to 40 MHz using a super-regenerative oscillator-detector of the Dean type with a frequency-modulation and phase-sensitive detection system. The S/N ratio of the signal of *p*-dichlorobenzene was better than 200 with this system. The frequency was determined with an eight-figure digital counter. For the visual detection, a Braun tube with a long decay time was employed, and the random noise was fairly well smoothed out with the S/N ratio—about five times better than that of an ordinary tube. The resonance frequencies observed are shown in Table 1 and Fig. 1.

TABLE 1.

	Mp, °C	Space group	NQR frequency at 77K, MHz	S/N
o-chlorobenzamide	142.3	$P2_1/a$	35.593	3
m-chlorobenzamide	132.0	$P2_1/a$	34.876	3
p-chlorobenzamide	177.6	$P\bar{1}$	35.130	3
			34.944	2.5
			34.731	2.5

The thermal behavior of these materials between −100°C and their melting points was studied by means of a differential scanning calorimeter of the Rigakudenki Co., 8001 SC, with a heating and cooling rate of 10°C/min and with a sensitivity of 0.5 mcal/sec in full scale. About 10 mg of each sample was placed in a shallow aluminum dish, covered with an aluminum plate or packed with pressure, and then used for the DSC measurement.

1) o-*Chlorobenzamide.* One NQR signal was observed with the crystal grown from the melt, bu

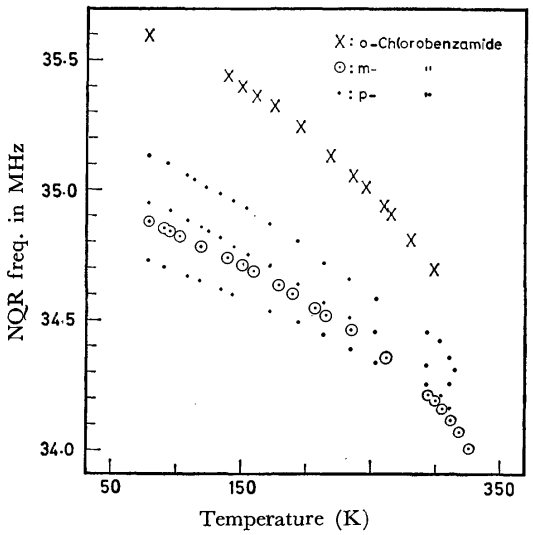

Fig. 1. Frequency *versus* temperature curves of the NQR frequencies of *o*-, *m*-, and *p*-chlorobenzamide.

no signal was detected with the crystals grown from water, ethanol, or acetone. The X-ray study[1] showed that the former crystal belonged to the space group $P2_1/a$ with $Z=4$ and had an ordered structure, while the latter ones seemed to be mixtures of three modifications, one with the space group $P2_12_12_1$ and two with some disordered structures. The crystallographically-equivalent chlorine atom in the unit cell is expected to be one in the former case; this agrees with our findings. The reason for the absence of the NQR signal in the latter case may be that the sample was a mixture of different crystal modifications, two of which have disordered structures. No thermal anomaly was detected with any of these crystals.

2) m-*Chlorobenzamide.* The crystals grown from the melt and from water or ethanol possess the same space group, $P2_1/a$, with $Z=4$ according to the X-ray study.[1] These crystals showed only one signal each, all of the same frequency. The crystallographic consideration of this structure described in section 1 agrees with those NQR results. No anomalous thermal behavior was observed in this study with these crystals.

3) p-*Chlorobenzamide.* Three signals were observed with the crystal grown from the melt in the temperature range from 77 K to about 316 K. This finding agrees well with the crystallographic consi-

1) Y. Harada, T. Taniguchi, Y. Takaki, and K. Sakurai, *Mem. Osaka Kyoiku University*, **18**, *Ser.* III, 1 (1969); Y. Kato, Y. Takaki, and K. Sakurai, Symposium on the Molecular Structure, Chem. Soc. Japan, 1970.

derations that the crystal at room temperature possesses the space group $P\bar{1}$ with $Z=6$[1] and the three different electric fields are supposed to surround the chlorine atoms in this unit cell. A phase transition from the room-temperature phase to the phase with the same space group and $Z=2$ was found at about 43°C by the X-ray study[1]; this was confirmed by DTA measurements.[2] The six molecules in the unit cell of the low-temperature phase displace a small amount at the phase transition, and the crystal assumes a disordered structure. The periodicity or the length of the *a*-axis of the unit cell of the high-temperature phase decreases to one third of that of the low-temperature phase, while the lengths of the *b*- and *c*-axes are kept the same, with a small entropy of transition (about 0.40 e. u., according to the present DSC measurement). The temperature coefficient of the curves of the NQR frequencies of this material against the temperature in Fig. 1 increases gradually near the transition point; these signals fade out at the transition point, 43°C. This result suggests that the thermal motion of the molecule in the low-temperature phase begins to increase near the transition temperature and that this thermal motion and the disorder of the structure of the upper phase[1] make it impossible to observe the signal above the phase transition. The signal frequencies of these three compounds have values similar to those of other monochlorobenzene derivatives. The frequency of *o*-chlorobenzamide has the highest value and, therefore, the largest covalent character of the C–Cl bond.

This research was partly supported by the Science Research Fund of the Ministry of Education of Japan.

Hydrogen-transfer Reaction between Ketones and Alcohols over Metal Oxide Catalysts

Yasuaki OKAMOTO, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka

(Received December 17, 1971)

Intermolecular hydrogen-transfer reactions have been studied by many workers. According to Schächter and Pines,[1] when a mixture of isopropyl alcohol and 2-butanone was passed over calcium oxide at about 320°C, both acetone and butanol were produced. Niiyama *et al.*[2] have reported the hydrogen-transfer reaction between alcohol and ketone over silica-magnesia catalysts and proposed a mechanism similar to that of the Meerwein-Ponndorf reduction. In our preceding papers,[3] it was found that the reactions between allyl alcohol and propionaldehyde or propylene oxide are accelerated by silica-magnesia and metal oxide catalysts. In this paper, the mechanism of the hydrogen-transfer reaction on metal oxides was studied using a conventional pulse reactor (carrier gas: He) at 260°C.

Materials. The metal oxides used were MgO, CaO, SrO, and BaO of a commercial grade. The properties of the metal oxides used are given in Table 1.

TABLE 1. THE PROPERTIES OF METAL OXIDE CATALYSTS AND THE REACTIVITIES OF THE HYDROGEN TRANSFER REACTION BETWEEN METHYL ETHYL KETONE AND 2-PROPANOL OVER THESE OXIDES AT 260°C

Catalyst	Surface area (m^2/g)	Basicity[a] (mmol/g)	Activity/g[b] (arbitrary unit)
MgO	55.6	0.288	65.5
CaO	13.3	0.014	62.6
SrO	5.3	0.004_5	1.6
BaO	1.9	0.005_3	3.4

a) Measured at $H_0 = +7.2$.
b) Obtained from the formation of *sec*-butyl alcohol.

Results and Discussion

The hydrogen-transfer reaction was carried out over metal oxides using an equimolar mixture of alcohol and ketone. Under our reaction conditions, the reactivity of the dehydrogenation of alcohol was very small. In all cases, the dehydrogenated product of alcohol and the hydrogenated product of ketone were obtained. Table 1 shows the reactivities of the reaction between 2-propanol and methyl ethyl ketone (MEK) over several metal oxides. The reactivities were calculated from the formation of 2-butanol. The reactions are poisoned by dichloroacetic acid. Though the basicity[4] (measured at $H_0 = +7.2$) of magnesium oxide is much larger than that of calcium oxide, the activities of these metal oxides are almost the same. According to Take *et al.*[5] these metal oxides have the same amount of a strong base, which is stronger than $H_0 = +24$, but strontium oxide has only a small amount of the strong base. Therefore, it is considered that the strong base is favorable for the reaction.

Table 2 gives the reactivities of the reaction between

MEK and several alcohols, while Table 3 shows the kinetic isotope effects on the reaction. Fig. 1 shows the relation between the reactivity and the delocalizability, $D_r^{(R)}$, of the hydrogen attached to the α-carbon of alcohol.[6] On the basis of these fact, it may be concluded that the rate-determining step is the hydrogen-abstraction process from the α-carbon, not from the hydroxyl group. When intermolecular hydrogen-tansfer reactions between 2-propanol and several ketones were carried out, a good parallel relation between the reactivity and the electron-donating power of ketone ($\Delta\nu_D$; cm^{-1}) was found, as was revealed in a preceding paper.[3] The electron-donating power of a compound is defined[7] as the relative difference (countered as wave numbers) of the O–D adsorption band of methanol-*d* observed in the compound from that in benzene.

The poisoning effect of pyridine on the reaction was

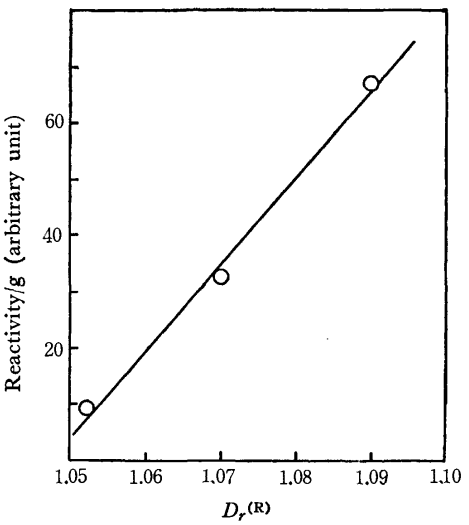

Fig. 1. Correlation between the reactivity of the hydrogen transfer reaction and $D_r^{(R)}$ of α-hydrogen of alcohol.

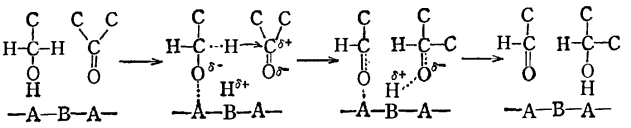
studied over a magnesium-oxide catalyst in order to make it clear which were the active centeres, but pyridine has no effect on the reaction, whereas magnesium oxide is considered to have a very weak acid site.[3,8] It is considered that alcohol is adsorbed on a strong basic site, thus dissociating the hydroxyl group, and that the basic strength of the anion formed is stronger than that of pyridine. As the electron-donating power of pyridine ($\Delta\nu_D$; 128 cm^{-1}) is much larger than those of the ketones used, the reaction must be poisoned, if the weak acid site also favorable for the adsorption of ketones. Therefore, it is considered that ketone is not adsorbed and not activated by the acid site on metal oxide. Taking these facts into consideration, the reaction mechansim on metal oxides is deduced to be as follows:



A: Weak acid site
B: Strong basic site

Polymorphic Transformation in Copper Ferrite and Manganite by Grinding

Yasuhiko UEHARA

Electron Tube Division, Hitachi Ltd., Hayano, Mobara, Chiba, 297

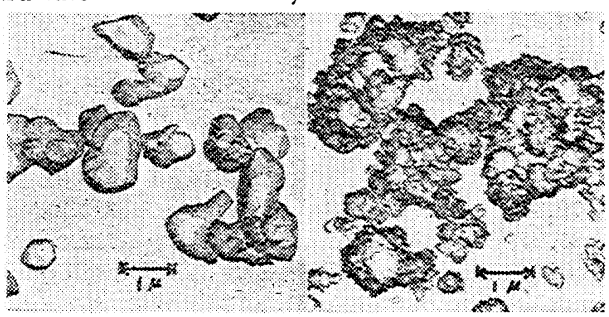
(Received January 25, 1972)

Many spinels such as $CuFe_2O_4$ and Mn_3O_4 have a tetragonally-distorted structure. The origin of the tetragonal distortion is the cooperative Jahn-Teller ordering of Cu^{2+} or Mn^{3+} at octahedral sites of the spinel structure. The tetragonality $\sigma=(c-a)/a$ is about 6% for $CuFe_2O_4$ and about 16% for Mn_3O_4 at room temperature. The variation of the tetragonality, σ, with the temperature has been studied by Ohnishi and his co-workers[1] for $CuFe_2O_4$ and by McMurdie and his co-worders[2] for Mn_3O_4. The transformation from the tetragonal to the cubic structure occurs at 360°C for $CuFe_2O_4$[1] and at 1170°C for Mn_3O_4.[2] The observation to be described here is that $CuFe_2O_4$ can be transformed from the tetragonal to the cubic structure by mechanical grinding at room temperature, while Mn_3O_4 can not be transformed by the same procedure.

$CuFe_2O_4$ was prepared from powders of CuO and Fe_2O_3 by heating at 930°C for 3 hr and by subsequent cooling to room temperature. Mn_3O_4 was prepared from powder of MnO_2 by heating at 1000°C for 3 hr and by subsequent quenching in water. These samples were ground in a ball mill with water for intervals up to 190 hr. The ground samples were examined by means of an electron microscope and by the X-ray diffraction method, using Mn-filtered Fe$K\alpha$ radiation.

The electron micrographs of the tetragonal $CuFe_2O_4$ particles before and after grinding are shown in Fig. 1. Before grinding, each particle is fairly rounded in shape and has a size between 0.5 and 1.0 μ. As the grinding progresses, the particles became smaller and irregular and the amount of small-size chipping increases.

X-Ray diffraction diagrams of the tetragonal $CuFe_2O_4$ at various stages of grinding are given in Fig. 2. As the grinding increases, the (311) peak of the cubic structure appears, in the intermediate-time grinding it is seen that both tetragonal and cubic structures existing, while in long-time grinding the tetragonal structure is almost entirely transformed into the cubic one. Such changes in diffraction lines by grinding are similar to those caused by heating.[3]



Original Ground for 190 hr

Fig. 1. Electron micrographs of $CuFe_2O_4$ particles before and after grinding.

X-Ray diffraction lines gradually broaden with grinding, as is shown in Fig. 2. Such a fact was more clearly seen in the experiment of grinding cubic $CuFe_2O_4$ (quenched from 930°C). The analysis of line-broadening using Hall's method[4] revealed that the strain increased and the crystallite size decreased with grinding. The increased strain might be described in terms of large dislocation density, whereas the small crystallite might be due to multiple twinning.[5] Therefore, it can be presumed as the main effect of polymorphic transformation that the cooperative Jahn-Teller ordering is destroyed by lattice imperfections, such as dislocation and stacking fault generated by grinding. As the another factor in the transformation, the change in the surface energy should also be considered. However, since there are no suitable methods for the measurement and theoretical calculation of the surface energy, it is beyond the scope of this discussion to consider the contribution of surface energy to the transformation.

On the other hand, Mn_3O_4 could not be transformed by grinding, even after 100 hrs' grinding. In the case of the transformation of Mn_3O_4, a greater amount of energy will be required, because Mn_3O_4 has a much higher transition temperature than $CuFe_2O_4$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3210—3211 (1972)

Vapor Pressure of Acetylacetone below Normal Boiling Point

Koichiro NAKANISHI* and Osamu TŌYAMA

Department of Industrial Chemistry, Shinshu University, Wakasato, Nagano-shi

(Received May 8, 1972)

Acetylacetone(2,4-pentanedione) has been used frequently in studies on keto-enol tautomerism and complex formation with metals, but no vapor pressure data are available in literature. This note describes new vapor pressure data for acetylacetone from room temperature up to the normal boiling point.

Experimental

Acetylacetone was purified by distillations under reduced nitrogen pressure. Since the affinity of acetylacetone to metals is fairly large, final distillation was carried out in a column with glass packing.

The vapor pressure was measured by means of the following apparatus:

(a) Vapor pressure apparatus (16—50°C)

(b) Isoteniscope[1] (40—70°C)

(c) A modified Swietoslawski-type ebulliometer[1] (60—138°C)

A sketch of (a) is given in Fig. 1. Purified liquid was confined in a mercury-sealed cell and degassed in a vacuum at liquid nitrogen temperature. Mercury was then introduced to form a manometer in a U-tube on the left-hand side of the cell which was immersed in a thermostat maintained on a laboratory jack. After temperature equilibrium was reached, the pressure was read both on the manometer and an open manometer with a travelling microscope and a Shimadzu Model HV-100 cathetometer.

The apparatus (b) and (c) were connected to a vacuum system and operated by conventional methods.[1] Reduced pressures required were obtained by introducing dry nitrogen into the system. A porous-disk type manostat was used to keep the whole system at a constant pressure of ±0.2 mmHg. The isoteniscope was immersed in a glycerine thermostat controlled within ±0.05°C during the course of measurement.

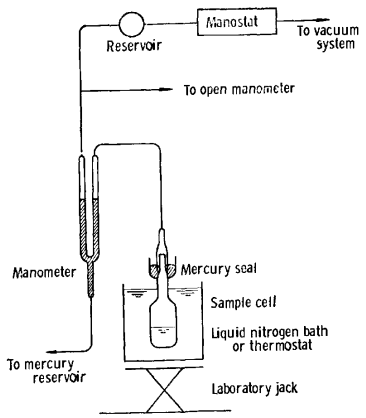

Fig. 1. Schematic diagram of vapor pressure apparatus.

The temperature was measured by a thermistor calibrated against a standard thermometer. The overall average error of the vapor pressure measurement was believed to be less than ±0.2 Torr at lower temperatures, but larger at temperatures above 100°C.

In order to confirm the validity of the data, the vapor pressure of toluene was measured between 92° and 107°C with our ebulliometer and the results were compared with the accepted values.[2] No systematic deviation from literature values was observed, and the average deviation was less than ±0.6 Torr or ±1.2%.

Results and Discussion

Vapor Pressure Data. The vapor pressure of acetylacetone from 16° to 137°C is given in Table 1. The mean value of the barometric pressure during the measurements was 733 mmHg, where acetylacetone boiled at 137.3°C. Extrapolation of the data to 1 atmosphere yields 138.3°C as the normal boiling point. This is between the two literature values, 137.7 and 140.2°C.[3] Mutual consistency among the

data obtained with different apparatus may be confirmed by the P *vs.* t plot in Fig. 2, where the ranges of the applicability of each apparatus are seen to overlap.

Correlation with Empirical Equations. An attempt to correlate the data for the whole range of the measurement by means of the Antoine equation was not successful. We assigned two set of constants of the Antoine and Clapeyron-Clausius equations for different temperature ranges. They were evaluated by the method of least squares. The resulting vapor pressure equations are as follows.

$$\log P(\text{Torr}) = A - \frac{B}{C+t(^\circ\text{C})}$$

$A = 6.86495$, $B = 1377.34$, $C = 208.35$
for $t = 15$—105°C

$A = 7.3522$, $B = 1840$, $C = 273.16$
for $t = 105$—138°C

The experimental points scattered nearly at random from the values obtained by these equations, overall average deviation being ± 1.2 Torr or $\pm 2.3\%$ in P.

In order to express the whole data by one single equation, the following Antoine-type equation is suggested.

$$\log P(\text{Torr}) = 6.86495 - \frac{1377.34}{207.35+t(^\circ\text{C})}$$

Heat and Entropy of Vaporization. The heat and entropy of vaporization at normal boiling point have been estimated from the log P *vs.* $1/T$ plot. They are 8.42 kcal/mol and 20.5 cal/deg·mol, respectively.

Discussion. The Antoine equation has been widely used and proved satisfactory for correlating the vapor pressure curve of organic liquids. In view of the relatively narrow pressure range covered by the present measurement, it was expected that any three-constant equation would correlate the data. It is tempting to ascribe this failure to the fact that the keto-enol equilibrium in acetylacetone molecule also changes with temperature.[4,5] However, acetylacetone is rather unstable at higher temperatures and, unless the atmosphere is completely inert, it undergoes partial decomposition as the temperature approaches normal boiling point. In fact, prolonged boiling has led to a pronounced brown coloration. Thus we might assume that there would be a slight boiling point elevation under such conditions. In practical distillation processes, it is possible that an even higher boiling point than that reported might be observed. We thank Mr. K. Sato and Mrs. H. Shirai-Tsujimoto for their assistance in the experiments.

Thin-layer Chromatographic Behavior of Transition Metals on a Weakly Basic Cellulosic Ion-Exchanger in Hydrazoic Acid Medium

Rokuro KURODA and Nobuo KOJIMA

Laboratory for Analytical Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba

(Received February 9, 1972)

Metal complexes containing azide ions have received considerable attention recently; the preparation and physical properties of azido complexes of the transition metals have been investigated extensively.[1,2] However, little information is available so far on the ion-exchange behavior of metals in hydrazoic acid media. We have examined the anion-exchange behavior of transition metals in aqueous hydrazoic acid solution. Because of its simplicity and rapidity, the thin-layer chromatographic technique using diethylaminoethyl-cellulose as an adsorbent was employed to study the adsorbability of metals from the aqueous hydrazioc acid solution.

"..." Denotes a weak streak.

Experimental

About 12 g of diethylaminoethylcellulose(abbreviated as DEAE), Serva, was treated batchwise by 0.1 M sodium hydroxide and washed with deionized water. DEAE was then converted to the azide form by treating with 0.5 M sodium azide solution acidified with hydrazoic acid to pH 5. In order to obtain hydrazoic acid, a 0.5 M sodium azide solution was passed through a column of cation-exchange resin in the hydrogen form. After washing with deionized water by centrifugation, DEAE was slurried with 35 ml of deionized water and spread 250 μ thick on five 20×20 cm glass plates. The 250 μ thick thin-layer plates of microcrystalline cellulose, Avicel SF(Avicel Sales Division, FMC Corp.), were also prepared.[3] All the plates were dried at 40°C for 3 hr and stored in a desiccator containing a saturated potassium bromide solution. For most metals the test solutions were 0.1 M metal chlorides of varying hydrochloric acid concentration. The test solutions of Nb(V), Mo(VI), Ag(I), W(VI), and Re(VII) were prepared as reported previously.[3]

A 0.5 μl portion of the test solutions was applied to the plate at 2 cm from the edge. After drying the plate in the desiccator for 30 min, it was developed in a tank(23×11×22 cm) equilibrated with 0.1 M hydrazoic acid solution for 1 hr. After developing (solvent front 15 cm high) and drying the plate, metals were detected.[3] Mn(II) and V(IV) were detected by spraying 0.1% alkaline PAR solution, and Ti(IV) by 0.1% tannic acid solution.

Results and Discussion

In Table 1 the R_f values are given for 29 metals on DEAE together with those on a plain cellulose Avicel SF as a reference, both in 0.10 M hydrazoic acid solution. We see that almost none of the metals are adsorbed on Avicel SF from 0.1 M hydrazoic acid. Ag(I) forms an insoluble precipitate with azide, giving the R_f value of approximately zero. In contrast to Avicel SF, enhanced adsorption can be observed for most metals on DEAE in hydrazoic acid solution. Within the group of the first transition metals, Mn(II), Co(II), Ni(II), and Zn(II) are not adsorbed on DEAE while the other metals including Sc(III), Ti(IV), V(IV), Cr(III), Fe(III), and Cu(II) exhibited increased adsorption on DEAE relative to Avicel SF, although marked streaks were often found for some of them.

It is of interest to note that the hydrazoic acid allows the strongest adsorption on DEAE of Mo(VI), W(VI), Re(VII), and the platinum group of metals including Pd(II), Ir(IV), and Pt(IV). All the metals except for Ir(IV) have been reported to be adsorbed strongly on DEAE from thiocyanic acid,[4,5] which resembles hydrazoic acid in many aspects, both being grouped to pseudohalogenic acid.

Considerable differences in the adsorbability between DEAE and Avicel SF are also observed for Zr(IV), Nb(V), Hf(IV), Au(III), Hg(II), Th(IV), and U(VI). This is also the case for Y(III) and the rare earth metals, the difference being less remarkable. Cd(II) behaves like Zn(II). Diethylaminoethyl group does not seem to be responsible for the R_f value of Cd(II) on DEAE, even though a weak azido complex formation takes place.[6] The R_f value is rather high for Hg(II).

3) K. Oguma and R. Kuroda, *J. Chromatogr.*, **52**, 339 (1970).

4) K. Ishida and R. Kuroda, *Anal. Chem.*, **39**, 212 (1967).

5) K. Ishida, T. Kiriyama, and R. Kuroda, *Anal. Chim. Acta*, **41**, 537 (1968).

6) P. Senise and E. F. de A. Neves, *J. Amer. Chem. Soc.*, **83**, 4146 (1961).

This might not allow the uptake of Hg(II) on a DEAE column from 0.1 M hydrazoic acid. This is in contrast to its behavior in thiocyanate media, where the pronouced adsorption of Hg(II) takes place, permitting a very specific column separation of Hg(II) from about 40 metals.[7]

The absorption of the transition metals on DEAE from the hydrazoic acid solution may be mostly accounted for, by assuming azido complex formation and the subsequent anion-exchange. However, it might be possible for some metals that adsorption is caused merely through the anion-exchange of their oxyanions.

The Effects of Additives on the Chemical Behavior of ^{60}Co Recoil Species in Neutron-irradiated Benzene Solutions of Tris(acetylacetonato)cobalt(III)

Takeshi TOMINAGA and Yasuo NISHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 24, 1972)

In the course of our investigation of the behavior of recoil species in organic solutions of metal chelate complexes, we found that some metal salts could work as effective scavengers to suppress thermal reactions and thus minimize the apparent retention in the irradiated solutions as well as in solutions of the irradiated solids.[1-4] While the use of such metal salts as scavengers has proved to be a very useful technique for studying recoil reactions in solutions or solids, the detailed mechanism of the scavenging reactions has not yet been fully clarified. Accordingly, we have further investigated the effects of additives other than metal salts on the reactions of recoil species in irradiated organic solutions of metal complexes.

In the present article, a probable mechansim of the scavenging effect by metal salts is proposed on the basis of our recently obtained data concerning the change in the ^{60}Co retention with the time in irradiated $Co(acac)_3$ benzene solutions containing metal acetylacetonates as additives.

Experimental

The 0.2 M solutions of $Co(acac)_3$ in benzene containing 10% (by volume) of ethanol and small quantities of additives, such as metal acetylacetonates, metal chlorides and acetylacetone, were prepared by procedures similar to those described previously.[2] About 1-m*l* portions of $Co(acac)_3$ benzene solutions containing various additives were irradiated with slow neutrons for 5 min at room temperature in the rotary specimen rack of a TRIGA Mark II reactor at Rikkyo University (thermal neutron flux: 5×10^{11} n/cm^2·sec; γ dose: 7×10^4 R for 5 min). After the irradiated solutions had been kept standing for a desired length of time at room temperature, chemical separation was performed by means of a solvent-extraction method described previously.[2] The ^{60}Co retention, or the radiochemical yield of the parent chemical form, $^{60}Co(acac)_3$, was obtained as the percentage of the total ^{60}Co activity found in the organic phase after the solvent extraction.

Results and Discussion

Figure 1 illustrates the change in the apparent ^{60}Co retention with the time after the irradiation of the $Co(acac)_3$ benzene solutions containing metal acetylacetonates and other additives. The ^{60}Co retention remains unchanged even after a solution has stood 7 days in the presence of ferric chloride as an additive, while it increases appreciably when the solution stands in the presence of magnesium chloride. It is worth mentioning that as additives both $Ni(acac)_2\cdot2H_2O$ and $Mg(acac)_2$ (3×10^{-3} M) enhance the increase in the ^{60}Co retention remarkably, as compared with the retention curve in the absence of an additive, whereas $Fe(acac)_3$ has practically no effect as an additive. It appears that the transfer of the ligand acetylacetonate ion from the less stable metal acetyl-

acetonates (*i. e.*, $Mg(acac)_2$ and $Ni(acac)_2 \cdot 2H_2O$) to the ligand-deficient ^{60}Co recoil species mainly contributes to the increase in the ^{60}Co retention in the presence of such metal acetylacetonates as additives. Similar effects were observed when the irradiated solid $Co(acac)_3$ was dissolved in benzene containing such additives and the mixture was then kept standing.

As is shown in Fig. 2, the scavenging power (percentage of the thermal reactions scavenged by an equal

—○—: Separated within a few hours after irradiation;
--■--: Separated after 7 days.

molar concentration of a scavenger) of metal salts measured within a few hours after irradiation[2] and after 7 days' standing apparently correlates well with the thermodynamic stability constants[5] of their acetylacetonates. Based on the present results, the mechanism of the overall phenomenon (apparent scavenger effect) may be explained in terms of the following reactions:

(1) Recombination. $[^{60}Co(acac)_{3-x}] + acac^- \longrightarrow {}^{60}Co(acac)_3$

(2) Scavenging reaction. $MX_n + acac^- \longrightarrow M(acac)_n$

(3) Ligand transfer. $[^{60}Co(acac)_{3-x}] + M(acac)_n \longrightarrow {}^{60}Co(acac)_3 + M(acac)_m \quad (n>m)$

where $[^{60}Co(acac)_{3-x}]$ denotes the ligand-deficient ^{60}Co recoil species ($x=1$, 2, or 3; cationic) and MX_n, scavenger salt. In the period immediately after irradiation, the competition between (1) and (2) is important, whereas the (3) reaction may still be relatively unimportant. The competition between (1) and (2) predominantly favors (2), and the correlation curve in Fig. 2 should closely approach the 100%-scavenged level for most of the metal salts investigated if the irradiation and storage periods become as brief as possible. If the (3) reaction gradually proceeds between the unreacted ligand-deficient ^{60}Co recoil species and $M(acac)_n$ remaining in the system,[6] the ^{60}Co retention increases, and the apparent scavenging power decreases, on standing. Hence, the corresponding plot-point on the correlation curve may be lowered from the 100%-scavenged level by a magnitude equivalent to the contribution of (3). Accordingly, the correlation between the apparent scavenging power and the stability constant may be explained by presuming that the extent of the (3) reaction reached after a solution has stood for a sufficiently long time depends mainly upon the stability of the metal acetylacetonate relative to $Co(acac)_3$. The present results on the effect of acetylacetonates of Fe, Ni, and Mg (Fig. 1) indicate that the extent of such a reaction actually increases with the decreasing stability of the acetylacetonates. Very similar results were obtained with irradiated $Cr(acac)_3$ benzene solutions.[7]

In conclusion, the scavenging effect of the salts of metals which can form more stable acetylacetonates may be ascribed mainly to the competition between the recombination (1) and the scavenging reactoin (2) to capture acetylacetone. For the salts of metals which form less stable acetylacetonates, however, the ligand transfer (3) may proceed appreciably on standing and may apparently diminish the overall scavenging effect.

The present authors wish to express their thanks to Professor Nobufusa Saito, The University of Tokyo, for his encouragement.

6) Although the decomposition of the parent complex was spectrophotometrically found to be almost negligible even after standing, the irradiated solutions might contain very small amounts (10^{-4}—10^{-3} M) of free acetylacetone (as radiolytic product or impurity), from which resulted $M(acac)_n$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3215—3216 (1972)

The Effect of Intramolecular Hydrogen Bonding on Benzoylation of 2-(*N*,*N*-Dialkylamino)ethanols

Kunihiro ICHIMURA and Junko YOSHIDA*

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama

** Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba*

(Received December 4, 1971)

We have synthesized some *O*-acylated 2-(*N*,*N*-dialkylamino)ethanols by the action of acyl chloride on aminoalcohols. When an equimolar amount of acyl chloride was used, the yields of the hydrochloride of *O*-acylated aminoalcohol were found to be relatively low, the hydrochloride of aminoalcohol also being formed. Although various *O*-acylated 2-(*N*,*N*-dialkylamino)ethanols have been synthesized, the mechanism does not seem to be fully understood. We have examined the reaction mechanism of some 2-(*N*,*N*-dialkylamino)ethanols with benzoyl chloride by means of IR-spectrometry. It was found that the reaction rate is affected by the intramolecular hydrogen bonding of the aminoalcohols.

Results and Discussion

It was observed that the reaction of acyl chloride with equimolar 2-(*N*,*N*-dialkylamino)ethanol at room temperature gives a mixture of the hydrochloride of *O*-acylated aminoalcohol and of the parent aminoalcohol. The yields of acylated amines were thus reduced, although the reaction was expected to proceed smoothly through the intramolecular base-catalysed mechanism. Because of the good solubility of the hydrochloride of products in dichloromethane, benzoylation of aminoalcohols was followed by means of infrared spectrometry.

As soon as an equimolar amount of *N*,*N*-diethylaminoethanol (Ia) was mixed with benzoyl chloride (3.30×10^{-2} M) in dichloromethane at room temperature, the ester C=O band of diethylaminoethyl benzoate (IIa) at 1717 cm^{-1} and OH stretching vibration of diethylaminoethanol hydrochloride (Ia-HCl) at 3280 cm^{-1} began to develop. After 24 hr, the C=O ester band was found to shift to 1727 cm^{-1} due to formation of the hydrochloride of diethylaminoethyl benzoate (IIa-HCl), as the OH band at 3280 cm^{-1} weakened. About 42% benzoyl chloride remained. The products were identified with the authentic samples.

However, the IR-spectrum of a reaction mixture of benzoyl chloride and twofold molecular amount of aminoalcohol differs from the above result. The ester carbonyl band of IIa-HCl at 1727 cm^{-1} and OH band of Ia-HCl at 3280 cm^{-1} increase monotonously and isoabsorptive points at 3400 cm^{-1} are observed. This indicates that a twofold molecular amount of aminoalcohol is neccessary to complete the reaction to afford diethylaminoethyl benzoate and hydrochloride of diethylaminoethanol. The spectral change during the course of the reaction of equimolar amount of

$$C_6H_5COCl + \underset{\text{I}}{R^1_2NCHR^2CHR^3OH} \xrightarrow{k_1} \underset{\text{II-HCl}}{C_6H_5COOCHR^3CH\overset{+}{R}^2NHR^1_2\cdot Cl^-} \quad (1)$$

$$\text{II-HCl} + \text{I} \xrightarrow{k_2} \underset{\text{II}}{C_6H_5COOCHR^3CHR^2NR^1_2} + \underset{\text{I-HCl}}{R^1_2\overset{+}{N}HCHR^2CHR^3OH\cdot Cl^-} \quad (2)$$

$$C_6H_5COCl + \text{II} + \text{I-HCl} \xrightarrow{k_3} 2\ \text{II-HCl} \quad (3)$$

Scheme 1. Benzoylation of 2-(*N*,*N*-dialkylamino)ethanols (Ia: $R^1=CH_3CH_2$, $R^2=R^3=H$; Ib (*threo*), Ic (*erythro*): $R^1=R^2=CH_3$, $R^3=C_6H_5$).

aminoalcohol is then interpreted by the following scheme (scheme 1). Aminoalcohol (Ia) is at first benzoylated to give ester hydrochloride (IIa-HCl) according to reaction (1), which, in turn, is readily deprotonated by aminoalcohol (Ia) to form Ia-HCl and free ester (IIa)(reaction (2)). Reaction (2) was confirmed by the fact that the infrared spectrum of an equimolar mixture of IIa-HCl and Ia is essentially the same as that of IIa and Ia-HCl.[1] Twofold molar aminoalcohol is thus consumed according to reactions (1) and (2). Remaining benzoyl chloride reacts then more slowly with the hydrochloride of aminoalcohol (Ia-HCl), free ester (IIa) acting as the scavenger of hydrogen chloride formed (reaction (3)). From observation of the infrared spectral change we assume that the rate constants are qualitatively in the order; $k_2 \gg k_1 > k_3$, where k_1, k_2, and k_3 are the rate constants of reactions (1), (2), and (3), respectively.

Using the stationary state approximation, we obtain the kinetic equation

$$dx/dt = k_1(a-x)(b-2x) \quad (4)$$

$$\text{if } a = b,\ k_1t = 2.303\log((a-x)/(a-2x)) \quad (5)$$

$$\text{if } 2a = b,\ k_1t = x/(2a(a-x)) \quad (6)$$

where a and b are the initial concentrations of benzoyl chloride and aminoalcohol, respectively, and x is the concentration of the product or benzoyl chloride consumed at time t. The rate at 24°C was thus calculated by estimating the disappearance of carbonyl band of benzoyl chloride at 1775 cm^{-1}. The second order kinetic plots according to Eq. (6) gave a straight line

1) It is reported that aminoethanol (pK_a=9.50) is more basic than the *O*-acetylated derivative (9.10).[2]

2) D. D. Perrin, "Dissociation Constants of Organic Bases in Aqueous Solution," Butterworths, (1965).

Table 1. Physical properties of 2-(*N*,*N*-dialkylamino)ethanols

				Cinchonidine
rate const. (k_1)[a] (l mol^{-1} sec^{-1})	2.64×10^{-2}	3.94×10^{-3}	1.01	too rapidly
pK_a (26°C)[2]	9.74[b]	10.00	9.26	8.40[c]
ν_{OH} (cm^{-1})[d]	3420	3300	3400	3280
ν_{OH} of HCl salt[d]	3280	3280	3240	3280

a) Although the rate constants may be lacking accuracy with respect to constancy and homogeneity of temperature of the reaction mixture during the kinetic measurement, the present method (see Experimental) is sufficient for a discussion of the difference in rate under the same conditions. b) Corrected to 26°C.[5] c) In 80% Methyl Cellosolve at 15°C.[4] d) The wave numbers did not change in the range 0.12—0.024 M in dichloromethane.

when twofold molecular amount of aminoalcohol was used. In the case of equimolar aminoalcohol a straight line was also obtained only up to 40% consumption of benzoyl chloride according to Eq. (5). The second order rate constants in both cases are identical within experimental error. It is therefore noteworthy that the concerted push-pull mechanism is excluded, in contrast to the alcoholysis of some acyl chloride which have been found to be second order in alcohol.[3] In order to obtain further information with regard to the acylation, benzoylation of *threo*-1-phenyl-2-dimethylaminopropanol-1 (Ib) and the diastereomeric *erythro* compound (Ic) was carried out in the same manner. A remarkable difference in reaction rate between these diastereomers was observed (Table 1). If the rate determining step of reaction (1) is the attack of benzoyl chloride upon hydroxy group of aminoalcohol, then the stronger the intramolecular hydrogen bonding, the faster the reaction. Although the hydrogen bonding of *threo* compound (Ib) is stronger than that of *erythro* isomer (Ic) as a result of the steric requirement (see ν_{OH} in Table 1), the benzoylation of *erythro* isomer (Ic) is about 250 times faster than that of *threo* isomer (Ib). The effects of molecular structure of these diastereomers on the rate should predominantly arise from the intramolecular hydrogen bonding. We can thus conclude that the intramolecular hydrogen bonding reduces the nucleophilicity of nitrogen atom to form *N*-acylammonium cation (III). In view of failure to detect the intermediate and from observation of isoabsorptive points during the course of reaction by means of IR-spectroscopy, we propose that the intermediate (III) undergoes immediately the *N-O* acyl rearrangement to yield hydrochloride of *O*-acylated aminoalcohol.

The rate of benzoylation (k_1) increases apparently with decrease in pK_a of aminoalcohol. Cinchonidine whose pK_a is 8.40 was in fact found to be benzoylated so rapidly that measurement of the rate by the present method failed. The correlation could be caused by the effect of intramolecular hydrogen bonding which gives rise to depression of the nucleophilicity of nitrogen atom as mentioned above and contrariwise to enlargement of pK_a value. It is seen that the geometrical isomer of β-aminoalcohol with a stronger intramolecular hydrogen bonding is more basic than that with a weaker one.[4]

Such acyl chlorides as phenylacetyl- or phthaloylaminoacyl chloride also react too rapidly with 2-(*N*,*N*-dialkylamino)ethanols to make observation of the infrared spectral change of the reaction mixture possible. This suggests another mechanism where hydrogen at the α-position of acyl chloride could readily be eliminated to give ketene as Pracejus has proposed from the results of the asymmetric esterification of acyl chloride in the presence of alkaloids.[5]

Experimental

Materials: Benzoyl chloride was distilled before use. Diethylaminoethanol was fractionally distilled and used immediately. *erythro*- and *threo*-1-Phenyl-2-dimethylaminopropanol-1 were obtained by the Leuckardt reaction of ephedrine and ψ-ephedrine and purified by distillation or sublimation. Cinchonidine was recrystallized from aqueous propanol-2 and dried *in vacuo*. 2-*N*,*N*-Diethylaminoethyl benzoate (bp$_7$ 140—141°C), hydrochloride of the ester (mp 124—125°C) and 2-(*N*,*N*-diethylamino)ethanol hydrochloride (mp 134—135°C) were synthesized in the usual way. Dichloromethane was purified and dried.

Kinetic Measurement: The absorbance of benzoyl chloride at 1775 cm^{-1} in dichloromethane was found to be proportional to concentration in the range 0.8×10^{-2}—3.5×10^{-2} M. A solution of benzoyl chloride of 3.30×10^{-2} M(1 m*l*) in dichloromethane was mixed rapidly with shaking with equi- or twofold molecular amount of aminoalcohol solution (1 m*l*) in a test tube immersed in a water bath, the temperature of which was equilibriated with room temperature controlled at 24°C. This instant was taken as the origin of time. The KBr cell (0.5 mm thick) was then filled with the combined solution. These operations required at least 30 sec. The IR-spectrum was recorded at intervals with a JASCO DC-402 Type IR-Spectrometer. We could observe no other band than that due to aromatic ring system within the range 2400—1800 cm^{-1}. The concentration of benzoyl chloride in the reaction mixture was calculated by the estimation of absorbance of carbonyl band at 1775 cm^{-1}. The second order kinetic plots of Ia, Ib, and Ic according to Eq. (5) or (6) deviated from a straight line within 4%, 10%, and 5% error, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3217—3218 (1972)

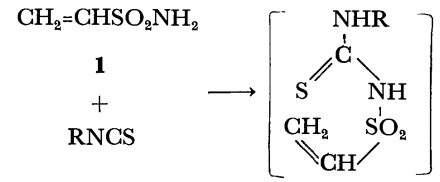
Synthesis of the New 1,4,2-Dithiazine 1,1-Dioxides[1)]

Kazuaki NAKAHASHI, Syuzi HIROOKA, and Kiyoshi HASEGAWA

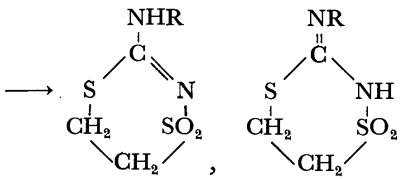
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi

(Received January 10, 1972)

Previously, the synthesis of *N*-(2-phenylethene-1-sulfonyl)-*N'*-alkylthioureas and their intramolecular cycloadducts, 3-alkylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines, from 2-phenylethene-1-sulfonamides was reported.[2)]



2



3 **4**

The present paper will describe the reaction of vinylsulfonamide (**1**) with isothiocyanates to give new heterocyclic compounds, 3-alkylamino-1,1-dioxo-5,6-dihydro-1,4,2-dithiazines (**3**) and 3-phenylimino-1,1-dioxo-2,3,5,6-tetrahydro-1,4,2-dithiazines (**4**), which are the intramolecular Michael cycloadducts of the probable intermediates, vinylsulfonyl thioureas (**2**).

The reaction of **1** with carbon disulfide and dimethyl sulfate in DMF in the presence of sodium hydroxide yielded 3-methylthio-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (**5**). The treatment of **5** with chlorine in chloroform gave the 3-chloro derivative (**6**), and the reaction of **6** with alcohol or amines afforded 3-alkoxy (**7**) or 3-amino derivatives (**8**), respectively.

Analogous syntheses starting from 2-phenylethene-1-sulfonamides were reported in a previous work,[3)] but the ethylenic bond in vinylsulfonamide is very reactive and we failed to secure the vinylsulfonylated thioureas **2** and dithiocarbamate, which are the noncyclic intermediates between **1** and **3**, and between **1** and **5**, respectively.

Experimental

3-Methylamino-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine (***3a***). To vinylsulfonamide (2.6 g, 0.025 mol) in acetone (15 *ml*), we added methyl isothiocyanate (2.2 g, 0.03 mol) and anhydrous potassium carbonate (4.2 g, 0.03 mol); the reaction mixture was then refluxed for 10—15 hr with stirring and subsequently filtered. The acetone layer was concentrated *in vacuo*, and the crude residue was cooled to give 3.0 g of a solid. Recrystallization from methanol gave colorless crystals. IR (KBr): 3260 (ν_{NH}), 1550—1570 ($\nu_{C=N}$), 1200—1300, 1120—1160 (ν_{SO_2}) cm^{-1}. NMR (DMSO-d_6): δ 2.710 (s, $=NCH_3$), 2.713 (d, J_{NHCH_3}=4.6 Hz), 3.16—3.56 (m, 4H, CH_2CH_2), 8.56 (broad, 0.53H, NH). Ms: *m/e* 45 (CHS), 180.061 (calculated molecular weight, 180.059).

3-Phenylimino-1,1-dioxo-2,3,5,6-tetrahydro-1,4,2-dithiazine (***4c***). To vinylsulfonamide (1.0 g, 0.009 mol) in acetone (10 *ml*), we added phenyl isothiocyanate (1.4 g, 0.010 mol) and anhydrous potassium carbonate (1.4 g, 0.010 mol); the reaction mixture was then refluxed for 10—15 hr with stirring and subsequently filtered; the potassium salt of **4c** thus obtained was dissolved in water, and the resulting solution was acidified to give 2.2 g of **4c**. Although crude **3c** was obtained by concentrating the acetone layer *in vacuo*, it was converted to **4c**

Studies of Dithiobiurets. I. Some New Cyclization Reactions of 1,1-Dimethyl-2,4-dithiobiuret

Isao IWATAKI

Chemical Research Laboratory, Nippon Soda Co., Ltd., Khozu, Odawara

(Received March 2, 1972)

Several cyclization reactions of dithiobiurets have been known hitherto. For instance, alkyl or aryldithiobiurets (**1**) react with aldehydes or ketones in the presence of hydrogen chloride to give hexahydrotriazine derivative (**2**).[1] Another example is their oxidation. They are easily oxidized with bromine or iodine to yield 1,2,4-dithiazole derivatives (**3**), which are known as thiurets.[2] Dixit obtained the same compounds by the oxidative debenzylation of the *S*-benzylisodithiobiurets, (**4**) and (**5**).[3] He also obtained benzothiazole and 1,2,4-thiadiazole derivatives, (**6**) and (**7**),[3] which were formed as by-products when a large quantity of nonpolar solvents were used at the time of the oxidation.

We wish to report here some cyclization reactions of 1,1-dimethyldithiobiuret (**8**). Like thiourea, it reacted with α,β-dichloroethyl acetate to form a thiazole derivative (**9**) in a 27% yield. Fromm and Philippe[4] reacted phenyldithiobiuret with monochloroacetone and obtained a product which melted at 163°C. They considered that the structure was **10** or **11**. Compound **10** can easily be obtained by the reaction of 4-methylthiazole and phenylisothiocyanate (mp 174—175°C)[5] or 4-methyl-2-thiazolylisothiocyanate and aniline (mp 168—169°C).[6] We tried Fromm's method and confirmed that the product had not an **11** but a **10** structure; the structure was identified by the undepressed mixed melting points and by comparing the infrared spectrum with that of an authentic sample. Choubey and Singh[7] obtained 2-arylimino-3-arylthiazolidin-4-ones when arylthioureas were

treated with monochloroacetyl chloride in the presence of sodium acetate. Compound **8** also reacted with the chloride to give a thiazolin-4-one derivative (**13**). When an equimolar pyridine was used instead of sodium acetate, monochloroacetylation occurred at the 3-position and **12** was obtained as a by-product. It was converted to the thiazoline derivative **13** by acid treatment. 1,1-Dimethyl-4-*S*-methylisodithiobiuret (**14**) reacted with phosgene and thiophosgene to yield 1,3,5-thiadiazine derivatives, (**15**) and (**16**). Imidoyl dichlorides also reacted with **14** to give 2-substituted imino-1,3,5-thiadiazine derivatives, (**17**) and (**18**).

Experimental

*2-(3,3-Dimethylthioureido)thiazole (**9**).* A suspended solution of 1,1-dimethyldithiobiuret **8** (16.3 g) in 100 m*l* of water was heated at 70°C, and then 19 g of α,β-dichloroethyl acetate were added with stirring. The solution gradually become homogeneous. The reaction mixture was then stirred for 1 hr and cooled at 0°C. The crystals thus precipitated were filtered and recrystallized from methanol; 6 g of white plates (hydrochloride) were thus obtained. Mp 175—176°C with decomposition.

Found: C, 32.43; H, 4.57; N, 18.85; S, 28.30; Cl, 16.05%. Required for $C_6H_{10}ClN_3S_2$: C, 32.14; H, 4.47; N, 18.75; S, 28.57; Cl, 16.07%. This was converted to the free base by treatment with aqueous sodium hydroxide. Mp 122—123°C.

Found: C, 38.55; H, 4.82; N, 22.25; S, 34.30%. Required for $C_6H_9N_3S_2$: C, 38.50; H, 4.81; N, 22.46; S, 34.22%.

*4-Methyl-2-(3-phenylthioureido)thiazole (**10**).* A mixture of phenyldithiobiuret (3 g) and monochloroacetone (2.7 g) was heated at 85°C for 10 min, and then 50 m*l* of acetone were added. The precipitate was filtered and recrystallized from ethanol. Then 2.8 g of the hydrochloride, melting at 162—163°C (Ref. 4: mp 163°C), were obtained. The hydrochloride (2.8 g) was dissolved in 15 m*l*) of pyridine, a 50-m*l* portion of ice water was added, and then the precipitate was collected. Recrystallization from ethanol gave 2.2 g of white prisms; mp 173—174°C. No depression of the melting points was observed when this substance was mixed with an authentic sample, obtained from 2-amino-4-methylthiazole and phenylisothiocyanate.

*2-(3,3-Dimethylthioureido)thiazolin-4-one (**13**).* A mixture of 1,1-dimethyldithiobiuret **8** (5 g), anhydrous sodium acetate (2.5 g), and monochloroacetyl chloride (3.4 g) in 50 m*l* of absolute ethanol was refluxed for 1.5 hr. After the sodium chloride had been filtered off, the solvent was evaporated *in vacuo*. The residue was washed with 30 m*l* of 1 N-hydrochloric acid and recrystallized from ethanol as yellow scalies (3.5 g); mp 208—209°C with decomposition. IR: 1700 cm^{-1} (C=O), 1580, 1550, NMR: δ 3.27 ppm (s, 6H, NMe_2), 4.50 (s, 2H, CH_2). UV: λ_{max} (in alc) 224 mμ (log ε 4.26), 241 (4.23), 287 (4.15). Found: C, 35.21; H, 4.43; N, 20.50; S, 31.74%. Required for $C_6H_9N_3OS_2$: C, 35.47; H, 4.43; N, 20.69; S, 31.53%.

*3-(N,N-Dimethylthiocarbamoyl)-2-iminothiazolin-4-one (**12**).* Into a solution of 1,1-dimethyldithiobiuret **8** (2 g) and pyridine (1 g) in 10 m*l* of acetone, monochloroacetyl chloride (1.5 g) was added at 0°C, after which the mixture was allowed to stand for 10 hr at room temperature. The precipitated plates were filtered and dissolved in 50 m*l* of water. After the solution had then been neutralized with sodium carbonate, the yellow powder was separated and recrystallized from ethanol to give 0.3 g of yellow prisms; mp 138—139°C with decomposition.

IR: 3400 cm^{-1} (NH), 1720 (C=O), 1605, 1530. UV: λ_{max} (in alc) 283 mμ (log ε 4.48). NMR: δ 3.45 ppm (s, 2H, CH_2), 3.30 and 3.18 (s, NMe_2). Found: C, 35.58; H, 4.58; N, 20.63; S, 31.74%. Required for $C_6H_9N_3OS_2$: C, 35.47; H, 4.43; N, 20.69; S, 31.53%.

From the reaction mixture, 1.3 g of **13** were obtained.

*Isomerization of 3-(*N,N-*dimethylthiocarbamoyl)-2-iminothiazolidin-4-one (**12**).* The sample (0.1 g) was dissolved in 10 m*l* of 1N-hydrochloric acid, and the mixture was allowed to stand overnight. The precipitated yellow scalies were collected. This substance was identified with **13** by means of IR, tlc, and a mixed mp determination.

*6-Dimethylamino-4-methylthio-2*H-*1,3,5-thiadiazin-2-one (**15**).* 1,1-Dimethyl-4-*S*-methylisodithiobiuret **14** (2.5 g) was dissolved in 50 m*l* of tetrahydrofuran, and then phosgene (5 g) in 20 m*l* of tetrahydrofuran was added at 0°C. An insoluble white powder was filtered off and dried. Recrystallization from ethanol afforded 2 g of white crystals (hydrochloride); mp 170—172°C with decomposition. Found: C, 29.89; H, 4.17; N, 17.28; S, 26.47; Cl, 14.78%. Required for $C_6H_{10}ClN_3OS_2$: C, 30.06; H, 4.18; N, 17.54; S, 26.72; Cl, 14.82%. IR: 1690 cm^{-1}(C=O), 1600, 1530. The neutralization of this hydrochloride with potassium carbonate gave the base **15**; it was then recrystallized from ethanol as white plates. Mp 157—158°C. IR: 1650 cm^{-1} (C=O), 1560. UV: λ_{max} (in alc) 224 mμ (log ε 3.66), 283 (4.08), 302^{sh} (4.01). Found: C, 35.23; H, 4.33; N, 20.52; S, 31.65%. Required for $C_6H_9N_3OS_2$: C, 35.47; H, 4.43; N, 20.69; S, 31.53%.

*6-Dimethylamino-4-methylthio-2*H-*1,3,5-thiadiazin-2-thione(**16**).* The isodithiobiuret **14** (1 g) was dissolved in 50 m*l* of tetrahydrofuran, and then thiophosgene (0.7 g) in 5 m*l* of the same solvent was added at 0°C. After the reaction mixture had been stirred for 1 hr, a yellow precipitate was filtered off. The solid (0.8 g) was recrystallized from ethanol as yellow crystals. Mp 192—193°C. UV: λ_{max} (in alc) 238 mμ (log ε 4.18), 297 (4.36), 379 (4.14). Found: C, 32.93; H, 4.15; N, 19.01; S, 43.78%. Required for $C_6H_9N_3S_3$: C, 32.88; H, 4.11; N, 19.18; S, 43.84%.

*6-Dimethylamino-4-methylthio-2-tosylimino-2*H-*1,3,5-thiadiazine (**17**).* To a mixture of the isodithiobiuret (3.2 g) and tosylcarbonimidoyl dichloride (5 g) in 50 m*l* of dry benzene, triethylamine (2 g) was added. The solution was warmed at 50°C for 1 hr and then poured into ice water. The benzene layer was washed with 1N-hydrochloric acid and dried over sodium sulfate. After the solvent had been evaporated, the residue was washed with methanol and recrystallized from acetone. White scalies (1.5 g) were thus obtained. Mp 159—160°C. UV: λ_{max} (in alc) 228 mμ (log ε 4.39), 301 (4.35), 333 (4.28). NMR: (in $CDCl_3$) δ 2.41 ppm (s, 3H, Me), 2.50 (s, 3H, SMe), 3.18, 3.35 (s, s, NMe_2), 7.28 (d, 2H, arom), 7.95 (d, 2H, arom). Found: C, 43.71; H, 4.63; N, 15.72; S, 26.84%. Required for $C_{13}H_{16}N_4O_2S_3$: C, 43.82; H, 4.50; N, 15.73; S, 26.96%.

*6-Dimethylamino-4-methylthio-2-methylsulfonylimino-2*H-*1,3,5-thiadiazine (**18**).* This was prepared by the same method from 3.2 g of the isodithiobiuret, 3.5 g of methylsulfonylcarbonimidoyl dichloride, and 2 g of triethylamine. The yield was 2 g. It was recrystallized from acetone as white scalies. Mp 174—175°C. UV: λ_{max} (in alc) 226 mμ (log ε 4.33), 298 (4.40), 327 (4.29). NMR: (in $CDCl_3$) δ 2.58 ppm (s, 3H, SMe), 3.13 (s, 3H, SO_2Me), 3.22 and 3.39 (s, s, 6H, NMe_2). Found: C, 29.84; H, 4.33; N, 19.95; S, 34.37%. Required for $C_7H_{12}N_4O_2S_3$: C, 30.00; H, 4.29; N, 20.00; S, 34.29%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3220—3222 (1972)

Studies of Dithiobiurets. II. The Thermal Decomposition of 1,1-Dimethyl-5-acetyl-2,4-dithiobiuret

Isao IWATAKI and Akiyoshi UEDA

Chemical Research Laboratory, Nippon Soda Co., Ltd., Khozu, Odawara

(Received March 2, 1972)

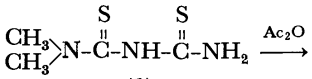
1,1-Dimethyl-5-acetyl-2,4-dithiobiuret (**2**), which is obtained by ordinary acetylation from 1,1-dimethyl-2,4-dithiobiuret (**1**), is thermally unstable and decomposes with a strong acidic odor, even at room temperature, upon standing more than 10 days.

We carried out the decomposition under various conditions and confirmed that a crystalline substance (**3**) was obtained in a 10% yield when **2** was heated at 100°C without a solvent or was refluxed in alcohol or acetone. Compound **3** shows a strong absorption band at 2030 cm^{-1} which corresponds to a SCN or NCS group and a carbonyl band at 1680 cm^{-1} in the infrared spectrum. It is soluble in water or diluted mineral acid and reacts with heavy metal ions, especially the Fe^{3+} ion, showing a pink color. An aqueous solution of it is acidic ($pK_a'=4.5$) and, upon neutralization with potassium carbonate, affords a crystalline substance (**4**) which gives analytical results corresponding to the molecular formula of $C_6H_9N_3OS_2$. Compound **4** is only two hydrogen atoms less than the starting acetyldithiobiuret **2** and still contains a singlet methyl proton at δ 2.35 ppm in addition to the *N,N*-dimethyl peaks in the NMR spectrum, but no absorption band appears in the carbonyl region of the infrared spectrum except for two sharp bands at 1580 and 1600 cm^{-1}. The high-resolution mass spectrum of **3** gave useful information for the structural elucidation of **3**. The molecular ion peak appeared at *m/e* 203; it consisted of $C_6H_9N_3OS_2$. The base peak was *m/e* 161, and the loss of the element of ketene (42 molecular units) was observed.

N,N-Dimethylthiocarbamoyl fragment was absent in **3** and **4**; the fragment peak at *m/e* 88, $Me_2N^+=C=S$, which was prominent in the mass spectrum of **2**, could not be observed in the spectra of **3** and **4**. Meanwhile, **4** was reconverted quantitatively to **3** by the addition of aqueous potassium thiocyanate to an acidic solution of **4**.

From the above results, it is clear that **3** is the hydrothiocyanate of **4**. When **4** was treated with methanolic sodium hydroxide, a yellow crystalline substance **5** was obtained; its molecular formula was identified with that of **4**. Compound **5** shows a carbonyl absorption band at 1710 cm^{-1} in the infrared spectrum, and a new singlet methylene signal appears at δ 4.50 ppm instead of the singlet methyl peak at δ 2.35 ppm

in the NMR spectrum.



(1)

(2)

(5)

It showed the same molecular ion peak (*m/e* 203) as those of **3** and **4**, and the presence of the prominent ion peak at *m/e* 88 suggested that the acetylimino-dithiazole system of **3** was rearranged to the *N,N*-dimethylthiocarbamoylthiazoline system. The structure of **5** was confirmed synthetically by the reaction of **1** and monochloroacetyl chloride described previously.[1] The acetyl methyl group in **2** was effected to be very active, and the dithiazole skeleton isomerized to the thiazoline one under alkaline conditions.

Since the starting substance **2** was presumed to be oxidized to yield **4**, **2** was oxidized under various conditions. When **2** was oxidized with iodine in alcohol or acetic acid, deacetylation occurred at the same time and gave the product **6**, which was stable; however, its free base could not be isolated. As for other non-acidic conditions, the potassium-permanganate oxidation of **5** in acetone affords **4** in a 20% yield. When **6** was treated with acetic anhydride in the presence of an equimolar triethylamine, a crystalline substance which was identified with **4** was obtained.

From the above results, the thermal decomposition product **3** from **2** was confirmed to be the hydrothiocyanate of 3-acetylimino-5-dimethylamino-3*H*-1,2,4-dithiazole (**4**).

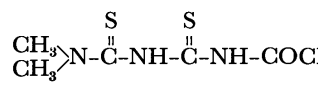
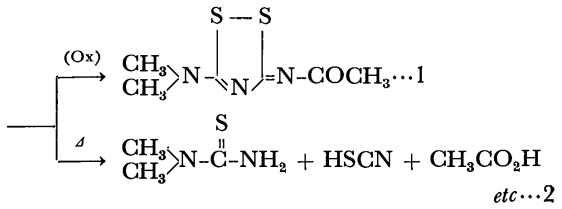
(6) HI

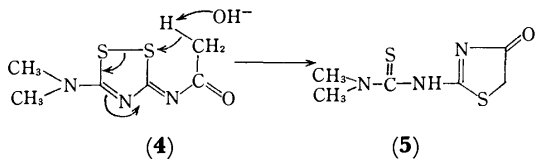
Generally, alkyldithiobiurets were obtained by the reaction of perthiocyanic acid and alkylamines at an ordinary temperature. When perthiocyanic acid was treated with amines at a higher temperature, alkyldithiobiurets were once formed and then decomposed further to yield sulfur, aminothiocyanate, H_2S, *etc.*[2] In the case of **2**, it is presumed that the acetyldithiobiuret **2** is oxidized by oxygen (from air) or isolated sulfur, as is shown in Scheme 1, and that then its salt is formed with the thiocyanic acid which is derived from the decomposition of **2**, as is shown in Scheme 2.





An analogous reaction was observed by Fairfull *et al*, in the preparation of 1-(2-pyridyl)dithiobiuret.[3] They reacted perthiocyanic acid with 2-aminopyridine and thus obtained 2-aminopyridine hydrothiocyanate.

The reaction mechanism from **4** to **5** was considered to be as in the following scheme:



(4) (5)

Experimental

Preparation of Starting Products. 1,1-Dimethyl-2,4-dithiobiuret **1** was prepared from aqueous dimethylamine and perthiocyanic acid by the method of Dixit.[2] 1,1-Dimethyl-5-acetyldithiobiuret **2** was obtained by the standard acetic anhydride-pyridine method.

*The Thermal Decomposition of **2**, the Preparation of 3-Acetylimino-5-dimethylamino-3H-1,2,4-dithiazole **3**.* *Procedure 1*: 1,1-Dimethyl-5-acetyldithiobiuret **2** (10 g) was heated for 1 hr at 100°C in a round-bottomed flask; then a 100 m*l* portion of acetone was added, and the insoluble crystalline substance was filtered off and washed with acetone. Recrystallization from methanol gave 1 g of white needles melting at 183—184°C with decomposition. IR: 2020 cm^{-1} (S-CN), 1690 (C=O), 1610 (C=N). NMR: δ 3.45 ppm (broad s, 6H, NMe_2), 2.18 (s, 3H, Ac). Mass: *m/e* 205, 204, 203, 188, 163, 162, 161, 146, 128, 116, 102, 97. UV: λ_{max} (in alc) 274, 302 mμ. Found: C, 31.65; H, 3.92; N, 21.46; S, 36.20%. Calcd for $C_7H_{10}N_4OS_3$: C, 32.06; H, 3.81; N, 21.37; S, 36.64%.

Procedure 2: A suspended solution of 1,1-dimethyl-5-acetyldithiobiuret **2** (10 g) in 20 m*l* of ethanol was refluxed for 4 hr and then cooled. The solution turned dark red at that time. The precipitated white needles were collected and washed with cold ethanol. The yield was 1.2 g.

Procedure 3: A mixture of the dithiobiuret (10 g) in 50 m*l* of acetone and 5 m*l* of picoline was refluxed for 5 hr, when the precipitate was then collected, 1.2 g of white or pale pink needles were obtained.

*3-Acetylimino-5-dimethylamino-3H-1,2,4-dithiazole **4**. As Obtained from the Hydrothiocyanate **3***: The hydrothiocyanate (2 g) was dissolved in 20 m*l* of 3.5 N-hydrochloric acid and made alkaline with an excess of aqueous potassium carbonate. The white precipitate was filtered and recrystallized from isopropyl alcohol to give 1.4 g of white needles, melting at 160—161°C. IR: 1600, 1570 cm^{-1}. NMR: δ 2.38 ppm (s, 3H, Ac), 3.28, 3.47 (s,s, 6H, NMe_2). UV: λ_{max} (in alc) 298 mμ (log *e* 4.3). Mass: *m/e* 203 (M^+), 161, 141, 97, 82. Found: C, 35.27; H, 4.67; N, 20.68; S, 31.46%. Calcd for $C_6H_9N_3OS_2$: C, 35.47; H, 4.43; N, 20.69; S, 31.53%.

*As Obtained from the Potassium-permanganate Oxidation of **2**.* 1,1-Dimethyl-5-acetyldithiobiuret (1 g) was dissolved in

1) I. Iwataki, This Bulletin, **45**, 3218 (1972).
2) S. N. Dixit, *J. Indian Chem. Soc.*, **38**, 44 (1961).
3) A. E. S. Fairfull and D. A. Peak, *J. Chem. Soc.*, **1955**, 796.

40 ml of acetone, and then 3 g of potassium permanganate in 60 ml of acetone were stirred in, drop by drop, at room temperature. After the manganese dioxide had been filtered off, the solvent was distilled off and the residue was dissolved in water and made alkaline with potassium carbonate. The precipitate was filtered and dried to give 0.2 g of **4**.

As Obtained from the Acetylation of 5-Dimethylamino-3-imino-3H-1,2,4-dithiazole hydroiodide ***6***: The hydroiodide **6** which was prepared by Dixit's method[2] (5 g) was suspended in 20 ml of acetone, and then 5 ml of acetic anhydride and 2 g of triethylamine were stirred in. After 30 minutes, the solution was poured into ice water and neutralized with potassium carbonate to give 3 g of **4**.

The Preparation of the Dithiazole Hydrothiocyanate ***3*** *from* ***4*** *with Thiocyanic Acid.* 3-Acetylimino-5-dimethylamino-3*H*-1,2,4-dithiazole **4** (0.1 g) was dissolved in 3.5 N-hydrochloric acid (3 ml), and then 1 g of potassium thiocyanate in 1 ml of water was added. The white needles thus precipitated were collected. The mp, IR, and NMR coincided with those of **3**.

The Isomerization of ***4*** *to* ***5***, *the Preparation of 2-(3,3-Dimethylthioureido)thiazolin-4-one.* A solution of the dithiazole **4** (0.3 g) in 8 ml of ethanol and 2 ml of 5N-KOH was kept at room temperature for 15 hr, and then poured into ice water and acidified with hydrochloric acid. The precipitate was extracted with chloroform, dried over magnesium sulfate, and evaporated *in vacuo*. Recrystallization from methanol gave 0.1 g of yellow scalies melting at 208—209°C Ref. 1: mp 208—209°C).

Studies on the Derivatives of Thiiranes. II.[1] Ring-opening of 2-Alkoxymethylthiiranes and Their Derivatives[2]

Eiichi KAMEYAMA, Motoki NAKAJIMA,* and Tsunehiko KUWAMURA

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjincho, Kiryu

(Received May 20, 1972)

2-Chloromethylthiirane (**1**)[3,4] and many other thiiranes[5-7] predominantly yield their corresponding abnormal ring-opening products. We found, however, that **1** predominantly yields a normal ring-opening product by the reaction with hydrogen chloride and chloroxidation.[8] Schwartz[9] later reported a similar results. The reaction of 2-alkoxymethylthiiranes (**2**) with some nucleophilic reagents has been found to yield a normal product.[10]

The present work was undertaken to clarify the ring-opening direction of **2** on chloroxidation and to establish a synthetic route to some alkoxylated sulfonyl compounds from **2**. The reaction of **2** with hydrogen chloride at low temperature exclusively gave a normal product, 1-alkoxy-3-chloropropane-2-thiol (**3**). On chloroxidation in water, **2** and **3** gave the same product, 1-alkoxy-3-chloropropane-2-sulfonyl chloride (**4**).

These results are similar to those for **1**. Dominance of the normal ring-opening on these reactions of **1** and **2** is seemingly due to both polar and steric effects of the substituents on the site of attack on an episulfonium ion intermediate by the nucleophile.[9]

8	Et	54	—	—	34.72 (35.89)	6.59 (6.45)	13.71 (13.69)	9.82 (9.82)

On the reaction with a tertially amine and metal alkoxide at low temperature, **4** gave new olefinic sulfonyl compounds and bisalkoxy derivatives, in good yields.

The reactions are summarized in the following scheme. The yields and other data are listed in Table 1.

Although **7** and **8** could also be derived from 2-chloromethylthiirane,[1] the present route is much more advantageous with respect to the yield. Some higher homologues of **8** have been prepared by the same method and found to be highly surface active.[11]

Experimental[12]

Materials. Alkoxymethylthiiranes were prepared from the corresponding glycidylethers by the method of Bordwell and Andersen.[13] The methyl homologue, bp 54—55°C/20 mmHg, n_D^{25} 1.4775. The ethyl homologue, bp 56.5°C/20 mmHg, n_D^{25} 1.4705.

Addition of Hydrogen Chloride to ***2****.* The reactions with anhydrous hydrogen chloride were carried out by the same method as that for the addition to **1**.[1] Spectra of **3**(R: CH_3); IR(neat), 2580(SH), 1118 (C-O-C) cm^{-1}; NMR(in CCl_4), 1.95 (d, 1H, *sec.* SH), 3.30 (s, 3H, CH_3), 3.48—3.69 m, 5H, CH_2 and CH), no triplet band at 1.5—2.0 ppm assignable to a prim. thiol proton[1] could be found.

Chloroxidation of ***2*** *and* ***3****.* The thiirane **2** was added dropwise at −10—5°C to an aqueous solution saturated with chlorine. Concurrently chlorine was bubbled through the mixture at such a rate that an excess was always present. After addition of **2**, chlorine was further bubbled for 1 hr. The heavy oil layer was separated, diluted with ether and then washed successively with water, 5% bisulfite solution and water. The ether solution was distilled in a stream of nitrogen to give **4** in a good yield. Spectra of **4**(R : CH_3); IR(neat), 1380(SO_2), 1170(SO_2), 1120(C-O-C), 757(C-S) cm^{-1}; NMR (in benzene), 3.18(s, 3H, CH_3), 3.75—3.90 (m, 5H, CH_2 and CH).

Chloroxidation of **3** was similarly carried out, giving **4** in 60—70% yield.

*3-Alkoxypropene-2-sulfonyl Chloride (****5****).* An equimolar solution of triethylamine at −50—−40°C was added dropwise to an ether solution of **4**. After being stirred for 1 hr, the mixture was filtered and then distilled to give **5** in 40—50% yield. Spectra of **5**(R : CH_3); IR(neat), 3110 (=CH_2), 1630(C=C), 1370(SO_2), 1183(SO_2), 1105(C-O-C) cm^{-1}; NMR(in CCl_4), A 3.40(s, 3H, CH_3), B 4.30(t, 2H, J_{BC}=1.5, J_{BD}=1.5 Hz, $CH_3OC\underline{H}_2$-), C 6.18(q, 1H, J_{CD} =3.0 Hz, CH_2=C *trans* proton against $-SO_2Cl$), D 6.43 (q, 1H, CH_2=C *cis*).

Reaction of ***4****(R : Et) with Sodium Ethoxide.* When **4** was treated in ethanol with an equimolar solution of ethoxide, **4** remained mostly unreacted and gave a small amount of three unknown products difficult to isolate. A solution of ethoxide(0.1 mol) at −5°C was added dropwise over a period of 30 min with stirring to a solution of **4**(11 g, 0.05 mol) in ethanol(18 m*l*). After the addition, the mixture was centrifuged from the salt and distilled to give two fractions, **6** (1.8 g) and **7**(5.4 g). Spectra of **6**; IR(neat), 3120(=CH_2), 1650(C=C), 1350(SO_2), 1160(SO_2), 1105(C-O-C-), 800(C-S) cm^{-1}; NMR(in CCl_4), A 1.23(t, 3H, $C\underline{H}_3CH_2OCH_2$), B 1.38(t, 3H, $C\underline{H}_3CH_2O_3S$), C 3.57(q, 2H, J_{AC}=7.0 Hz, $CH_3C\underline{H}_2OCH_2$), D 4.14(q, 2H, J_{BD}=7.0 Hz, $CH_3C\underline{H}_2O_3S$), E 4.18(t, 2H, $EtOC\underline{H}_2$), F 6.09(t, 1H, J_{EF}=1.0, J_{FG}=1.0 Hz, CH_2=C *trans* proton against $-SO_3Et$), G 6.25(t, 1H, J_{EG} =1.0 Hz, CH_2=C *cis*).

A 3-fold molar quantity of ethoxide relative to **4** was added in the same manner. The mixture was stirred for 10 hr at 25—30°C, neutrallized, centrifuged and evaporated. The residue was recrystallized three times from acetone to yield the pure product **8**. The IR and NMR spectra of **7** and **8** agreed with those of the same products[1] derived from **1**.

Free-Radical Chlorination of Alkylsilanes. VII.* The Hydrogen Abstraction from 1-Silabicyclo[2.2.1]heptane by the Trichloromethyl Radical

Yoichiro NAGAI, Shin-ichi INABA, Hideyuki MATSUMOTO, and Hamao WATANABE

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received May 22, 1972)

In general, carbon free radicals are assumed to have either the pyramidal configurations undergoing rapid inversion, or the planar structures, so that the bridgehead carbon radicals are formed only with difficulty.[1] For example, the homolytic chlorination of norbornane results in the formation of 2-chloronorbornane exclusively, the 1-chloro isomer being not formed in any appreciable amount.[2] In harmony with this fact, Applequist and Kaplan[3] reached a conclusion that the 1-bicyclo[2.2.1]heptyl radical is less stable than simple alkyl radicals from their results of the decarbonylation of aliphatic and bridgehead aldehydes. In constrast, simple silyl radicals tend to maintain the original tetrahedral geometry without turning itself inside out, and some spectroscopic evidence supporting this point has recently been obtained by several workers.[4–6] Also, two groups of workers[7,8] have reported that silyl radicals, consistent with their tetrahedral structures, abstract a chlorine atom from carbon tetrachloride with high retention of configuration. These preceding evidences might lead to an assumption that the 1-silabicyclo[2.2.1]hept-1-yl radical would readily be formed by the hydrogen abstraction from the corresponding bridgehead hydrosilane, but confirmation of this hypothesis must provide a desirable research objective. The present paper describes the homolytic hydrogen-chlorine exchange reaction between 1-silabicyclo[2.2.1]heptane and carbon tetrachloride which involves the hydrogen abstraction by the trichloromethyl radical from the bridgehead silicon hydride, the silicon analogue of norbornane.

Experimental

All the boiling and melting points are uncorrected. Spectral data of the bicyclic silicon hydride and chloride are presented in Table 1.

1-Silabicyclo[2.2.1]heptane. This compound was prepared by the method of Sommer and Bennett.[9] The pure product was a white crystalline solid which sublimed very readily and had mp 75°C in a sealed tube (lit.[9] mp 63°C)[10]

Chlorination of 1-Silabicyclo[2.2.1]heptane with Carbon Tetrachloride. Chlorination procedures were essentially the same as described previously.[11–13] Results obtained are summarized in Tables 2 and 3.

Results and Discussion

1-Silabicyclo[2.2.1]heptane was heated with carbon tetrachloride at 80°C in the presence or absence of benzoyl peroxide. As is seen from Table 2, the hydrogen-chlorine exchange reaction between the bridgehead hydrosilane and carbon tetrachloride readily occurs under homolytic conditions, giving a pair of the expected products, the corresponding chlorosilane and chloroform. The reaction can most pro-

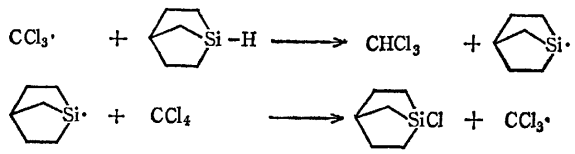
a) $[A]_{i'}$ $[B]_{i'}$ represent the initial concentrations of two hydrosilanes, $[A]_{f'}$ $[B]_{f'}$ the final concentrations and k_A/k_B the ratio of rate constants for the attack of the abstracting reagent on the two species.

bably be explained in terms of the following chain carrying processes and thus confirms an anticipation previously raised that the SiH hydrogen atom at the bridgehead position can be abstracted by carbon radicals with ease.



The reactivity of the bicyclic silicon hydride toward the trichloromethyl radical was next determined by competition experiments. A mixture of 1-silabicyclo-[2.2.1]heptane and triethylsilane was allowed to react with carbon tetrachloride at 80°C in the presence of benzoyl peroxide. The relative rate was calculated with the equation of Ingold and Shaw[14] from concentrations of the reactants or products as determined by glpc (Table 3). Results show that 1-silabicyclo-[2.2.1]heptane reacts with carbon tetrachloride 0.45 times as fast as triethylsilane. The hydrogen abstraction rate from the bridgehead silicon hydride was thus found to be comparable to that from its open chain analogue, triethylsilane.* However, it is noteworthy that the bridgehead hydride reacts distinctly slower than triethylsilane. This trend cannot be explained

14) C. K. Ingold and F. R. Shaw, *J. Chem. Soc.*, **1927**, 2918.

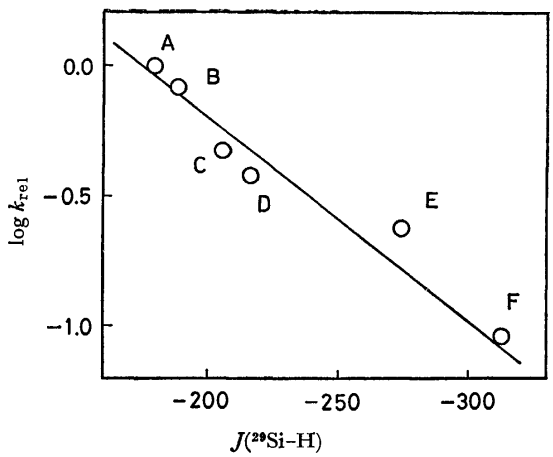


Fig. 1. A plot of relative rates for reactions of hydrosilanes toward the trichloromethyl radical (80°C) *versus* $J(^{29}Si-H)$. (A): Et_3SiH, (B): $PhMe_2SiH$, (C): 1-silabicyclo[2.2.1]-heptane, (D): Et_2ClSiH, (E): $EtCl_2SiH$, (F): Cl_3SiH.

on the basis of electronic effects of substituents alone, since there is by no means expected any appreciable difference in the magnitude of the electronic effect between the bridgehead and open chain structures. An attractive explanation for the observed reactivity of the bicyclic system can be advanced, however, by taking into consideration the change in bond hybridization at the bridgehead silicon atom. The fraction of *s* character employed by the silicon in its bond to hydrogen[15] would be forced to increase by special geometrical situation which exists. This was found to be the case as indicated by the large value (in the absolute sence) of $J(^{29}Si-H)$ for 1-silabicyclo-[2.2.1]heptane, −205.8 Hz, compared to that for triethylsilane, −179.6 Hz. It should be noted at this point that the relative reactivities of a variety of Si-H bonds toward the trichloromethyl radical are linearly correlated with values of $J(^{29}Si-H)$ which reflect the magnitude of *s* character employed by silicon in the Si-H bonds.[16] In view of this relationship, data for the bridgehead silicon hydride were treated in a similar fashion (Fig. 1). Obviously, the point for 1-silabicyclo[2.2.1]heptane falls on the straight line with a reasonable precision and this fact again indicates that the trichloromethyl radical preferentially attacks a Si-H bond of smaller *s* character. More significant is that the special conformation modifies the electronic structure and hence the reactivity of the molecule to some appreciable extent.

Inositol Derivatives. VI. Convenient Synthesis of DL-*proto*-Quercitol from *myo*-Inositol

Tetsuo SUAMI, Seiichiro OGAWA, Tsunehisa UEDA, and Hayashi UCHINO

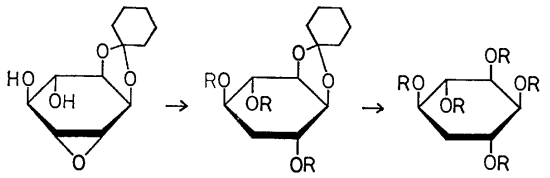
Department af Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama

(Received June 8, 1972)

(+)-*proto*-Quercitol was discovered in acorns in 1849,[1] and its configuration was established in 1932,[2] whereas, levorotatory isomer remained unknown until 1961.[3] Plouvier[3] prepared a racemic form of *proto*-quercitol by mixing an equal weight of the two enantiomers, and it was shown to exist as a solid solution.

The total synthesis of (−)-*proto*-quercitol was first accomplished in 1966 by McCasland and his coworkers[4] starting from quebracitol or, somewhat less conveniently from (−)-*chiro*-inositol. Their identical procedure applied to (+)-*chiro*-inositol should lead to (+)-*proto*-quercitol, and, similarly, DL-*proto*-quercitol should be synthesized from DL-*chiro*-inositol.

Since we require large quantities of DL-*proto*-quercitol in order to synthesize deoxyinosadiamines and pseudo sugars of biological interest, we have been studying its alternative and facile preparation from *myo*-inositol. In the present paper, we wish to report the convenient synthesis of DL-*proto*-quercitol from readily avairable DL-1,2-anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**2**).[5]



2 **3a** R=H **b** R=Ac **4a** R=H **b** R=Ac

Treatment of DL-1,2-*O*-cyclohexylidene-3-*O*-*p*-tolylsulfonyl-*myo*-inositol (**1**)[6] in methanol with a slight excess of sodium methoxide gave **2** almost exclusively in 86% yield. Reduction of **2** with lithium aluminum hydride in tetrahydrofuran at refluxing temperature for 4 hr gave DL-1,2-*O*-cyclohexylidene-4-deoxy-*muco*-inositol (**3a**) predominantly in 87% yield, which was converted into the tri-*O*-acetyl derivative (**3b**) in the usual way. Hydrolysis of **3a** with boiling 6N hydrochloric acid gave crystals of DL-*proto*-quercitol (**4a**) in 80% yield. The crystalline pentaacetate (**4b**) was also prepared from **4a**.

Assuming that an epoxide-migration occurred under the reduction condition, two stereoisomers of deoxyinositols should be formed from **2**; namely, DL-*proto*- and DL-*vibo*-quercitols. In the proton magnetic resonance (PMR) spectrum of **4b** in deuteriochloroform ($CDCl_3$), the signals of five acetyl methyl protons appeared as three singlets at τ 7.86, 7.97, and 7.99 in the relative intensities of 2 : 2 : 1, which could be assigned to the signals of two axial, two equatorial and one equatorial acetoxy groups, respectively.[7] Therefore, the spectrum was not compatible with the *vibo*-configuration, since it has only one axial acetoxy group. Moreover, an authentic sample of the pentaacetate of DL-*vibo*-quercitol[8] was proved to be different from **4b** in all respect.

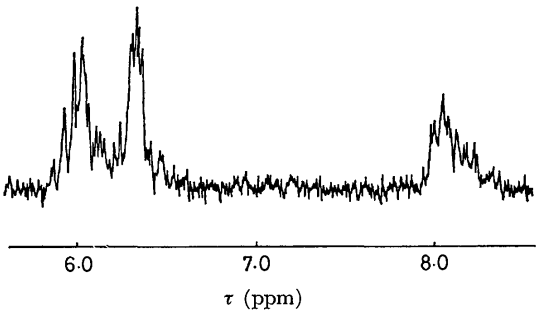


Fig. 1. PMR spectrum of DL-*proto*-quercitol (**4a**) in D_2O at 60 MHz,

The PMR spectrum of **4a** in deuterium oxide (D_2O) was shown to be identical with that of (−)-*proto*-quercitol reported by McCasland[9] (Fig. 1). Consequently, the structure of **4a** was established unequivocally, and it was found that the reduction of **2** with lithium aluminum hydride proceeded almost stereospecifically to afford **3a**. The overall yield of **4a** from **1** was 60%.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. PMR spectra were measured on a Varian Associates A-60D (60 MHz) spectrometer with tetramethylsilane as an internal standard. Chemical shifts are expressed in τ-values. Thin layer chromatography (tlc) was done with silica gel (Wakogel B-10, Wako pure chemical industries Ltd.) and the compounds were detected by heating after spraying 50% sulfuric acid.

DL-*1,2-Anhydro-5,6-O-cyclohexylidene*-chiro-*inositol* (*2*). This compound was prepared from DL-1,2-*O*-cyclohexylidene-3-*O*-*p*-tolylsulfonyl-*myo*-inositol (**1**)[6] in 86% yield, following the procedure previously mentioned.[5]

DL-*1,2*-O-*Cyclohexylidene-4-deoxy*-muco-*inositol* (**3a**). To a solution of **2** (7.5 g) in dry tetrahydrofuran (350 m*l*) was added lithium aluminum hydride (5.0 g) in dry tetrahydrofuran (50 m*l*) and the mixture was refluxed for 4 hr. After cooling, water (30 m*l*) was added dropwise to destroy the excess of metal hydride. The solution was allowed to stand overnight at room temperature, and then the white precipitates were collected by filtration. The filtrate was evaporated to give a crystalline residue which was digested with ethanol and filtered to afford practically pure **3a** (5.2 g, 71%), mp 164—166°C. An additional crop (1.2 g, 87%) was recovered by extraction from dried white precipitates using Soxhlet extractor with tetrahydrofuran. An analytical sample was obtained by recrystallization from ethanol, mp 165—167°C. Tlc indicated a single spot (methyl ethyl ketone-toluene=1 : 1 volume).

Found: C, 58.97; H, 8.11%. Calcd for $C_{12}H_{20}O_5$: C, 59.00; H, 8.25%.

The tri-*O*-acetyl derivative (**3b**) was prepared by treatment of **3a** with acetic anhydride and pyridine at room temperature in a quantitative yield. Recrystallization from ethanol gave a pure sample, mp 103—104°C. Tlc indicated a single spot (methyl ethyl ketone-toluene=1 : 10 volume). PMR ($CDCl_3$): τ 4.57 (1, quartet, H-3, J=3.0 Hz), 7.89, 7.92, 7.98 (3, singlet, OAc).

Found: C, 58.71; H, 7.03%. Calcd for $C_{18}H_{26}O_8$: C, 58.37; H, 7.08%.

DL-proto-*Quercitol* (**4a**). Compound **3a** (1.0 g) was treated with boiling 6N hydrochloric acid (20 m*l*) for 2 hr. Then the mixture was evaporated to dryness to give an oily product which was crystallized from ethanol-water to give crystals (540 mg, 80%) of **4a**, mp 208—215°C (decomp.). Recrystallization from the same solvent afforded an analytically pure sample, mp 236.5—238°C (lit,[4] mp 238—239°C). The PMR spectrum in D_2O was superimposable with that of an authentic sample of (−)-*proto*-quercitol reported by McCasland.[9]

Found: C, 44.01; H, 7.12%. Calcd for $C_6H_{12}O_5$: C, 43.90; H, 7.37%.

DL-proto-*Quercitol Pentaacetate* (**4b**). Compound **4a** (50 mg) was acetylated with acetic anhydride (5 m*l*) and pyridine (5 m*l*) overnight at room temperature. The mixture was evaporated to give an oily product which was crystallized from ethanol to give pure crystals (73 mg, 63%) of **4b**, mp 114—116.5°C. Tlc indicated a single spot (methyl ethyl ketone-toluene=1 : 10 volume).

Found: C, 51.63; H, 5.81%. Calcd for $C_{16}H_{22}O_{10}$: C, 51.33; H, 5.92%.

The authors are grateful to Professor Sumio Umezawa for his kind advice, and to Mr. Saburo Nakada for his elementary analyses. The authors thank Professor G. E. McCasland for an identification of DL-*proto*-quercitol by mixed melting point determination. The financial support from the Ministry of Education for this work is gratefully acknowledged.

SHORT COMMUNICATIONS

Three Crystalline Phases of Octachloropropane as Evidenced by Chlorine NQR

Masao HASHIMOTO and Koichi MANO*

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe

** Research Institute for Atomic Energy, Osaka City University, Sumiyoshi-ku, Osaka*

(Received July 3, 1972)

In this communication, we wish to report the existence of three crystalline phases of octachloropropane (OCP), found by means of the NQR technique.

The experimental procedures of NQR measurements have been reported previously.[1] For the NQR experiments, a purified sample was used.[2] The sample was fused and packed in an ampoule.

The experimental results are given in Table 1, in which we can see that OCP posesses three crystalline phases (α, β, and γ). The phases were prepared by the following procedures:

The α phase. OCP was once sufficiently cooled at 77°K in the ampoule; next, it was left to stand at about 245°K and finally at 196°K for twenty minutes each. The last two procedures were repeated several times. Subsequent cooling in liquid nitrogen yielded the α spectrum.

The β phase. After the sample tube has been left to stand at room temperature for two days, it was immersed in a dry ice-petroleum ether bath (196°K) and then left to stand at the same temperature for two hours. Subsequent cooling in liquid nitrogen yielded the β spectrum.

The γ phase. After the sample has been once completely fused, the sample tube was immediately thrown into a dry ice-petroleum ether bath and left to stand at the same temperature for fifteen minutes. Subsequent cooling in liquid nitrogen yielded the γ spectrum.

The NQR spectrum of OCP has already been reported by Zeil and Haas.[3] Their results are also shown in Table 1. It can be seen in Table 1 that none of the three spectra, α, β, or γ, coincide with the Zeil's results. After certain annealings, we frequently observed an NQR spectrum corresponding to a mixture of the α and γ phases.[4] In this connection, it should be noted that Zeil's results are in rather good agreement with a superposition of the lower-frequency parts of the α and γ spectra.

Our DSC experiments showed that OCP posesses a plastic crystalline phase at room temperature (mp: *ca.* 433°K, ΔH_{mp}: *ca.* 560 cal/mol, and ΔS_{mp}: *ca.* 1.3 e. u.).[5] This is consistent with the apparent plasticity of OCP at room temperature and with the fact that the NQR signals were not observed at room temperature.[6,7]

Details of the NQR and DSC studies will be reported in a later publication.

Complexes of Copper(II) with Cyclodextrins

Yoshihisa MATSUI, Toyoaki KURITA, and Yoshio DATE

Department of Agricultural Chemistry, Faculty of Agriculture, Shimane University, Nishikawazu, Matsue

(Received June 22, 1972)

It is known that a number of organic and inorganic substances are enclosed and fixed within the void spaces of cyclodextrins, thus forming inclusion compounds.[1] However, the inclusion of metal cations in the dextrins has never been studied. We wish here to report that copper(II) reacts with cyclodextrins in alkaline solutions to form soluble complexes.

When two aqueous solutions, 0.2 N NaOH and 0.02 M $CuSO_4$, of an equal volume were mixed, the precipitate of $Cu(OH)_2$ formed immediately. The supernatant was virtually colorless and contained no appreciable amount of Cu(II) (below 10^{-5} M). However, upon the addition of β-cyclodextrin (I) to the mixture, a part of the precipitate was dissolved and the supernatant became blue. The concentration of the dissolved Cu(II) was titrimetrically determined by the use of EDTA and murexide, as a titrant and an indicator respectively, after the neutralization of the supernatant by an aqueous HCl. The Cu(II) concentration determined was then plotted against the concentration of I added (Fig. 1, Plot a). It is obvious that

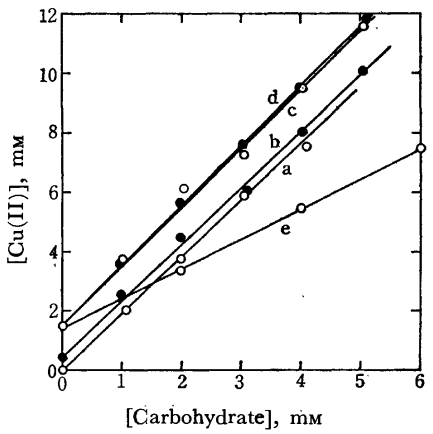

Fig. 1. Plots of the concentration of the dissolved Cu(II) *vs.* those of carbohydrates added.
a, I in 0.1 N NaOH; b, I in 0.5 N NaOH; c, I in 1 N NaOH; d, II in 1 N NaOH; e, III in 1 N NaOH

the plot is linear with the slope of *ca.* 1.9. Similar plots were obtained in solutions more basic than 0.1 N NaOH (Fig. 1, Plots b and c), although a small amount of Cu(II) had been dissolved before the addition of I. The results indicate that Cu(II) forms a complex with I in which two Cu(II) ions are bound to a molecule of I (2 : 1 complex).

The Cu(II)-I complex was isolated from a solution. When 10 m*l* of ethanol was added to 12 m*l* of 2 N NaOH containing 0.01 M I and 0.02 M $CuSO_4$, blue crystal were precipitated; they were then filtered off, washed with aqueous ethanol, and dried *in vacuo*. The content of Cu(II) in the crystals was titrimetrically determined to be 0.59 mmol/g. The content of I was estimated to be 0.29 mmol/g by the measurement of the optical rotation of an aqueous solution of the crystals buffered at pH *ca.* 7, where the complex dissociates into I and Cu(II). In this estimation, the specific rotation of I was taken to be 162.5°.[1] The results also show the formation of the 2 : 1 Cu(II)-I complex.

The dissolution of $Cu(OH)_2$ in an alkaline solution also took place on the addition of α-cyclodextrin(II) or of methyl-α-D-glucopyranoside(III). In each case, the plot of the concentration of the dissolved Cu(II) *vs.* that of the carbohydrate added is linear (Fig. 1, Plots d and e). The slope of the plot for II was 2.0, while it was 1.0 for III. This shows that Cu(II) forms 2 : 1 and 1 : 1 complexes with II and III respectively.

The structures of the Cu(II)-I and -II complexes are presumed to be as is shown schematically in Fig. 2.

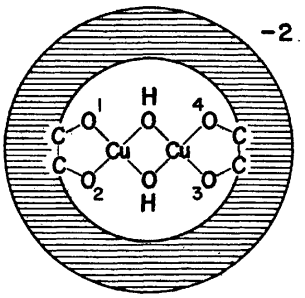

Fig. 2. Schematic structure of the Cu(II)-cyclodextrin complex.

The two pairs of C-2 and C-3 secondary hydroxyl groups of I and II may be ionized and cross-linked by the $Cu(OH)_2Cu$ ion bridge. Such a coordination of 1,2-diols to Cu(II) has often been reported to occur in alkaline solutions.[2] Since each bond length of Cu–O may be about 2 Å,[3] the distance between the oxygen atoms numbered 1 and 3 may be about 6.3 Å; this agrees well with the internal diameter (6 Å[4]) of the void of II. Thus, it seems that the $Cu(OH)_2Cu$ bridge is tightly fixed within the void of II. In the Cu(II)-I complex, the length of the $Cu(OH)_2Cu$ bridge may be somewhat shorter than the internal diameter (7.5 Å[4]) of the void of I. Hence, the direction of the bridge may not coincide with that of the internal diameter. In the Cu(II)-III complex, two molecules of III may be coordinated to both ends of the $Cu(OH)_2Cu$ bridge to form the 2 : 2 Cu(II)-III complex. The structures of the complexes will be discussed further in a subsequent communication.

The spectra of the Cu(II)-I and -II in 0.1 N NaOH at 25°C are characterized by maxima at 668 mμ ($\varepsilon=128\pm1$) and 666 mμ ($\varepsilon=118\pm1$) respectively.

Novel Radical Salts Polymer Catalyst Carrying Enhanced Para-Ortho-Hydrogen Conversion

Kentaro MURANO, Hiroshi KAWAZURA,* Hiroo INOKUCHI, and Toshio OHMORI*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

** Research Laboratory, Japan Synthetic Rubber Co., 7569, Ikuta, Kawasaki*

(Received July 12, 1972)

The catalytic behaviour of aromatics-alkali metal ion radical salts has been extensively studied since the disclosure of the catalytic activity of the tetracyanopyrene-cesium complex in the hydrogen-deuterium exchange reaction.[1] In this paper, we will establish that novel polymeric radical salts obtained by alkali metal insertion into poly(tetrahalophenylene sulphide)s and into semiconducting materials derived therefrom exhibit a strongly enhanced catalytic activity in para-ortho-hydrogen conversion.

The poly(tetrahalophenylene sulphide)s were prepared by the careful polycondensation of sodium pentahalothiophenoxide, while the semiconducting materials were obtained by dehalogenating poly(tetrahalophenylene sulphide)s in the presence of polar solvent such as pyridine at about 200°C. A possible structure of these semiconducting materials as likely to consist of a dibenzothiophene nucleus was suggested in a preceding paper,[2] along with the details of their preparations.

The radical salts complexes were easily obtained by placing the poly(tetrahalophenylene sulphide)s or the semiconducting materials in contact with alkali metal vapour in vacuum at the evaporation temperature of the alkali metal.

Table 1 shows the characteristics of the resulting complexes, which were obtained by inserting the Cs metal into the acceptor polymers to approximately saturation amounts. In spite of much occlusion of the Cs metal, the resulting complexes were stable in air—*i.e.*, they were not inflammable and did not show a rapid decomposition, though they absorbed much gaseous oxygen and humidity,—contrary to the generally-accepted idea of the unstable character of the organic-alkali metal ion salts. It is apparent that the stability of the complexes does not depend on the fact that the acceptor is simply polymeric, since we have confirmed that the complexes[3] of alkali metal poly(phenylene oxide) and alkali metal poly(phenylene sulphide), which constitute the basic skeleton of the poly(tetrahalophenylene sulphide)s, cause a rapid decomposition when in contact with air. The stability may be due to some specific structure of the semiconducting materials formed by the dehalogenation of the poly(tetrahalophenylene sulphide)s.

The para-ortho-hydrogen conversion on these complexes as catalysts was conducted in a manner analogous with that preported previously.[4] The same table, Table 1, summarizes the rate constants of the hydrogen conversion obtained by assuming a first-order reaction and the activation energies of the conversion. As is seen from Table 1, the rate constants in the range of 10^{-1}—10^{0} min^{-1} are obviously extraordinarily high, since the rate constants of the radical-salt catalysts so far studied have lain in the range of 10^{-2}—10^{-4} min^{-1}.[5]

At any rate, the high rate constants indicate enhanced catalytic activities of the present complexes in hydrogen-participating reactions. Applications of the present new catalysts to these reactions are in progress, along with the more precise elucidation of the relation between the para-ortho-hydrogen conversion and their structures.

TABLE 1. THE ELECTRICAL RESISTIVITY, THE SPIN CONCENTRATION, THE RATE CONSTANT (k), AND ITS ACTIVATION ENERGY (E) OF THE PARA-ORTHO-HYDROGEN CONVERSION OF POLY(TETRAHALOPHENYLENE SULPHIDE)-Cs AND THE SEMICONDUCTIVE POLYMER-Cs COMPLEX

An MO Approach to the Interpretation of Organic Mass Spectra. I. Relative Bond Energy of the Molecule Ion by the Extended Hückel Method

Michihiko OGATA and Hiroshi ICHIKAWA
Hoshi College of Pharmacy, Ebara, Shinagawa-ku, Tokyo
(Received August 6, 1971)

A method of comparing the relative bond energies is applied to the interpretation of the simple cleavage and the McLafferty rearrangement reactions in organic mass spectrometry. A qualitative correlation between the relative bond energy and the charge density at the highest occupied orbital is found. The behavior of the highest occupied and some lower vacant orbitals is discussed.

In the molecular orbital approaches to the interpretation of organic mass spectra, many papers have appeared[1-6] discussing only the relationship between the scission probability and the charge density at the highest occupied (HO) orbital of the molecule ion. Some[2,3,6] of these studies explain well the experimental data. However, some explanation is needed for the correlation between the bond energy and the charge distribution at the HO orbital, since apparently the bond energy is governed not only by the electron(s) of the HO orbital, but by all the electrons included. Besides, it has been shown that σ-π interactions play a significant role in the organic reactions.[7,8] The characteristic allylic cleavage and the McLafferty rearrangement reactions give evidence of direct and/or spacial σ-π interactions in the fragmentation processes of the electron-impact state. Some authors[9,10] have pointed out the significance of the excitation of electrons to some vacant orbitals.

Our object is to solve those problems by using a simple expression for the correlation between the electronic state and the bond energies, including all the valence electrons. In this paper we will adopt the extended Hückel (EH) MO theory,[11] which has the simplest form as an MO for valence electrons.

Method

The bond energies may vary according to the electronic state. Though the electronic state for the molecule ion remains an unsolved problem,[9,10] for the sake of simplification, we will consider the states in which a single electron occupies the HO orbital and will consider that only one electron is excited in a vacant orbital from the HO orbital. (The extension to multi-excited states may be straightforward.)

The total energy (E^j) is expressed by using the LCAO wave functions to give the Coulomb (H_{pp}) and the exchange (B^j_{AB}) terms. If the unpaired electron occupies the jth orbital, E^j is calculated by means of the following equations:

$$E^j = \sum_p [\sum_i^{occ-1} 2(C_p^i)^2 + (C_p^j)^2] H_{pp} + \sum_{A>B} B^j_{AB} \quad (1)$$

$$B^j_{AB} = \sum_p^{onA} \sum_q^{onB} K(H_{pp}, H_{qq})(4 \sum_i^{occ-1} C_p^i C_q^i + 2C_p^j C_q^j) \quad (A \neq B) \quad (2)$$

where H_{pp} is the Coulomb integral and where C_p^i is the coefficient for the atomic orbital (ϕ_p) of the ith wave function. *occ* is the number of the occupied orbitals in the ground state of the molecule. $\sum_p^{onA}$ indicates the summation on the atom, A. $K(H_{pp}, H_{qq})$ represents the function which gives the approximate exchange integral; *e.g.*, in the present calculation, we adopted the Wolfsberg-Helmholtz's approximation,[12] $0.5K(H_{pp}+H_{qq})S_{pq}$, where S_{pq} is the overlap integral between ϕ_p and ϕ_q and where the value of K is 1.75, according to Hoffmann's result.[11]

The exchange term (B^j_{AB}) is considered to express the relative bond energy[13] between two atoms, A and B. The Coulomb integrals are usually approximated by the negative values of the valence-state ionization potentials (VSIP) in terms of eV. Therefore, B^j_{AB} has the unit of eV, where a negative value indicates a bonding character and a positive value, an antibonding character.

A neglect of the explicit consideration of electron-electron repulsions causes, in some cases, an inversion of the orbitals which may play an important role in the chemical reaction.[14,15] The iterative extended Hückel (IEH) method for the self-consistent charge distribution has been reported[14-18] to improve the

faults of the original EH method. Besides, the converged Coulomb integrals which are obtained from the calculation of the IEH method for small molecules are shown[14] to be successfully applicable, as parameters, to large molecules. This enables self-consistent calculations for such large molecules as steroids by medium-sized computers.

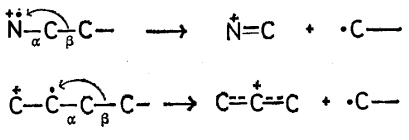
The iteration was carried out according to the following equation:

$$H_{rr}(n+1) = H_{rr}(0) - (Z_X - M_X(n))(I_{pr} - A_r) \quad (3)$$

Here, $H_{rr}(n+1)$ is the Coulomb integral at the $(n+1)$-th turn. X indicates the atom to which the atomic orbital (ϕ_r) belongs, Z_X is the number of the valence electrons, and $M_X(n)$ is the atomic population of the nth turn. A_r is the electron affinity of ϕ_r.

Results and Discussion

Energetic Consideration on Simple Cleavage. It has been established[19] that, under electron-impact, amines and unsaturated hydrocarbons go mainly through the paths which are shown by a "fishhook" as below:



For convenience, we call this type of simple cleavage "β-bond cleavage." It has been reported[6] for alkylamines that there is a quantitative correlation between the scission probability and the charge density at the HO orbital of the molecule ion. Our first purpose is to find out the relationship between the relative bond energy and such a charge density. If we can determine this relationship for these simple compounds, it can probably be adapted to discussions of the fragmentation mechanisms of their derivatives.

The relative bond energies of ethylamine, *n*-propylamine (by the IEH method), and 1-butene (by the EH method) are calculated. The input parameters are as follows:

Atom	H	C		N	
ϕ	1*s*	2*s*	2*p*	2*s*	2*p*
$H_{rr}(0) = -I_{pr}$(eV)[20]	−13.60	−21.43	−11.42	−27.50	−14.49
A_r(eV)[20]	0.75	9.26	0.58	13.79	1.58

and the bond lengths are, C-H 1.09, N-H 1.02, C=C 1.35, =C-C 1.50, C-C 1.54, and C-N 1.50 (in Ångstroms).

In Tables 1, 2, and 3, we set the conformation of the amines so that the lone pair is *trans* (Conformation *A*), perpendicular (Conformation *B*), and *cis* (Conformation *C*) to the β bond respectively. For each electronic state of the electron-impact ion, the difference in energy from its closed-shell ground state (which is referred to as the normal state), that is, $B'_{AB} - B^{normal}_{AB}$, is listed. In all the conformations, the

relative bond energies of the C–C bonds are lower than those of C–N in the closed-shell ground state. These are qualitatively in the same inclination as the experimental values. (They are not directly comparable to the experimental values, since the energies of the electronic and internuclear interaction among all non-bonding atoms are not taken into account in determining the relative bond energy.) On the other hand, in the *A* and *C* conformations, the removal of one electron from the HO orbital ($j=10$ and 13 respectively for ethylamine and *n*-propylamine) causes the energy of the β C–C bond to be higher than that in the closed-shell ground state, while the α C–N bond is strengthened. In the *B* conformation, however, this inclination is not clearly observed. Instead, the β C–H bond is weakened. It should be pointed out that the β C–H bond *trans* to the lone pair is more weakened than that of *cis*. These results indicate that the conformation of the nitrogen atom plays an important role in the strength of the β bond. This will be discussed in the next section.

Though it is well known that the Hückel method is not well adapted to the study of excited states, the general behavior of the excited molecule ion is considered to be significant. In all conformations, the excitation to the lowest vacant (LV) orbital weakens the α C–N bond. Usually, however, the M-NH_2 peaks are not intensely observed in alkylamines. It should also be pointed out that the positive charge remains not on the fragment of NH_2 but on the alkyl site, judging from Stevenson's rule.[21] That is, the

ionization potential (I_p) of NH_2 might almost be equal to that of the $2p$ orbital of the nitrogen atom in the valence state.[22] The I_p's of alkyl radicals are considered to be lower than that of the $2p$ orbital of the carbon atom because of hyperconjugation (*e.g.*, 8.64, 8.35, 7.93, and 7.42 eV for *n*-, *iso*-, *sec*-, and *t*-butyl radicals respectively.[23] The I_p's of the $2p$ orbitals of nitrogen and carbon atoms have been shown[20] to be 14.49 and 11.42 respectively. Therefore, the positive charge is located predominantly on the fragment of the alkyl group.

This consideration raises a question concerning the role of the electronic excitation. As for higher excitation, it is significant that excitation to the second level (LV+1; $j=12$ and 15 respectively for ethylamine and *n*-propylamine) makes the β bond sharply antibonding. Thus, interestingly, electronic excitation to a vacant orbital makes a certain bond extraordinarily loose. Similar results are obtained for 1-butene. In this case, π electrons play a role similar to that of the lone pair in amines. On calculations, two kinds of conformations were chosen. Conformation *D* shows that all the carbon atoms are on the *x*-*y* plane, while Conformation *E* shows only the bond of C_1–C_2 as perpendicular to the *x*-*y* plane (Table 4).

Characteristics of the HO and Some LV Orbitals.
As has already been shown, the bond energy of β C–C varies according to the conformation of the nitrogen atom. This indicates that the lone pair which occupies the HO orbital of amine plays an important role in determining the strength of the

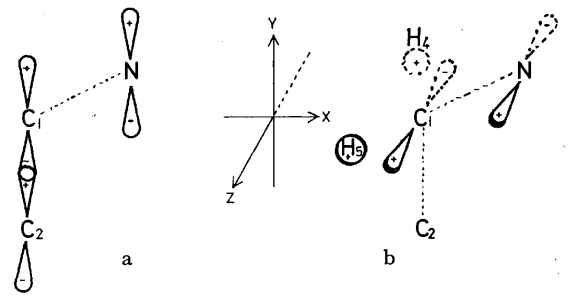

Fig. 1. Coordinate-dependent atomic orbitals of ethylamine.

β bond. In Table 5, the coefficients of the HO and some lower vacant orbitals are listed. In the *A* and *C* conformations, the electron of the HO orbital is predominantly distributed on the $2p_y$ atomic orbitals of N_3, C_1, and C_2. The sign of the coefficient for N_3 is positive, and that for C_1 is negative. The π-overlap integral ($S_{\pi\pi}$) between these atomic orbitals has a positive value (Fig. 1-a). Therefore, the HO orbital has an antibonding effect on the C_1–N_3 bond, since the interaction energy (e^j_{pq}) between atomic orbitals, ϕ_p and ϕ_q, given by singly-occupied jth orbital is expressed by Eq. (4), where H_{pp} is negative:

$$e^j_{pq} = C_p{}^j C_q{}^j K(H_{pp}+H_{qq})S_{pq} \qquad (4)$$

The sign of the coefficient for the $2p_y$ of C_2 is positive, while the σ-overlap integral ($S_{\sigma\sigma}$) between the $2p_y$ atomic orbitals of C_1 and C_2 is negative. Hence, the HO orbital is bonding in this bond. On the other hand, in the *B* conformation it is shown in Fig. 1-b and Table 5 that the HO orbital is antibonding in N_3–C_1, while it is bonding in both the C_1–H_4 and

22) The configurations of those radicals are assumed to be sp^2.
23) F. P. Lossing and J. B. de Sousa, *J. Amer. Chem. Soc.*, **81**, 281 (1959).

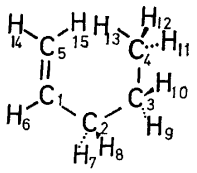
C_1–H_5 bonds. Likewise, it will be shown below that the LV and LV+1 orbitals are sharply antibonding in the C_1–N_3 and C_1–C_2 bonds respectively.

From the above considerations, it can be understood that the removal of one electron from the HO orbital makes the α C–N bond stronger (because the HO orbital is antibonding on this bond), while the β bond especially *trans* to the lone pair of the nitrogen atom becomes weaker. The behavior of the HO orbitals in other homologous amines is found to be analogous to that of ethylamine.

It may be evident that the positive charge is not distributed on the position where the HO orbital is antibonding, but where the HO orbital is bonding. We now recognize a correlation between the bond scission and the net positive-charge density. It is, however, not observed that the bond energy of the α C–N is lower than that of β C–C. The actual difference in energy becomes almost zero. There are two probable reasons for this. One might be the rough application of the MO theory, in which the molecule ions are calculated on the basis of the parameters for the closed-shell ground state. The electron distribution of the HO orbital is concentrated on the nitrogen atom under the electron-impact state; the values of the Coulomb integrals for the atomic orbitals belonging to the nitrogn atom should be lowered compared to those in the normal state. The other is that there may be other factors that regulate the reaction path, *e.g.*, the stability of the ions produced.

The McLafferty Rearrangement Reaction. Boer *et al.*[24] have already treated the McLafferty rearrangement reaction on 2-pentanone by means of Mulliken's population analysis. The following results, therefore, may serve to reconfirm the reaction processes proposed by them.

It has been established[25–26] that the γ-hydrogen



1-Pentene

atom is transferred in the rearrangement. Hence, it can be expected that, as the molecule ion takes a conformation favorable for the rearrangement, the bonding interaction between γ-hydrogen and the hydrogen-accepting atoms increases, while that between γ-hydrogen and the hydrogen-leaving atoms decreases.

The values of B^j_{AB} between those atoms when the distances between γ-H(H_{13}) and C_4 are 2.4 Å (Conformation *F*) and 1.7 Å (Conformation *G*) were calculated for 1-pentene; they are listed in Tables 6 and 7 respectively. On the *F* conformation, it is shown in all the electronic states of the molecule ion (j=15—17)

that: (1) C_5 has a strong bonding interaction with H_{13} and (2) the relative bond energy between C_4 and H_{13} becomes quite small, indicating cleavage at this bond. This inclination becomes more apparent when the molecule ion takes the *G* conformation. The relative bond energy between C_2 and C_3, however, is not weakened by changing the conformation from *F* to *G*. As for the electronic gound state (j=15), those observed are quite analogous to Boer's results. It may be worth considering that the excited molecule ion has a similar reaction tendency.

Conclusion

(1) There is a clear correlation between the bond energy and the charge density at the HO orbital of the molecule ion, which might support Hirota's assumption.[2,3,6] However, there also seem to be other

24) F. P. Boer, T. W. Shannon, and F. W. McLafferty, *J. Amer. Chem. Soc.*, **90**, 7239 (1968).

factors that regulate the reaction path. (2) The conformation of the nitrogen atom plays an significant role in connection with the strength of the β-bond. The β bond *trans* to the lone pair is more weakened than that of *cis*. (3) Electronic excitation from the HO orbital to a vacant orbital makes a certain bond extraordinarily loose. (4) As for the simple β cleavage of amines, electronic excitation to a vacant orbital is in doubt. (5) A method of comparing the relative bond energies is useful in the interpretation of rearrangement reactions.

The calculations were carried out on a HITAC 5020E computer at the computation center of the University of Tokyo. The authors wish to thank Dr. C. Kaneko (Tokyo Medical and Dental University) and Dr. S. Nakajima and Miss Y. Miyaji (Hoshi College of Pharmacy) for their helpful discussions. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3236—3240 (1972)

Adsorption of *N*-Vinyl-2-pyrrolidone at the Mercury/Solution Interface

Tadashi YOSHIDA, Tetsuya OHSAKA, and Hajime YAMAMOTO
Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-Okubo, Shinjuku-ku, Tokyo 160

(Received October 4, 1971)

The adsorption of *N*-vinyl-2-pyrrolidone (NV2P) or the monomer of polyvinylpyrrolidone (PVP) at the mercury/solution interface was examined by means of differential capacity *vs.* potential relations (*C-E* curves). The usual *C-E* curve obtained in 1N sulfuric acid was similar to that of the saturated aliphatic compounds. However, in 1N sodium sulfate or sodium hydroxide potential dependence of C_{min} (minimum differential capacity) was observed as a result of π-electron interaction of adsorbed molecules. The adsorption behavior in 1N sulfuric acid followed the Langmuir isotherm. The peculiar behavior in 1N sodium sulfate or sodium hydroxide was explained by means of the Frumkin isotherm with the potential dependence of interaction constant (g), which varied linearly with potential in a range more negative than *ca.* -0.6 V (SCE) in contrast to nearly constant values in a more positive range. At a relatively high bulk concentration, there was a slight deviation from the Frumkin isotherm and the standard free energy of adsorption (ΔG^0) *vs.* $\theta^{3/2}$ plot revealed a sharp break in the same way as pointed out by Conway and his co-worker. The C_{min} value of NV2P coincided approximately with that of its polymer of PVP in aqueous sulfuric acid, sodium sulfate or sodium hydroxide, respectively. The results are utilized for the discussion on the configuration of adsorbed PVP at the interface.

For *N*-vinyl-2-pyrrolidone (NV2P)[1] with pyrrolidone and vinyl radicals, π-electron seems to have a strong influence upon its adsorption behavior.

The role of π-electron interaction on adsorption was first pointed out by Gerovich[2] and further has been discussed by several authors.[3-6] Klyukina and Damaskin[7] investigated the Frumkin adsorption isotherm considering the potential dependence of interaction constant (g) among adsorbed molecules, while Conway[5] discussed the molecular orientation due to the π-electron interaction in connection with the coverage (θ) dependence of standard electrochemical free energy of adsorption (ΔG^0) obtained by means of the Langmuir adsorption isotherm.

We have investigated the adsorption of NV2P as regards the results[8,9] obtained for its polymer or polyvinylpyrrolidone (PVP) by measurement of the differential capacity at the mercury/solution interface.

Experimental

Electrodes. A dropping mercury electrode (DME) with a flow rate of *ca.* 4.5×10^{-4} g/sec was used, with a ring-like platinum wire of sufficiently large suface area as the counter electrode. The electrode potentials were measured with reference to a 3.3N calomel or mercury/mercuric oxide electrode, and the results are given against the saturated calomel electrode (SCE).

Apparatus and Materials. The differential capacity at the mercury/solution interface was determined at 22°C by

the universal bridge (Yokogawa BV-Z13A) equipped with an oscilloscope as a detector and d.c. polarization circuit. The balance time (*i.e.*, time, elapsed from the beginning of a drop growth) was set at 8 sec with a sinusoidal wave of 1 kHz adjusted to a input voltage of *ca.* 10 mV_{p-p} or less. Interfacial impedance was assumed as series equivalent circuit of capacitance and resistance. NV2P of pure chemical grade prepared by Tokyo Kasei Co. was used without further purification. All the solutions were prepared from triply-distilled water and pure chemicals. Observation was carried out in the atmosphere of purified nitrogen.

Results and Discussion

Variation of Differential Capacity with Potential. The relations between differential capacity and potential (*C-E* curves) caused by the addition of NV2P were observed in 1N sulfuric acid, 1N sodium sulfate and 1N sodium hydroxide. The results are shown in Figs. 1—3.

The *C-E* curves in Figs. 1—3 can be regarded as the results of the adsorption equilibrium except for peak regions, since the capacity data per unit area are independent of the balance time exceeding 8 sec in the solution containing 1 mmol/*l* NV2P.

In the case of low bulk concentration of NV2P in 1N sulfuric acid the peak caused by ad- or desorption appears on the positive side, but none on the negative owing to hydrogen evolution. In 1N sulfuric acid with a relatively high content of NV2P, the differential capacity (*C*) attains almost a constant value in the range more negative than *ca.* −0.5 V(SCE).

In 1N sodium sulfate, the peak appears both on the positive and negative sides (Fig. 2) and the differential capacity is depressed in the adsorption range as the potential becomes negative. However, it is well-known that the potential dependence of capacity is hardly observed for the adsorption range in usual cases. Both peaks are asymmetric and the cathodic peak becomes somewhat negative and sharp with the increase of bulk concentration of NV2P (Fig. 2). This tendency might be due to the attractive interaction among the adsorbed molecules. The peculiar adsorption is also found in 1N sodium hydroxide (Fig. 3). Similar behavior was discussed for pyridine in potassium chloride by Damaskin.[7] The anodic peak seems to be due to reorientation of adsorbed pyridine molecules and not to ad- or desorption. Nearly the

same values of capacity obtained by the solutions with and without pyridine in the more positive range than the anodic peak may result from the interfacial structure, not from the adsorbed layer because of the strong interaction between the π-electron and the electrode. The anodic peak in Figs. 1 and 2 might be assumed as the above. For the unusual adsorption of NV2P in 1N sodium sulfate or 1N sodium hydroxide, π-electron interaction seems to play an important role.

Potential Dependence of Coverage (θ-E Curves). The θ-E relations in sulfuric acid (Fig. 4) were given from the C-E curves (Fig. 1) by means of Frumkin's parallel condenser model. The computation was carried out for the region with a slight potential dependence of C. The θ-E curves (Fig. 4) reveal an usual bell-type form, their maximum adsorption being attained at *ca.* −0.7 V (SCE).

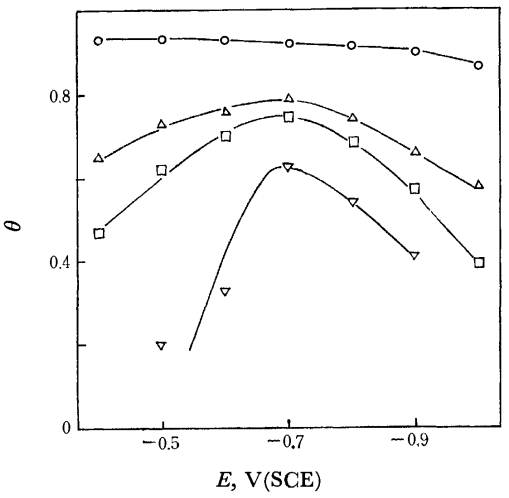

Fig. 4. Coverage *vs.* potential curves.
22°C, 1N sulfuric acid +NV2P (▽: 1.0×10^{-2} mol/*l*, □: 5.0×10^{-2}, △: 1.0×10^{-1}, ○: 3.1×10^{-1}).

It is necessary to find the minimum differential capacity (C_{min}) for determination of coverage by Frumkin's model. In the case of 1N sodium sulfate or 1N sodium hydroxide, however, no definite value can be found for C_{min} owing to its potential dependence (Figs. 2 or 3). In these cases, the lowest value within the adsorption range may be taken, while the lowest value at each potential may be used respectively for the determination of coverage in consideration of the potential dependence of capacity due to the gradual reorientation of adsorbate. The θ-E curves in sodium sulfate solution (Fig. 5) were derived from C_{min} at each potential. At a relatively low bulk concentration (Fig. 5), the bell-type θ-E curves were obtained. The maximum coverage at *ca.* −0.45 V (SCE) increased with bulk concentration. In the case of high bulk concentration, the tendency was reversed and minimum coverage was observed contrary to the usual cases. This tendency was also shown by another θ-E plot where θ was evaluated by the lowest common capacity instead of respective C_{min} at each potential.

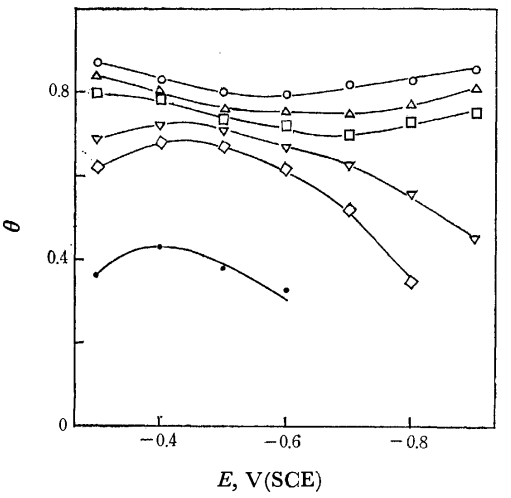

Fig. 5. Coverage *vs.* potential curves.

Adsorption Isotherm. The Langmuir adsorption isotherm was always applied to the adsorption of NV2P in 1N sulfuric acid, while the Frumkin adsorption isotherm was applied to that in 1N sodium sulfate or 1N sodium hydroxide in view of the potential dependence of interaction constant (g). The adsorption isotherm in 1N sodium sulfate is shown in Fig. 6, where the coverage is calculated with the respective C_{min} at each potential. The curve becomes somewhat S-type at the negative potential (Fig. 6), which might indicate the change from repulsive to attractive interaction. In the adsorption isotherm of pyridine given by the potential dependence of interfacial tension, almost the same tendency as above was also pointed out by Gierst,[10] Conway and Barradas,[5] and Nürnberg and Wolff.[6] The adsorption isotherm of NV2P in sodium sulfate or sodium hydroxide solution is similar to that of pyridine to some extent.

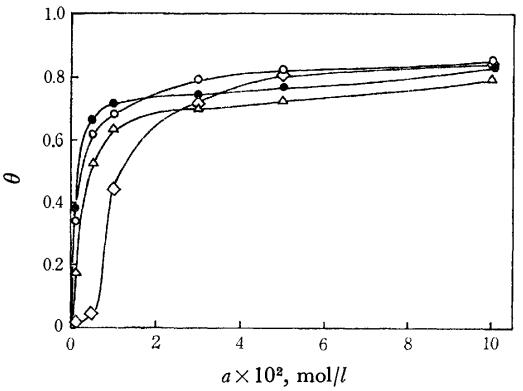

Fig. 6. Adsorption isotherms.
22°C, 1N sodium sulfate +NV2P [○: −0.3 V(SCE), ●: −0.5 V, △: −0.7 V, ◇: −0.9 V].

Potential Dependence of Interaction Constant. The coverage of NV2P in 1N sodium sulfate or 1N sodium hydroxide solution was evaluated by Frumkin's condenser model with minimum capacity at each potential on the assumption of full coverage at each C_{min}. The

10) L. Gierst, "Transactions of the Symposium on Electrode Processes," ed. by E. Yeager, John Wiley and Sons Inc., New York, (1961), p. 294.

interaction constant (g) is given by the Frumkin isotherm

$$\beta a = \frac{\theta}{1-\theta}\exp(-2g\theta) \quad (1)$$

where β, a, θ, and g are the adsorption coefficient, the bulk concentration, the coverage, and the interaction constant, respectively. According to Frumkin and Damaskin,[11] the interaction constant (g) might be obtained by means of the adsorption isotherm.

Substituting the relative concentration $y=a/a_{\theta=0.5}$ into Eq. (1), we have

$$y = \frac{\theta}{1-\theta}\exp[g(1-2\theta)] \quad (2)$$

and

$$(dy/d\theta) = \frac{(1-2g\theta+2g\theta^2)}{(1-\theta)}\exp[g(1-2\theta)] \quad (3)$$

At $\theta=0.5$:

$$(dy/d\theta)_{\theta=0.5} = 4-2g \quad (4)$$

Thus, g can be determined graphically. The results are shown in Fig. 7.

The g value gives a constant of *ca.* -1.3 in the range from -0.3 to nearly -0.6 V (SCE). This might indicate a certain repulsive interaction between the molecules. In the range from -0.6 to about -0.9 V

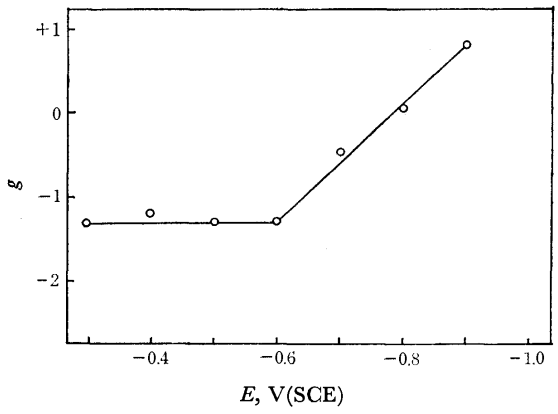

Fig. 7. Potential dependence of interaction constant.
22°C, 1N sodium sulfate +NV2P.

(SCE), the g value varies almost linearly with a slope of *ca.* 6.7 (V^{-1}) as the potential becomes negative, and the g value turns positive at *ca.* -0.8 V (SCE). This indicates the attractive interaction between the adsorbed molecules.

Coverage Dependence of Standard Free Energy of Adsorption ($\Delta\bar{G}^0$). For the purpose of investivating some deviations from the Frumkin isotherm in Fig. 5 or 6 (*i.e.*, the unusual shape of θ-E in Fig. 5 and the slight rise of isotherm at a relatively high concentration in Fig. 6), the results were examined in terms of the coverage dependence of $\Delta\bar{G}^0$ [12] after Conway.[5]

If no interaction is assumed for the adsorbed molecules at the interface, $\Delta\bar{G}^0$ is given by the Langmuir isotherm.[5]

$$\ln\left(\frac{55.5}{a}\frac{\theta}{1-\theta}\right) = -\frac{\Delta\bar{G}^0}{RT} \quad (5)$$

When the surface interaction of the adsorbates is taken into account, Eq. (5) can be written as follows:[5]

$$\ln\left(\frac{55.5}{a}\frac{\theta}{1-\theta}\right) - \ln f_\theta = -\frac{\Delta\bar{G}^0}{RT} \quad (6)$$

where the surface activity coefficient (f_θ) at a coverage θ consists of an electrostatic dipole-dipole interaction term ($\theta^{3/2}$) and van der Waals-London interaction term (θ^3).[5]

Equation (6), then, becomes:

$$\ln\left(\frac{55.5}{a}\frac{\theta}{1-\theta}\right) + \frac{P_a\theta^{3/2}-Q_a\theta^3}{RT} = -\frac{\Delta\bar{G}^0}{RT} \quad (7)$$

where P_a and Q_a are constants dependent on the characteristics of adsorbed layer. If θ is not too close to unity, the term $Q_a\theta^3$ is almost negligible and the relation between $\Delta\bar{G}^0$ and $\theta^{3/2}$ becomes approximately linear. $\Delta\bar{G}^0$ varies with $\theta^{3/2}$ as expected, although a remarkable break is revealed on each curve as shown in Fig. 8. Such a sharp inflection may be attributed to onset of extensive orientation with the increase of coverage.[5]

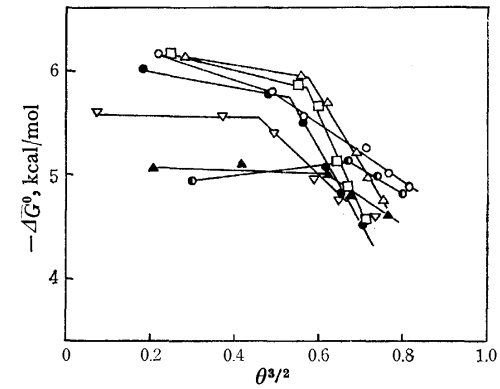

Fig. 8. Coverage dependence of $\Delta\bar{G}^0$.
22°C, 1N sodium sulfate +NV2P [○: −0.3 V(SCE), △: −0.4 V, □: −0.5 V, ●: −0.6 V, ▽: −0.7 V, ▲: −0.8 V, ◐: −0.9 V].

The Frumkin isotherm can be written as follows, where the value of 55.5 is taken for a comparison with Conway's treatment and $\beta=(1/55.5)\exp(-\Delta\bar{G}^0/RT)$ in Eq. (1)

$$\ln\left(\frac{55.5}{a}\frac{\theta}{1-\theta}\right) - 2g\theta = -\frac{\Delta\bar{G}^0}{RT} \quad (8)$$

The correction term for surface interaction on the adsorbed layer is assumed to be $-2g\theta$ instead of $(P_a/RT)\theta^{3/2}$ term in Eq. (7). $\Delta\bar{G}^0$ is expected to vary linearly with θ. This relation was verified for the adsorption of phenol by Blomgren[4] except for the case where θ is close to unity. In the case of NV2P, a sharp break was also shown in $\Delta\bar{G}^0$-θ plot. The result does not seem to be in line with the Frumkin isotherm. The Frumkin isotherm, however, is approximately applicable to the adsorption of NV2P at a relatively low coverage ($0<\theta<$*ca.* 0.7), because the g values at $\theta=0.5$ derived from Eq. (8) with $\Delta\bar{G}^0$ of

the Langmuir isotherm nearly coincided with the values in Fig. 7, where the g values at $\theta=0.5$ were chosen for convenience as the typical data in the range of low coverage before the appearance of the sharp break. The sharp variation of $\Delta\bar{G}^0$ with θ at relatively high coverage is considered to be mainly caused by reorientation of adsorbed molecules, although the variation might be explained by the Frumkin isotherm modified with the association number of adsorbed water molecules.[15]

Orientation of NV2P at the Interface. For NV2P in aqueous sodium sulfate or sodium hydroxide, the variation of differential capacity within the adsorption range seems to be due to π-electron interaction. The reorientation of adsorbed molecules may take place gradually in the above range, as discussed by Damaskin for the adsorption of pyridine[7] or aniline,[16] where results analogous to Figs. 2 and 3 are obtained.

g values of NV2P in Fig. 7 change with the potential in the range more negative than *ca.* −0.6 V (SCE) but they are nearly constant in the range more positive than the above. The tendency might be related to surface charge, since the point of zero charge for mercury in the solution with no adsorbates is about—0.43V (SCE).[17] In the negative range, a nearly perpendicular form of the adsorbed molecules may be expected because of the repulsion between the electrode surface and π-electron while the attractive force between adsorbed molecules is considered to increase as the potential becomes negative. In the range more positive than *ca.* −0.6 V (SCE), the repulsive force between adsorbed molecules is considered to become nearly constant because the gradual reorientation of the adsorbed molecule may be expected as the potential becomes positive, or the attraction between the electrode surface and π-electron increases. The reorientation might take place gradually as the electrode potential changes, since the differential capacity varies gradually with the potential in the adsorption range.

Examination of Minimum Differential Capacity. The relation between the minimum differential capacity (C_{min}) and the thickness (δ) of adsorbed layer is as follows:

$$C_{min} = \varepsilon/(4\pi\delta) \quad (9)$$

where ε is the dielectric constant of adsorbed layer. The values of C_{min} of NV2P in several solutions are shown in Table 1, where almost the same values of C_{min} are given for both cases of sodium sulfate and sodium hydroxide solutions, while C_{min} value in sulfuric acid is about 1.1 times those in the above solutions. This difference of C_{min} is considered to result from the difference of δ on the assumption that ε hardly varies with supporting electrolyte.

The perpendicular/planar ratio of orientation for NV2P is about 2.5 from the approximate calculation with the molecular model. It appears from the C_{min} ratio 1.1 that the variation of orientation with electrolytes does not take place completely from perpendicular to planar. In the adsorption range of NV2P in sulfuric acid, the nearly constant C_{min} may be due to the alleviation of π-electron interaction by the highly concentrated hydrogen ion, but the conclusion from only C-E relations is somewhat doutful as pointed out by Damaskin[16] for the adsorption of aniline.

Table 1. C_{min} of NV2P and PVP (μF/cm^2)

Electrolyte	C_{min} of NV2P (Monomer)	PVP (Polymer) $\bar{M}$	PVP (Polymer) C_{min}
1N H_2SO_4	6.4	10000	6.5
		26000	6.3
		37000	6.15
		750000	6.05
1N Na_2SO_4	5.6	10000	5.8
1N NaOH	5.7	10000	5.7
		750000	5.9

Adsorption Behavior of PVP Expected from That of NV2P. The adsorption behavior of PVP at the mercury interface may be discussed in reference to that of NV2P or the monomer of PVP. In Table 1 of the C_{min} values of PVP depending a little upon $\bar{M}$ (mean molucular weight), the values of C_{min} for $\bar{M}$ of 10000 are used for the discussion in view of the lieast difference between the values of PVP and its monomer.

In aqueous solutions of sulfuric acid, sodium sulfate and sodium hydroxide, C_{min} of NV2P hardly differs from that of PVP in each solution as shown in Table 1. Thus, it may be considered that the thickness of adsorbed NV2P layer is similar to that of its polymer layer adsorbed in each solution, if ε remains nearly constant.

It is interesting that C_{min} value of the polymer or PVP varies with a supporting electrolyte similarly to the case of its monomer or NV2P. However, the variation of C_{min} due to reorientation of the adsorbed polymer is almost impossible. Therefoe, the dependence of C_{min} value on the supporting electrolyte may be connected with the compactness of adsorbed layer in the case of polymer.

The dependence of inhibition effect by PVP upon the supporting electrolyte is observed[18] from the comparison of inhibition effect for some electrodeposition processes. It is considered to be also related to the compactness of adsorbed layer to a certain extent.

It appears from C_{min} value of PVP in accordance with that of its monomer that the configuration of adsorbed PVP at the interface is spread or flattened as assumed previously.[8] Strictly speading, however, the above assumption is a mere approximation in consideration of the fact that C_{min} of PVP depends slightly on $\bar{M}$.

Competitive Adsorption of Polyvinylpyrrolidone with *n*-Alkyl Alcohols at the Mercury/Solution Interface

Tadashi Yoshida, Tetsuya Ohsaka, and Yasuo Iida

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-Okubo, Shinjuku-ku, Tokyo, 160

(Received October 12, 1971)

Competitive adsorption of polyvinylpyrrolidone (PVP, $\bar{M}=10000$) with *n*-hexanol, *n*-pentanol, or *n*-butanol was examined by observation of the differential capacity at the mercury interface in 1 N sulfuric acid. Adsorption of PVP coexistent with alcohol hardly differed from the single adsorption[1] controlled by its diffusion. The competitive adsorption curve of *C* (differential capacity) *vs.* $t^{1/2}$ (adsorption time) was expected from the sum of the individual capacity depressions by the single adsorption at −0.5 or −0.6 V (SCE) and the expected curve of *C vs.* $t^{1/2}$ was compared with the curve observed. The competitive behavior of alcohol coexistent with PVP was examined by the relation "θ_{Alc}^{com} (coverage of coexistent alcohol) *vs.* $t^{1/2}$" at −0.5 or −0.6 V (SCE), where θ_{Alc}^{com} was estimated from the difference between the differential capacities with and without PVP, in view of the fact that behavior of PVP is nearly independent of the coexistent alcohol. The results are discussed in terms of four types of models assumed for the competitive behavior of coexistent alcohols with different adsorbability. It is considered that the alcohol is replaced with PVP as soon as the latter reaches the interface by diffusion, the adsorption equilibrium of an alcohol being achieved immediately. The relation $\theta_{Alc}^{com}=(1-\theta_{PVP})\theta_{Alc}$ holds in the case of *n*-butanol coxistent with PVP, where θ_{PVP}, θ_{Alc}, and θ_{Alc}^{com} are the coverages due to the single adsorption of PVP and butanol and to the competitive adsorption of butanol, respectively. The tendency of alcohol to be replaced with PVP is inversely proportional to its adsorption coefficient. *n*-Butanol was most sensitive to the coexistence of PVP.

The adsorption of PVP(polyvinylpyrrolidone) at the mercury/solution interface was previously discussed[2] in terms of the process controlled by diffusion. We have investigated the competitive adsorption of PVP with *n*-alkyl alcohol of low molecular weight at the mercury interface with the alcohol attaining its adsorption equilibrium immediately.

Not many electrochemical studies on competitive adsorption have been published. Only the tensammetry wave for competitive adsorption has been shown by Jehring.[3] The treatment of the Flory-Huggins adsorption isotherm[4] and analyses of the reorientation of the adsorbed molecules at equilibrium[5,6] may be applied to the equilibrium of the competitive adsorption. The analyses, however, are useless for the competitive process influenced by the diffusion of PVP.

The results of competitive adsorption of PVP with an alcohol will, therefore, be discussed with respect to the behavior of the single adsorption of each compoent.

Experimental

The test electrode and counter electrode were a dropping mercury electrode (DME) with a drop time *ca.* 11 sec and a cylindrical platinum net. The potentials were referred to the saturated calomel electrode (SCE). The differential capacity was observed by a transformer impedance bridge[2] with an input of 1 kHz wave adjusted to below 10 mV_{p-p}. PVP ($\bar{M}=10000$) prepared by BASF was used without further purification. Observation was always conducted with 1 N sulfuric acid at 22°C in the atmosphere of purified nitrogen. The DME[2] was composed of Pyrex parts and a molybdenum glass capillary with a ground glass joint, the other conditions being the same as described previously.[2]

Results and Discussion

Differential Capacity vs. Potential Curves (C-E Curves) for Competitive Adsorption. An example of *C-E* curves at the adsorption time (t_B) of 8 sec for the competitive adsorption of PVP with *n*-butanol is given in Fig. 1. 1 N sulfuric acid containing 0.1 mol/*l* *n*-butanol and various amounts of PVP ($\bar{M}=10000$) were employed. The *C-E* relation for the single adsorption of *n*-butanol is also shown. The adsorption process of PVP revealed at $t_B=8$ sec is expected to be controlled by diffusion. In the case of the single adsorption of PVP, an ad- or desorption peak is revealed at *ca.* 75 mV (SCE) and the peak height increases with bulk concentration. The differential capacity is depressed by the adsorption of PVP in the more cathodic potential than the above peak. The inhibitive action of PVP on the adsorption of *n*-butanol can be seen in Fig. 1, since the adsorption or desorption peak due to *n*-butanol is depressed and the peak due to PVP grows with PVP concentration. In the competitive adsorption of PVP with *n*-pentanol or *n*-hexanol, the tendency of the *C-E* relation was similar to that for *n*-butanol.

Time-Dependence of Differential Capacity for Competitive Adsorption (C-t Curves). For the purpose of examining competitive adsorption accompanied by the process controlled by the diffusion of PVP, the time-dependence of differential capacity was observed at *ca.* −0.5 V (SCE), where the saturated adsorption of

1) "Single adsorption" is used in contrast to "competitive adsorption" and means the adsorption of an organic substance contained solely in a supporting electrolyte.

PVP is always attainable.[2] Figure 2 shows typical plots of time-dependence of the observed capacity (C_E) for competitive adsorption in 1N sulfuric acid containing PVP (30 mg/*l*) and various amounts of *n*-hexanol, where the adsorption of PVP is controlled by diffusion.[2]

Single adsorption of PVP was found to approach saturation after the appearance of maximum value of C_E (Fig. 2). The transient range from diffusion-controlled to saturated adsorption becomes gradually ambiguous as *n*-hexanol content increases. It appears that the individual adsorption equilibrium is attained in the case of relatively high hexanol content. The C–$t^{1/2}$ plot obtained from the C_E–t relation is shown in Fig. 3, where (a) and (b) refer to the competitive adsorption of PVP with *n*-hexanol and *n*-butanol, respectively.

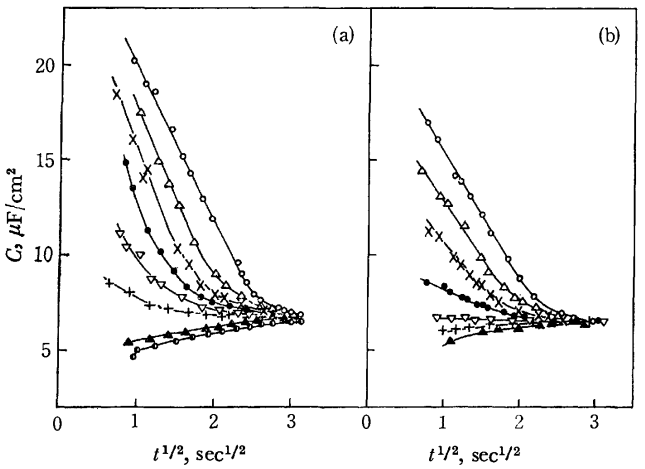

Fig. 3. Relation between differential capacity and square root of time at the competitive adsorption.

In the case of adsorption controlled by the diffusion of adsorbates, the behavior on a DME is approximately explained in terms of the Koryta equation.[7] The following equation[8] can be derived by substitution of the Koryta equation into the relation for the Frumkin parallel condenser model:

$$C = C_0 - 0.736(C_0 - C_1)D^{1/2}\Gamma_m^{-1}at^{1/2} \quad (1)$$

where C_0 and C_1 are the differential capacities at θ=0 and θ=1, respectively, and D, Γ_m, and a are diffusion coefficient (cm²/sec), maximum surface concentration (mol/cm²) and bulk concentration (mol/cm³). Equation (1) holds for $t<t_m$, where t_m is the time required to attain the saturated adsorption. When $t \geq t_m$, we have

$$C = C_1 \quad (2)$$

In Fig. 3, the linear portion of C–$t^{1/2}$ plot decreases and the transient range from diffusion-controlled to saturated adsorption increases with the content of *n*-hexanol or *n*-butanol. In each single adsorption, the minimum differential capacities of PVP ($\bar{M}$= 10000), *n*-hexanol and *n*-butanol were found to be 6.5, 4.7, and 5.2 μF/cm², respectively. It is expected that the hexanol molecules are replaced gradually

by the PVP molecules which reach the interface by diffusion.

In the case of competitive adsorption of PVP with *n*-butanol shown in Fig. 3-(b), or with *n*-pentanol, a similar tendency to that in the case of hexanol was also observed in the relation C-$t^{1/2}$.

Competitive Adsorption Curves (C-$t^{1/2}$) Observed and Expected. The C-$t^{1/2}$ relation of competitive adsorption was expected from the sum of individual capacity depression[9] for PVP and alcohol. The expected behavior was compared with the result obtained from competitive adsorption in the same electrolyte. Typical cases[10] of competitive adsorption of PVP with *n*-hexanol and *n*-butanol are shown in Fig. 4-(a) and (b). The capacity due to the adsorption of hexanol

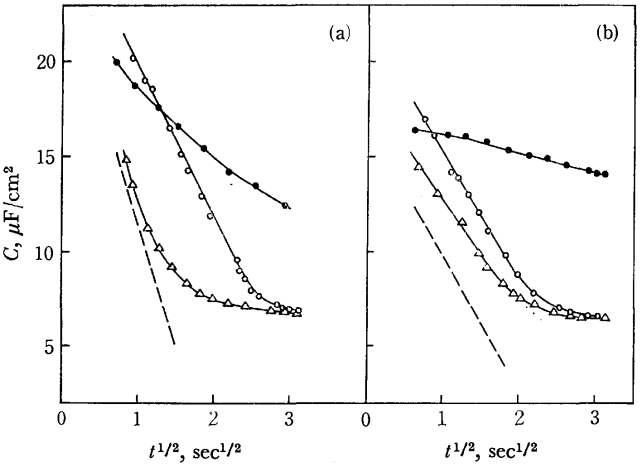

Fig. 4. Relation between differential capacity and square root of time at the competitive adsorption.

decreases with time. The adsorption equilibrium is not attained but influenced somewhat by the diffusion process under such hexanol content. The expected curve of C-$t^{1/2}$ agrees approximately with that observed for competitive adsorption in the initial stage of the linear portion. The observed curve, however, approaches the minimum differential capacity due to the saturated adsorption of PVP. Results nearly analogous to the above were obtained for the competitive adsorption of PVP with *n*-pentanol. With *n*-butanol, however, the expected curve is relatively isolated from the observed one [Fig. 4-(b)].

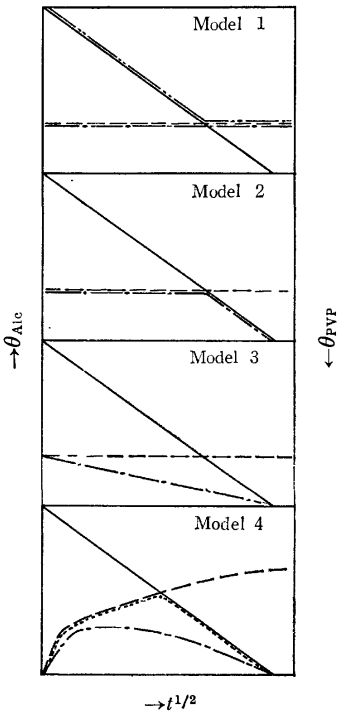

Fig. 5. Models assumed for the competitive adsorption of *n*-aliphatic alcohol with PVP.
solid line: the behaviour of diffusion-controlled adsorption of PVP at the single adsorption whose coverage is shown by θ_{PVP}, dashed line: the behaviour of adsorption equilibrium of *n*-aliphatic alcohol at the single adsorption whose coverage is shown by θ_{Alc}, dashed-two-dotted line in Model 1: the behavior of PVP at the competitive adsorption (*cf.* In the other models, the behavior of PVP at the competitive adsorption is nearly the same as that at the single adsorption.), dotted and dashed-dotted lines: the behavior of alcohol at the competitive adsorption with PVP, where the coverage of alcohol coexistent with PVP is shown by $\theta_{Acl}^{com.}$.

Behavior of Alcohols during Competitive Adsorption. Some models of competitive adsorption are shown in Fig. 5. One of the adsorbates (PVP) undergoes diffusion-controlled adsorption and the other (alcohol) easily attains adsorption equilibrium. In each single adsorption, the coverage of PVP and alcohol are expressed by θ_{PVP} (solid line) and θ_{Alc} (dashed line), respectively. The coverage of alcohol during competitive adsorption is expressed by θ_{Alc}^{com} and plotted with dashed-dotted lines. The coverage of PVP coexistent with alcohol is assumed to be nearly analogous to θ_{PVP}.

Model 1 (Fig. 5) is the case in which interaction or replacement between alcohol and PVP hardly takes place, and θ_{Alc}^{com} remains constant after the full coverage of ($\theta_{PVP}+\theta_{Alc}=1$) is established. The behavior of PVP in single adsorption, expressed by the dashed-two-dotted line, differs only for this case from that in competitive adsorption. Since the behavior of PVP in single and competitive adsorption is considered to be the same in the other models, it is always shown by a solid line. Model 1 is impractical because PVP has a higher adsorbability than that of the saturated alcohol.

9) The individual capacity depression is the difference between the capacity of the individual adsorbate for the single adsorption and that in the solution without adsorbates at a certain potential and adsorption time.

10) Extrapolation of the three solid lines in Fig. 4 should coincide at $t=0$. The results of differential capacity at t less than 1 sec are not shown, an accurate estimation of the mercury drop surface being difficult.

Model 2 is the case in which the adsorbed alcohol in its equilibrium begins to be replaced by PVP arriving after the full coverage of ($\theta_{PVP}+\theta_{Alc}=1$) is achieved. In this case, the space in the electrode is preferentially covered by PVP until the time ($\theta_{PVP}+\theta_{Alc}=1$), the rate of the replacement being controlled by the diffusion of PVP.

Model 3 is the case in which replacement of the adsorbed alcohol with PVP takes place as soon as PVP reaches the interface by diffusion. The amount of alcohol replaced by PVP is proportional to that of the adsorbed PVP. Thus the coverage of θ_{Alc}^{com} (dashed-dotted line) is given by $\theta_{Alc}^{com}=(1-\theta_{PVP})\theta_{Alc}$.

It is necessary to assumed another model in consideration of practical cases in which the adsorption of saturated alcohol is somewhat controlled by its diffusion dependent on the adsorption isotherm. This diffusion process was discussed by Delahay[11] by means of Henry's law, by Reinmuth[12] by means of the Langmuir isotherm and by Rampazzo[13] by means of the Frumkin isotherm. In view of these discussions, Model 4 is shown qualitatively as a practical case. The dashed-dotted line corresponds to that in Model 3. The plot is also expressed by the relation $\theta_{Alc}^{com}=(1-\theta_{PVP})\theta_{Alc}$, and the dotted line corresponds to the dashed-dotted line in Model 2.

θ_{Alc}^{com} was expected from the difference between the capacity depressions for the competitive and single adsorption of PVP by means of the relation "$\theta=(C_0-C)/(C_0-C_1)$" on the assumption that the adsorption behavior of PVP coexistent with alcohol is analogous to that of the single adsorption in view of the results in Figs. 1, 2, and 3. The θ_{Alc}^{com}-$t^{1/2}$ relations

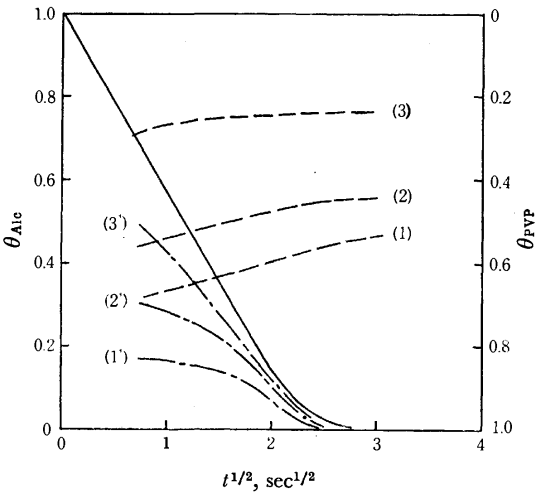

Fig. 6. Relation between coverage and square root of time in the case of hexanol.

(3): 0.04], dashed-dotted lines: the competitive adsorption of n-butanol expected from the capacity depression, PVP 35 mg/l+n-butanol M/l: [(1)′: 0.01, (2)′: 0.02, (3)′: 0.04].

expected for the competitive adsorption of PVP with n-hexanol, n-pentanol, and n-butanol are shown by the dashed-dotted lines in Figs. 6, 7, and 8, respectively. θ_{Alc} given by the dashed lines is obtained from the capacity depression observed for the single adsorption.

The values of θ_{Alc}^{com} somewhat deviates from θ_{Alc} in the early stage of the adsorption for n-hexanol (Fig. 6), the deviation becoming greater at lower bulk concentration. The θ_{Alc}^{com} plots come closer to the θ_{PVP} curve with increasing adsorption time. The

tendency shows the gradual replacement of the adsorbed alcohol with PVP which reaches the interface. This behavior of *n*-hexanol coexistent with PVP is explained in terms of the intermediate type between the dashed-dotted and dotted lines in Model 4, *viz.*, between Models 2 and 3.

The value of θ_{Alc} for *n*-pentanol (Fig. 7) shows a relatively smaller dependence on t than that for *n*-hexanol. The adsorption behavior of *n*-pentanol, coexistent with PVP is similar to that of *n*-hexanol.

The plot of θ_{Alc}^{com} for butanol (Fig. 8) approaches the θ_{PVP} curve in a relatively early stage and the effect of the coexistence of PVP is remarkable as compared with the other cases. This behavior might correspond to that shown by the dashed-dotted line in Model 4 or 3, since the values agree approximately with those of θ_{Alc}^{com} derived from the relation $\theta_{Alc}^{com}=(1-\theta_{PVP})\theta_{Alc}$.

The adsorption behavior of alcohol coexistent with PVP is considered to be dependent on its adsorbability. The adsorption coefficients of *n*-butanol, *n*-pentanol, and *n*-hexanol were found to be 1.25×10^2, 5.00×10^2, and 2.20×10^3 (l/mol), respectively, assuming the Langmuir isotherm. These are approximately in agreement with those published by Delahay,[11] Lorenz,[14] and Kalvoda,[15] and the order of the magnitude of the adsorbability is as *n*-hexanol>*n*-pentanol>*n*-butanol. Thus, it is considered that the influence of coexistent PVP with high adsorbability is the largest for *n*-butanol and relatively small for *n*-hexanol during the course of competitive adsorption.

Models 1—3 (Fig. 5) are shown in the order of magnitude of the adsorbability of alcohol. It is natural that the relation $\theta_{Alc}^{com}=(1-\theta_{PVP})\theta_{Alc}$ holds in the case of *n*-butanol because of its low adsorbability. In conclusion, the behavior during competitive adsorption of *n*-butanol is explained by Model 3, and that of *n*-hexanol and *n*-pentanol by an intermediate type between Models 2 and 3 due to their somewhat higher adsorbability.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3245—3250 (1972)

Adsorption of Polyethyleneglycol at the Mercury/Solution Interface

Tadashi YOSHIDA, Tetsuya OHSAKA, and Masayuki SUZUKI

Applied Electrochemical Laboratory, Graduate School of Science and Engineering, Waseda University, Nishi-Okubo, Shinjuku-ku, Tokyo, 160

(Received December 8, 1971)

The adsorption of polyethyleneglycol (PEG) was investigated at the mercury/solution interface by the observation of the differential capacity and the inhibitive action on the deposition of cadmium or copper. From the differential capacity measurements, the adsorption of PEG was found to be controlled by the diffusion of the adsorbate to the dropping mercury electrode under the present experimental conditions. The relation between the time required to attain the saturated adsorption and the bulk concentration (a) was explained approximately by the Koryta equation, though its deviation from the Koryta equation was somewhat larger than that for polyvinylpyrrolidone. When the maximum surface concentration and the mean molecular weight of PEG were expressed by Γ_m and $\bar{M}$ respectively, the plot of $\log \Gamma_m$-$\log \bar{M}$ revealed two linear parts crossing each other at $\bar{M}=ca.$ 600. The slope for $\bar{M}\geq 600$ was *ca.* -1, which implied the relation of "$\bar{M}\cdot\Gamma_m=$const.", *i.e.*, the segment numbers of PEG molecules adsorbed per unit area were constant, independently of $\bar{M}$, in the region of $\bar{M}\geq 600$. The configuration of PEG of $\bar{M}<600$ at the interface was considered to be different from that of PEG of $\bar{M}\geq 600$ because the slope for $\bar{M}<600$ was different from that for $\bar{M}\geq 600$. From the polarographic current measurements (*i.e.*, the inhibitive effect on the reduction of Cd^{2+} or Cu^{2+}), the time (t_{ml}) needed to achieve the maximum inhibition was obtained; it was then compared with that obtained from the capacity data. The relation of "$\log a=(-1/2)\log t_{mi}+$const." based on the Koryta equation was approximately applicable to the cases with a relatively large $\bar{M}$ value.

In many cases, organic high polymers are adsorbed so strongly at the electrode/solution interface, that the adsorption from its dilute solution is mainly controlled by the diffusion. Such a diffusion process was discussed for PVP (polyvinylpyrrolidone)[1] and the Koryta equation[2] was approximately applicable to the adsorption of PVP. Electrochemical studies on the adsorption of polyethyleneglycol (PEG) have been scarcely published, though Jehring and Horn[3] computed the maximum surface concentration (Γ_m) at the mercury interface by means of AC polarography. In this paper, the adsorption of PEG[4] at the mercury inter-

face was investigated by the observations of differential capacity and of inhibitive effect on the electrodeposition. The time (t_{me}) needed to attain the saturated adsorption was observed by the capacity measurement and it was compared with that (t_{mi}) obtained from the inhibitive effect of PEG on the electrodeposition of cadmium or copper.

Experimental

Electrodes. For the measurements of the differential capacity and the instantaneous current, a DME (dropping mercury electrode) and a counter electrode of cylindrical platinum net were used. The drop time of DME was about 12 sec, while it was nearly 5 sec for the polarography. All the potentials were referred to the saturated calomel electrode (SCE).

Differential Capacity Measurements. The impedance bridge used for the capacity measurements was a condenser-connected type with both arms composed of 1 μF mica condensers; the input of 1 kHz sinusoidal wave was adjusted to be less than *ca.* 10 mV_{p-p}. The balance of the bridge was detected with a selective amplifier and a cathode-ray oscilloscope. The series-equivalent circuit with resistance and capacitance was assumed in balancing the bridge.

Instantaneous Current vs. Time Curves (i-t Curves). The instantaneous *i-t* curves were observed by connecting a recorder or oscilloscope in parallel with 2 kΩ resistance equipped in series with the polarizing circuit of DME.

Polarograph and Others. The polarograph was the PA102 type of Yanagimoto. The test cell and DME were the same as have been described previously;[1] all the experiments were conducted in an atmosphere of purified hydrogen at 25°C.

Materials. Seven kinds of chemical-grade PEG by the Sanyo Chemical Industry Co. were used without further purification. The mean molecular weights ($\bar{M}$) were calculated from those OH values obtained by end-group determination; they were 200, 300, 400, 600, 1000, 3100, and 8400 respectively. Mercury was distilled twice *in vacuo*, and all the solutions were prepared from chemical-grade reagents and triply-distilled water.

Results and Discussion

I) Differential Capacity Measurements. Differential Capacity vs. Potential Curves (C-E Curves): Some typical *C-E* curves of PEG $\bar{M}$=600 and 8400 in 1N potassium chloride are shown in Fig. 1, where t_B is the duration from the beginning of a drop growth to the balancing the bridge. In Fig. 1-(a) with PEG $\bar{M}$=600, ad- or desorption peaks are observed at *ca.* −0.2 and *ca.* −0.6 V (SCE). Figure 1-(b) with $\bar{M}$=8400 is similar to the case of $\bar{M}$=600, though the anodic peak shows only a steep slope on the right side. The potential of the ad- or desorption peak for PVP[1] or PMA[5] has been reported to be almost independent of the bulk concentration; for PEG however, the peak potential is dependent to some extent on the bulk concentration. The peak becomes steeper with the increase in $\bar{M}$; this tendency suggests that the interaction among the adsorbed molecules

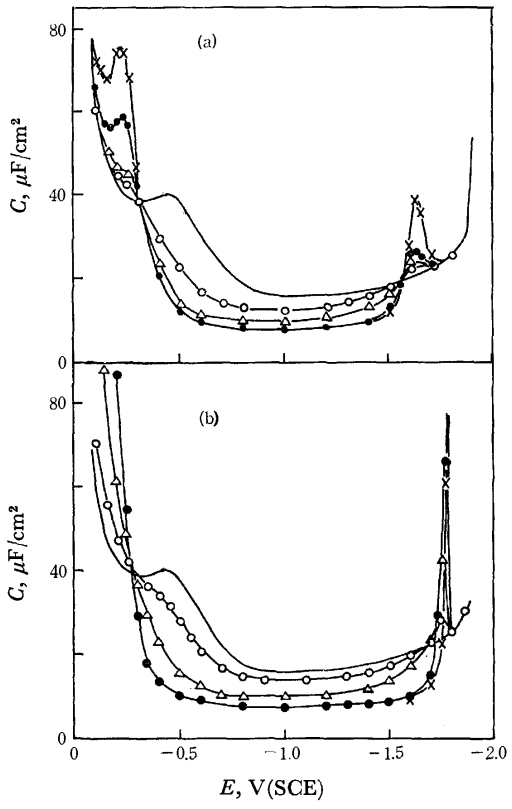

Fig. 1. Differential capacity *vs.* potential curves.
1 kHz, t_B=8 sec, (a) 1N potassium chloride+PEG $\bar{M}$=600, −: 0 mg/*l* PEG, ○: 5 mg/*l*, △: 10 mg/*l*, ●: 50 mg/*l*, ×: 200 mg/*l*, (b) 1N potassium chloride+PEG $\bar{M}$=8400, −: 0 mg/*l* PEG, ○: 6 mg/*l*, △: 15 mg/*l*, ●: 30 mg/*l*, ×: 100 mg/*l*.

becomes stronger with the increase in $\bar{M}$. The differential capacity is depressed as the concentration increases in the adsorption range of PEG between the two peaks. The increase in the adsorbability of PEG with $\bar{M}$ may be expected from the extension of the adsorption range by the increase in $\bar{M}$ under a constant *a*. When the saturated adsorption of PEG was attainable, the differential capacity became approximately constant at −0.9——1.2 V, where the time-dependence of the capacity and of the instantaneous current were examined. The *C-E* curves for the adsorption of PEG in 1N solutions of hydrochloric acid, sulfuric acid, and sodium sulfate were similar to Fig. 1; however, the cathodic peak in the acid solution was not revealed because of the hydrogen evolution.

Observed Capacity vs. Time Curves (C_E-t Curves): The C_E-*t* curves at −1.2 V in 1N potassium chloride are shown in Fig. 2, where (a) and (b) are concerned with $\bar{M}$=600 and 8400. In the solution without adsorbates, the observed capacity (C_E) increases with $t^{2/3}$ or with the growth of a mercury drop;[6] further, the same tendency is also shown after the attainment of the adsorption equlibrium in a relatively concentrated PEG solution. In a relatively concentrated PEG solution the curve for the process controlled

mainly by the diffusion seems to approach that of the adsorption equilibrium with the increase in time. Such a transition from a diffusion-controlled adsorption to an equilibrium one is clearly revealed in the adsorption of PVP,[1] whereas the transition range for PEG is not so clear.

Differential Capacity vs. Square Root of the Time Curves (C-$t^{1/2}$ Curves): For the adsorption controlled by the diffusion of adsorbates, the surface concentration (Γ_t) on a DME at the time (t) was introduced by Koryta;[2]

$$\Gamma_t = 0.736 D^{1/2} a t^{1/2} \qquad (1)$$

where Γ_t, D, a, and t are the surface concentration of adsorbates at time t in mol/cm², the diffusion coefficient in cm²/sec, the bulk concentration in mol/cm³, and the time from the beginning of its adsorption in sec. For the sake of convenience, the bulk concentration in mg/*l* was used for the experiments instead of that in mol/cm³. By replacing Eq. (1) in the relation of Frumkin's parallel condencer model with $\theta=\Gamma_t/\Gamma_m$, the time-dependence of C on the diffusion-controlled adsorption is obtained as follows:

$$C = C_0 - 0.736(C_0 - C_1) D^{1/2} \Gamma_m^{-1} a t^{1/2} \qquad (2)$$

where C is the differential capacity in μF/cm², θ, the coverage; C_0 or C_1, the differential capacity at $\theta=0$ or $\theta=1$, and Γ_m, the maximum surface concentration. When t_{mc} is the time required to attain the saturated adsorption, Eq. (2) holds for $t \leq t_{mc}$. For $t > t_{mc}$,

$$C = C_1 \qquad (2)'$$

Figure 3 is obtained from C_E-t curves with Eqs. (2) and (2)', where (a) and (b) are concerned with $\bar{M}=600$ and 8400. The linear decrease in C with $t^{1/2}$ is due to the diffusion-controlled adsorption, while a nearly constant C is revealed, independently of t,

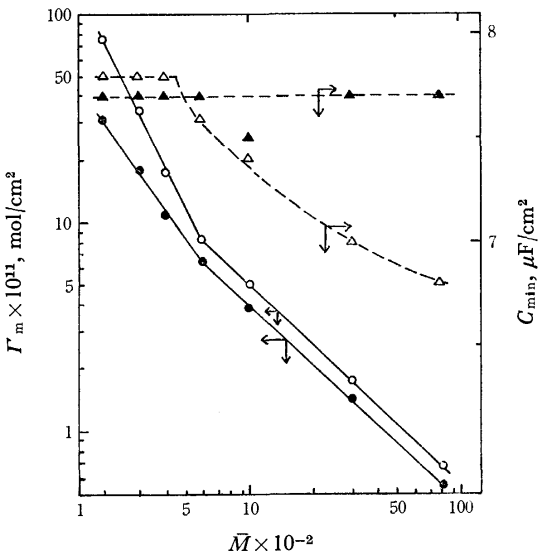

Fig. 4. Relation between mean molecular weight and maximum surface concentration (solid lines) or minimum differential capacity (broken lines).
solid lines: Γ_m—$\bar{M}$ curves (○: 1N potassium chloride+PEG, ●: 1N hydrochloric acid+PEG), broken lines: C_{min}—$\bar{M}$ curves (△: 1N potassium chloride+PEG, ▲: 1N hydrochloride acid+PEG).

with the adsorption equilibrium. The behavior of PEG deviated somewhat from Eqs. (2) and (2)', unlike that of PVP,[1] which was approximately consistent with the Koryta equation based on pure diffusion except for the transient range from the diffusion-controlled to the saturated adsorption. Such a deviation is obviously revealed by the curves for PEG of an especially low $\bar{M}$, as is shown in Fig. 3-(a), where each curve seems to attain an individual capacity at the adsorption equilibrium dependent on the concentration. This tendency is due to the lower adsorbability of PEG as compared with that of PVP. The time (t_{mc}) needed to attain Γ_m can be estimated by extrapolating the linear relation of C-$t^{1/2}$ to the minimum differential capacity; then, Γ_m is obtainable from the Koryta equation [Eq. (1)] on the assumption of its diffusion coefficient.

Relation between the Maximum Surface Concentration and the Mean Molecular Weight (Γ_m-$\bar{M}$ Curves): It is necessary to assume the diffusion coefficient (D) of adsorbates in order to evaluate Γ_m from the Koryta equation. Scholtan's relation[7] between D and $\bar{M}$, which is used for the assumption of D, is as follows:

$$D^2\bar{M} = 10^{-8} \quad (3)$$

In Fig. 4, the Γ_m obtained from Eq. (1) is plotted against $\bar{M}$ by the solid line; the values of Γ_m in 1N potassium chloride are larger than those in 1N hydrochloric acid by *ca.* 20%. Both plots of log Γ_m *vs.* log $\bar{M}$ reveal linear relations with the slope of *ca.* -1 in the range of $\bar{M}\geq 600$. The relation of the $\bar{M}\cdot\Gamma_m =$ const. may be found from the above slope. From this relation, obtained also for PVP,[1] the total segment numbers of PEG molecules adsorbed per unit area at the interface can be considered to be constant, regardless of $\bar{M}$. In the range of $\bar{M}<600$, each slope of logΓ_m *vs.* log$\bar{M}$ plots is different from that for $M\geq 600$; therefore, the configuration for $\bar{M}<600$ at the interface can be considered to be different from that for $M\geq 600$. The Γ_m values dependent on the electolyte may result from a small change in the adsorbed layer influenced by the pH value of the solution.

Relation between the Minimum Differential Capacity and the Mean Molecular Weight (C_{min}-$\bar{M}$ Curves): The thickness of the adsorbed layer can be examined by means of the following well-known relation:

$$C_{min} = \varepsilon/(4\pi\delta) \quad (4)$$

where C_{min}, ε, and δ are the minimum differential capacity, the dielectric constant, and the thickness of the adsorbed layer. In the case of $\bar{M}\geq 600$, the $\bar{M}$-dependence of C_{min} may be negligible because of nearly constant segment numbers adsorbed per unit area, as found previously from the Γ_m-$\bar{M}$ relation, and the C_{min} observed in 1N hydrochloric acid is independent of $\bar{M}$, whereas the C_{min} in 1N potassium chloride depends on $\bar{M}$ in the range of $\bar{M}\geq 600$, as is shown by the broken line in Fig. 4. The maximum difference between C_{min}'s in 1N solutions of potassium chloride and hydrochloric acid is about 1 μF/cm^2; it may be caused by the variation in the thickness or in the dielectric constant of adsorbed layer. From such a difference as about 10% of C_{min}, however, hardly no basic variation in the adsorbed structure is considered to take place. In this connection, it may be considered, with a constant segment numbers per unit area, that the decrease in C_{min} in aqueous potassium chloride is mainly due to the change in the compactness of the adsorbed layer, which is itself related to the inhibitive action of PEG.

Consequently, for PEG of $\bar{M}\geq 600$, the configuration at the interface may be a spread or flat form consisting of a chain, as may be expected from the Γ_m-$\bar{M}$ relation, and the compactness of the adsorbed layer somewhat depends on $\bar{M}$ in some cases, while in relation to the PEG of $\bar{M}<600$, the configuration at the interface may be quite different from that for PEG of $\bar{M}\geq 600$, in view of the results shown in Fig. 4.

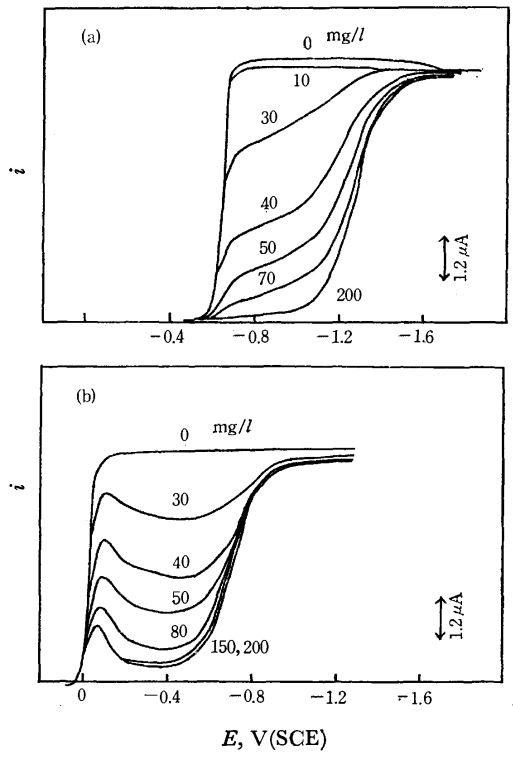

Fig. 5. Polarograms inhibited by PEG.
1N sodium sulfate+PEG $\bar{M}$=8400, (a) depolarizer: 1 mM Cd^{2+}, (b) depolarizer: 1 mM Cu^{2+}.

II) Inhibitive Effect of Adsorbed PEG. Polarograms: Figure 5 consists of typical polarograms which show the inhibitive effect of the PEG of $\bar{M}$=8400 on the reduction of Cd^{2+} or Cu^{2+} in 1N sodium sulfate. In Fig. 5-(a) for Cd^{2+}, the reaction current is depressed as the bulk concentration of PEG is increased, and the depression becomes less with the negative potential. The maximum depression of the reaction current is revealed at nearly -0.9 V, where the instantaneous *i-t* relations are observed, as will be shown later. Judging from the results shown in Fig. 1-(b), it is difficult to consider the current rise at *ca.* -1.2 V to be due to the desorption of PEG, but it may be ascribed to the inhibition weakened at a sufficiently negative potential.

7) W. Scholtan, *Makromol. Chem.*, **7**, 209 (1951).

In Fig. 5-(b) for Cu^{2+}, a current peak appears at *ca.* -0.1 V; it seems to be due to the desorption of PEG because of the increase in capacity at *ca.* -0.1 V in Fig. 1-(b), though the formation of an intermediate product[8] should also be taken into account. For the copper deposition, instantaneous *i-t* curves were observed at -0.4 V.

In 1N solutions of potassium chloride and hydrochloric acid, no inhibitive effect of adsorbed PEG was revealed because of the effect of the chloride ion, as has been discussed by Delahay.[9] Therefore, the inhibitive effect of PEG was examined in 1N solution of sodium sulfate or sulfuric acid.

Instantaneous Current vs. Time Curves (i-t Curves): The instantaneous *i-t* curves for the inhibitive effect of PEG on the reduction of Cu^{2+} revealed a tendency similar to that for Cd^{2+}; therefore, only the latter will be discussed here as an example. Figure 6 shows the *i-t* curves for the reduction of Cd^{2+} in 1N sodium sulfate with several concentrations of PEG, where (a) and (b) are related to the PEG of $\bar{M}=600$ and 8400 These curves are nearly analogous to the results by Schmid and Reilley[10] obtained for the adsorption of Triton X, which is controlled by the diffusion. The time t_{mi} (or t_{mc}) needed to complete a monolayer or the full coverage may be computed from Eq. (1) or (5)[11] modified as follows on the assumption that the complete inhibition takes place under full coverage by the adsorbates, whose process is controlled by the diffusion.

$$t_{mi} = t_{mc} = 1.82\Gamma_m^2/a^2D \qquad (5)$$

Therefore, t_{mi} should be in accordance with the t_{mc} obtained from the C-$t^{1/2}$ relation in Fig. 3.

In the adsorption of PVP,[12] t_{mi} was in good agreement with t_{mc}; in this case, t_{mi} was estimated by extrapolating the steeply depressed part to the time of zero current in the *i-t* relation.

In the case of PEG, the adsorption behavior somewhat deviates from that of the process simply controlled by the diffusion as has been stated previously, and a complete inhibition can not always be expected, even for the full coverage. Therefore, the value of t_{mi} for PEG was determined from the intersection obtained by extrapolating the steeply depressed part of the current to the extremely inhibited current in a considerably concentrated solution of PEG, on the assumption that the extremely inhibited current corresponded to the minimum current in the case of the maximum inhibition.

Comparison of t_{mc} with t_{mi}: The relations of log *a* *vs.* log t_{mi} are shown in Fig. 7. Further, the values of $at_{mc}^{1/2}$ and $at_{mi}^{1/2}$ are listed in Table 1, where $at_{mi}^{1/2}$ and $at_{mi}^{1/2}$ are shown instead of Γ_m since they are the values obtained directly without assuming the diffusion coefficient. The result for $at_{mc}^{1/2}$ shown in Table 1 was evaluated by extrapolating the C in the C-a relation to the minimum differential capacity at a constant t on the basis of Eq. (2). The value of $at_{mc}^{1/2}$ or $at_{mi}^{1/2}$ should be equal to a at $t_{mi}=1$ in Fig. 7.

Equation (5) can be rewritten as follows:

$$\log a = (-1/2)\log t_{mi} + \text{const.}$$

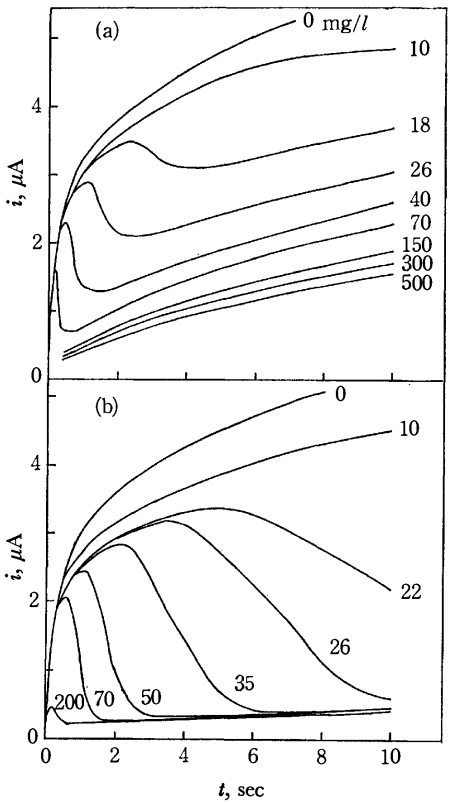

Fig. 6. Instantaneous current *vs.* time curves.

Table 1. Comparison of $at_{mc}^{1/2}$ with $at_{mi}^{1/2}$

PEG $\bar{M}$	$at_{mc}^{1/2}$ (mg·sec$^{1/2}$·l^{-1})$^{a)}$		$at_{mi}^{1/2}$ for Cd^{2+} $^{b)}$	
	1N KCl	1N HCl	1N Na_2SO_4	1N H_2SO_4
200	76.2 (−0.9 V)	89.2 (−0.9 V)		
300	60.5 (−1.2 V)	34.7 (−0.9 V)		
400	40.3 (−1.2 V)	29.1 (−1.0 V)		
600	32.8 (−1.2 V)	25.1 (−1.0 V)	43.6 (−0.9 V)	40.9 (−0.9 V)
1000	35.5 (−1.2 V)	27.8 (−1.0 V)	36.0 (−0.9 V)	38.7 (−0.9 V)
3100	55.3 (−1.2 V)	45.8 (−1.0 V)		
8400	71.8 (−1.2 V)	59.2 (−1.0 V)	79.4 (−0.9 V)	79.4 (−0.9 V)

a) The mean values of $at_{mc}^{1/2}$ at t of 3, 5, and 7 sec from *C-a* curves.
b) The mean values of $at_{mi}^{1/2}$ at several concentrations from *i-t* curves.

As can be expected from this relation, the log t_{mi} *vs.* log a plot in Fig. 7 reveals a nearly linear relation with the slope of *ca.* −1/2, regardlesss of $\bar{M}$, and so the adsorption process of PEG is controlled by the diffusion under the present experimental conditions.

The data in Table 1 are markedly scattered. In the case of $\bar{M}$=1000, however, the result of $at_{mc}^{1/2}$ in aqueous potassium chloride is approximately accordance with that of $at_{mi}^{1/2}$ in aqueous sodium sulfate or sulfuric acid. The results of t_{mi} for PEG of $\bar{M}$=1000 and 8400 are considered to be approximately reliable.

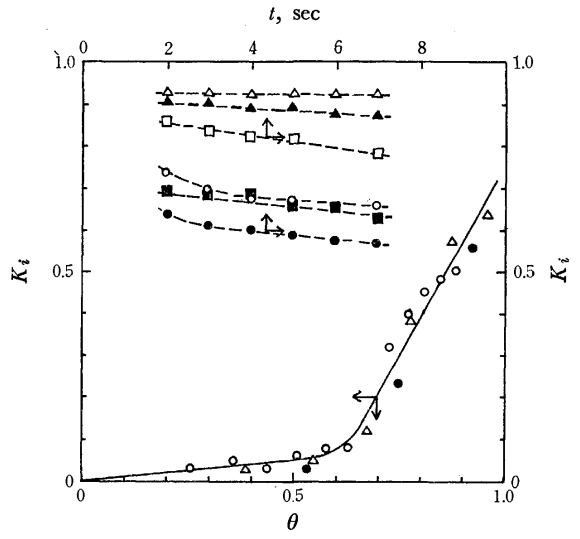

Fig. 8. Dependence of inhibitive efficiency on coverage, or on time after the attainment of saturated adsorption.
at E=−0.9 V, depolarizer: 1 mM Cd^{2+}, solid line: K_i—θ ($t \leq t_{mi}$) curve, 1N sodium sulfate+PEG of $\bar{M}$=1000 (○: 10 mg/l PEG, △: 15 mg/l, ●: 20 mg/l), broken lines: K_i—t ($t > t_{mi}$) curves, 1N sodium sulfate+PEG (○: PEG of $\bar{M}$=600, □: $\bar{M}$=1000, △: $\bar{M}$=8400), 1N sulfuric acid+PEG (●: PEG of $\bar{M}$=600, ■: $\bar{M}$=1000, ▲: $\bar{M}$=8400).

For $\bar{M}$=600,, the data are too scattered, perhaps because the behavior deviates somewhat from that of the adsorption simply controlled by the diffusion, as is revealed in Fig. 3-(a). The result in aqueous hydrochloric acid differs considerably from those in other solutions, though the dependence on the supporting electrolyte remains to be explained.

Relation between the Inhibitive Efficiency and the Coverage (K_i-θ Curve): The inhibitive efficiency (K_i) is given by $(i_b-i)/i_b$, where i and i_b are the instantaneous currents in the solution with and without PEG. At the time $t \leq t_{mi}$ during the diffusion-controlled adsorption, the coverage can be written by means of the Koryta equation as follows: $\theta = \Gamma_t/\Gamma_m = (t/t_{mi})^{1/2}$. The solid line in Fig. 8 is a typical plot of the K_i-θ relation, where the inhibition is hardly shown until θ=0.6; then, the sharp increase in K_i is revealed. When the inhibitor and the depolarizer are adsorbed by the process controlled the diffusion, the inhibitive effect on the reaction current is hardly revealed soon compared with t_{mi}; this tendency is clearly shown in Fig. 8. The tendency is revealed by the adsorption of the PEG or PVP of several $\bar{M}$, regardlesss of a. If a blocking effect of adsorbates is solely considered, K_i should be proportional to θ, however, this relation hardly holds usually and other effects must be taken into account in order to explain the behavior of the solid line in Fig. 8. The behavior of the K_i-θ plot may be explained by the geometrical relation between the effective radius of the congregated molecules adsorbed at the interface and the thickness of diffusion paths of the depolarizer. Matsuda[13] derived a theoretical *i-t* relation similar to the above case from the fundamental model assumed for the adsorbed layer; recently he has introduced a relation even more useful for analysis.

In the case of $t > t_m$, the K_i-t relations after the attainment of the saturated adsorption are plotted by the broken lines in Fig. 8. For the purpose of making the inhibitive condition uniform, regardless of $\bar{M}$, the value of K_i for any $\bar{M}$ is always determined in a solution containing PEG of 100 mg/l, because the segment numbers of the PEG adsorbed per unit area are nearly constant, independent of $\bar{M} \geq 600$, and the concentration in mg/l may be approximately proportional to that in segment numbers/l.

The variation in K_i after the completion of the saturated adsorption is shown somewhat in the figure, and it may be discussed from the viewpoint of the rehomogeneity proposed by Kastening.[14] The broken lines also reveal some dependence of K_i on $\bar{M}$ or on the supporting electrolyte. The inhibitive efficiency, K_i, after the attainment of the saturated adsorption increases with $\bar{M}$, which can be expected from the $\bar{M}$-dependence of adsorbability, as is revealed in Figs. 1—3. In the reduction of Cd^{2+}, the observed K_i in 1N sodium sulfate is always higher than that in 1N sulfuric acid; however, the reverse is the case in the reduction of Cu^{2+}, though the cause remains to be explained.

The Isomerization of Propylene Oxide on Zeolite Catalysts

Toshinobu IMANAKA, Yasuaki OKAMOTO, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka

(Received October 9, 1971)

The selectivity and activity of propylene oxide isomerization have been investigated over zeolite catalysts at 100°C. It has been found that the acid strength of a catalyst is a dominant factor in the selectivity and activity. The stronger the acid strength, the larger the ratio of acetone to propionaldehyde. The reaction intermediates are deduced to be a propylene oxide protonated or that adsorbed on a Lewis-acid site. It has also been found that, in the cases of HY, Silnex (SiO_2), and HY treated with pyridine, the selectivity and activity correlate with the strength of the interaction between the propylene oxide and the surface hydroxyl group. Moreover, it has been clarified that the H_0 value of the surface hydroxyl group observed at 3660 cm^{-1} on HY is -8.2——5.6, while that found at 3540 cm^{-1} is $+4.0$—$+4.8$.

The activities and selectivities for reactions catalyzed by solid acid are determined by means of the acid properties of catalysts. The relations between activities for reactions catalyzed by acid and the observed acidities of catalysts have already been reported by many investigators,[1-7] but there have been few studies of the relations between the selectivity and the acid properties. Misono and his coworkers[8,9] have shown that the selectivities for the isomerization of *n*-butenes over metal sulfates are controlled by the acid strength of the catalysts or by the electronegativities of the metal ions. The acid strength determines the electron distributions of the reaction intermediates and consequently controls their stabilities and reactivities. Therefore, it is considered that the acid strength elucidates the selectivity of an acid-catalyzed reaction. In this investigation, the isomerization of propylene oxide on zeolite catalysts was studied in order to clarify the reactions between the selectivity and the acid strength.

Venuto and Landis[10] have reported that propylene oxide is isomerized to propionaldehyde, acetone, and allyl alcohol on NaX and REX catalysts at 100—200°C. Matsumoto and his coworkers[11] have studied the selectivity for propylene oxide isomerization over metals supported on silica, metal oxides, and metal sulfates. Mathieu *et al.*[12,13] have reported that propylene oxide is isomerized to allyl alcohol on the basic sites of lithium phosphates and to propionaldehyde on acid sites of the 3.9 $Cr_2O_3 \cdot 1.1\ WO_3 \cdot 1.8\ H_2O$ catalyst.

In this report, the isomerization of propylene oxide will be studied and the relation between the selectivity (acetone/propionaldehyde) and the acid strength will be discussed. Moreover, the relation between the selectivity for isomerization and the strength of the interaction of the surface hydroxyl group with the reactant will be studied.

Experimental

Materials. The NaY and 10X zeolites were commercial grade. The HY was prepared by conventional ion-exchange procedures using analytical-grade NH_4Cl. The exchange degree of the sodium ion in NaY was found to be 75% according to flame-photometric analysis. The PtY, PdY, and PdHY were prepared from NaY and NH_4Y by the ion-exchange method using chloroplatinic acid and palladiumtetramine dichloride respectively. The degrees of ion exchange were 3.8% for PtY and PdY, and 6.9% for PdHY. PyHY represents the catalyst which was exposed to pyridine vapor of 5 mmHg at 150°C for 30 min and then evacuated at the same temperature for 1 hr under a vacuum of 10^{-4} mmHg. The Silnex (P-526N); SiO_2 was supplied by the Mizusawa Chemical Company.

Procedures. The isomerization of propylene oxide was carried out in a batch reactor at 100°C for 1 hr after treating the catalysts at 400°C for 4 hr under a vacuum of 10^{-4} mmHg. The total pressure was maintained at 10 cmHg by adding propylene oxide to the system in order to compensate for the pressure drop due to adsorption on the catalyst. The weight of the catalyst used was 0.5 g in all cases. The mixture was trapped in a glass ampoule at the temperature of liquid nitrogen, and the liquid components were analyzed by means of gas chromatography.

The infrared spectra of pyridine and propylene oxide adsorbed on catalysts were observed in a IR cell by means of a Hitachi infrared spectrometer. The disks of zeolites and Silnex were prepared by pressing them between polished stainless steel plates to a pressure of about 10 ton/cm^2. After the disks had been treated at 400°C for 4 hr in the IR cell under a vacuum, adsorption experiments were carried out at room temperature.

The acid strength of the catalysts, which had been evacuated at 400°C for 4 hr, were measured by a conventional indicator method using Hammett indicators.

Results and Discussion

The main products arising from the isomerization of propylene oxide on zeolite catalysts were propional-

NaY	0.0_{02}	0.0_1	0.20	4.0—4.8
PyHY	0.07	0.23	0.37	4.0—4.8
Silnex	0.27	6.2	0.043	4.0—4.8

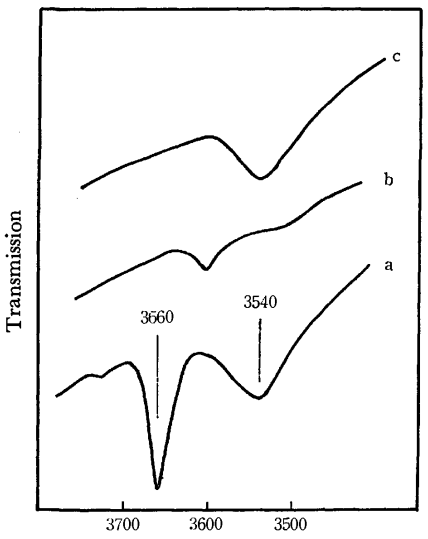

Fig. 1. IR spectra of HY and PyHY catalysts. a: HY, b: HY treated with pyridine vapor of 5 mmHg at 150°C for 30 min c: PyHY —— after treatment with pyridine vapor, evacuation was carried out at 150°C for 1 hr.

dehyde and acetone. Traces of allyl alcohol, acrolein, water, and condensed products were observed. Table 1 shows the conversions of propylene oxide to propionaldehyde and acetone and the selectivities (acetone/propionaldehyde) for each catalyst. The observed acid strength of each catalyst is presented in the last column of Table 1. The acid strength of PyHY (H_0=+4.0—+4.8) is as weak as those of NaY and Silnex. The IR spectra of PyHY and HY are shown in Fig. 1. HY zeolite has two species of surface hydroxyl groups, which are observed at 3660 cm^{-1} and 3540 cm^{-1}. However, the PyHY catalyst has only one kind of surface hydroxyl group, observed at 3540 cm^{-1}. Therefore, it is considered that the H_0 value of the surface hydroxyl group observed at 3660 cm^{-1} is −8.2——5.6, while the one found at 3540 cm^{-1} is +4.0—+4.8. The acid strength of each surface hydroxyl group has been measured by Hair and Hertl[14] by comparing the frequency shifts observed during the adsorption of basic compounds on surface hydroxyl

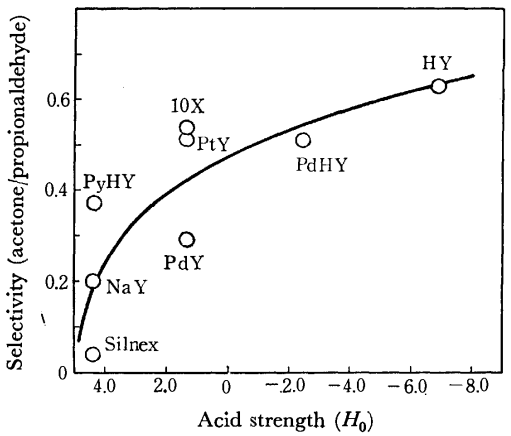

Fig. 2. Correlation between the selectivity (at 100°C) and the acid strength of the zeolite catalyst.

groups of several oxides with those of alcohols. However, no measurements have been reported using the indicator method.

Figure 2 shows the relation between the selectivities for propylene oxide isomerization and the acid strengths of the catalysts used. It is surprising that the stronger the acid strength, the larger the ratio of acetone to propionaldehyde. The only product may be propionaldehyde when the acid strength of the catalyst becomes weaker.

The IR spectra of the HY and Silnex catalysts exposed to propylene oxide are shown in Fig. 2. In the case of Silnex catalyst, the surface hydroxyl group observed at 3740 cm^{-1} interacts with propylene oxide and produces a new broad absorption band at 3370 cm^{-1}, but the surface hydroxyl group found at 3650 cm^{-1} has no interaction with the reactant. The difference between these two hydroxyl groups has been reported by Basila[15] for several compounds adsorbed on silica gel. The adsorption band due to CH_2 in the epoxide ring of propylene oxide exists at 3040 cm^{-1}, and there is no absorption band due to a carbonyl group. These

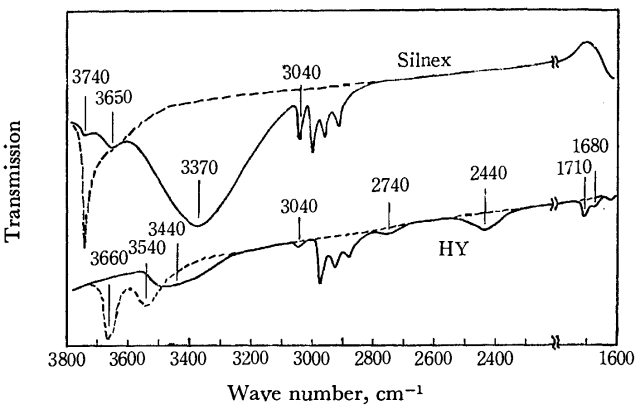

Fig. 3. IR spectra of HY and Silnex after exposure to propylene oxide. Dotted line: before exposure, Solid line: after exposure. Introduction of propylene oxide (pressure; HY: 8 mmHg, Silnex: 18 mmHg), subsequent evacuation for 1 hr, and measurements of IR spectra were carried out at room temperature.

14) M. L. Hair and W. Hertl, *J. Phys. Chem.*, **74**, 91 (1970).

15) M. R. Basila, *J. Chem. Phys.*, **35**, 1151 (1961).

facts show that the epoxide ring is not open, and that propylene oxide adsorbs on Silnex to form a protonated propylene oxide. In the case of the HY catalyst, however, a weak absorption band of CH_2 is observed and new bands appear immediately after exposure to propylene oxide at room temperature; these bands are 1710 cm^{-1} (due to carbonyl groups of physisorbed acetone and propionaldehyde), 1680 cm^{-1} (carbonyl groups of chemisorbed acetone and propionaldehyde), 1380 cm^{-1} (CH bending of acetone), and 2740 cm^{-1} (CHO of propionaldehyde). These facts show that acetone and propionaldehyde are produced. Both of the surface hydroxyl groups on HY catalysts observed at 3660 cm^{-1} and 3540 cm^{-1} are considered to interact with propylene oxide to form broad new bands at 3440 cm^{-1} and 2440 cm^{-1}. The reason for this is that when a small amount of acetone or propionaldehyde is adsorbed on the HY catalyst, strong absorption bands due to carbonyl group are observed, but the strength of the band due to surface hydroxyl group is not particularly reduced. The weak absorption bands due to carbonyl groups are observed only in the case of propylene oxide adsorption. Therefore, it is considered that the shifts of the hydroxyl groups can be ascribed to the interaction with propylene oxide. The surface hydroxyl group observed at 3540 cm^{-1} on the PyHY catalyst interacts with propylene oxide to produce a new band at 3440 cm^{-1}, but no bands at about 1700 cm^{-1} and 2440 cm^{-1}. Consequently, the surface hydroxyl group observed at 3660 cm^{-1} interacts with the oxygen atom of the propylene oxide to form a new band at 2440 cm^{-1} and produces two isomerized products, acetone and propionaldehyde, immediately after exposure, while that observed at 3540 cm^{-1} gives a new band at 3440 cm^{-1} because of the interaction with propylene oxide. In the cases of the other catalysts, the propylene oxide interacting with a proton of adsorbed water and the propylene oxide adsorbed on a Lewis-acid site may be reaction intermediates.

The strength of interaction between the surface hydroxyl group and the propylene oxide is measured in terms of $\Delta\nu_{OH}$ that is, the difference between the wave number of the perturbed hydroxyl group and that of the unperturbed hydroxyl group. The values of $\Delta\nu_{OH}$ are 1220 cm^{-1}, 370 cm^{-1}, and 100 cm^{-1} for

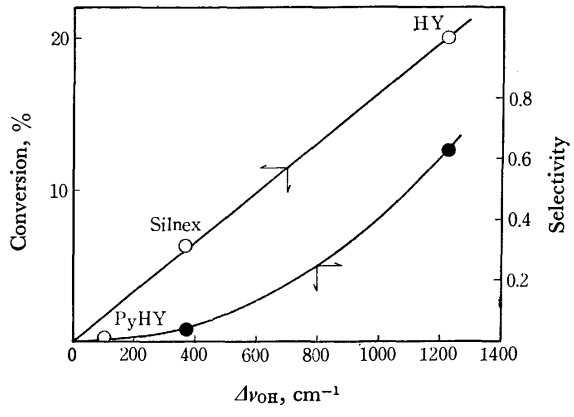

Fig. 4. Correlation between $\Delta\nu_{OH}$ and the reactivity of propylene oxide isomerization.

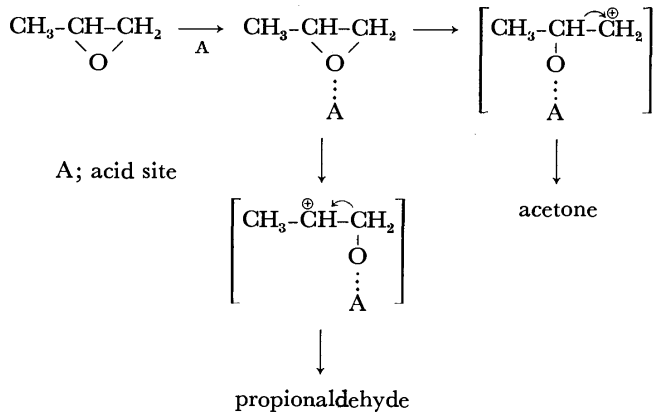
3660 cm^{-1} on HY; 3740 cm^{-1} on Silnex, and 3540 cm^{-1} on the HY and PyHY catalysts. The total conversions of propylene oxide to acetone and propionaldehyde are 20.0, 6.47, and 0.30% for the HY, Silnex, and PyHY catalysts, as is shown in Table 1. Fig. 4 shows the relation between the strength of the interaction and the conversion. The relation between the selectivity and $\Delta\nu_{OH}$ is also shown in Fig. 4. It has been reported[16,17] that the acidities of the HY catalyst are about 1 mmol/g in the regions of $-8.2 \leqq H_0 \leqq -5.6$ and $-5.6 \leqq H_0 \leqq +4.8$, and that the acid content of silica gel is also about 1 mmol/g. Therefore, it can be deduced that Fig. 4 shows the approximate effect of the acid strength. The selectivity of isomerization to acetone on the PyHY catalyst in Table 1 is higher than the value estimated from Fig. 4. It is considered, from the IR studies, that the pyridine interacting with the 3660 cm^{-1} hydroxyl group is desorbed partially by the adsorption of propylene oxide during the reaction, and that consequently the isomerized products on PyHY contain some products arising from the HY catalyst. These facts support the idea that the protonated propylene oxide is a reaction intermediate on the HY, PyHY, and Silnex catalysts, and that the acid strength of catalyst controls the selectivity. Therefore, the reaction path may be as follows:



The selectivity for this reaction is determined by the acid strength of the catalyst, as is shown in Fig. 2 and 4. This fact can be explained as follows. It is generally considered that the stronger the acid strength of the catalyst, the more strongly is the electron drawn from carbon-oxygen bonds in the epoxide ring by the acid site. In the case of strong acid, the bond strengths of O-CH(α-bond) and O-CH_2(β-bond) are consequently weakened, but the methyl group releases electrons and strengthens the α-bond. Therefore, the ratio of the probability of β-bond opening to that of α-that is, the selectivity of acetone to propionaldehyde-is large. However, in the case of weak acid, since the acid site draws the electron mildly, the electron released by the methyl group enters the antibonding

16) S. Otoma, Y. Arai, and H. Ukihashi, Preprints for the 20th Annual Meeting of the Chemical Society of Japan (April 1967), No. 11209.

17) W. K. Hall, H. P. Leftin, F. J. Cheselske, and D. E. O'Reilly, *J. Catal.*, **2**, 506 (1963).

level[18] of the α-bond and the strength of the α-bond is weakened. Hence, the α-bond opening becomes more easily than the β-bond opening; that is, the selectivity of acetone to propionaldehyde becomes lower.

In this reaction, the deactivation for HY and PdHY is caused by the formation of coke and polymerized products which have an absorption band at 1570 cm^{-1}. Propylene oxide is dehydrated by sulfuric acid and forms cokes, but no coke is formed by hydrochloric acid, which has no dehydration ability. Therefore, the deactivation may be due to the large dehydration ability of the surface hydroxyl groups on HY and PdHY, mainly the 3660 cm^{-1} hydroxyl groups.

The selectivity of isomerization at 200°C becomes lower than that at 100°C except for PtY; (selectivity at 200°C; 0.53) and PdY (0.99). Matsumoto and his co-workers[11] have reported that the selectivity of acetone to propionaldehyde is high on platinum (0.42 at 350°C) and palladium metals (1.89 at 256°C). It is considered that the activity of metal ions becomes comparable at 200°C with that of acid sites. The metal ions on zeolites are deduced to be active as metals supported on silica, metal sulfates, and metal oxides.

18) K. Simizu, H. Kato, and T. Yonezawa, Preprints for the 20th Annual Meeting of the Chemical Society of Japan (April, 1967), No. 1, 92.

Conclusions

The activity and selectivity of the propylene oxide isomerization of a zeolite catalyst are found to be controlled by the acid strength of the catalyst. It is considered that the reaction intermediates are the protonated propylene oxide and propylene oxide adsorbed on the Lewis-acid site. The electron distributions of intermediates may be determined by the acid strength of the catalyst, and, consequently, the selectivity and activity may be controlled by the acid strength.

Interestingly, it is found that, in the cases of the HY, PyHY, and Silnex catalysts, the activity and selectivity are related to the strength of the interaction, which is represented by $\Delta\nu_{OH}$.

Moreover, it is clarified that the H_0 value of the surface hydroxyl group observed at 3660 cm^{-1} on HY zeolite is -8.2——5.6 while that found at 3540 cm^{-1} is $+4.0$—$+4.8$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3254—3261 (1972)

Studies on Intermolecular Complex Formation. II. Crystal Structure of Cytosine-*N*-Benzoylglycine Complx Monohydrate

Chihiro TAMURA, Tadashi HATA, Sadao SATO, and Noriko SAKURAI

The Central Research Laboratories of Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received December 28, 1971)

Many intermolecular complexes between *N*-acylamino acids and nucleotide bases have been found by means of X-ray powder diffractometry. Among these, the crystal structure of *N*-benzoylglycine cytosine complex monohydrate has been determined by the direct method. The crystal data are: $a=18.71$, $b=7.11$, $c=18.37$ Å, and $\beta=144.0°$. The space group is $P2_1/c$; $D_{obsd}=1.37$; $D_{calcd}=1.35$ g/cm^3. The final R factor was 0.131. In the crystal, a cytosinyl cation and a *N*-benzoylglycyl anion are joined by two NH···O hydrogen bonds, of which the shorter one is 2.652 Å long. Such a complex formation may exist *in vivo*.

Complementary hydrogen bonding between purine and pyrimidine bases in the Watson-Crick model of DNA is widely known, and several crystals of model complexes of nucleotide bases have been studied by single-crystal analysis.[1-7] Such base pairs are also assumed in explaining the structure of the stem in the clover model of *t*-RNA and the codon-anticodon interaction between *t*- and *m*-RNA. In biological systems, similar hydrogen bonding may exist not only between these bases, but also between nucleotides and peptides. However, no structural studies of the latter hydrogen bonding have yet been published. As we have previously reported,[8] a survey of the complex formation ability by means of X-ray diffractometry showed that none of the amino acids binds with any bases in spite of the fact that the carboxylic acid could give rise to an affinity for adenine and/or cytosine. It was assumed that the inertness of amino acids was due to their zwitterion structure. Subsequently, we have continued the survey using some modified amino acids which were presumed to suppress the zwitterion

formation; we found that many *N*-acylamino acids combine with adenine and/or cytosine. Herein we will describe the formation of the complexes of N-acylamino acids with nucleotide bases[9] and the crystal structure of one such complex: *N*-benzoylglycine-cytosine complex monohydrate.

Experimental

The ability of complex formation for nucleotide bases was examined in a similar manner, as has already been reported[8]

The procedure may be described briefly as follows: equivalent moles of the *N*-acylamino acid derivative and the base were dissolved in hot 70% aqueous ethanol, and the mixture was allowed to stand for several days in a refrigerator. X-ray diffractions of the materials obtained were measured up to $2\theta=50°$ (for CuK_α) with a Rigaku Denki model D6C diffractometer. These materials were generally fine crystalline powders which were not suitable for X-ray single-crystal analysis. The formation of new crystalline species was verified by comparing their diffraction patterns with those of the components. The only complex obtained as a single crystal at this stage was *N*-benzoylglycine-cytosine.

Because of the coexistence of the component crystals, single crystals of the complex were separated under a stereomicroscope; two components, cytosine and *N*-benzoylglycine, were detected by means of a mass spectrogram. The unit-cell dimensions and the space group were determined from Weissenberg photographs, and the density of the crystals was measured by the floatation technique. The crystal and physical data obtained are as follows: Monoclinic, $a=18.71$, $b=7.11$, $c=18.37$ Å, $\beta=144°$, Volume$=1436.4$ Å^3, $Z=4$, $D_{obsd}=1.37$, $D_{calcd}=1.35$ g/cm^3. Space group $P2_1/c$. Three-dimensional intensity data were collected from the equi-inclination Weissenberg photographs along the *b* axis through the layers of *h*0*l*—*h*6*l*. The intensities of 1993 independent reflections were measured by means of visual comparison with a standard scale. Lorentz-polarization corrections were made in the usual way, and the structure factors on an absolute scale were derived by Wilson's plot.

Structure Analysis

The phases of the structure factors were determined directly by the symbolic addition procedure for a centrosymmetric case. All the structure factors were converted to $|E|$'s. For the reflections with $E\geqq1.50$, triple-product sign relationships and the associated probabilities were listed by the use of the $\sum$ 2 list program. As a starting set, three linearly independent reflections which had large $|E|$ magnitudes and a large number of interactions (9,1,-6; 5,1,9; 7,6,-3) were assigned to +, and four other reflections were given symbols (2.2,8;A: 6,0,-4;B: 12,3,1;C: 0,1,13;D). After the symbolic addition procedure using $|E|$'s greater than 1.50, the B,C, and D symbols were uniquely assigned to −, +, and − respectively. For two possible signs of A, the E-maps were synthesized, and a satisfactory molecular structure was obtained when A is +; the structure factor calculation on the basis of this approximate structure gave an *R* factor of 0.55. After three cycles of a full-matrix least-squares refinement with isotropic thermal parameters, the *R* factor decreased to 0.45. Since the temperature factors of some of the atoms became large, the Fourier synthesis was carried out. In the resulting map, the water molecule was found, and it was revealed that two of the atomic positions had been incorrectly assigned. Starting from the new set of atomic coordinates, six cycles of the full-matrix least-squares refinement with isotropic thermal parameters were carried out; the *R*-factor was thus reduced to 0.17. The hydrogen coordinates were given by the optimum positional calculation, assuming the distances of 1.05 Å for C–H and N–H bonds, since only a few hydrogen atoms were revealed on the difference map. Final cycles of the full-matrix least-squares, with anisotropic thermal parameters except for hydrogen atoms, dropped the *R* to 0.131. The structure factor amplitudes are listed in Table 1, while the final positional and thermal parameters are listed in Table 2(a) and (b).

Results and Discussion

General Ability of Complex Formation of N-*Acylamino acids for Nucleotide Bases.* Table 3 shows the ability of complex formation of *N*-acylamino acid with the nucleotide bases. A + sign denotes the formation of a new crystalline species, and a − shows that no change in diffraction patterns was observed under these conditions. It is remarkable that many *N*-acylamino acids produce complex crystals, contrary to the case of free amino acids. In a previous paper, the inertness of free amino acids for nucleotide bases was assumed to be due to their zwitterion form, which has been established in the crystal structures of many amino acids.[10-15] On the other hand, the crystal analysis of 2-amino-3-methyl-benzoic acid,[16] which can bind with adenine, shows that proton transfer from the carboxylic acid to the amino group does not occur, probably because the amino group is stabilized by π electrons in the benzene ring. Similarly, the *N*-acylation of the amino acids gives rise to a decrease in the proton-accepting ability of the amino group because of the formation of the peptide bond. Consequently, the carboxylic group can donate a proton to any proton-accepting group other than the amino group.

About 88 and 78% of the acidic and neutral *N*-acylamino acids form complex with adenine and/or cytosine under the present experimental conditions, while neither of the basic *N*-acyl derivatives, histidine or arginine, produces any complexes. Therefore, it can be assumed that the acidity of *N*-acylamino acid strongly affects the complex formation with nucleotide bases. How-

ever, it should be noticed that, in some cases, a small structural differece in neutral *N*-acylamino acids may play a major role in forming a complex; for instance, *N*-acetylleucine and *N*-acetylisoleucine have a similar acidities, but the former binds only with adenine, and the latter, with cytosine.

The Geometry of the Complex. From the structure determination of the present crystal, it is established that the complex is formed by two hydrogen bonds between cytosine and *N*-benzoylglycine. The interatomic distances and angles in the complex between cytosine and *N*-benzoyl glycine were calculated from the parameters in Table 1, as is shown in Fig. 1(a) and (b), and in Table 4. The maximum standard deviation was 0.017 Å for the bond length in cytosine and the carboxyl group and 0.033 Å for that in the benzoyl group.

The bond lengths and angles of the cytosine moiety of the complex do not agree well with those found in the crystal of cytosine hydrate. Table 5 shows a comparison with related structures. The significantly large bond angle of 124.3° for C1–N2–C3 implies that the hydrogen atom might be attached to N2, since the mean bond angles of C–NH–C and C=N–C are 125° and 116° respectively.[17] In the pyrimidine ring, the rather short distance, 1.298 Å might indicate that the C5–C6 bond is a double bond. The short bond distance, 1.322 Å, for C1–N7 might be attributed to the double-bond character. The C–O bond lengths of 1.223 and 1.252 Å, and the O10–C9–O11 angle of 125° are close to those observed in many amino acids and suggest the formation of a carboxyl anion. Although the difference electron density map is not good enough

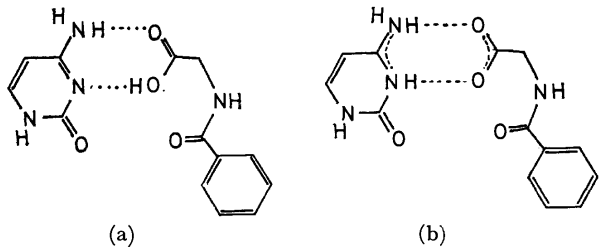
*sign indicates C-NH-C type of bond angles while no sign indicates C=N-C type of bond angles.

for obtain the positions of all the hydrogen atoms, the peaks for the H1 and H3 involved in the hydrogen bond are observed rather clearly. Each of the nitrogen atoms, N2 and N7, obviously possesses a hydrogen atom, while the carboxyl oxygens, O10 and O11, do not. From these results, it may be concluded that the complex consists of a cytosinyl cation and an *N*-benzoylglycyl anion as a result of proton transfer from the carboxyl group to the amidine group; the complex can be well represented by the formula of Fig. 2(b) rather than by that of Fig. 2(a). The NH···O



(a) (b)

Fig. 2. Hydrogen bond system between cytosine and *N*-benzoylglycine.

hydrogen bond distances are 2.697 and 2.652 Å, fairly shorter than the normal value,[18] probably because of the enhancement of some ionic force. The intermolecular hydrogen bond between the carboxyl and guanido groups in an arginine crystal[19] is analogous to that in the present complex. The least-squares planes of cytosine, the carboxylic group, and a benzene ring in *N*-benzoylglycine were calculated; the displacements of the atoms from each plane are shown in Table 6. The maximum deviation is 0.04 Å for O8 in the cytosine ring. The dihedral angle between cytosine and the carboxyl group is 3.0°.

As may be seen from Fig. 3, the component molecules have several sites, (A), (B),···(F), which are capable

of forming an intermolecular hydrogen bond. The favourable condition of the pairing might be affected not only by their characteristic atomic arrangements, but also by their crystalline fields. Therefore, the hydrogen-bonded complexes found in crystal structures might be rather limited. We expect that the hydrogen-bond systems in some of the complexes

listed in Table 3 are similar to that in cytosine—*N*-benzoylglycine.

The principal architecture of the present complex crystal is as follows; the complexes are linked to form an infinite column in the direction of the *b*-axis by hydrogen bonds between N7 and O8 in the cytosine molecules, with a distance of 2.758 Å. In this column, water molecules are located between O11 and O10 with distances of 2.789 and 2.884 Å, respectively so as to be hydrogen-bonded along the column. Two of these columns are joined through the hydrogen bonds of N4 with O15 at 2.742 Å. The intermolecular contacts shorter than 3.9 Å are given in Table 7.

Implications concerning Biological Aspects. The details of the interaction between *N*-acylamino acids and nucleotide bases in crystalline complexes can now be presented on the basis of our results. Similar types of molecular interaction may exist *in vivo*, but it is as yet impossible to predict such complex formation in a particular biological process. Here we will only point out some features of the present results which may be of biological significance.

At the terminal position of *t*-RNA molecules, the ususal sequence is CCA. Cytosine and adenine, not uracil nor thymine, are the bases with which *N*-acylamino acid from the complexes. This coincidence seems very attractive in considering the interaction of *t*-RNA and amino acids.

Another point is *N*-acylation, which is necessary for complex formation between amino acids and nucleotide bases. It is widely known that the hydrogen atom of a terminal amino group in many peptides is replaced by formyl or acetyl groups.[20–23] Marcker[24] discovered that methionine-*t*-RNA, which can tranfer a formylated amino acid into polypeptide, is involved in the initiation of protein synthesis in *E. Coli*. Thus, we assume that the binding of *N*-acylamino acid and a nucleotide base, similar to that of the present complex, has occurred in several steps of the protein synthesis.

In conclusion, the complex formation of adenine and cytosine with *N*-acylamino acid occurs generally. The molecular arrangement in the present complexes may be thought of as a candidate in considering possible interactions in biological systems.

We wish to thank Professor Yoshio Sasada of Tokyo Institute of Technology for his valuable discussions and suggestions.

(Received January 6, 1972)

The liquid-phase isomerization of *m*-xylene was studied over a silica-alumina catalyst under pressure on the additions of 2% of 8 higher-boiling compounds and 20—50% of benzene to reactant *m*-xylene. The catalyst activity in the isomerization was not greatly affected by hexamethylbenzene, naphthalene, α-methylnaphthalene, diphenyl, or *s*-dibenzyl. On the other hand, the activity was greatly lowered by 1,6-dimethylnaphthalene, diphenylmethane, and anthracene. Moreover, a very rapid exchange reaction occurred between an aromatic ring of diphenylmethane and a reactant xylene molecule, while the content of the isomerization product decreased linearly with an increase in the amount of benzene. From these results, the chemisorption states of xylene were discussed as follows. Most xylene molecules may be deduced to be chemisorbed on acid sites by those benzene rings. On the other hand, the fact that diphenylmethane inhibits the isomerization implies the existence of such a chemisorption state of xylene as a methylbenzylcarbonium ion, which may be an intermediate in the disproportionation reaction of xylene. The acid sites available for the chemisorption of diphenylmethane and for the disproportionation were speculated to be common and to have both acidic characters, protonic and Lewis.

In an earlier paper[1] the present authors reported that a silica-alumina catalyst revealed high activity in the isomerization of *m*-xylene in a liquid-phase reaction under pressure and that no practical decline in activity was observed even after 20 days at a temperature below 380°C. The enhanced activity in the liquid-phase reaction may be ascribed to the cleaning effects of the reactant: the higher-boiling by-products, which are inhibitors, are successively dissolved in the liquid reactant. The dissolution effect suggests the possibility of experiments using higher-boiling compounds in the liquid-phase reaction.

The components of the higher-boiling by-product were studied by the mass spectrometry.[1] However, they could not be identified precisely, since several probable components have the same mass number. This problem may be solved by comparing the effects of pure higher-boiling compounds on the isomerization of *m*-xylene with those of the higher-boiling by-products.

The first purpose of this paper is to study the effects of the pure higher-boiling compounds on the isomerization of *m*-xylene and to discuss the above problem. The second is to examine the pure higher-boiling compounds for the relative intensity of chemisorption on the acid site available for the reactions of xylene and to discuss the chemisorption state of xylene.

Experimental

The equipment used was the same as that described in previous papers.[1,2] The catalytic activity was measured by 4 hr's operations at a feed rate of 24 g/h under a pressure of 300 kg/cm², with using pure *m*-xylene or *m*-xylene solutions containing 2 weight per cent of the higher-boiling compounds. Between these measurements, pure *m*-xylene was fed into the reactor at a rate of 6 g/h in order to desorb the higher-boiling compounds from the catalyst surface or to keep the catalytic activity constant.[1] A temperature as low as 280°C was selected as the reaction temperature, because the change in catalytic activity could be observed sensitively at a low concentration of the isomerization product.

The catalyst used (2.5 g) was powdered Nikki N633L silica-alumina; it was calcined at a temperature of 500°C for 20 hr. The purity of *m*-xylene (produced by Mitsubishi Gas Chemical Co., Inc.) was 99.6%, and it contained 100—130 ppm of water. The other reagents were commercial grade and were used for the experiments without any further purification.

The product was analyzed by gas chromatography at 57°C. The column used for this measurement was 4 m in length, 1 mm in dia., and packed with 5% bentone 34+5% DIDP on diasolid L (100—200 mesh). The higher-boiling compounds were analyzed by means of a Hitachi double-beam mass spectrometer. The mass spectra were obtained at an ionization voltage as low as 15 V in order to allow only the parent peaks of the compounds to appear.

Results

The higher-boiling compounds used were hexamethylbenzene, naphthalene, α-methylnaphthalene, 1,6-dimethylnaphthalene, diphenyl, diphenylmethane, *s*-dibenzyl(1,2-diphenylethane), and anthracene; the results are shown in Figs. 1—5. In these figures, the arrow signs designate the results of 4 hrs' operations using *m*-xylene solutions containing 2 weight per cent of high-boiling compounds. The other points show results when pure *m*-xylene was used as the reactant. The figures show that hexamethylbenzene, naphthalene, α-methylnaphthalene, diphenyl, and *s*-dibenzyl did not greatly affect the activity in the isomerization of *m*-xylene. On the other hand, 1,6-dimethylnaphthalene, diphenylmethane, and anthracene lowered the activity greatly. However, when reactants were changed from the *m*-xylene solutions to pure *m*-xylene, different behavior was observed in the recovery of the activity among

the three cases: in the case of dimethylnaphthalene, the recovery was 100%; in the case of diphenylmethane, it was 90%, and in the case of anthracene, it was only 60%. It was noted that the addition of diphenylmethane to the *m*-xylene reactant resulted in the production of 0.5% of benzene.

An experiment was carried out using dried *m*-xylene and a dried *m*-xylene solution containing 2 weight per cent of diphenylmethane; we intended to examine the effects of water on the chemisorption of diphenylmethane with reference to the results in Fig. 4. However, when a catalyst was packed in the reactor in a dried box, the catalyst was moistened by *m*-xylene containing a small amount of water in order to obtain a high activity.[3] This reaction was carried out at a temperature of 290°C and at a feed rate of 13 g/h. The *m*-xylene solution was fed into the reactor for

6 hr at the time designated by the arrow sign in Fig. 6. Also, diphenylmethane lowered the activity in the isomerization in this case, and 1.3% of benzene was produced. When the reactant was changed from the solution to pure and dried *m*-xylene, there was a gradual recovery of activity.

Fugures 7 and 8 show the mass spectra of higher-boiling compounds at the times designated by the arrow signs in Figs. 4 and 6 respectively. The compositions of the higher-boiling compounds were obtained from the spectra; they are tabulated in Table 1. The results show that diphenylmethane was converted mainly to di and tetramethyldiphenylmethane.

The influence of benzene on the activity in the isomerization of *m*-xylene was also studied in order to compare the intensity of the chemisorption of benzene on the acid sites available for the reaction with that of xylene. Figure 9 shows a linear decrease in the contents of *p*- and *o*-xylene with an increase in the amount of benzene.

a) The concentration of diphenylemthane in the *m*-xylene reactant was 2.22%.
b) The concentration of diphenylmethane in the *m*-xylene reactant was 1.98%.

Discussion

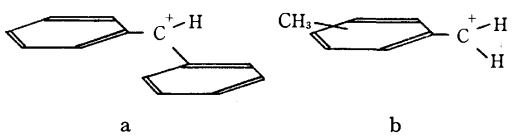
1. The Main Compounds of the Higher-boiling By-product in the Isomerization of m-*Xylene.* As was shown in earlier papers,[1,3] the mass numbers of the main compounds of the higher-boiling by-products were 182, 196, 210, 224, and 238 in the isomerization and the disproportionation of *m*-xylene over a silica-alumina catalyst.

Furthermore, the addition of 2% of the main compounds to the *m*-xylene reactant resulted in a decrease in activity in the isomerization and the production of about 1% of toluene.

Considering only the mass numbers, the main compounds may be polymethyldiphenyl, polymethyldiphenylmethane, or polymethyl-*s*-dibenzyl. However, only diphenylmethane exhibited the behavior shown in Fig. 4, where the activity for the isomerization decreased greatly and about 0.5% of benzene was produced. This was the same behavior as shown by the main compounds in an earlier paper.[1] The production of benzene seemed to correspond to that of toluene on the addition of the main compounds to the *m*-xylene reactant, since the main compounds were polymethyl-ones. On the other hand, the addition of 2% of diphenyl or 2% of dibenzyl to the *m*-xylene reactant did not greatly decrease the catalytic activity and resulted in the production of neither benzene nor toluene. Therefore, it can be concluded that polymethyldiphenylmethanes are the main compounds. This conclusion is consistent with the NMR data in the earlier paper.[1]

2. Effects of Benzene on the Isomerization. As is shown in Fig. 9, the addition of a large amount of benzene to the *m*-xylene reactant resulted in a decrease in the yields of both *p*- and *o*-xylene. However, the ratio of the *p*-xylene yield to the total xylene content as well as that of the *o*-xylene yield to the total xylene content was constant, independent of the benzene concentration, as is shown in Fig. 9. Since the coverage of the active site is 1 under these reaction conditions,[2] this means that the ratio of the number of molecules of benzene adsorbed on the sites available for the isomerization to that of *m*-xylene is equal to the ratio in the reactant. Therefore, the intensity of the adsorptivity of benzene on the sites is equivalent to that of *m*-xylene. Furthermore, this conclusion implies that most molecules of *m*-xylene adsorb on the sites by the benzene rings, not by the methyl groups, since a benzene molecule has no methyl group. This is supported by the fact that the addition of 2% hexamethylbenzene to the *m*-xylene reactant did not greatly affect the activity in the isomerization, as is shown in Fig. 1; the intensity of the adsorptivity of *m*-xylene is approximately equivalent to that of hexamethylbenzene.

3. Chemisorption of Diphenylmethane. It has been well known electronic-spectrally that a triphenylmethylcarbonium ion is formed from triphenylmethane over a silica-alumina.[4-6] The high stability of the ion can be ascribed partly to its character as a resonating structure because of the presence of three phenyl groups. Hence, it may be expected that a stable diphenylmethylcarbonium ion is formed from diphenylmethane on an acid site, since the ion has two phenyl groups, as is shown in Fig. 10. The stable ion may result in a strong chemisorption of diphenylmethane and may be responsible for the relatively larger influence of diphenylmethane on the activity in the isomerization in comparison with the influences of diphenyl or *s*-dibenzyl. In addition, the fact that most of the diphenylmethane added to *m*-xylene was recovered as polymethyldiphenylmethane seems to support the formation of the diphenylmethylcarbonium ion.

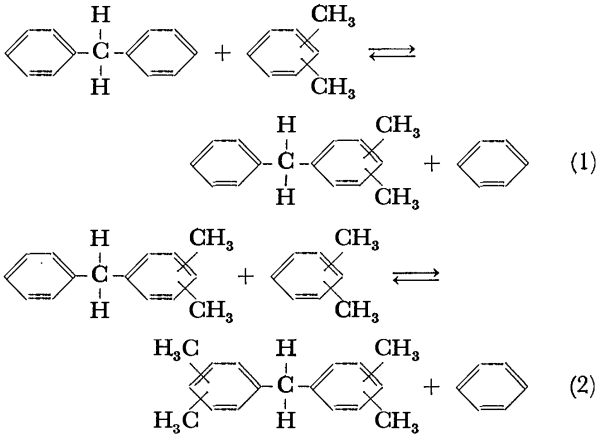


a b

Fig. 10. Possible chemisorption states of diphenylmethane (a) and xylene (b).

Diphenylmethane is considered to be chemisorbed by its methylene group on an acid site. If one of the two phenyl groups in a diphenylmethylcarbonium ion (Fig. 10a) is formally replaced by a hydrogen atom, the ion is converted to a benzylcarbonium ion (Fig. 10b). The benzylcarbonium ion suggests the possibility that xylene chemisorbs on an acid site by means of its methyl group.

4. Exchange Reaction between the Aromatic Ring of Diphenylmethane and Reactant m-*Xylene.* In Table 1, the order of increasing yield is: tetra≥di>trimethyldiphenylmethane, while the yield of monomethyldiphenylmethane is zero. When considering that 0.5—1.3% of benzene was produced in Figs. 4 and 6, this order suggests the occurrence of a rapid exchange reaction between an aromatic ring of diphenylmethane and a reactant *m*-xylene molecule, as is shown in Eqs. (1) and (2). When considering the chemisorption state



(1)

(2)

of diphenylmethane (Fig. 10a) and the nucleophilic property of aromatic compounds,[7] Fig. 11a is a possible intermediate for the exchange reaction. Hamanaka *et al.*[8] studied the same kind of reaction catalyzed by aluminum chloride at room temperature using methylbenzylbenzene and *p*-xylene, and suggested a benzylcarbonium ion as the intermediate. In the present paper, however, the benzylcarbonium ion can be excluded as the intermediate since the stability of the benzylcarbonium ion is lower than that of the diphenylmethylcarbonium ion. The low stability of the benzylcarbonium ion is confirmed by the fact that most xylene molecules chemisorb on acid sites

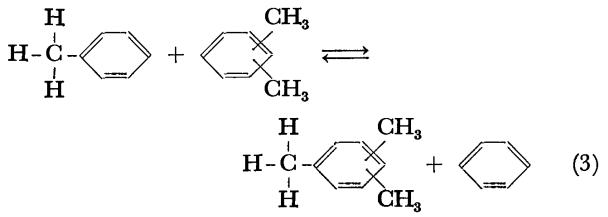
a: for the exchange reaction, b: for the disproportionation reaction.

by means of the benzene rings, not the methyl groups, under the present reaction conditions.

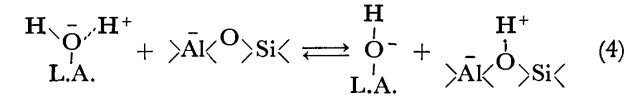
The exchange reaction is similar to the transalkylation reaction which includes the disproportionation of xylene. When an aromatic ring of diphenylmethane is formally replaced by a hydrogen atom in Eq. (1), we obtain Eq. (3), which corresponds to a transmethylation reaction. Figure 11b is a possible intermediate for the transmethylation (or the disproportionation) reaction. This model is consistent with the results reported in an earlier paper.[3]



(3)

5. The Acid Site Available for the Chemisorption of Diphenylmethane. On the basis of the discussion in the preceding sections, a common acid site may be available for the formation of a triphenylmethylcarbonium ion, a diphenylmethylcarbonium ion, and a benzylcarbonium ion, and for both the exchange and disproportionation reactions. The reaction of triphenylmethane with a silica-alumina catalyst to form a chemisorbed triphenylmethylcarbonium ion has been interpreted by Leftin and Hall as a hydride abstraction by Lewis-acid sites on the surface.[4] Following this interpretation, the decrease in the catalytic activity for the isomerization on the addition of diphenylmethane to the *m*-xylene reactant indicates that the chemisorption of diphenylmethane on Lewis-acid sites decreases the protonic acidity of the catalyst, since it has been generally accepted that the isomerization is catalyzed by a protonic acid site.[3,9-12] Hence, the acid site available for the chemisorption of diphenylmethane may be considered to have both acidic characters, protonic and Lewis. Figure 12 shows a possible model of such an acid site, which was proposed by Uytterhoeven over H–Y zeolite[13]; (a) is a protonic acid state and (b) is a Lewis acid state. When diphenylmethane is chemisorbed on the b state, the protonic acidity of the site disappears.

It has been reported that the presence of a small amount of water is preferable for the disproportionation of xylene[3] and for carbonium-ion formation from triphenylmethane.[14] On the basis of the above consideration of the acid site, this fact may be interpreted as follows. In a reaction system containing a small amount of water, the chemisorption of water on free Lewis-acid sites may be considered to generate the acid site of Fig. 12, as is shown in Eq. (4). Here, the words "free Lewis-acid sites" mean all the Lewis-acid sites except for the type of Fig. 12b.



(4)

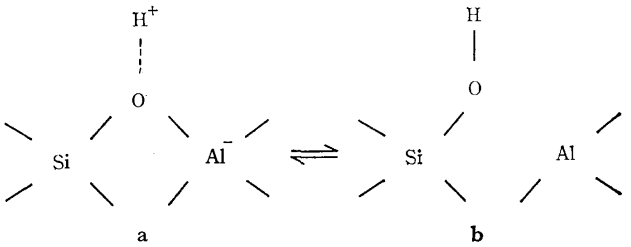


Fig. 12. A model for the acid site which has both acidic characters protonic and Lewis one.
a: a protonic acid state, b: a Lewis acid state.

In view of the fact that only a strong acid such as concentrated sulfuric acid above 85% converts triphenylmethane to the carbonium ion, the strength of the Lewis acid of Fig. 12b has to be stronger than that of a free Lewis acid, since it has been proposed that only the Lewis acid of Fig. 12b is available for the chemisorption of triphenylmethane and for the disproportionation. The consideration that the strength of the binding of an oxygen atom or a hydroxyl group to a Lewis acid increases with an increase in the strength of the Lewis acid supports the above consideration of the acid site of Fig. 12b—that an oxygen atom is still bound to an aluminum atom in the second term in Eq. (4). The aluminum atom is a Lewis acid site in Fig. 12b. Therefore, Eq. (4) indicates the possibility that the adsorption of water on a weak Lewis-acid site may generate a strong Lewis-acid site in a reaction system containing a small amount of water.

There is a different interpretation possible in the case of the chemisorption of diphenylmethane on Lewis-acid sites. It may be considered that the adsorption of water on a Lewis-acid site generates a protonic acid, and that the reverse reaction generates a Lewis one. Hence, the chemisorption of diphenylmethane on a Lewis-acid site results in a decrease in the protonic acidity. However, this interpretation does not seem to be reasonable in view of the results in Fig. 6. In the experiment of Fig. 6, the dried *m*-xylene was used with the intention of preventing a Lewis-acid site from being converted to a protonic acid by the adsorp-

tion of water. Therefore, the adsorption of diphenylmethane on a Lewis-acid site does not affect a protonic one directly. However, the isomerization activity was greatly lowered by diphenylmethane.

Hirshler[6] showed the possibility of the chemisorption of triphenylmethane on a protonic-acid site. He found that triphenylmethane is oxidized by chemisorbed oxygen to triphenylcarbinol, followed by the reaction with a protonic acid to generate the triphenylmethylcarbonium ion, and that 90% or more of the chemisorbed triphenylmethylcarbonium ion was recovered as triphenylcarbinol. On the other hand, Porter[5] reported that it is not necessary to oxidize triphenylmethane to triphenylcarbinol preliminary to carbonium-ion formation. Furthermore, most of the diphenylmethane was recovered as polymethyldiphenylmethane in the present experiment. Therefore, the chemisorption mechanism proposed by Hirschler may be excluded under the reaction conditions of the present paper.

Our and others results do not seem to exclude the possibility of the chemisorption of diphenylmethane on strong protonic-acid sites. However, the interpretation seems to suffer from the defect that the chemisorption state can not be drawn easily. Further investigations will be necessary to solve this problem.

Monolayers of Copolymers of Methyl Acrylate and *n*-Butyl Acrylate and Mixed Monolayers of Thier Homopolymers

Seiichiro HIRONAKA,* Takashi KUBOTA, and Kenjiro MEGURO

Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received January 18, 1972)

Poly(methyl acrylate), poly(*n*-butyl acrylate), and their copolymers were prepared by radical polymerization. The monolayers of these polymers and the mixed polymers were studied at the air/water interface. The limiting areas obtained experimentally for various copolymers corresponded well to the theoretical values as calculated from the areas per methyl acrylate and butyl acrylate residues. However, those obtained for their corresponding polymer mixtures were larger than the theoretical limting areas.

Many studies of the relation in surface monolayers between several individual polymers and their mixtures have been reported. Crisp[1] established that the areas and the surface potentials of mixed monolayers of poly(vinyl acetate) and poly(vinyl alcohol) were linear averages of the individual pure monolayers. Ries and his co-workers reported their surface pressure-area measurements of mixtures of stearic acid with poly(vinyl acetate)[2] and poly(vinyl benzoate),[3] both of which acted as ideal surface mixtures. Wu and Huntsberger[4] studied the surface mixtures of polymethacrylate and poly(vinyl acetate) and indicated that most polymers are compatible in the monolayers at the air/water interface, although they are incompatible in the bulk. Isemura *et al.* studied various copolymers of vinyl acetate and vinyl stearate.[5]

However, there have been few studies of the relation of copolymers in surface monolayers and their corresponding polymer mixtures.[1] In the present work, we have investigated the relation between the monolayer properties of various copolymers of methyl acrylate and *n*-butyl acrylate and those of polymer mixtures whose monomer components are nearly the same as those of the copolymers. Then, the relation between the limiting area and the composition ratio of the copolymer and that of the corresponding polymer mixture will be dicussed.

Experimental

Sample Polymers. The methyl actylate and *n*-butyl acrylate were supplied by Toagosei Co., Ltd. The methyl acrylate was purified by reduced-pressure distillation (nitrogen atmosphere) after the removal of the inhibitor by washing it with a 5% sodium hydroxide aqueous solution and distilled water and by subsequent dehydration with silicon dioxide. The *n*-butyl acrylate was purified by reduced-pressure distillation (nitrogen atmosphere) after dehydration with silicon dioxide.

Poly(methyl acrylate), poly(*n*-butyl acrylate), and various copolymers of methyl acrylate and *n*-butyl acrylate were prepared by radical polymerization at 60°C under a nitrogen gas flow. α,α′-Azobisisobutyronitrile was used as the initiator, and benzene as the solvent. The products were purified by repeated precipitation from their acetone solutions into a large excess of methanol. The purified polymers were dried by the refrigeration method, and then the trace solvent was removed *in vacuo* at room temperature.

The average molecular weights of these polymers were

determined by viscosity measurements. Their average molecular weights were about 6.59, 2.35, 2.89, 3.08, and 2.95×10^5 for poly(methyl acrylate), copolymer A, copolymer B, copolymer C, and poly(*n*-butyl acrylate) respectively.

The composition ratios (mol%) of the copolymers were calculated by means of the following equation:

$$\frac{mX/100+b(100-X)/100}{MX/100+B(100-X)/100}\times 100 = C(\%) \qquad (1)$$

where X is the mole percentage of methyl acrylate in the copolymers; where M and B are the apparent molecular weights of a methyl acrylate and a butyl acrylate residue respectively; where m and b are the weights of carbon in a methyl acrylate and a butyl acrylate residue respectively; and where C (%) is the percentage of carbon as obtained by elemental analysis. Table 1 lists the results of elemental analyses and the composition rarios (mol%) of the three copolymers.

TABLE 1. THE ELEMENTAL ANALYSES AND THE COMPOSITION RATIOS OF COPOLYMERS

	Elemental analysis (%)		Composition ratio (mol%)	
	Carbon	Hydrogen	Methyl acrylate	*n*-Butyl acrylate
Poly (methyl acrylate)	55.84	6.86	100	—
Copolymer A	59.60	8.00	69.7	30.3
Copolymer B	61.00	8.12	56.3	43.7
Copolymer C	63.76	8.78	24.9	75.1
Poly (*n*-butyl acrylate)	65.63	9.14	—	100

Surface-pressure Measurements. A modified Wilhelmy-type film balance[6] was used to measure the surface pressure. The balance was enclosed in the chamber to allow thermostatic control at 20.0 ± 0.2°C. The water in the trough was kept at 20.0 ± 0.2°C by circulating the water from the thermostat bath. The distilled water used as the substrate had a pH of 5.0—6.0 at 20.0 ± 0.2°C. The polymer solutions (0.03 to 0.04 g polymer/100 m*l* benzene) were spread with an "Agla" microsyringe. Thirty minutes were allowed for the solvent to evaporate before compression was started. The rate of compression was 7.5 cm²/min. The surface pressure value was read after the film has first been allowed to reach equilibrium for 5 min. The surface-pressure measurements for all the polymers were repeated several times; the results were reproducible within the range of experimental error (±0.1 Å²/residue in area).

Results and Discussion

The surface pressure-area isotherms obtained for poly(methyl acrylate), poly(*n*-butyl acrylate), and various copolymers of methyl acrylate and *n*-butyl acrylate are shown in Fig. 1. The limiting areas of poly(methyl acrylate) and poly(*n*-butyl acrylate), as determined from the surface pressure-area isotherms shown in Fig. 1, were 21.6 and 29.5 Å²/residue respectively. These values correspond well to those determined by Crisp (21.5 and 29.3 Å²/residue)[7,8] and to our results.[9,10]

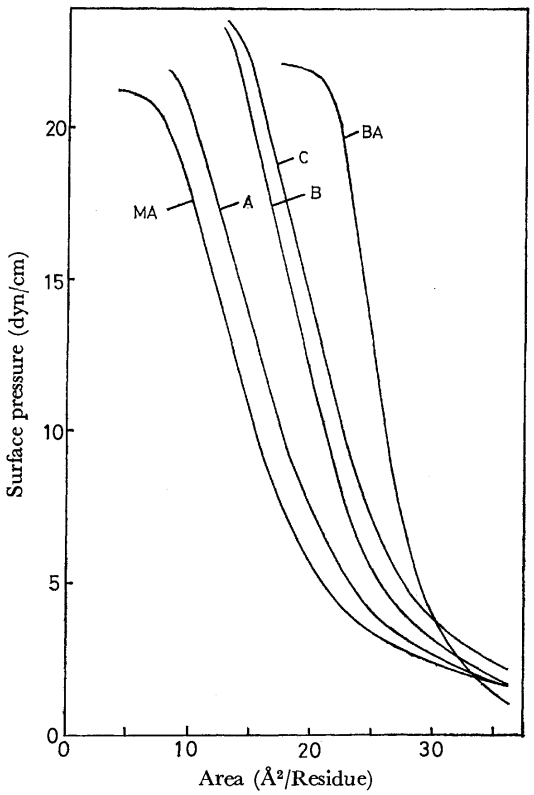

Fig. 1. The surface pressure-area isotherms of copolymers of methyl acrylate and *n*-butyl acrylate on distilled water. MA: poly (methyl acrylate), A: copolymer A, B: copolymer B, C: copolymer C, BA: poly(*n*-butyl acrylate).

With the use of the limiting areas (21.6 Å²/methyl acrylate residue and 29.5 Å²/butyl acrylate residue), the theoretical limiting area (A_t) of the copolymer, assuming the additivity rule between the limiting area and the composition ratio of each polymer component in the copolymer, was calculated by means of the following equation:

$$A_t = 21.6\frac{X}{100} + 29.5\frac{(100-X)}{100} \qquad (2)$$

where X is the mole percentage of methyl acrylate in the copolymer.

The experimental limiting areas of the copolymers and the theoretical limiting areas calculated by means of Eq. (2) *vs.* the composition ratios of methyl acrylate and *n*-butyl acrylate in the copolymers are shown in Fig. 2. It is found that the limiting areas obtained experimentally for various copolymers coincided well with the theoretical ones calculated by means of Eq. (2). The fact that the copolymers did not show such transition points in the surface pressure-area isotherms as were observed in the mixed monolayers suggests that copolymers are very slightly contaminated with traces of the homopolymer. Generally, the monolayers of copolymers do not behave as mixtures of the corresponding homopolymers would, and the introduction of a little comonomer often produces effects far out of proportion to its amount. Fig. 3. The surface pressure-area isotherms of mixtures of poly(methyl acrylate) and poly(*n*-butyl acrylate) on distilled water. MA: poly(methyl acrylate), A: mixture A, B: mixture B, C: mixture C, BA: poly(*n*-butyl acrylate).

et al. indicated this for the surface pressure-area isotherms of various copolymers of vinyl acetate and vinyl stearate.[5]

Figure 3 shows the surface pressure-area isotherms for mixtures of poly(methyl acrylate) and poly(*n*-butyl acrylate). The experimental limiting areas obtained for the mixed polymers were larger than those obtained for the copolymers with the same ratios of components and the theoretical ones calculated by Eq. (2). Figure 4 shows the experimental and the

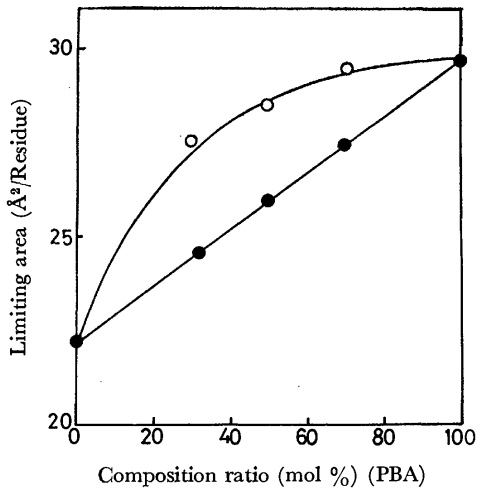

Fig. 4. The limiting areas of mixtures of poly(methyl acrylate) and poly(*n*-butyl acrylate) *vs.* the composition ratio by mixing. ○: experimental, ●: theoretical, PBA: poly(*n*-butyl acrylate).

theoretical limiting areas *vs.* the composition ratios of the mixed polymers. The experimental values deviated largely and positively from the theoretical limiting areas. When the deviation ratio was calculated by means of the following equation:

$$\text{Deviation ratio} = \frac{A_e - A_t}{A_t} \times 100 \qquad (3)$$

the values calculated for mixtures A, B, and C were 12.7, 10.4, and 6.9% respectively. A_e is the experimental limiting area and A_t is the theoretical limiting area, as calculated by Eq. (2). The mixture rich in poly(methyl acrylate) showed the largest positive deviation from the theoretical limiting area. These deviations can be explained by the assumption that the monolayer of poly(methyl acrylate) can expand more than that of poly(*n*-butyl acrylate).

The transition points were observed for the isotherms of each mixed polymer (in Fig. 3). The transition points obtained for mixtures A, B, and C were about 14, 18, and 19 dyn/cm respectively. These values were smaller than the collapse pressures of the individual pure monolayers (20.5 dyn/cm for poly(methyl acrylate) and 22.1 dyn/cm for poly(*n*-butyl acrylate)). The surface pressure at the transition increased with an increase in the amount of poly(*n*-butyl acrylate). Further, the reductions of area occurred after the transition point. The reduction of area after the transition point increased with the amount of poly(*n*-butyl acrylate) present in the mixed polymer. While the mixture rich in poly(*n*-butyl acrylate) had a high transition point and acted like that of poly(*n*-butyl acrylate) below the transition point, the mixture rich in poly(methyl acrylate) behaved at low surface pressures as poly(methyl acrylate) did. The behaviors of these mixed polymers may be affected by the composition. The mixture rich in poly(*n*-butyl acrylate) is mainly subject to poly(*n*-butyl acrylate) and gives the higher transition point, but it also produces the larger reduction of area because of the condensation of poly(*n*-butyl acrylate) at rela-

TABLE 2. THE COMPOSITIONS AND THE LIMITING AREAS OF THE COPOLYMERS AND THEIR CORRESPONDING MIXED POLYMERS

	Components of copolymer (mol%)		Limiting area (Å²/residue)		Deviation ratio (%)
	Methyl acrylate	*n*-Butyl acrylate	Experimental	Theoretical	
Poly(methyl acrylate)	100	—	21.6	21.5 (by Crisp)	
Copolymer A	69.7	30.3	25.0	24.4	2.5
Copolymer B	56.3	43.7	25.8	25.9	−0.4
Copolymer C	24.9	75.1	27.7	27.4	1.1
Poly(*n*-butyl acrylate)	—	100	29.5	29.3 (by Crisp)	
	Components of corresponding polymer mixture (mol%)				
	Poly(methyl acrylate)	Poly(*n*-butyl acrylate)			
Mixture A	69.9	30.1	27.5	(24.4)	12.7

Mixture C	29.4	70.6	29.3	(27.4)	6.9

tively high pressures.

Finally, the limiting areas of the copolymers were compared with those of mixed polymers in which the compositions were nearly the same as those of the corresponding copolymers. Table 2 shows the compositions and the limiting areas of the copolymers and their corresponding mixed polymers. The limiting areas of the mixed polymers deviated largely and positively from the theoretical limiting areas as calculated by Eq. (2), while those of the copolymers corresponded well to the theoretical ones. This difference suggests that poly(methyl acrylate) in the mixed polymer can expand more than the methyl acrylate component in the copolymer. The additivity holds good in copolymers, but the mixed polymers expand to give larger limiting areas than the theoretical ones.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3270—3276 (1972)

Studies of the Sodium Salts of Homologues of Alkyl Sulfates in Aqueous Solutions in Relation to the Water Structure

Harumi ENDO

Department of Applied Physics, Defense Academy, Yokosuka

(Received January 20, 1972)

The adiabatic compressibility (β) and the partial molar volume at an infinite dilution ($\bar{V}_0$) were obtained for aqueous solutions of the sodium alkylsulfates (SAS) of lower homologues. The sound velocity (U) and the density (ρ) were determined by the use of an ultrasonic interferometer and the float-balance method respectively. The results indicate that the slope at an infinite dilution $(d\beta/dC)_0$ of β *vs.* the concentration (C) diagram is in a linear relation with the carbon number (ϕ) of SAS. A similar relation was obtained between $\bar{V}_0$ and ϕ. We have derived these two relations by a statistical thermodynamical treatment based on the interstitial model of water, consisting of two species, one constituting the framework of an extended ice-1 structure with many cavities, and the other species, non-hydrogen-bonded water, occupying part of these cavities. The occupancy of the cavity with alkyl radical leads to a decrease in the structural compressibility, while the hydration of the ionic parts of the solute leads to a decrease in the compressibility due to the electrostriction. According to the calculations, the theoretical dependency of $(d\beta/dC)_0$ on ϕ is about three times larger than the experimental value. The theoretical dependency of $\bar{V}_0$ on ϕ is nearly in agreement with the experimental value, while the constant-addivite term is different.

It is known that sodium salts of sulfates of higher alkyl, such as *n*-tetradecyl, *n*-dodecyl, and *n*-octyl, are surface-active substances in aqueous solutions. The dissolved state and properties of these salts in an aqueous solution have been studied by various methods. The adiabatic compressibility is a very useful parameter in elucidating the dissolved state and properties of a solution. Shigehara[1-3] has studied the adiabatic com-

3) K. Shigehara, *ibid.*, **39**, 2643 (1966).

pressibility and density of these salts in aqueous solutions. He has found that the slope at an infinite dilution $(d\beta/dC)_0$ of the β *vs.* concentration (C) diagram is in a linear relation:

$$(-d\beta/dC)_0 = (0.776\phi+5.94) \times 10^{-12} \text{ (cm}^2\text{/dyn)/(mol/}l\text{)}$$

with the number of carbon atoms (ϕ) of alkyl chains. A similar relation, $\bar{V}_0=15.9\phi+46$ (cm^3/mol), is obtained between the partial molar volume at an infinite dilution ($\bar{V}_0$) and the number of carbon atoms (ϕ) of sodium alkylsulfate (SAS). He discussed the dissolved state and properties of SAS in aqueous solutions.

In this investigation, we investigated the SAS of lower alkyl homologues (methyl (SMS), ethyl (SES), and butyl (SBS)) in aqueous solutions by means of an ultrasonic interferometer, and found that the systematic dependences of $(d\beta/dC)_0$ and $\bar{V}_0$ are obtained also for lower homologues, the relations in this case being:

$$(-d\beta/dC)_0 = (0.68\phi+5.85) \times 10^{-12} \text{ (cm}^2\text{/dyn)/(mol/}l\text{)}$$

$$\bar{V}_0 = 16\phi + 53 \text{ (cm}^3\text{/mol)}$$

Also, we derived these two relations by a statistical thermodynamical treatment based on the interstitial model[4,5] of the water structure.

Experimental

Materials. The alkylsulfates used are SMS, SES, and SBS. They were prepared from their corresponding alcohols by reactions with chlorosulfonic acid and by further neutralization with sodium hydroxide, and were then purified with alcohol by means of recrystallization. Sodium hydrogen sulfate (SHS) was also used for the purpose of comparison. It was prepared by dissolving an equimolar amount of pure sulfuric acid and sodium sulfate in water, and was obtained as a precipitate.

Apparatus. The apparatus used for the measurement of the sound velocity was a differential ultrasonic interferometer of 1.432 MHz designed by Sasaki and Yasunaga,[6] with an accuracy of ± 3 cm/sec. The measurements were carried out in a thermostat at 30.000 ± 0.003°C. The density of the solution at 30.000°C, controlled to ± 0.001°C, was determined by the float-balance method. The accuracy of the measurements was $\pm 10^{-6}$ (g/cm^3).

The adiabatic compressibility of solutions was calculated from the sound velocity (U) and density (ρ) by the following relation:

$$\beta = 1/(\rho U^2).$$

Determination of Concentration. All the solutions used in the experiment were prepared at a constant temperature of 30°C. The volume of the liquid was measured by means of a measuring flask (250 cc) and a full transfer pipet previously maintained at 30°C. Distilled and degased water was used for the preparation of the solution and for further dilution. A known amount of the solute, measured by means of a chemical balance, was used to obtain a stock solution of 250 cc. When v_0 cc of the stock solution (density ρ_0) is added to v_w cc of water (density ρ_w), we obtain a diluted solution (density ρ) of the volume, V:

$$V = (v_0\rho_0+v_w\rho_w)/\rho.$$

Although V is nearly equal to v_0+v_w for the dilute solutions here investigated, we used the above-mentioned relation as the computed V value; the molarity of the concentration thus determined is better than 0.2%.

Results

Figure 1 shows the density difference ($\Delta\rho$) between the solution and solvent as a function of the concentration (C) for various solutes. The increment of the density difference is proportional to the concentration in all cases.

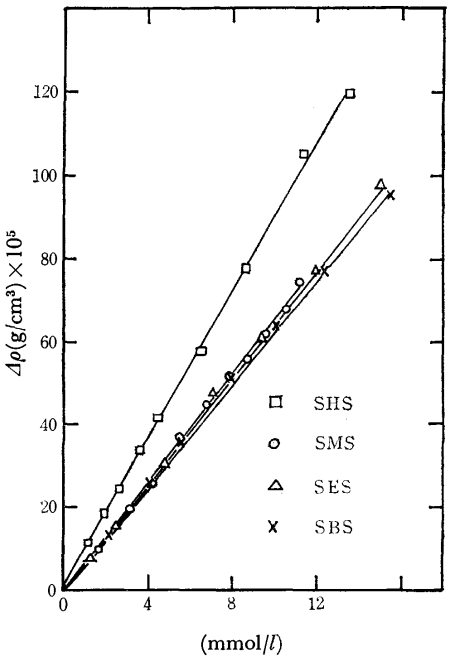

Fig. 1. The difference of density ($\Delta\rho$) between solution and solvent as function of concentration in aqueous solutions at 30°C.

Figure 2 shows the increments in the sound velocity (ΔU) against the concentration for aqueous solutions of SHS, SMS, SES, and SBS, where $\Delta U=U-U_0$ is the difference between the sound velocity for a solution and for the solvent respectively. The increment in sound velocity is proportional to the concentration, except for the case of SHS. The slope $(\partial\Delta U/\partial C)$ of the sound velocity-against-concentration curves increases with an increase in the molecular weight for SAS.

Figure 3 shows the difference in adiabatic compressibility $\Delta\beta(=\beta-\beta_0)$ between a solution and the solvent as a function of the concentration for various salts. Except for the SHS solution, $\Delta\beta$ is proportional to the concentration, the $(|\partial\Delta\beta/\partial C|)$ slope becoming larger with an increase in the molecular weight: -6.6, -7.1, and $-8.5\times(10^{-12})$ (cm^2/dyn)/(mol/l) for SMS, SES, and SBS respectively.

By plotting the value of $(-d\beta/dC)_0$ against the number of carbon atoms (ϕ) for SMS, SES, and SBS, we obtain a linear relation (solid line in Fig. 4). It can be represented by the following empirical relation:

4) O. Nomoto and H. Endo, *ibid.*, **44**, 1519 (1971).
5) A. H. Narten, M. D. Danford, and H. A. Levy, *Discuss. Faraday Soc.*, **43**, 97 (1967).
6) T. Sasaki and T. Yasunaga, *Kagaku to Kogyo*, **7**, 138 (1954).

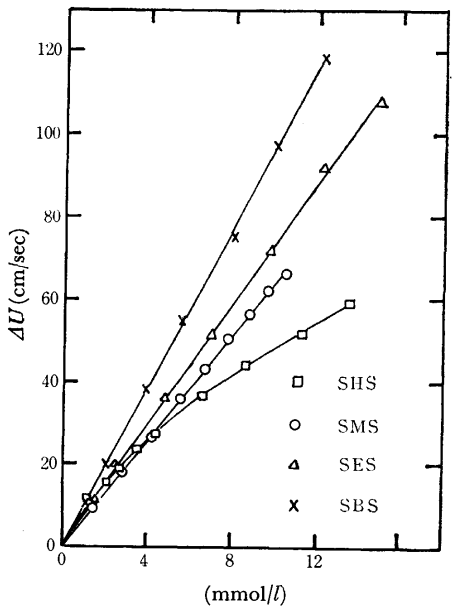

Fig. 2. The difference of sound velocity (ΔU) between solution and solvent as a function of concentration in aqueous solutions at 30°C.

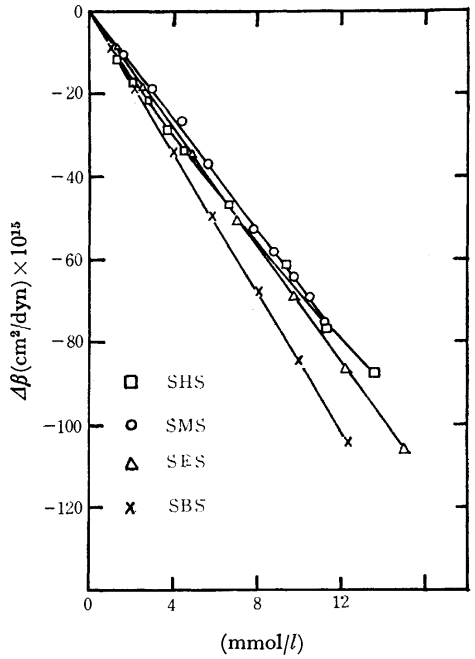

Fig. 3. The difference of adiabatic compressibility ($\Delta\beta$) between solution and solvent as a function of concentration in aqueous solutions at 30°C.

$$(-\mathrm{d}\beta/\mathrm{d}C)_0 = (0.68\phi + 5.85) \times 10^{-12}\ (\mathrm{cm^2/dyn})/(\mathrm{mol}/l) \quad (1)$$

It means that the contribution to $(-\mathrm{d}\beta/\mathrm{d}C)_0$ of each CH_2 (or CH_3) radical in the alkyl chain is constant, being 0.68×10^{-12} per unit of methylene (or methyl) radical. This may indicate that the effect of the destruction of the water structure with a CH_2 (or CH_3) radical, irrespective of the position in the molecule, is always the same.

The values of the partial molar volume ($\bar{V}_0$) at an infinite dilution of the sulfate, obtained from the density of the solution, are plotted as a solid line in Fig. 5.

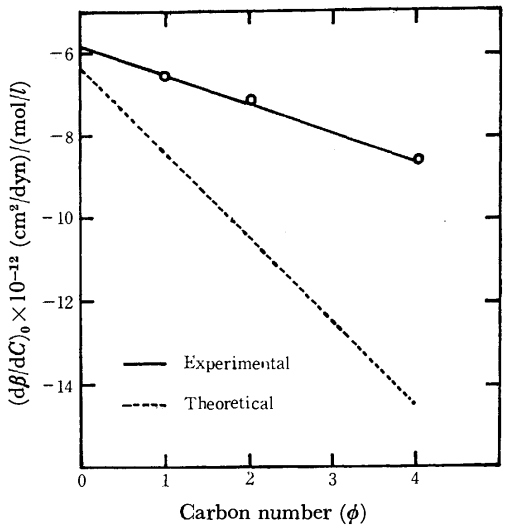

Fig. 4. The slope at infinite dilution $(\mathrm{d}\beta/\mathrm{d}C)_0$ of β against concentration (C) *vs.* carbon number (ϕ) of SAS.

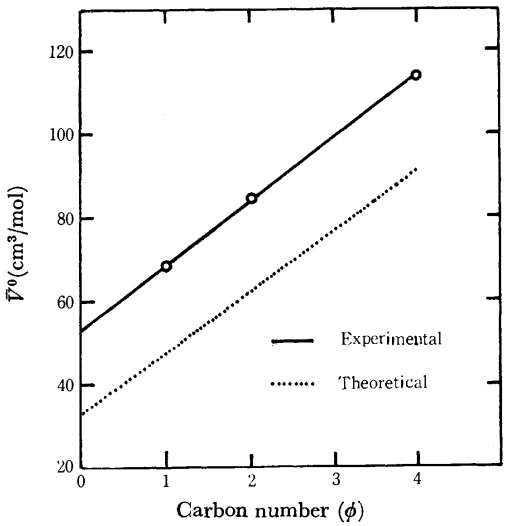

Fig. 5. The partial molar volume at intinite dilution $(\bar{V})_0$ *vs.* carbon number of SAS.

The relation between the partial molar volume and the carbon number in the alkyl chain is also linear and is expressed by the following equation:

$$\bar{V}_0 = 16\phi + 53\ (\mathrm{cm^3/mol}) \quad (2)$$

Theoretical

From their X-ray diffraction studies of liquid water, Narten *et al.*[5] proposed an interstitial model of liquid water, a kind of mixture model. This model consists of two species of water molecules, one constituting the framework of an extended ice-I structure with many cavities, and the other species, non-hydrogen-bonded water, occupying part of these cavities.

Acoustic pressure in water accompanies two sorts of compression: a) the compression of the intermolecular distance, and b) the breakdown of the intermolecular bonds, accompanied by the destruction of the open structure. The former is represented by the instantaneous compressibility, β_∞, while the latter is

the origin of the structural compressibility, β_{st}.

In the case of an aqueous solution, we may expect some changes in the adiabatic compressibility corresponding to changes in water structure under the influence of the solutes. In estimating these changes, we make the following assumptions:

(I) We treat the partial molar volume and the partial molar compressibility extrapolated to "infinite dilution," so that the solute-solvent interaction alone needs to be considered.

(II) When SAS is dissolved in water, we have alkylsulfate anions and sodium cations, almost entirely dissociated. In estimating the influence of the alkylsulfate anion on the partial molar volume and the adiabatic compressibility, we postulate the effect to be composed of two parts, one due to the alkyl chain, $C_\phi H_{2\phi+1}$, and the other, due to OSO_3^-. This is presumably admissible, at least for an infinite dilution.

(III) As regards the effect of the ionic parts (OSO_3^- and Na^+ ions) on $(d\beta/dC)_0$ and $\bar{V}_0$, we use empirical quantities in place of making theoretical treatments. The hydration of the ionic parts of the solute results in a decrease in the volume and compressibility due to the destruction of the water structure by the electrostriction.

(IV) The framework water makes cavities which are large enough to accommodate moderate-sized molecules and various radicals (*cf.* Narten *et al.*,[5,7,8] *etc.*[9-12]); therefore, the solute occupies sites in it as in a quasiclathrate. Since the alkyl chain of the anion is considered to be easily located in the cavity, the carbon-water interaction is very weak, and we assume the framework structure of ice-I not to be deformed or dilated by the occupation of alkyl radicals.

(V) The occupancy of the cavity by a methyl, ethyl, or butyl radical leads to a decease in the structural compressibility, this decrease becoming larger with an increase in the carbon number. When the ethylene radicals successively occupy the cavities, we do not take the C–C bond angle of the alkyl radical into consideration in order to avoid complicated calculations.

(VI) Both the alkyl chain in the cavity sites and the water molecules in the cavity sites have no effective volume. This means that the dimentions of the framework remain the same, whether the cavity is vacant or not. Therefore, the volume of the solution is assumed to be proportional to the number of framework sites.[9] When the cavities are crushed by acoustic pressure, the cavity occupied by the alkyl radical or water molecules leads to a smaller decrease in the cavity volume than does the unoccupied one.

(VII) Each methylene (or methyl) radical occupies one cavity.

(VIII) It is known that the heat of dissolution[13-17] in water of the alkyl homologues series is nearly of a constant increment for each CH_2 group of the alkyl chain. Such a relation may be applicable for SAS. Also, in the SAS aqueous solution, there is a linear relation[18] between ΔC_p (the change in heat capacity at a constant pressure) and the carbon number in SAS molecules.

In considering the molar free energy (G_H) of SAS in an aqueous solution, it is convenient to define the hypothetical state including the term of enthalpy change due to the water-solute interaction at an infinite dilution as the standard state of the Gibbs free energy (G^0_H) of SAS in water. This is the free energy for the hypothetical state in which SAS is imbedded in the cavity at the state of infinite dilution in water, but of the unit mole fraction. Therefore, G^0_H is the standard molar free energy of SAS in the quasiclathrate solution. When the solute (the part of hydrocarbon) is allowed to occupy the cavities to form a quasiclathrate solution, it becomes a "regular solution," *i.e.*, with an ideal entropy of mixing. Accordingly, we can discuss this system by means of the entropy term alone. Also, Frank and Franks[19] have made their treatments of the water-urea-hydrocarbon system based on the entropy terms only.

Now we will derive Eqs. (1) and (2) on the basis of the above assumptions. Let us consider one mole of water containing N molecules (N=Avogadro's number), of which the w fraction is in the network position, while the $(1-w)$ fraction is the non-hydrogen-bonded water situated in the cavities. If z is the number of cavity sites per network site, then the number of total cavity sites becomes Nwz. If f_2 is the occupancy of cavity sites by water molecules, we have:

$$f_2 = \frac{(1-w)}{wz} \tag{3}$$

Here we assume that the cavity sites are independent of each other, whether occupied or not, and, further, that all the sites are occupied with equal probability by non-hydrogen-bonded water. The number of ways in which the non-hydrogen-bonded water can be distributed among the sites are:

$$\Omega_1 = \frac{Nwz!}{(f_2 Nwz)!\{(1-f_2)Nwz\}!} \tag{4}$$

Next we have to distribute the alkyl chain $C_\phi H_{2\phi+1}$ in the remaining cavities. Here, ϕ is the number of carbon atoms constituting the alkyl chain. We will denote the total number of solute molecules by N_H. Then, the ratio of the number of solute molecules to the number of cavity sites is:

$$f_H = \frac{N_H}{Nwz} \tag{5}$$

According to our seventh assumption, each CH_2 (or CH_3) of the alkyl chain occupies one cavity site. Therefore, the number of ways of occupation is diffrent according to the length of the chain.

First, we will consider the case of the methyl radical, *i.e.*, $\phi=1$. In this case, the number of states is:

$$\Omega_{CH_3} = \frac{\{(1-f_2)Nwz\}!}{(f_H Nwz)!\{(1-f_2-f_H)Nwz\}!} \tag{6}$$

In the case of the ethyl radical ($\phi=2$), the CH_2-adjacent to CH_3 must, naturally, occupy the neighboring cavity site. Therefoe, we have, as the number of ways to distribute the second carbon atom (CH_2) in the remaining cavities:

$$\{(\zeta-1)(1-f_2-2f_H)\}^{f_H Nwz} \tag{7}$$

Here, ζ is the cavity-site-nearest-neighbors and $(1-f_2-2f_H)$ is the probability that this is vacant. Similarly, we have, as the number of states for distributing the 3rd carbon atom (CH_2) of the propyl radical:

$$\{(\zeta-1)(1-f_2-3f_H)\}^{f_H Nwz} \tag{8}$$

and as the number of states for distributing the ϕth carbon atom (CH_2) of the $C_\phi H_{2\phi+1}$ radical:

$$\{(\zeta-1)(1-f_2-\phi f_H)\}^{f_H Nwz} \tag{9}$$

Thus, the number of all possible configurations of the alkyl chain in the cavity sites becomes:

$$\Omega_2 = \frac{\{(1-f_2)Nwz\}!}{(f_H Nwz)!\{(1-f_2-f_H)Nwz\}!}[\{(\zeta-1)(1-f_2-2f_H)\}\{(\zeta-1)(1-f_2-3f_H)\}\cdots\{(\zeta-1)(1-f_2-\phi f_H)\}]^{f_H Nwz} \tag{10}$$

The total number of possible configurations for the system containing N_H solute molecules (of $C_\phi H_{2\phi+1}$) and N water molecules, of which the f_2 fraction is in the cavity, is given by $\Omega=\Omega_1\cdot\Omega_2$ or by:

$$\Omega = \frac{(Nwz)!}{(f_2 Nwz)!(f_H Nwz)!\{(1-f_2-f_H)Nwz\}!} \times[\{(\zeta-1)(1-f_2-2f_H)\}\{(\zeta-1)(1-f_2-3f_H)\}\cdots\{(\zeta-1)(1-f_2-\phi f_H)\}]^{f_H Nwz} \tag{11}$$

By employing the approximations of Stirling's formula: $N!\cong\sqrt{2\pi N}\ (N/e)^N\cong(N/e)^N$ and the Boltzmann relationship $S^M=k\ \ln\Omega$. We obtain S^M the entropy of mixing per mole of water. Here $k=\boldsymbol{R}/N$ is the Boltzman constant, and $\boldsymbol{R}$ is the universal gas constant.

$$S^M = \boldsymbol{R}wz[-f_2\ln f_2 - f_H\ln f_H - (1-f_2-f_H)\ln(1-f_2-f_H) + f_H\{(\phi-1)\ln(\zeta-1) + \ln(1-f_2-2f_H) + \ln(1-f_2-3f_H) + \cdots + \ln(1-f_2-\phi f_H)\}] \tag{12}$$

Therefore, we obtain as the molar Gibbs free energy (G):

$$G = wG_N^0 + (1-w)G_I^0 + mG_H^0 - TS^M \tag{13}$$

or:

$$G = G_I^0 + w\Delta G_I^0 + mG_H^0 - TS^M \tag{14}$$

Here, G_N^0, G_I^0, and G_H^0 are the hypothetical standard molar free energies of network molecules, cavity molecules, and SAS molecules respectively. $\Delta G_I^0=G_N^0-G_I^0$, and T and m are the absolute temperature and the N_H/N mole ratio. By differentiating Eq. (14) with respect to w and setting $(\partial G/\partial w)_{P,T,m}=0$, we obtain:

$$\Delta G_I^0 = T\frac{dS^M}{dw} \tag{15}$$

while from Eq. (12) we get:

$$\frac{dS^M}{dw} = \boldsymbol{R}\Big[\ln f_2 - (1+z)\ln(1-f_2-f_H) + \frac{m}{w^2 z}\Big\{\frac{1}{(1-f_2-2f_H)} + \frac{1}{(1-f_2-3f_H)} + \cdots + \frac{1}{(1-f_2-\phi f_H)}\Big\} + \frac{m^2}{w^2 z}\Big\{\frac{2}{(1-f_2-2f_H)} + \frac{3}{(1-f_2-3f_H)} + \cdots + \frac{\phi}{(1-f_2-\phi f_H)}\Big\}\Big] \tag{16}$$

By substituting Eq. (16) into Eq. (15) and by assuming $f_H\ll1$, we obtain approximately:

$$\Delta G_I^0 = \boldsymbol{R}T\Big[\ln f_2 - (1+z)\ln(1-f_2) + \frac{m(1+z)}{wz(1-f_2-f_H)} + \frac{m(\phi-1)}{w^2 z(1-f_2-\phi f_H/2)} + \frac{m^2(\phi-1)(\phi+2)}{2w^2 z(1-f_2-\phi f_H/2)}\Big] \tag{17}$$

Now, we can use the relation $(\partial\Delta G_I^0/\partial p)=V_{fr}-V_I$ to obtain $(\partial w/\partial p)$ from Eq. (17). Here, V_{fr} and V_I mean the molar volumes of the framework water and the cavity water respectively, and we obtain $V_I=0$ using the sixth assumption. Therefore, we obtain from Eq. (17), by differentiating both sides with respect to pressure (p), and after rearrangements the following relation:

$$-\frac{1}{(\partial w/\partial p)} = \frac{\boldsymbol{R}T}{V_{fr}}\Big[\frac{1}{w(1-w)} + \frac{z+1}{w\{w(z+1)-1\}} + \frac{m(m+1)(z+1)}{w^3 z^2(1-f_2-f_H)^2} + \frac{m(z+1)}{w^2 z(1-f_2-f_H)} + \frac{2m(\phi-1)(m\phi+2)}{w^4 z^2(2-2f_2-\phi f_H)^2} + \frac{4m(\phi-1)}{w^3 z(2-2f_2-\phi f_H)} + \frac{m^2(\phi-1)(\phi+2)(m\phi+2)}{w^4 z^2(2-2f_2-\phi f_H)^2} + \frac{2m^2(\phi-1)(\phi+2)}{w^3 z(2-2f_2-\phi f_H)}\Big] \tag{18}$$

From the sixth assumption, the molar volume of the solution, V, is given by the following relation:

$$V = wV_{fr} + mV_{ion}, \tag{19}$$

since the interstitial alkyl chain radical has no effective volume. Therefore, the effective volume of the solution consists of two parts, one the volume of framework water and the other, the molar volume of the ionic parts.

The adiabatic compressibility is thermodynamically given by the following equation: $\beta=-1/V\cdot(\partial V/\partial p)_s$. When we treat the compressibility of aqueous solutions at low concentrations, we assume that the adiabatic compressibility of solutions is nearly equal to the isothermal one, since the ratio of specific heat in water is nearly 1. Therefore, we calculate the compressibility of solutions at the isothermal condition. As the ionic parts have no structural compressibility, we have from Eq. (19) $\beta_{st}=V_{fr}/V\cdot(-\partial w/\partial p)$, where $(-\partial w/\partial p)$ and V are given by Eqs. (18) and (19)

respectively. Here, the constant terms of derivatives are omitted for the simplicity of description. We write Eq. (19) as $-1/(\partial w/\partial p)=(\boldsymbol{RT}/V_{fr})\cdot A$; therefore, we have:

$$\beta_{st}=\frac{V_{fr}}{V}\cdot\left(-\frac{\partial w}{\partial p}\right)=\frac{(V_{fr})^2}{\boldsymbol{RT}}\cdot\frac{1}{VA} \tag{20}$$

We intend to calculate the dependency of β_{st} on the mole ratio, m. We obtain from Eq. (20), by taking logarithm $\log\beta_{st}=\log\{(V_{fr})^2/\boldsymbol{RT}\}-\log V-\log A$:

$$\frac{1}{\beta_{st}}\cdot\frac{d\beta_{st}}{dm}=-\left\{\frac{1}{V}\frac{dV}{dm}+\frac{1}{A}\frac{dA}{dm}\right\} \tag{21}$$

Here, the first term in the parentheses from Eq. (19) as:

$$\frac{1}{V}\left(\frac{dV}{dm}\right)=\frac{V_{fr}}{V}\cdot\left(\frac{dw}{dm}\right)+\frac{\bar{V}_{ion}}{V} \tag{22}$$

By employing Eq. (17), we obtaine (dw/dm) from the equilibrium conditions at the concentration m:

$$(d\Delta G_I^0/dm)=(\partial\Delta G_I^0/\partial w)(dw/dm)+(\partial\Delta G_I^0/\partial m)=0$$

Now, (dw/dm) becomes, at the limit of low concentrations, $\lim_{m\to0}(dw/dm)=(dw/dm)_0$, and, after some calculations, we attain the result:

$$\left(\frac{dw}{dm}\right)_0=\frac{(1-w_0)}{z}\{\phi+w_0(z+1)-1\} \tag{23}$$

where w_0 is the value of w for pure water. Therefore, we obtain from Eqs. (22) and (23) the relation:

$$\frac{1}{V_0}\cdot\left(\frac{dV}{dm}\right)_0=\frac{(1-w_0)}{w_0z}\{\phi+w_0(z+1)-1\}+\frac{(\bar{V}_{ion})_0}{V_0} \tag{24}$$

where $V_0(=w_0V_{fr})$ and $(\bar{V}_{ion})_0$ mean the molar volume of pure water and the molar volume at an infinite dilution of the ionic parts of SAS. The second term in parentheses in Eq. (21) becomes, at the limit of low concentrations:

$$\lim_{m\to0}\left(\frac{1}{A}\frac{dA}{dm}\right)=\frac{1}{A_0}\left(\frac{\partial A}{\partial w}\frac{dw}{dm}+\frac{\partial A}{\partial m}\right)_{m=0}$$

where:

$$A_0=\frac{z}{w_0(1-w_0)\{w_0(z_0+1)-1\}},$$

$$\left(\frac{\partial A}{\partial w}\right)_0=\frac{2w_0-1}{\{w_0(1-w_0)\}^2}-\frac{(z+1)\{2w_0(z+1)-1\}}{[w_0\{w_0(z+1)-1\}]^2},$$

and:

$$\left(\frac{\partial A}{\partial m}\right)_0=\frac{z+1}{w_0\{w_0(z+1)-1\}}+\frac{z+1}{w_0^2z\{w_0(z+1)-1\}}+\frac{(\phi-1)}{[w_0\{w_0(z+1)\}]^2}+\frac{2(\phi-1)}{w_0^2\{w_0(z+1)-1\}}.$$

After some computation, we finally obtain the relaton:

$$\left(-\frac{d\beta_{st}}{dm}\right)_0=\beta_{st}^0\left[\frac{3(1-w_0)}{w_0z}+\frac{(2w_0-1)\{w_0(z+1)-1\}}{w_0z^2}-\frac{(z+1)(1-w_0)^2\{2w_0(z+1)-1\}}{w_0z^2\{w_0(z+1)-1\}}+\frac{(1-w_0)}{w_0z\{w_0(z+1)-1\}}\right]\phi+\frac{(2w_0-1)\{w_0(z+1)-1\}^2}{w_0z^2}-\frac{(z+1)(1-w_0)^2\{2w_0(z+1)-1\}}{w_0z}+\frac{(1-z)(1-w_0)}{w_0z}+\frac{(1+z)(1-w_0)}{z}-\frac{(1-w_0)}{w_0z\{w_0(z+1)-1\}}+\frac{(1-w_0)\{w_0(z+1)-1\}}{w_0z}+\frac{(\bar{V}_{ion})_0}{V_0} \tag{25}$$

where $\beta^0{}_{st}$ is the structural compressibility of pure water. Using the concentration of C mol/l in place of the mole ratio, m, we obtain $(d\beta_{st}/dC)_0=(1/55.5)\,(d\beta_{st}/dm)_0$. Then we can obtain the theoretical relationship for the concentration dependence of the compressibility (extrapolated to infinite dilution) $(-d\beta/dC)_0$ in SAS solutions:

$$(d\beta/dC)_0=(d\beta_{st}/dC)_0+(\Delta\beta_{ion})_0 \tag{26}$$

where $(\Delta\beta_{ion})_0$ is the decrease in the compressibility due to the ionic parts of SAS at an infinite dilution.

On the other hand, the partial molar volume at an infinite dilution being thermodynamically defined as $\bar{V}_0=\lim_{m\to0}\left(\frac{\partial V}{\partial m}\right)_N$ we get from Eq. (19):

$$\bar{V}_0=V_{fr}\left(\frac{dw}{dm}\right)_0+(\bar{V}_{ion})_0 \tag{27}$$

or, by substituting Eq. (23):

$$\bar{V}_0=\frac{V_{fr}(1-w_0)}{z}\cdot\phi+\frac{V_{fr}(1-w_0)\{w_0(z+1)-1\}}{z}+(\bar{V}_{ion})_0 \tag{28}$$

Numerical Computation

We[4] have previously obtained w_0 and z as functions of the temperature using the data[5] of Narten *et al.*; it has been shown that w_0 and z, at 30°C, are 0.808 and 0.295 respectively. The structural compressibility of pure water, β_{st}^0 is 26.7×10^{-12} cm^2/dyn[20] at 30°C.

Generally, the hydration number of ions depends on the methods[21,22] used. The hydration numbers for SO_4^{2-}, as obtained by various methods, range from 4 to 16,[21-23] and those of Na,$^+$ from 1 to 71.[22,23] Here we used the values obtained by the ultrasonic method,[23] *i.e.*, 16 for SO_4^{2-} and 4.7 for Na,$^+$ and assumed the hydration number for the OSO_3^- ion to be 3/4 the value(=12) for SO_4^{2-}. Then, the hydration number for OSO_3^- and Na^+ amounts to 16.7. The decrease in compressibility $(\Delta\beta_{ion})_0$ due to ionic parts becomes -13.4×10^{-12} (cm^2/dyn)/(mol/l). Then, we obtain the theoretical relationship for the concentration dependence of the compressibility (extrapolated to an infinite dilution) $(-d\beta/dC)_0$ as a function of the carbon number, ϕ, of the alkyl group in SAS solutions:

$$(-d\beta/dC)_0=(2.02\phi+6.45)\times10^{-12}\ (\text{cm}^2/\text{dyn})/(\text{mol}/l) \tag{29}$$

The dotted line in Fig. 4 shows this relation.

Now let us consider the partial molar volume. We assume the partial molar volume of $HOSO_3Na$ to be equal to 32.0 cm^3/mol at moderate concentrations,

where the solution is considered to contain $HOSO_3^-$ and Na^+ ions. Here, we assume the $(\bar{V}_{ion})_0$ of SAS to be equal to the partial molar volume of SHS. On this assumption, we obtain, as the theoretical relationship between the carbon number, ϕ, in SAS and the partial molar volume at an infinite dilution ($\bar{V}_0$), the following equation:

$$\bar{V}_0 = 14.6\phi + 32.7 \text{ (cm}^3\text{/mol)} \quad (30)$$

The dotted line in Fig. 5 shows this relation.

Disscussion

According to the interstitial model, we can explain the linear chage in the sound velocity and compressibility *vs.* the concentration for the systems of SMS, SES, and SBS. The marked deviation from linearity of these quantities in the SHS solution (*cf.* Figs. 2 and 3) is attributable to the dissociation[24] of the HSO_4^- into H^+ and SO_4^{2-} at low concentrations. At moderate concentrations, SHS behaves as a uni-divalent electrolyte because of its dissociation into $Na,^+$ $H,^+$ and SO_4^{2-}. The $(d\beta/dC)$ in the SHS solution slowly decreases untill the limiting value of about -5.9×10^{-12} $(cm^2/dyn)/(mol/l)$ is reached at *ca.* 15 mmol/*l*; it is considered to act as a uni-univalent electrolyte composed of HSO_4^- and $Na.^+$

The linear dependence of $(d\beta/dC)_0$ on the carbon number ϕ in the alkyl chain can also be explained. The approximate agreement between the constant terms in Eqs. (1) and (29) may indicate that our assumption regarding the hydration number of the ionic parts (OSO_3^- and Na^+) is rather adequate.

The slope of the $(d\beta/dC)_0$ *vs.* ϕ curve, however, indicates that the theoretical dependency on the carbon number is about three times larger than the experimental value. In the theoretical calculation, we used the seventh assumption, that a cavity may be occupied by only one methylene (or methyl) radical. The experimental results may be explained by allowing one cavity to be occupied by up to three radicals. The length of the hydrogen bond in water is 2.76[25]—2.88[5] Å, the diamater of the hexagonal cavity is about 6 Å, and the cavity is wide enough to accommodate up to three methylene radicals, since the length of the C-C bond is about 1.5[26] Å.

As regards the relationship between $\bar{V}_0$ and ϕ, on the other hand, the theoretical dependency on the carbon number is nearly in agreement with the experimental value, while the constant term is different. Also, from the studies of $\bar{V}_0$[27] for the homologue series of alkylamine hydrogen halides and tetraalkylammonium salts, it has been reported that the increment per CH_3 (or CH_2) radical added to the homologue series is $\bar{V}_0$=*ca.* 16.7 m*l*/mol, a value which is nearly in agreement with the present results per carbon atom.

The modification of the theory to admit up to three methylene groups may decrease the slope of the $\bar{V}_0-\phi$ curves. This results that the slope deviates from the experimental results, although the avarage value of $\bar{V}_0$ may approach the experimental value.

An interstitial-solute model similar to that employed here has also been proposed by Glew[28] on the basis of studies of hydrates. Evidence of the occupation of the cavity by the solute is also given by the kinetic study in the solvolysis of *t*-butyl chloride in an alcohol-water system.[29] More direct evidence is afforded by the X-ray diffraction study of aqueous solutions.[7,8]

The author wishes to thank Professor T. Sasaki of Tokyo Metropolitan University for his helpful discussions about and generous support of this research, and also Professor O. Nomoto of the Defense Academy for his valuable suggestions and discussions.

Bond Alternation in Tropone as Studied by Gas Electron Diffraction[1)]

Makoto OGASAWARA,* Takao IIJIMA, and Masao KIMURA**
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received February 18, 1972)

Assuming a planar conformation with C_{2v} symmetry, and using the estimated mean amplitudes of vibration, the bond alternation in tropone was confirmed. The average C–C and C=C distances were determined by the least-squares method to be 1.454 ± 0.010 and 1.362 ± 0.013 Å respectively; moreover, two probable sets of the structure parameters were obtained. On the basis of conformational arguments regarding the structures of related compounds, the following set of the bond lengths was preferred: C–H, $1.09_8\pm0.01_6$ Å; C_1–O, $1.22_5\pm0.01_2$ Å; C_1–C_2, $1.44_5\pm0.01_2$ Å; C_2–C_3, $1.36_4\pm0.01_2$ Å; C_3–C_4, $1.46_2\pm0.01_2$ Å; and C_4–C_5, $1.34_2\pm0.01_8$ Å.

Since the geometrical configurations of nonbenzenoid aromatic seven-membered ring compounds have been the subject of much interest in conjunction with their aromaticity, a number of X-ray structure analyses have been undertaken regarding tropone derivatives,[2)] tropolone[3)] and its derivatives,[4)] dicyanoheptafulvene[5)] and its derivatives,[6)] and many other related compounds. From the results of these studies, it may be said that the planarity[7)] and bond alternation of the seven-membered rings of compounds, commonly classified as nonbenzenoid aromatics, have been established. As a natural consequence, tropone itself can also be expected to have a planar configuration with alternating bond lengths. This is in accordance with the theoretical consideration that the aromaticity of tropone originates from a significant contribution of a polar structure to the ground state.[8)] Indirect but fairly conclusive experimental evidence for bond alternation was provided, for example, by the presence of the infrared bands assigned to the stretching vibrations of the C–C and C=C bonds.[9,10)] In a previous electron diffraction study, one of the present authors and his coworkers were unable to draw a definite conclusion as to the bond alternation, instead, a regular heptagonal model was assumed.[11)]

Many molecular orbital calculations were carried out[8,12–15)] in order to interpret the ultraviolet absorption spectrum[8,12,16)] and the dipole moment.[17,18)] There still exist two alternative interpretations of the characteristic absorption bands of tropone; one was presented by Hosoya *et al.*[8a)] and the other, by Weltin *et al.*[12)] Because of a lack of accurate structural data, in most of the calculations the bond lengths were assumed at either the values determined by the previous electron-diffraction study or at those estimated from the observed bond lengths for olefins. Hosoya and Nagakura[8b)] and Kunii and Kuroda[15)] estimated the bond lengths on the basis of the resulting bond orders, but they had no experimental data by which to check their results. The former authors then remarked in their paper that a more precise determination of the lengths would provide an effective clue to settle the problem.[8b)] Since it was expected that the current technique of electron diffraction by gases would yield more accurate bond lengths, we decided to reinvestigate this molecule.

After initiating this reinvestigation, we noticed that Bertelli and Andrews, Jr.,[19)] had analysed the dipole

7) The planarity of the seven-membered rings is not unexceptional. If the 2 and/or 7 positions of a ring (Fig. 3) are substituted by atoms or groups bulkier than the hydrogen atom, the ring may deviate from a plane and take a boat form by steric interactions between the carbonyl oxygen and the substituents.[2e,4e,6a,6b)]

moments and NMR spectra of tropone and analogous compounds by the aid of CNDO/2 molecular-orbital calculations for two assumed models, a regular heptagonal ring and a planar ring built from bond lengths suitable for olefins.[20] As a result, they were led to the conclusion that the dipole moment and NMR data are consistent with the planar ring with alternating bond lengths. Furthermore, through several critical discussions of its aromaticity, they stated that tropone resembled a polyenone more closely than an aromatic system and could be best classified as the former. If accurate bond lengths can be determined, they will provide useful information for discussions along this line.

In carrying out the present study, our attention was directed mainly to obtaining experimental evidence for bond alternation and, if possible, bond lengths useful for discussing the properties of tropone. Making some plausible assumptions regarding the molecular symmetry and the parameter values, which are necessary to analyze the diffraction patterns of relatively complex molecules, we obtained two probable sets of structural parameters. Unfortunately, a unique result could not be obtained from the electron diffraction data alone. However, the bond alternation in tropone has unquestionably been verified.

Experimental

The sample of tropone was kindly provided by Professor Yoshio Kitahara of Tohoku University and was used without further purification. The diffraction photographs were taken with an apparatus equipped with an r^3-sector at the camera length of 124.47 mm.[21] The sample vapor was injected into the diffraction chamber by means of a high-temperature nozzle maintained at 108°C. The exposure time was 8 min, with a beam current of 0.15 μA. The wavelength of the beam (an accelerating voltage of about 52.9 kV) was determined by the use of the pattern of carbon disulfide.[22] Three plates were selected from among several plates and were microphotometered.

Data Processing and Structure Determination

The molecular intensity, $qM(q)$, was obtained from the observed total intensities[23] by determining the experimental background by means of the radial distribution curve and its Fourier inverse transformation. In the calculations of the radial distribution curves, the correction factors for non-nuclear scattering were introduced by Bonham and Bartell's method.[24] The other details of data processing have been described elsewhere.[25]

The determination of the molecular parameters was carried out by the least-squares method based upon the molecular intensity.[26] According to our conventional weighting scheme, the data were weighted down from $q=30$ to 21 and from $q=100$ to 130 in order to reduce the influence of uncertainties in the experimental molecular intensities at both small and large scattering angles. In general, accurate determination of interatomic distances are practically impossible for atom pairs which make relatively small contributions to the molecular intensity. Besides, the skeletal heptagonal ring of tropone consists of bonds which are only slightly different in length from one another. In such a case, the mean amplitudes and the differences between the bond lengths are strongly correlated if one wishes to determine all of them from the diffraction pattern by the least-squares method. After various preliminary least-squares treatments, it was found best for our present purpose to use reliable estimates of the mean amplitudes in order to fix some of the strongly correlated parameters and to determine the bond lengths more precisely. The following assumptions were made with respect to the geometrical configuration and mean amplitudes:

(1) Configuration. The molecule has a planar configuration, with C_{2v} symmetry. All the C–H bonds have the same length, and each of them bisects the CCC valence angle. The molecular configuration is, then, defined by the eight interatomic distances, the bonded C–H, C_1–O, C_1–C_2, C_2–C_3, C_3–C_4, C_4–C_5 and non-bonded $C_1\cdots C_3$, $C_1\cdots C_4$ distances (see Fig. 3).

(2) Mean Amplitudes. The mean amplitude used were estimated from the spectroscopic data in the following way. By assuming an appropriate molecular configuration, the Urey-Bradley force constants were determined from the vibrational frequencies observed by Ikegami.[9] The mean amplitudes were then calculated at 373°K, the approximate temperature of the nozzle when the diffraction experiments were carried out. The calculation was limited to in-plane vibrations. The calculated mean amplitudes for the ring and the force constants are shown in Tables 1 and 2 respectively.

Table 1. Mean amplitudes used for the analyses (at $T=373$°K)

Table 2. Adjusted values of the force constants for tropone (in mdyn/Å)

Bond	K	Angle	H	F
C=O	7.5	OCC	0.32	0.80
C_1–C_2	4.2	CCC[a)]	0.33	0.37
C_2=C_3	6.0	HCC[a)]	0.20	0.48
C_3–C_4	4.2			
C_4=C_5	6.6			
C–H	4.56			

a) The same values were assumed for all CCC and for all HCC force constants.

(3) Asymmetry Constants. The asymmetry constants were fixed at values of 30×10^{-7} and 127×10^{-7} Å^3 for the bonded distacnes in the skeleton and the C–H bond respectively, and were ignored for the non-bonded distances.[27)]

In practical refinements, a strictly constrained least-squares method was not used; rather, unadjusted parameters at each step of calculation were fixed at values evaluated from the r_a distances obtained just before the step, without taking the shrinkage effect into account.[28)]

The observed molecular intensities thus obtained for one arbitrarily selected plate are shown by dots in Fig. 1, while the corresponding radial distribution curve is depicted in Fig. 2, curve a. In the radial distribution curve, there are two complex peaks extending from 1.0 to 1.6 Å, and from 2.0 to 2.7 Å, with maxima at about 1.40 and 2.55 Å respectively. The former corresponds to the bonded atom pairs, and the latter, to the short non-bonded atom pairs. The peaks at about 3.15 and 3.55 Å represent the long non-bonded C:::C and the long non-bonded C:::O and C:::H distances respectively. The still longer distacnes, C:::O and C:::H, contribute to the peak beyond 4.0 Å.

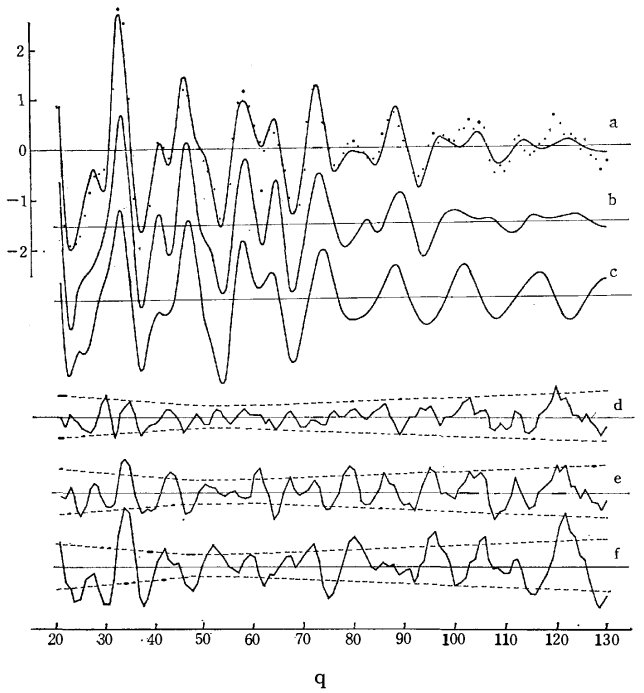

Fig. 1. The molecular intensity and difference curves.
dots: experimental, a: theoretical II, b: theoretical average (see text), c: theoretical non-alternating, d: Exp–a, e: Exp–b, f: Exp–c. The scale of the ordinate is the same for all the curves and is entered only for the experimental one. Broken lines indicate the limit of estimated uncertainties in the experimental intensities.

Results

Non-equality of Bond Lengths and Average C–C and C=C Bond Lengths. The possibility of a configuration with non-alternating bond lengths was rejected after examining the results of least-squares fittings for various models. When a least-squares fitting was performed, for instance, with respect to the four independent parameters, the C=O, C–C, C···C, and C:::C, by fixing the mean amplitudes at the estimated values in Table 1 and the C–H distance at 1.092 Å, the structure parameters resulting from the data plotted in Fig. 1 were as follows: r_a(C=O), 1.284±0.016;

28) See, *e.g.*, S. J. Cyvin, "Molecular Vibrations and Mean Amplitudes," Universitetsforlaget, Oslo and Elsevier, Amsterdam (1968).

Table 3. Average C–C and C=C, and other interatomic distances determined by the least-squares adjustment

Parameter	r_g	σ	limit of error[a)]
C—C	1.454	0.002	0.010

$C_1 \cdots C_4$	3.197	0.013	0.035
C—H	1.098	assumed	

a) Described in the succeeding paragraph of the most probable structures.

r_a(C–C), 1.422 ± 0.004; r_a(C···C), 2.507 ± 0.029; r_a(C:::C), 3.109 ± 0.044 Å, and the index of resolution, 0.55 ± 0.03. The theoretical curve based upon these parameters and its differences from the experimental values are shown in Fig. 1c and f respectively. The disparities between the experimental and theoretical curves are far beyond the estimated uncertainties in the observed intensities, shown by broken lines in Fig. 1. The average C–C and C=C bond lengths were then determined by dividing bonds in the ring into two groups, a single bond C_1—C_2, C_3—C_4, *etc*, and a double bond, C_2—C_3, C_4—C_5 *etc*. The results of the least-squares refinement are shown in Table 3. In this table, each structure parameter was given by the average of the results obtained from the three sets of data, while the standard deviation, σ, was estimated by the equation, $\sigma = \langle\sigma\rangle/\sqrt{3}$, where $\langle\sigma\rangle$ is the average of the three standard deviations. The corresponding theoretical intensity curve and its differences from the experimental values are depicted in Fig. 1b and e respectively. The agreement between the theoretical curve and the experimental one was improved to some extent; the sum of square residuals was reduced by a factor of about 2, while the index of resolution increased to 0.82 ± 0.04.

The Most Probable Parameters. Further least-squares refinements were carried out for models with different bond lengths. Since it was difficult to make the refinements converge by allowing the index of resolution and the eight independent distances to vary simultaneously, the index of resolution, the five bonded distances in the skeleton, the C–H distance, and each of the two non-bonded distances were adjusted iteratively so as to make a best-fit theoretical molecular intensity curve. By reference to the average C–C and C=C bond lengths, and also to the reported values for tropone derivatives in the crystalline state, a model with C_1–O=1.23, C_1–C_2=1.48, C_2–C_3=1.37, C_3–C_4=1.43, C_4–C_5=1.34, and C–H=1.10 Å, and others with bond lengths exchanged with respect to either one or both of the C_1–C_2 and C_3–C_4 and the C_2–C_3 and C_4–C_5 pair, were selected initially in order to search for the most probable structure. As a result, we found two sets of parameters which were equally probable and gave the same least-square residuals. Table 4 summarizes the results obtained by the least-squares refinements from the data for three plates. In what follows, these two sets of the parameters will be referred to as I and II.

The two sets of parameter values thus derived explain the experimental molecular intensities equally well, the indices of resolution and the standard deviations being substantially equal in both refinements. The agreement of the theoretical intensity curves for these models with the experimental one was much improved over the previous case, and the sum of the squared residuals was reduced to about one-half the value obtained for the model with the grouped C–C bond lengths. The two theoretical curves based upon the sets I and II differ from each other in some details. However, this cannot be used in discriminating a better model, since the magnitudes of the differences are within the range of random fluctuations, or the limit of uncertainty in the observed intensities. For example, the theoretical intensity curve calculated from the parameters of the set II and its difference curve are shown

Table 4. Results of the least-squares adjustments and their estimated limits of error (distances in Å, angles in degrees)[a)]

Parameter	I			II		
	r_g[b)]	σ[c)]	Limit of error	r_g[b)]	σ[c)]	Limit of error

a) Distances in Å, angles in degrees and the indices of resolution are dimensionless.
b) Calculated from the observed r_a distances and the mean amplitudes listed in Table 1.
c) σ does not include the systematic errors.
d) Calculated from the r_g distances for the best-fit structure.

in Fig. 1 a and d respectively. Curve b in Fig. 2 shows the theoretical curve based upon the set II parameters. The agreement with the observed curve is satisfactory except for the peaks in the region beyond 4.0 Å, which are associated with the longest non-bonded distances.

The limits of error quoted in Tables 3 and 4 include the random error, taken as 2.5 times the standard deviation, σ, and the systematic errors. The most significant systematic errors are the error in the scale factor, which was estimated to be 0.15% of the interatomic distance from the results of analysis for the diffraction patterns of the reference material, carbon disulfide, and the errors due to the probable uncertainties in the mean amplitudes and the ignoring of the shrinkage effects. The last two errors were not evaluated numerically, but were estimated roughly as follows.

It is generally known that calculated mean amplitudes are not very sensitive to variations in the force constants of the internal force field if they are only chosen to account a same extent for the observed vibrational frequencies. There is, therefore, little probability that the mean amplitudes for tropone deviate more than 5% from the calculated values listed in Table 1. Five percent of the mean amplitudes in our case amounts to 0.0025 Å for the bonded distances and 0.0030 Å for the short non-bonded distances. These deviations will influence the results, particularly similar distances such as the C_1–C_2 and C_3–C_4, and the C_2–C_3 and C_4–C_5 distances. It was reported by Karle that if the neighboring C–C bonds of benzene differed in length by $2a$ Å, as much as $a/3$ Å smaller mean amplitudes would result.[29] This estimate seems reasonable. If this estimate is applied to the present case, we get, in a very crude approximation, values of the errors due to the uncertainties in the mean amplitudes of 0.008 Å and 0.009 Å for the bonded and short non-bonded distances respectively. For the long non-bonded distances, the error was estimated to be 0.011 Å by assuming simply the uncertainties in their mean amplitudes to be 10%. Since the C–H distance could be determined almost independently of its mean amplitude, an error of this sort was not included.

The shrinkage effects for various molecules have been dealt with by many workers.[28] By examining these results, we assumed the magnitude of shrinkage to be 0.006 Å, a value which is almost the largest value found for ordinary molecules with no extremely low deformaiton frequencies. The uncertainties due to the ignoring of the shrinkage effect in the analyses do not exceed this value. Thus, this amount of uncertainty was included in the limits of error. In considering the limits of error thus estimated, it should be remarked that we can attach no great significance to the differences obtained between the C_1–C_2 and C_3–C_4 distances and between the C_2–C_3 and C_4–C_5 distances by Refinement II.

Discussion

Bertelli and Andrews[19] employed, in their CNDO/2 calculations, the standard bond lengths proposed by Pople and Gordon,[20], and after some critical discussion of the aromatic character of tropone they stated that, although there were no direct measurements available, tropone must have bond lengths within the range found for polyolefinic compounds. Roughly speaking, their prediction about the bond lengths coincides with the results of the present study.

Now we have two probable sets of structural parameters. Unfortunately, it is impossible to select a preferred model on the basis of the electron diffraction data alone. Therefore, some other information is needed to decide which structure is more favorable. Hosoya and Nagakura estimated the average C–C and C=C bond lengths to be 1.46 and 1.35 Å respectively, by grouping the data into single and double bonds and by using various empirical relationships among the bond orders, bond length, overlap integrals, and core resonance integrals.[30–32] Kunii and Kuroda[15] estimated the self-consistent bond lengths to be 1.45, 1.37, 1.43, and 1.37 Å for the respective consecutive C–C bonds, and 1.27 Å for the C=O bond by the use of another relationship.[33] The bond lengths given by Hosoya and Nagakura are in perfect agreement with the average distances determined by the present study and are close to the set II structure, while those reported by Kunii and Kuroda agree better with the set I structure except for the C=O distance. As for the C=O distance, the former authors assumed it to be 1.26 Å, while the latter authors estimated it to be 1.27 Å. These values are unacceptably longer than the observed values, 1.22 Å. All of the molecular orbital calculation[8b,15,19] carried out so far lead to very similar bond orders for the C_1–C_2 and C_3–C_4 bonds, resulting in a difference in length of only 0.02 Å or less. If the similarity of the bond orders is a unique solution to be drawn from the molecular-orbital calculations, set I might be ruled out. However, this cannot be stated definitely at present.

It may be instructive to compare the present results with the bond lengths in ethylene,[34] *cis*-2-butene,[35] 1,3-butadiene,[36] 1,3,5,7-cyclooctatetraene (COT),[37] and 1,3,5-cycloheptatriene (CHT).[38] The structures of these molecules are illustrated in Fig. 4. The definitions of the distances shown in Fig. 4 are not identical with one another. However, they will not be affected by more than a few thousandths of one angstrom

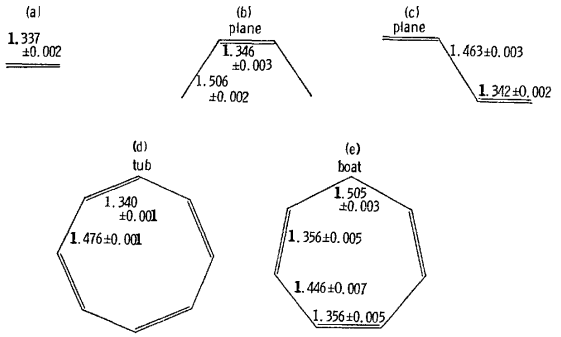

Fig. 4. Bond lengths for compounds related to tropone.
(a): ethylene, r_g, Ref. 34, (b): *cis*-2-butene, r_a, Ref. 35, (c): 1,3-butadiene, r_a^0, Ref. 36, (d): 1,3,5,7-cyclooctatetraene (COT), r_a, Ref. 37, (e): 1,3,5-cycloheptatriene, r_a, Ref. 38. The r_a^0 is the distance r_a extrapolated to the absolute zero temperature.

when they are transformed into distances of the same physical significance. While no significant difference can be found between the C–C bonds of COT and butadiene, the C–C bond length in COT is longer than that in butadiene, and COT has a boat form.[37] The observed bond lengths in CHT except for the C_1–C_2 bond indicate a more conjugate-bond character than those in butadiene. Nevertheless, CHT takes a boat form with C=C–C valence angles of about 120° to relieve the strain in valence angles. Similar phenomena were observed[7] in the X-ray structure analyses of dibenzo[b,f]tropone,[2e] 1-isopropyl-8,8-dicyanoheptafulvene,[6a] and 1,6-dimethyl-8,8-dicyanoheptafulvene,[6a] all of which have $C_2C_3C_4C_5C_6$ frames very close to that in CHT. In such molecules which favor boat forms, however, the C_1–C_2 and C_1–C_7 bonds are usually longer than other single bonds in the same molecule. These facts imply that the conformations of such molecules are determined by a subtle compromise among various factors *e.g.*, π-electron delocalization, steric interaction, and strain in valence angles. When we compare our results with these facts, the set II structure seems to be more likely than the set I structure to have planar structure.

By considering additionally the fact that the vibrational spectra of tropone could be explained by using two kinds of force constants, 4.0 mdyn/Å for the longer bonds and 6.0 and 6.2 mdyn/Å for the shorter bonds, we are inclined to prefer, for the time being, the set II structure, where the bond lengths of the C_1–C_2 and C_3–C_4 bonds are about 1.45 Å, the C_2–C_3 and C_4–C_5 about 1.36 Å, and the C–O about 1.22 Å, and where the planarity is attained by π-electron delocalization.

We wish to thank Professor Y. Kitahara of Tohoku University for providing us with the sample. We are also indebted to Professor K. Ohno of the Department of Chemistry, Hokkaido University, for making it possible for us to use the FACOM 270-20 computer in his laboratory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3282—3286 (1972)

The Singlet-triplet Absorption Spectra of Heterocyclic Amine *N*-Oxides (I)

Tanekazu KUBOTA, Masumi YAMAKAWA, and Yoshiko MIZUNO

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

(Received February 19, 1972)

The singlet-triplet absorption ($T_1 \leftarrow N$) spectra of pyridine *N*-oxide, quinoline *N*-oxide, isoquinoline *N*-oxide, and acridine *N*-oxide have been observed by applying the oxygen-intensification technique. The correlation between the $T_1 \leftarrow N$ absorption bands and the singlet-singlet ($S^* \leftarrow N$) absorption bands of these *N*-oxides has been established and discussed theoretically. The lowest triplet state of the *N*-oxides has been assigned as the π-π^* transition of a ^3L_a (CT) nature. The $T_1 \leftarrow N$ absorption bands obtained show a blue shift in polar solvents. The results have been compared with the case of $S^* \leftarrow N$ transitions and have been reasonably explained by taking into account the contribution from the intramolecular charge transfer.

In the field of the studies of photochemical reactions, heterocyclic amine *N*-oxides constitute one group of substances which are being quite extensively studied at present.[1] Needless to say, the knowledge of excited singlet and triplet states is important for interpreting the mechanism of photochemical reactions. Although the nature of the excited singlet states of heterocyclic amine *N*-oxides has been intensively investigated,[2]

there have as yet been few studies of their excited triplet states.[3] The main reason for this is some difficulty for measuring the phosphorescence spectra because of their very weak intensity or some instability accompanying a photochemical reaction. In these cases, the observation of the singlet-triplet ($T_1 \leftarrow N$) absorption spectra is very useful in determining the energy level of the lowest triplet state. Several techniques for measuring the $T_1 \leftarrow N$ absorption spectra have already been reported.[4]

In our present case, the technique of high-pressure oxygen perturbation developed by Evans[4a] was the most useful technique for obtaining the $T_1 \leftarrow N$ absorption spectra of the aromatic amine *N*-oxides studied here. In this paper we would like to report on these $T_1 \leftarrow N$ absorption spectra and their interpretations.

Experimental

Absorption Cell. Figure 1 shows the absorption cell employed in this study; it was made of stainless steel and was constructed by referring to the ones used by Evans[4a] and by Robin.[5] A suprasil silica plate 8 mm thick was used as a window. The effective light pass length was ~5.2 cm. This absorption cell was safe for oxygen pressures of ~200 kg/cm^2. The equilibrium state of the sample solution saturated with compressed oxygen gas was easily obtained by shaking the absorption cell moderately. All the spectral measurements were made at room temperature. The sample concentrations are dependent on the solubility and on the degree of the enhancement of the $T_1 \leftarrow N$ absorption with oxygen. In the case of $CHCl_3$ solution, the most suitable concentrations are 0.93, 0.75, and 0.99 mol/*l* for pyridine *N*-oxide (PNO), quinoline *N*-oxide (QNO), and isoquinoline *N*-oxide (IQNO) respectively. However, a saturated solution was used for acridine *N*-oxide (ANO) because of the low solubility. The instrument used for recording the singlet-triplet absorption spectra was a Beckman DK-2A Far-UV spectrometer.

Solvents and Samples. All the solvents used, except for chloroform, were spectro-grade in purity; they were dried sufficiently with calcium chloride, *etc.*,[6] and then rectified carefully. Spectro-grade chloroform containing about 1% ethanol as a stabilizer was used with no further treatment. As to samples, PNO, QNO, IQNO, and ANO were used in this study. The details of the preparation and the purification of these samples have already been reported.[7] Finally, they were again sublimated or distilled before use. In the case of ANO, an alumina column chromatographic method was also used,[8] the *N*-oxide being eluted first with an ether-pentane mixture and later with ether alone. The pure *N*-oxide has been obtained from the ether fraction.

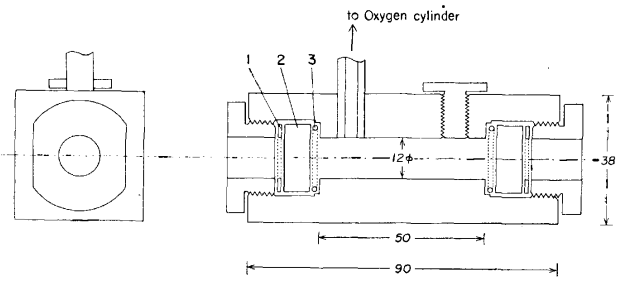

Fig. 1. High pressure cell used for obtaining the singlet-triplet absorption spectra under compressed oxygen perturbation. Dimension is in mm unit. Suprasil silica plate of 8 mm thickness (2) is held between the Teflon O-ring (3) and the Teflon washer (1).

Results and Discussion

$T_1 \leftarrow N$ *Absorption Spectra of PNO, QNO, IQNO, and ANO.* To confirm our experimental technique, we have first examined the $T_1 \leftarrow N$ absorption spectra of naphthalene, *etc.*, under almost the same experimental conditions as those reported by Evans.[4a] The spectra thus obtained reproduced Evans' well. Our experiments can, therefore, be believed to be correct.[9] As a typical example, the oxygen-pressure dependence of the $T_1 \leftarrow N$ absorption spectrum is illustrated in Fig. 2 for a relatively high concentration (~1 mol/*l*) of the PNO chloroform solution. It is now clear that a new absorption band appears in the wavelength region of 370—500 nm and that the intensity of this new band increases in a linear fashion with an increase

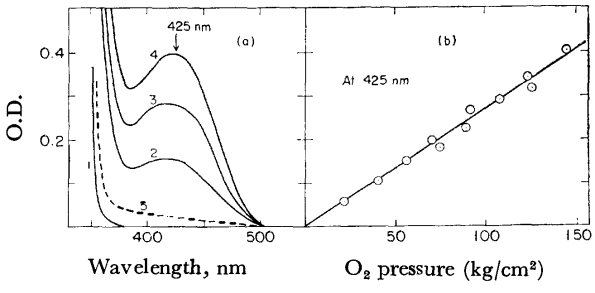

Fig. 2. Oxygen pressure dependence of the $T_1 \leftarrow N$ absorption spectrum of pyridine *N*-oxide in $CHCl_3$ solution (0.93 mol/*l*). (a): The change in the spectrum with no oxygen perturber (curve 1) upon the applied oxygen pressure (kg/cm^2) of 57 (curve 2), 108 (3), and 145 (4). The curve 5 is for the spectrum after removal of the oxygen. The intensity of the curve 5 is a little larger than that of the curve 1. The main reasons would be that the removal of oxygen is incomplete, and thus contact charge transfer spectra caused by weak oxygen complex formation may appear as a tail toward a longer wavelength region. (b): The linear relation of the enhanced $T_1 \leftarrow N$ absorption intensity to the applied oxygen pressure.

9) The trial is deemed to have failed in obtaining the $T_1 \leftarrow N$ absorption spectra of the present *N*-oxides in solvents with heavy atoms, such as CH_2Br_2 and CH_2I_2, since the enhancement of the $T_1 \leftarrow N$ absorption intensity in these solvents seems to be small. In addition, there also occurred other kinds of solute-solvent interactions in the case of the present system.

in the oxygen pressure, as may be seen in Fig. 2b. In addition, when the oxygen pressure is reduced to atmospheric pressure, the new absorption band disappears, and the spectrum almost completely returns to that before the introduction of oxygen gas. The reproducibility of this spectral behaviour was quite good. Comparing these expermental results with those found in the literature,[4a,10,11] one can conclude that the above-mentioned new absorption band of PNO is due to the $T_1 \leftarrow N$ transition enhanced by oxygen gas. Quite recently, Bellamy *et al.*[10] carried out the photochemical sensitization reaction of 2-cyanopyridine *N*-oxide, *etc.*, sensitizers which have triplet energy levels of 74 (Xanthone) and 79 kcal/mol (tetrabuthylammonium phenyltetrazolide) being effective. These results are in accord with our experimental results presented above. Furthermore, the contact charge-transfer (CCT) spectra due to the CCT complex formation of PNO with the oxygen molecule may appear as an end-absorption, overlapped with the spectrum of PNO itself, at the shorter-wavelength region than the $T_1 \leftarrow N$ absorption band, since the existence of this kind of CCT spectrum is well known.[11,12]

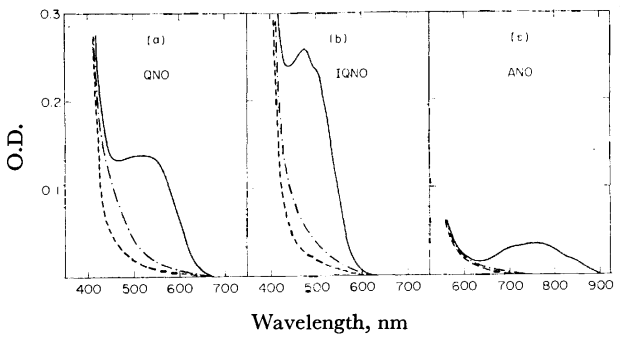

Fig. 3. Singlet-triplet absorption spectra of quinoline *N*-oxide (a), isoquinoline *N*-oxide (b), and acridine *N*-oxide (c) in $CHCl_3$ solution. The concentration (mol/*l*) and the oxygen pressure (kg/cm^2) are in this order: 0.75, 128; 0.99, 100; and the saturated solution, 152; for QNO, IQNO, and ANO, respectively.
----: for initial solution, ——: under high pressure oxygen perturbation, -·-·-: after removing the oxygen gas.

A new absorption band brought about by compressed oxygen gas was also clearly found for QNO, IQNO, and ANO. The spectral behaviour for the oxygen-pressure dependence and the reproducibility of the intensified new band were both very similar to those in the case of PNO discussed above. These absorption bands can, therefore, reasonably be assigned to the $T_1 \leftarrow N$ transition, the spectra being shown in Fig. 3. It should be noticed that the accuracy of the $T_1 \leftarrow N$ absorption spectra of ANO seems to be less than that of the other *N*-oxides, because the solubility of ANO in a $CHCl_3$ solvent, *etc.*, is small; thus, the intensity of the $T_1 \leftarrow N$ transition arising from the oxygen perturbation also becomes small. Nevertheless, the wavelength region and the maximum position of the $T_1 \leftarrow N$ absorption of ANO seem correct.[13] The band positions of the obtained $T_1 \leftarrow N$ spectra, the singlet-singlet π-π^* transition energies in intimate correlation with the $T_1 \leftarrow N$ spectra, and the values of the singlet-triplet separation are all shown in Table 1 for the *N*-oxides studied here. Figure 4 depicts a correlation diagram of all the transitions (see Table 1) pertinent to PNO, QNO, and ANO, the correlation curves of the $S^* \leftarrow N$ transitions having previously been reported by us.[14]

TABLE 1. TRANSITION ENERGIES TO THE T_1, ^1L_b, AND ^1L_a (CT) EXCITED STATES, AND THE T_1—^1L_a (CT) ENERGY SEPARATION (in kK unit)

N-oxide of	$T_1 \leftarrow N$[a]	$^1L_a \leftarrow N$[b]	$^1L_b \leftarrow N$[b]	T_1—^1L_a separation[c]
Pyridine[d]	23.98	35.44	30.7	11.46
Isoquinoline	21.03	32.3	26.5	11.3
Quinoline	18.64	28.6	29.4	10.0
Acridine	13.07	22.1	27.2	9.0

a) Obtained in chloroform.
b) Obtained in *n*-heptane.
c) The $S^* \leftarrow N$ spectra shift considerably to shorter wavelength in $CHCl_3$ (contain ~1% ethanol), in which $T_1 \leftarrow N$ spectra have been recorded, so that the S^*—T_1 separation in $CHCl_3$ should be larger than that listed in this Table.
d) The $T_1 \leftarrow N$ absorption maximum in various solvents is: 23.49 kK (Diethyl oxalate), 23.18 (Benzene), 22.68 (Ether), 23.16 (Ethyl acetate), 23.46 (Dichloromethane), 23.39 (Acetone), 23.87 (Acetonitrile), 24.99 (Ethanol), 25.51 (Methanol), and 25.89 (Water).

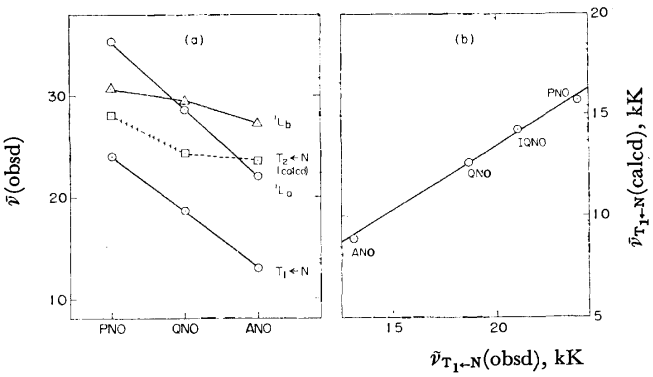

Fig. 4. (a): Correlation curves of the experimentally and the theoretically (only for $T_2 \leftarrow N$ transition) obtained transition energies among the *N*-oxides of pyridine, quinoline, and acridine. (b): Calculated $T_1 \leftarrow N$ transition energies of the *N*-oxides.

Solvent Effect on the $T_1 \leftarrow N$ *Transition of PNO.* It is well known that the singlet-singlet π-π^* bands of aromatic amine *N*-oxides exhibit a dominant blue shift phenomenon in polar solvents, especially in

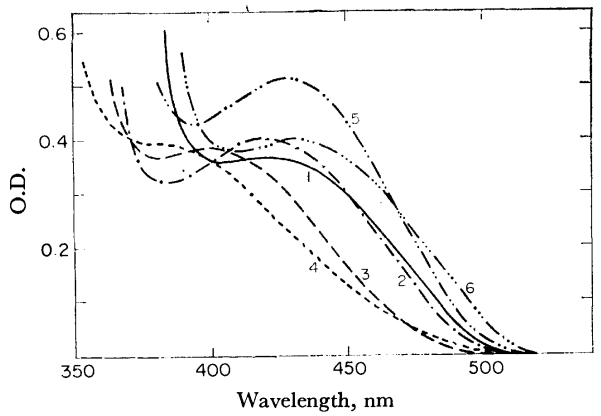

Fig. 5. Enhanced absorption spectra of the $T_1 \leftarrow N$ transition of pyridine *N*-oxide with high pressure oxygen in various solvents.
Solvents; 1: CH_3CN, 2: $CHCl_3$, 3: C_2H_5OH, 4: H_2O, 5: CH_2Cl_2, 6: benzene. All the spectra were drawn so as to give almost the same intensity as that in $CHCl_3$ solution (see Fig. 1) by suitably multiplying the original curves.

protic solvents,[15] where the hydrogen-bonding effect plays an important role.[16] This was attributed to the fact that the solute-solvent interaction, including the hydrogen-bonding effect, is much larger at the ground state than at the π-π^* excited singlet states, because the charge transfer from the oxygen atom of the *N*-oxide group to the ring π electron system is larger at the excited singlet π-π^* states than at the ground state. It is of great interest what kind of solvent shift can be expected for the case of the $T_1 \leftarrow N$ absorption bands. This sort of study was caried out in detail for PNO, the spectra yielded in several solvents being shown in Table 1 and its footnote d), and in Fig. 5. It is clear in Fig. 5 that the $T_1 \leftarrow N$ transition of PNO is quite sensitive to the solvent change and is blue-shifted with an increase in the polarity of the solvents, particularly in protic solvents such as water and ethanol. These are results similar to those observed generally for the singlet π-π^* bands of many *N*-oxides.[15,16] However, note that the degree of the blue shift for the $T_1 \leftarrow N$ transition is smaller than that of the intramolecular CT ($^1A_1$-282 nm) band of PNO. For example, the blue shifts due to the solvent change from CH_3CN (dielectric constant $D=37.5$) to C_2H_5OH (24.55), CH_3OH (32.70), and water (78.38) are 1120, 1360: 1640, 1700: 2020, 3140: (in cm^{-1} units) respectively. Here, in each set the first number should refer to the $T_1 \leftarrow N$ band, and the second, to the above $^1A_1$ CT band. It has been reported that the intramolecular charge transfer from such substituents as OH, and NR_2 to a ring π electron system like benzene and naphthalene is, in general, larger at the singlet excited state than at the lowest triplet state.[17] If the same argument as the above can be applied to the PNO system, since PNO and the phenolate ion are isoelectronic in the π electron system, the aforementioned blue shift of the $T_1 \leftarrow N$ transition, smaller than that of the $^1A_1$ band, seems to be reasonable.[18] Actually, our calculation results obtaind by the PPP method, as well as the CNDO results reported by other authors, all support this kind of consideration, although the difference in CT magnitude between the $^1A_1$ and the $^3A_1$ states of PNO is not very large.[14,19]

Nature of the $T_1 \leftarrow N$ *Transition of PNO, QNO, IQNO, and ANO.* Although it is not easy to discuss the character of the lowest triplet state from the $T_1 \leftarrow N$ transition alone, the nature of the $T_1 \leftarrow N$ absorption spectra will become somewhat clear if we check the singlet-triplet splitting values (see Table 1) and the correlation diagram shown in Fig. 4a, where the energies of the $T_1 \leftarrow N$ and $S^* \leftarrow N$ transitions are plotted in order to make the comparison clear. We can see there that the T_1 energy level is smoothly red-shifted according to the increase in the ring number. This tendency is very similar to that of the ^1L_a (CT) correlation curve among PNO, QNO, and ANO. In addition, the ^1L_a-T_1 energy separation turns out to become smaller with the increase in the ring size, but just the reverse order holds for the energy separation between the ^1L_b and the $T_1 \leftarrow N$ bands. These results are the same as those of the experiments and the theoretical S^*-T_1 energy separations of cata-condensed aromatic hydrocarbon;[20] they lead to the conclusion that the T_1 states of these *N*-oxides correspond to ^3L_a (π-π^*): $^3A_1$ for PNO and ANO, and to $^3A'$ for QNO. The conclusion is also supported by the quite large values of singlet-triplet energy separation listed in Table 1.

In the case of IQNO, systematic discussions based on the correlation diagram can not be applied. Nevertheless, it may be said that the T_1 state has the character of the π-π^* transition because of the fact that there is a good correlation between the observed T_1 energy levels and the calculated values (*vide infra*) for the PNO, QNO, IQNO, and ANO compounds, as may be seen in Fig. 4b.

In order to examine the above-mentioned character of the T_1 states theoretically, we undertook molecular orbital calculations. The calculations were made by the PPP-type SCF-MO-CI method.[14] Special attention was paid to the two-electron repulsion integral, $\gamma_{\mu\nu}$. We used the form given by Beveridge and

18) Here, the following discussion seems appropriate. In the lowest equilibrium triplet state, the electron distribution and the molecular geometry can be expected to be different from those in the singlet excited state. Thus, the solute-solvent interaction potential curve in the triplet state may differ from that in the ground state or in the singlet excited state. Light absorption occurs, according to the Frank-Condon principle, from the ground state. In the present case, therefore, these circumstances would bring about a more exaggerated blue shift than the energy difference of the solute-solvent interaction in the equilibrium state between the lowest triplet and the ground states.

Hinze:[21] $\gamma_{\mu\nu}=e^2/[a_{\mu\nu}\cdot\exp(-r_{\mu\nu}^2/2a_{\mu\nu}^2)+r_{\mu\nu}]$; here $a_{\mu\nu}=2e^2/[\gamma_{\mu\mu}+\gamma_{\nu\nu}]$.[22] The calculated results are given in Fig. 4, along with the observed ones. We found that the calculated lowest triplet energy level, T_1, lies quite apart from the other calculated triplet levels T_2, T_3, *etc.* For example, the T_2-T_1 and T_3-T_2 separations (in cm^{-1} unit) are 12296, 1988; 11610, 3408; and 14734, 1045 for PNO, QNO, and ANO respectively. In other words, the change in the character of the T_1 states, which become the ^3L_a species from a consideration of the molecular symmetry, may not occur even if more rigorous calculations are performed.[22] The calculated T_1 state also shifts smoothly to a longer wavelength in the order of PNO, QNO, and ANO, just the observed T_1 states do. Therefore, these calculated results support the previous discussion of the character of T_1 states, although the calculated values themselves are unsatisfactory compared with the observed values because the parametrization seems to be insufficient for a better description of the triplet energy levels of the *N*-oxides. Quite recently, Leibovici and Streith[19] calculated the triplet energy levels of pyridine *N*-oxide using the CNDO-CI method as modified by Bene and Jaffé.[23] They concluded that (i) the lowest triplet state, T_1, is of a π-π^* nature, with its polarization along the molecular axis, and (ii) the charge transfer from the *N*-oxide-group oxygen atom to the pyridine ring π system occurs, to thus reducing the dipole moment at the T_1 state, but the degree is smaller than for the $^1A_1$ CT band. Therefore, the blue shift of the T_1 band can be expected in polar solvents. These theoretical predictions are in accord with our experimental and calculated results discussed hitherto.

Here it should be noticed that, in general, the character of the T_1 state can also be obtained from a study of the phosphorescence spectra if the substances in question phosphoresce. In the case of some heterocyclic amine *N*-oxides, the phosphorescence spectra and their characteristics have been examined by means of the *photographic method.*[3] We repeated these measurements carefully using a Hitachi fluorescence-phosphorescence spectrophotometer, Model MPF-2A, using a red-sensitive photomultiplier for recording the spectra appearing in the longer-wavelength region. However, our experiment on the rigid glass solution at the temperature of liquid nitrogen indicated that, in the present case, the phosphorescence spectra obtained consist of those of heterocyclic amine *N*-oxide and its photochemical reaction product, and that the ratio of these two components is dependent on the solvents and samples. For example, the phosphorescence spectrum of QNO in alcohol reported by Dörr *et al.*[3] may be identified as that of 2-quinolone produced by a photochemical reaction.[24] The true phosphorescence spectra of the *N*-oxides can, then, be estimated by extrapolating the somewhat time-dependent spectra to time zero. Because of these circumstances, the experimental data of the $T_1\leftarrow N$ absorption spectra are very important.

Next, let us pay attention to the intensity of the enhanced $T_1\leftarrow N$ absorption bands. Recent theoretical studies have indicated that the enhancement of $T_1\leftarrow N$ absorption is mainly brought about by the electron-exchange interaction[25] and by the contact charge-transfer interaction[12,26] occurring in the contact-weak complex formed from an electron donor (organic molecules) and an acceptor (a perturber like oxygen). Here, note that these quantum mechanical interactions may lead to the $T_1\leftarrow N$ absorption stealing a part of the strong intensity of the singlet-singlet transitions. The degree of the intensity borrowing is, however, dependent on the molecular orbitals and on the energies of the electron donor and the acceptor. In our experimental results reported here, the $T_1\leftarrow N$ absorption of PNO is most strongly enhanced by the oxygen perturber. However, the oxygen perturbation effect is in the order: PNO>QNO>ANO. This means that the above-mentioned quantum mechanical interactions may decrease with an increase in the π-conjugate system in the present *N*-oxides. The quantitative theoretical treatment of these experimental results is thus quite interesting; it is now proceeding in our laboratory.

22) From the viewpoint of correlation energy, the importance of the parametrization and the approximation was recently discussed for the case of the PPP-type calculation of triplet and singlet transition energies.[21] In the present case, however, the adoption of the Nishimoto-Mataga approximation[14] for $\gamma_{\mu\nu}$, and the calculation according to Zahradnik *et al.* (who suggested simple modifications of the parametrization to fit the experimental triplet energy levels to the calculated ones) both gave the same results for the state symmetry and for the relative correlation among the energy levels, as is stated in the text (see Fig. 4), although the absolute values themselves are different, especially for the NM approximation. Ultrasonic Study on Dilute Aqueous Solutions of Diamines

Katsutaka SASAKI and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received February 21, 1972)

Ultrasonic experiments were carried out on aqueous solutions of diamines (ethylenediamine, 1,3-propanediamine, 1,4-butanediamine, 1,5-pentanediamine, and 1,6-hexanediamine) by means of pulse technique in order to study solute-solvent interactions. Sound velocity and absorption coefficient were determined in the frequency range 15—45 MHz. The magnitude of absorption coefficient for each solution increased rapidly with concentration up to about 0.4 mol%. It is concluded that the initial rapid increase is attributed to the proton transfer in base equilibria. The absorption coefficient at the same molar concentration of each solution increases appreciably with the size of hydrocarbon chain from $-(CH_2)_2-$ to $-(CH_2)_3-$. This is ascribed to the formation of icebergs around hydrocarbon groups.

The influence of solute molecules on the structure of liquid water has been discussed for dilute aqueous solutions,[1-3] and aqueous solutions of alcohols and amines have been extensively investigated.[4-7] However, many problems remain unsolved as yet. Alcohol-water and amine-water interactions have been explained on the basis of the following: polar group-water interaction and hydrocarbon group-water interaction ("hydrophobic interaction").

We have investigated the nature of solute-solvent interactions in various aqueous solutions by means of ultrasonic measurements.[8-10] We have carried out an ultrasonic study on dilute aqueous solutions of diamines with the intention of investigating the polar group-water interaction and hydrocarbon group-water interaction. These compounds are suitable, because of their large solubility in water despite relatively large hydrocarbon groups. This report describes the behavior of ethylenediamine, 1,3-propanediamine, 1,4-butanediamine, 1,5- pentanediamine and 1,6-hexanediamine in water.

Experimental

An ultrasonic pulse technique was used for the measurement of sound velocity and absorption coefficient. The apparatus and procedures of measurements have been described.[11] Sound velocity was measured at a fixed frequency, 5 MHz. The absorption coefficient was measured in the frequency range 15—45 MHz. Temperature range was 10—20°C, the accuracy being within ± 0.1°C. Ethylenediamine and 1,3-propanediamine, obtained from Wako Pure Chem. Ind. Co., Ltd., were used after being refluxed and distilled over sodium metal. The boiling points of ethylenediamine and 1,3-propanediamine were 116 ± 0.3°C and 137 ± 0.3°C, respectively. 1,4-Butanediamine, 1,5-pentanediamine and 1,6-hexanediamine (m.p., 40 ± 0.5°C) were obtained from Aldlich Co., Ltd. and were used without further purification. Viscosity coefficient and density of aqueous solutions of ethylenediamine, 1,3-propanediamine and 1,6-hexanediamine were measured by means of an Ostwald type viscometer and pycnometer at 20°C. The value of pH for each diamine solution was measured by a pH meter (model MH-5A, Toa Electronics Ltd.). The values of pH for ethylenediamine and 1,6-hexanediamine were found to be 11.8 ± 0.1 and 12.2 ± 0.1, respectively.

Results

Sound Velocity and Compressibility. The accuracy of sound velocity data was within ± 1 m/sec. The data obtained for aqueous solutions of 1,3-propanediamine are plotted against concentration in Fig. 1. It was found that the velocity *vs.* concentration curves for the solutions closely resemble each other. Compressibility *vs.* concentration relations calculated from velocity and density data at 20°C are given in Fig. 2, for solutions of ethylenediamine, 1,3-propanediamine and 1,6-hexanediamine. The compressibility data are

○: ethylenediamine ◐: 1,3-propanediamine
●: 1,6-hexanediamine

consistent with the results obtained by Hirata and Arakawa,[12] in which the structure of icebergs is found to be more incompressible than ice-like structure in liquid water.

Ultrasonic Absorption. The data of absorption coefficient α were reproducible within $\pm 2\%$. The absorption coefficient *vs.* frequency curves for 1,3-propanediamine solutions are given in Fig. 3. The magnitude of α/f^2 decreases gradually with $\log f$ (f, frequency) for all solutions. α/f^2 *vs.* concentration curves at 35 MHz are given in Fig. 4. The results of α/f^2 *vs.* concentration for ethylenediamine are consistent with the data obtained by Blandamer *et al.*[4] We see that the magnitude of α/f^2 increases rapidly with concentration up to about 0.4 mol%, and increases slightly at higher concentrations.

Viscosity coefficient η was measured in order to obtain the values of classical absorption, which is given by

$$(\alpha/f^2)_{class.} = \frac{8\pi^2\eta}{3\rho V^3} \qquad (1)$$

where ρ is density and V sound velocity. The structural absorption is given by

$$(\alpha/f^2)_{struct.} = (\alpha/f^2)_{obsd.} - (\alpha/f^2)_{class.} \qquad (2)$$

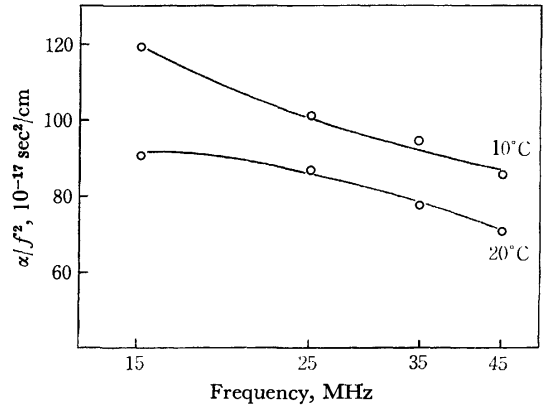

Fig. 3. Ultrasonic absorption for aqueous solutions of 1,3-propanediamine at 0.19 mol % (1 vol %).

12) F. Hirata and K. Arakawa, to be published.

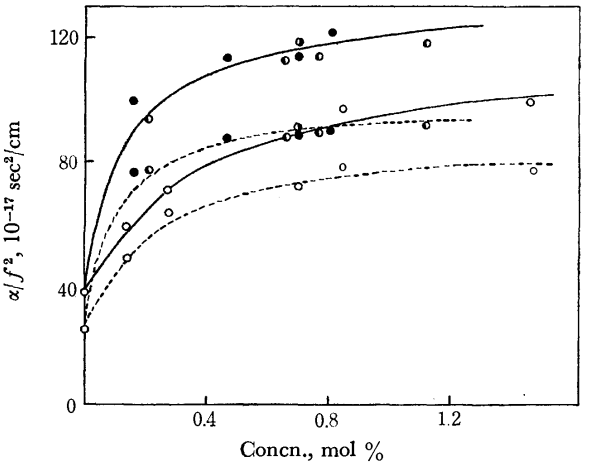

Fig. 4. Concentration dependence of ultrasonic absorption for aqueous solutions of diamines at 35 MHz. (solid line, at 10°C, broken line, at 20°C)
○: ethylenediamine, ◐: 1,3-propanediamine,
◑: 1,4-butanediamine, ●: 1,6-hexanediamine.

The results at 20°C are given in Fig. 5. Since the magnitude of classical absorption is found to increase slowly in this concentration range, the initial rapid increase of α/f^2 is attributed to the increase of $(\alpha/f^2)_{struct.}$

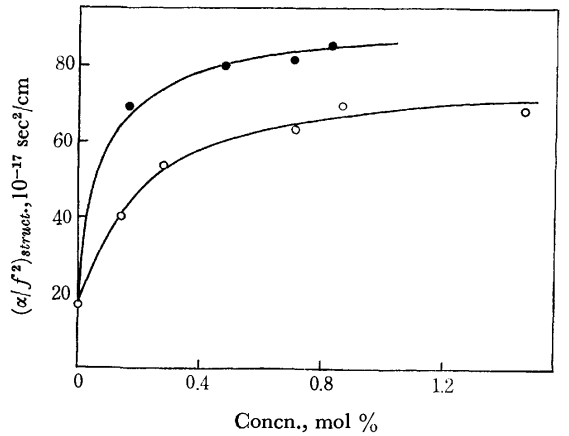

Fig. 5. Concentration dependence of structural absorption for aqueous solutions of diamines at 20°C (35 MHz).
○: ethylenediamine, ●: 1,6-hexanediamine

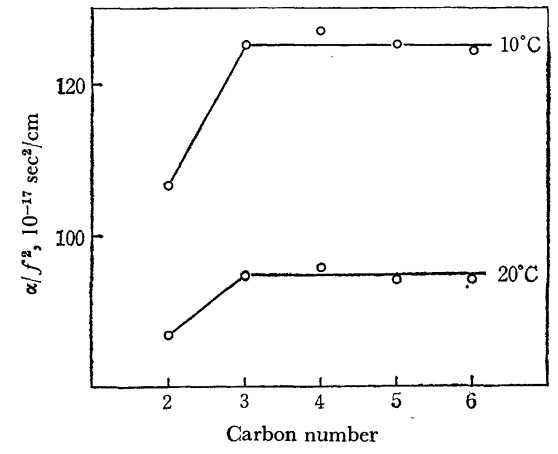

Fig. 6. Ultrasonic absorption for aqueous solutions of diamines as a function of the carbon number in solute molecules. (25 MHz).

The magnitude of α/f^2 in Fig. 6 at the same molar concentration (0.7 mol%) is plotted against the size of hydrocarbon chain of solute molecules. We see that the magnitude of α/f^2 for ethylenediamine is less than that of other higher homologues.

Discussion

Polar Group-Water Interaction. Let us first discuss the initial rapid increase of α/f^2 appearing in all diamine solutions (Fig. 4). It has been pointed out that for dilute aqueous solutions of alcohols, dioxane, urea *etc.*, the value of α/f^2 are nearly equal to those for pure water.[2,9,13] The magnitude of α/f^2 for aqueous solutions of dioxane is nearly the same as that of pure water up to about 4 mol%.[9] On the other hand, for aqueous amine solutions, there is a significant increase in extremely dilute concentration of the order of 1 mol%.[2,4,14] A similar increase of α/f^2 is observed for diamines (Fig. 4). The origin of the initial rapid increase seems to be ascribed to amino groups.

Blandamer *et al.* attributed the ultrasonic absorption caused by the addition of amine molecules to the acid-base equilibria.[14]

$$RNH_2 + H_2O \rightleftarrows RNH_3^+ + OH^- \quad (3)$$

On the other hand, Berfield and Schneider,[15] and Mckellar and Andrea[16] concluded that the hydrogen-bond formation and breaking between amine and water molecules cause the increase of $\alpha/$ [2].

Alei *et al.*[17,18] showed that the proton negative shift by amino groups in aqueous solutions of ethylenediamine as well as the viscosity coefficient reaches maximum at 33 mol% concentration. They proposed that there is a stable dihydrate complex linked with hydrogen-bond in aqueous solutions of ethylenediamine. If the presence of dihydrate complex give rise to the initial excess ultrasonic absorption in dilute aqueous solutions of diamines, the magnitude of α/f^2 should increase linearly with concentration. However, the α/f^2 *vs.* concentration curves become nearly flat above 0.4 mol% after the initial rapid increase (Figs. 4 and 5). Thus we might say that the behavior of α/f^2 in dilute aqueous solutions of diamines does not result from the formation and breaking of hydrogen-bond.

It can be said that in dilute aqueous diamine solutions, the initial rapid increase of absorption and saturation of its magnitude above 0.4 mol% concentration is caused by the proton transfer of base equilibria:

$$NH_2RNH_2 + H_2O \rightleftarrows NH_2RNH_3^+ + OH^- \quad (4a)$$

$$NH_2RNH_3^+ + H_2O \rightleftarrows NH_3^+RNH_3^+ + OH^- \quad (4b)$$

The measured value of pH for each diamine solution is found to correspond to the value of pK in the second dissociation.[19] Thus, it is concluded that the cause of the initial rapid increase of absorption observed for all solutions is the dissociation given by (4b).

Hydrocarbon Group-Water Interaction. We have pointed out the initial rapid increase of α/f^2 as a general property of each diamine solution (Fig. 4). It is seen that the magnitude of α/f^2 above 0.4 mol% becomes nearly flat with concentration (Figs. 4 and 5). We see that the magnitude of α/f^2 increases with the size of hydrocarbon chain of solute molecules from $-(CH_2)_2-$ to $-(CH_2)_3-$ and exhibits a saturation effect in higher homologues (Fig. 6).

We observed[10] that the magnitude of α/f^2 for aqueous solutions of α-amino acids is independent of the size of hydrocarbon chain in solute molecules. Thus, it was concluded that the behavior of neutral α-amino acids in water is essentially similar to each other, and the structure-forming effect due to alkyl groups in amino acid molecules was cancelled out by the strong structure-breaking effect due to the dipolar field by zwitter-ions irrespective of their size.

On the other hand, for aqueous non ionic solutions (alcohols, ethers *etc.*), we see that the formation of icebergs becomes significant around hydrocarbon groups which are larger than methyl groups.[20,21] In liquid water, 1,3-dimethylurea molecules behave as a weak structure breaker but 1,3-diethylurea molecules behave as a structure former.[8]

In diamine solutions, the structure-breaking effect due to ionic dissociation of amino groups is less than that due to dipolar field by zwitter-ions in amino acid solutions. The structure-forming effect by hydrocarbon groups in diamine molecules can not be cancelled out completely by the structure-breaking effect due to ionic dissociation of amino groups. The increase of α/f^2 with the size of hydrocarbon chain from $-(CH_2)_2-$ to $-(CH_2)_3-$ in Fig. 6 can be attributed to the structure-forming effect of hydrocarbon chain in diamine molecules.

Thus, it is concluded that the iceberg formation becomes appreciable above the carbon number 3 in diamine molecules. The structure of icebergs is more incompressible than ice-like structure in liquid water (Fig. 2). This is in line with the idea of Wicke.[22] However, it should be pointed out that the iceberg formation is not dependent linearly on the size of hydrocarbon chain in these molecules, since the magnitude of α/f^2 is saturated above the carbon number of 3.

Concluding Remarks

The following conclusions are obtained from ultrasonic measurements.

1) An initial rapid increase of ultrasonic absorption for the diamine solutions is attributed to the proton

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 45, 3290—3293 (1972)

Comparison of the Electronic Spectra of Geometric Isomers. II. 1,2-Disubstituted Ethylenes

Takayuki FUENO and Kizashi YAMAGUCHI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 21, 1972)

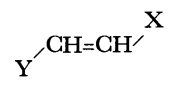
The ultraviolet absorption spectra of the *cis* and *trans* isomers of various 1,2-disubstituted ethylenes were measured in isopentane solution. Each isomer showed a single intense band assignable to the lowest π—π^* transition. For the majority of the compounds studied, both energy and oscillator strength of transition are found to be greater for *trans* isomers than for the corresponding *cis* isomers, in accord with the general trend predicted by the Pariser-Parr-Pople calculations. Existence of some anomalous cases which contradict the generalization indicates a limited validity of the usual assumption of virtual orbitals.

Despite abundant data available for the ultraviolet absorption spectra of unsaturated compounds,[1] very few comparative studies have been made on the spectra of *cis* and *trans* isomers of olefins. A study on the π—π^* transitions of *cis*- and *trans*-stilbenes revealed that the *cis* isomer shows absorption peaks in shorter wavelength regions than does the *trans*.[2] Several workers agreed in attributing the higher-energy shift of the lowest transition peak of *cis*-stilbene to its nonplanarity resulting from the *steric repulsion* between the two phenyl groups located *cis* to each other.[3-6]

We recently reported[7] that in both gaseous phase and *n*-hexane the lowest π—π^* transition energy of the majority of terminal-substituted butadienes is more or less greater for isomers bearing the substituent(s) at the *trans* placement(s). Since all these compounds are likely to be planar in structure, the observed trend must be taken as a reflection of a certain *electronic effect* of the fully conjugated chromophores. The LCMO-SCF-CI computations of the Pariser-Parr-Pople (PPP) type[8,9] showed that this electronic effect might be related with the smaller inter-frontier-orbital Coulombic repulsion J_{hl} for the isomers having more of the *trans* ethylenic moieties.

Experimental data which may be tested for the above argument are very scanty for ethylene derivatives. Walsh[10] reported that the lowest π—π^* excitation energies Δ^1E for *trans*- and *cis*-dichloroethylenes in the gaseous phase are 6.36 and 6.53 eV, respectively. Gary and Picket[11] reported that, in the same phase, the values of Δ^1E for the *trans* and *cis* isomers of butene-2 are 6.975 and 7.066 eV, respectively. Both these sets of data show that the excitation energies are smaller for *trans* isomers, in contradiction to the generalization found for the butadiene derivatives. The situation has led us to examine the electronic spectra of 1,2-disubstituted ethylenes more extensively.

We have thus undertaken to measure the ultraviolet absorption spectra of *cis* and *trans* isomers of a variety of 1,2-disubstituted ethylenes.



X = CH_3, Cl, OCH_3, CN, or COR

Y = CH_3 (1-substituted propenes)
Y = X (symmetrically 1,2-disubstituted ethylenes)

It has turned out that the generalization also holds for most of the ethylene derivatives here studied. Theoretical treatments of the PPP type rationalize the observed trend. Dichloroethylene and butene-2 have been verified to be exceptions. Most likely, the usual assumption of virtual orbitals is greatly invalidated in such compounds. These results will serve as a guide in the study of the excited electronic structure of olefin isomers.

Experimental

Methyl propenyl ether (**1**),[12] 1,2-dimethoxyethylene (**9**),[13]

and 1,2-dicyanoethylene (**10**)[14] were prepared according to the methods given in the literature. They were separated into geometric isomers by means of preparative gas chromatography. Column packings used were poly(ethylene glycol). Column length (3—5 m) and operating temperature (80—150°C) were so chosen as to best suit the separation. Hydrogen was used as a carrier gas at a flow rate of 25 ml/min.

The *cis* and *trans* isomers of crotononitrile (**2**), crotonic acid (**4**), crotoamine (**5**) and methyl propenyl ketone (**6**) were supplied by Dr. Kobuke, Kyoto University. *trans*-Crotonaldehyde (**3**) and diethyl maleate and fumarate (**11**) were purchased and distilled.

All the geometric isomers were identified from the magnitudes of NMR coupling constants observed between the olefinic hydrogen atoms. Gas chromatography showed that all samples had an isomeric purity exceeding 95%.

The absorption spectra were measured on isopentane solutions. Isopentane was purified by passing through an alumina column of 1.5 m in length and 2 cm in diameter. Sample solutions were prepared by dissolving *ca.* 20 mg of olefin in 10 cc of isopentane. The solutions were further diluted down to *ca.* 10^{-5}M, and were degassed before observation. A quartz cell with a 1 cm path length was used. The spectra were recorded on a Cary Model 15 spectrophotometer at room temperature under an atmosphere of nitrogen gas. The extinction coefficient obtained was not corrected for possible isomeric impurities.

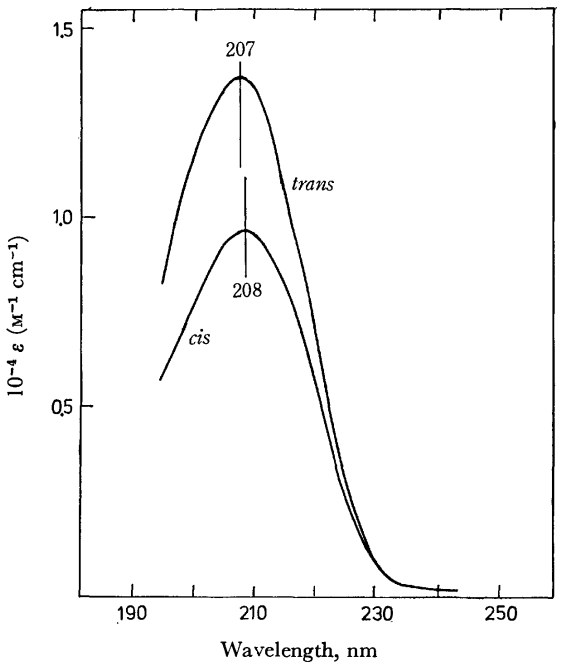

Fig. 1. Absorption spectra of *cis*- and *trans*-crotonic acids in isopentane.

Method of Calculation

The LCAO-MO-CI method of the Pariser-Parr-Pople (PPP) type was used for calculating the energies and oscillator strengths of the π—π^* transitions. The integral parameters used for the present calculations were all the same as those adopted previously.[7]

All the ethylene derivatives were assumed to be coplanar. The bond lengths and angles of the various 1,2-disubstituted ethylenes were taken from the literature.[15]

The spin configurations were constructed using the SCF closed-shell virtual orbitals. The configuration interactions were treated by including lower 10 (at maximum) singly excited configurations. All computations were perfomed on a KDC-II at the Computation Center of Kyoto University.

Results and Discussion

A. Absorption Spectra. Figure 1 shows the absorption spectra of the *cis* and *trans* isomers of crotonic acid (**4**) as an example. They show a strong absorption miximum at 208 and 207 nm, respectively. Although the Franck-Condon maxima are hard to locate, these band maxima may be used for our present purposes.

The spectral data obtained are summarized in Table 1, together with those for butene-2 (**7**)[11] and dichloroethylene (**8**).[10] All the compounds show one intense band with or without vibrational structure in the wavelength region 190—250 nm. No doubt, the observed bands correspond to the lowest π—π^* excitation.

Inspecion of the experimental data given in Table 1 indicates that, except for **2**, **7**, **8**, and **11**, both energy A^1E and oscillator strength f of the lowest π—π^* excitation of a given 1,2-disubstituted ethylene are more or less greater for the *trans* isomer. This tendency has no direct bearing on the relative stabilities of geometric isomers; *cis*-**9** is probably more stable than its *trans* isomer,[16,17] whereas *trans*-**1** is known to be thermochemically more stable than its *cis* isomer by *ca.* 0.9 kcal/mol at ordinary temperature.[17] The exceptions **2**, **7**, **8**, and **11** will be discussed later.

The energy difference between the *cis* and *trans* isomers of **6** is large compared to those for the other carbonyl compounds, **4** and **5**. This is probably due to the concurrent effects of the configurational and conformational differences between the isomers. While α,β-unsaturated carbonyl compounds exist predominantly in the planar *s-trans* conformation, the most stable form of *cis*-**6** is the *s-cis* conformation because of the steric repulsion between the two methyl groups.[18] The *s-trans* conformation of a conjugated framework generally tends to give greater excitation energies than does the *s-cis* counterpart.[19,20]

As regards the oscillator strength, **2** is not anomalous; the *trans* isomer has a greater f value, in harmony with

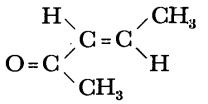
cis-**6** (*s-cis*)



trans-**6** (*s-trans*)

the trend for the majority of "normal" compounds. Butene-2 (**7**), however, is still anomalous.

B. Calculated Excitation Energies. Calculations of the PPP type were performed for all the compounds **1** through **11**. For all isomers of these compounds, the lowest π—π^* excitation was the only intense transition in our wavelength range of interest. In what follows, we will be concerned only with the lowest π—π^* transition. The calculated excitation energies Δ^1E are listed in Table 1.

It may be noticed in Table 1 that the Δ^1E values calculated for *trans* isomers are, without exception, greater than those for the corresponding *cis* isomers. The differences between the calculated values are *ca.* 1% the excitation energies, in rough agreement with those observed for "normal" cases. As our present problem lies in the comparison of geometric isomers, we will not concern ourselves with numerical agreement between the calculated and observed values for individual isomers.

The isomeric difference calculated for **6** is in better agreement with the observed, when the *s-cis* conformation is assumed for the *cis* isomer than when the *s-trans* conformation is assumed. Also, the calculated results for **9** are best correlated with observation, if it is assumed that the *cis* isomer is in the *s-trans,s-cis* conformation while the *trans* isomer is in the *s-trans, s-trans* conformation.

The anomaly encountened in **11** is apparently due to the twisting of the *cis* isomer around its C-C single bonds because of the steric repulsion between the methoxycarbonyl groups. The essential discord between theory and experiment for the cases **2**, **7**, and **8** cannot be interpreted from the conformational consideration. Neither can it be remedied by means of all valence-electron theories. For example, the excitation energies of **2** calculated by the INDO method[21] are 11.137 and 11.163 eV for the *cis* and *trans* isomers, respectively.

21) J. A. Pople, D. L. Beveridge, and P. A. Dobosh, *J. Chem. Phys.*, **47**, 2026 (1967).

By our modified INDO method,[22] they are calculated to be 6.801 and 6.833 eV. Both these calculations give a higher excitation energy for *trans*-**2**, in disagreement with observation. The disagreements in **2**, **7**, and **8** will be discussed in Subsection D.

We previously ascribed the greater excitation energies for *trans* isomers of butadiene derivatives to their smaller Coulomb repulsion J_{hl} between the highest occupied and lowest vacant π orbitals.[7] Exactly the same situation has been confirmed with th Δ^1E values calculated for ethylene derivatives. For the sake of comparison, the calculated values of J_{hl} are included in Table 1. It is our working hypothesis that J_{hl} somehow measures a relief of a molecule from intramolecular electronic repulsion upon excitation, so far as the virtual orbital approximation is not greatly in error. That *cis* isomers have greater values of J_{hl} than the corresponding *trans* isomers is obvious from the relatively small spatial separations between the substituents. Apparently, the hypothesis is invalidated in the cases of **2**, **7**, and **8**.

C. Oscillator Strengths. The oscillator strength f may be calculated from the expression

$$f = 1.085\times10^{-5}\nu(r_x^2+r_y^2) = f_x + f_y \qquad (2)$$

where ν is the frequency of transition (cm^{-1}) and r_s ($s=x$ or y) is the transition moment length (Å) in the specified direction, x or y (Fig. 2). The values of f_x and f_y calculated for isomers of various ethylene derivatives are given in Table 1.

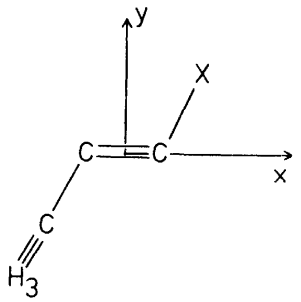


Fig. 2. Coordinate axes chosen for 1-substituted propenes.

It can be seen from Table 1 that there is little difference in the f_x value between the isomers, whereas the f_y value is considerably greater for the *trans* isomers. As a consequence, the sum f_x+f_y for a *trans* isomer is greater than that of the corresponding *cis* isomer, in agreement with observation. However, the unusually large f value reported for *cis*-**7** is hardly justifiable.

D. Ionization Potential. As has already been mentioned, the anomalous spectral features of **2**, **7**, and **8** cannot be attributed to steric strains in the *cis* isomers. A comparison of the ionization potentials of geometric isomers shows this to be the case.

Table 2 gives the observed[23] and calculated (PPP) vertical ionization potentials I_p for the *cis* and *trans* isomers of **1**, **2**, **7**, and **8**. The I_p values observed for *cis* isomers are greater than those for *trans* isomers only by a few hundredths of an electron volt. The isomeric differences calculated by assuming planar structures are found to be in good agreement with the observed. Thus, so far as the ground-state structure is concerned, nothing anomalous is perceptible for those spectroscopically anomalous olefins **2**, **7**, and **8**. If the *cis* isomers were greatly twisted in the ground state, their I_p values relative to the *trans* isomers would be more marked. For the sake of comparison, the relevant data for 1-phenyl-1-propene $C_6H_5CH{=}CHCH_3$ are included in Table 2. The isomeric difference found for this compound is as great as 0.11 eV, which should be attributed to the nonplanarity of the *cis* isomer.[24] All these results lead to the conclusion that stereostructures of the *cis* isomers of **1**, **2**, **7**, and **8** do not differ greatly, irrespective of their excitation characteristics.

Table 2. Vertical ionization potentials of some 1,2-disubstituted ethylenes

c) The phenyl group is assumed to be rotated out of plane by 30°.[24]

Concluding Remarks

For most of the 1,2-disubstituted ethylenes the energy of the lowest singlet excitation is greater for *trans* isomers than for the corresponding *cis* isomers. Of the various ethylene derivatives studied, butene-2 (**2**), crotononitrile (**7**), dichloroethylene (**8**) were anomalous in the above respect. The oscillator strength is greater for *trans* isomers, with virtually no exceptional case. The generalization can be rationalized by the PPP calculations.

Changes in electronic population upon excitation might be drastic in some ethylene derivatives. In cases where reorganization of the electronic structure upon excitation is considerable, the virtual orbitals would no longer be capable of depicting the Franck-Condon excited states with reasonable accuracy. Anomalous spectral behaviors of the *cis* isomers of **2**, **7**, and **8** could be ascribed to this change. However, the reason for it to occur only in these particualr compounds is still unclarified.

Comparison of the Electronic Spectra of Geometric Isomers. III. β-Substituted Styrenes

Takayuki FUENO, Kizashi YAMAGUCHI, and Yuji NAKA*

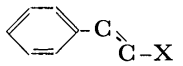
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 21, 1972)

The ultraviolet absorption spectra of *cis* and *trans* isomers of various β-substituted styrenes have been measured both in the gaseous state and in *n*-hexane solution. The excitation energies observed for *cis* isomers are either smaller or greater than those of the *trans*, depending on the type of β-substituents. The isomeric difference in the energy of the lowest allowed transition was found to be linearly correlated with Taft's steric substituent constants. The electronic states of the various isomeric pairs were calculated by the LCAO-SCF-CI method of the Pariser-Parr-Pople type. The results were found to be entirely in line with the observed spectral features.

We have previously shown that *trans* isomers of terminal-substituted butadienes and ethylenes exhibit ultraviolet absorption at greater energy than do the corresponding *cis* isomers.[1,2] It is known, on the other hand, that *cis*-stilbene has greater excitation energies than its *trans* isomer.[3] Such contradistinctive cases can be characterized by the relative importance of the *electronic* and *steric* effects of substituent groups. Thus, if the entire chromophore of a *cis* isomer is in full π-conjugation, it should show smaller excitation energy as compared with its *trans* isomer.[1,2] The situation is reversed when a *cis* isomer cannot exist in planar form as a result of the steric repulsion between the substituents. The LCAO-SCF-CI theory of the Pariser-Parr-Pople (PPP) type fully rationalizes these interpretations.[1,4]

It is to be expected that β-substituted styrenes lie in between the above two extreme cases. Some compounds of this family would resemble stilbene in their spectral feature while others would be close to the butadiene type in nature, depending on the bulkiness of the β-substituent attached. Examination of this question is the purpose of the present work. The compounds investigated are the following:



X = CH_3, C_2H_5, COOH, $CONH_2$, $CH{=}CH_2$, CN, OC_2H_5, or F

Spectra of the *cis* and *trans* isomers were measured in the vapor phase and in *n*-hexane solution. Expected results were obtained. The experimental results were justified by the PPP treatments.

Experimental

The β-methyl (1-phenyl-1-propene, **1**),[5] ethyl (1-phenyl-1-butene, **2**),[6] vinyl (1-phenyl-1,3-butadiene, **5**),[7] and ethoxy (styryl ethyl ether, **7**)[8] derivatives of sryrene were prepared according to the methods given in the literature. β-Fluorosryrene (**8**) was synthesized by the method of Bergmann *et al.*[9] All these compounds were then separated into geometric isomers by means of preparative gas chromatography: column packings, poly(ethylene glycol); column length, 3—5 m; operating temperature, 100—170°C; and carrier gas, hydrogen. The *cis* and *trans* isomers of cinnamic acid (**3**), cinnamide (**4**) and cinnamonitrile (**6**) were supplied by Dr. Kobuke, Kyoto University. Isomeric purity of each sample as determined by gas chromatography was no less than 95%.

All the geometric isomers were identified by the magnitudes of the NMR coupling constants observed between the ethylenic hydrogens. In the case of **8**, the HF coupling constants were also useful; $J_{\alpha F}$(Hz) = 45 (*cis*-**8**) and 20 (*trans*-**8**).

The absorption spectra were recorded on a Cary Model 15 spectrophotometer for both gas and solution samples at room temperature. Sample preparation and observation were carried out in the same manner as conducted previously for the butadiene derivatives.[1] Extinction coefficients were determined only for the solution spectra.

Method of Calculation

The LCAO-SCF-CI method of the Pariser-Parr-Pople type[10,11] was used to calculate the energies and oscillator strengths of the π—π* transitions. The necessary atomic parameters were taken from the tables of Hinze and Jaffé[12] and Moore,[13] and listed in a previous article.[1] The one- and two-center repulsion integrals were evaluated according to the Pariser formula[14] and the Nishimoto-Mataga[15] formula, respectively.

The off-diagonal core resonance integrals H_{rs} between

two neighboring atoms r and s were evaluated according to the Wolfsberg-Helmholtz formula[16]

$$H_{rs}^{0} = -\frac{\kappa}{2}S_{rs}(I_r + I_s) \quad (1)$$

where S_{rs} is the overlap integral between the parallel Slater $p\pi$ atomic orbitals on atoms r and s, and the parameter κ values were empirically determined as to reproduce the state energies observed. The κ values finally adopted were 0.85 for compounds **3**, **5**, and **7**, and 0.9 for the rest.

We assume that molecular geometries of β-substituted styrenes are such as to be constructed schematically by replacing the vinyl group of the parent styrene with a substituted ethenyl group. The bond lengths and angles of both styrene and substituted ethylenes were taken from the literature.[17] The hyperconjugation model was assumed for the methyl group.[1] For nonplanar geometries of *cis* isomers in which the phenyl ring was assumed to be rotated out of plane, the resonance integral for the bond *t*-*u* connecting the benzene ring and the C=C double bond was modified to be

$$H_{tu} = H_{tu}^{0}\cos\theta \quad (2)$$

where θ is the rotation angle. The coordinate axes were chosen as shown in Fig. 1.

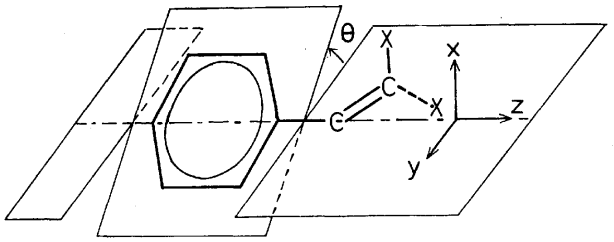

Fig. 1. Coordinate axes and conformation of *cis*-β-substituted styrenes.

The configuration interactions were treated by including lower 10 singly excited configurations. All computations were performed on a KDC-II at the Computation Center of Kyoto University.

Results and Discussion

A. Observed Spectra. Figure 2 shows the absorption spectra of the *cis* and *trans* isomers of β-methylstyrene (**1**), as an example, both in the gaseous state and in *n*-hexane solution. In either phase, the observed spectra have three bands in the wavelength range 200—300 nm. The first band appearing at about 280 nm is very weak, whereas the second (230—260 nm) and the third (~200 nm) are both strong. In the vapor spectra of the geometric isomers, we see that the second absorption peak of the *trans* isomer (λ_{max}= 238 nm) is at a greater wavelength than that of the *cis* isomer (λ_{max}=233 nm). The same is true with the solution spectra. The extinction coefficient was found to be greater for *trans*-**1** (ε=17100) than for its *cis* isomer (ε=12300).

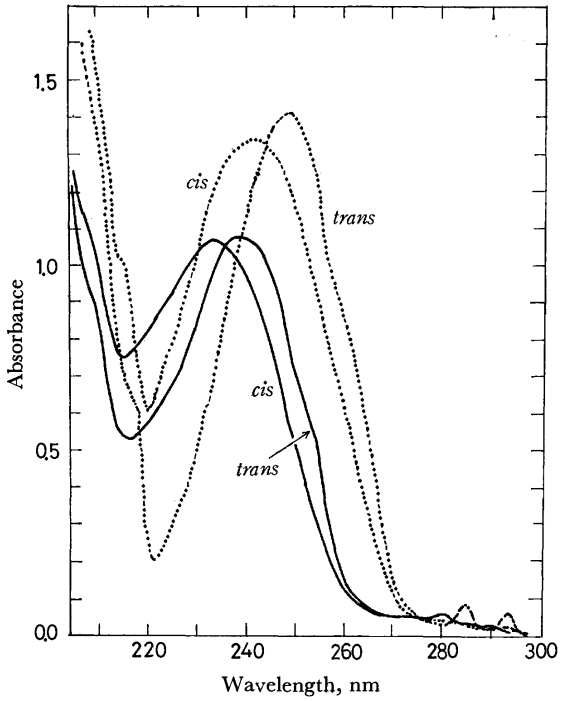

Fig. 2. Absorption spectra of *cis*- and *trans*-β-methylstyrenes (**1**) in the vapor phase (——) and in *n*-hexane solution (·····). Concentration in *n*-hexane: *cis*, 106.0 μM; *trans*, 86.8 μM.

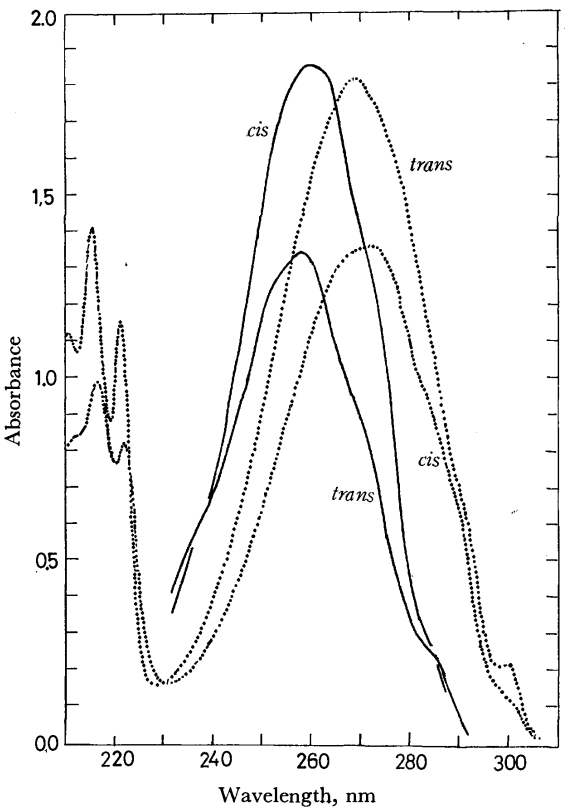

Fig. 3. Absorption spectra of *cis*- and *trans*-cinnamonitriles (**6**) in the vapor phase (——) and in *n*-hexane solution (·····). Concentration in *n*-hexane: *cis*, 78.0 μM; *trans*, 91.0 μM.

The spectral features of the β-ethyl (**2**), the β-carboxy (**3**), β-carbamido (**4**) and β-vinyl (**5**) derivatives were

a) The extinction coefficients ε_{max} and oscillator strengths f were determined from the spectra in solution. Solvent is *n*-hexane, unless otherwise noted.
b) The rotation angle of the phenyl ring in *cis* isomers (Fig. 1) was assumed to be: 30° for **1** and **2**; 45° for **3**, **4**, and **5**; and 0° for **6**, **7**, and **8**.
c) The symbol (*i*—*j*) indicates the singlet spin configuration resulting from the one-electron transition from the *i*th to the *j*th molecular orbital of the ground-state configuration.
d) In ethanol.
f) R. J. Dolter and C. Curran, *J. Amer. Chem. Soc.*, **82**, 4155 (1960).
g) Ref. 7.

found to be essentially the same as those of **1**. All the data observed for compounds **1** to **5** are summarized in Table 1.

The spectra of cinnamonitrile (**6**) shown in Fig. 3 are in contrast to those of β-methylstyrene. The second ultraviolet absorption of the *trans* isomer (λ_{max}= 269 nm) occurs at a shorter wavelength than that of the *cis* isomer (λ_{max}=272 nm). The tendency is the reverse of that found for **1**.

The β-ethoxy (**7**) and β-fluoro (**8**) derivatives are similar to **6** in their spectral feature (Figs. 4 and 5); the second bands of *cis* isomers are shifted, though only slightly, to longer wavelength relative to the *trans*. The bands show considerable vibrational structure, indicating a planar conformation. The spectral data for **6**, **7**, and **8** are also given in Table 1.

The second excitation energy Δ^1E_2 of the *cis* isomers relative to the *trans* appears to be correlated with the steric repulsion between the *cis* β-substituent and the phenyl group. The isomeric differences

$$\delta\Delta^1E_2 = \Delta^1E_2(cis) - \Delta^1E_2(trans) \quad (3)$$

for the various β-substituted styrenes including stilbene are given in Table 2, together with the steric substituent constants E_s[18] available for the β-substituents. The steric repulsion is the greatest in *cis*-stilbene. The negative values of $\delta\Delta^1E_2$ found for **6**, **7**, and **8** might

18) R. W. Taft, in "Steric Effects in Organic Chemistry," ed., M. S. Newman, Wiley, New York, N. Y. (1956), Chapter 13.

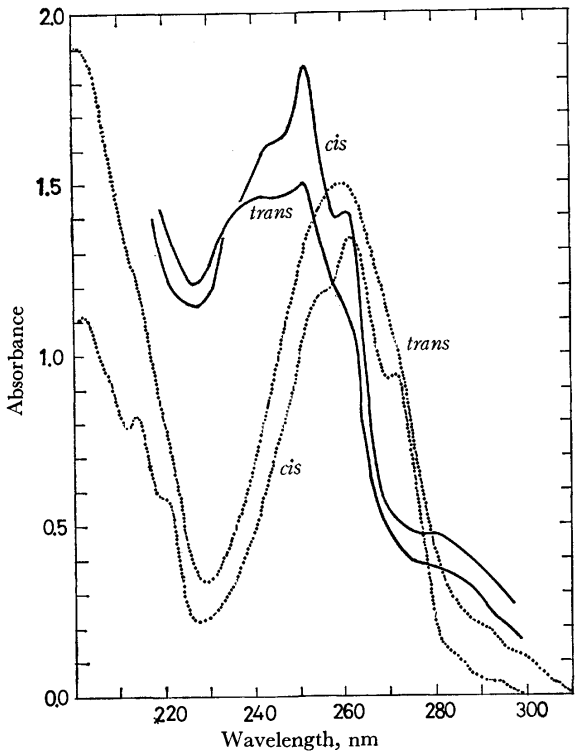

Fig. 4. Absorption spectra of *cis*- and *trans*-β-styryl ethyl ethers (**7**) in the vapor phase (——) and in *n*-hexane solution (·····). Concentration in *n*-hexane: *cis*, 81.1 μM: *trans*, 65.2 μM.

indicate the electronic effect of *cis* substitutions surpassing their steric contribution.

Plots of $\delta\Delta^1E_2$ against E_s give a good linear relationship (Fig. 6). The solution data are better correlated

TABLE 2. DIFFERENCES BETWEEN THE SECOND EXCITATION ENERGIES OF *cis*- AND *trans*-β-SUBSTITUTED STYRENES

Substituent[a]	$\delta\Delta^1E_2$, eV[b]		E_s[c]
	Gas	Soln

a) Substituents are listed in decreasing order of $\delta\Delta^1E_2$ in solution.
b) Eq. (3).
c) Steric substituent constants defined from the hydrolysis rates of *o*-substituted benzoic esters (except for C_2H_5, for which the value derived from aliphatic esters has been adopted).[18]
d) The energies corresponding to the Δ^1E_2 are 4.56 (in ethanol) and 4.22 eV (in heptane) for the *cis* and *trans* isomers, respectively.[3]

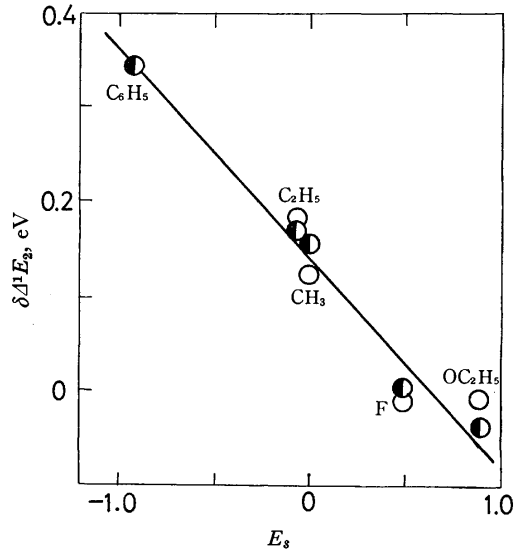

Fig. 6. Linear correlation of $\varepsilon\Delta^1E_2$ with E_s. ○, gas phase; ◐, solution.

with E_s than are the gas-phase data, the regression line being obtained by use of only the former. The linearity in turn permits estimation of the E_s values for substituents for which no such data are available as yet. The estimated values are −0.65, −0.17, 0.00, and 0.90 for the groups $CH{=}CH_2$, $CONH_2$, COOH, and CN, respectively.

B. Electronic States. *cis*- and *trans*-β-methylstyrenes (**1**) were first treated. Figure 7 gives the energy diagram of *trans*-**1** before and after configuration interactions. Each state is characterized as if the molecule were of the C_{2v} symmetry with respect to its pseudo-long axis (z). The transition to the lowest $^1B_2$ state is forbidden, while the second transition to the $^1A_1$ state is allowed. The third ($^1B_2$) and fourth ($^1A_1$) transitions are both allowed and are situated close to each other. The calculated results are consistent

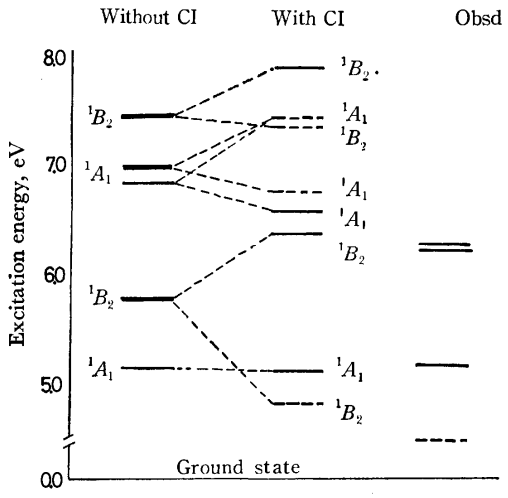

Fig. 7. Energy diagram of *trans*-β-methylstyrene. ——, allowed; ——, forbidden.

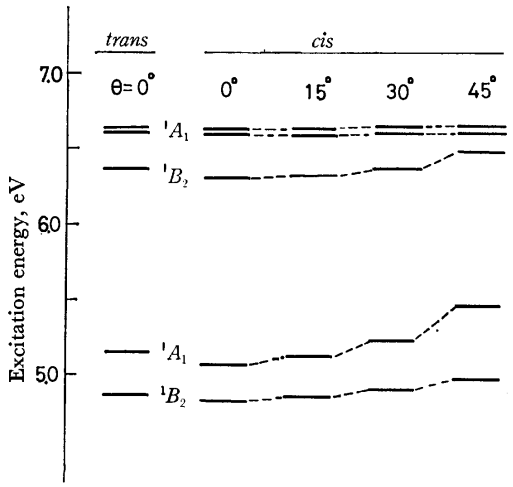

Fig. 8. Dependences of the calculated excitation energies of *cis*-β-methylstyrene on the out-of-plane rotation angle θ of the phenyl ring.

with the observed spectrum.

Fugure 8 illustrates the dependences on θ of the excitation energies calculated for *cis*-**1**. The energies cannot exceed those of the *trans* isomer unless θ is greater than 20°. The angular dependence of energy is the largest for the second excited state. The calculated value of the second excitation energy Δ^1E_2 for *cis*-**1** relative to *trans*-**1** was found to be in best agreement with the observed gas-phase value, when θ was assumed to be 30°.

The excitation energies and oscillator strengths culculated for the *cis* (θ=30°) and *trans* (θ=0°) isomers of **1** are listed in Table 1, together with the weight% of the spin configurations which most importantly contribute to each electronic state. For either isomer the second excited state is well represented by the spin configuration $^1\Phi_{5,6}$ alone, which corresponds to the one-electron transition from the highest occupied (h) to the lowest vacant (l) obrital in the ground configuration. On the other hand, both the first and third excited states are described as superpositions of two configurations, $\Phi_{5,7}$ and $\Phi_{4,6}$, where the orbitals ϕ_4 and ϕ_7 respectively denote the next-highest occupied and next-lowest vacant levels, which are essentially localized in the phenyl ring. Thus, the first and third bands are considered to be analogs of the $^1B_{2u}$ and $^1E_{2u}$ bands of benzene, respectively, whereas the second band ($^1A_1$) is characteristic of the entire chromophore of **1**. It is natural that the Δ^1E_2 value calculated should be the most sensitive to the conformational change of the molecular framework.

Analogous calculations have been performed for all the remaining compounds. The results are summarized in Table 1. For every isomeric compound studied, the second π—π^* excitation is allowed and well represented by a single spin configuration, which corresponds to the electronic promotion from orbital h to l. However, *trans*-**3** and *cis*-**6** are somewhat unusual in this respect. For compounds **1** through **5**, the deformations of the *cis* isomers were necessary to reproduce their increments in Δ^1E_2 value relative to the *trans* isomers. For compounds **6**, **7**, and **8** on the other hand, the planar structure (θ=0°) was found to be plausible even for *cis* isomer.

Numerical agreement between theory and experiment is good for the second band energies but less satisfactory for the first and third bands. Nonetheless, we may be content with the present results in view of the limited accuracy of the virtual orbital approximation.

The oscillator strengths calculated were larger for *trans* isomers than for the corresponding *cis* isomers. The results are in good agreement with those found experimentally. It deserves special mention that the oscillator strengths are larger for *trans* isomers in all the three systems investigated (ethylenes, butadienes, and styrenes). Their values are most reliable in discriminating geometric isomers.

C. Structural Effect on Δ^1E_2. Elucidation of the structural effect on Δ^1E_2 can be achieved most expediently by analyzing the configurational energy $\Delta^1E_2^0$. In the PPP approximation, the energy is given by

$$\Delta^1E_2^0 = \varepsilon_l - \varepsilon_h - J_{hl} + 2K_{hl} \quad (4)$$

where ε_l and ε_h are the energies of the lowest vacant and highest occupied orbitals, respectively, and where J_{hl} and K_{hl} are the inter-frontier-orbital Coulomb and exchange repulsions, respectively.

Variations of these energy terms with structure are diagrammatically shown in Fig. 9, taking β-methylstyrene as an example. It can be seen that the energy gap $\Delta\varepsilon_{hl}$ between the frontier orbitals for the hypothetical planar *cis* isomer (θ=0°) is essentially equal to that for the *trans* isomer. The K_{hl} terms are also nearly equal for both isomers. Clearly, it is the J_{hl} term that would lower the $\Delta^1E_2^0$ for the planar *cis* isomer relative to the *trans*. As θ for the *cis* isomer increases, however, its ε_l increases while ε_l decreases monotonically. The progressive spread of the gap with θ tends to counterbalance the increase in the term (J_{hl}—$2K_{hl}$). The relative magnitudes of $\Delta^1E_2^0$ for the two isomers are thus offset when θ is greater than about 20°. Note that the variation of $\Delta^1E_2^0$ with structure is essentially the same as that of Δ^1E_2 shown in Fig. 8. Incidentally, the considerable lowering in ε_h with θ is compatible with the observation that the vertical

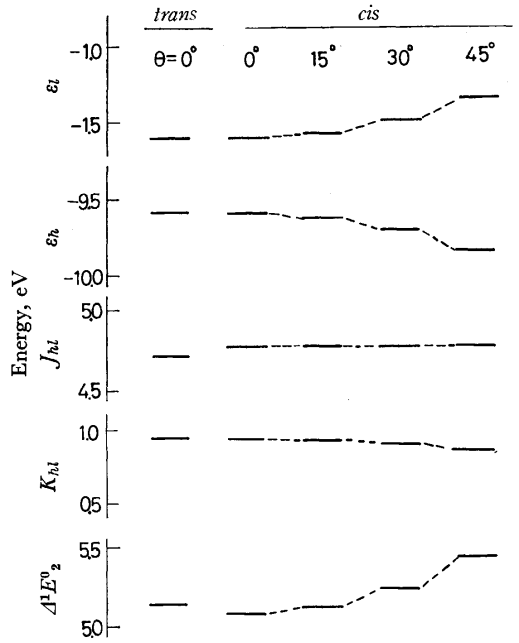

Fig. 9. Concentrations of various energy terms to $\Delta^1E_2^0$ of *cis*- and *trans*-β-methylstyrenes.

ionization potential of *cis*-**1** is greater than that of *trans*-**1** by as much as 0.11 eV.[2]

Exactly the same situation is encountered with all the remaining compounds. In order for the calculated isomeric differences of $\Delta^1E_2^0$ to agree with the observed, rotational angles of $\theta=30°$ (for **1** and **2**) and $\theta=45°$ (for **3**, **4**, and **5**) had to be assumed. For compounds **6**,**7**, and **8**, on the other hand, $\theta=0°$ sufficed to interpret the observed differences. The results of calculations for these conformations are given in Table 3. The relative magnitudes of $\Delta^1E_2^0$ remain much the same as those of Δ^1E_2.

The lower excitation energies for the *cis* isomers of **6**, **7**, and **8** as compared with the *trans* counterparts are noteworthy. We have previously interpreted the lower excitation energies of planar *cis* isomers to imply that they experience greater relief from intramolecular electronic repulsion upon excitation.[1] An alternative interpretation may be possible if the promoted electron is considered to be under the Coulombic field of the rest of the molecule. Withdrawal of an electron from orbital *h* of a molecule would leave an electron hole which is distributed over the molecule with partial positive charges. When the electron withdrawn is placed in orbital *l*, it is subjected to Coulombic attraction ($-J_{hl}$) from the hole. Apparently, the electron-hole attraction is larger for *cis* isomers, for which the molecular framework is relatively compact. We feel that the latter interpretation is of conceptual importance, particularly because it can readily be extended to intermolecular charge-transfer interactions.

Conclusion

The second excitation energy Δ^1E_2 of *cis*-β-substituted styrenes is either smaller or greater than that of the *trans* isomers, depending on the nature of the β-substituents. The relative magnitudes are well correlated with the steric substituent effects. PPP calculations taking account of the out-of-plane rotation of the phenyl group lead to results which are compatible with observation. The greater Δ^1E_2 values for *cis* isomers are attributable to their greater inter-frontier-orbital energy gap due to the steric hindrance between the substituent groups. The smaller values of Δ^1E_2 for presumably planar *cis* isomers can be understood from the concept of intramolecular electron-hole Coulombic attractions.

Behavior of Oxygen Species on the Nickel Oxide Catalyst Surface

Safee CHAUDHRI, Yoshiya KERA, and Kozo HIROTA
Department of Chemistry, Faculty of Science Osaka University, Toyonaka, Osaka
(Received February 25, 1972)

The ^{18}O-oxidation of carbon monoxide was studied on nickel oxide catalysts, and the oxygen exchangeability with the oxide during the reaction was determined. The activities of three oxide samples, obtained under different preparation conditions, were compared. The samples were prepared at 350, 600, and 850°C; they are denoted as NiO-I, NiO-II, and NiO-III respectively. In the case of NiO-I, two kinds of oxygen species, weakly and strongly bound to the surface, were observed. Above 120°C, not only weakly but also strongly bound surface oxygen become reactive; however, the binding energy distribution was quite broad. Similar observations were made in the case of NiO-II, with a similar change above 170°C and with a sharp energy distribution. In contrast, for NiO-III, only a small percentage of the monolayer of the surface oxygen became active and exchangeable below 200°C, but above 250°C about three layers became activated. Models are proposed for the surface state of these oxides on the basis of the behavior of the surface oxygen.

A number of studies have been devoted to the investigation of the oxidation of carbon monoxide over nickel oxide catalysts, but the proposed rate expressions and reaction mechanisms differ from author to author.[1-9] This very fact suggests that the surface structure and properties of the nickel oxide used differ intricately with its biography.

Recently, Uchijima *et al.*[10] successfully measured the amount of "surface excess oxygen" and its oxidation power distribution, and showed that the surface state of nickel oxide varied delicately, depending upon the preparation conditions, especially the sintering temperature of the oxide. Such conclusions were also reported by Dere'n *et al.*[11] However, a main problem still remains whether or not the surface excess oxygen is an effective parameter in the discussion of the mechanism.

In order to examine the behavior of the surface oxygen under the conditions of the working state, the oxidation of carbon monoxide was investigated in the present study by the use of ^{18}O-tracer on nickel oxides, which had been prepared under three different preparation conditions.

Experimental

Material. The NiO catalysts were prepared by the decomposition of $NiCO_3$, followed by sintering. $NiCO_3$ precipitated by mixing an aqueous solution of $Ni(NO_3)_2$ and $(NH_4)_2CO_3$ (both special grade; Wako Pure Chem. Ind. Co.) was completely washed, filtered and dried in a vacuum desiccator containing $CaCl_2$. The preparation conditions, the B.E.T surface area, and colors of the catalysts are summarized in Table I. The B.E.T. surface areas were determined from the adsorption of nitrogen at 77°K.

TABLE 1. PREPARATION CONDITIONS AND SOME CHARACTERISTICS OF THE NiO SAMPLES

Catalyst	Preparation conditions: Temperature (°C)	Preparation conditions: Decomposition time (hr)	Preparation conditions: Sintering time (hr)	BET surface area (m^2/g)	Color
NiO-I	350	3	15	64.0	Black
NiO-II	600	3	15	4.1	Grayish Green
NiO-III	850	3	15	0.9	Green

Carbon monoxide was obtained by the reaction of formic acid and conc. sulfuric acid. Heavy oxygen (4.8 atom% ^{18}O) was obtained by the electrolysis of heavy water containing ^{18}O. Both gases were purified by the usual methods and were found to be mass-spectrometrically pure.

Reaction Apparatus and Procedure. The reaction was carried out in a thermo-cyclic reaction vessel (265 cc), as is shown in Fig. 1. The amount of the catalyst used was 0.5 g in the cases of NiO-I and NiO-II and 2.0 g in the case of NiO-III. After the heat treatment at 300°C in a vacuum (10^{-5} Torr) for 2 hr, 32—36 mmHg of the reaction gas (CO: O_2=2: 1) was introduced into the reaction vessel. The change in the total pressure was measured with a mercury manometer, and the change in the composition

of reacting gases and their ^{18}O-concentration, with a mass spectrometer.

The errors of the ^{18}O-concentration were within 0.02—0.1 atom%. The temperature was kept constant within ± 1.0°C.

Results

Carbon Monoxide Oxidation on NiO-I and the Distribution of ^{18}O among the Components during the Reaction. The reaction was carried out in the temperature range from 50° to 350°C, and arrived at equilibrium in all runs except the run at 50°C. The ^{18}O-concentration in unreacted oxygen remained almost the same at its initial value (4.8 atom% ^{18}O), and that in unreacted carbon monoxide gave a constant value equal to the natural abundance or a slight increment during the reaction. On the other hand, the ^{18}O-concentration in the produced CO_2 varied with the time, depending upon the reaction temperature, as is shown in Table 2. From the findings that the ^{18}O-concentrations in oxygen and carbon monoxide remained the same at their initial values, while the $C^{16}O^{18}O$% in carbon dioxide always changed with a value lower than the ^{18}O atom% in oxygen during the reaction, it is clear that oxygen species in the catalyst, NiO-I take part in the catalytic oxidation.

TABLE 2. CHANGE IN $C^{16}O^{18}O$% IN PRODUCED CO_2 DURING THE COURSE OF REACTION ON NiO-I, 0.5 g

Reaction temperature (°C)	Time (min) 2	5	10	15	60
50	—	4.47	4.48	4.58	4.44
80	—	4.71	4.05	4.13	3.82
100	—	3.59	3.71	3.66	3.52
120	—	3.30	3.50	3.60	3.45
150	—	3.33	3.46	3.40	3.38
200	—	3.06	3.25	3.13	3.13
250	—	2.70	2.97	2.82	2.73
300	1.89	—	2.42	2.45	2.46
350	—	2.14	2.04	2.01	1.73

Considering the material balance of ^{18}O during the oxidation, the relation for obtaining the amount of exchangeable or reactive oxygen in the catalyst can be represented by Eq. (1):

$$(\alpha-\beta)n_g = (\beta/2)n_s \quad (1)$$

where the notations are:

α: ^{18}O atom% in gaseous oxygen
β: $C^{16}O^{18}$ O% in carbon dioxide
n_g: number of molecules in the produced carbon dioxide
n_s: number of exchangeable or reactive oxygen atoms in the catalyst.

The left-hand side of Eq. (1) indicates the number of ^{18}O atoms which disappear from the gaseous phase, and the right-hand side, the number of ^{18}O atoms captured by the catalyst, on the assumption of an isotopic equilibrium between the ^{18}O-concentrations in the produced carbon dioxide and that in the catalyst. Then, the number of the exchangeable or reactive oxygen atoms, n_s, is given by Eq. (2):

$$n_s = 2(\alpha-\beta)n_g/\beta \quad (2)$$

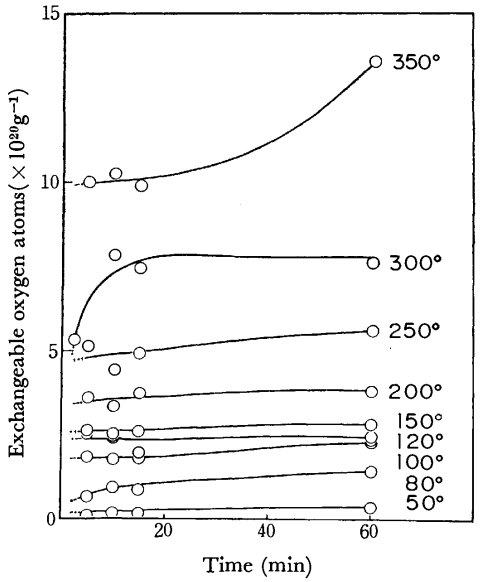

Fig. 2. Temperature dependency of exchangeable oxygen atoms of the surface (n_s) during the oxidation on NiO–I.

The change in n_s with the time, obtained for NiO-I by Eq. (2), are compared in Fig. 2. The figure shows that the n_s remained practically the same after 15 min in all temperatures except at 350°C, though the magnitude depends upon the reaction temperature. This shows that the exchange process of oxygen between carbon dioxide and the catalyst (NiO-I) is very fast. The assumption of the exchange equilibrium, therefore, may be unnecessary at 60 minutes in all runs except that at 350°C.

Carbon Monoxide Oxidation on NiO-II and the Distribution of ^{18}O among the Components during the Reaction. The reaction was carried out in the temperature range from 100° to 400°C, and the reaction equilibrium was practically reached within 10—15 min, except for the run at 100°C. The ^{18}O-concentrations in unreacted O_2 and CO almost remained at their initial values, as in the case of NiO-I. The ^{18}O-concentration in the produced CO_2 changed with the time, as is shown in Table 3.

The numbers of the exchangeable or reactive oxygen atoms, obtained from the Eq. (2), are given in Fig. 3. The n_s in NiO-II is about ten times smaller than that

TABLE 3. CHANGE IN $C^{16}O^{18}O$% IN PRODUCED CO_2 DURING THE COURSE OF REACTION ON NiO-II, 0.5 g

Reaction temperature (°C)	Time (min) 2	5	10	15	60
100	4.60	4.67	4.66	4.65	4.71
150	4.75	4.75	4.70	4.70	4.76
170	4.65	4.62	4.62	—	4.67
190	4.61	4.64	4.63	—	4.67
200	4.70	4.72	4.66	—	4.51
300	4.56	4.59	4.55	4.45	4.27
400	4.09	4.20	4.18	4.20	4.00

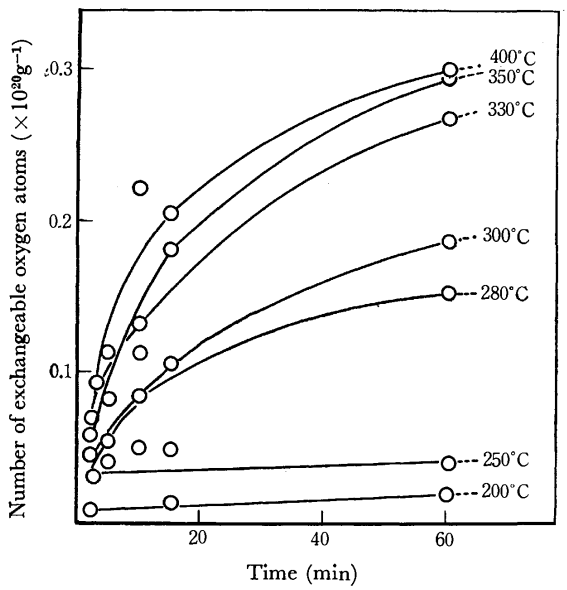

Fig. 4. Temperature dependency of exchangeable oxygen atoms of the surface (n_s) during the oxidation on NiO–III.

in NiO-I; therefore, the errors are estimated to be more or less large. However, it can be observed that the values of n_s remained the same after 10—15 min, at least at temperatures below 190°C. In the case of NiO-II, the exchange equilibrium is not established even after one hour above 200°C, which is lower than in the case of NiO-I.

Carbon monoxide Oxidation on NiO-III and the Distribution of ^{18}O among the Components during the Reaction. The reaction was carried out in the temperature range from 200° to 400°C. The reaction equilibrium was reached within 10—15 minutes in all runs except that at 200°C. The ^{18}O-concentrations in unreacted oxygen and carbon monoxide remained constant at all runs during the course of the reaction, as in the cases of NiO-I and NiO-II. On the other hand, the $C^{16}O^{18}O$% in the CO_2 produced varied with the time, as is shown in Table 4.

The numbers of the exchangeable or reactive oxygen atom, n_s, obtained from Eq. (2), are recorded in Fig. 4. The n_s values show that, in the runs above 280°C, the isotopic equilibrium between CO_2 and the catalyst is still not established even after 60 minutes.

Discussion

The crystal structure of nickel oxide belongs to that of the NaCl type. If it is assumed, for the sake of convenience, that the exposed surface consists of only the (100) plane, the number of the exchangeable or reactive atoms, n_s, can be easily transformed into the surface fraction of the oxygen atom, θ (n_s). The surface fractions, θ (n_s), obtained on the assumption from the n_s values at 60 min shown in Figs. 2, 3, and 4 are shown in Figs. 5, 6, and 7 respectively.

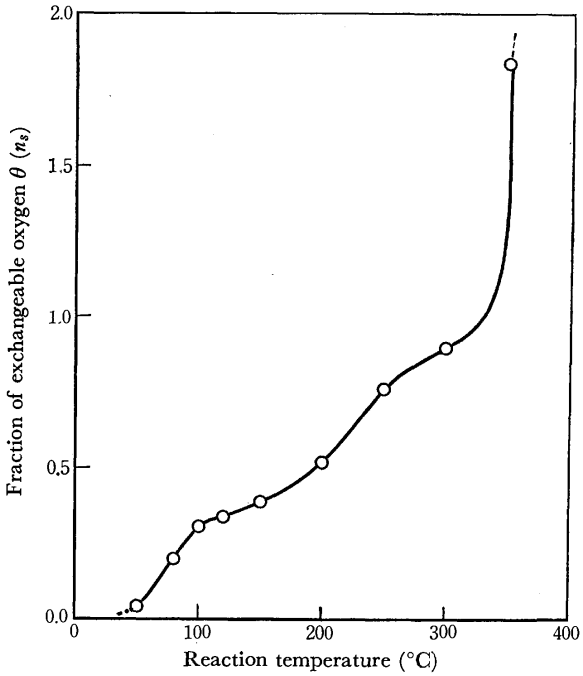

Fig. 5. Fraction of the exchangeable oxygen to the monolayer *versus* reaction temperature on NiO–I.

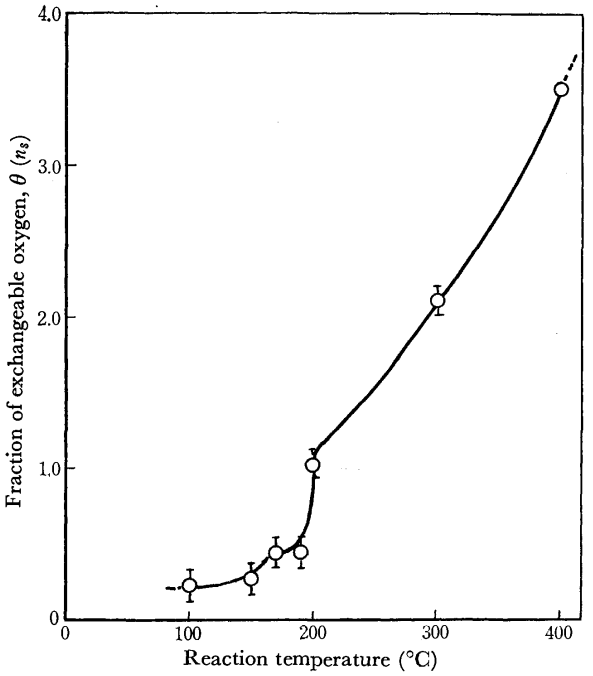

Fig. 6. Fraction of the exchangeable oxygen to the monolayer *versus* reaction temperature on NiO–II.

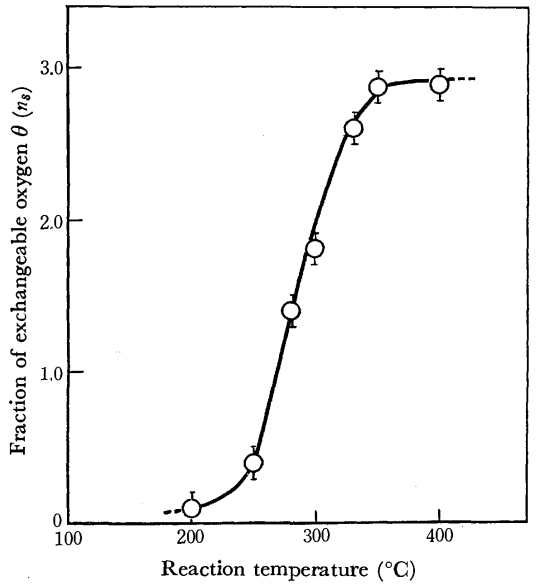

Fig. 7. Fraction of the exchangeable oxygen to the monolayer *versus* reaction temperature on NiO–III.

NiO-I (Fig. 5) shows clear changes in the exchangeability of the oxide at about 120 and 300°C. Oxygen species, which are exchangeable with carbon dioxide or which take part in the reaction below 120°C, correspond to about 30% of the surface, while those in the temperature range between 120 and 300°C correspond to about 60%. By raising the reaction temperatute to above 300°C, the oxygen species in the second layer or below also become exchangeable.

NiO-II (Fig. 6), though the errors are estimated to be more or less large, shows a clear change in the exchangeability at two temperatures, *i.e.*, between 150 and 170°C and between 190 and 200°C. About 40% of the surface is covered with the oxygen species, which can exchange with carbon dioxide or take part in the reaction below 170°C, while about 60% of the remaining surface is covered with the oxygen species, which can participate in the reaction at a temperatute between 170 and 200°C. Since Fig. 6 shows an abrupt change in the exchangeability in the higher-temperature region within a narrower temperature range in comparison with Fig. 5, the surface of NiO-II seems to have less heterogeneity than that of NiO-I.

In the case of NiO-III, the exchangeability increases rapidly and monotonously above 250°C, reaching a constant value at 350° and 400°C, indicating that the amount of the exchangeable or reactive oxygen corresponds practically to the three layers near the surface, that is, the binding state of the oxygen of the first three layers is homogeneous; moreover, the state in the three layers near the surface and that below the layers are clearly different in exchangeability from the above layers.

From the above discussion, the following surface models can be proposed for nickel oxide catalysts:

(i) NiO-I: The surface oxygen is roughly classified in two groups based on the difference in binding energy. About 30% of the surface oxygen is weakly-bound oxygen (W-site), and about 60%, strongly-bound oxygen (S-site). The former becomes reactive even below 120°C, and the latter, in the temperature range between 120 and 300°C, but the distribution of the binding energy is widespread.

(ii) NiO-II: The surface oxygen is composed of about 40% weakly-bound oxygen (W-site) and about 60% strongly-bound oxygen (S-site). The former becomes reactive below 170°C, and the latter, in the temperature range between 170 and 200°C, and the distribution of the binding energy is not so widespread.

(iii) NiO-III: The three layers near the surface are very homogeneous, and the layers below them are clearly different in exchangeability.

Dere'n *et al.*[11] suggested that "excess oxygen," *i.e.*, the ionosorbed oxygens of NiO, are almost entirely concentrated on the surface and are completely removed by evacuation for several minutes at 400°C. According to their suggestion, the surface oxygen which is not in the form of the surface-excess oxygen has become the object of the present research, because in our research the surface-excess oxygen can be removed by pretreatment. From this viewpoint, the results of other authors obtained by kinetic studies, desorption studies of oxygen and carbon dioxide, ^{18}O-exchange studies, and so on will be compared with ours and examined in connection with the above surface model.

Kondo *et al.*[1] observed the desorption of carbon dioxide with the elevation of the temperature on NiO, which seems to have nearly the same properties as NiO-I, because it was prepared by the decomposition and sintering of $NiCO_3$ at 350°C for 24 hr. They found the existence of two types of adsorption sites on the surface; which correspond to the maxima of the desorption curve at 80 (weak adsorption site) and at 300°C (strong adsorption site). Moreover, they measured the rate of the CO-oxidation on the NiO, poisoned by carbon dioxide, and suggested that the strongly-

adsorbed carbon dioxide exists on the site of weakly-bound oxygen of the surface, while, conversely, the weakly-adsrobed carbon dioxide exists on that of strongly-bound oxygen. They concluded that the oxidation rate was controlled by the process on the former site below 110°C and by that on the latter site above this temperature.

The temperature, 120°C, above which the S-site also becomes reactive on NiO-I corresponds fairly well to their transition temperature. However, it is difficult to understand their conclusion that, at lower temperatures, the oxidation rate is controlled by the process on the site of the strong adsroption of carbon dioxide, because the carbon dioxide produced cannot be desorbed from the site at such a temperature, but can be desorbed only at around 300°C. The present results, that the values of $C^{16}O^{18}$ O% increase with the time in the initial stage, suggest that the CO-oxidation is initiated by the extraction of the surface oxygen with carbon monoxide; below 120°C, only the W-site takes part in the oxidation, while above that temperature the W-site and also the S-site in accordance with the reaction temperature take part in the oxidation. Since the ^{18}O-concentration in both carbon monoxide and oxygen gases remained unchanged during the reaction, the stoichiometric change in the reacting gases was observed, and no poisoning effect was indicated, so it is clearly shown by Fig. 8 that Step I or Step II is a very slow process. However, it is not

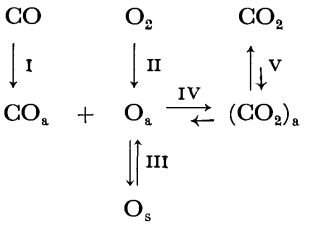

Fig. 8. Schematic representation of carbon-monoxide oxidation

yet clear whether Step I or Step II corresponds to the rate-controlling step below and above the transition temperature.

Kondo *et al.*[1] carried out the same experiment on NiO, which seems to have nearly the same properties as NiO-II; *i.e.*, their oxide was prepared by the decomposition and sintering of $NiCO_3$ at 700°C for 4 hr. The peaks of the CO_2 desorption curve shifted to a higher temperature and the transition temperature of the CO-oxidation became 160°C. Therefore they drew the same conclusion as above. This transition temperature may correspond to the temperature, 170°C, above which the S-site on NiO-II also becomes reactive, but their mechanism has been found to be inconsistent with the present one, as will be discussed below. Parravano[2] investigated the kinetics of carbon-monoxide oxidation on NiO, which seems to have nearly the same properties as NiO-II; *i.e.*, their oxide was prepared by firing $NiCO_3$ at 640°C for 3 hr. He showed that the rate expression between 106 and 174°C was different from that between 205 and 222°C, while the Elovich equation holds in both temperature ranges at the initial stage. He concluded that, at the initial stage, Eq. (3) controlled the reaction rate. At the stationary state of the reaction, Eq. (3) became the rate-determining step in the lower temperature range, while Eq. (4) was that step in the higher:

$$CO + O(s) \longrightarrow CO_2 + (s) \quad (3)$$

$$\frac{1}{2}O_2 + (s) \longrightarrow O(s) \quad (4)$$

The finding for NiO-II that the values of $C^{16}O^{18}$ O% tend to increase rapidly at the initial stage is consistent with Parravano's conclusion that the reaction is initiated by the extraction of surface oxygen with carbon monoxide. Based on the surface model of NiO-II, it can be expected that the oxidation rate in the temperature range between 174 and 205°C, where Parravano did not give any rate expression, is controlled by a different process. Up to 170°C, only the oxygen in the W-site would take part in the reaction, while in the range from 170 to 200°C not only the oxygen on the W-site but also that on the S-site would take part, according to the temperature. Since the ^{18}O-concentrations of O_2 and CO remained the same during the reaction, Step I or Step II in Fig. 8 must be very slow.

Winter[3] investigated the CO-oxidation in the temperature range between 40 and 211°C on $Ni^{18}O$, which was obtained by means of the ^{18}O-exchange between $C^{18}O_2$ and NiO, which seems to have nearly the same properties as NiO-III; *i.e.*, it was prepared by the decomposition of $NiCO_3$ at 870°C for 24 hr. The result indicated that only 2.3% of the surface oxygen takes part in the oxidation. Recently, Gay[12] measured the desorption spectra of adsorbed oxygen on NiO, prepared by the decomposition of $NiCO_3$ at 850°C for 9 hr. He indicated that only a small percentage of surface oxygen became desorbable by the elevation of the temperature to 750°C. The results of both Winter and Gay suggest that only a small percentage of the surface oxygen is active on NiO prepared at the higher temperature. The present results for NiO-III show that the surface oxygen, activated below 200°C in the oxidation, is less than 10%, but otherwise, above 250°C, about three layers of the surface are activated to the same degree. Therefore, it might be expected that the reaction mechanisms in the temperature ranges below 200 and above 250°C are different.

The above discussions were done without considering the surface excess oxygen or ionosorbed oxygen, but the contributions of these species cannot be ruled out, especially at room temperature. Not only CO-oxidation but also interactions among the adsorbed species, O_2, CO, and CO_2, on NiO have been investigated at such low temperatures by several authors.[13–18] For

instance, Teichner,[13] Garner,[14] and Stone[15] measured the heat of adsorption of CO, O_2, and CO_2, and their heat of reactions on the catalyst. They pointed out the existence of a CO_3-complex, and also suggested that the oxidation reaction could proceed through the path of the formation of the complex on NiO, though they used very different catalysts. Teichner[16] and Eischens[18] have confirmed the existence of the CO_3-complex by measuring the IR spectra of the reacting system. From these results, it can be expected that the site of excess oxygen plays an important role in the formation of the CO_3-complex and in the course of the oxidation reaction at low temperatures.

The authors wish to express their gratitude to Professor Keiji Kuwata for his continued interest in this work and for his valuable suggestions and discussions.

Directly Bonded Carbon-Hydrogen Coupling Constants of *n*-Pentane

Isao ANDO, Atsuo NISHIOKA, and Masao KAMBE

Department of Polymer Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 28, 1972)

The values of the directly-bonded carbon-hydrogen coupling constants (J_{C-H}) of the methyl and methylene groups in *n*-pentane were calculated by using the CNDO/2 method, taking into account its rotational isomers, and it was found that the calculated values of J_{C-H} agree closely with the observed values.

The groundwork for the theoretical evaluation of spin-spin coupling constants was first laid by Ramsey *et al.*,[1,2] and since then several authors[3-7] have developed the valence-bond or molecular-orbital theory for the spin-spin coupling constants, using the average excitation energy (ΔE), based on Ramsey's theory. Then, on the basis of those theories, the correlation between the observed, directly-bonded carbon-hydrogen spin-spin coupling constant, J_{C-H}, and the degree of hybridization of the carbon atom in various compounds has been studied.[8-18] Recently Maciel *et al.*[19] have also interpreted the observed J_{C-H}'s of a number of compounds using finite pertubation techniques[20] which they have developed. However, in these studies there has been scarcely no study of the J_{C-H} values of molecules which have the various rotational isomers in liquids. In this paper, we will consider the relation between the experimental and the calculated carbon-hydrogen spin-spin coupling constants of the methyl and methylene groups of *n*-pentane, which can take various rotational isomers, and will also study their temperature dependences, using the CNDO/2 (Complete Neglect of Differential Overlap) method[21] as the molecular-orbital method.
